Welcoming remarks

It is my great pleasure and honor to welcome you to the 12th ISAP Conference on Asphalt Pavements in Raleigh, North Carolina, USA. ISAP conferences have been the premier forum for asphalt engineers around the world to exchange their research and practice on asphalt materials and pavements. We received over 250 papers from 35 countries that resulted in 181 podium presentations, 29 poster presentations, and 19 student poster presentations. Four main themes of the 12th ISAP conference are design, materials, construction, and preservation, and I am pleased to introduce you to the four excellent plenary speakers to cover these topics.

This program book contains the daily program, abstracts, general information on the conference, maps, and other information that will help you enjoy the conference and surrounding areas. One of the approaches we have taken in this conference is to publish the conference proceedings in an online e-book by Talyor and Francis. You will be receiving instructions on how to access the e-book after the conference.

In addition to the technical depth and breadth this conference will provide, we have inserted a few fun events in the program. You will enjoy the welcoming reception and visit to the Hunt Library in the Centennial Campus of North Carolina State University. We hope that you enjoy North Carolina style barbeque on Monday evening at the Troxler Electronic Laboratory in Research Triangle Park. Tuesday evening's time with the North Carolina Symphony at the magnificent Meymandi Hall will give you some relaxation from the busy conference schedule. Finally the Wednesday evening banquet and special performance will leave you with a memory to cherish for years to come.

North Carolina is one of the most popular tourist destinations in the United States during summer time due to its beautiful beaches, mountains, and historic attractions. Raleigh, along with Durham and Chapel Hill, is one of the three vertices of the Research Triangle Park, which is one of the largest research parks in the world. This area has been consistently considered one of the best cities to live and one of the highest PhD per capita areas in the USA. We hope you will enjoy the LEED Silver-certified Raleigh Convention Center with stimulating design and enjoy our Southern style hospitality.

I would like to acknowledge and thank all of our sponsors, ISAP board members, conference committee members, and volunteers from North Carolina Department of Transportation and North Carolina State University. I look forward to a very successful ISAP conference in Raleigh, North Carolina!

Best Regards,
Y. Richard Kim, Ph.D., P.E., F.ASCE
Distinguished University Professor, NC State University
Chair of the 12th ISAP Conference

M-E flexible pavement design: Issues and challenges

Marshall R. Thompson
Civil Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, USA

ABSTRACT: M-E flexible pavement design procedures have evolved since the late 50's and early 60's. In the analyses of the AASHO Road Test data it was demonstrated that pavement response (surface deflection) was a good indicator of pavement performance (equally as good as the Structural Number)!! Significant advances have been achieved in the last 50+ years. Current procedures and developments for materials characterization, structural modeling, distress transfer functions, and other issues are considered in the presentation. Emphases are placed on those concepts/approaches that support the development of readily useable/implementable flexible pavement design procedures.

Keywords: Mechanistic-empirical design, flexible pavements

1 INTRODUCTION

The SHELL Pavement Design Manual was presented at the 4th International Conference on Structural Design of Asphalt Pavements [1] and was published by Shell in 1978 [2]. USA interest (AASHTO) in M-E design initiated in the md-1980s. Other agencies and groups have also been engaged in developing M-E pavement design procedures. The development/evolution of the current AASHTO procedure [3] is presented in the following sections.

"Mechanistic-Empirical Design Procedures" is the title of Part IV of the 1986 AASHTO Guide [4]. The Introduction (Section 1.1) of Part IV, states:

> For purposes of this Guide, the use of analytical methods refers to the numerical capability to calculate the stress, strain, or deflection in a multi-layered system, such as a pavement, when subjected to external loads, or the effects of temperature or moisture. Mechanistic methods or procedures will refer to the ability to translate the analytical calculations of pavement response to performance. Performance, for the majority of procedures used, refers to physical distress such as cracking or rutting.
>
> However, researchers recognize that pavement performance will likely be influenced by a number of factors which will not be precisely modeled by mechanistic methods. It is, therefore, necessary to calibrate the models with the observations of performance, i.e. empirical correlations. Thus, the procedure is referred to in the Guide as a mechanistic-empirical design procedure.

Activities associated with the development of the revised "AASHTO Guide for the Design of Pavement Structures" [4] prompted the AASHTO Joint Task Force on Pavements (JTFOP) to recommend that research should be initiated immediately with the objective of developing mechanistic pavement analysis and design procedures suitable for use in future versions of the AASHTO Guide. NCHRP Project 1-26 (Calibrated Mechanistic Structural Analysis Procedures for Pavements/J. L. Brown—Texas DOT—Panel Chairman)) was the first NCHRP Project to be sponsored. The M-E principles and concepts stated in the 86 AASHTO Guide were included in the NCHRP Project 1-26 Project Statement.

The University of Illinois cooperated with the Asphalt Institute and the Concrete Technology Laboratories in the conduct of NCHRP 1-26. It was not the purpose of NCHRP Project 1-26

to devote significant effort to develop new technology, but rather to assess, evaluate, and apply available M-E technology. Thus, the proposed processes/procedures were based on the Best Demonstrated Available Technology (BDAT). NCHRP Project 1-26 was completed in December, 1992 and comprehensive reports [5,6,7] were prepared summarizing the study.

2 M-E DESIGN CONCEPTS

Figure 1 illustrates the general concepts of a M-E model as presented in NCHRP 1-26 [7]. The pavement design process is complex. The major components of the M-E procedure are: INPUTS, STRUCTURAL MODELS, TRANSFER FUNCTIONS, and RELIABILITY. These components were comprehensively discussed in the NCHRP 1-26 reports. Three of the most significant components are MATERIAL CHARACTERIZATION, STRUCTURAL MODELS and TRANSFER FUNCTIONS.

Calculated pavement structural responses are for "given time," "given climate," "given pavement structure," "given material properties," and "given loading" inputs. Pavement responses change as these inputs vary throughout the pavement service life. Pavement performance is a long term consideration and mechanistic analysis and design procedures must account for the effect of the varying time-related inputs to the STRUCTURAL MODEL.

3 STRUCTURAL MODELS

A major task in Phase 1 of NCHRP 1-26 [5,6] was the review/evaluation of available mechanistic analysis procedures. It was concluded that the available flexible pavement structural models and computer codes for mechanistic analysis are adequate for supporting the development and initiating implementation of M-E thickness design procedures. Stress dependent finite element programs (like ILLI-PAVE, MICH-PAVE, and Texas ILLI-PAVE) and elastic layer computer programs (like BISAR, WESLEA, JULEA, CHEVRON, ELSYM 5, CIRCLY) were recommended for flexible pavements. The finite element programs are more versatile and can accommodate stress dependent moduli properties (stress-hardening for

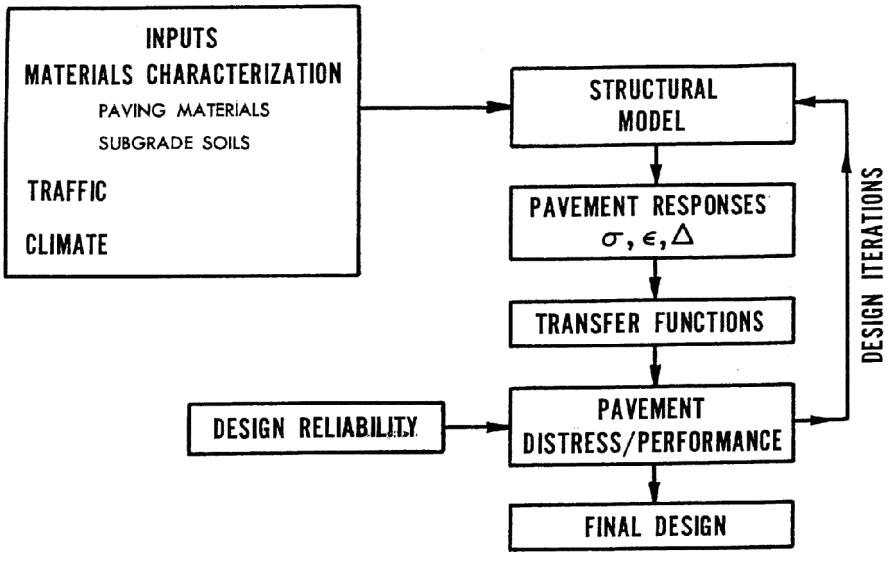

Figure 1. M-E flow chart.

granular materials; stress-softening for fine-grained soils) and also can incorporate failure criteria (such as the Mohr-Coulomb model in ILLI-PAVE).

4 TRANSFER FUNCTIONS

Transfer functions (distress models) relate the pavement responses determined from mechanistic models to pavement performance as measured by the type and severity of distress (rutting—cracking—roughness—etc.). Transfer functions were extensively reviewed in NCHRP 1-26. Modes of distress such as the fatigue and permanent deformation of paving materials and subgrade soils can be characterized from extensive testing of specimens under controlled laboratory conditions. The effects of such factors as stress level, frequency of load repetitions, rest periods, mixture variables, moisture content/density factors, etc. can be readily considered in laboratory-based studies.

The most common flexible pavement TRANSFER FUNCTIONS are a) Asphalt Concrete (AC) flexural strain—fatigue life algorithms, b) subgrade vertical strain—pavement life relations (for a given level of pavement rutting), c) permissible subgrade stress ratios [subgrade stress/subgrade strength] for various ESAL levels, and d) surface deflection—pavement life relations (surface deflection is a reliable indicator of AC flexural strain, subgrade vertical strain, and subgrade stress ratio).

Other flexible pavement distress phenomenon like AC block cracking and AC thermal cracking are more complex and are generally studied/evaluated from actual field performance data. In the field, the significant influencing factors can not be readily controlled/measured as for laboratory-based conditions. Thus, it is more difficult to develop accurate/refined TRANSFER FUNCTIONS for these distress modes.

The NCHRP 1-26 study concluded transfer functions are **weak links** in the M-E design approach. Extensive field calibration and verification are required to establish reliable distress prediction models. The NCHRP 1-26 study indicated:

- Useable flexible pavement transfer functions (distress models) are available for AC fatigue and subgrade rutting.
- The transfer functions for AC and granular material rutting are marginal.
- AC rutting is best considered by material selection and mixture design procedures and practices. (NOTE: The SUPERPAVE Level I Mixture Design procedure is a good example of this approach).
- Granular material rutting considerations can be accommodated by establishing "minimum" AC surface thickness requirements for given classes (based on shear strength and moisture sensitivity) of granular base/subbase materials.

5 NCHRP-1-26/PAVEMENT DESIGN

In NCHRP 1-26 working versions of M-E design processes and procedures were proposed for flexible pavements (Conventional Flexible Pavements, FULL-DEPTH AC pavements, High Strength-Stabilized-Base Pavements). The proposed procedures relate pavement responses (stresses, strains, and deflections) to the development of specific pavement distresses. As opposed to running a PC program, the responses can be predicted from pavement response prediction algorithms [9,10,11] to accomplish routine pavement designs. The pavement response algorithms were developed from comprehensive ILLI-PAVE data bases.

NCHRP 1-26 calibration activities were minimal due to the lack of adequate data. As an alternative, the concept of "Design Confirmation" was suggested. In this approach, the M-E procedure is utilized to explain pavement performance "SUCCESSES" and "FAILURES." (NOTE: Care should be taken to ensure that undue weighting is not given to "long term survivor" sections and inadequate attention provided to "early life" failures.) Modifications and adjustments are made in the M-E procedure to reconcile identified discrepancies.

Confidence and improved accuracy/reliability are thus developed in the M-E procedure. The design confirmation approach can be employed as a "check procedure" for the SHA's current pavement design procedure. In most cases, additional information and data (beyond that required for the current SHA procedure) will be required. Frequently, the pavement FAILURES associated with a section designed by the routine SHA procedure can be explained by M-E analysis and design concepts/procedures.

NCHRP 1-26 emphasized that M-E pavement design is very important, but it is only a segment of a larger scenario. A M-E design process can not realistically adequately address all pertinent factors and issues associated with or related to load responses, distress development, and ultimate pavement system performance. Thickness related factors are most readily addressed by M-E pavement design and that was the emphasis of NCHRP 1-26. AC fatigue and pavement rutting were the distresses that were considered. Some other significant and important factors are material selection practices and material specifications, construction policies and specifications, quality control/quality assurance procedures, maintenance and rehabilitation practices.

6 NCHRP 1-37A

A follow-up project (NCHRP 1-37A—Development of the 2002 Guide for the Design of New and Rehabilitated Pavement Structures: Phase II) was initiated in February, 1998 with ARA, Inc.—Eres Consultants Division. The Flexible Pavement Team was led by Dr. Matt Witczak (University of Maryland/Arizona State University). The following excerpts from "The Manual of Practice ([12] present the evolution and development of the MEPDG (Mechanistic-Empirical Pavement Design Guide).

> From the early 1960s through 1993, all versions of the American Association for State Highway and Transportation Officials (AASHTO) Guide for Design of Pavement Structures were based on limited empirical performance equations developed at the AASHO Road Test in the late 1950s. The need for and benefits of a mechanistically based pavement design procedure were recognized when the 1986 AASHTO Guide for Design of Pavement Structures was adopted. To meet that need, the AASHTO Joint Task Force on Pavements, in cooperation with the National Cooperative Highway Research Program (NCHRP) and the Federal Highway Administration (FHWA), sponsored the development of an M-E pavement design procedure under NCHRP Project 1-37A.
>
> A key goal of NCHRP Project 1-37 A—Development of the 2002 Guide for Design of New and Rehabilitated Pavement Structures: Phase II—was the development of a design guide that utilized existing mechanistic-based models and data reflecting the current state-of-the-art in pavement design. This guide was to address all new (including lane reconstruction) and rehabilitation design issues, and provide an equitable design basis for all pavement types.
>
> The Mechanistic-Empirical Pavement Design Guide (MEPDG), as it has now become known, was completed in 2004 and released to the public for review and evaluation. A formal review of the products from NCHRP Project 1-37 A was conducted by the NCHRP under Project 1-40A. 'This review has resulted in a number of improvements, many of which have been incorporated into the MEPDG under NCHRP Project 1-40D. Project 1-40D has resulted in Version 1.0 of the MEPDG software and an updated design guide document.
>
> Version 1.0 of the software was submitted in April 2007 to the NCHRP, FHWA, and AASHTO for further consideration as an AASHTO provisional standard and currently efforts are underway on Version 2.0 of the software. Simultaneously, a group of state agencies, termed lead states, was formed to share knowledge regarding the MEPDG and to expedite its implementation. The lead states and other interested agencies have already begun implementation activities in terms of staff

training, collection of input data (materials library, traffic library, etc.), acquiring of test equipment, and setting up field sections for local calibration.

The NCHRP 1-37A project was much more comprehensive and broad-based than NCHRP 1-26 and considered the development of the following distresses: HMA alligator cracking, HMA longitudinal cracking, HMA transverse cracking, and pavement rutting. A considerable emphasis was placed on predicting pavement IRI (International Roughness Index). An important feature of the MEPDG is that reliability estimates are provided for the distress models and IRI.

The elastic layer program (JULEA—Jacob Uzan Linear Elastic Analysis) is the flexible pavement structural model in the current version of the MEPDG. In the initial versions of the MEPDG, a 2-D finite element program was included. However, the program was not used in the calibration studies and it is not available for use in the current software. AASHTO initially issued the MEPDG as "DARWIN-ME." The most recent version of the MEPDG [3] was issued as "AASHTOWare Pavement ME Design" in 2013. The software is periodically modified as it is utilized.

Comprehensive reports on many topics/issues were prepared by the Flexible Pavements Team during the conduct of NCHRP 1-37A. The major findings and recommendations were presented in the March 2004—NCHRP 1-37A Final Report (Part 1. Introduction/Part 2. Design Inputs/Part 3. Design Analysis/Part 4. Low Volume Roads).

7 NCHRP 1-37A CALIBRATION

GLOBAL CALIBRATIONS for pavement distress were developed in the NCHRP 1-37A project. The calibration results [as presented in Ref.12] for fatigue, rutting, and IRI are shown in Figures 2–4. The statistical summary data shown in the figures (R^2, Se, Sy, Se/Sy) indicate the difficulty in establishing accurate/precise transfer functions on a large scale.

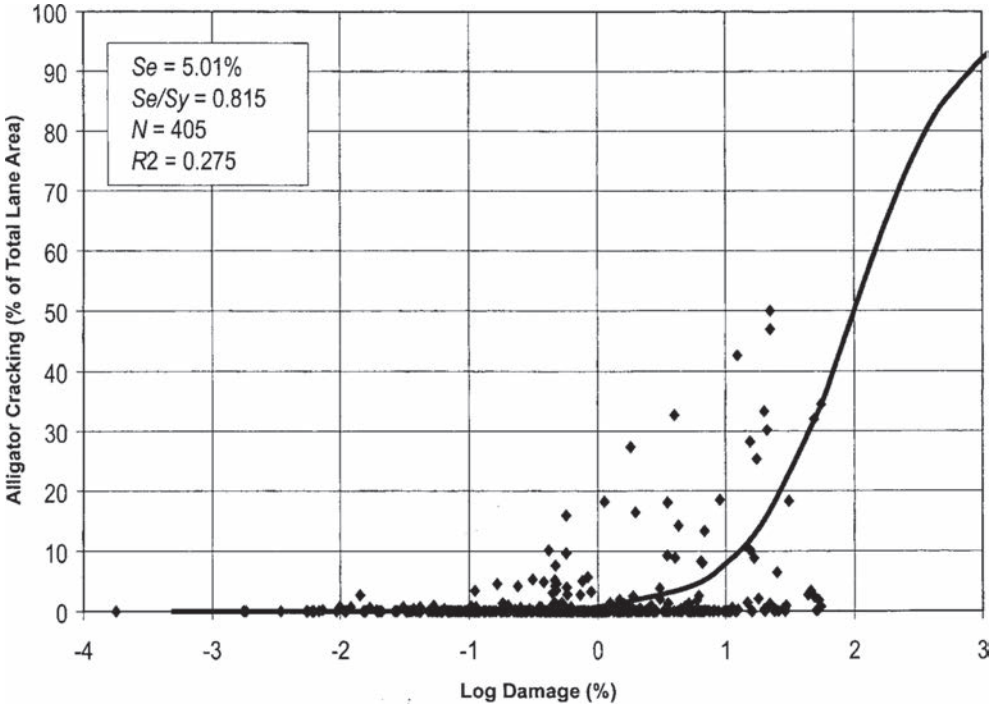

Figure 2. Alligator cracking calibration.

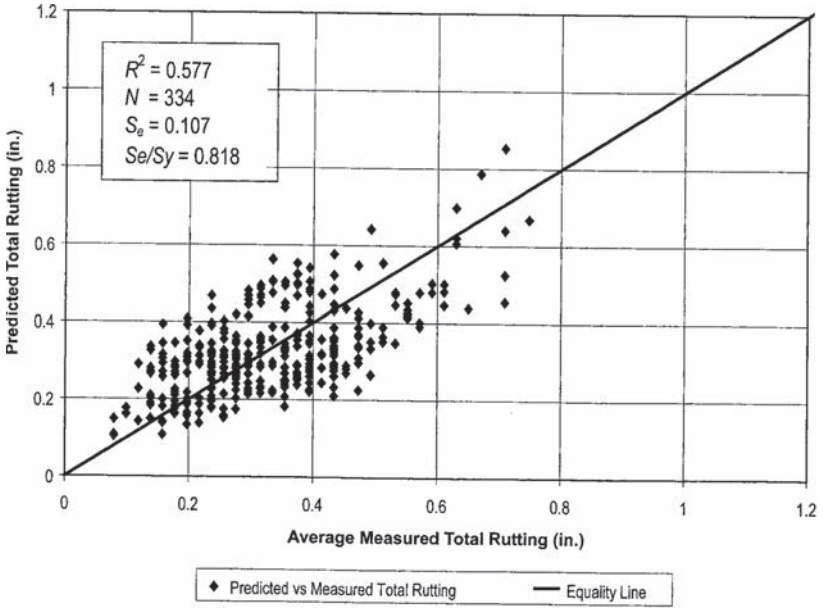

Figure 3. Rutting calibration.

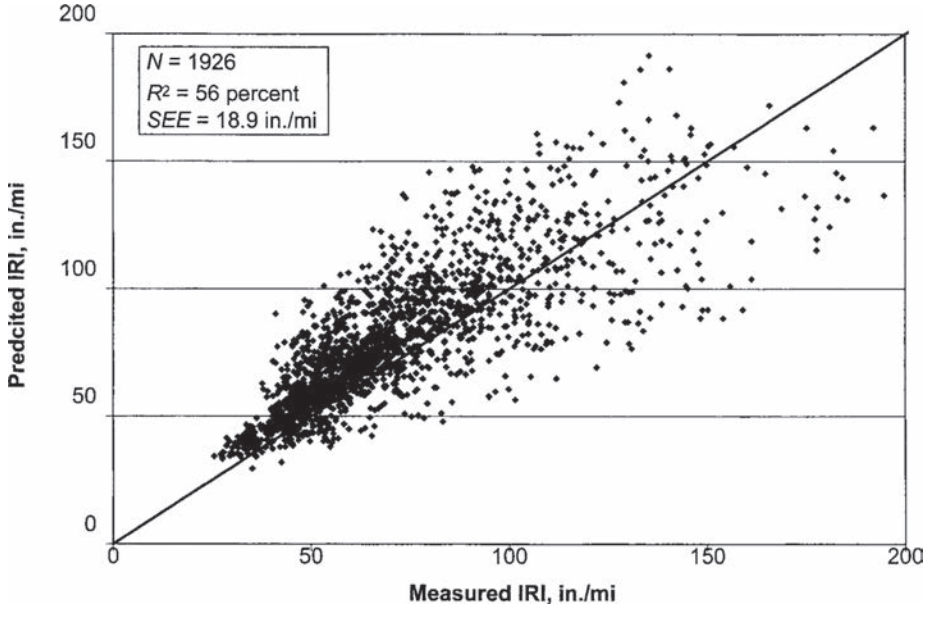

Figure 4. IRI calibration.

AASHTOWare [3] has indicated:

> "AASHTO encourages each licensing agency to calibrate and validate using local materials."

Many agencies have conducted calibration studies and established "typical" input values for routine pavement design. The distress prediction models are "tweeked" by adjusting the model β factors to achieve better model statistics.

8 EXISTING TECHNOLOGY

It is important to note that both NCHRP 1-26 and NCHRP 1-37A were to utilize "currently available technology."

- It was not the purpose of NCHRP Project 1-26 to devote significant effort to develop new technology, but rather to assess, evaluate, and apply available M-E technology.
- A key goal of NCHRP Project 1-37A was the development of a design guide that utilized existing mechanistic-based models and data reflecting the current state-of-the-art in pavement design.

As implementation issues emerge and new technology is developed, there are ongoing efforts to incorporate the developments into AASHTOWare Pavement ME Design.

9 ISSUE AND CHALLENGES

M-E flexible pavement design has made significant progress since the late 50's and early 60's. There are many examples of successful utilization of M-E procedures by various US and international entities. However, as noted in previous sections of this paper, there are still issues and challenges to be addressed that are common to many of the procedures.

Several important (per the author's opinion) issues and challenges are noted below.

- Stress dependent moduli characterization of soils and granular materials.
- Stress dependent finite element models that can accommodate stress dependent soil/material moduli and failure criteria should be further considered for implementation.
- Transfer functions (HMA fatigue/HMA fatigue endurance limit, HMA rutting, granular material and subgrade soil rutting).

Progress continues in addressing these issues and challenges. The resources/ability to develop/provide good inputs, ease of use/complexity, implementation potential, ability to accommodate new technology/developments (particularly new materials and pavement loading conditions) are some key factors that should be considered as M-E flexible pavement design procedures continue to evolve and improve.

Asphalt Pavements – Kim (Ed)

Insights into binder chemistry, microstructure, properties relationships—usage in the real world

Jean-Pascal Planche
Western Research Institute, Laramie, WY, USA

ABSTRACT: Asphalts/bitumens have been extensively used for years in road paving, making them perceived as commodity materials by most road stakeholders. However, bitumen production has changed significantly over the past two decades, following the impact of oil recovery from bituminous/tar sand and oil shales. Refining processes have adapted to this new context as well as to changes in fuel demand. This evolving context not only has made asphalt/bitumen a specialty product for oil companies but an even more complex material with chemical composition and properties more dependent on the crude oil source and process. Simultaneously, worldwide economic crises and environmental awareness have shown the need for more durable pavements and increased recycling of old pavements, promoting the use of modified binders, long lasting roads concepts, Warm Mix Asphalts, Reclaimed Asphalt Pavement recycling and their combinations. Consequently needs have been created for R&D efforts and more engineered bituminous binders meeting Life Cycle Cost Assessment constraints. New sophisticated analytical tools, rheological measurements and concepts are emerging that will certainly impact binder selection and modification.

This paper gives examples and trends to help understanding the relationships between binder chemical composition, microstructure and properties and using this understanding in the binder selection or formulation. This challenge has stakes of the utmost importance in the new economic and environmental context.

Keywords: Asphalt, composition, microstructure, properties, relationships

1 INTRODUCTION

Asphalts/bitumens (terms used interchangeably in this paper) have been extensively used for years in road paving, so much that they are part of the scenery and are perceived as standard engineering materials by the road users and even by most of the stakeholders. But are they?

Bitumen production has changed significantly over the past two decades. Crude oil availability has gone towards heavier, higher sulfur crudes, ultimately to residues from bitumen/tar sands. Meanwhile, economics and demand for lighter petroleum products have driven the refining industry to modify refinery processes and install cokers, notably in North America, which can quasi-eliminate bitumen production. This complex evolving context has made bitumen a specialty product as opposed to a commodity product from an oil company marketing and strategy standpoint. From a technical standpoint the impact is also significant, since asphalt is a very complex material with chemical composition and properties highly dependent on the crude oil origin and refinery process.

Simultaneously, worldwide economic crises and environmental awareness have shown the need for more durable pavements and recycling of old pavements. This evolving context has impacted regulations and asphalt materials application techniques tremendously. Although materials specifications differ a lot from one country to another, there is a common trend in developed countries to move towards Performance Related Specifications (PRS). This move is more or less advanced whether in the US or in Europe, for example, but it exists for both

binders and mixes. Implementation of durable pavements has promoted the use of modified binders [1, 2] and new concepts for long lasting roads, whereas the search for more sustainable and economic application techniques has favored the use of Warm Mix Asphalt (WMA) technologies, Reclaimed Asphalt Pavement (RAP) recycling and combinations of all.

As a result of these context changes, needs have been created for research and development efforts to develop more relevant characterization methods and more engineered bituminous binders to meet life cycle cost assessment constraints.

For the most part, binder engineering has been trial and error, but new sophisticated analytical tools will certainly have an impact on binder selection and modification. This paper gives some examples of those evolutions in binder characterization and the main insights to take away from them in the understanding of binder behavior, particularly the relationships between asphalt composition/microstructure/physical properties.

2 ISSUES WITH ASPHALT CHARACTERIZATION

Regardless of the precision of a standard and application of best practices, difficulties inherent to asphalt binders tend to pop up when trying to characterize them.

The bitumen composition and structure are generally assumed to follow the model of a colloidal suspension of asphaltenes in a maltene matrix [3]. Although widely used, this model contains a few inherent issues: it describes a generic bitumen composition based on solubility properties which do not consider molecular weight of species and their possible interactions and/or associations.

Works by LCPC now IFFSTAR, the Highway Central Laboratory of the France Road Administration, on high concentration and fast Gel Permeation Chromatography showed in the late 80's how important these interactions were, and how they could increase with aging [4]. Works by others showed that asphaltenes were not such high molecular weight molecules but were susceptible to self association in clusters behaving as higher molecular weight materials [5].

Oxidative aging is another important parameter affecting all bitumen chemical and mechanical characteristics. It occurs during mixing with aggregates in the plant, continues during the asphalt pavement service life, and varies with pavement porosity and depth. Although studied for a long time [6], both reaction mechanisms and kinetics are still largely unknown and have prevented finding effective solutions to increase pavement service life.

Another issue with binder structure is its temperature dependency resulting from the chemical types present and from the strengths of the intermolecular interactions in the bitumen. The interactions can be Van der Waals forces, aromatic pi stacking, hydrogen and ionic bonds. Major contributors to the temperature dependency are paraffinic waxes which are naturally present in some bitumen. They have an impact on bitumen morphology or microstructure as well as on mechanical properties.

Temperature dependency makes bitumen morphology tricky to observe and to interpret.

Key questions are: at which temperature is the sample examined correlatively to the temperature at which it is tested, is the observed area an average or is it local? Risks of artifacts are enormous: many asphaltene observations in the past were in fact waxes!

Obviously, binder mechanical properties are temperature dependant. Bitumen may be the most temperature susceptible engineering construction material as it changes from a glassy solid brittle material to a true flowing liquid in less than 80 ºC. Whereas, for decades practitioners have used empirical testing to evaluate and grade bitumen, like penetration and ring and ball, the advance of bitumen modification and changes in refining practices have led to looking more and more into more rational binder rheology.

Dynamic oscillatory Shear Rheology (DSR) was largely developed during the Strategic Highway Research Program (SHRP) and was a huge move towards PRS. Based on measurement of modulus and phase angle in the linear viscoelastic domain, it captures the time and temperature related responses of straight-run bitumens. However it misses some features of modified binder, particularly their response to non linear solicitation under repeated heavy load.

Current test methods tend to underestimate the effect of thermal history on the material response as well, although the real impact on asphalt performance has not been fully established yet. Binder thermal properties play an important role in steric and physical hardening which occur during storage of a bitumen sample at temperatures near the bitumen glass transition. This time-dependent hardening is an intrinsic property of materials. It is widely observed and accounted for in the polymer field, but vastly ignored in the bitumen field, although it does play a role in the low temperature fragility of bitumen and pavement thermal cracking.

3 ADVANCES IN BINDER CHARACTERIZATION AND STRUCTURE KNOWLEDGE

This brief panorama of the main issues affecting binder characterization may sound pessimistic; however, researchers from various institutions have made tremendous progress in recent years opening doors to a better understanding of bitumen composition and behavior. Here are some examples, not meant to be exhaustive.

3.1 *Composition*

- Bitumens can be separated into five chromatographic fractions and three asphaltene solubility subfractions with the automated SAR-AD (saturates, aromatics, resins-Asphaltene Determinator) separation. The fractions obtained provide correlations with stability, phase separation propensity, and degree of aging [7, 8].
- Crystallized fractions measured by Differential Scanning Calorimetry (DSC) can compete with asphaltenes and lead to phase separation, affecting bitumen mechanical properties [9, 10]. See Figure 1.

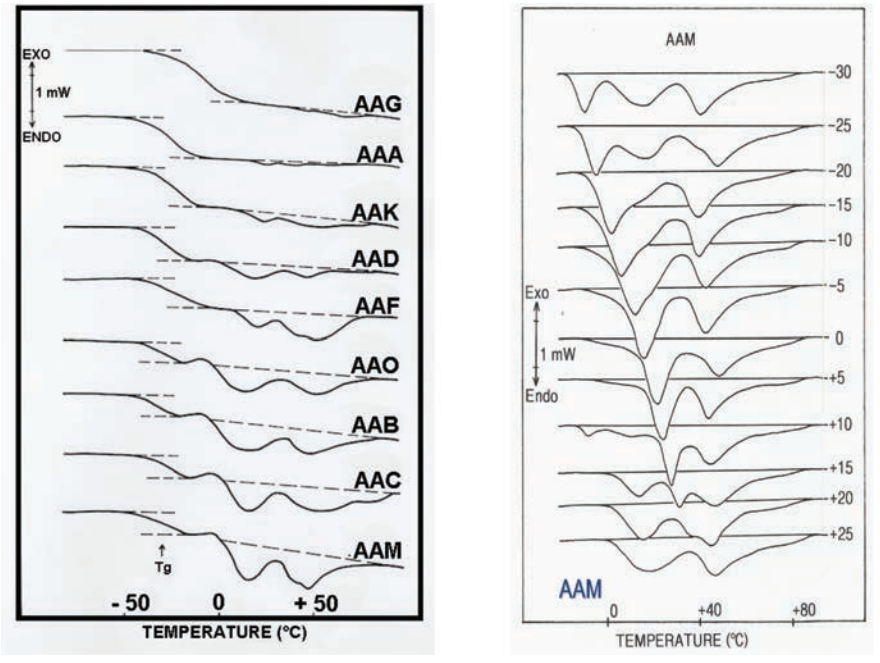

Figure 1. DSC measurement of the glass transition temperature and crystallized fraction for 9 SHRP core asphalts (left) and effect of 1 day isothermal conditioning (from −30 to +25C) on Waxy bitumen AAM thermal properties (right)—*Credit to Thermochimica Acta 324 (1998) 223−227.*

- 3D solubility parameter accounts for various interactions between the various bitumen molecules and helps to embrace solubility issues as a whole [11]. See Figure 2.

3.2 *Thermal properties*

- Bitumen thermal properties and history dependency as a function of conditioning temperature time can be assessed by Differential Scanning Calorimetry (DSC). This technique allows understanding the role of the crystallized fraction and the glass transition temperature in the binder mechanical properties [10].

3.3 *Morphology and microstructure*

- Crystallized fraction can be observed through optical microscopy techniques in phase contrast or dark field modes, upon cooling or heating [10]. See Figure 3. They stand out at the interface air-asphalt as a bee-like structure due to surface freezing as seen under Atomic Force Microscopy. See Figure 4 [12].

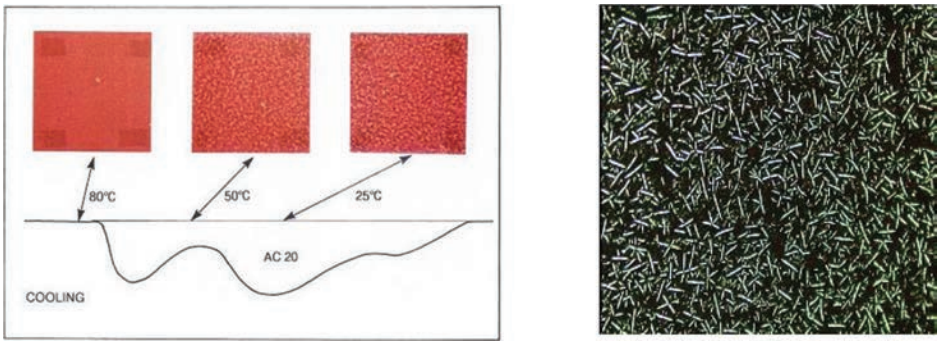

Figure 3. Observation of crystallized fraction precipitation upon cooling by DSC and phase contrast microscopic observation (left—*Credit to Thermochimica Acta 324 (1998) 223–227)*, and by dark field microscopy (right).

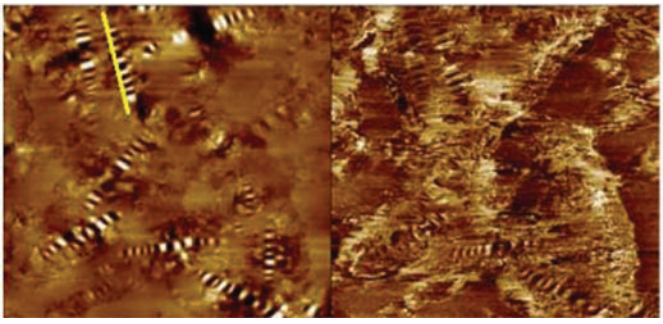

Figure 4. Observation of bee structures in asphalt by AFM—credit to T. Pauli, WRI.

- Polymer modified Binders (PmB) have very complex morphology depending on the polymer compatibility with the bitumen matrix. Polymer molecules usually swell with oily aromatic maltene molecules—this local phase separation can be quantified by FTIR microscopy [13]. How well-dispersed the polymer is affects its "reptation ability" which is highly responsible for some PmB mechanical properties—a phenomenon earlier described by Nobel prize De Gennes [14].

3.4 *Links with mechanical properties*

- Thermal susceptibility of binders impacts their rheology. Black space diagram plotting with no shift phase angle as a function of the stiffness modulus from DSR measurement shows a single smooth curve for rheologically simple binders, but not for complex binders. The shape of the black curve can be related to asphalt composition, particularly the asphaltenes and crystallized fractions contents [15] which undergo time dependent phase transition. See Figure 5.
- Isothermal physical hardening at low temperature has an effect on bitumen low temperature mechanical properties. This was shown during the SHRP program measuring bitumen stiffness and relaxation after various conditioning times. This was later related to some extent to the bitumen crystallized fraction and quantified relative to its glass transition temperature See Figure 6 [10]. These composition parameters also show up in steric hardening, affecting fatigue measurement.
- In real life, binders can be subjected to stresses outside the linear domain. The Multiple Stress and Recovery (MSCR) test allows measuring unrecovered strain which is related to permanent deformation and to the binder impact in mix rutting. Evaluating binders under conditions closer to field conditions is even more relevant for highly structured or modified binders which respond differently [16]. It shows reasonable relationships with mixture rutting performance evaluated in the lab, as shown in Figure 7.
- Other DSR tests are under development to capture binder fatigue properties, like the linear amplitude sweep or the time sweep. Fracture mechanics based tests run on notched specimens are getting attention for characterizing thermal cracking both in Europe and North America. These tests are pushing the limits of classical rheology theories.

3.5 *Aging*

- Bitumen oxidative aging has long been studied [6]. Work at Western Research Institute under the US Federal Highway Administration (FHWA) contracts has shown lately that formation of carbonyls and sulfoxides under reaction with oxygen, measured through Fourier Transform Infrared (FTIR) spectroscopy, accounts for changes in unmodified asphalt rheological properties as a function of oxidation time. These researchers also confirmed by modulated DSC that a change of molecular interaction under oxidative aging expands the bitumen glass transition temperature range.

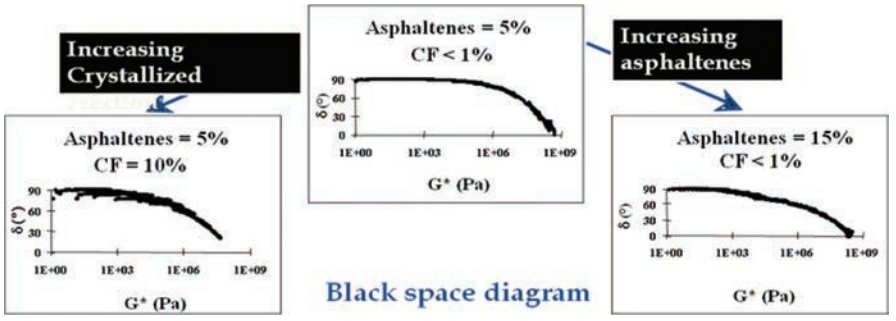

Figure 5. Effect of composition on black space diagram—from [15].

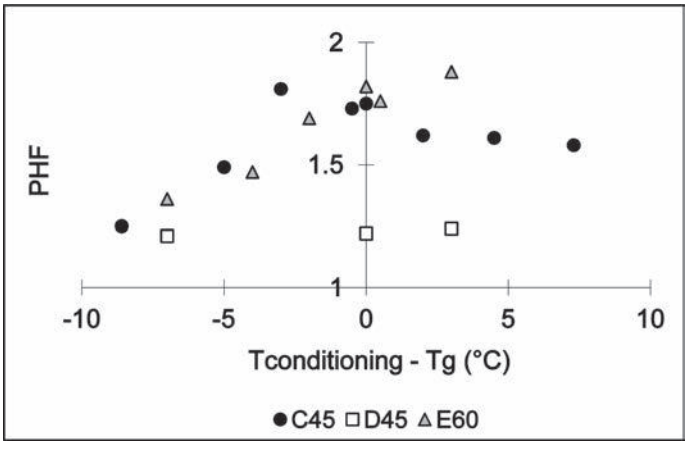

Figure 6. Effect of the glass transition temperature (Tg) and Crystallized Fraction (CF) on bitumen physical hardening—C45, D45, E60 having respectively 3.6, 0.5, 4.3% CF—*Credit to Thermochimica Acta 324 (1998) 223–227.*

- Polymer modified bitumen aging gets very complex: FTIR microscopy studies using an oxidation cell have shown that the respective oxidation of the bitumen and the polymer molecules change the system compatibility [13]. Homogeneous Polymer modified Binders (PmB's) tend to evolve less than heterogeneous materials from both a morphology and rheology standpoints. Polymer chain scission, although related to polymer degradation,

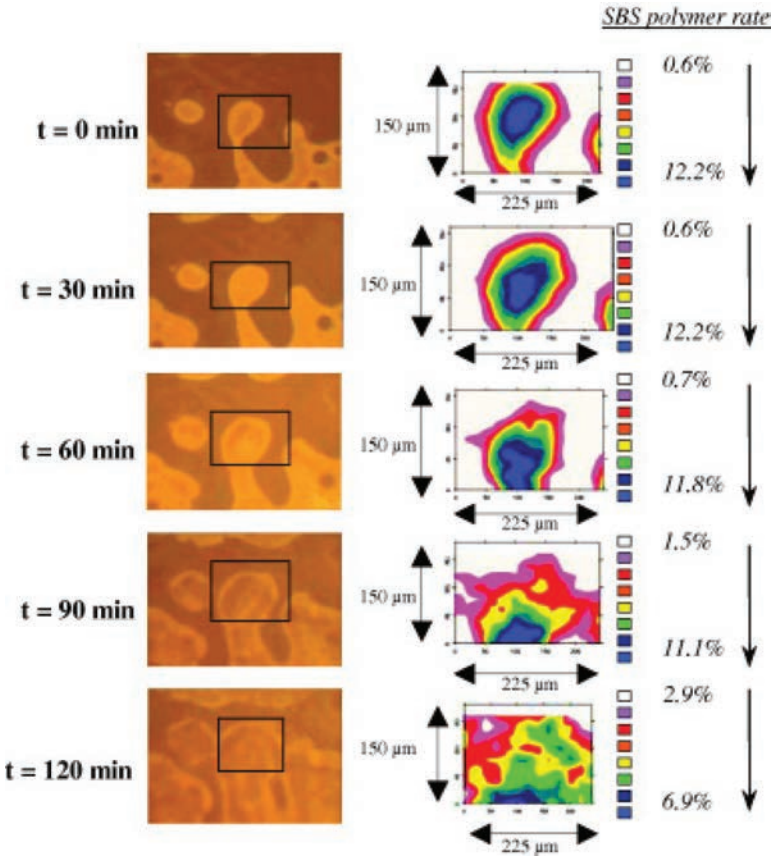

Figure 8. Kinetic evolution of the polymer network of a 6% SBS PmB by infrared mapping (130 °C under air during 2 h) (based on the ratio of SBS infrared absorption band at 965 cm^{-1} to the specific bitumen band at 1376 cm^{-1})—*Credit to Fuel 87 (2008) 1270–1280.*

can actually improve polymer dispersion, whereas stable macromolecules can become less compatible and phase separate. See Figure 8.

4 CONCLUSIONS AND PERSPECTIVES

Bituminous materials feature unique chemical and physical properties that make them difficult to analyze and characterize. Traps are numerous, but advances in this field are likely to improve binder understanding and create applications more relevant to the stakeholders, from researchers to producers, road users, all the way to tax payers.

Among those significant improvements, one must cite the assessment and understanding of molecular associations and interactions, phase separations, their impact on thermal history to compare binders in the same physical state. This will allow to measure intrinsic properties that ultimately influence pavement performance.

Powerful tools and research teams are becoming available to look at the fundamentals, from the nano molecular level all the way to the pavement performance. The FHWA Asphalt Research Consortium, for instance, looks at the mechanics of bitumen at nano-level using atomic force microscopy to attempt to predict field cracking behavior, with the support of TU Delft.

These advances will have an impact on binder production. Smart engineering will be able to replace classical refined asphalt “goodies” and make durable and performing binders.

There will be more cost effective additives that will be more widely used. They will include new polymer types, bio-additives and nanotechnology modifiers … Developing relevant analytical techniques for asphalt binders will foster innovation from industrial partners that are not currently present in the field.

Furthermore, governmental agencies have officially initiated the move towards greener/durable and LCA efficient pavements through projects like European "Forever open road" or "Every Day Counts Innovation Initiative" from the FHWA [16, 17]. Lately the Infravation Transnational Project was launched to boost innovation in infrastructure [18].

ACKNOWLEDGEMENTS

The author would like to acknowledge FHWA, WRI and Total Bitumen research teams and a number of experts whose stimulating input over the years has contributed in improving bitumen binder knowledge, particularly David A. Anderson, Pierre Claudy, John D'Angelo, Gayle N. King, Didier Lesueur, Claine Petersen, Per Redelius, Francis Rondelez, Christian Such and Jack Youtcheff.

Why preservation-definitions, treatment types, benefits, and challenges

R. Gary Hicks & Dingxin Cheng
CP2 Center, CSU Chico, Chico, CA, USA

ABSTRACT: Pavement preservation has been an important topic for flexible pavements for many years. It was not until the Foundation for Pavement Preservation (FP2) was established in 1992 that it became an important aspect in the area of system maintenance and preservation. There are several types of treatments included in the pavement preservation tool box including thin HMA overlay, chip seals, slurry surfacings, and cape seals. This paper addresses the definitions, types of treatments currently included in the tool box, the reported benefits of the treatments (including, cost, energy and environmental), and the challenges still facing agencies in documenting the benefits and increasing the use of these types of treatments. Recent developments with funding pavement preservation and rehabilitation and the implications of the new Technical Advisory for the ADA act are also discussed.

Keywords: Pavement preservation definitions, challenges, benefits, pavement management systems

1 INTRODUCTION

Americans are accustomed to easy mobility on safe, smooth, and well maintained roads. These same roads play a critical role in the nation's economy providing opportunities for agriculture, industry, commerce and recreation. Unfortunately, many of our road networks are deteriorating in quality requiring better management of our assets. This paper discusses the importance of preservation and many of its benefits and challenges. We have come a long way, but still have much to do.

2 BACKGROUND

Pavement preservation is similar in concept to conducting regular maintenance on an automobile or a house to keep them in good condition. For example, a low-cost maintenance activity such as routinely changing the motor oil in an automobile can improve the likelihood that the engine will not require a major overhaul prematurely and extend the lifespan of the engine. Similarly, paying for minor work now to prevent major work earlier in the future is an important concept of pavement preservation.

For example, the California Department of Transportation (Caltrans) has been describing the benefit of pavement preservation to that of pavement rehabilitation using a 6 to 1 ratio, meaning that the costs of pavement preservation treatments are about 1/6 of that for pavement rehabilitation [1]. Figure 1 illustrates this concept, where $1 invested in preventative measures while the pavement is in good condition can delay or avoid spending $6 for more substantive work. It is important to note that these figures are based on first costs only and do not consider the lives of the treatments, the life extension of the existing pavement associated with the treatments, and other costs such as user and safety costs; including these other factors and costs would result in even greater savings.

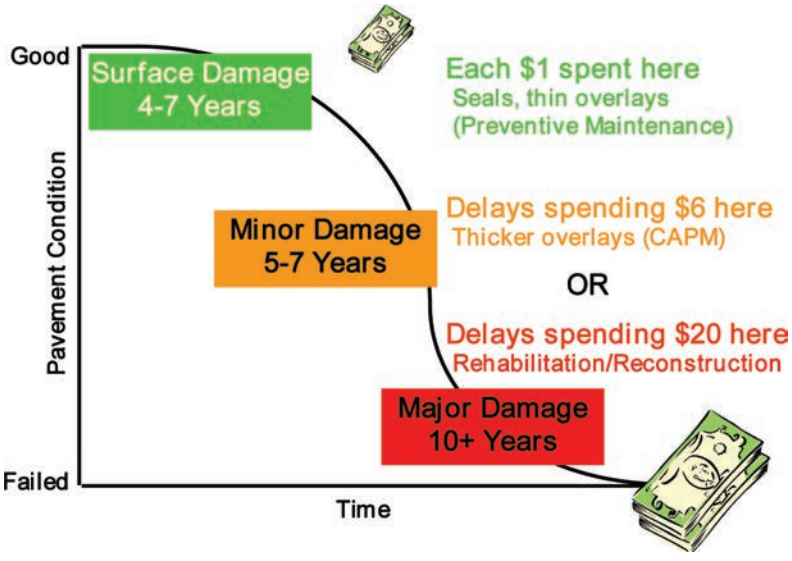

Figure 1. Pavement preservation concept used by Caltrans and other agencies.

3 DEFINITIONS

A clear presentation of pavement preservation in the United States requires the development and adoption of standard definitions. The following presents the current definitions related to pavement preservation used by the Federal Highway Administration (FHWA) and the American Association of State Highway and Transportation Officials (AASHTO).

3.1 *Asset management*

FHWA and AASHTO define asset management as a systematic process of maintaining, upgrading, and operating physical assets cost-effectively [2]. Asset management combines engineering principles with sound business practices and economic theory and provides tools to facilitate an organized, logical approach to decision-making. Asset management provides a framework for both short- and long-range planning. Asset management is important to state and local governments because of the Governmental Accounting Standards Board's (GASB) Policy Statement 34, "Basic Financial Statements for State and Local Governments," issued in June 1999. GASB 34 encourages government agencies to promote asset management practices and to report the value of capital assets such as utilities, roadways, and other infrastructure [3]. The value and maintenance of these assets eventually affects the bond ratings of government agencies, which in turn affect the government's ability to borrow the money to repair and replace the investments. The objective of an asset management program, therefore, is to:

- Consider various investment strategies,
- Provide a more rational decision process, and
- Improve the overall condition of the highway system at a lower cost.

3.2 *Preventive maintenance*

According to AASHTO, preventive maintenance is a planned strategy of cost-effective treatments that preserves, maintains, or improves a roadway system and its appurtenances and retards deterioration, but without substantially increasing structural capacity [4]. Preventive maintenance is a tool for pavement preservation where non-structural treatments are applied early in the life of a pavement to prevent deterioration and extend the life of pavement.

3.3 *Pavement preservation*

Pavement preservation is the sum of all the activities to provide and maintain serviceable roadways, including corrective and preventive maintenance, as well as activities such as pothole patching, rut filling, or unplugging drainage facilities. Reactive maintenance, therefore, is unscheduled; sometimes immediate response is necessary, to avoid serious consequences.

3.4 *Emergency maintenance*

Extreme conditions, when life and property are at risk, require emergency maintenance. Examples include washouts, rigid pavement blow-ups (the shattering or upward buckling of concrete slabs along a joint), and rockslides or earth slides.

4 TREATMENTS

In the past, many maintenance practices have not been effective, because they were applied reactively to roads in poor condition instead of proactively to roads still in good condition. Succinctly stated, the correct approach to preventive maintenance is to "place the right treatment on the right road at the right time." They also need to be placed in the right way.

Preservation became a topic in the early 1990s, when highway agencies examined effective maintenance practices. The preservation concept, whether for pavements or for bridges, is a departure from traditional approaches, which wait until deficiencies are evident and until reconstruction or major rehabilitation are the only means to correct the problem.

Preservation, however, addresses minor deficiencies early, before the defects become major problems, and extends the life of the asset at a relatively low cost. A strong preservation program is essential to asset management. Because preservation activities include so many kinds of treatments, agencies should build their own preservation toolboxes to serve their particular needs. Just as a mechanic's toolbox contains many different tools, each designed for a specific job, a preservation toolbox should include a host of treatments to address specific conditions.

No treatment will be suitable for every location. For example, a chip seal may be a long-lasting, cost-effective surface treatment in a rural area, but not in a large urban area. Conversely, concrete ultrathin white-topping may be cost-effective in a large urban area, but not in a rural area. Similarly, performance and cost-effectiveness should be evaluated in the context of the areas in which the preservation treatments are applied. Typical treatments used for flexible and rigid pavements in California are given in Table 1 [1].

8. Slurry seals	8. Full depth concrete repair
9. Microsurfacing	
10. Thin maintenance overlays	
11. Bonded wearing course	
12. Interlayers	
13. In-place recycling	

The preservation community has identified several potential benefits associated with implementing a pavement preservation program. The most significant benefits include the following:

- Life extension of the existing pavements. Pavement preservation treatments can extend the life of a pavement thereby delaying the need for pavement rehabilitation [5]. Figure 2 illustrates this conceptually. That is, timely, low-cost treatments that defer pavement rehabilitation or reconstruction preserve current funds for use on other more urgent or needed activities.
- Lower treatment costs. Pavement preservation treatments typically cost from $1–6 per square yard, while the cost to rehabilitate roads can be 6 to 10 times more expensive, and the cost to reconstruct roads can be 15 to 30 times more expensive [6].
- Reduced user costs. Driving on rough roads increases vehicle operating costs through accelerated vehicle depreciation, reduction in fuel efficiency, and damage to tires and suspensions. TRIP estimates an added cost of $335 annually for the average driver to as high as $746 annually for drivers in urban areas with high concentrations of rough roads [7].
- Improved safety (to the public and the workforce). As compared with rehabilitation work, pavement preservation treatments usually take less time to complete; that is, the contractor can get in and get out faster minimizing the chances for work-zone crashes during long work periods. Better roads surfaces also provide for good drainage and skid resistance thereby improving safety to road users [8].
- Improved overall network health. Some agencies have shown an improvement in overall network health by keeping good roads in good condition.
- Pavement preservation is "green." Use of preventative maintenance treatments such as chip seals and micro-surfacing consume 12 to 34% of the annualized energy and emit 10 to 27% of annualized greenhouse gases in comparison with major rehabilitation work involving a 4-inch hot mix asphalt overlay [9]. The comparisons include the energy required for and emissions produced in obtaining the raw materials from the earth and all the operational steps (i.e., transport, refining, manufacturing, mixing, and placement) required to produce a finished product. The comparison also accounted for differences in life extension of a pavement provided by the different treatments. According to the authors, energy savings are slightly lower and greenhouse gas emissions are about the same when compared to major rehabilitation work involving a 4-inch warm mix asphalt overlay. In addition, use of preventative maintenance treatments such as fog seals and cracking sealing resulted in substantially lower consumption of energy and emission of greenhouse gases.

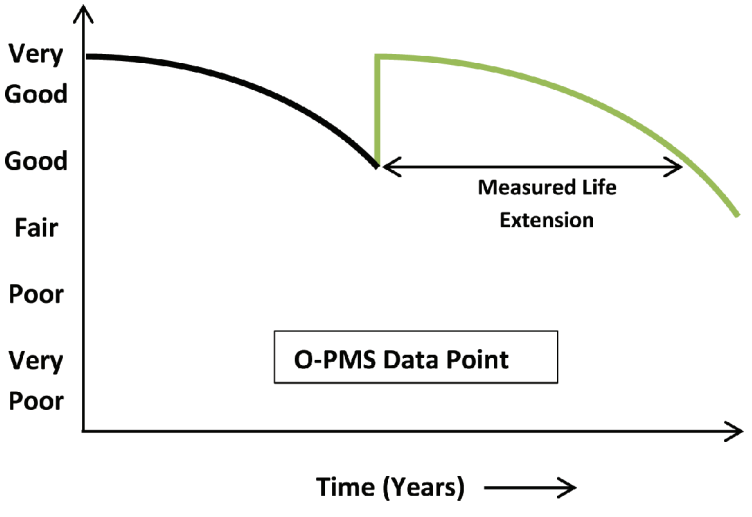

Figure 2. Life extension due to preventative maintenance.

To realize the above benefits, agencies and industry need better information to convince the transportation commission and the legislature (or the other decisions makers) to provide more dedicated funding for pavement preservation while at the same time finding additional funds to repair pavements beyond the preservation stage. Work has been accomplished at the California Pavement Preservation Center (CP2 Center) to provide better information on the economic benefits of pavement preservation [10].

5 CHALLENGES

Several issues and barriers can be identified for implementing pavement preservation. Some of these are discussed below.

5.1 *Agency issues*

The first and most important is dealing with the paradigm shift from fixing worst pavements first to fixing good pavements first. One of the biggest obstacles to overcome is to convince agency personnel to move from the conventional worst-first practice of fixing pavement problems to fixing good pavements first while letting the bad ones continue to deteriorate. People simply have a hard time making this adjustment without documented evidence of the cost savings associated with pavement preservation.

Next there is a need for top management commitment. Pavement preservation programs will not succeed without top management commitment. This includes getting a commitment for dedicated funding and for resources needed to collect information on the effectiveness of preventive maintenance treatments. Caltrans has done much in this area without the best of data due to an inadequate pavement management system. This is now being dealt with as Caltrans moves forward with the development of a new and improved pavement management system.

There is also a need to identify a champion for the program within the agency. Pavement preservation programs need a champion for them to be effective. As with any new effort or program within an agency, someone must be constantly promoting the importance and benefits of the effort. Without a champion, the new effort will simply not succeed. For example, Caltrans has champions for pavement preservation and they are promoting the benefits of the program to the legislature [11, 12].

It is necessary to show the early benefits of the pavement preservation program using pavement management system that is able to show treatment lives, life extensions, and/or reduced life cycle costs. In the absence of good data from Pavement Management Systems, alternative methods for estimating treatment lives and life extension may have to be employed.

Preventive maintenance treatments can be ineffective if the correct treatments are not used at the right time. One failure is equivalent to hundreds of successes in a new program such as one like pavement preservation. It is important that the right treatment be used on the pavement and that it is applied in a timely manner. In a recent study for FHWA, it was determined that the loss of life and increased costs of not placing treatments right can be significant as shown in Figure 3.

5.2 *Industry issues*

The issues and barriers for industry groups mostly involve reluctance to disturb the status-quo and include the following:

- Competition between the suppliers of maintenance and rehabilitation treatments. With the shift from the traditional rehabilitation programs of HMA overlays applied every 10 to 20 years to pavement preservation programs using new or different treatments, some resistance has occurred from the suppliers of traditional rehabilitation materials. For example, hot-mix suppliers might\resist new cold treatments because of the likely loss in market share.
- Competition between various suppliers of maintenance treatments. When markets have been established for certain types of treatments and a new treatment type is being

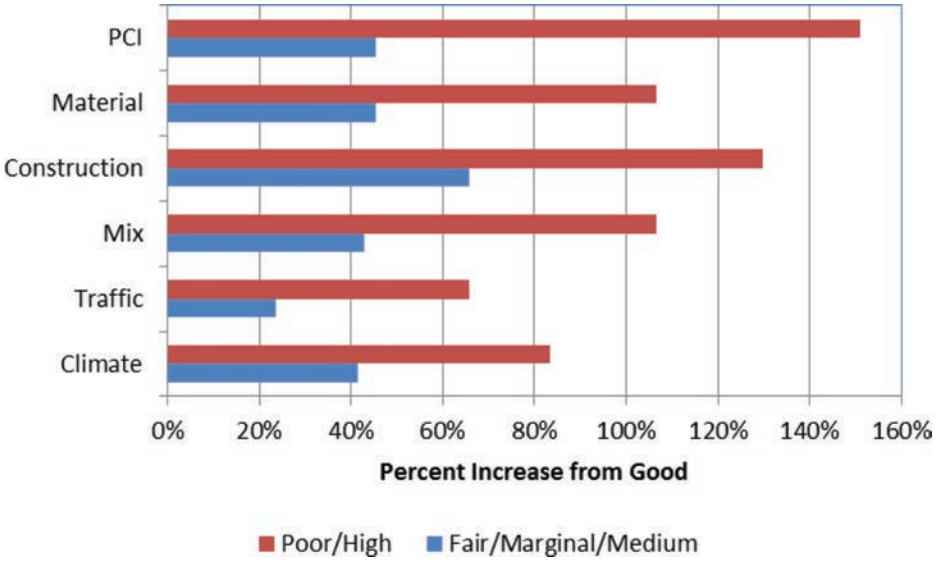

Figure 3. Cost impact if thin HMA treatments are not placed on the right road using good practice for climate, traffic materials and construction factors [13].

introduced, industry often works to block the new products, whether for technical reasons or for business reasons, again to avoid loss of market share.

- Political lobbying to prevent use of new maintenance treatments. In some cases, industry will resort to political lobbying to prevent new technologies from entering the market. Again the reasons may be technical but more than likely are related to the effect on the market if an agency adopts the new technology.
- Establishing the benefits of new technologies or treatments. Suppliers often introduce new technologies without adequate evidence of the benefits. The supplier must provide the agency with detailed documentation of the product's benefits and performance.

5.3 *Convincing the public*

The introduction of preservation programs also affects the traveling public, the ultimate customer, raising a different set of issues and barriers as follows:

- Understanding the shift from repairing the worst pavements first to the best pavements first. The public does not understand why agencies would be working on good roads but letting the bad roads deteriorate. Most of the public understands the importance of maintaining a car or a house to prevent major repairs. Pavement preservation engineers should be able to explain the value of preventive maintenance treatments now compared with the cost of major repairs later.
- Understanding the effects of the various maintenance and rehabilitation strategies on delays and vehicle costs. Primary benefits of pavement preservation include the potential for reducing traffic delays by using faster repair techniques and for reducing user costs by maintaining pavement net-works in better condition. Although widely acclaimed, these benefits still lack the documentation of national studies.
- Understanding safety issues. Increased safety for the traveling public and for workers in the work zone are other potential benefits from keeping roads in good condition through pavement preservation treatments; these benefits also need to be documented and communicated.
- Another challenge is to convince public that frequent short-term interruptions to their travel plans are better than less frequent long-term interruptions, especially in business districts.

5.4 *Regulatory*

A recent issue emerged in 2013 when the US Department of Justice and the USDOT jointly issued a technical advisory that redefines what maintenance and alteration is in terms of requiring curb ramps according to the Americans with Disabilities Act of 1990 (ADA) requirements. In the new technical advisory, slurry seals are defined as maintenance and microsurfacing is defined as alterations which requires construction of missing or upgrading of noncompliant curb ramps. Cape seals and thin bonded overlays are now alternations as well. It is expected that this issue will impact the treatments that will be used by agencies as well as the cost of providing well maintained roads and streets in urban areas [14].

6 SUMMARY AND RECOMMENDATIONS

Many agencies have been very successful in implementing a pavement preservation program, but there is still more to do. This section summarizes the major accomplishments during the past two decades:

- In the United States, formation of the FP2 Inc. and Preservation Centers at Michigan State, University of Texas, and CSU, Chico. Also, pavement preservation partnerships were developed for the various regions of the United States. These have aided in promoting the concept of pavement preservation and provide for opportunities to exchange ideas on treatments and specifications.
- Many agencies have developed and implemented a pavement preservation program with top management support. This includes permanent funds for pavement preservation. For example, Caltrans is currently funded at nearly $300 million per year for preservation. This should be increased to $800 million per year in order to treat 7,000 lane-miles per year. By doing this, they can save 50% or more of the rehabilitation budget each year, allowing the savings to help reconstruct the more distressed roads.
- Agencies have developed guidelines for preservation for flexible and rigid pavements. These have assisted the states as well as local agencies to become more aware of the available techniques and how and when to apply them.
- Agencies have developed innovative programs to place new preservation techniques. In California, these new technologies are monitored by the CP2 Center using a pavement preservation database that can be accessed by agencies or industry to help with this effort. This has been used by industry to show the performance of their new innovations.
- Caltrans developed a computerized strategy selection program which considers cost effectiveness of the various treatments. This is available on the CP2 Center website for use by state or local agencies. It continuously undergoes upgrades as new treatments or technologies are deployed.

Recommendations for the next several years included the following:

- Developing new and improved tests for mix designs and quality control and acceptance testing for pavement preservation treatments. The industry still has much to do in this regard.
- Upgrading performance based specifications for many of the treatments to minimize the chances for early failure.
- Providing continuous education on how to place successful pavement preservation treatments.
- Documenting the long term performance of the various treatments using improved databases

Urban heat island effect: Comparing thermal and radiation effects of asphalt and concrete pavements on adjacent buildings using CFD methods

Malcolm Swanson & Andrew Hobbs
Astec Inc., Chattanooga, TN, USA

ABSTRACT: There is a the perception among some that asphalt pavements, particularly as surfaces for parking lots for facilities such as shopping centers, apartment buildings, and office buildings, are contributing to global warming through the so called urban heat island effect. The contention is that Portland Cement Concrete (PCC) is a less significant contributor to global warming via this mechanism and is, therefore, the preferred paving material. This rationale with some supporting science has succeeded sufficiently to result in PCC being given an advantage in building codes toward obtaining building LEED certification. The basis for this thought is that, since asphalt pavements are black and concrete pavements are white, the asphalt will absorb more solar radiation and become hotter during the course of daylight hours. Because empirical data in urban environments is difficult to obtain and clouded by a myriad of other effects Computational Fluid Dynamics (CFD) was chosen to compare an idealized configuration of an office building and parking lot. Only the reflectivity (albedo) of the parking lot was altered to simulate both asphalt and concrete. The results showed that the building surface temperature was actually higher for the concrete parking lot than the asphalt lot indicating a higher cooling load would be required. These results run counter to commonly held beliefs about the superiority of concrete pavements in urban environments and suggest the need to re-examine the suitability of asphalt pavement in urban settings.

Keywords: Asphalt pavement, urban thermal loading, urban heat island effect, CFD, environmental radiation

1 INTRODUCTION

Urban areas with a high percentage of paved surfaces are often several degrees warmer than rural areas with less paved surfaces. Because most paved and roof surfaces are dark they absorb more solar radiation resulting in higher local temperatures. This is commonly known as the Urban Heat Island effect (UHI). Higher localized air temperatures increase the energy required for cooling and as a result contribute to global warming [1]. Some studies suggest that the mitigation of UHI can result in peak utility savings of 5 to 10% [2].

In an effort to mitigate UHI green infrastructure often requires the use of cool pavements—pavements which reflect more solar radiation. Cool pavements are in integral part of a strategy to minimize the effects of UHI put forward by the U.S. EPA [3]. Because PCC has greater reflectivity than traditional asphalt pavements it is often preferred [4]. However recent work has called into question the use of materials with higher reflectivity siting many potential negative effects [5].

Because uncluttered thermal data is difficult to collect in urban setting a computer simulation whereby all the environmental inputs are controlled is a good method to test the effects of pavement reflectivity on adjacent buildings, specifically the difference between two common paving materials: asphalt and PCC.

2 SIMULATION METHODS

Computational Fluid Dynamics (CFD) has been well established as a tool for simulating fluid phenomena in a wide range of industrial applications [6–8]. Because CFD methods are well documented only an overview of the models used in this study are mentioned. The governing equations are time averaged using the Reynolds Average Navier-Stokes (RANS) method. The equations are discretized over a computational grid and solved iteratively. The k-epsilon turbulence model was used and incompressible ideal gas which provides temperature dependent density was used for air. The Discrete Ordinates (DO) radiation model was used to calculate the radiation heat transfer. The DO model solves the Radiation Transport Equations (RTE) shown in Eq.(1) for emitting, absorption, and scattering within the fluid domain.

$$\frac{dI(\vec{r},\vec{s})}{ds} + (a+\sigma_s)I(\vec{r},\vec{s}) = an^2\frac{\sigma T^4}{\pi} + \frac{\sigma_s}{4\pi}\int_0^{4\pi} I(\vec{r},\vec{s}^{\,t})\Phi(\vec{s}\cdot\vec{s}^{\,t})d\Omega^t \tag{1}$$

where $\vec{r}$ = position vector
$\vec{s}$ = direction vector
$\vec{s}^{\,t}$ = scattering direction vector
s = path length
a = absorption coefficient
n = refractive index
σ_s = scattering coefficient
σ = Stefan-Boltzmann constant (5.672×10^{-8} W/m^2 – K^4)
I = radiation intensity, which depends on position $\vec{r}$ and direction $\vec{s}$
T = local temperature
Φ = phase function
Ω = solid angle

The RTE are solved for a finite number of discrete solid angles in the global Cartesian system each with a direction vector $\vec{s}$ as shown in the field equation for the RTE, Eq. (2). The DO model solves as many transport equations as there are directions defined by $\vec{s}$ with the angular discretization of $\vec{s}$ as a user input [9].

$$\nabla\cdot(I(\vec{r},\vec{s})\vec{s}) + (a+\sigma_s)I(\vec{r},\vec{s}) = an^2\frac{\sigma T^4}{\pi} + \frac{\sigma_s}{4\pi}\int_0^{4\pi} I(\vec{r},\vec{s}^{\,t})\Phi(\vec{s}\cdot\vec{s}^{\,t})d\Omega^t \tag{2}$$

The appropriate solar loading for the specified geographic location, time, and date was calculated using Fluent's Solar Calculator and applied as radiation emitter from the sky boundary. The solar load was applied using direction and intensity calculated according the solar conditions listed in Table 1. The Solar Calculator uses the ASHRAE Fair Weather Conditions method to solve for the direct normal solar irradiation given by Eq. (3) where A is apparent solar irradiation at air mass m = 0, B is the extinction coefficient, and β is the solar altitude in degrees above the horizontal.

$$Edn = \frac{A}{e^{\frac{B}{\sin(\beta)}}} \tag{3}$$

To pursue this analysis, it was arbitrarily decided that a 10 story office building with a large parking lot would represent an idealized test case. A 3D CAD model of the building, parking lot, and surrounding ground and air was created and a computational mesh generated comprising of 9.6 million cells with prism boundary layers on the building, ground, and parking lot. Dimensions of the building and parking lot along with boundary conditions are shown in Table 2.

Table 1. Inputs and outputs of solar calculator.

Inputs	
Date, time	July 4th, 1 PM
Position	Chattanooga, TN
Orientation	South facing parking lot
Outputs	
Sun direction vector	(–0.21, 0.975, –0.057)
Direct normal solar irradiation	880.02 W/m^2
Diffuse solar irradiation—vertical surface	78.372 W/m^2
Diffuse solar irradiation—horizontal surface	118.685 W/m^2
Ground reflected solar irradiation—vertical surface	97.74 W/m^2

Table 2. Building and parking lot dimensions and boundary conditions.

Parking lot	$228.6 \times 76.2 \times 0.61$ m
Building	$60.96 \times 30.48 \times 60.96$ m
Ambient temp	300 K
Wind	2.23 m/s West to East
Gravity	(0, –9.81 m/s, 0)

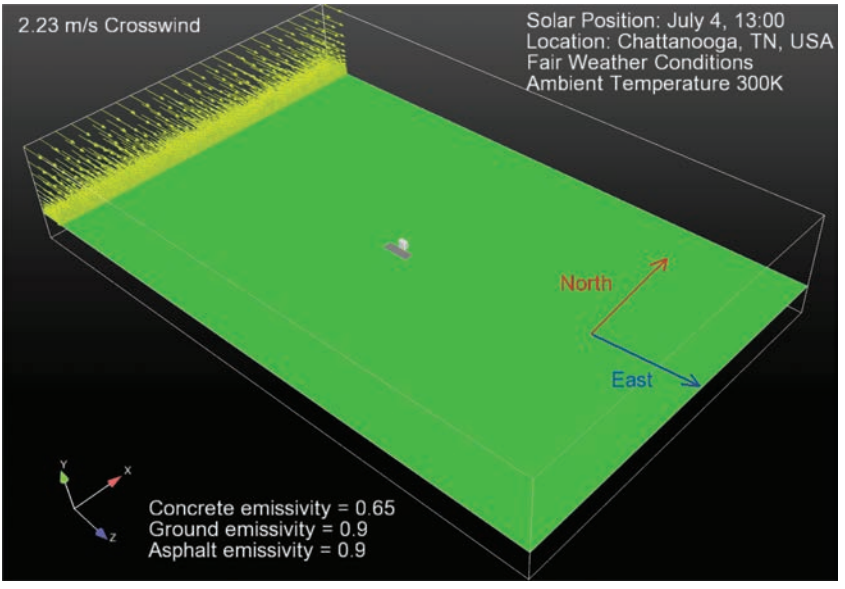

Figure 1. CFD boundary conditions with solar load inputs.

Table 3. Material properties.

	Asphalt	Concrete	Ground
Density (kg/m^3)	2240	2240	1600
Specific heat (J/kg-K)	750	750	800
Thermal conductivity (W/m-K)	1	1	0.5
Reflectivity	0.1	0.35	0.1
Emissivity	0.9	0.65	0.9

The CFD simulations were performed using the commercial CFD code ANSYS Fluent. The fluid domain and boundary conditions along with the dimensions of the building and parking lot are shown in Figure 1. A 2.23 m/s cross wind was set using a velocity inlet condition on the west wall with a pressure outlet on the east wall. The wall and sky boundaries were positioned far enough away to have minimal effect on the area of interest. The parking lot was modeled with a depth of 0.61 m while the ground layer surrounding the parking lot had a depth of 243.84 m. The building itself was modeled as a solid volume of concrete.

The Fluent radiation model assumes grey band radiation which implies that reflectivity or albedo of an opaque wall is defined as 1—emissivity. With the exception of reflectivity and emissivity identical physical properties were used for both asphalt and concrete. The material properties with surface emissivities and reflectivities are shown in Table 3.

3 RESULTS

The CFD results can be visualized by coloring the surfaces by the element value of the variable in question. Temperature contour plots show that the asphalt parking lot becomes hotter than the concrete parking lot (Fig. 2). Plotting reflected radiation on the same surfaces (Fig. 3) shows that indeed more radiation is reflected from the concrete parking lot and more is absorbed by the asphalt parking. However, closer examination of the building surface temperature reveals that higher temperatures are seen with the concrete parking lot (Fig. 4).

Temperature data was taken on a vertical line at the peak temperature on the southern face of the building to compare values. The data plotted in Figure 4 shows higher surface temperatures for the concrete parking lot.

The explanation for these higher temperatures is that lower absorptivity of the concrete parking lot reflects more radiation (Fig. 5) than the higher absorptivity of the asphalt.

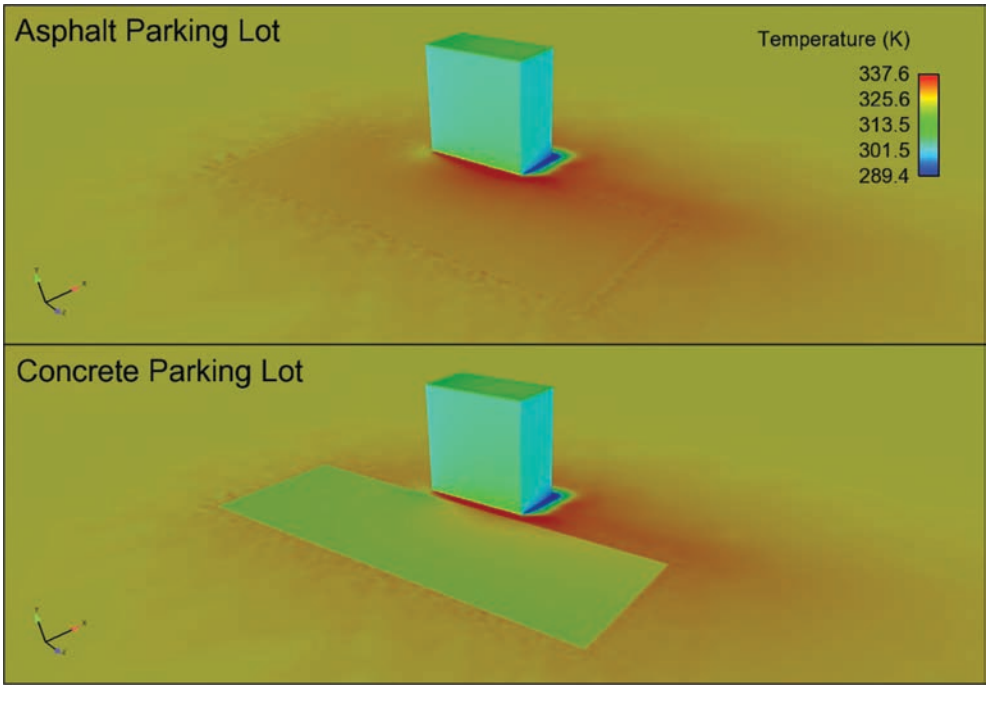

Figure 2. Surface temperature on ground, building, and parking lot.

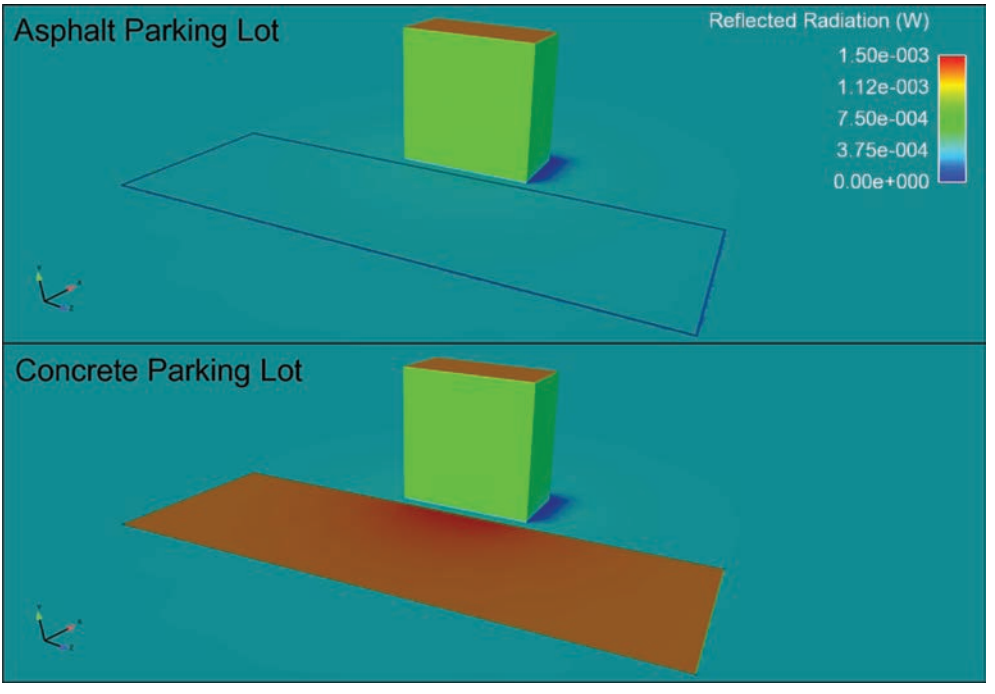

Figure 3. Reflected radiation heat flux on building, ground, and parking lot.

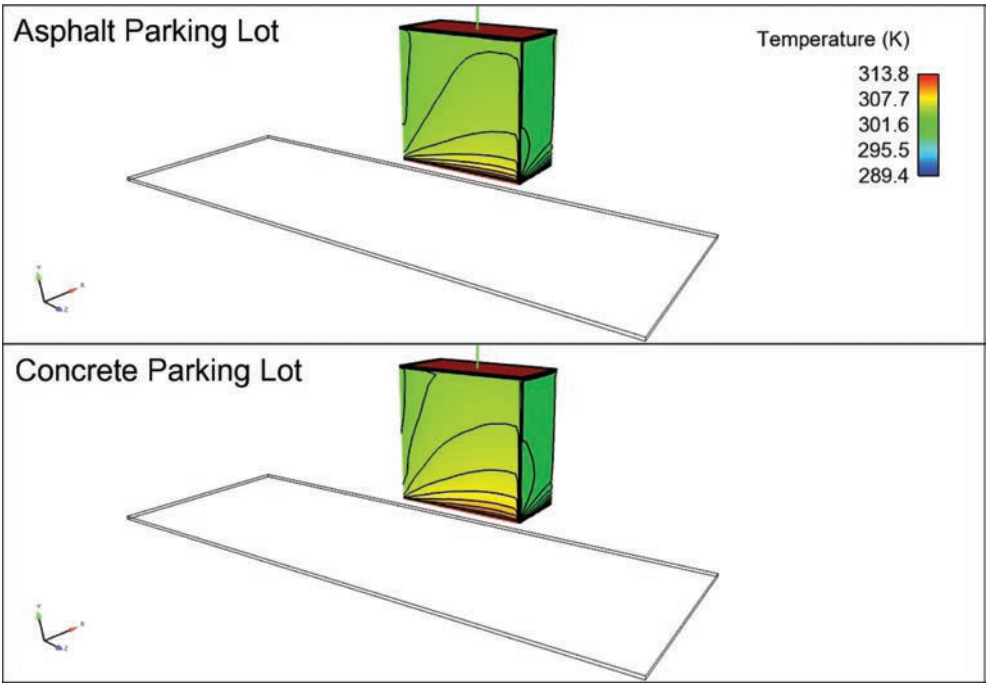

Figure 4. Contours of temperature on building surface.

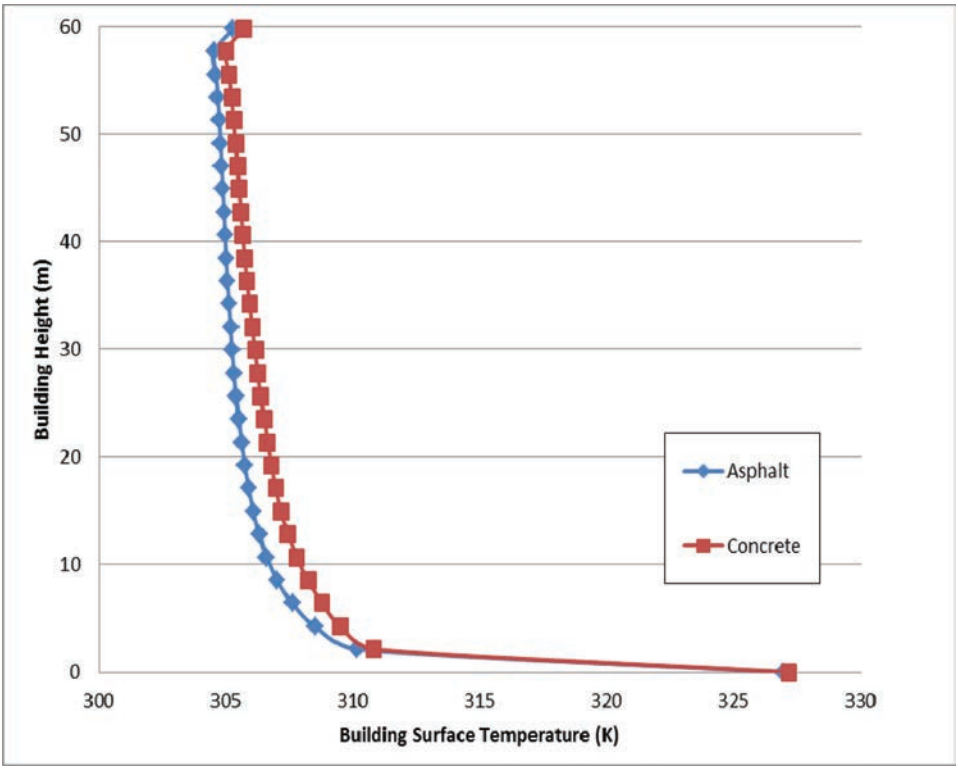

Figure 5. Building surface temperature on southern face.

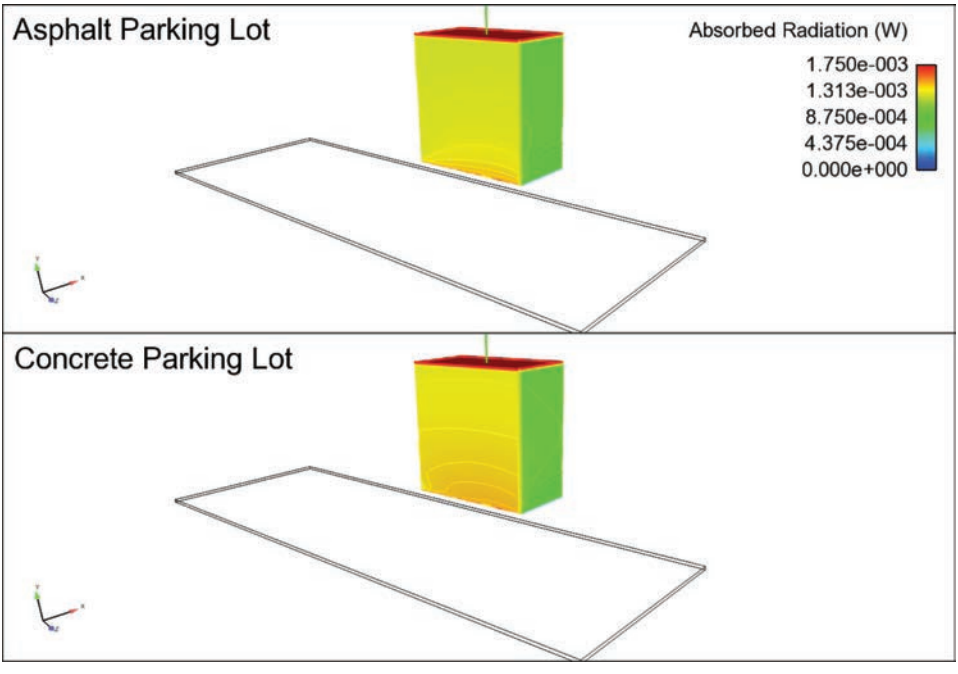

Figure 6. Absorbed radiation flux on the building.

Table 4. Summary of results.

	Asphalt	Concrete
Building average temperature (K)	327.01	326.99
Parking lot average temperature (K)	328.71	323.26
Parking lot reflected radiation (W)	1.898E+06	6.646E+06
Building incident radiation (W)	7.777E+06	7.882E+06
Building absorbed radiation (W)	5.055E+06	5.123E+06

As a consequence more incident radiation is received on the building surfaces for the concrete lot and more of this radiation is absorbed (Fig. 6) resulting in higher surface temperatures. Table 4 shows a summary of the results.

4 CONCLUSIONS

The results of the CFD study show that for this particular idealized case the pavement with lower absorptivity and highest reflectivity (PCC) actually created moderately higher building surface temperatures. This is clearly related to the increased amount of incident radiation on the building from radiation reflected by the PCC parking lot (Table 4). This runs counter to published advice [3] on mitigating UHI, and calls into question the use of so called cool pavements for all applications. This study demonstrates that for certain scenarios it is better for pavements to absorb rather than reflect solar radiation. The assumption that PCC is superior to asphalt for mitigating UHI is not supported by the results of this study. Certainly reducing energy consumption via mitigating UHI is a worthwhile endeavor, but a balanced approach that considers all modes of heat transfer including reflected radiation as well as the local urban infrastructure is needed.

Worker exposure to ultrafine particles in asphalt laboratory

Somayeh Asadi
Department of Civil and Architectural Engineering, Texas A&M University, Kingsville, TX, USA

Marwa M. Hassan
Department of Construction Management, Louisiana State University, LA, USA

ABSTRACT: Air pollution is a public health issue that may cause health problems for workers in the construction industry including workers involved in asphalt paving operations. Epidemiological studies have reported an increase loss of lung function among asphalt workers over the asphalt paving season. Therefore, the goal of this study is to quantify and characterize nanoparticle and ultrafine particle exposure to workers during asphalt mixture preparation activities in an asphalt laboratory. Scanning Mobility Particle Sizer (SMPS) was used to measure the size distribution, surface area, mass, and particle concentrations during pouring, mixing, and compaction activities. Particles were also characterized using Transmission Electron Microscopy (TEM) and Scanning Electron Microscopy (SEM) to get a better understanding of their particle size and morphology. Based on the results of the study, the highest number of particles was observed during the pouring process. Laboratory measurement showed that more than 70% of particles in asphalt preparation activities were ultrafine particles, which have diameter smaller than 0.1 micrometer. In addition, the size of the particles obtained by SMPS was compared to the particle size based on the TEM analysis. The estimated sizes obtained by TEM analysis in the asphalt workplace study were in agreement with the estimate size obtained by calculations using SMPS.

1 INTRODUCTION

The growth of using nanomaterials in different products increases the concern for their potential impacts on the environment and on the biological systems. Inhalation of nanoparticles has been associated with adverse health effects that range from myocardial infarction to decrements of lung function among asthmatics. Epidemiological studies have showed the relationship between ambient ultrafine particle concentrations and mortality or morbidity of urban populations. These studies indicated that exposure to ultrafine particles may cause pulmonary diseases, cardiovascular health effects and impairment of the immune system. The toxicological mechanisms behind these effects are not clear [1, 2]. Animal nanoparticles exposure studies also showed that ultrafine particles cause a stronger airway inflammation than similar mass concentrations of larger particles [3]. Epidemiological data indicated that exposure to ambient ultrafine particles worsens respiratory diseases [4].

Nanoparticle exposure can be from natural, incidental or engineered nanoparticles making risk assessments even more problematic. Naturally occurring nanomaterials such as volcanic ash, ocean spray, magnetotactic bacteria, mineral composites and others exist in our environment. Incidental nanoparticles, sometimes called ultrafine particles, are particles unintentionally produced during an intentional operation. Combustion, welding, metal processing, and emissions from diesel engines are examples of major sources of incidental nanoparticles. Engineered nanoparticles are particles designed and produced intentionally to have a certain structure and size, usually less than 100 nm. Both natural and incidental nanoparticles may have

irregular or regular shapes. Engineered nanoparticles most often have regular shapes, such as tubes, spheres, ring, etc. [5, 6]. However, the difficulties in distinguishing between engineered and incidental occurring nanoparticles complicate the assessment of exposure to humans and the environment. In order to understand the potential effect of the nanoparticles on the environment, the levels of the natural, incidental, and engineered nanoparticles should be quantified.

Safety in nanotechnology is determined through comprehensive studies that include exposure assessment, determination of metrics, toxicological and epidemiological studies, and life cycle analysis [7]. Studies show that a major route of exposure to ultrafine particles is through the respiratory system [8]. Several factors including size, shape and particulate matter density influence the impact of these particles on different parts of the respiratory system and the amount of time that it takes for them to settle [8]. Thus, exposure measurements that use an appropriate dose metrics such as number, mass and surface area concentration of particles should be considered. Several studies have investigated the toxicity and risk management of nanoparticles based on the different exposure scenarios that may occur during the production and use; however, little is known about nanoparticle exposure from construction activities [2, 6, 7, 9–13].

One reason for this trend is that there are currently no national or international standards on measurement techniques for nanomaterials in the workplace. The National Institute for Occupational Safety and Health (NIOSH) established a nanotechnology field research team that identified numerous techniques to measure airborne nanomaterials with respect to particle size, mass, surface area, number concentration, and composition. One of these measurement techniques is the Nanoparticle Emission Assessment Technique (NEAT) that uses a combination of measurement techniques and instruments to assess potential inhalation exposures in facilities that handle or produce nanomaterials [14]. The following instrumentations are recommended to be used by NEAT for measuring ultrafine particles in workplaces: the Condensation Particle Counter (CPC), Optical Particle Counter (OPC), Scanning Mobility Particle Sizer (SMPS), Fast Mobility Particle Sizer (FMPS), and Electrical Low-Pressure Impactor (ELPI). These technologies measure the number, surface area or mass metric directly or indirectly. In order to characterize morphology of the particles and verify the primary size distribution, Scanning Electron Microscopy (SEM) and Transmission Electron Microscopy (TEM) can be used [1].

The objective of this study is to assess the exposure to nanoparticles associated with different asphalt laboratory activities. To achieve this objective, the number concentration, size distribution, surface area concentration, and mass concentration were measured for different activities including dry mixing, wet mixing, pouring, and compaction in an asphalt laboratory using a SMPS. SEM and TEM were also used to characterize morphology, geometry, and to verify the primary size distribution of the particles.

2 METHODOLOGY

2.1 *Sampling site*

An AMRL accredited asphalt laboratory with an area of 23 m^2 was used as the test environment in this study. The total particle concentrations and size distributions were measured for asphalt mixture preparation activities in a laboratory environment under different preparation tasks including pouring, mixing, and compaction, see Figures 1 and 2. Background levels were measured every day prior to the start of any work and between tasks. The results of the nanoparticles released during each task were compared to background nanoparticles counts of the laboratory indicating that nanoparticles were released. The measuring instruments were located as close as possible to the job activities without disturbing the ongoing work. The experimental plan and testing conditions are summarized in Table 1.

2.2 *Sampling strategy*

Since nanoparticles naturally exist in the environment and to accurately assess occupational exposure risk, it is important to characterize background nanoparticles before quan-

Figure 1. Mixing aggregates with asphalt binder.

Figure 2. Asphalt compaction.

Table 1. Experimental plan and test condition.

Material type	Task	Task description
Asphalt	Pouring	Pouring binder into the aggregates
	Mixing	Mixing binder and aggregates
	Compaction	Compacting the ready mix by using gyratory compactor

tifying the nanoparticles resulting from the different laboratory activities. This includes particles that penetrate from outdoors to indoors and particles that are suspended by background activities in the facility. Thus, a preliminary measurement was conducted to quantify additional sources of ultrafine particles in order to distinguish those emitted from asphalt laboratory activities. The first step is to identify the sources of ultrafine emissions in the workplace atmosphere by measuring particle number, particles concentration, and size distribution. Thus, to determine the nanoparticle concentration level in the laboratory under normal conditions, background data were collected before the start of laboratory activities. Background measurements were collected before the beginning of each task.

2.3 *Particles measurements and characterization*

Characteristics of nanoparticles were measured in the workplace using a CPC and SMPS. Size distributions were measured by a SMPS system, which consists of an electrostatic

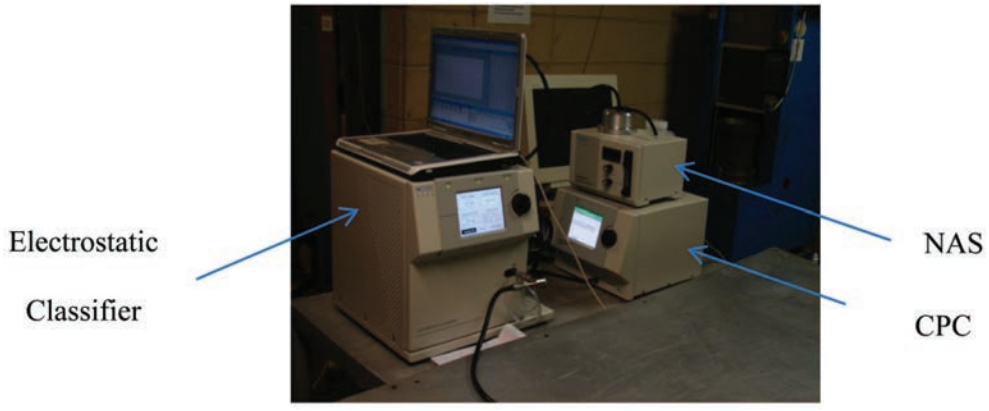

Figure 3. Scanning Mobility Particle Sizer (SMPS).

classifier (TSI Model 3080) and a Differential Mobility Analyzer (DMA, TSI 3081) coupled with CPC (TSI model 3776) (see Fig. 3). Scanning mobility particle sizer brings aerosol to electrostatic equilibrium ensuring that the aerosol has known charge distribution. The system was operated at 1.5 lpm of sheath flow rate and 1.5 lpm of aerosol inlet flow rate. The aerosol instrument manager software is capable of collecting data weighted by number concentration, diameter, surface area, volume, and mass, recorded the SMPS spectrometer data. Particles were collected on silicon nitride grids with 100 nm square membrane using a vacuum pump sample collector set to 7000 V. The collected particles were analyzed by SEM (Model Quanta 3D FEG, FEI Company, USA) and TEM (Model JEOL 100CX) for size and shape characterization.

3 RESULTS AND DISCUSSION

3.1 *Asphalt laboratory activities*

Figure 4 shows the particle number concentration as measured in the background before any activity, and after pouring, mixing, and compaction. Background level as measured prior to process was 9,436 particles per cm^3, background level after mixing was 11,851 particles per cm^3 and background level after compaction was 12,057 particles per cm^3. Peak concentration was 85,500 particles cm^3, which was during pouring process. As shown in Figure 4, the pouring process had the highest concentration. Furthermore, subtracting the total number of background particle concentration from the total number concentration of each activity shows that 1,179,000, 459,000, and 155,600 particles per cm^3 are emitted during pouring, mixing, and compaction, respectively.

Table 2 shows the total concentration, mean size, and ultrafine particle percentage for each task separately. As shown in this table, the mean size of pouring and mixing activities is almost the same while compaction has a higher mean size (160 nm). Based on these results, it was determined that the total concentration of pouring and mixing is higher than the total concentration for compaction.

Figure 5 shows the particle number size distribution of ultrafine particles during background, pouring, mixing, and asphalt compaction. The total number concentration of the particles during pouring, mixing, and compaction was 2×10^6, 1.28×10^6, 9.77×10^5 particles per cm^3, respectively. Ultrafine particles originated mainly from pouring and mixing. It is also noted that the background after mixing and compaction activities is slightly higher than the background before any activity began. This suggests that some of the ultrafine particles emitted remain in the air after completion of the activities.

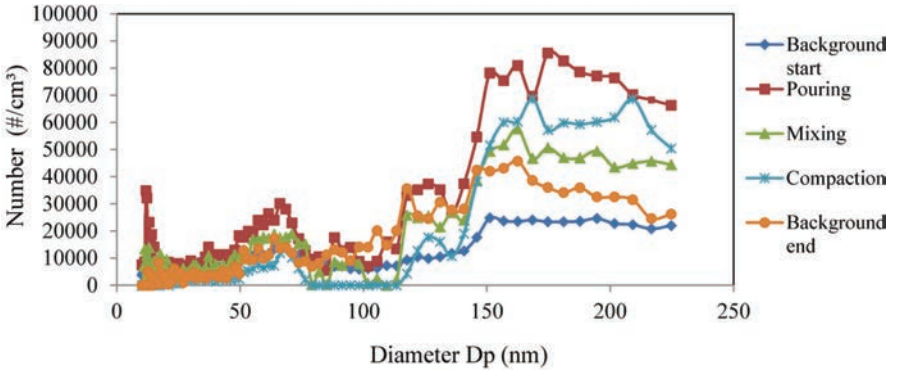

Figure 4. Particle number size distribution.

Table 2. Exposure measurement to nanoparticles during asphalt preparation activities.

Task (1)	Particle size measured		Total concentration (#/cm³) (4)	Mean particle diameter (nm) (5)	Mean mass (μg/m³) (6)	Ultrafine particle percentage (7)
	Min (nm) (2)	Max (nm) (3)				
Pouring	10.2	224.7	$2.00 \times 10^{\wedge 6}$	121	172	40%
Mixing	10.2	224.7	$1.28 \times 10^{\wedge 6}$	122	171.6	40%
Compaction	10.2	224.7	$9.77 \times 10^{\wedge 5}$	160	17.8	14%

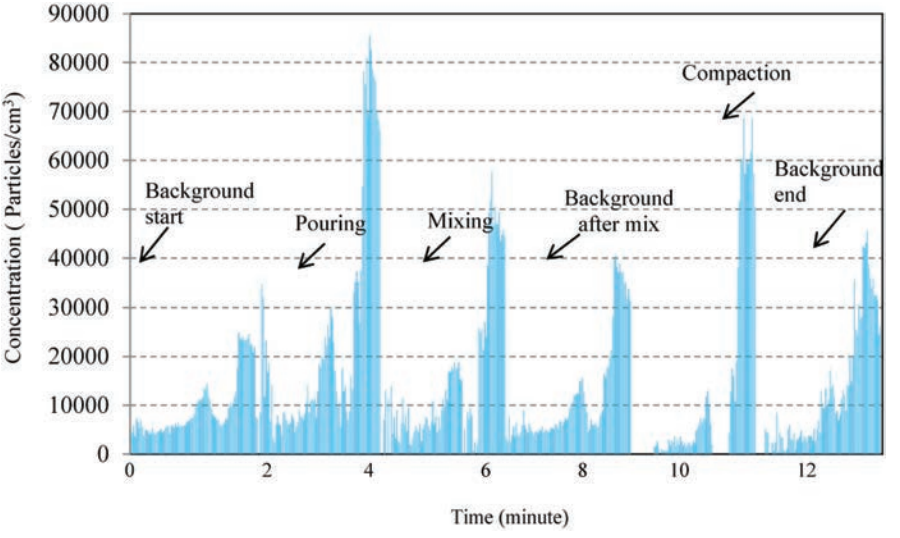

Figure 5. Particle number concentration.

The measurements carried during background, pouring, and mixing are presented in a box plot in Figure 6. The plot shows the minimum, the 25% percentile, the median value, the 75% percentile and the maximum nanoparticles concentrations. Pouring released more nanoparticles compared to the nanoparticles released during background, mixing, and compaction. As shown in Figure 6, the nanoparticle concentration is widely spread during pouring, mixing, and compaction activities.

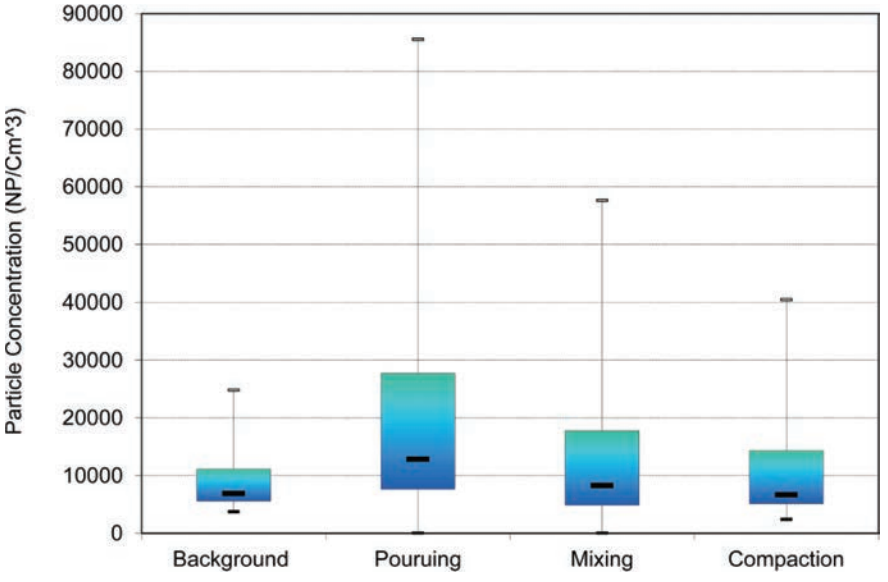

Figure 6. Concentration of nanoparticles released during the various asphalt construction activities.

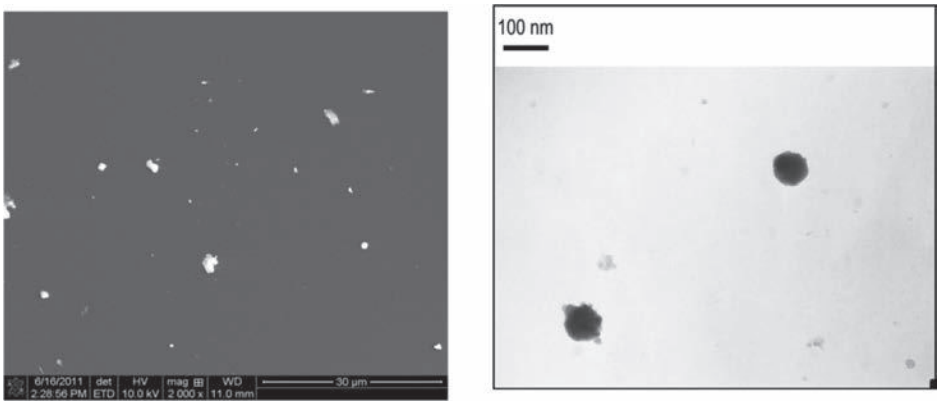

Figure 7. (a) SEM images of particles collected on electron microscope grids. (b) TEM images of particles collected on electron microscope grids.

3.2 *TEM and SEM characterization results*

The morphology, geometry, shape, surface, composition, and size of the nanoparticles released during asphalt preparation were characterized. To identify these properties, electron microscope analysis was used. Typical images obtained from SEM and TEM are presented in Figures 7(a and b). Figure 7 shows the size, shape, and morphology of the particles collected during asphalt preparation. SEM images show that the particles are spherical in shape with primary particle size less than 400 nm. To get a higher resolution image of the smaller particles, TEM was used. Figure 7(b) shows the size, shape, and morphology of the particles collected during asphalt mixture preparation. As shown in this figure, TEM images show spherical particles with primary particle size less than 100 nm. It is noted that several smaller particles were unstable and were destroyed by the electron beam, thus they were not detected in Figure 7(b). The estimated sizes that were obtained by TEM analysis are very similar to the sizes obtained by calculations using SMPS in the experimental study.

4 CONCLUSIONS AND RECOMMENDATIONS

Ultrafine particles are increasingly being recognized as a potential threat to human health. Aerosols in workplace environments may come from a wide variety of sources, depending on the type of activity and processes taking place. Measurements from a laboratory in this study showed that more than 70% of the particles in the asphalt preparation activities were ultrafine particles. However, the best choice of ultrafine particle metric in relation to health effects in workplaces is not yet fully understood. Therefore, it is important to measure several particle metrics in an attempt to find suitable particle characteristics to use in relation to health effects. The particle number is generally a good metric in the measurement of nano-sized particles since a high particle concentration is often connected to the presence of ultrafine particles. The estimated sizes obtained by TEM analysis in the asphalt workplace study were in agreement with the sizes obtained by calculations using SMPS in the experimental study. Based on the results of this study, further research is needed to characterize the hazardous nature and possible health effects of the emitted particles.

Method for calculating warm mix energy saving based on stack gas measurements

Bob Frank
Compliance Monitoring, LLC, Linwood, NJ, USA

Brian Prowell
Advanced Materials Services, LLC, Auburn, AL, USA

ABSTRACT: In the 1950's the Barber Greene Company studied aggregate dryers in an effort to understand thermodynamics involved with producing Hot-Mix Asphalt (HMA). To reduce variables, they recirculated aggregate feed and metered water onto completely dry material. Efforts today to measure energy savings at asphalt plants are similarly challenged to accurately measure properties that can easily vary over the period of investigation: aggregate moisture, exit temperatures, process rates, and etc.

Fortunately, United States Environmental Protection Agency (USEPA) developed stack test procedures that measure surrogate properties continuously to arrive at true average values. Consequently, stack test data can be used in conjunction with plant process data to calculate reasonably accurate energy balance at asphalt plants. Results still depend on accurate data collection, but produce a very detailed picture of plant efficiency and energy losses. It is possible to calculate energy used to heat and dry aggregate, energy in stack gases, and energy lost through uninsulated exposed steel surfaces.

A recent evaluation of stack test data for NCHRP 9-47 A found one-half of Warm Mix energy savings are due to reducing plant casing loss. This paper present the thermodynamics used to conduct an energy balance using stack test data. It also presents sensitivity analysis of process variables to demonstrate importance of accurate data collection.

Keywords: Warm Mix Asphalt (WMA), energy savings, stack testing, asphalt plant casing loss

1 BACKGROUND

1.1 *Energy to produce HMA/WMA*

Asphalt mixtures are produced by drying aggregate particles and mixing the dry aggregate with asphalt binder at a temperature sufficient to (1) coat the aggregates, and (2) allow the mixture to be properly compacted after storage (silo), haul, and placement. Aggregates start at ambient temperature with moisture contents that vary depending on how they are produced, stored, and local weather conditions. Aggregate is heated in the dryer drum for a batch plant or beginning portion of the drum for a drum plant. Fine aggregate tends to be heated by convection while showering through the hot exhaust gases due to its high surface area. Coarse aggregate is primarily heated by conduction from the fine aggregate while lying in the bottom of the dryer due to its large mass. This is why large stone mixes are so difficult to heat when all fines are provided by Reclaimed Asphalt Pavement (RAP). A significant amount of energy is required to turn water into steam or otherwise dry the aggregate. Theoretically, the temperature of the aggregate cannot increase above 100°C until surface moisture has evaporated. Once the aggregate is dry, continued heating will bring the aggregate to the mixing temperature. Energy to dry then heat aggregate is illustrated in Figure 1.

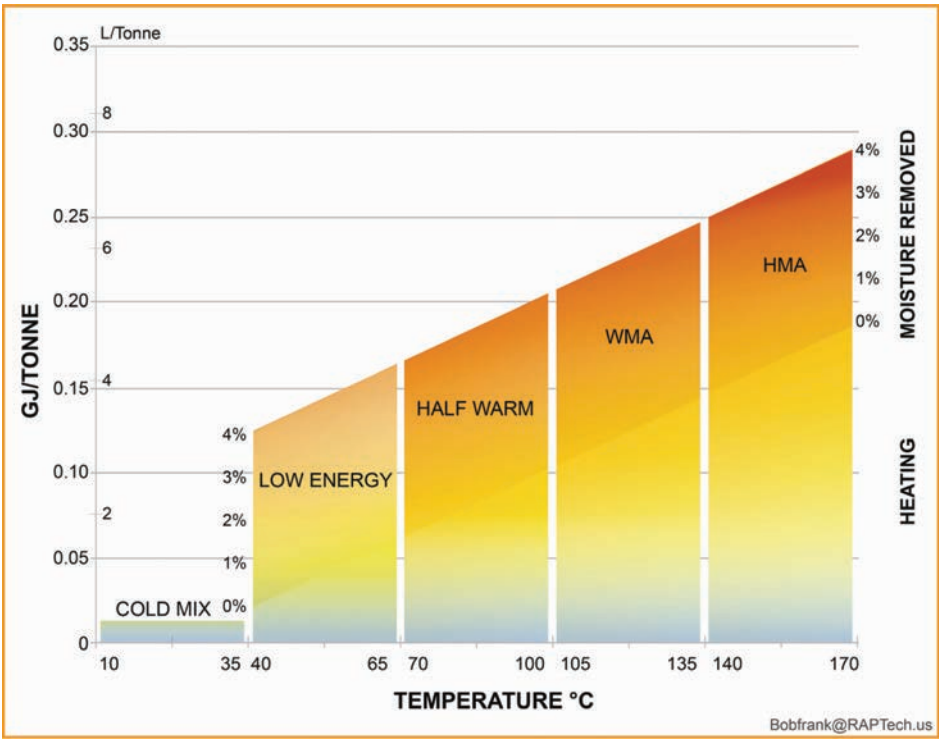

Figure 1. Energy use as a function of aggregate heating.

Figure 2 shows a frequency distribution of fuel usage based on data collected in the Mid-Atlantic region of the United States. The data includes both batch and drum plants. Fuel types include: natural gas, No. 2 fuel oil, and reclaimed oil. Two distributions are shown, one for data collected during stack emissions tests at 35 plants and another based on average use over a two-year period at the same plants. Typically, plants were operating at maximum design capacity for the full three hours of stack emission tests. The two-year average values, however, include fuel used during plant warm-up, plant waste, and unsold mix. Stack test data indicates drying/heating fuel usage for HMA average 0.271 GJ/tonne. By comparison, fuel usage based on year-end production totals averages 0.290 GJ/tonne, indicating 6.9 percent waste compared to steady-state production. This inherent difference between energy use during steady state operation and historical averages demonstrates comparisons between HMA and WMA must be based on identical time intervals to be meaningful.

1.2 *Reported energy savings from WMA*

WMA technologies allow the complete coating of aggregates, placement, and compaction of asphalt mixtures at lower temperatures than conventional hot-mix asphalt. Although the reduction in temperature varies by technology, WMA is generally produced at temperatures ranging from 20°C lower than hot-mix asphalt (HMA) to the approximate boiling point of water (100°C). Simply put, these technologies are workability and compaction aids.

A reported benefit of WMA technologies is reduced fuel usage. Reduced fuel consumption saves natural resources and cost. One objective of NCHRP 9-47 A, "Properties and Performance of Warm Mix Asphalt Technologies," was to document the relative energy usage between WMA and HMA. Theoretical calculations indicate that a temperature reduction of 28°C should result in a fuel savings of 11 percent [1]. Fuel savings reported from

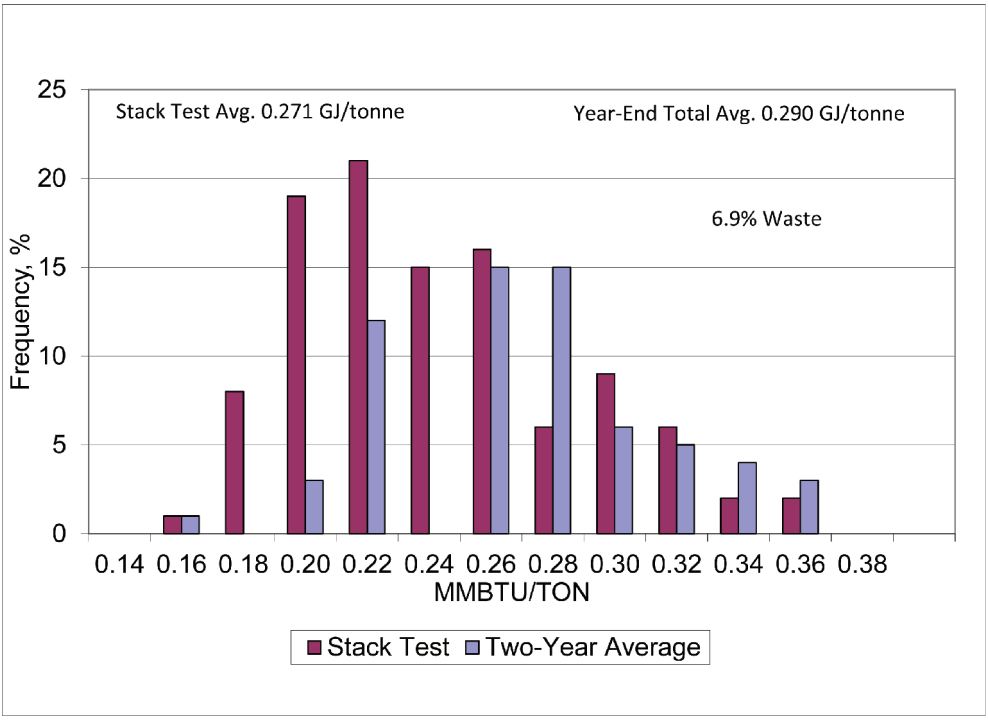

Figure 2. Typical HMA drying and heating fuel usage in MMBTU/ton (1 MMBTU/ton = 1.164 GJ/tonne).

early European WMA projects ranged from 24 to 55 percent [2–4] with typical values being between 20 and 35 percent [5]. Reported fuel savings from fifteen North American WMA projects, representing six technologies, ranged from a 15.4 percent increase to a 77 percent reduction [6–15]. The average fuel savings was 23 percent.

Larger fuel savings typically occurred with technologies like Low Emission Asphalt (LEA), WAM-Foam (Warm Asphalt Mix), and in some cases Evotherm™ ET (Emulsion Technology), which tend to have the lowest production temperatures. LEA and WAM-Foam production temperatures are usually close to 100°C. Casing losses and other inefficiencies are believed to account for some of the difference between theoretical and observed fuel savings [16] but these contributions were never quantified.

2 RESEARCH APPROACH

Data were collected from eight field projects as part of NCHRP 9-47 A. Fuel usage data was collected from six of the projects and stack emissions were measured for three, multi-technology projects. All projects included an HMA control section. The projects included in this study are shown in Table 1.

2.1 *Direct fuel usage measurements*

Fuel usage depends on a number of factors including, but not limited to: aggregate (and recycled materials, if used) moisture content, production rate, mix and stack temperatures, and excess air (leakage, baghouse pulse air, burner air). For this study, data collection forms were developed to collect information on plant energy usage, including many of the above factors, during production.

Table 1. Summary of information for projects used in the study.

Date	Project location	Plant site and description	Mixes
Jul. 19–21, 2010	County Road 315, Rapid River, MI	Escanaba, MI, uninsulated parallel flow drum	HMA, Advera, Evotherm 3G
Sep. 14–15, 2010	Calumet Ave., Munster, IN	Griffith, IN, insulated, counter flow dryer	HMA, Gencor foam, Evotherm 3G, Heritage Wax
Oct. 19–22, 2010	Little Neck Pkwy., Queens, NY	New York City, NY, batch plant with mini drum uninsulated dryer	HMA, Cecabase RT, SonneWarmix, BituTech PER
Apr. 19–20, 2010	US 12 near Walla Walla, WA	Walla Walla, WA, portable plant, uninsulated, parallel flow drum	HMA, Maxam foam
Jun. 21–22, 2010	I-66 eastbound, near Centreville, VA	Centreville, VA, Double Barrel counter flow	HMA, Astec foam
Aug. 11–12, 2010	MT route 322, south of Baker, MT	Baker, MT, Partially insulated parallel flow drum	HMA, Evotherm DAT

The participating contractors were requested to tune their plant's burner prior to producing for NCHRP 9–47 A. For the three projects where stack emissions tests were performed, at Rapid River, MI; Griffith, IN; and New York, NY, burner tuning was conducted by Bob Frank. Asphalt plant burners have actuator motors that drive dampers and fuel modulating valves. As the burner percentage is increased, dampers and fuel valves open to increase air and fuel proportionately. If plant operators increase fuel pressure to increase production rate, incomplete combustion is likely to occur, wasting fuel. One plant showed a 24.8 percent reduction in fuel usage for HMA after burner tuning. This was an important variable to correct prior to quantifying energy savings from lower mix temperatures.

There are a number of ways fuel usage has been reported in prior studies. As shown in Figure 2, fuel usage collected over the long-term includes fuel used during plant warm-up, plant waste, and for unsold mix, resulting in 6.9 percent increase when compared to steady-state runs. Typically, each mix evaluated in NCHRP 9-47 A represented one-day's production. Fuel usage was monitored with a number of techniques depending on the fuel used:

- Natural Gas—gas meter readings,
- Liquid Fuel Oils—fuel meters or tank sticks, and
- Liquid propane—percent of tank volume.

Cumulative production tonnage was collected at approximately the same time that the meter readings were taken. After the data were collected, it was found that commercial gas meters only update periodically (up to 15 minute intervals) and therefore could give inaccurate measurements of fuel usage over short-time intervals. Additional discussion will be provided in the results and analyses.

The Rapid River, MI project used reclaimed motor oil as fuel. Since the Rapid River plant did not have a fuel meter, fuel consumption was calculated using tank charts and tanks sticks at the beginning and end of each day's production. The Baker, MT project used Liquid Propane (LP). Fuel usage for the LP was based on percent tank volume. The Griffith, IN and New York, NY, projects used natural gas with gas meter readings taken hourly at beginning and end of each stack test run. Gas meter readings were taken at the beginning and end of each day's production for Centreville, VA and Walla Walla, WA.

2.2 *Stoichiometric fuel measurements*

Unfortunately, precision of direct fuel measurements was questionable for a number of reasons and an alternative method to determine average heat input was investigated. Stack

emission tests were conducted at Rapid River, MI; Griffith, IN; and New York, NY sites with flow rate and composition of the exhaust gases measured continuously for two, one-hour runs on each WMA technology and HMA control. These stack gas data enabled back calculating average heat input using US EPA's Method 19 f-Factor. EPA developed f-Factors for commercially available fuels to calculate the stoichiometric volume of exhaust gases generated by burning one MMBTU (1.06 GJ) of fuel. For example, burning 27.2 cubic meters of natural gas (1.06 GJ) results in 246.6 dry standard cubic meters of (exhaust) gas at zero percent oxygen. Zero percent oxygen is what makes it a stoichiometric volume.

Stack gas velocity was measured according to US EPA Method 2 based on velocity pressures. Molecular weight and percent water vapor of the gas stream were measured using US EPA Method's 3 and 4, respectively. Carbon dioxide (CO_2) and oxygen (O_2) concentrations were also determined using US EPA Method 3. Stack gas velocity was converted to dry volumetric flow rate at a standard temperature and pressure based on stack area and percent water vapor in exhaust gases. These calculations are typically provided in any stack test reports and are too complex to cover here.

Fuel firing rate can be calculated from the average exhaust flow rate and oxygen concentration using Equation 1:

$$\text{Fuel usage} = \frac{60 \times Q \times \left(\frac{20.9 - O_2\%}{20.9} \right)}{F}$$

where,
Fuel usage = MMBTU/hr, (1.0 MMBTU/hr = 1.06 GJ/hour)
60 = minutes/hr., converts flow per minute to flow per hour
Q = average stack gas dry volumetric flow rate (dscfm) at standard temperature and pressure,
20.9 = standard O_2% of air,
O_2% = percent stack O_2 by volume, dry basis, units are percent and not decimal.
$(20.9 - O_2\%/20.9)$ = correction factor to remove excess air and calculate resulting stoichiometric volume
F = volume of combustion products per unit of heat content dscf/MMBTU: 8,710 dscf/MMBTU for natural gas and propane and 9,190 for oil (US EPA Method 19).

3 RESULTS AND DISCUSSION

3.1 *Direct fuel usage measurements*

Table 2 summarizes fuel usage based on direct measurement and back calculated fuel consumption and the corresponding cumulative production. An error was made reading the gas meter for the Virginia HMA; therefore fuel usage for that mix is not reported.

The potential error in determining fuel usage over a short time period based on tank sticks is illustrated in Table 2. The Michigan Advera and Evotherm 3G mixes were produced at the same average temperature. The production rates are almost identical. The aggregate moisture content was 0.2 percent higher for the Evotherm 3G, which would tend to increase fuel usage. However, the fuel usage based on tank measurements for the Evotherm 3G production is 0.044 GJ/tonne (17 percent) less than that calculated for the Advera WMA. By comparison the fuel usage based on stoichiometric calculations, corrected for a slight difference in aggregate moisture, are identical.

Similar inconsistencies between measured mix temperature and fuel usage were noted for the Indiana mixes. The local Indiana stack emissions contractor did not take stack velocity readings during the HMA and Heritage Wax stack emissions runs. Readings were taken only at the end of the run. Therefore, the stoichiometric calculations of fuel usage for those two mixes are suspect. The Indiana fuel usage in Table 2 based on gas meter readings are

overall daily averages. Increased fuel usage of 0.261 GJ/tonne for the Gencor foam WMA was observed over the course of the day, including start up, pre-heat, plant waste, and shut down (values in Table 2 correspond to hourly readings taken during stack emissions tests). The production temperature of the Gencor foam mix was increased to HMA temperatures after stack emissions tests were completed.

3.2 *Fuel savings*

The average fuel usage for the HMA production based on five projects was 0.290 GJ/tonne. This compares well with the 0.271 GJ/tonne calculated based on the data from the Mid-Atlantic region reported in Figure 2. To make meaningful comparisons between the WMA and HMA, the WMA fuel usage were corrected for the difference between the HMA and WMA aggregate moisture content at each site. By definition, it takes 1 British Thermal Unit (BTU) (1055.1 J) to raise the temperature of 1 lb (0.454 kg) of water by 1 °F (0.556 °C). Similarly, it takes 4.184 J (one calorie) to raise the temperature of 1 g of water 1 °C. Therefore, it takes 142 BTUs to raise the temperature of water from an ambient temperature of approximately 70 °F to 212 °F and 1,000 BTU to vaporize 1 lb. of 212°F water. Similarly, it takes 330,118 J to heat 1 kg of water from 21.1 to 100 °C and 2,260,000 J to vaporize 1 kg of water. The fuel usage was corrected based on 2,590,118 J/kg (1,142 BTU/lb) of moisture difference. The fuel usage for the normalized WMA data indicated an average savings of 0.064 GJ/tonne, or approximately 22.1% for an average temperature reduction of 27 °C (48 °F). This compares well to the average 23 percent savings reported in the literature. Since final mix temperatures for all mixes were greater than 100 °C, the theoretical fuel savings should be equal to differences between WMA and HMA mix temperatures multiplied by the specific heat of the aggregate. Assuming a specific heat of 1004.8 J/kg/°C (0.24 BTU/lb/°F) for a bituminous mixture, a 27 °C reduction in temperature should result in 0.0268 GJ/tonne savings, or 9.3 percent. The question then becomes how to account for the additional 13 percent in fuel savings from WMA technologies over and above the theoretical 9.3 percent savings due to lower mix temperatures?

3.3 *Distribution of fuel savings*

Additional calculations were performed to allocate fuel savings for the multi-technology sites where stack emissions tests were performed. Thermal energy generated to produce hot or warm mix is consumed by drying aggregate moisture, heating aggregate, heating stack gases, and casing losses. Casing losses are thermal energy used to heat plant iron and then radiated to the atmosphere, rather than being used to heat the aggregate. Components that account for the majority of casing loss include aggregate dryer, duct work, baghouse and batch tower/mixing chamber (if applicable). The differences in fuel usage reported in Table 2 were allocated based on thermodynamic properties to three sources: 1) differences in mix temperature, 2) differences in stack exhaust mass, moisture, and temperature, and 3) the remainder, believed to be attributed to casing losses.

Table 3 shows the results of calculations to appropriately allocate energy savings. Differences in thermal energy based on mix temperature were calculated using a specific heat of 1005 J/kg/°C for the asphalt mixture. The difference in the average HMA and WMA mix temperature at a site were multiplied by 1004.8 J/kg/°C, converted to GJ, and expressed as a percentage of the difference (delta) in GJ/tonne, corrected for aggregate moisture. Differences in mix temperature (% Mix Temp.) explained 27 to 76 percent of the fuel savings, with an average of 45 percent. Actual stack exhaust flow rates in cubic feet per minute (ACFM) were converted to standard conditions at 21.1°C (SCFM). The energy required to heat the air and moisture in the exhaust gas between the minimum observed stack gas temperature of 90.6 °C and the average stack exhaust temperatures was calculated for each mix (GJ/tonne up stack). The average stack gas temperature for NY SonneWarmix was 90.6 °C, therefore its GJ/tonne up the stack = 0.000. The calculation used a specific heat of 1842 J/kg/°C for water vapor and 1005 J/kg/°C for dry air. Air at standard conditions has a mass of 1.227 kg/m^3. The difference between the HMA and WMA GJ/tonne up stack at a given site (relative to 90.6°C) was expressed as a percentage

Note: 1.0 CFM = 0.0283 cubic meters per minute.

of the total delta in energy usage per ton (% Stack Temp.). The remaining unexplained differences in the measured energy use are attributed to casing losses (% Casing Loss). These losses are heat lost through, for example, the shell of the drum and ductwork.

3.4 *Influence of aggregate moisture content*

A recommended best practice for both HMA and WMA is to minimize aggregate moisture content. Average aggregate moisture content for the Montana project was 1.4 percent; less than half the average moisture content from the other sites. Measured fuel usage for the Montana HMA was 0.183 GJ/tonne, compared to an average of 0.317 GJ/tonne for all other HMA and 0.299 for the Michigan and Indiana HMA, which were produced at the same average temperature. This indicates a savings of 0.061 GJ/tonne per percent of moisture reduction. Thus, a one percent reduction in stockpile moisture content can produce savings similar to the average savings between HMA and WMA, 0.064 GJ/tonne.

4 CONCLUSIONS

- To make meaningful comparisons, fuel usage between HMA and WMA should be compared over short, steady-state runs at similar production rates and aggregate moisture.
- WMA mixes were produced an average of 27 °C cooler than the corresponding HMA mixes, resulting, on average, in 22.1 percent fuel savings.
- The measured fuel savings were higher than predicted by calculations of energy required to dry then heat mix and exhaust gases.
- The additional fuel savings are attributed to casing losses—heat radiated through the drum, ductwork and baghouse or otherwise lost. Insulated plants will have lower fuel savings from WMA technologies than uninsulated plants.
- Best practices, such as burner tuning and reduced stockpile moisture, produced reductions of similar magnitude to the use of WMA.
- There is a high potential for error when calculating fuel usage over short intervals from tank fuel depth measurements (tank sticks), or natural gas meter readings. A difference of two minutes between fuel and tonnage produced measurements can result in a 3.3 percent error in hourly fuel usage calculations. A 2.5 mm (1/10 inch) error in a tank depth of a 75,708 liter (20,000 gallon) horizontal tank at the 37,854 liter (10,000 gallon) mark results in a 129 liter (34 gallon) (5.489 GJ (4.715 MMBTU)) error in measured fuel usage.

5 RECOMMENDATIONS

- Fuel *savings* should be based on comparison of steady state conditions and be of the longest duration possible. Historic average fuel use may be informative but a poor basis to quantify savings.
- Stoichiometric fuel calculations, in accordance with EPA Method 19, should be made in conjunction with direct measurements of fuel consumption when stack tests are part of demonstration or study.
- Take fuel meter and cumulative tonnage readings at the same time and over as long of an interval as possible to minimize errors due to measurement accuracy.

Highway and Railway Engineering, KTH Royal Institute of Technology, Stockholm, Sweden

ABSTRACT: For environmental reasons, low installation cost and initial investment; low energy infrastructure materials are becoming of high interest. A potential option to replace current hot mix asphalts is emulsifications, where bitumen binder is dispersed in a water phase aided by emulsifier and shear forces, and mixed at ambient temperature with unheated stones. Long term performance must, however, be guaranteed, otherwise the application benefits will be significantly diminished. In this paper, the main issues of cold mix (emulsion based) asphalt, like wetting in the presence of moisture and dust, and coalescence issues are discussed. Since both bitumen droplets and mineral surfaces were upscaled, pure mineral surfaces were investigated as stone material consists of different minerals. As a measure of the interfacial bond strength, surface free energies of different mineral aggregates and bitumen have been investigated in this paper as a stepping stone for further analyses of emulsions. From the analyses it was found that bitumen has only dispersive forces whereas most of the minerals surfaces have polar nature. According to Fowke's additive nature of the forces, bitumen and water are roughly equally strongly adsorbed to plagioclase and calcite, whereas water will displace bitumen from quartz, gypsum, potassium feldspar and mica surface.

Keywords: Low energy infrastructure materials, cold mix asphalts, bitumen emulsions, wettability, minerals Surface energy

1 INTRODUCTION

Bitumen is a highly viscous semi-solid at room temperature and there are many ways to reduce its viscosity and thus make it as an effective binder such as heating, dissolving in solvents (cut-back bitumen), foaming the bitumen, or making oil/water type bitumen emulsions. In the pavement industry, hot mix and, more and more, warm mix asphalts are rather common practices. Cold mixture is however much less used and its applications have been mainly limited to recycling of low traffic roads. There are several options in cold mix technology like foaming the bitumen, cutback bitumen and bitumen emulsions. In bitumen emulsification, the bitumen phase is heated and dispersed in water in the presence of emulsifier by the application of shear forces. The process of manufacturing bitumen emulsions must be highly controlled to ensure the storability, workability and adhesion, making it thus an effective binder for road products. In cold asphalt mixtures, the aggregates are not heated and, as a result, a lot of energy can be saved. In addition to this, initial investment cost in terms of cold mix setup and transportation of raw material is low as compared to hot mix technology [1–2].

All types of emulsions (except for micro emulsions) are thermodynamically unstable and generally separate into two phases over a certain period of time [3]. Bitumen emulsions are classified in grades according to their reactivity, particle charge and physical properties. These are basically o/w type emulsions and contain 60–80 wt% bitumen, around 0.15–2 wt% emulsifier [4] and 20–40 wt% water plus minor additives like salts. The particle size of bitumen in bitumen emulsions is generally in the range of few μm (0.5–10 μm) and size distribution is strongly influenced by the emulsion recipe, temperature of the bitumen and water phase, mechanics and the operating conditions of the emulsion manufacturing mill [5]. Furthermore, the size of the droplets and the nature of the bitumen are two major variables that affect the breaking and coagulation of bitumen emulsions. But how they affect the breaking rate and curing process is not yet clear [6].

The emulsions are formulated to have a sufficient level of repulsive force between the particles that prevents any premature coagulation. The coalescence will occur if changes occur in the hydrophilic/lipophilic balance of the emulsifier, a variation in the pH, an increase in the ionic force of the medium or desorption of surfactant at bitumen-water interface. The interaction between the emulsion and the aggregates is the main cause for one of more of these changes [6]. The main purpose and an effective use of emulsification are to transport bitumen to the right location between the aggregates. The phase separation must thus take place at the right place followed by wetting of the stone surfaces and gluing the aggregates together. Along with water separation from the bitumen; a good adhesion to the stone surface is also required. Generally due to the hydrophilic nature of the stone surface, affinity for the water at aggregate surface is higher as compared to the bitumen that can be modified with emulsifiers which displace water from the stone surface and improve adhesion between the binder and the aggregates. This desired breaking process varies according to the required applications e.g. fast, medium and slow breaking as well as some other applications like dry, wet, clean or dusty stone surface. The exact nature of breaking mechanism of bitumen emulsion is not completely known. The bitumen emulsions are destabilized due to the adsorption of emulsifiers on the aggregate surface and agglomeration of bitumen particles forming a cheesy state that further more leads to coalescence of the bitumen droplets. A complete adhesion between binder and aggregate surface is achieved after complete evaporation of water and the strength of the asphalt is improved with time [7].

Bitumen emulsions are designed to start breaking or rupturing when mixed with aggregates, and a phase separation by flocculation and coalescence should quickly occur that leads to partial loss of water in emulsion as shown in Figure 1. A continuous film of bituminous

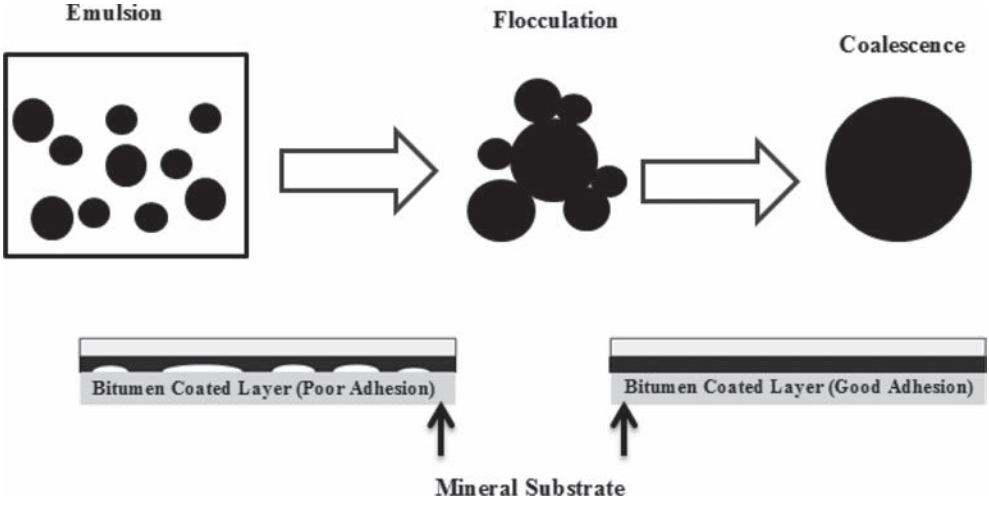

Figure 1. Coalescence process in bitumen emulsion and bitumen interactions with aggregates.

binder is developed that, if all is well, covers the aggregates completely followed by curing or setting of the binder which eventually gives the mechanical strength. Considering the relative complexity of emulsion technology compared with hot mix technology, there are several components in emulsion technology that need to be investigated more closely to ensure the long term performance of cold mix asphalt and reduce the sensitivity of their application. With regard to asphalt pavements, it is common knowledge that adhesion between bitumen and stones can be reduced in the presence of moisture (stripping) and that dust particles on the surface of the aggregates can lead to poor adhesion. In the case of bituminous emulsion, this risk is amply present, since moisture is available from the emulsions as well as the wet aggregates and dust can be present on the (unheated) stones, Figure 1. But on the other hand a well-chosen emulsifier could improve the bitumen wetting of the stones.

The coalescence process plays an important role in the water separation and evaporation process. It is possible that during this process, some of the water after separation from the emulsion, cannot evaporate and gets trapped inside the mixture. The presence of trapped water in the wrong locations can seriously affect the durability and performance of the pavement. This is one of many factors that must be considered carefully when designing the emulsion. Thus an in depth understanding of the forces that come into play during the breaking and curing of bitumen emulsion binders is fundamental in order to control their behavior and to produce high quality pavements.

To investigate the thermo-dynamical interface properties of bitumen-stone combinations, the surface energy properties of both binder and aggregates need to be determined. Sessile drop is one method utilized for such investigations. In this paper, pure mineral and bitumen surfaces were examined using surface chemistry principles by measuring static contact angles of different probe liquids. Both dispersive and non-dispersive surface free energy components for the binder and aggregates were calculated using the Fowkes theory, as it is more applicable to the situations where adhesion occurs in the stone-bitumen system.

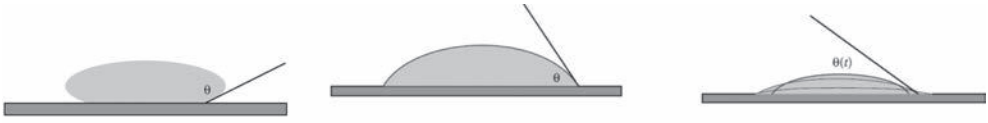
1.1 *Theoretical background*

The theories of adhesive and cohesive bonding are well established in the fields of surface chemistry and physics. All materials, including bitumen and aggregate, have surface energies that can be measured independently from each other. From this information, one can predict how well asphalt mixture component will wet each other and thus their bonding potential. Investigations of surface free energies of bitumen and aggregates have been performed over the last years by many researchers. [e.g. 8–9] whereby the focus mainly lied on hot mix asphalt applications.

Surface energy 'γ' is the amount of work required to create a unit area of a given materials in a vacuum. This surface energy is known to have dispersive (non-polar) and non-dispersive (polar and hydrogen bonding) components. The direct measurement of surface energy of a solid is for practical reasons not a very common practice and usually indirect methods are used to measure surface energies of solids. Therefore, some methods [10] have been developed to study the interactions between liquid, solid and gas surfaces that among others include contact angle measurements, gas adsorption, inverse gas chromatography and micro calorimetry. Among all, contact angle measurement is the most economical, easy to operate and less time consuming. Surface tension and contact angles are outcomes of short-range intermolecular forces. Methods for measuring interfacial tension include Wilhelmy Plate, Du Nouy Ring, Pendant Drop and Sessile Drop. Each method describes the surface energy parameters and Wilhelmy plate and Sessile drop are today the most commonly used for liquid-solid substrates. The Wilhelmy plate method is used for dynamic contact angle measurement while sessile drop measure static contact angle. The Du Nouy Ring method is developed for liquid-air interface and Pendent drop method is opted for liquid-liquid interface. An in depth understanding of the surface forces action is very important to explain the wetting and spreading processes.

Young-Laplace developed a relation between contact angle and surface energy as below;

$$\gamma_S = \gamma_{SL} + \gamma_L * \cos\theta \quad (1)$$



No Wetting (θ is bigger than 90^0) | Partial Wetting (θ is between 0 and 90^0) | Complete Wetting (θ become Zero with time)

Figure 2. Wettability as a function of contact angle [11].

γ_S is solid surface energy, γ_L is liquid surface energy, γ_{SL} is solid-liquid interface energy and θ is contact angle as shown in Figure 2.

Fowkes developed a theory to calculate the component of surface energy from the known surface tension as shown below; (D represents the dispersive component of surface energy)

$$\gamma_{SL} = \gamma_S + \gamma_L - 2\sqrt{(\gamma_S^D * \gamma_L^D)} \quad (2)$$

Later on, Fowkes uses the above relationship in Equation 2 combined with Young's equation, Equation 1, to create an equation 3 based upon the contact angle.

$$\cos\theta = 2\sqrt{(\gamma_S^D)} * [1/\sqrt{\gamma_L^D}] - 1 \quad (3)$$

By plotting the contact angle versus the known dispersive surface energy of the liquid, this equation can be used to find the dispersive surface energy of the solid, which is the slope of the line. The polar component is also found using a linear regression relationship. Fowkes extended equation 2 to include the polar components of surface energy by the following equation.

$$\gamma_{SL} = \gamma_S + \gamma_L - 2[\sqrt{(\gamma_S^D * \gamma_L^D)} + \sqrt{(\gamma_S^P * \gamma_L^P)}] \quad (4)$$

In the Sessile method, dispersive and polar components required a minimum of two probe liquids with known surface tensions.

2 MATERIALS AND EXPERIMENTAL METHODS

A bottom-up approach was considered to investigate surface free energy of aggregate material. Stone materials that are mostly being used for the roads constructions consist of many minerals like quartz, mica, potassium feldspar, gypsum, biotite, calcite, plagioclase and others. For example Skärlunda granite in Sweden contains 40 vol.% quartz, 35.5 vol.% k-feldspar, 14 vol.% plagioclase, 4 vol.% mica, 3 vol.% biotite, 2.5 vol.% chlorite and 1 vol.% other materials. Since in this research, emulsions are the main focus point, bitumen droplets are being up-scaled to (later on) represent the microscale droplets present in emulsions. Similarly, mineral surfaces are up-scaled by studying each mineral individually. Hereby the future assumption is made that the different types of aggregated stone material can be described as the sum of its component minerals, as well as to develop fundamental understanding of the effect of the individual minerals themselves.

The samples have been cut using power hexa machine and surfaces of these minerals were polished using different mesh size Silicon Carbide papers starting from coarse to a fine mesh. No polishing aids have been used since they may affect surface tension. The surface smoothness of the minerals was given much more importance, since the investigation is focused on the surface interaction of between the liquid and mineral. The level of smoothness or texture was compared under optical microscope. Later on, these polished samples were mounted on

glass slides to achieve plane symmetry condition for getting precise measurement of contact angles. KRÜSS DSA100—Drop Shape Analysis System was used to measure contact angles of known probe liquids drops on the analyzing substrate surface. KRÜSS uses optical method for contact angle measurement and DSA100 setup can be used for sessile drop as well as pendent drop methods. It contains four automatic dosing units on its left arm that are connected through four channels for different probe liquids and one manual dosing unit. Contact angle is measured when drop is static and gravitational forces are balanced with inter facial tension. In this study, drop size was 7 µl for all probe liquids and deposition height was optimized to avoid splashes. Bitumen 160/220 samples were heated around 90 °C and coated on glass slides and cooled down till room temperature under covered glass hood to prevent any dust on the surface of the bitumen coating. An emulsion grade unaged and unmodified straight run bitumen 160/220 was investigated in this study and provided by Nynas AB, Sweden. The chemical constituents according to latroscan or SARA fractions for bitumen 160/220 are 9% Saturates, 54.3% Aromatics, 22.2% Resin and 14.5% Asphaltenes.

3 RESULTS AND DISCUSSIONS

From the Sessile drop contact angle measurement, the drop shape [12] was analyzed using three different approaches known as height-width, Young-Laplace and circle fitting methods. Each method has advantages and limitations. For example, all methods are applicable for static drops and not valid for dynamic drops. The reason behind this comparison was to achieve precision and accuracy in results. In height-width method, the drop contour line is enclosed within a rectangle. In this method, the drops are regarded as being symmetrical that means contact angle at left side is equal to the contact angle at right. This is the main limitation of the height-width method. In the circle method, the drop contour is fitted to a segment of a circle and it follows the same assumption of drop being symmetrical as in height-width method. In the case of Laplace-Young method, a complete drop contour is evaluated that is why it is the most complicated. It includes both interfacial and gravitation effects in the calculations. The slope of the contour line at three phase contact point is represented in terms of mathematical equation that is very well known and often called Laplace-Young equation (1).

The liquid used, called the probe liquid, must be a non-reactive, homogeneous liquid, for which the surface energy components (Dispersive, Polar, H-H, acid, base, etc.) are known. Generally, there are five liquids recommended for use with this method, water, ethylene glycol, methylene iodide, glycerol, and formamide. Commonly, two to four probe liquids are used to find the surface energy of the solid substrate [13]. For investigation of surface free energy and contribution of surface interactions has been studied by using following three probe liquids as shown below in Table 1a.

The liquids, used for contact angle measurement and in surface energy calculations, are very well known from a chemistry point of view and many references can be found in the literature [14–28] where surface tensions and surface energy components are reported for such liquids. Many researchers proposed different surface tensions of the liquids used in this study as presented in Table 1b. Thus, selected values of surface tensions in Table 1a are the most commonly agreed ones in surface chemistry society.

Table 1a. Probe liquids used and their surface tensions [14–15].

Probe liquids	Total liquid IFT (l) [mN/m]	Dispersive part (d) [mN/m]	Polar part (p) [mN/m]
Diiodo-methane	50.80	48.50	2.30
Formamide	58.20	39.50	18.70
Water	72.80	21.80	51.00

Table 1b. Referred surface tensions of probe liquids in literature.

Substance	Total IFT [mN/m]	Dispersive [mN/m]	Non-dispersive (polar) [mN/m]
Water	72.10[16]	19.90	52.20

The contact angles were evaluated with three different methods which have resulted in different surface energy calculations. These methods are Laplace-Young (LY), Height-Width (HW) and Circle (CIR) methods, which are based on different approaches to analyze drop shapes. Tables 2, 4 and 6 present the mean contact angles of different probe liquids evaluated on the surface of different minerals by LY, HW and CIR methods respectively.

Table 5. Surface energy contributions of different minerals based on HW-method.

Mineral	Total IFT [mN/m]	Dispersive [mN/m]	Non-dispersive (polar and H-H) [mN/m]
Gypsum	68.1 ± 0.22	25.9 ± 0.07	42.2 ± 0.15
Quartz	67.9 ± 1.09	27.5 ± 0.47	40.4 ± 0.62

Biotite	43.8 ± 5.36	23.2 ± 1.78	20.6 ± 3.58
Calcite	40.5 ± 2.04	32.3 ± 1.48	8.2 ± 0.56

Fowke's theory was used to calculate the surface free energy of different minerals. Tables 3, 5 and 7 show the calculations based on contact angles measured by LY, HW and CIR methods respectively. All these methods are well explained in many literatures [29–30].

Based on the measured sessile drops contact angles using LY, HW and CIR methods, it can be observed that results of HW and CIR methods are very much overlapping quantitatively as compared to LY method. Similar observation can be made in surface energy calculations where the HW and CIR methods seem to agree very well, whereas the LY-method seems to deviate from the other two on the lower IFTs. These small deviations depend upon different factors for example physics behind shape analysis, optical resolution of the image and base line position. The results obtained with HW and CIR methods are more accurate as compared to LY method.

The results in Table 3 indicate that gypsum, quartz, potassium feldspar and mica have very high total Interfacial Tensions (IFTs) due to high wettability. Furthermore, non-dispersive (Polar and H-H) interactions for these minerals are very dominant as compared to the dispersive part. The high polarity of these mineral surfaces will make them more hydrophilic than hydrophobic. On the other hand, plagioclase and calcite surfaces appeared in the range with major dispersive interaction with low total IFTs. Biotite mineral has a low total IFT similar to plagioclase and calcite, but its surface is more polar. Plagioclase and calcite have similar polarity but plagioclase is more dispersive than calcite as shown in Table 3.

The contact angles that are presented in Tables 2, 4 and 6 are mean contact angles based on at least five repeated measurement.

Surface free energy contributions of same minerals were calculated using Fowkes approach in Table 5 as well. The quantitative results were slightly different from this method as presented in Table 3 but qualitatively they followed similar paths. Biotite surface that seems to be more polar than dispersive with LY method, turned out more dispersive with the HW method. Whereas plagioclase showed almost double polarity as compared to calcite in HW calculations.

So we can conclude from these results that though most minerals have dominance of polar interactions, they do have some subtle differences which can become important especially in sensitive systems such as emulsified bitumen. Results of all these methods are comparable with each other and Table 7 shows that major contribution in the total interfacial tension is due to polar interactions for gypsum, quartz, potassium feldspar and mica. The results obtained in HW and CIR methods are very much similar and according to the calculations calcite has the lowest total IFT with high dispersive surface energy contribution. An important observation could be the surface energy and almost hydrophobic surface nature of the calcite mineral.

In the methodology section it was earlier described how the bitumen samples were prepared for the surface energy studies. Table 8 shows the mean contact angles of same probe liquids described in Table 1a on bitumen surface.

Table 8. Mean contact angles of probe liquids on the surface of emulsion grade binder.

Bitumen substrate	Mean contact angle [deg.] (Laplace-Young method)	Mean contact angle [deg.] (circle method)	Mean contact angle [deg.] (height-width method)	Probe liquids
160/220	37.4	32.8	33.0	Diiodo-methane
	91.9	86.5	87.2	Formamide
	97.7	93.4	93.7	Water

Table 9. Image views of contact angles measurements on binder surface.

Bitumen substrate	Mean contact angle [deg.] (Laplace-Young method)	Mean contact angle [deg.] (circle method)	Mean contact angle [deg.] (height-width method)	Probe liquids
160/220				Diiodo-methane
				Formamide
				Water

Table 10. Surface energy contributions of emulsion grade binder.

Bitumen (160/220)	Total IFT [mN/m]	Dispersive [mN/m]	Non-dispersive (polar and H-H) [mN/m]
Laplace-Young method	37.7 ± 1.46	37.5 ± 1.41	0.2 ± 0.05
Circle method	39.0 ± 1.36	39.0 ± 1.24	0.0 ± 0.12
Height-width method	38.9 ± 1.43	38.8 ± 1.32	0.0 ± 0.11

In Table 8, it can be seen that Circle and Height-Width methods results for bitumen surface are also very close as compared to Laplace-Young method. Height-Width method is less robust than Circle fit whereas Laplace-Young fit is reliable for angles above 30°. As wetting angle of the water on bitumen surface is greater than 90°, thus it is truly hydrophobic. These variations in contact angles and profiles can be visually observed in Table 9 that shows image views of these measurements. Accuracy of the results can be compared only when such comparison are made. Accurate baseline detection, smooth and clean surface, optical clearance and gray levels; these all parameters contribute to high quality results.

Surface free energy calculations of bitumen are presented in Table 10 and here the major contributions are due to dispersive interactions. From the results, it can be expected with regards to Fowke's hypothesis that the two categories of forces are additive! Bitumen has only dispersive forces i.e. it can develop bonds to minerals which are equal to the smaller of the mineral and bitumen. For water it is the sum of the smallest dispersive force acting between the mineral and bitumen and the smallest non-dispersive forces acting between water and the mineral. Furthermore, bitumen and water are roughly equally strongly adsorbed to plagioclase and calcite, whereas water will displace bitumen from the other minerals.

As bitumen emulsions contain water, it is of paramount importance that water is either pushed out completely from the mineral-bitumen interface, giving it the opportunity to evaporate or drain off. Furthermore, the above measurements will be important when introducing the emulsifier itself to the system and will largely determine where it will go after the breaking of the system or in other words phase separation.

4 CONCLUSIONS

It can be concluded from the above research work that bitumen has only dispersive forces whereas most of the minerals surfaces have polar nature. According to Fowke's additive nature of the forces, bitumen and water are roughly equally strongly adsorbed to plagioclase and calcite, whereas water will displace bitumen from quartz, gypsum, potassium feldspar and mica surface. Height-Width method is less robust than Circle fit whereas Laplace-Young fit is reliable for angles above 30°. Future research will focus on the introduction of emulsions into the bitumen mineral system and the effect of adding mineral fillers to the bitumen and the characterization of long term performance of emulsion based asphalts, taking into consideration the fundamental properties, such as Surface Free Energy (SFE).

ABSTRACT: The dynamic complex modulus test for asphalt mixtures is conducted in the linear viscoelastic region and measurements assume that no damage is induced during the testing process. In contrast, the level of damage taking place in the flow number test is expected to be significant but it has not been quantified. The objectives of this study are to quantify the levels of damage in the dynamic complex modulus and flow number tests using x-ray Computed Tomography (CT) and to characterize the heterogeneous properties of asphalt mixtures under loading. Four asphalt mixtures, one conventional Hot-Mix Asphalt (HMA) and three Warm-Mix Asphalt (WMA) mixes, were evaluated. Two WMA processes (i.e., water foaming and Rediset™ additive) were used in the preparation of the WMA mixes. Results of the experimental program indicated that the damage taking place in the dynamic modulus test is minimal and homogeneous while the damage taking place in the flow number test is significant and heterogeneous. In addition, preparation procedure may significantly influence the three-dimensional air voids distribution in laboratory-compacted specimens.

Keywords: Asphalt pavements, x-ray computed tomography, dynamic modulus test, damage, warm mix asphalt

1 INTRODUCTION

The Mechanistic-Empirical Pavement Design Guide (MEPDG) introduced new concepts and methodologies that address limitations in previously employed semi-empirical design models such as the 1993 AASHTO design guide [1]. A major milestone of the MEPDG is that Hot-Mix Asphalt (HMA) is no longer described as a purely linear elastic material. Instead, both the effects of temperature and rate of loading on the behavior of HMA are considered through the complex modulus |E*| [2]. The dynamic modulus test was introduced in NCHRP 9-19 as a Simple Performance Test (SPT) that can be used to predict field performance of asphalt mixes [3]. Research activities in NCHRP 9-19 also recommended the use of the Flow Number (Fn), from the triaxial repeated load test, as a performance indicator of mix resistance to permanent deformation.

The standard test method for determining the dynamic modulus of asphalt mixes, AASHTO T342 "Standard Method of Test for Determining Dynamic Modulus of Hot-Mix Asphalt Concrete Mixtures," assumes that measurements are conducted within the linear viscoelastic region, in which the dynamic modulus is independent of the stress or strain amplitude. To ensure that the relationship between stress and strain is linear, the axial strains in the specimen should range between 50 and 150 microstrains. Calculation of the dynamic modulus also assumes proportionality of the induced strain to the applied stress on the specimen. Therefore, no damage should be induced in the specimen in order to ensure validity of the measurements and the calculations. In contrast, the flow number test is continued until 10,000 cycles or until the specimen fails through excessive tertiary permanent deformation. Therefore, substantial damage is expected to occur during the test process.

Although the assumptions made in the dynamic modulus test and the flow number test are well-defined, the levels of damage taking place during testing have not been quantified. The objectives of this study are to quantify the levels of damage in the dynamic complex modulus and flow number tests using x-ray Computed Tomography (CT) and to characterize the heterogeneous properties of asphalt mixtures under loading. Results of this experimental program were used to provide insight into damage and Three-Dimensional (3D) air voids distribution in asphalt mixes prior to and after loading. While this approach neglects the area of micro-cracks in the CT image, it provides a valid indication of damage in the material.

2 BACKGROUND

Digital image analysis allows one to enhance desired features in acquired digital images and to analyze the images based on the differences in grayscale intensities of the features. Enhanced digital images can also be converted into a numerical FE mesh. In the 1990s, digital image analysis techniques were utilized to analyze the surface characteristics of HMA [4]. This methodology was utilized to investigate the influence of compaction levels on the internal structure of HMA in the field and in the laboratory [5]. Elseifi and co-workers (2008) employed a high resolution digital camera to investigate the concept of asphalt binder film thickness in asphalt mixtures [6]. Adhikari and You (2007) used x-ray CT imaging technology to characterize aggregate orientation, aggregate gradation, mastic distribution, and air void distribution in HMA [7]. The locations of aggregates, air voids, and mastic were defined based on the grayscale intensities of x-ray CT images. Kassem et al. (2009) successfully employed 3D x-ray CT to evaluate the quality of the compaction of asphalt layers within full-depth pavements [8]. Image analysis technique was used to determine the average percent of air voids through the depth of the HMA layer. In general, it is widely recognized that x-ray CT is an effective method to evaluate the internal structure of asphalt mixtures.

3 EXPERIMENTAL PROGRAM

3.1 *Test materials*

Four dense-graded asphalt mixtures including one conventional HMA and three Warm-Mix Asphalt (WMA) mixes were evaluated. Two processes (i.e., water foaming and Rediset™ additive) were used in the preparation of the WMA mixes. In addition, Reclaimed Asphalt Pavement (RAP) was used in the preparation of the mixes at a content ranging from 15 to 30%. Table 1 provides a description of the eight test specimens. For the dynamic modulus specimens, loose mixtures were sampled from plant-produced materials for a project in Louisiana, located on US 171, and were compacted in an on-site mobile laboratory using a Superpave pneumatic gyratory compactor with no reheating to a target air voids content of 7.0%. Dynamic complex modulus specimens were compacted to a 165-mm height and a 150-mm diameter. Test specimens were then cored and cut from the center of the gyratory specimens to result in 100-mm diameter by 150-mm high specimens. For the flow number specimens,

Table 1. Descriptions of the test specimens.

Mix type	Specimen ID	Test	VTM[1] (%)	
			Before testing	After testing
WMA 15% RAP foamed	1	Dynamic modulus	7.3	7.4
	2	Flow number	6.3	9.5
WMA 30% RAP foamed	3	Flow number	5.5	9.2
	4	Dynamic modulus	5.8	5.8
Conventional 15% RAP	5	Flow number	7.1	9.9
	6	Dynamic modulus	7.0	7.5
WMA 15% RAP rediset™	7	Dynamic modulus	7.8	8.2
	8	Flow number	7.4	10.2

[1] VTM: Voids in the total mix.

loose asphalt mixtures sampled from the same project were transported to the Louisiana Transportation Research Center (LTRC) laboratory, reheated, and were compacted using a pneumatic Superpave gyratory compactor to a target air voids content of 7.0%. Flow number specimens were compacted to a 165-mm height and a 100-mm diameter. Test specimens were cut to result in 100-mm diameter by 150-mm high specimens.

3.2 *The dynamic modulus test*

The dynamic modulus test was conducted in accordance with AASHTO T342. The test was conducted by applying a uniaxial sinusoidal (i.e., haversine) compressive stress to an unconfined HMA cylindrical test specimen. The haversine compressive stress was applied on each specimen to achieve a target vertical strain level of 100 micro-strains in an unconfined test mode. The dynamic modulus test was conducted at four temperatures (4.4, 20.0, 37.8, and 54.4 °C) and at six loading frequencies of 0.1, 0.5, 1.0, 5.0, 10.0, and 25.0 Hz at each temperature.

3.3 *The flow number test*

The flow number test was used to assess the permanent deformation characteristics of paving materials by applying a repeated dynamic load for several thousand repetitions on a cylindrical asphalt specimen [9]. The "Flow Number" is defined as the starting point, or cycle number, at which tertiary flow occurs on a cumulative permanent strain curve obtained during the test. A loading cycle of 1.0 second in duration was used and consisted of applying 0.1-second haversine load followed by 0.9-second rest period. Permanent axial strains are recorded throughout the test. The test was conducted at an effective temperature (T_{eff}) of 54 °C and at a stress level of 207 kPa.

3.4 *X-ray computed tomography*

The x-ray CT system in the Advanced Characterization of Infrastructure Materials (ACIM) laboratory at Texas A&M University was used to scan the test specimens. The x-ray system had a 350 kV x-ray source and a linear detector with a resolution of 0.17 mm/pixel. The following imaging parameters were used; x-ray tube current = 1.6 mA, voltage = 345 kV, and copper filter = 3.2 mm thick. The test specimen was placed on a sample stage in between the x-ray source and the detector. The specimen stage rotates a full rotation with a constant speed during the scanning, and moves down at a specific distance. In this study, the interval between two subsequent x-ray CT images was 1 mm and scanning time of each x-ray CT images was 2 minutes. The intensity of the x-rays changes after going through the test specimen. The change in the intensity of the x-rays is related to the linear attenuations of different constituents within the test specimen, where the linear attenuation of a substance is related to

its density among other things. In an x-ray CT image, the low density material is represented with a darker color, while the high density material is represented by a brighter color (on a 256 gray level scale). Figure 1(a) shows an x-ray CT image for one of the asphalt mixture specimens.

In this study, the main focus was to determine the internal air voids distribution along the height of the test specimen. Macros that were developed in the Image-Pro® software were used to conduct the analysis [10]. By choosing the proper gray level, the air voids phase was thresholded from the other constituents (mastic and aggregates). This method relies on matching the calculated percent air voids using Equation (1) with the measured laboratory percent air voids. The total percent of air voids ($\%AV_t$) in a test specimen was calculated using Equation (1), while the average percent air voids in an image ($\%AV_i$) and the average radius of air voids (R) were calculated based on Equations (2), and (3), respectively:

$$\%AV_t = \frac{1}{N}\sum_1^N \%AV_i \tag{1}$$

$$\%AV_i = \frac{A_{tv}}{A_t} \tag{2}$$

$$R = \sqrt{\frac{A_{tv}}{\pi n}} \tag{3}$$

where N *is* the number of images, A_{tv} is the total area of the air voids an image, A_t is the total cross-sectional area of an image, and n is the number of the air voids in an image.

A scalar variable ξ was defined to quantify the levels of irreversible damage in HMA [11, 12]:

$$\xi = 1 - \frac{\overline{A}}{A_o} \tag{4}$$

where A_o is the initial area of the undamaged section and $\overline{A}$ is the effective cross-sectional area in the current damaged state. The variable ξ describes a positively monotonically increasing function. For the undamaged material, ξ is equal to 0, while for the totally damaged material, ξ is equal to 1. The effective cross-sectional area of the specimen was

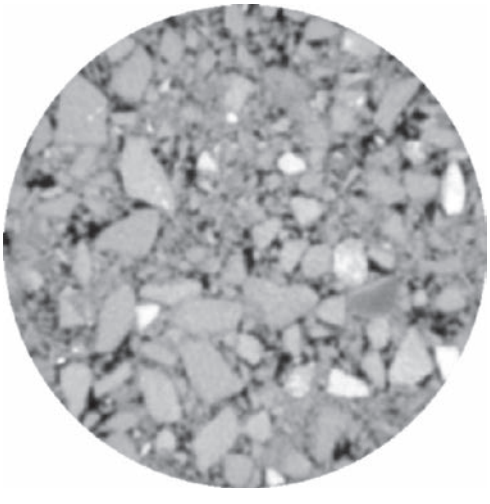

Figure 1. Two-dimensional X-ray image of an asphalt mixture.

determined by calculating the total area of air voids in a CT image using image analysis and then subtracting the areas of air voids from the total cross-sectional area of the CT image.

4 RESULTS AND ANALYSIS

4.1 *Air voids distribution*

Figure 2 presents the air voids distribution along the depth of two of the eight specimens before and after testing. While Specimen 1 is a dynamic modulus sample, Specimen 2 is a flow number sample. Similar air voids distributions were measured for the other test specimens. As shown in Figure 2, air voids distributions were distinctively different for the dynamic modulus and flow number specimens. For the dynamic modulus specimens, a relatively homogeneous air voids distribution was observed along the specimen height with higher air voids content in the top or bottom parts of the specimen. While past research has reported a "C" shape for the air voids distribution [4], the reason that only a partial C-shape was observed in this study is possibly due to the uneven cutting of the top and bottom parts of the specimen. To ensure uniformity of air voids, an equal length should be cut from both edges of the specimen. In contrast, the flow number specimens were highly heterogeneous with low air voids concentration in the bottom and the top thirds and a significant greater air voids concentration in the middle third of the specimen.

The discrepancy in air voids distribution is due to the different specimen sizes used in the compaction of the dynamic modulus and the flow number specimens and the reheating of the mixtures used in the preparation of the flow number specimens. Although both sets of specimens were compacted to a target air voids content of 7.0%, dynamic modulus specimens were compacted to a 150-mm diameter and flow number specimens were compacted to a 100-mm diameter. As shown in Figure 2, the gyratory compaction process results in a

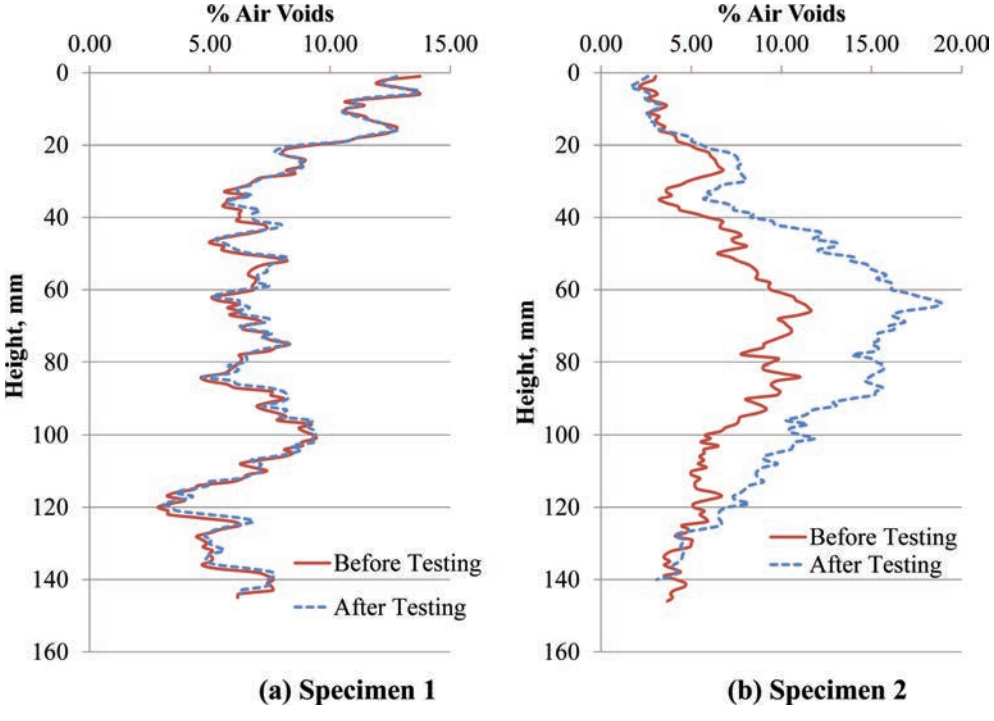

Figure 2. Air voids distribution along the depth for Specimens 1 and 2.

more uniform air voids distribution in the center of the specimen than around its circumference, which may explain the relatively more uniform air voids distribution observed in the dynamic modulus specimens. The effect of the foaming agent and WMA additive in facilitating the compaction process may have also been reduced upon reheating of the asphalt mixtures.

The concentration of air voids in the top, middle, and bottom thirds of Specimens 1 and 2 is quantified in Figure 3 before and after testing. The values presented in this figure confirm the homogeneous air voids distribution in the dynamic modulus specimen and the heterogeneous air voids distribution in the flow number specimen. It also indicates that the air voids contents in the dynamic modulus specimen remained relatively unchanged after testing while a significant increase in air voids occurred in the flow number specimen after testing.

4.2 *Damage analysis*

Figure 4 presents the x-ray visualization of the dynamic modulus and flow number specimens prior to and after testing (Specimens 1 and 2). As shown in Figure 4(a), the general visualization of the dynamic modulus specimen before and after testing appears to be similar indicating that little or no damage occurred during testing. In contrast, the specimen used in the flow number test experienced significant volume change especially in the middle third indicative of damage taking place during testing in a localized area of the specimen.

The level of damage taking place during testing was quantified through the damage parameter, ξ, previously defined in Equation (4). Figure 5 illustrates the calculated damage parameters for the dynamic modulus and flow number specimens after testing. As shown in Figure 5, little damage occurred during the dynamic modulus testing. In addition, the damage parameter was practically uniform throughout the height of the test specimens. In contrast, the damage experienced in the flow number test was not uniform with respect to the specimen height with little to no damage occurring in the top and bottom thirds of the specimens and most of the damage taking place in the middle third of the specimens. These results confirm that the assumption of no damage taking place in the dynamic modulus test is valid. In contrast, the damage taking place in the flow number test is heterogeneous with most of the damage occurring in the middle third of the specimen. These findings agree with Tashman et al. [11], who reported that damage in HMA is a localized phenomenon occurring in a critical location in the specimen due to the heterogeneity of the mix.

Figure 5. Levels of damage for (a) Specimen 1 (dynamic modulus) and (b) Specimen 2 (flow number).

5 CONCLUSIONS

The objectives of this study were to quantify the level of damage taking place in the dynamic complex modulus and flow number tests using x-ray CT and to characterize the heterogeneous characteristics of asphalt mixtures under loading. Based on the results of the experimental program, it was determined that the damage taking place in the dynamic modulus

test is minimal and homogeneous while the damage taking place in the flow number test is significant and heterogeneous. These results confirm that the assumption of no damage taking place in the dynamic modulus test is valid. In addition, specimen preparation may significantly influence the air voids distribution in HMA. To achieve relatively homogeneous air voids distribution, 150-mm in diameter by 165-mm in height specimens should be prepared, cored, and evenly cut from both sides of the specimen.

ACKNOWLEDGMENTS

This research was funded by the Louisiana Board of Regents—Research Competitiveness Subprogram (RCS). The assistance of the Louisiana Transportation Research Center (LTRC) and B. Vallabhu in preparing the asphalt concrete specimens is greatly appreciated.

The Universal Simple Aging Test (USAT): Simulating short- and long term hot and warm mix oxidative aging in the laboratory

Michael J. Farrar, Jean-Pascal Planche, R. William Grimes & Qian Qin
Western Research Institute, Laramie, WY, USA

ABSTRACT: In a recent article Farrar et al. [Eurasphalt & Eurobitume Congress, Istanbul, Turkey, June 13–15, 2012] report development of a thin film (300 μm) short- and long-term aging test as an alternative to the standard Rolling Thin Film Oven (RTFO) and Pressure Aging Vessel (PAV) tests. This new thin film oven test is referred to as the Universal Simple Aging Test (USAT). The RTFO is not suitable for simulating the oxidative aging that occurs during "warm" mix production and is problematic for aging highly modified binders. The USAT resolves both of these problems. The focus of the previous paper was applying the USAT for unmodified asphalt. This one examines and proposes application of the USAT for modified asphalt binders. In addition, we propose application of the USAT for simulating warm mix asphalt production in the laboratory. The technology that makes the USAT feasible is a Dynamic Shear Rheometer (DSR) technique recently developed at Western Research Institute as an alternative to the Bending Beam Rheometer (BBR). The new DSR method is commonly referred to as 4-mm DSR. This new DSR technique allows testing to very low temperature (−40°C), requires only 25 mg of binder, and can estimate BBR m-value and creep stiffness.

Keywords: Asphalt, aging, oxidation, RTFOT, durability

1 INTRODUCTION

The Universal Simple Aging Test (USAT) is a new thin film (300 μm) short- and long-term aging test developed at Western Research Institute (WRI) and proposed as an alternative to the standard Rolling Thin Film Oven (RTFO) and Pressure Aging Vessel (PAV) tests. The new test can be applied to neat and modified asphalt binders for Hot Mix Asphalt (HMA) and warm mix asphalt (WMA). Also, the USAT can be applied to emulsion residue recovery and oxidative aging of the residue [1].

The USAT, and its use in conjunction with 4-mm DSR was first described in 2012 by Farrar et al. [2] and was developed by adapting and extending previous research on thin film aging, particularly the work performed by Glover et al. [3,4] and Petersen [5].

Before the Strategic Highway Research Program, there was considerable interest in static thin film aging. However, the RTFO test, which at the time was already in common use, was adopted for short term aging because of the large amount of aged asphalt needed for the Bending Beam Rheometer (BBR) test. Since the adoption of the RTFO, it has been found problematic for aging highly modified binders. In the case of warm mix binders, RTFO testing at lower temperature to simulate a "warm" plant limits the rolling needed to uniformly age the material. The USAT eliminates the "rolling" issue for more viscous polymer modified and warm mix asphalts.

A new Dynamic Shear Rheometer (DSR) technique, recently developed at WRI allows DSR testing from intermediate to very low temperature (–40°C) and requires only 25 mg of binder [6,7]. The technique which uses 4 mm diameter plates is commonly referred to as 4-mm DSR. By combining 4-mm DSR with the USAT, the low and intermediate temperature

rheology of short and long-term aged asphalt binders can be determined, including estimating BBR m-value and creep stiffness, as well as the thermal stress build-up in the binder and mix from a cooling event [2,8,9]. In addition to low and intermediate temperature DSR, the USAT generates sufficient aged material to perform high temperature DSR using 25 mm diameter plates.

The first USAT report in 2012 considered only unmodified asphalts and proposed USAT aging protocols to simulate RTFO and standard PAV. In this report USAT aging of two polymer modified asphalt binders has been analyzed to support and supplement the 2012 Farrar et al. study [2], and a USAT short-term aging protocol to simulate the aging that occurs in a "warm" plant is proposed. The approach taken to establish a USAT short-term aging protocol for WMA was simply to compare differences in rheological properties between HMA and WMA recovered binders and find a USAT WMA short term aging time and temperature that results in similar differences between USAT HMA and WMA short term aging.

2 EXPERIMENTAL AND MATERIALS

2.1 *Dynamic shear rheometry using 4 mm diameter parallel platens*

Rheology was performed on a Malvern Kinexus stress control Dynamic Shear Rheometer (DSR), and in a few cases on a TA Instruments ARES strain control rheometer. Results from both instruments were very comparable. The low and intermediate temperature rheological properties of the recovered binders were measured with 4 mm diameter parallel plate geometry (4-mm DSR). High temperature rheological properties were measured using 25 mm diameter parallel plate geometry.

The 4-mm DSR test method is described elsewhere by Sui et al. [6] and Farrar et al. [7]. Low and intermediate temperature frequency sweeps were typically performed at 15 or 20°C intervals over a temperature range of –30 to 30°C and an angular frequency range of 0.1 to 50 rad/sec. High temperature frequency sweeps using 25 mm diameter plates were typically performed at 50 and 70°C.

2.2 *Materials*

Table 1 describes the four asphalt binders used in this study. They are tank asphalts collected during construction. Two of the four asphalts were modified at the refinery with Styrene Butadiene Styrene (SBS) copolymer.

2.3 *Development of the USAT for simulating RTFO and RTFO/PAV*

Using a thin film aging procedure is not a completely new idea. Asphalt thin-film oxidative aging has been extensively studied over the last 70 years; a good summary of the literature has been performed by Airey [10].

Behera et al. [11] recently reported a study on thin film aging as an alternative to standard RTFO and PAV aging and some aspects and conclusions of the Behera et al. study are similar to this study and the Farrar et al. study [2]. Behera et al. concluded that a binder of 650 μm

Table 1. Description: asphalt binders used in the USAT study.

Olmsted County, MN, CR 113	2006	MN1-3	58-28	Unmodified binder
S Manitoba Hwy 14	2010	MB	58-28	Unmodified binder

film thickness aged in a non-forced draft oven at 163°C can produce a similar effect as RTFO aging. The time at 163°C varied from 3 to 4.5 hours depending on the type of asphalt. Also, Behera et al. concluded that 3 to 4 days of oven aging at 85°C for normal binders and 4 to 5 days for modified binders produced long-term aging similar to PAV aging.

The USAT aging protocols developed in the Farrar et al study [2] and validated in this study for polymer modified asphalt are summarized in Table 2. The option of using a forced draft oven for the long term aging rather than a PAV was included in the Farrar et al. study [2].

One of the principal goals during development of the USAT was to make the asphalt film as thin as possible to reduce oxygen diffusion effects. The USAT film thickness of 300 μm was arrived at as a compromise in trying to prepare a uniform thin film without solvent casting and yet obtain the amount of sample required for rheological and chemical testing.

Figure 1A shows the latest USAT prototype for short and long-term thin film aging. There are three slots on the plate to allow aging of three separate films. Each slot requires 1.00 g of asphalt binder, which produces a film thickness of about 300 μm. The film thickness is a function of the specific gravity of the particular binder and temperature. The film thickness variation is estimated to be ±10 μm.

Preparing USAT asphalt thin films for oxidative aging involves bringing a hot plate to approximately 120°C in a nitrogen saturated glove box or tent and then placing the USAT plate (with asphalt) onto the hot plate. The nitrogen atmosphere is used to prevent undesirable oxidation. As the asphalt temperature approaches 120°C it spreads out to roughly two-thirds of the slot surface. A small spatula is used to spread the asphalt to the remaining unwetted surface as shown in Figure 1B. After spreading, the asphalt is allowed to remain at temperature for several minutes to level and evenly spread out. The USAT plate is then removed from the hot plate and allowed to return to room temperature under nitrogen.

The USAT short and long-term aging scheme is illustrated in Figure 2. The USAT plate is placed on a preheated block of aluminium to rapidly bring the USAT plate to temperature. The plate dimensions were selected so the plate can be inserted into a standard pressure aging vessel tray.

Table 2. USAT HMA binder protocol descriptions.

USAT protocol	Description	Equivalent AASHTO aging test
ST USAT HMA	Short term universal simple aging test 50 min. at 150°C in a forced draft oven	RTFO (ASTM D2872, AASHTO T240)

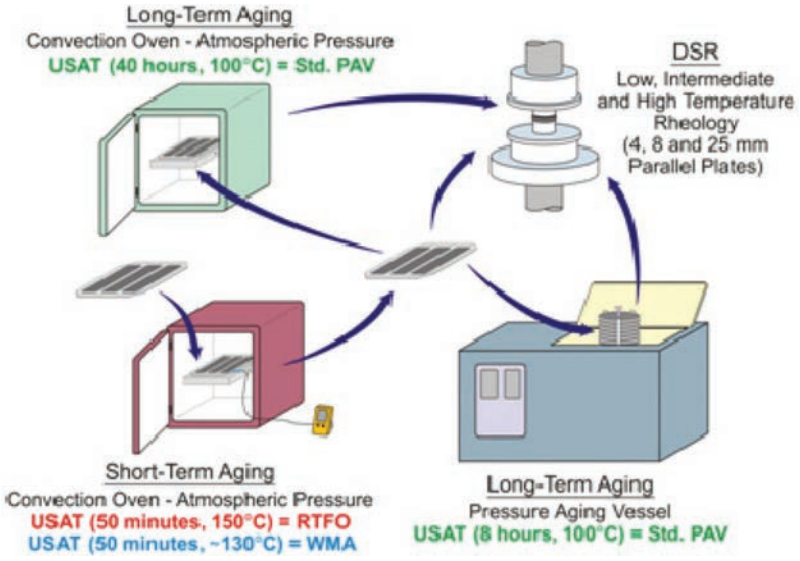

Figure 2. USAT short and long term aging scheme.

3 CONTINUOUS GRADE AND RHEOLOGICAL COMPARISON (USAT VS. RTFO AND RTFO/PAV) FOR MODIFIED ASPHALTS

3.1 *Linear viscoelastic region*

The continuous grade of the RTFO, RTFO/PAV, and USAT aged binders are presented in Table 3 for the YNP and WCD binders. For both the short and long-term aging, good agreement was found between USAT aging (Table 2 aging protocols) and RTFO and RTFO/PAV aging.

Comparisons of the low (m-value) and creep stiffness S(t), intermediate (G* sin δ), and high temperature (G*/sin δ) grading criteria for the USAT, RTFO and RTFO/PAV are shown in Figure 3. All of the asphalt binders either fall within or are close to falling within the single operator precision limits (d2 s%), indicating the USAT and RTFO and RTFO/PAV rheological measurements are comparable.

3.2 *Nonlinear viscoelastic region*

Table 4 compares the MSCR non-recoverable creep compliance (J_{nr}) at 64°C and 58°C and 0.1 and 3.2 kPa stress levels for the YNP and WCD aged using the USAT short term HMA aging protocol and RTFO aging. The J_{nr} results are surprisingly close.

4 DEVELOPMENT OF THE USAT FOR SIMULATING THE SHORT-TERM AGING THAT OCCURS IN A "WARM" PLANT

Table 5 describes the short term USAT aging protocol considered for WMA in this study.

4.1 *Rheological differences in recovered asphalt binder: HMA versus WMA*

4.1.1 *Linear viscoelastic region*

In a recent study, Bonaquist [12] evaluated the low, intermediate and high continuous grades of recovered binders from a number of HMA/WMA projects. Bonaquist found that for

the high-temperature grade of the binder an approximately 28°C reduction in production temperature resulted in less than a 1°C decrease in high-temperature grade. Bonaquist also reported that an approximate 28°C reduction in production temperature resulted in an average improvement in the low temperature grade of the binder of 1.5°C.

To supplement Bonaquist's findings the continuous grades for the recovered binders from the YNP and WCD HMA/WMA projects were determined and are shown in Table 6. The results indicate that for an SBS modified binder and an approximate 31°C reduction in the production temperature results in about a 1.3°C improvement in continuous high temperature grade and a 2.4°C improvement in the low temperature grade.

These results tend to support Bonaquist's [12] contention that binder grade changes are not necessary for WMA since the average differences in continuous grade are only one to two degrees. However, it is particularly interesting to note the WMA process resulted in an

improvement not only in the low temperature continuous grade, which was expected, but also in the high temperature continuous grade, which was not totally expected. However such an improvement has already been reported by Fort et al [13] in the case of polymer modified asphalt used in WMA. Fort et al attributed this effect to a lower aging of the polymer network, maintaining a stronger integrity under warm mixing conditions as opposed to chain scissions occurring during high temperature HMA mixing.

4.1.2 *Nonlinear viscoelastic region*

To help evaluate the results presented in Table 6, the Multiple Stress Creep Recovery (MSCR) test was performed on YNP and WCD recovered binders. Table 7 presents the MSCR non-recoverable creep compliance (J_{nr}) at 64°C and 58°C and 0.1 and 3.2 kPa stress levels for the YNP and WCD recovered binders. In the case of the YNP binder there is a slight increase in J_{nr} at both temperatures and stress levels in terms of the effect of a lower production temperature; and in the case of the WCD binder there is a slight decrease in the J_{nr} at both temperatures and stress levels in terms of the effect of a lower production temperature. Overall, an average reduction of 31°C in the production temperature results in essentially no change in J_{nr}.

5 ESTABLISHING THE USAT TIME AND TEMPERATURE NECESSARY TO SIMULATE THE OXIDATIVE AGING THAT OCCURS IN THE "WARM" PLANT DURING THE PRODUCTION OF WMA

The approach taken here to establish the USAT short-term aging protocol for WMA is simply to compare the differences in rheological properties between HMA and WMA recovered binders and find a USAT time and temperature for WMA binders that results in similar differences in rheological properties between USAT HMA and WMA aging.

5.1 *USAT linear viscoelastic region*

Table 8 summarizes the continuous grade temperatures using the proposed ST USAT WMA protocol (Table 5) and the established ST USAT HMA protocol (Table 2) for both SBS

Table 8. Continuous grading: HMA and WMA ST USAT aged asphalt binders.

		Continuous grade temperature (°C)		
Project asphalt	USAT protocol	Low	Intermediate	High
MB	ST USAT HMA 150°C	–37.9	11.3	58.9
	ST USAT WMA 130°C	–40.4	9.8	57.1
	Difference	–2.5	–1.5	–1.8
MN1-3	ST USAT HMA 150°C	–36.6	14.5	61.8
	ST USAT WMA 130°C	–36.8	12.9	58.5
	Difference	–0.2	–1.6	–3.3
Average difference unmodified binders		–1.4	–1.6	–2.6
Average difference (Bonaquist, ref [12])		–1.5		–1.0
YNP	ST USAT HMA 150°C	–41.7	9.1	59.4
	ST USAT WMA 130°C	–41.2	9.7	60.5
	Difference	0.5	0.6	1.1
WCD	ST USAT HMA 150°C	–39	11.9	70.6
	ST USAT WMA 130°C	–39.1	11.2	71.6
	Difference	–0.1	–0.7	1.0
Average difference modified binders		0.2	–0.1	1.1
Average difference modified recovered binders (Table 6)		–2.4	–2.7	1.3

Table 9. J_{nr} HMA WMA ST USAT aged asphalt binders.

		J_{nr} 58°C (kPa^{-1})		J_{nr} 64°C (kPa^{-1})	
Project asphalt	USAT protocol	0.1 kPa	3.2 kPa	0.1 kPa	3.2 kPa
YNP	ST USAT HMA 150°C	2.33	3.42	5.09	7.89
	ST USAT WMA 130°C	1.79	2.55	3.96	6.06
	Difference	–0.54	–0.87	–1.13	–1.83
WCD	ST USAT HMA 150°C	0.16	0.15	0.26	0.36
	ST USAT WMA 130°C	0.17	0.16	0.28	0.42
	Difference	0.01	0.01	0.02	0.06
Average difference		–0.27	–0.43	–0.56	–0.89
Average difference recovered binders (Table 7)		0.02	0.03	0.01	0.04

modified binders (YNP and WCD) as well as two unmodified binders (MN1-3 and MB). For the unmodified asphalts, the average differences between the USAT HMA and WMA short term aging protocol results are compared to the differences reported by Bonaquist [12]. For the modified asphalts, the differences between the USAT HMA and WMA short term aging protocol results are compared to the differences of the recovered binders (Table 6). Overall, the average differences compare reasonably well.

5.2 *USAT nonlinear viscoelastic region*

Table 9 presents the MSCR J_{nr} results at 64°C and 58°C and 0.1 and 3.2 kPa stress levels for the YNP and WCD binders aged using the ST USAT WMA and HMA protocols. The average differences between the USAT and recovered binders are compared. As with the continuous grade temperature, the differences compare favourably although the J_{nr} of the recovered binders tends somewhat lower than the USAT aged binders.

6 CONCLUSION

The USAT short and long term aging protocols for HMA when applied to polymer modified asphalt compare favourably to RTFO and RTFO/PAV aging of the same asphalts. This conclusion is based on evaluation of the rheology in both the linear and nonlinear viscoelastic regions.

In terms of applying the USAT for WMA, the differences in linear and nonlinear viscoelastic properties between the short term USAT WMA and HMA aging and the differences in recovered binder for the same asphalts are similar, which indicates the USAT short term aging protocol for WMA is a relatively robust and promising method. To the authors' knowledge, this is the only method currently available for WMA short term aging in the laboratory.

Performance study of fog or rejuvenating seals on gap and open graded surfaces for Caltrans

Dingxin Cheng & Lerose Lane
California Pavement Preservation Center, Chico, CA, USA

Peter Vacura
Caltrans, Sacramento, CA, USA

ABSTRACT: Based on Caltrans Maintenance Technical Advisory Guide (MTAG), there are many advantages of using fog or rejuvenating seals. Fog seals improve sealing or waterproofing of existing pavement, reduce aging of binder or prevent further stone loss by holding aggregate in place, or by simply improving the surface appearance. Rejuvenating seals are a combination of various rejuvenating oils, and/or a mixture of asphalt emulsion and recycling oils applied to the asphalt pavement surface. Rejuvenating emulsions restore the maltenes or light components that have oxidized and soften the existing binder, thus reducing the viscosity and improving the flexibility of the binder. Caltrans has been using fog or rejuvenating seals on shoulders and highways through maintenance activities. In order to safely utilizemore fog or rejuvenating seals on the mainline of its highways, Caltrans placed a series of pilot projects during the past five years.

This paper documents the findings from the fog or rejuvenating seal pilot studies on gap graded and open graded surfaces. Caltrans built test sections from 2007 to 2009 with six different fog or rejuvenating seal products on gap- and open- graded surfaces. Through field and laboratory studies on these products, Caltrans quantified the benefits and performance of the fog or rejuvenating seal products commonly used in California. After reviewing the positive results from these test sections, Caltrans placed another 12 pilot projects in 2012 and 9 pilot projects in 2013 under various surface types, locations, climates, and traffic levels. Project reports were generated by the California Pavement Preservation Center (CP2 Center) to document the surface texture, application rates, performance, and skid resistance for these pilot projects. These results were used to support Caltrans with its new specification development for fog or rejuvenating seal applications.

Keywords: fog seals, rejuvenating seals, surface texture, skid resistance, open grade, gap grade

1 INTRODUCTION

1.1 *Background*

Asphalt binders harden as they age because they gradually loss lighter molecular weight part of oils and become oxidized. Asphalt hardening takes place at different rates depending on environmental conditions and the exposure to air. Permeable pavements or pavements with high void contents such as open graded mixes can therefore age faster. Water ingress can also carry dissolved oxygen and trace elements that may promote aging. This means that pavements with open surfaces tend to age faster than those with closed surfaces. Aging of binder can cause cracking under traffic and loss binding ability and raveling (MTAG, 2008).

Based on the Asphalt Emulsion Manufactures Association (AEMA), the fog seal is defined as a light spray application of dilute asphalt emulsion used primarily to seal an existing

asphalt surface to reduce raveling and enrich dry and weathered surfaces (MTAG, 2008). The rejuvenating seal is a combination of various rejuvenating oils or a mixture of asphalt emulsion and recycling oils applied to the asphalt pavement surface. Rejuvenating emulsions restore the light components that have oxidized and soften the existing binder, thus reducing the viscosity and improving the flexibility of the binder (MTAG, 2008).

Fog or rejuvenating seals are used to seal the existing surface, prevent raveling, and/or restoring properties of aged or oxidized binders, and such extending the pavement service life. In California, fog seals are also used right after the chip seals to improve rock retention and prevent windshield damage.

On shoulders, gores, or dikes, surface texture with the application of fog seals is not as critical. Fog seals will protect the surface from weathering and aging. On travel ways, fog seals should only be used on surfaces with adequate surface texture. Fog seals applied on tight surface without addings and will create a slippery surface with safety concerns.

1.2 *Objective*

The objectives of this paper are to

- Evaluate the performance of various fog or rejuvenating seal products commonly used in California, and
- Study the texture requirements for fog seal applications on travel way of Caltrans roadway network and relate it to skid resistance.

2 PERFORMANCE STUDIES ON 2009 PROJECTS (ROSE TO REVIEW)

After a test site was built in 2007 on SR58 near Mojave, three additional sites were constructed in 2009 to evaluate different fog or rejuvenating seal products and their performances. At each site, Caltrans placed a total of six different products including CQS-1h, CRF, PASS-QB, Reclamite, TOPEIN C, and Styraflex (Stroup-Gardiner et. al., 2011).

The SR 128 in Boonville test sections were the first to be placed on June 7 and 8, 2009. This rural roadway is a located in slightly rolling terrain, and has two lanes with no shoulders and has an AADT level below 3,500. The existing surface was open-graded hot mix asphalt. Boonville is located in a cool coastal California climate in Caltrans, District 1. The US 395 sections in Alturas were placed on June 16, 2009. Alturas is located in the upper northeast portion of California near both the Oregon and Nevada state lines in Caltrans, District 2. This area is located in the high desert plains and has severe winters. The existing surface was ½ inch rubberized gap graded hot mix asphalt with high void content (greater than 10%) and a low binder content (about 7%) by weight of the mix. The highway is two lanes without shoulders.

The third project was located on US 395 in Inyo County in Caltrans District 9. The existing surface was dense-graded hot mix asphalt which was constructed in 2009.

The following are discussions of the performance of open-graded surface on State Highway 128 in Boonville and gap-graded rubberized asphalt surface on US 395 in Alturas. The dense graded projects were not the focus of this study.

A number of tests were performed on these sections including texture and skid tests, tests on the recovered binder, and Hamburg tests. Only a portion of the test results is included in this paper.

2.1 *Fog or rejuvenating seals on open graded mix on SR 128 in Boonville*

2.1.1 *Field performance study*

Before construction, there was some pumping of base fines up through existing cracks. The open-graded HMA surface was raveled in places, particularly in the wheel paths. There were occasional small depressions or potholes. Figure 1 shows typical distresses of the existing pavement. CP2 Center revisited the project site in 2011, two years after the seal coats.

Figure 1. Existing pavement showing cracking and raveling.

Table 1. SR 128 test section two year pavement condition survey summary.

Section	Transverse cracking	Longitudinal cracking	Potholes	Ravelling	Overall condition
Control	Throughout the section	Isolated	None	Extensive	Poor
Product A	Similar to the control, but less	None	None	Some	Fair
Product B	Similar to the control but less	None	Some	Some	Not as good as the Product A
Product C	Similar to control but less	Isolated	Some	Some	Fair to good
Product D	Similar to control but less	Isolated	Some	Some	Fair to good
Product E	Similar to control but less	Isolated	Some	Some	Fair to good
Product F	Similar to control but less	Isolated	Some	Some	Fair to good

Table 1 summarizes the condition of the various test sections. The major distresses were raveling, transverse cracking, and some potholes. All products performed better than the control section, and especially had less ravelling distress.

2.1.2 *Laboratory performance study*

To evaluate the performance of the seal coat at the SR128 test site, a set of 6 inch cores were taken at the control section as well as six different products test sections. Several tests were performed using the cores including penetration and viscosity tests on recovered binders, stiffness test using Bending Beam Rheometer, and Hamburg Wheel Tests on control and treated cores. The Hamburg Wheel test has the advantage over the BBR test because it utilizes larger samples. CP2 Center conducted Hamburg Wheel Tests on the core samples. The tests were performed under water with temperature of 50°C. The fog or rejuvenating seal products had better resistance to rutting and moisture damage based on the graph shown in Figure 2. The results of the other tests are included in the full report (Stroup-Gardiner et. al., 2011).

2.2 *Fog or rejuvenating seals on gap graded mix on US 395 in Alturas*

2.2.1 *Field performance study*

The CP2 Center reviewed the performance of this project two years after construction in 2011. The results indicated that the seals were effective in controlling ravelling compared to

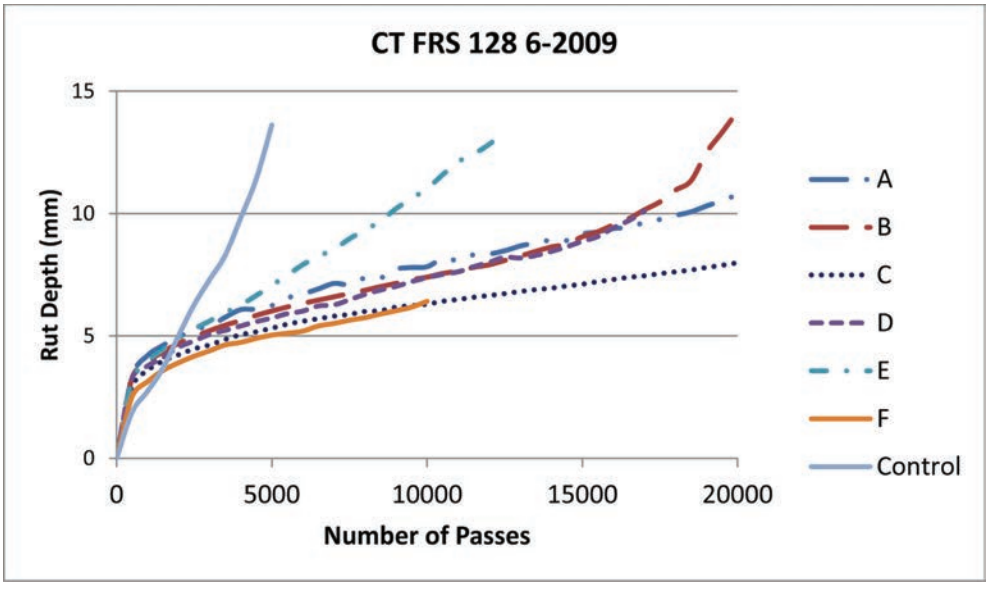

Figure 2. Hamburg test results for core samples from SR 128 in Boonville.

Figure 3. Visual comparison of sealed with non-sealed section at the US 395 test site.

the control section. Figure 3 illustrates that a fog sealed section seals the surface and lessens ravelling when compared with the non-sealed control section.

Table 2 summarizes the condition of the pavement in 2011. The predominant distress was thermal cracking with some minor longitudinal cracking.

2.2.2 *Laboratory performance study*

To evaluate the performance of the seal coat at the US 395 test site, a set of 6 inch cores were taken at the six different products test sections before and after fog or rejuvenating seal applications. CP2 Center conducted Hamburg Wheel Tests on the core samples. The tests were performed under water with temperature of 50°C. Figures 4 and 5 show the Hamburg Wheel

Table 2. US 395 testing section two year pavement condition survey summary.

Section	Transverse cracking	Longitudinal cracking	Potholes	Raveling	Overall condition
Control-in between test sections pavement	Throughout the section	Isolated	None	Some	Fair
Product A	Similar to the control	None	None	Little to some	Fair
Product B	Similar to the control	None	None	Little	Fair to good
Product C	Similar to control	Isolated	None	Little	Fair to good
Product D	Similar to control	Isolated	None	Little	Fair to good
Product E	Similar to control	Isolated	None	Little	Fair to good
Product F	Similar to control	Isolated	None	Little	Fair to good

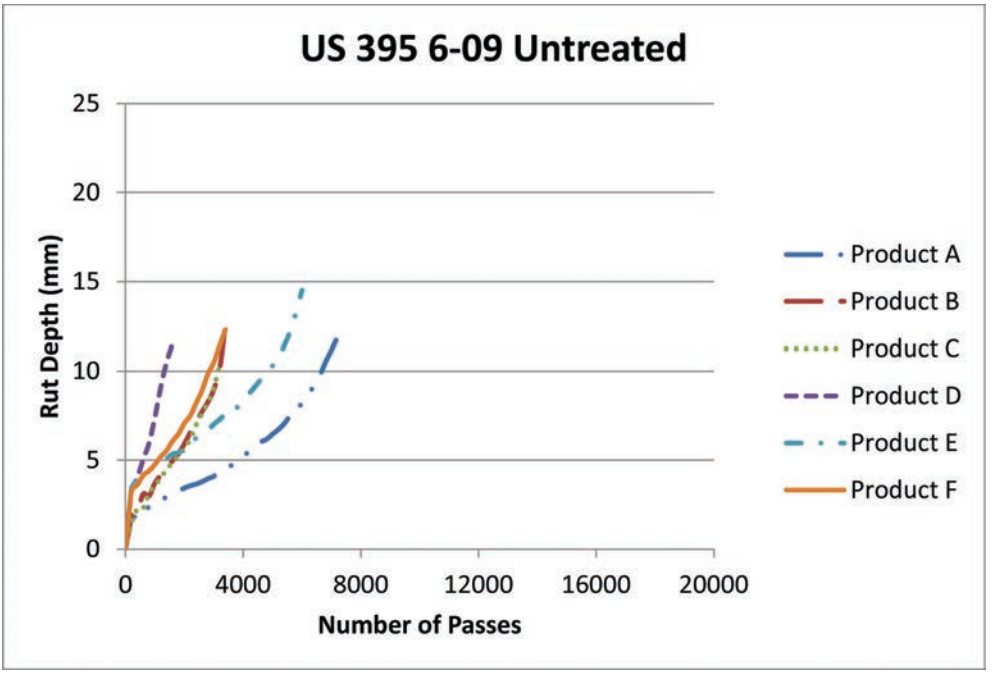

Figure 4. Hamburg tests on samples before fog seal treatment from US 395 test site.

Testing results for the six products sites before and after treatments. The fog or rejuvenating seal products had better resistance to rutting and moisture damage as the number of passes to reach 10 mm rut depth were much higher for treated than untreated surfaces.

2.3 *Summary of 2009 performance studies*

Based on the field evaluation and laboratory study on the performance of the 2009 pilot projects, the following conclusions can be drawn:

- The field evaluation clearly showed that fog or rejuvenating seal treatment sections performed better than the untreated or control sections. The treatment reduced the rock loss and preserved the surface with slower rate of deterioration.
- Six different fog or rejuvenating seal products were evaluated in the fields. Although they all performed better than the control section, they performed differently.

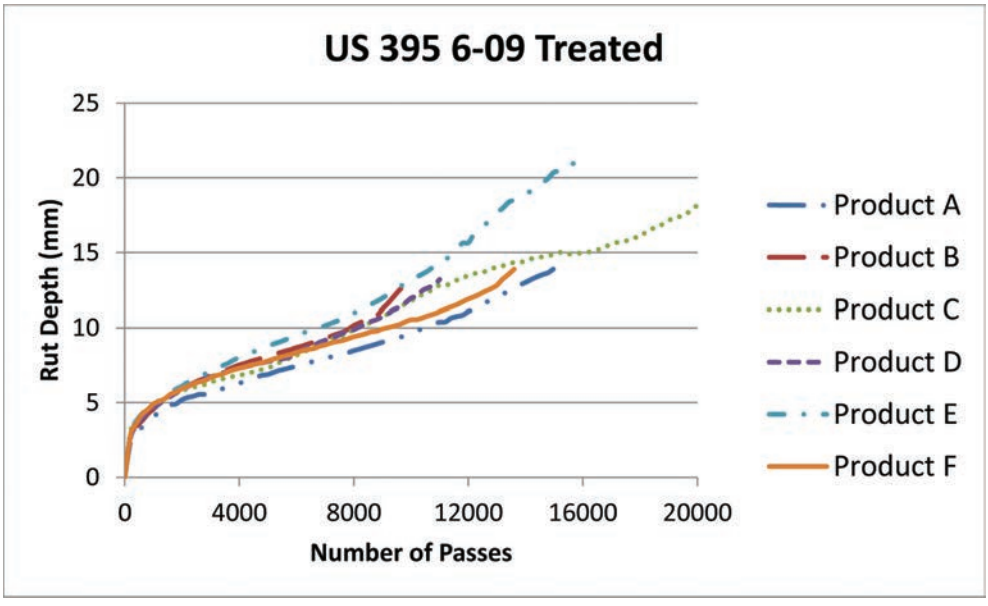

Figure 5. Hamburg tests on samples after fog seal treatment from US 395 test site.

- Performance based laboratory testing was conducted using the cores extracted at various locations of the 2009 pilot projects. The Hamburg Wheel Track tests showed that fog or rejuvenating seal treated cores had better rutting resistance and less moisture damage than the control cores, but different products performed differently.

3 TEXTURE AND SKID STUDY ON GAP AND OPEN GRADED SURFACES IN 2012 AND 2013

After the positive results of the 2007 and 2009 test sections, Caltrans continued the pilot projects in 2012 to further study the surface texture, skid resistance, and proper application rates for fog and rejuvenating seals. The following tests were conducted at the 2012 pilot sites.

3.1 *Field performance testing*

Several tests were performed on the various projects to evaluate the effectiveness and safety of the fog seals. Tests included Circular Track Meter (CTM) ASTM E2157, Dynamic Friction Test (DFT) ASTM E1911, Ring Test, Sand Patch Test ASTM E965, British pendulum test (BPT) ASTM E303, and the ASTM skid trailer ASTM E274.

3.2 *2012 pilot projects*

In an effort to return to the use of fog seals as a strategy to extend the life of mainline pavements in California, Caltrans conducted a series of fog or rejuvenating seal pilot projects in 2012. The goals of these projects were to measure surface textures before and after fog seals; to determine optimum applications rates for the fog seal, and the friction coefficient of the pavement. Application rates were studied using the ring test, the surface texture information such as mean texture profile and Mean Texture Depth (MTD) were explored using a Circular Track Meter (CTM) and sand patch test, respectively. Pavement skid resistance was studied using a Dynamic Friction Tester (DFT), British Pendulum Tester (BPT), and the ASTM E274 skid trailer (Winter, et. al., 2012).

Table 3. Caltrans 2012 fog or rejuvenating seal pilot projects information.

A total of 12 pilot projects were visited in Caltrans Districts 2, 3, and 10 with a variety of pavement types including open-graded, gap-graded, dense-graded, and chip sealed surfaces. Table 3 shows the locations, application rates, and surface type information of these pilot projects.

3.3 *2013 pilot projects*

To further study the performance and safety of fog or rejuvenating seals, Caltrans conducted 9 additional pilot projects in 2013. The goals of these projects are the same as the earlier pilot projects. These pilot projects were placed in Caltrans Districts 2, 3, and 10 with a variety of pavement types including open-graded, gap-graded, and dense-graded. Because of the rough texture and high skid resistance of chip seals, no chip seal surface was selected for the 2013 study. Table 4 shows the locations, application rates, and surface type information of the 2013 pilot projects.

3.4 *Summary of the 2012 and 2013 pilot projects*

From the testing conducted in this study, the following conclusions were made:

- Generally, with all pavement types the MTD decreased when the fog seal application was applied. This was verified by both the sand patch test and the CTM. In addition, a direct correlation was demonstrated between the CTM and sand patch test results.
- The emulsion breaking times of the ring tests using fog or rejuvenating seals were highly dependent on the temperature, climate, type of fog seal material, application rate, and pavement type.
- Generally, skid resistance of the pavement surfaces decreased after the fog seal was applied but then increased on the projects that included sanding or texture sealing as a precaution. The ASTM skid trailer and the DFT, which both provided data for high speed skid resistance, supported this trend. The BPT was used to determine the low speed skid resistance and how it changed with applications. The data gathered from the BPT tests also supported the same findings mentioned above.
- With increased application rates on both the open-graded and chip sealed surface, the MTD decreased. The effects of increased application rates on the gap-graded pavement were inconclusive and increased application rates on dense-graded pavements did not significantly change the MTD.
- Depending on materials, project sizes, and locations, the costs of fog seals are between $0.40/sqyd and $0.6/sqyd for these projects.

4 TEXTURE AND SKID STUDY ON GAP AND OPEN GRADED SURFACES

One purpose of this study was to measure the surface friction and texture of an asphalt pavement after applying a fog or rejuvenating seal. When applied, the surface of asphalt pavement will experience a short term reduction of friction and loss of texture. Friction is affected by a combination of microtexture and macrotexture of pavement surface, and fog seal application rates. Sand Patch, CTM are simply measures of the macrotexture. This study measured those characteristics to assess whether the reduced skid resistance levels were still acceptable for placing traffic on the roadway. Table 5 is a summary of skid and macrotexture measurement results for the gap-and open-graded flexible pavement surfaces of the 2012 and 2013 pilot projects. Friction was measured with a ASTM skid trailer (ASTM E274). Texture was measure using the Sand Patch (SP) (ASTM E965). Tests were performed before and after applying the fog or rejuvenation seals.

4.1 *Macrotexture summary*

The pavement experienced a slight reduction in the macrotexture measurements after treatment based on Table 5. The reduction can be attributed to both the fog seal and application

Table 5. Summary of skid and macrotexture measurements for 2012 and 2013 pilot projects.

Note: The empty cell in the table means that no test was performed due to construction schedule conflict.

of sand filing up valley of the surface texture. The purpose of the sanding was to enhance the friction of the surface immediately after fog seal applications. The skid number usually increased after sanding applications.

The texture test results show that texture levels for open-graded asphalt were between 1.15 to over 2.00 mm before fog seal applications and were reduced between 0.87 and 1.90 mm after fog seal applications. For gap-graded asphalt surfaces, the macrotexture levels were between 0.75 and 1.38 mm before fog seal applications and between 0.66 and 1.05 mm after fog seal applications. These are typical values for the surfaces measured for RHMA-G and HMA-O, which are greater than typical macrotexture on HMA surfaces (0.50 and 0.75 mm).

4.2 *Skid testing summary*

In all cases, the average friction measurement exceeded the 30 minimum threshold recommended by Caltrans on all pavement surfaces except at one location on Tehama County I-5 between post mile 17.3 and 22.1. The skid number on the first day after fog seal application at this location dropped to 29, and then the skid number came back to 34 a month later. Generally, the skid numbers dropped right after the fog seal application and returned to higher values within a few days. The application of sand increases the short term skid numbers.

4.3 *Texture and skid correlations*

Both microtexture and macrotexture contribute to the friction between tire and pavement. The microtexture dominates the friction at low speed while the macrotexture is an important high speed component for overall friction. The macrotexture provides both the escape for the surface water and subsequently good contact between the tire and pavement when a vehicle travels at high speed. The friction component due to macrotexture increases with speed significantly, and at speeds above 65 mph (105 km/hr) accounts for over 95 percent of the friction (PIARC, 1987).

4.4 *International friction index*

The International Friction Index (IFI) was developed by Permanent International Association of Road Congress (PIARC) to harmonize different friction and texture measurement methods. The IFI is composed of two numbers, F(60) and SP, while F(60) is the international friction number and *Sp* is the speed constant (gradient). Both F(60) and Sp are closely related to the macrotexture of pavement surface.

4.4.1 *Speed constant*

The friction changes with different sliding speed. The speed constant is related to the gradient of the friction—sliding speed curve. Based on ASTM E1960, S_p can be calculated using the following equation:

$$S_P = a + b \times TX \tag{1}$$

where TX = Macrotexture, mm, and
a, b = Calibration constants dependent on the method used to measure macrotexture. For the CTM, measuring *MPD* (ASTM E1845) (Liu and Steven, 2006),

$$S_P = -3.75 + 107.6\ MPD_{CTM} \tag{2}$$

The MPD can be calculated using Sand Patch, MTD value as following:

$$MPD = 1.056 \times MTD - 0.073 \tag{3}$$

4.4.2 *International friction number*

The international friction number can be calculated using the following equation:

$$F(60) = A + B \times FR(60) + C \times TX \tag{4}$$

where A, B = Calibration constants dependent on friction measuring device,
C = Calibration constant required for measurements using ribbed tire, and $FR(60)$ = Adjusted value of friction measurement $FR(S)$ at a slip speed of S to a slip speed of 60 km/hr.

Based on a study by UCPRC (Liu and Steven, 2006), the constant A, B, and C for ASTM skid trailer are—0.023, 0.607, and 0.098, respectively. The $FR(60)$ can be calculated using the following equation:

$$FR(60) = FR(S) \times e^{\left(\frac{S-60}{S_p}\right)} \tag{5}$$

where $FR(S)$ = Friction value at selected slip speed S.
S = Selected slip speed, km/hr.

Vice versa, one can calculate the friction at any speed $FR(S)$ if the friction value are given for the standard speed, $FR(60)$ by following equation:

$$FR(S) = FR(60) \times e^{-\left(\frac{S-60}{S_p}\right)} \tag{6}$$

4.5 *Recommended minimum macrotexture*

Based on the previous section, both S_p and F(60) are directly related to the macrotexture of the pavement surface. From Equation 1, the higher the macrotexture, the higher the speed constant, S_p. From Equation 4, the higher the macrotexture, the higher the international friction number, F(60).

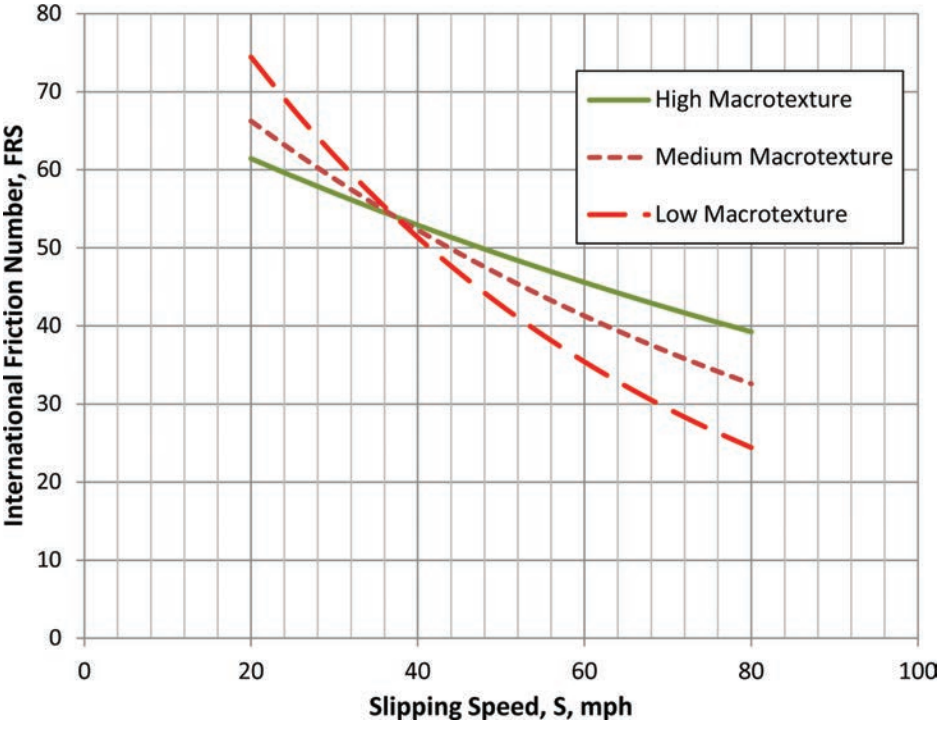

Figure 6. IFI friction model for different macrotexture depths.

To further illustrate the importance of macrotexture, especially at high speed, the friction speed curve shown in Figure 6 was developed using the constants developed by UCPRC in Equation 4. Figure 6 shows that the higher the macrotexture, the flatter the friction-speed curve and higher the friction at high speed. For low macrotexture surfaces, the friction drop significantly at high speed. Therefore, minimum macrotexture level should be provided to ensure the safety of vehicles under high speed and wet pavement conditions.

Based on the testing results of the 2012 and 2013 skid and texture measurement, the recommended minimum macrotexture for open-and Gap Graded RHMA are 1.15 and 0.75 mm, respectively. These two macrotexture values are corresponding to skid numbers that are greater or equal to 30 for ASTM skid trailer test.

Calculated using the UCPRC developed constants, the IFI corresponding to the minimum macrotexture for the HMA open-graded are $F(60) = 19$, and $S_p = 74$ mph, while the IFI corresponding to the minimum macrotexture for the RHMA-Gap Graded are $F(60) = 19$, and $S_p = 46$ mph.

5 CONCLUSIONS AND RECOMMENDATIONS

Based on the fog or rejuvenating seal studies in 2007 and 2009, and the pilot project placed by Caltrans in 2012 and 2013, the conclusions and recommendations are as follows:

5.1 *Conclusions*

The following are the major conclusions of the fog or rejuvenating studies of Caltrans:

- The field evaluation showed that fog or rejuvenating seal treatment sections performed better than the untreated or control sections. The treatment reduced the raveling and had fewer distresses. However, different products performed differently.

- Performance based laboratory testing were conducted on field cores. The Hamburg Wheel Track test results showed that fog or rejuvenating seal treated cores had better rutting resistance and less moisture damage than the control cores. Again different products performed differently.
- Generally, the macrotexture decreased when the fog seal application was applied. This was verified by both sand patch test and the CTM.
- The emulsion breaking times of the ring tests using fog or rejuvenating seals were highly dependent on the temperature, climate, type of fog seal material, application rate, and pavement type. Based on the pilot projects, a 15–20 minutes emulsion breaking time can help to determine the proper fog or rejuvenating seal application rates. Longer breaking time indicates that application rates is too heavy and may cause skid loss.
- Generally, skid resistance of the pavement surfaces decreased after the fog seal was applied but then increased on the projects that included sanding or texture sealing.
- High macrotexture surface generally has higher high speed friction than low macrotexture surface for the same type of pavement. Macrotexture is a very important parameter for increasing speed constant and friction number of the international friction index.
- For the 2012 and 2013 pilot projects, the range of texture levels for open-graded asphalt were from 1.15 to over 2 mm. Generally, the skid numbers of these open-graded pilot projects were higher than Caltrans recommended minimum skid number.
- For the 2012 and 2013 pilot projects, the range of texture levels for gap-graded asphalt were from 0.75 to 1.38. The skid numbers of these gap-graded pilot projects were higher than Caltrans recommended minimum skid number.

5.2 *Recommendations*

The following are the recommendations from this Caltrans fog seal study:

- To account for these varying textures and pavement types, a ring test (similar to CT 345) should be run to determine the appropriate application rate of the fog seal. This test determines the rate that provides adequate coverage and also has break time approximately 15–20 minutes. This is an important feature when considering opening to traffic. The finished surface will typically be dry and slightly tacky.
- Good results can be attained when the fog seal is placed at the pavement temperature above 50°F, ambient temperatures above 60°F, no anticipated precipitation for 3–5 days.
- The higher the macrotexture levels, the less the risk for safety issue due to high speed skid loss. Based on the 2012 and 2013 Caltrans pilot studies, the recommended minimum macrotexture for open-graded mixes is 1.15 mm, and the recommended minimum macrotexture level for rubberized gap-graded mixes is 0.75 mm.
- Different fog or rejuvenating seal products perform differently. Some would have less friction than others. Sanding should be applied to ensure the initial friction right after these fog seal applications on highways.

ACKNOWLEDGEMENT

We would like to extend our gratitude to Caltrans Engineers in Headquarters, Districts 2, 3, 9, and 10, who provided continuous support to this project. The authors also appreciate the support from Dr. R. Gary Hicks who provided detailed review to this paper. CP2 Center Student assistants Brian Winter, Brandon Fraser, Katie Fitzgerald, Brennen Urbanek provided support and performed testing for this project.

Evaluation of early aggregate retention performance of chip seals with Polymer-Modified Emulsions

Jeong Hyuk Im & Y. Richard Kim
Department of Civil, Construction and Environmental Engineering, North Carolina State University, Raleigh, NC, USA

ABSTRACT: One of the most cost-effective pavement preservation treatments is the chip seal. Roads with newly constructed chip seals normally are opened to traffic three to four hours after construction, so it is important that the chip seals reach a sufficient performance level within three to four hours. In order to evaluate this early performance of chip seals, this study compares PMEs to an unmodified emulsion for their usage in chip seals in terms of curing and aggregate retention. The curing and adhesive behavior study of the two types of emulsion was performed using the evaporation test, Bitumen Bond Strength (BBS) test, and Vialit test. The third-scale Model Mobile Load Simulator (MMLS3) was employed for aggregate retention testing.

Based on the test results, the main findings presented in this paper are: (1) the use of PMEs improves chip seal performance and (2) four hours is not long enough for the CRS-2 (unmodified) emulsion to exhibit sufficient aggregate retention performance, but within four hours (at least three hours) is enough time for the PMEs to exhibit sufficient aggregate retention performance.

Keywords: Chip seal, early performance, aggregate retention, curing and adhesive behavior, Polymer-Modified Emulsion

1 INTRODUCTION

Chip seals are one of the most efficient and cost-effective methods of pavement preservation and offer significant advantages in terms of skid resistance and fast construction. Chip seals have proved to be cost-effective due to their low initial costs in comparison with thin asphalt overlays and due to other factors that affect treatment selection decisions where the structural capacity of the existing pavement is sufficient to sustain its existing loads [1].

Due to the low-cost maintenance benefits of chip seals, state highway agencies would like to extend their use to include roadways with traffic volumes that are higher than those typically used. For high-volume roads, Polymer-Modified Emulsions (PMEs) can be used in the chip seal design because the polymer modification decreases the pavement's susceptibility to changes in temperature, increases adhesion to reduce aggregate loss, and allows the road to be opened to traffic earlier than would otherwise be the case. Together, these benefits have led to the increased use of PMEs by the chip seal industry.

The use of emulsions is very common in pavement preservation because emulsions do not require a hot mix set-up, they have a low sensitivity to temperature changes, and they are not likely to be hazardous to the construction crew. In addition to these benefits, most sources agree that the use of PMEs also provides benefits to the binder after modification. Most scientific sources are also in agreement that the best and most effective concentration of polymers is one that allows for the formation of a continuous polymer, and 3% to 5% is a typical advisable application rate for polymers [2, 3].

The adhesion of the emulsion to the aggregate in a chip seal system is strongly associated with the performance and service life of the chip seal. Wood et al. [4] explain that the addition of polymer can enhance certain properties of an asphalt emulsion. Generally, four types of polymers can be used in PMEs: natural latex, synthetic latex, Styrene Butadiene Rubber (SBR), and Styrene Butadiene Styrene (SBS). Typically, approximately 2.5% to 3% polymer, by weight, is added to the emulsion. When polymer is added to the emulsion, several benefits emerge; e.g., early aggregate retention raises the softening point of the base asphalt, the chip seal is better protected, and fewer materials are wasted.

One of the most prevalent failures of chip seals is the aggregate loss that occurs from traffic loading. One of the benefits of using PMEs for chip seals is that PMEs mitigate such aggregate loss. Takamura [5] compared the aggregate retention performance of unmodified emulsion and PME (3% cationic SBR latex). The brush test, which was developed to reduce problems associated with loose aggregate in chip seal operations, was used. The brush test was conducted using eight different aggregate types after five hours of curing at 35°C (95°F). A comparison of the unmodified emulsion and the emulsion modified with SBR latex showed that the SBR latex-modified asphalt emulsion provided faster strength development, with above 80% aggregate retention, than the unmodified emulsion.

Kim and Lee [6] compared the aggregate retention performance of an unmodified emulsion (CRS-2) and two PMEs (CRS-2L and CRS-2P). They performed the third-scale Model Mobile Load Simulator (MMLS3) test, flip-over test, Vialit test, bleeding test, and rutting test on both laboratory and field-fabricated samples under different temperature conditions. The benefits of using PMEs in chip seal construction are supported by this study. The CRS-2L emulsion manifested a reduction in the amount of aggregate loss during early curing times, less curing time needed to obtain the desired adhesion, and the ability to allow traffic on the newly constructed road safely and relatively soon. Also, the CRS-2L emulsion improved the aggregate retention performance at low temperatures. The CRS-2L emulsion tested by the Vialit test met the Alaska Department of Transportation specifications criterion of 10% maximum allowable aggregate loss at –20°C and 5°C.

Building on the work of these previous studies, this study investigates the curing and adhesive behavior and the aggregate retention performance properties of chip seal samples fabricated in the laboratory using an unmodified emulsion and five PMEs to evaluate the early performance of chip seals.

2 OBJECTIVE

The objective of this paper is to evaluate the early aggregate retention performance of chip seals made with PMEs in the laboratory based on a comparative study. Because public traffic typically is allowed on roads with newly constructed chip seals three to four hours after construction is completed, the early aggregate retention performance plays a vital role in the success of chip seals.

3 MATERIALS

One unmodified emulsion (CRS-2) and five PMEs (PME-A, PME-B, PME-C, PME-D, and PME-E) are used in this study. The CRS-2 and PME-A (SBR latex-modified) emulsions were selected because they are used widely in North Carolina and best match the surface charge of the granite aggregate that is commonly used in North Carolina. In order to compare the emulsion properties of the PMEs, PME-B and PME-C were selected as SBS PMEs. In addition, PME-D and PME-E are employed in this study because they are produced especially for high performance chip seals. Based on the most common usage for chip seal construction in North Carolina, a 78 M graded granite aggregate was used to fabricate the laboratory samples. Figure 1 shows the gradations of the granite aggregate plotted on the 0.45 power chart.

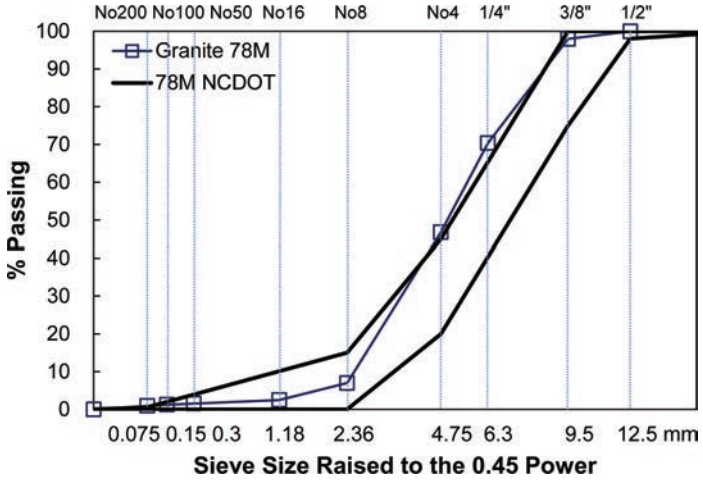

Figure 1. Aggregate gradations for granite aggregate.

For the aggregate loss tests (the Vialit test and MMLS3 test), single-seal specimens were fabricated using the granite 78 M aggregate. The optimal Aggregate Application Rates (AARs) and Emulsion Application Rates (EARs) were determined for these single seals based on an earlier chip seal mix design study [7]. All the specimens were fabricated with AARs of 8.7 kg/m^2 (16 lb/yd^2). For all the specimens, an EAR of 1.13 L/m^2 (0.25 gal/yd^2) was applied for all the emulsion types.

4 EXPERIMENTAL PROGRAMS

In order to evaluate the curing and adhesive behavior of the chip seals, evaporation testing was used for a direct comparison of the curing characteristics of the test emulsions. The BBS test and the Vialit test were conducted at four curing times (30, 60, 120, and 240 minutes) and at three curing temperatures (15°C, 25°C, and 35°C) to investigate the performance within the early curing times. The aggregate retention performance, which reflects one of the main failure characteristics of chip seals, i.e., aggregate loss, was evaluated using the Vialit test and MMLS3 test.

Figure 2 (a–c) show the apparatus used for the evaporation test, BBS test, and Vialit test, respectively.

4.1 *Evaporation test*

It is important to determine the curing times that are required for the respective emulsions to reach their asymptotic percentage of water loss, that is, the point at which no more water loss occurs. This determination requires a direct comparison of the curing characteristics of the test emulsions. For these evaporation tests, emulsions were heated to the application temperature, 60°C, and placed in small cans 90 mm diameter each. All emulsion samples were exposed to the same curing condition; i.e., each was subjected to the same curing temperature, 35°C, and EAR of 0.25 1.13 L/m^2 (gal/yd^2) in the environmental chamber.

4.2 *Bitumen Bond Strength (BBS) test*

In the pavement field, the Pneumatic Adhesion Tension Testing Instrument (PATTI) test can be used to measure the bond strength between the hot asphalt binder and aggregate surface or between the emulsion and aggregate surface by providing the maximum pull-off tensile

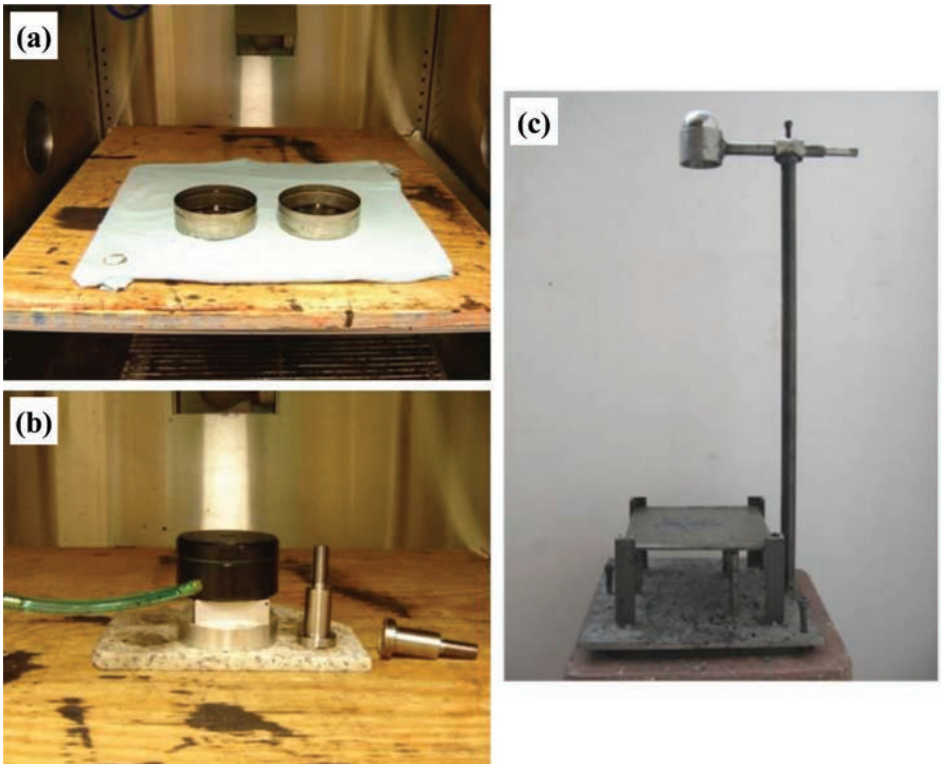

Figure 2. Apparatus used for: (a) Evaporation test, (b) BBS test, and (c) Vialit test.

strength that is converted from air pressure. AASHTO TP-91 was developed for asphalt binders and emulsions and provides the specifications for the BBS test [8].

In this study, the BBS test is used to compare the adhesive behavior of each emulsion as a function of different curing times and temperatures. Therefore, the BBS test results are used to determine not the bond strength itself, but the change in bond strength as a function of curing time. In previous fog seal research [9], the BBS procedure was modified so that it can be applied to fog seal emulsions. From the fog seal BBS test results, it was found that the modified BBS procedure works well. The only difference between the BBS procedure and the modified BBS procedure is the testing time. In the BBS procedure [8], once the pull-stubs are affixed, one hour is required to allow the samples to acclimate to the test conditions. Therefore, when the BBS test is conducted for two hours of curing, the actual test is performed at three hours of curing. This additional one hour not only can affect the bond strength but it also can be a major variable in determining the emulsion curing rates, because any significant change in the curing rate of the emulsion normally occurs during the early part of the test. Therefore, in this study, the modified BBS test procedure, whereby the actual test is performed at an exact curing time in an environmental chamber, is used for analysis of the adhesive behavior of each emulsion.

The BBS tests were conducted for all the test emulsions with granite aggregate under the same conditions. In order to capture the early bond strength, the BBS tests were performed at four curing times (30, 60, 120, and 240 minutes) and at three curing temperatures (15°C, 25°C, and 35°C).

4.3 *Vialit test*

The Vialit test was developed by the French Public Works Research Group and is standardized in BS EN 12272-3 [10]. This test method can be used as an indicator of aggregate

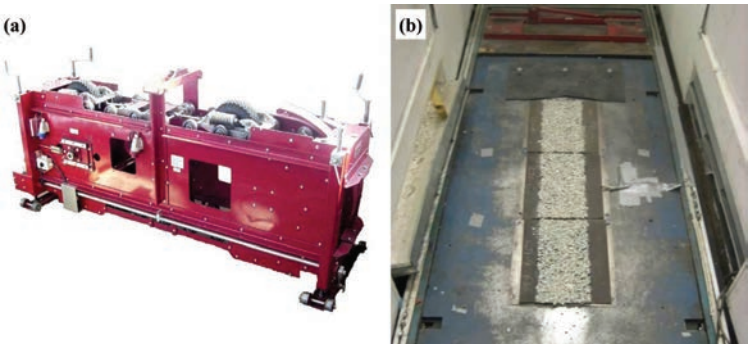

Figure 3. (a) MMLS3 and (b) Samples in MMLS3 chamber.

retention for chip seal specimens. A stainless steel ball is dropped three times from a height of 50 cm (19.7 inches) onto an inverted chip seal specimen. The averaged percentage of aggregate loss after three ball drops is used to evaluate the aggregate retention of the specimen.

In this study, the Vialit test was performed for granite aggregate to determine the adhesive behavior of the chip seal specimens and to evaluate their aggregate retention performance at different curing times (30, 60, 120, and 240 minutes) and at different curing temperatures (15°C, 25°C, and 35°C). Four replicates were fabricated for each condition to ensure confidence in the resultant data.

4.4 *Third-scale Model Mobile Load Simulator (MMLS3) test*

Figure 3 (a) and (b) present the MMLS3 and chip seal samples in the environmental chamber, respectively. The MMLS3 uses a continuous loop for trafficking. It is comprised of four bogies each with one wheel, which is a pneumatic tire that is 30 cm (11.8 inches) in diameter, one-third the diameter of a standard truck tire approximately, per bogie. The MMLS3 provides repeated wheel loads onto the pavement surface at a consistent rate (990 wheel loads applied every 10 minutes) and accelerates wear on the pavement. The MMLS3 allows researchers to simulate years of damage in mere days. Also, the MMLS3 can simulate the actual wandering of vehicles across the wheel path by wandering across the entire width, 17.8 cm (7 inches), of chip seal specimens. In order to control the test temperatures, the MMLS3 is placed inside a temperature chamber during testing.

Specimens for MMLS3 testing can be fabricated in the field or in the laboratory. For the laboratory-fabricated specimens, asphalt felt disks are cut to 30.5 cm by 35.6 cm (12 inches by 14 inches), and emulsion is applied on the felt paper in dimensions of 17.8 cm (7 inches) wide and 30.5 cm (12 inches) long, which covers the MMLS3 wheel path (Kim and Lee 2005). The MMLS3 test procedure involves the following steps [6, 7, 11]:

1. Cure the specimens in the temperature chamber at 35°C (95°F) for 12 hours and 35 ± 3% relative humidity, as specified by ASTM D7000 [12].
2. Weigh the initial specimen.
3. Condition the specimens to 25°C (77°F) for 3 hours.
4. Apply MMLS3 loading for 10 minutes, which is the time required for the MMLS3 to complete one wandering cycle, and then weigh the specimen.
5. Apply MMLS3 loading for 120 minutes, and weigh the specimen periodically.

5 PERFORMANCE EVALUATION BY LABORATORY TESTING

5.1 *Curing and adhesive behavior*

Figure 4 (a) shows the evaporation test results and (b), (c), and (d) show the BBS test results for curing at 15°C, 25°C, and 35°C, respectively.

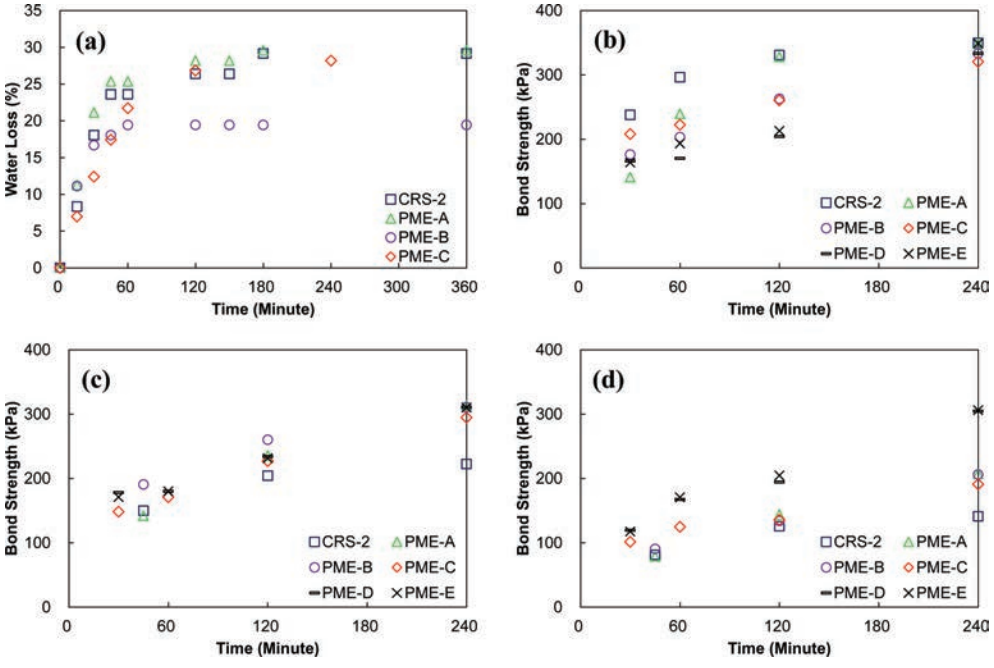

Figure 4. Curing and adhesive behavior test results: (a) Evaporation test; and BBS test at (b) 15°C, (c) 25°C, and (d) 35°C.

5.1.1 *Evaporation test*

Figure 4 (a) presents the evaporation test results that indicate that the PME-B emulsion reaches its asymptotic final percentage of water loss (curing) the fastest of all the emulsion types. It reaches its asymptotic curing value in approximately one hour, and the PME-C emulsion reaches its asymptotic curing value in two hours. Both the CRS-2 and PME-A emulsions reach their asymptotic curing values at around three hours. Thus, in this test, the PME-B emulsion cures about two times faster than the PME-C emulsion and about three times faster than the CRS-2 and PME-A emulsions.

5.1.2 *Bitumen Bond Strength (BBS) test*

The BBS test results (see Fig. 4 (b–d)) indicate that the PMEs show better bond strength than the CRS-2 unmodified emulsion at 35°C and 25°C not only during curing, but also after curing. However, at 15°C, the PMEs show lower bond strength values than the CRS-2 emulsion in the early curing times (before four hours). The bond strength values of the PMEs after four hours of curing are similar to that of the CRS-2 unmodified emulsion. This unexpected behavior at 15°C seems to be related to the contact area between the pull-off stubs and aggregate substrate and seems also to be dependent on the test temperature. The test temperature may affect the viscosity of the emulsion, and the viscosity will then affect the penetration of the emulsion into the voids in the aggregate substrate. For BBS testing, it is important to maintain the same contact areas in order to compare the bond strength values directly, because a smaller contact area causes less bond strength when the same load is applied to the specimen. The porosity of the aggregate substrate also can affect the bond strength because air can be trapped in the surface voids when the emulsion is poured [13].

5.1.3 *Vialit test*

Figure 5 (a–c) show the Vialit test results as percentages of aggregate loss at the different curing times for all six emulsion types with granite aggregate at 15°C, 25°C, and 35°C, respectively. Figure 5 shows that low curing temperatures lead to more aggregate loss than

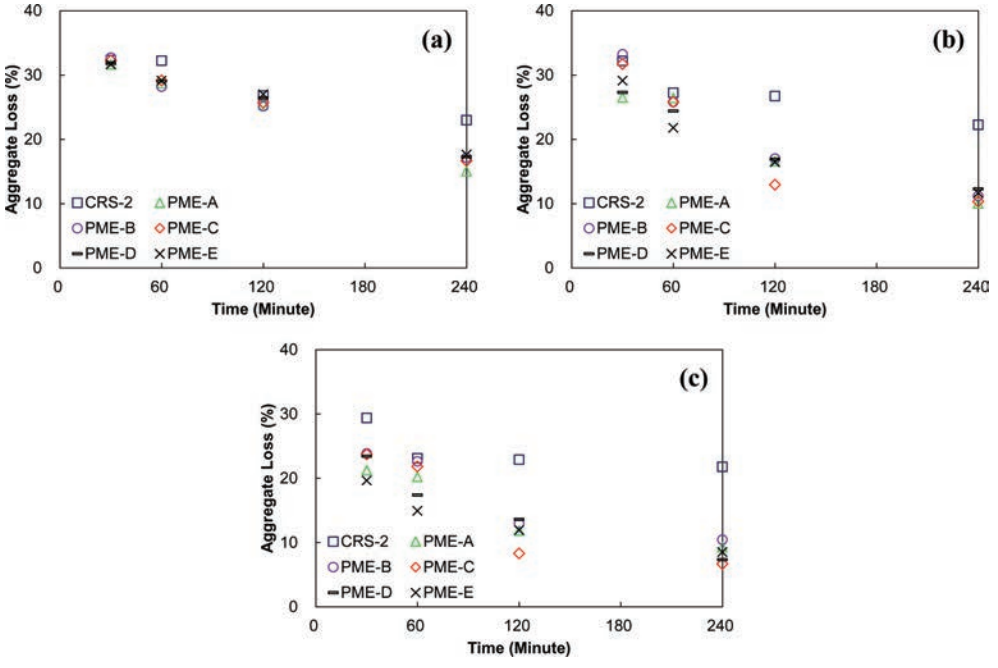

Figure 5. Vialit test results at: (a) 15°C (b) 25°C (c) 35°C for granite aggregate.

high curing temperatures. The reason for this outcome is that emulsion is more fluid at higher temperatures, and this emulsion state allows the aggregate particles to be reoriented in a manner that maximizes the embedment depth in the compaction state and improves aggregate retention. As expected, a direct relationship is found between the curing temperature and aggregate loss results, regardless of emulsion type.

At four hours of curing, the CRS-2 specimens show more aggregate loss than the PME specimens regardless of the PME type and test temperature. The difference in aggregate retention performance between the unmodified emulsion and the PMEs becomes greater as the temperature increases. Recognizing that the chip seals are constructed more frequently at temperatures closer to 25°C and 35°C, the improved aggregate retention benefits of the PMEs would be an important factor in the early aggregate retention performance of chip seals.

5.2 *Aggregate retention performance*

Figure 6 (a) and (b) present the cumulative aggregate loss results obtained by the MMLS3 tests and the aggregate loss comparison between the MMLS3 and Vialit test results, respectively. Figure 6 (a) presents aggregate retention test results that show that the CRS-2 chip seal performs the worst of all the emulsion types; in particular, the CRS-2 samples show approximately 12% aggregate loss after MMLS3 loading. This result can be considered to be a failure of chip seal performance according to the maximum allowable aggregate loss (10%) criterion established by the Alaska Department of Transportation. The PMEs meet the criterion.

Figure 6 (b) shows that the Vialit test leads to more aggregate loss than the MMLS3 test for all emulsion types. In particular, the difference in aggregate loss between the Vialit and MMLS3 test results is the greatest for the CRS-2 emulsion. The benefit of improved aggregate retention in the PMEs over the CRS-2 emulsion is more dramatically captured by the Vialit test than by the MMLS3 test. This difference is probably due to different loading mechanisms employed by the two test methods to cause aggregate loss in chip seal samples, i.e., the third scale of tire loading in the MMLS3 test and the impact loading by steel ball drop in the Vialit test.

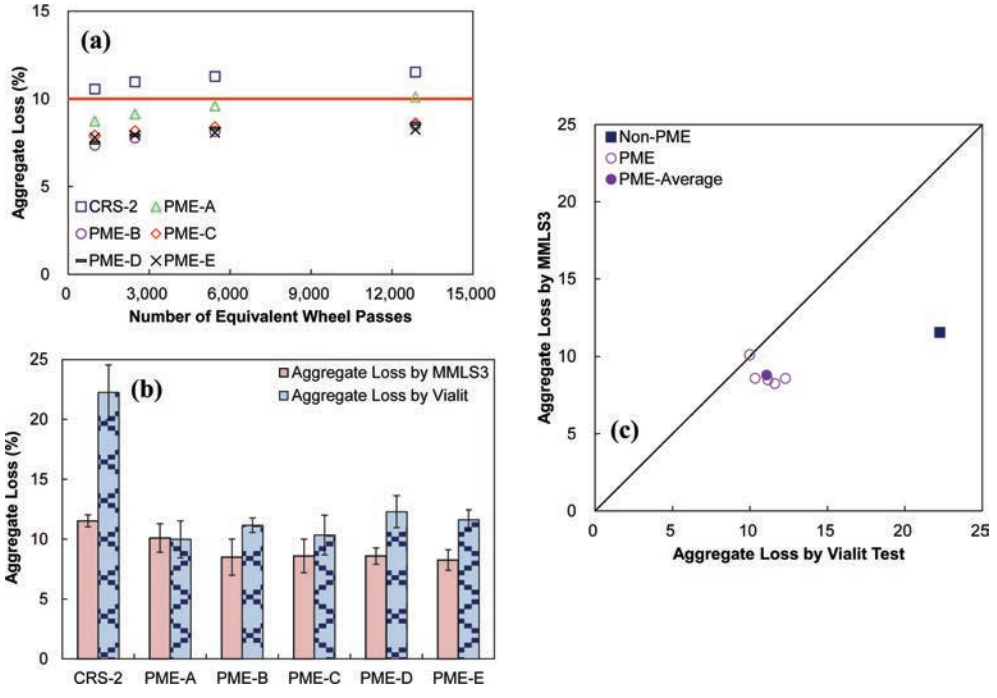

Figure 6. (a) Cumulative aggregate loss from MMLS3 test, (b) Aggregate loss comparison between MMLS3 and vialit test results, and (c) Correlation between aggregate loss by vialit test and by MMLS3 test.

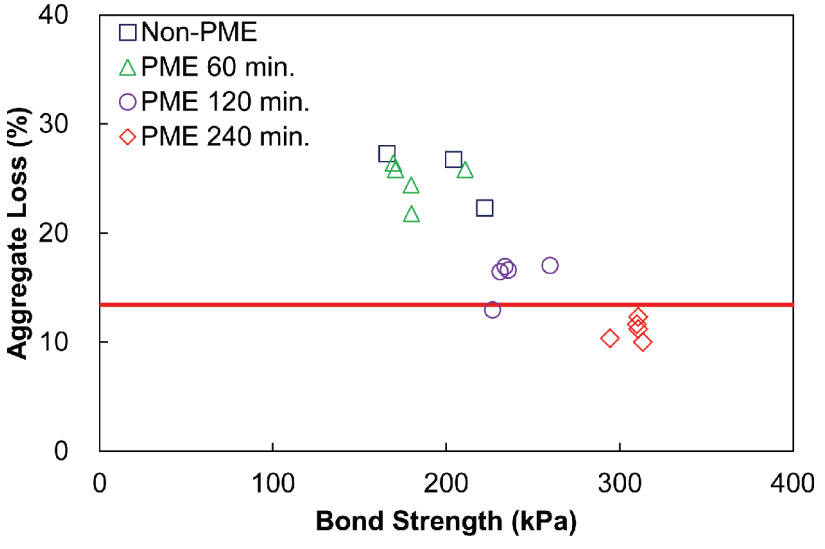

Figure 7. Correlation between vialit and BBS test results.

The relationship between the aggregate loss measured by the Vialit test and by the MMLS3 test is depicted in Figure 6 (c). It is noted that the aggregate loss under real traffic is better represented by the moving load imparted by the MMLS3. However, the Vialit test is much simpler and more practical to be used in specifications and routine evaluation of chip seals by state highway agencies. Therefore, there is a need to convert the maximum allowable

aggregate loss (10%) criterion established by the Alaska Department of Transportation into the aggregate loss by the Vialit test. According to the relationship shown in Figure 6 (c), the 10% aggregate loss in the MMLS3 test is approximately 13% aggregate loss in the Vialit test.

5.3 *Correlation between BBS and aggregate loss by vialit test*

Figure 7 presents the correlations between the Vialit test results and the BBS test results in terms of aggregate loss. The inverse relationship between the aggregate loss and the bond strength is clearly shown in Figure 7. The maximum allowable aggregate loss of 13% from the Vialit test results in the minimum bond strength of approximately 270 kPa. According to the data shown in Figure 7, all the emulsions at 2 hour curing time do not meet this criterion. Also the CRS-2 emulsion does not meet the criterion even after 4 hours of curing time. This approach can be used to develop the emulsion specification criteria for chip seals.

6 CONCLUSIONS

This paper presents an evaluation of the early aggregate retention performance of polymer-modified chip seals. For the evaluation, the curing and adhesive behavior of different emulsions was investigated, and chip seal aggregate retention performance testing was conducted in the laboratory. Based on the test data and findings, the following conclusions are drawn:

- PMEs show better performance in curing and adhesive behavior and aggregate retention than the unmodified emulsion (CRS-2 in this study).
- The curing temperature of 15°C is too low for the Vialit specimens made of granite aggregate and for PMEs to be cured completely within four hours.
- Maximum allowable aggregate loss criteria of 10% in the MMLS3 test is equivalent to about 13% of aggregate loss in the Vialit test.
- There exists a strong inverse relationship between the aggregate loss in the Vialit test and the bond strength in the BBS test. The maximum allowable aggregate loss of 13% in the Vialit test translates to about 270 kPa of bond strength.
- The CRS-2 unmodified emulsion does not exhibit sufficient aggregate retention within four hours, but PMEs do exhibit sufficient aggregate retention within four hours.

Pavement and Materials Technology Review for municipalities—including a case study

Ludomir Uzarowski & Vimy Henderson
Golder Associates Ltd., Mississauga, Ontario, Canada

ABSTRACT: Pavement and Materials Technology Review (PMTR) is a method that can provide guidance in assessing improvements and advancements that are applicable to a specific municipality. A PMTR first involves an evaluation of typical pavement condition in the area and determining the current state-of-the-practice. This includes thorough assessment of the current specifications, submittals from contractors, construction testing results, laboratory testing results that cover the span of multiple recent years, acceptance and follow ups. With this information it is possible to identify practices that are working well and producing quality results and also highlight areas where improvements or changes are required.

Findings of a PMTR and action recommendations are specific to a particular area and may include any or all of the following: appropriate technology; modification to specifications; acceptance; enforcement of specifications; follow ups; staff training and education/workshops within the area including owners, contractors and consultants; and implementation of new technologies. The conclusion of a PMTR is intended to be the development of a clear system that can be routinely applied to projects within the municipality.

The PMTR completed for the City of Moncton in 2010 is used as a case study in this paper.

Keywords: technology review, state-of-the-practice, pavement performance, specifications, training

1 INTRODUCTION

Advancements and improvements in technologies are continual in the pavement industry. Some of the current areas of advancement and growth include: materials including asphalt cements; mix designs; recycling; rehabilitation methods; pavement preservation; and pavement design methodologies. Various reasons lead to the advancement of pavement technology. Economics are generally a substantial contributor when there is a need to change the current method or materials. Other contributing factors include performance improvements and sustainability. Evaluating and understanding which of these is applicable for a particular municipality can be challenging. In order to effectively determine when and which method or technologies should be integrated it is necessary to understand the current state of the practice in the municipality. By understanding the current state of the practice it is possible to select new methods and technologies that will at least maintain the current quality of pavement or possibly lead to improvements in quality of pavements.

It is necessary to understand the current practices before new technologies and methods can be implemented. A Pavement and Materials Technology Review (PMTR) carried out by an experienced pavement engineer can provide guidance in assessing improvements and advancements that are applicable to a specific municipality. A PMTR involves pavement condition inspection and identifying typical pavement distresses in new, relatively new and older pavements and an evaluation of the current state-of-the-practice in a municipality. This includes a thorough assessment of the current specifications, submittals from contractors,

construction testing results, laboratory testing results that covers the span of multiple recent years, acceptance, and follow ups. With this information it is possible to identify practices that are working well and producing quality results and also highlight areas where improvements or changes are required. A successful PMTR is a combined effort between the municipality technical staff members and the reviewing engineer, with the goal of both parties aiming to continually improve the quality of pavements in a municipality.

Many municipalities find premature distresses developing on pavements and the causes are often unclear. Probably the most common premature distresses noticed by Canadian municipalities are: poor longitudinal joint performance; early ravelling; and premature cracking. The purpose of a PMTR is to work with the municipality and identify areas in the current practice that could be improved and determine what improvements would be most effective, suitable and feasible.

2 OBJECTIVE

The intent and objective of a PMTR is described in the following section. The objective of this paper is to describe the basics of PMTR and describe a case study. A PMTR was completed for the City of Moncton (City) in 2009 and will be presented in this paper to demonstrate the various aspects of the PMTR. The objective of carrying out the PMTR in the City was to identify problems with pavement performance and to evaluate the current state of the practice of the pavement industry in the City. After identifying and understanding the current state of the practice the intent was to build on the successful aspects and identify those that could be improved or changed.

3 PAVEMENT AND MATERIALS TECHNOLOGY

A PMTR is an objective method of evaluating the current state of the practice of the pavement industry in a particular municipality. It is a tool that can assist a municipality in effectively managing its pavement assets. A PMTR can be carried out in municipalities of various sizes and is highly dependent on the involvement of municipal staff members. A PMTR includes the following steps, each of which will be discussed in the following sections:

- Document and results review from current and previous years;
- Field visits and condition evaluation of new, relatively new and older pavements;
- Specification review;
- Evaluation of current state of the practice;
- Identification of effective aspects;
- Identification of possible areas of improvement;
- Implementation, including staff training;
- Monitoring; and
- Updating.

Figure 1 presents a flowchart describing a PMTR.

Figure 1 shows the connections between various aspects of a PMTR. The terms referenced in Figure 1 generally represent aspects of a PMTR and change slightly depending on the specific municipality. The ability to link these various aspects within a municipality is one of the key reasons that PMTR are successful. Municipalities vary in size and many have multiple departments that all contribute to work with the paving industry, such as tenders and contracts, design, field inspection and maintenance. It can be challenging to connect the work from various departments together and objectively assess the effectiveness of the final outcome: short and long term quality of pavement. In a PMTR an objective review is undertaken with the assistance and involvement of the municipal staff. The outcome is an understanding of the current state of the practice in a municipality, that bridges across all involved groups.

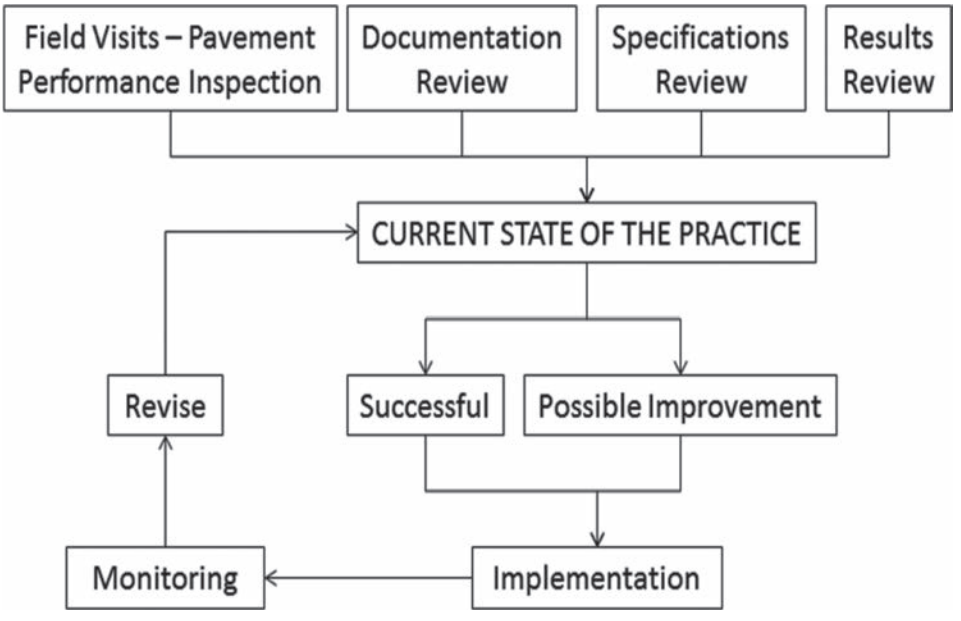

Figure 1. Flowchart describing PMTR.

3.1 *Field visits—pavement performance inspection*

Site visits typically start with a meeting with municipal technical staff to discuss their concerns and observations about pavement performance, pavement design methodology, types of materials used including granular materials and asphalt and concrete mixes and their quality, concern about specifications and quality of construction, effectiveness of Quality Control (QC) and Quality Assurance (QA), capability of local contractor in delivering quality products, suggestions about technology improvements including rehabilitation methods, pavement preservation and maintenance. The technical people have often years of experience and deep knowledge of local sources of material and potential problems with technology currently being used. Their input is particularly important to achieving better quality, longer lasting pavements.

During the PMTR it is important to complete field visits on a variety of roads throughout the municipality. At minimum this should include those currently under construction or just completed (less than one year old), roads two to five years old and roads more than five years old. Visits should also be made to construction sites to evaluate the construction practice. Also, if there are issues with the quality of aggregates and granular materials, a visit to aggregate quaries or pits can be arranged, if feasible. Staff members are typically directly involved in the projects since they are very familiar with the roads in the municipality. These individuals will be able to highlight pavements that are performing well and any that are deemed to be under performing. Comments and experiences shared by the municipal staff is critical in fully assessing the current state of the practice in a municipality.

The quality of the construction of a pavement will be one of the ultimate factors in the long term performance. The combination of pavement design, materials, construction and maintenance will determine the long term performance. However, if one of the three initial items is insufficient then maintenance will typically not be able to correct it. Observations made during construction field visits can be very useful to municipal staff members as well. Findings should be shared with staff members, especially during the implementation stage and with management. It is unfair to expect staff members to be able to adequately inspect construction practices if they have not had the opportunity to learn about the methods themselves.

Properly carried out pavement condition inspections by an experienced pavement engineer will not only identify the types, severity and density of the distresses but will also help in identifying their causes, such as deficient pavement design, poor materials, poor construction practice or environmental impact. The most commonly observed pavement distresses can be grouped as follows:

- Structural—including alligator cracking on rutting in the wheel path. They occur mainly due to insufficient pavement structure to support the traffic loading. They should be addressed by proper design including necessary geotechnical/soil information, anticipated traffic loading calculation and using proper design methodology;
- Materials—including polished aggregate, shoving and swelling. These distresses occur due to the characteristics of the materials throughout the pavement structure. The maintenance or repair to address these distresses varies dependent on the distress. Proper selection of the materials and laboratory testing should eliminate these distresses.
- Construction—including ravelling, bleeding, bumps, sags, depressions, edge cracking, longitudinal cracking, joint opening and slippage cracking. These distresses develop due to the practices that were used during construction. Depending on the severity of the distress is maybe possible to apply maintenance such as crack sealing. Otherwise the material that was poorly constructed would need to be replaced. The major objective here is to make sure that proper construction practice is followed so that premature distresses can be avoided.
- Environmental—including transverse cracking, frost heaves and block cracking. These distresses develop due to an inability for the pavement structure to perform under changing climatic conditions, particularly freeze-thaw cycling.

Although it is impossible to eliminate the impact of the environment on the pavement, the potential for environmental distresses can be reduced or minimized by using proper design, particularly rehabilitation of existing pavements, and good quality materials.

3.2 *Document review*

Available documentation is provided to the pavement engineer carrying out the review. The documentation would typically include annual paving plans, pavement designs, contract documents, specification requirements, QC/QA, reports, municipality inspection reports and maintenance plans.

Additionally, information about the current pavement design practices in the municipality would be provided for review. Municipalities are often responsible for a wide range of roadways and it is understood that having simple templates or a design matrix is often considered to be a feasible solution. The templates or matrices should consider relevant design inputs, such as, soil and water conditions, traffic and pavement materials characteristics. It is also important to ensure that adequate design information is used for the new construction, reconstruction or rehabilitation design for at least major roads in the municipality. Pavements will begin to deteriorate immediately following construction but sufficient pavement structure, materials and construction will decrease the rate of deterioration. Suitable maintenance throughout the life of the pavement is necessary as well to achieve the optimum performance.

The documentation should also include all documents associated with submitted mix designs. The submitted documents for each mix would be compiled and reviewed to evaluate if all required information was being submitted to the municipality prior to the initiation of construction of a project. These submittals should be complete for each project.

3.3 *Specification review*

Specifications are very important to a municipality as they are one of the steps in ensuring that the pavement that is constructed is as intended. As with many of the aspects of a PMTR, the specifications do not alone ensure that a quality pavement will be constructed, they need to be updated periodically and need to be understood between various areas

in the municipality. A PMTR goes through the existing specifications in detail and provides an objective interpretation of them. Some of the key considerations when reading a municipality's specifications include:

- Clarity;
- Do they reflect current practices being used in the municipality and by the industry;
- Are requirements for acceptance payment outlined; and
- Are consequences of failure to meet requirements described.

Although municipality's specifications are a critical tool in achieving quality pavement, they are often large documents and can be intimidating and challenging to work with. An objective review can be helpful as it will assist in the interpretation of the existing specifications and identify if areas exist that should be improved or changed to reflect the municipality's goals and affordable budgets. The state of the specifications will be reflected in the quality of pavement that is produced in a municipality.

3.4 *Results review*

All results from years in consideration should be provided to the pavement engineer carrying out the review for compilation and analysis. Results will be analyzed in consideration of a variety of aspects, such as type, year, specific mix design, construction, QC/QA and acceptance. Analysis of the available results, generally construction QA can identify aspects of the current practices that are effective; and lead to success as well as those that are not meeting the acceptance criteria. The analysis of the results combined with the field visits can help to identify which particular distress or scenario is occurring. Figure 2 shows an example of the analysis of asphalt cement content variance in QA sample results for a municipality.

Figure 2 shows the asphalt cement content variance from the JMF results from all projects in a municipality in 2011. Figure 2 presents a clear picture of the asphalt cement content variance

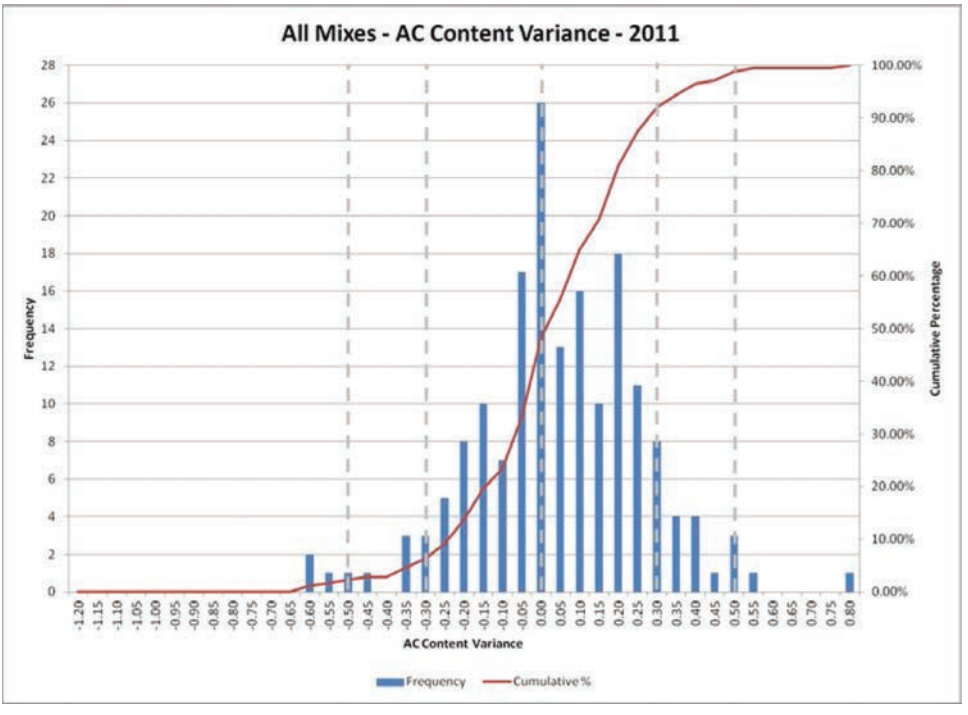

Figure 2. Asphalt cement content variance results compiled for a municipality.

results that are experienced in this municipality and it would be challenging to appreciate this data without it being compiled in this manner. The dashed vertical lines represent the acceptable, borderline and rejectable result limits. Figure 2 shows that although the majority of the results are in the acceptable zone of the designed asphalt cement content (+/–0.3% tolerance), there are a number of results within the borderline zone (+/–0.3% to +/–0.5%) and a few results in the rejectable zone (>+/–0.5%). Comparing asphalt cement content variance in a few subsequent years will show what the trend is. In some cases tightening the specification tolerance limits may be effective in getting much closer to the designed value.

3.5 *Evaluation of current state of the practice*

By compiling the four previously discussed areas: field visits; documentation review; specification review; and results review then the current state of the practice in the municipality can be evaluated. This is one of the largest aspects of the PMTR. During this evaluation, the intent is to draw links between the four noted areas. In general, identify a pavement that showed good and poor performance in the field visit and then examine the specifications that were used as well as the associated documentation. By compiling all of this information for both good and poor performing pavements it will be possible to identify trends within the municipality.

In addition to looking at specific projects, all data is also analysed. The available data is typically examined based on year and type. As an example, the asphalt cement content results from 2011, would be compiled and plotted to evaluate if trends existed, such as routinely lower asphalt cement content within borderline or rejectable limits for one particular mix type. Analysis of the data in this manner allows for repeat occurrences to be highlighted that may not have been evident in the evaluation of specific projects.

Evaluation of the current state of the practice is a relatively cumbersome process; however, is one of the most effective aspects of a PMTR. The conclusions drawn from this evaluation are applied in the following steps.

3.6 *Identification of effective aspects*

Using the conclusions and findings from the evaluation of the current state of the practice it is possible to identify aspects that are effective. Effective aspects would be those that lead to quality pavement performance. These include effective specifications, suitable materials and quality construction practices.

3.7 *Identification of possible areas of improvement*

Through analysis of all results and field visits, areas that are inadequate will be identified. The analysis of all results can clearly highlight aspects that are being missed or not performed sufficiently, such as mix design verification or implementing consequences if there are unacceptable results in quality assurance testing. Observations during field site visits will trigger areas that may require improvement. Distresses observed in the field that are typically caused by unsuitable mix designs can reinforce the need to evaluate the mix designs and acceptance method. Observations in the field and in analysis of all results may also identify a weakness in the specifications that needs to be revised. Practical experience with pavement and material technology reviews shows that poor specifications and lack of specification enforcement are the major reasons for poor quality pavement.

3.8 *Implementation*

After evaluating the current state of the practice in the municipality and identifying both effective and not effective aspects it is important to discuss what, if any changes, should be made for future projects. Results of the PMTR to this point and possible revisions to current practices would initially be discussed with management at the municipality. Following discussions, agreed upon revisions would be carried out where necessary. These revisions would

typically be covered in two aspects, modifications to current specifications and supplementary education for staff members.

If modifications to existing specifications are needed they would be carried out with the intent of updating any out of date specifications and providing clarity where current requirements may lead to confusion. One method of revising specifications that can be effective for both material suppliers, contractors and owners (the municipality) is to develop special provisions to the currently existing provincial specifications. An example of this would be for a city in the province of Ontario. An outcome of the PMTR would be a set of Special Provisions for the city, to the Ontario Provincial Standard Specifications (OPSS) [1].

After agreed upon revisions have been completed it is critical to share the findings of the PMTR with the current staff of the municipality. If the staff members are not included in the findings then it will not be possible to implement changes in the current practices effectively as these individuals who are involved in the day to day activities. The results of the PMTR should be made available to staff members and clearly explained, which can be effectively carried out through a training and open question and answer session. If new technologies or methods have been implemented in the municipality given the findings of the PMTR then it is critical to educate associated staff members on these new areas.

3.9 *Monitoring*

Following the implementation of the proposed revisions from the PMTR results it is important to monitor if the improvement or changes are effective. Initially some challenges may exist if transitions in technologies or methods are being carried out, such as for example moving from Marshall mix design to Superpave mix design. Challenges during transitions are common and expected. Part of the PMTR is the involvement of the review engineer in finding solutions to these challenges, should they arise. In many cases the solution is to provide explanation and education to not only municipality staff members but also common suppliers and contractors. Explanation of changes to prior specifications can be extremely beneficial to everyone involved as this can reduce unneeded expenses and delays in the future and lead to improved performance of the pavements in some areas.

Changes may also be incremental in a municipality, such as trialing a new method on lower volume roads before implementing it on all projects. Monitoring these types of initiatives is important to achieving success on projects in the future.

3.10 *Updating*

The final step of a PMTR is updating the findings of the initial evaluation of the current state of the practice. Through monitoring the implementation of new methods and technologies and revisions to the specifications, areas maybe identified that should still be updated. Additionally, results from subsequent years after the initial PMTR should be compiled and analyzed as was done previously, to evaluate the effects of the implemented changes. It is anticipated that deficiencies in the initial PMTR will have been addressed; however, if they remain then further investigation will be required to determine the continuing cause of these challenges.

4 CITY OF MONCTON CASE STUDY

The City of Moncton (the City) in New Brunswick worked with Golder Associates Ltd. (Golder) to carry out a PMTR in 2008. The City retained Golder to carry out a PMTR in order to improve the state of pavement technology in the City. The PMTR involved the following tasks:

- Meeting with the City's technical staff to get an understanding of the current state of the practice;
- Review of the current City and New Brunswick Department of Transportation (NBDOT) specifications and pavement design methodologies;

- Pavement visual condition inspection of selected roads and streets;
- Site visits to suppliers of aggregates typically used in the City;
- Review of laboratory and field testing results from consultants and contractors/suppliers;
- Site visits to construction sites to review the current construction practice and QC/QA procedures;
- Review of the City's current subdrain installation practice;
- Recommendations for improvements in pavement and materials technology; and
- Training of City's technical staff.

The following sections describe the findings of each of above noted tasks in the project.

4.1 *Meeting with city's technical staff*

Two meetings were arranged with key staff from the City of Moncton to gain an appreciation for the current practices in the City. The discussion included:

- Pavement design methodologies—the City was concerned that the pavement designs used in Moncton were outdated and did not take into account all necessary aspects;
- The type of asphalt cements used such as Penetration Grade or Viscosity Grade;
- The quality of granular materials and aggregates—some of the quarries were known to supply materials that generally did not meet the specified requirements (mainly freeze-thaw); how, if at all, could the substandard quality be compensated in the pavement designs and construction;
- The type and range of asphalt mixes—what kind of improvement would be necessary;
- The quality of construction with particular emphases on the effectiveness of the QA system used by the City;
- The capability of the local contractors in terms of constructing quality pavements, techniques used to rehabilitate existing pavements; and
- Construction specifications including the clarity of the QA system used.

These factors were discussed as particularly important to achieving better quality, longer lasting flexible pavements. The subjects discussed at the meetings formed the basis for the pavement and materials technology review.

4.2 *Review of city specifications and pavement design procedures*

The City's specifications related to pavement and materials were reviewed and the following is a summary of the findings:

- Requirements for QC/QA testing were generally not specified;
- Mix design details in terms of type and required documentation were unclear; and
- Work acceptance criteria and corrective action for inadequate results were not determined.

From the earlier meeting with the City's technical staff it was apparent that there was interest throughout to update the specifications to achieve quality, better performing pavements.

The existing pavement design procedure used in the City was reviewed by Golder. The procedure was found to be overly generalized and over simplified and did not consider traffic volumes.

4.3 *Review of laboratory and field results*

The City provided Golder with available laboratory and field testing results for analysis purposes. Golder reviewed the results and found that often the results were outside the acceptable criteria but no corrective action was recorded as having been carried out. This was found in the results of aggregate and granular materials and during construction. A limited number of mix designs had been provided to the City. In general only a part of the supplied

information for each mix met the requirements in the City's specifications. However, only a small amount of the required documentation was provided to the City for each mix.

4.4 *Construction and existing pavement site visits*

Representatives of Golder visited construction sites and existing pavements in the City. During the construction visits, Golder was able to observe the techniques commonly used in the City. Having observed the current techniques, appropriate recommendations were made for specification revisions and inspector training.

Pavements of varying ages were visited (from newly constructed to more than five years since construction). The most commonly observed distresses were fatigue cracking, rutting, premature longitudinal and transverse cracking, joint failure and material segregation. The premature distresses were likely due to a combination of factors: inadequate pavement design; poor quality granular materials; poor quality mixes and mix ingredients; poor construction practices; poor QC/QA system; insufficient inspection; lack of specification enforcement and follow ups and unclear specifications. Figures 2 and 3 show examples on the pavement observed during the field site visits.

4.5 *Recommendations*

The conclusions of the PMTR were the following recommendations to advance the state of the practice in the City:

- Revise current specifications to meet NBDOT requirements where feasible;
- Include requirements for asphalt mix designs, aggregate materials and granular materials in revised specifications;
- Revised specifications should include acceptance criteria and corrective actions that will be required in criteria is not met and clear methods of enforcing them;
- Updating of pavement design matrix for future projects to include traffic loading and soil type;
- Avoidance of cold joint construction by using infrared joint heaters or paving in echelon, using good quality construction methods if it is necessary to construct cold joints [2];
- Adequate inspection during construction;
- Development and implementation of effective QC/QA program;
- Training of the City's technical staff;
- Implementing new feasible methods of pavement rehabilitation; and
- Implementing pavement preservation [3].

Prior to the initiation of the PMTR with the City, their current state of the practice was not reflecting currently available methods and technologies. The PMTR was a combined effort by the City and Golder. The conclusion was a thorough evaluation of the current practices and the development of simple guidelines for updating the current practices in the City. Golder provided an objective review of the practices in the City and worked closely with staff members to identify potential areas of improvement that would ultimately increase the quality of pavement in the City.

5 CONCLUSIONS

Pavement materials and technology reviews are an objective method of evaluating the current state of the practice in a municipality. An experienced pavement and materials engineer meets with the municipality technical staff to discuss their concerns and observations about pavement performance, pavement design methodology, types of materials used including granular materials and asphalt and concrete mixes and their quality, concern about specifications and quality of construction, effectiveness of Quality Control and Quality Assurance, capability of local contractor in delivering quality products, suggestions about technology

improvements including rehabilitation methods, pavement preservation and maintenance. Field visits are then completed to assess the typical condition of pavements of various ages. A thorough review of documentation, specifications and results is completed to determine the reasons for the performance observed in the field visits. All of these aspects are compiled to evaluate the current practices in a municipality and determine where areas exist that could be improved or changed. Following this the pavement engineer works closely with the municipality to implement recommended changes, such as modifications to current specifications, training for technical staff members and integration of new methods and technologies. This is later followed by monitoring if the improvements or changes were effective and making any updates, if necessary.

The City of Moncton retained Golder to carry out a pavement materials and technology review in 2008. The current practices in the City were evaluated and it was identified that improvements could be made in aspects of the pavement designs, specifications, required documentation, quality assurance testing, specification enforcement and construction practices. Recommendations were provided to the City for these various improvements and training was provided to technical staff members. The completion of the pavement materials and technology review enabled the City to understand the current practices being carried out and direct efforts to the most important aspects, with the intent of improving the quality of their pavements.

ABSTRACT: The scope of the SHRP2 Renewal Project R 06(B) involved evaluating applications of field spectroscopy devices to fingerprint a variety of asphalt materials commonly used in pavement construction. In particular, portable infrared spectrometers in reflection sampling mode were found successful in identifying additives in asphalt binders and emulsions without special sample preparation. An ongoing study targets pavement aging-related changes in chemical composition of asphalt recycled and warm-mix asphalt products over the service life. Powdered samples are collected from road and airport asphalt surfaces in New England and scanned by Attenuated and Diffused Reflectance spectrometers. The absorbance spectra of asphalt samples are processed to quantify aging rate of pavements constructed with non-modified and polymer-, RAP- modified hot and warm mix asphalts. Preliminary results indicate that in-situ oxidation measurements by portable infrared devices can be incorporated in pavement management systems to determine optimal timing of pavement preservation treatments.

Keywords: Infrared spectroscopy, asphalt, field aging, oxidation, Recycled Asphalt Pavement, Warm-Mix Asphalt

1 INTRODUCTION

It is apparent that the aging highway system in the U.S. has increasingly become the focus of the transportation agencies, industry, and research community. The adequate design and Quality Control/Quality Assurance (QC/QA) of construction process remains crucial to ensure durability and satisfactory performance of asphalt pavements that comprise the majority of roads in the U.S. In order to explore innovative field testing methods, the second Strategic Highway Research Program (SHRP 2) Renewal project R-06(B) targeted evaluation of handheld spectroscopic equipment for in situ analysis of commonly used construction materials [1]. The most significant portion of this study concerned asphalt products (binders, emulsion, and mixes) and their additives, i.e. polymers, and anti-stripping agents. Recycled asphalt binders and mixes were included in the project as well.

The major outcome of the SHRP2 R06(B) project was the identification of portable Fourier Transform Infrared (FT-IR) spectrometer with Attenuated Total Reflectance (ATR) accessory as the most successful device for the analysis of polymer-modified asphalt binders and emulsions at the plant and in the field [1, 2]. The follow-up studies report significant progress in using portable FT-IR spectrometers in Diffused Reflection (DR) mode for direct measurements of oxidation levels in Hot Mix Asphalts (HMA) and Recycled Asphalt

Pavements (RAP) [3, 4]. This manuscript presents the historical background and the current status of FT-IR applications to asphalt products.

2 BACKGROUND

2.1 *Infrared spectroscopy techniques*

Infrared spectroscopy relies on measuring energy of the infrared electromagnetic waves (0.78 to 1000 μm wavelengths) transmitted, absorbed, or reflected by a material [5]. FT-IR spectrometers record the absorption of electromagnetic energy by the specific groups of atoms in molecules. Specific peaks are easily identified on a spectrogram and can be used to fingerprint a compound in a mixture once its IR peaks are known from the analysis in a pure state.

Most IR spectrometers operate in transmission sampling mode (Fig. 1 left), which is very accurate in determining the concentration of a specific chemical moiety [6]. The transmission IR testing of asphalts requires elaborate sample preparation including the use of solvents and potassium bromide (KBr) pellets, which only make it suitable for testing extracted binders [7]. Attenuated Total Reflection (ATR) sampling method (Fig. 1 center) allows for direct testing both viscous and liquid samples (Harrick1967). In case of asphalt binder, the ATR method does not require any special sample preparation. One disadvantage of using ATR technique for evaluating the HMA samples is that it interrogates only 1 to 2 μm of sample thickness and a very small area. In the case of HMA, aggregate particle size and uniformity may influence the variability in ATR measurements [1].

The Diffused Reflection (DR) sampling method (Fig. 1 right) is best suited for measurements on the rough solid surfaces of powdered samples (Fuller1978). Conversion of the DR measurement units to log (1/Reflectance) not only increases intensity, hence readability of DR spectrum but also facilitate their direct comparison with traditional absorbance and transmittance equivalents [8]. The main advantage of the DR over ATR is that it captures entire sample depth. Control over of the particle size is necessary to achieve a good signal-to-noise ratio.

2.2 *Historical studies of asphalts by FT-IR*

Asphalt researchers have successfully used FT-IR spectroscopy since as early as 1960s. The most remarkable progress was made under SHRP asphalt binder study in studying chemical structure of asphalt binders and its evolution during short- and long-term aging [9–11]. Using transmission IR mode, the researchers polar chemical Functional Groups (FG) naturally occurring in asphalts, such as 2-Quinolone, phenolics, and pyrrolics. They also studied FG that formed during oxidative aging, i.e. ketones, dicarboxilic anhydrides, carboxylic acids, and sulfoxides [9–11]. Later studies concentrated on relating carbonyl content to the changes in asphalt viscosity [12, 13].

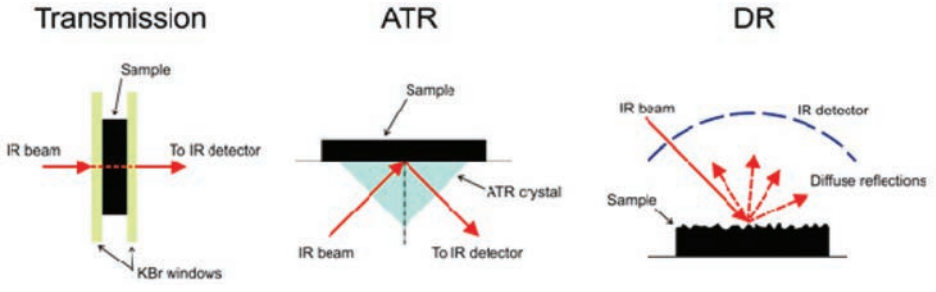

Figure 1. Infrared spectroscopy sampling modes: transmission (left), attenuated total reflectance (center), and diffused reflectance (right).

With the advance in asphalt technology and introduction of polymers, antioxidants, and antistripping agents, the FT-IR technique have been successfully used for identification and quantification of these additives in asphalt binders. Numerous studies investigated effect of Styrene-Butadiene–based polymers (e.g., SBS and SBR) as well as n-polyethylene-based polymers (e.g., Elvaloy, EVA) on chemical and physical properties of asphalt [14–16]. Only a few studies used FT-IR to explore changes in cured emulsions [17, 18]. Lastly, FT-IR was used to study the effect of highly reactive deicers on degradation of flexible airport pavements [19].

The vast majority of asphalt studies by FT-IR spectroscopy have been performed on solutions of virgin or extracted asphalt binders in transmission mode. However, a few attempts to fingerprint asphalt mix samples and evaluate level of oxidation in asphalt mixes span early 1970s and late 2000s [20, 21]. Obviously, until recently, the limitations of the commercially available FT-IR instruments prevented asphalt researchers and engineers from using this technology outside the laboratories and research facilities.

3 SHRP-2 ADVANCES IN FIELD FT-IR STUDIES OF ASPHALT PRODUCTS

3.1 *Field testing protocol*

One of the major goals of the SHRP2 R06(B) project was to evaluate feasibility of using portable ATR FT-IR spectrometer in the field environment for direct measurements on various asphalt products. To achieve this goal, first, the typical IR absorbance spectra of asphalt binder, mix, and emulsion samples were obtained in the laboratory. Next, a series of field tests were undertaken where the FT-IR instrument was set up in the back of a van in the proximity of the paving project. The field spectra of a targeted material were compared with those obtained in the lab to evaluate repeatability and reproducibility of the test. Table 1 summarizes project locations, materials and description of samples evaluated in the field phase of the project. Figure 2 illustrates the field process of the testing a polymer-modified emulsion.

To obtain spectra for the material in Table 1, several drops of a liquid or approximately 0.5 g of a solid were placed on the ATR sampling plate and 24 co-averaged scans were collected at a resolution of 4 cm^{-1}. In the case of thin films and powders, pressure was applied to the sample to ensure full contact with the ATR prism surface. The main issue with ATR testing of HMA was relatively high (up to 30%) standard deviation from the mean of 5 replicates, mostly due to variability in particle size and material composition. The pulverized HMA samples, however, did not yield variation higher than 15% of the mean.

During field experiments, it was helpful to analyze the binder component of the HMA mixes using dichloromethane (DCM) extraction. The DCM was found to be a more reactive, faster evaporating, and less toxic alternative to the AASHTO-standardized TCE solvent. The DCM extraction procedure included shaking 1HMA:3DCM solution for 1–2 min and filtering the solution through the regular 2-layer tissue paper. To collect ATR spectra, several drops of the solution were placed on the ATR prism and left for 2 min to allow the DCM to evaporate completely. Next, the ATR absorbance spectrum was collected in the same fashion as the rest of liquid materials.

Table 1. Summary of field tests by portable ATR FT-IR.

Project type	Material category	Sample type
HMA paving	Polymer modified asphalt binders and mixtures	Fresh mix from the truck Extracted binder solution
Nova chip seal paving	Polymer-modified asphalt emulsions	Emulsion from the road surface (before breaking) Coated seal aggregate from the road surface
Rubberized chip seal paving	Polymer-modified asphalt binders	Binder from the truck Coated aggregate from the truck Binder from the road

3.2 *Polymers in binders, emulsions, and HMA*

The analysis of the IR spectra of the field samples aimed at (1) verification of the presence of an additive (polymer, anti-strip agent etc.) in a binder or mix, and (2) quantification of an additive within a compound. The elastomer styrene-butadiene-based polymers were easily identified in the liquid samples of polymer-modified emulsions (Fig. 3) and solid samples of

Figure 2. Sampling emulsion (top left), Novachip application (top right), ATR testing setup (bottom left), sample placement (bottom right).

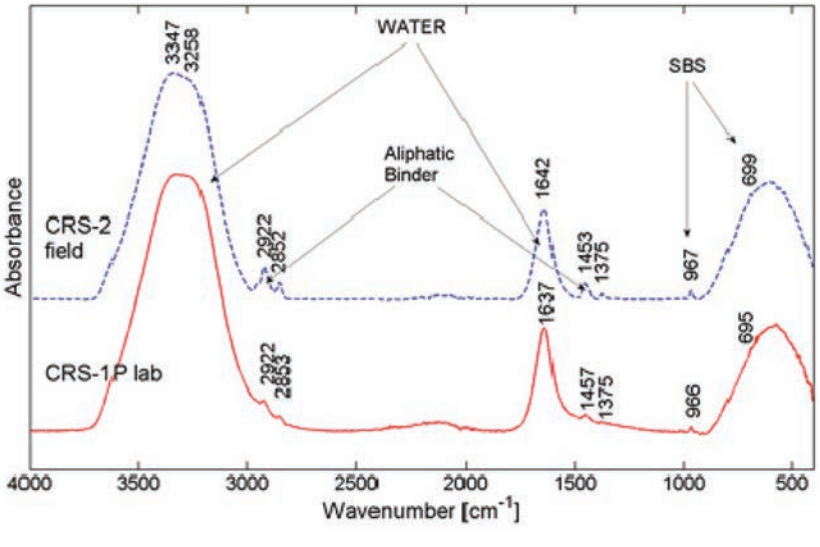

Figure 3. ATR spectra of polymer-modified emulsions.

polymer-modified binders. While identification of polymer in the field HMA mix and coated seal aggregates presented a challenge, the fast binder extraction procedure in the field with using DCM solvent appeared to be a feasible alternative to direct evaluation of binder- and emulsion-coated aggregates (Fig. 4).

The quantitative method of spectral analysis involved normalization of Polybutadiene (PB) or Polystyrene (PS) absorption peak intensity at ~965 and ~700 cm^{-1} wavenumbers, correspondingly, to that associated with aliphatic CH stretching or bending vibrations at ~2920 cm^{-1} that did not change with increase in polymer concentration (e.g., A966/A2920 and A700/A2920). Typical spectrum of an SBS-modified binder is shown in Figure 5. It was recommended to use A966/A2920 ratio for calibration curves. Note that increase in variation in measured absorption peaks with an increase in polymer concentration can be attributed to non-uniform distribution of polymer phase within asphalt binder matrix [1]. Quantifying an additive in a compound may be dependent on the coefficient of absorptivity (or extinction) of the additive within a given moiety. Therefore, the same SBS polymer was added to the binders from at least three different sources across the continent to compare the slopes of calibration curves, i.e. coefficients of absorptivity. Remarkably, the SHRP2 R-06(B) study found no significant difference in coefficient of extinctions between three sources [1].

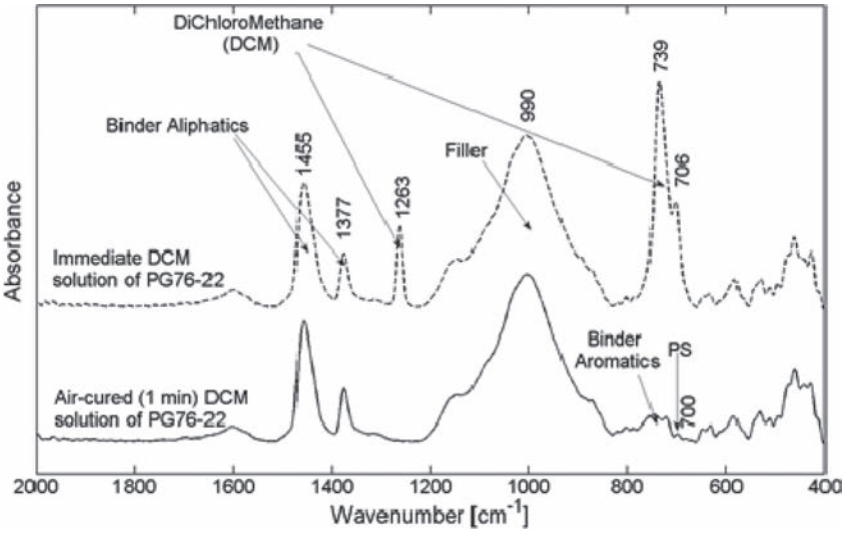

Figure 4. Identification of SBS polymer in asphalt binder PG76-22 extracted from HMA.

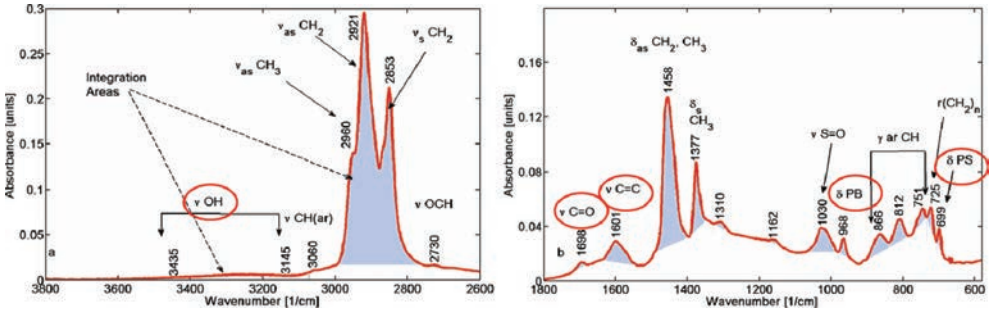

Figure 5. Typical ATR spectrum of an SBS-modified asphalt binder.

3.3 *Oxidation in recycled asphalt pavements*

The ATR FT-IR experiments on Recycled Asphalt Pavements (RAP) targeted the feasibility of the identification of elevated oxidation level in the RAP-modified binder blends and HMA mixes. Of the particular interest was a possibility of the determination of RAP content in binder blend/ HMA mix based on the concentration of the oxidized chemical functionalities. The SHRP2 study explored two types of samples were prepared in the laboratory: (1) binder blends containing 15 to 40 percent weight RAP-binder and (2) loose HMA samples modified by up to 80 percent weight RAP.

To track the changes in chemical composition of the RAP-modified samples due to an increase in RAP content, the ATR FT-IR spectrum of each sample was analyzed both qualitatively and quantitatively. The qualitative analysis involved identifying characteristic IR absorption bands for the binder and aggregates to separate them from, the oxidation products such as hydroxyls (OH), carbonyls (C = O), and sulfoxides (S = O) as shown in Figure 6. To quantify spectral changes due to RAP presence in binder blends, bands area for OH, C = O, and S = O functionalities were valley-to-valley integrated within the limits shown in Figure 7 and normalized to the sum of all band areas to calculate individual oxidation indices

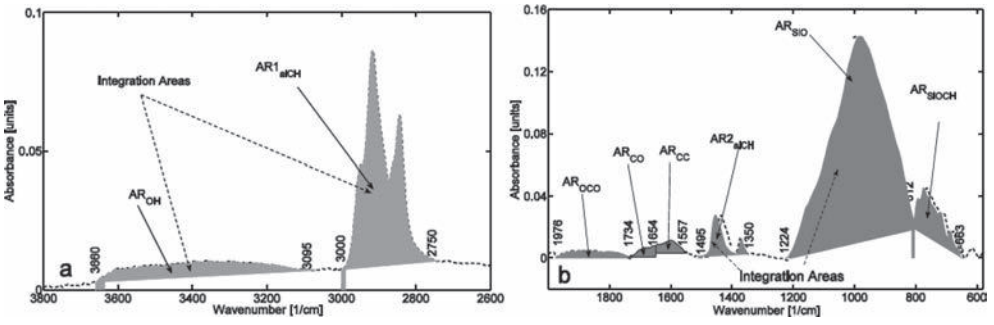

Figure 6. Typical ATR FT-IR spectra of 80-wt% RAP-modified HMA mix (Yut_Rap2012).

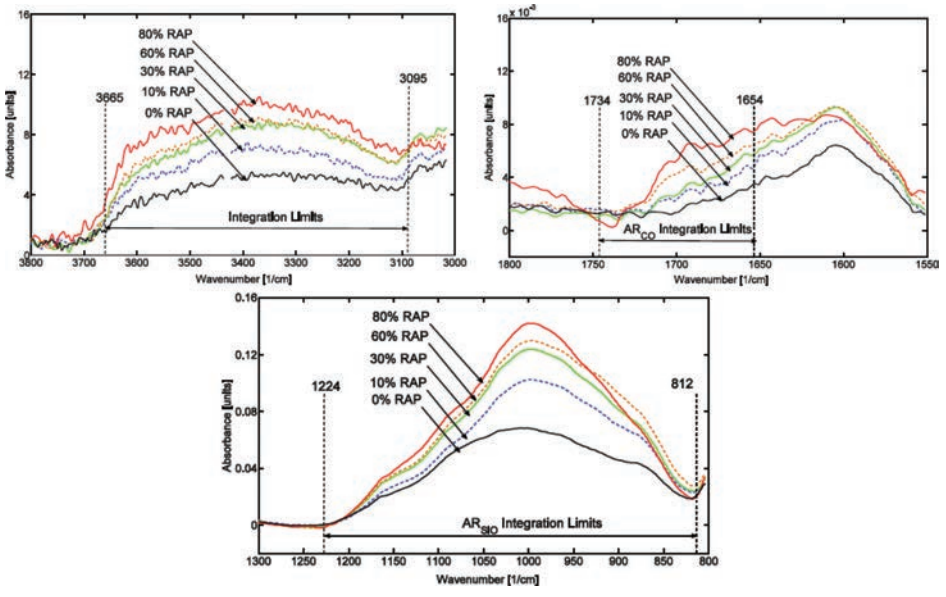

Figure 7. Integration limits for hydroxyl (AR_{OH}) (top left), carbonyl (AR_{CO}) (top right), and silicate/ sulfoxide (AR_{SiO}) (bottom) absorption bands (Yut_RAP2012).

I_{OH}, I_{CO}, *and* I_{SO} (). A similar approach was applied to the RAP-modified HMAs. The only difference was associated with using SiO absorption band instead of S = O band because of their large overlap.

Based on the multiple correlation analysis of the oxidation indices against RAP content (C_RAP), the best-fit linear models were developed for predicting the RAP content in binder blends and RAP-containing mixes. A sum $I_{OH} + I_{CO} + I_{SO}$ appeared to yield best prediction for binder blends with R-squared of 0.97 and standard error of 7 percent. The best-fit model for the RAP mixes, on the other hand, utilized I_{CO} and I_{SiO} as independent predictors with significantly lower R-squared of 0.86 and standard error of 11 percent. Two reasons would explain a lower agreement in prediction models in HMA. First, a much higher standard error for HMA data as compared with binders' data is mostly governed by non-uniformity of replicate samples due to variation in particle size. Second reason for lower linear agreement can be a lack of interaction between binder adsorbed to RAP particles and the virgin binder (no blending).

4 FURTHER APPLICATIONS OF PORTABLE FT-IR TO AGED ASPHALTS

4.1 *Accelerated aging of asphalt binders*

Based on the success in fingerprinting asphalt binders during SHRP2 study (Zofka_SHRP2) and previous progress in use of transmission IR mode for evaluating oxidation levels in dissolved binders (Lamontagne2001), the research team has developed a prototype of an accelerated aging apparatus based on a portable ATR FT-IR spectrometer [3]. The apparatus employs a compact Attenuated Total Reflection spectrometer and airflow Aging Cell (ATRAC) equipped with a temperature controller (Fig. 8). In ATRAC, a small sample of asphalt binder is subjected to heated airflow at 135 ºC for 45 minutes. Concurrently, the absorbance spectra are collected every 5 minutes. The carbonyl content is computed for each spectrum, and the aging rate of a binder sample, $\mathbf{r_{CA}}$, is evaluated as a slope of Carbonyl Area (CA) versus time (Fig. 9).

The ATRAC device demonstrated high sensitivity to temperature susceptibility of asphalts. For instance, the aging slopes of the three SHRP core asphalts depicted in Figure 9, clearly show that softer asphalt AAC oxidizes much faster than harder asphalt AAA. The slope of increase in CA for AAK, which has the highest viscosity of the three, can be neglected. When compared with Superpave™ aging procedures, the ATRAC system demonstrated higher sensitivity to the presence of polymers in the binder than the standard Pressurized Aging Vessel

Figure 8. Image of ATRAC prototype.

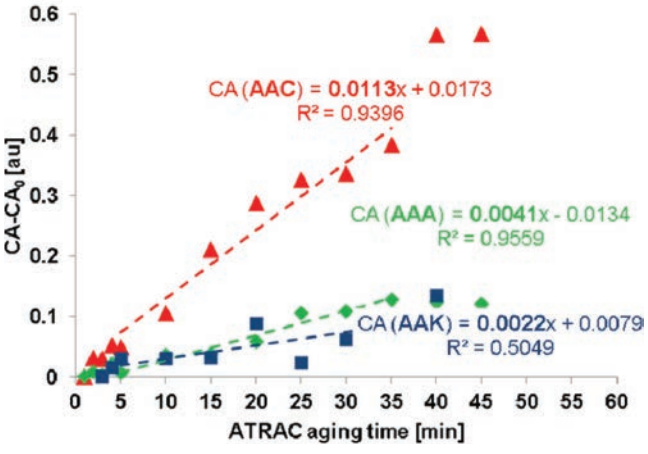

Figure 9. Comparison of ATRAC oxidation rates for SHRP core asphalts.

Table 2. Summary of origin, PG and ATRAC parameters for binder ranking.

Binder ID	Source	True PG, RTFO	r_{CA} in ATRAC ($*10^{-5}$)
Conn 64-22	Venezuela	74.7	0.9
AAK	Venezuela	73.2	1.4
AAM	W Texas	70.8	2.6
AAG	Ca. Valley	66.6	3.3
Conn 58-28	Venezuela	61.6	3.7
AAB	Wyoming	61.5	3.9
AAC	Redwater	58.4	4.1
AAD	Ca. Valley	63.4	4.2

(PAV) procedure. Furthermore, the proposed setup was found capable of inducing similar oxidation rates to the PAV in minutes rather than hours [3].

4.2 *High-temperature performance ranking of asphalt binders*

The optimistic results of ATRAC and well-documented aging history of the SHRP core asphalts [22] motivated the attempt at ranking asphalts by ATRAC oxidation rate ($\mathbf{r_{CA}}$) and superimposing it with reported Performance Grade (PG) values. In addition, two binders from Connecticut, U.S.A. (source unknown) were included in the dataset. While examining the values of listed in Table 2, one can note that only binder AAD does not follow the inverse trend between the oxidation rate and true PG of binders aged by the Rolling Thin Film Oven (RTFO) procedure.

4.3 *In-situ aging diagnostics of asphalt pavements*

As mentioned earlier, the DR sampling method was found best suited for powdered HMA samples. The first field feasibility study of portable DR spectrometer on asphalt pavement has showed that powdered asphalt mix samples with nominal maximum aggregate size of 150 μm produced very smooth spectra with minimum noise [3]. The most recent studies at the University of Connecticut proved direct correlation between DR and ATR spectra of the same asphalt binder/mix sample [3, 23]. A study on Connecticut and Rhode Island

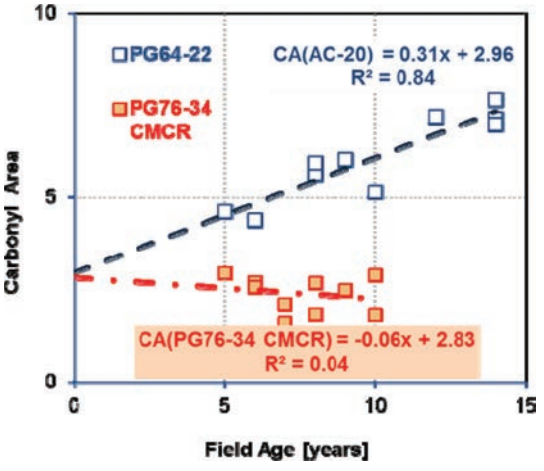

Figure 10. In-situ oxidation trends for PG64-22 and PG76-34.

pavements of similar age, structure located a similar climate yet paved with different binders demonstrated ability of portable DR spectrometer to differentiate aging rate of in-situ asphalt surfaces [3]. The field samples were obtained by hammer-drilling 1-in deep at 1-in diameter holes in pavement surface and collecting the resultant powdered residue. Figure 10 contrasts the aging rates of the pavement surfaces in Connecticut and Rhode Island. The approximated linear trends in Figure 10 clearly distinguish between increase in carbonyl content, i.e. oxidation, in HMA pavement where non-modified PG64-22 binder was used and virtually no change in CA for HMA produced with crumb rubber-modified PG76-34-CMCR binder.

5 SUMMARY OF FINDINGS

This manuscript presents the recent development in the use of portable FT-IR spectrometers for fingerprinting asphalt products and applications of the FT-IR technique to evaluating aging of asphalt pavements.

The SHRP 2 R-06(B) project has identified portable FT-IR spectrometer with ATR accessory as a potentially useful tool for verification of presence of additives and contaminants in asphalt as long as the concentration of additive/contaminant is higher than 0.5 percent weight. In particular, the ATR spectrometer allowed for determining chemical composition of polymer-modified binders, emulsion, and HMA mixes. In addition, the ATR measurements on RAP-containing binder blends and mixes allowed evaluating the effect of RAP content on the extent of oxidation in binders and mixes.

Based on the success in ATR measurements on aged asphalt binders, an original accelerated aging apparatus with use of ATR and miniature aging cell (ATRAC) was developed. The ATRAC apparatus appeared to be sensitive to temperature susceptibility of asphalt binders. Furthermore, the oxidation rates measured by ATRAC seem to be highly correlated with the high-temperature performance grade of binder, which make ATRAC suitable candidate to replace RTFO procedure in predicting short-term aging trends.

Most recently, a portable DR spectrometer has been used to evaluate aging of pavement surfaces by direct measurements of carbonyl content on powdered asphalt mix residues. The DR technique appears to be successful in in-situ ranking of in-service asphalt pavement. It is believed that in-situ DR measurements of oxidation can be incorporated into a pavement management program as a quantitative QC/QA process to determine thresholds for pavement preservation treatments.

Experimental investigation of frost/thaw effects on bituminous mixes under wet conditions

Caroline Mauduit, Éric Crégut, Sylvain Joly & Sébastien Liandrat
CEREMA/Laboratoire des Ponts et Chaussées de Clermont-Ferrand, France

Olivier Chupin, Ferhat Hammoum & Jean-Michel Piau
IFSTTAR, France

ABSTRACT: Subsequently to serious pavement disorders appearing suddenly during winters and characterized by series of potholes, CEREMA and IFSTTAR launched an experimental program to understand the mechanisms at play and possibly provide technical recommendations for the future. Based on *in-situ* observations showing the concomitance of frost/thaw cycles and wet conditions during these events, the study focused on the impact of frost propagation on the behavior of asphalt mixes partially saturated with water. Cyclic thermal tests performed free of external loading (except the own weight of the samples) show significant swelling and contraction of the samples because of the phase changes of pore water from liquid to solid and *vice versa*. Additional tests intended to the measurement of the complex modulus of bituminous mixes also show evidence of a frost effect on wet samples, characterized by the stiffening of the material. These effects could be at the origin of the disorders under consideration. Further work should help validate this hypothesis and find remedies to the problem.

Keywords: Pavement, winter disorders, potholes, frost/thaw, bituminous mix, porous material, water saturation, swelling, complex modulus

1 INTRODUCTION

During their lifetime, pavements are exposed to important thermal and mechanical constraints because of traffic and climatic conditions. In particular, pavements undergo important temperature variations and are subjected to frost/thaw phenomena. Nowadays, the mechanisms affecting soil frost are understood and are integrated into pavement design to avoid structural disorders. However, in recent winters, sudden deteriorations at the surface of pavements were observed in the North and East of France and also in parts of the borderlands. These events occur in a few hours and lead to series of potholes over tens or hundreds of kilometers. Investigations done on the French network show that the sudden degradations occur during wet periods of alternating frost and thaw cycles, and temperatures reaching around –10 °C. These deteriorations often affect bituminous pavements which have been through maintenance works, consisting in placing a new layer either on the old wearing course or after milling. Cores drilled close to potholes show that generally damages are localized within the old layers. Note also that the same problem but with origin found deeper in the structure was observed on old rigid pavements reinforced with a bituminous base course after slab breaking. However in all cases the investigations revealed an important quantity of water stored in the layer of bituminous mix from which the raveling was initiated [1], [2].

In order to understand the mechanisms of the disorders and to answer the questions of road owners (how to repair, to detect road sections at risk and to avoid the problem in the future?) CEREMA and IFSTTAR launched an experimental program. Based on the

field observations, it focused on the evaluation of the effect of frost/thaw phenomena on bituminous mixes under wet conditions. Cyclic thermal tests (without external stress) were first performed on homogeneous and then on two-layer samples using the experimental device dedicated until now to study soil frost. Complex modulus tests were also conducted to analyze the impact of frost on the stiffness of wet bituminous concrete.

2 EXPERIMENTAL SET-UP AND MATERIAL TESTED

This section presents the test device used to apply freeze/thaws cycles to bituminous mixes, the properties of the materials tested and the instrumentation that allows to record temperature as well as strain during a test.

2.1 *Test device*

The tests on bituminous mixes are performed using an experimental device adapted from that used to study frost heaving of soils. This device makes frost propagate in the vertical direction (one-dimensional condition). It is composed of 6 cells in which different samples can be tested simultaneously. A vertical cross-section showing one cell is displayed in Figure 1. The device consists of a tank filled up with a liquid maintained at a temperature slightly above 0 °C in which the cells are located. A refrigerated metal piston is used to apply freeze/thaw cycles at the top surface of the samples placed in the cells. Although not used in the experiments presented in this paper, a temperature-controlled water bath at 1 or 2 °C can be added at the bottom of the specimens to better control the boundary condition at this location.

2.2 *Properties of materials tested and built-up of the specimens*

The materials tested are hot bituminous mixes as those commonly used for wearing courses in France. They are formulated in the laboratory from crushed Rhyolite aggregates of

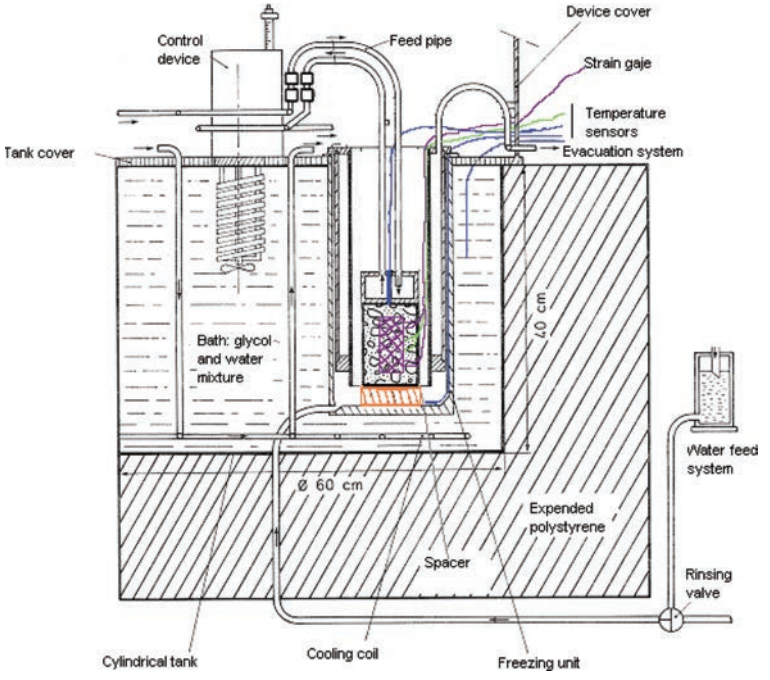

Figure 1. Cross section of the experimental testing apparatus.

which the distribution of the grain size is shown in Table 1. The binder utilized is bitumen of type 35/50.

Cylindrical samples of height 90 mm and diameter 80 mm are molded by compaction following the standard EN 12697-12, method B for homogeneous samples. For two-layer samples, the compaction is performed in several phases: compaction of the lower layer, application of a bitumen emulsion until its break and compaction of the upper layer. Homogeneous sample present 11% of voids content. Two-layer samples, composed of the same bituminous mix but compacted at different levels, present a void content of 11% in the upper layer and 6% in the lower layer.

The samples are partially saturated by first applying a negative pressure to the dry sample and then by immersing the sample maintaining the depression. The degree of saturation (S_w) obtained for a negative pressure of 98 kPa is equal to 65% and 78% for the upper and the lower layers respectively. The corresponding volumetric water content (ϕS_w) are 7.1% and 4.7%.

2.3 *Instrumentation*

2.3.1 *Temperature measurement*

Preliminary tests are performed to evaluate the temperature to be applied at the surface of the samples and the duration of frost/thaw cycles. Cycles of 24 hours varying between +10 °C and −10 °C allowed to obtain sufficient negative temperatures within the sample and avoid supercooling phenomena. Figure 2 shows the temperature variation recorded by sensors located at different heights of the two-layer sample during these cycles. The extreme values of temperature go from +8 °C to −5.5 °C in the upper part of the sample, from +7.5 °C to −4.0 °C

Table 1. Hot bituminous mix sample.

Granular fraction	Nature	Mass percentage
0/4	Rhyolite	43
4/6	Rhyolite	12
6/10	Rhyolite	41
Filler	Limestone	4
Bitumen	35/50	5.8

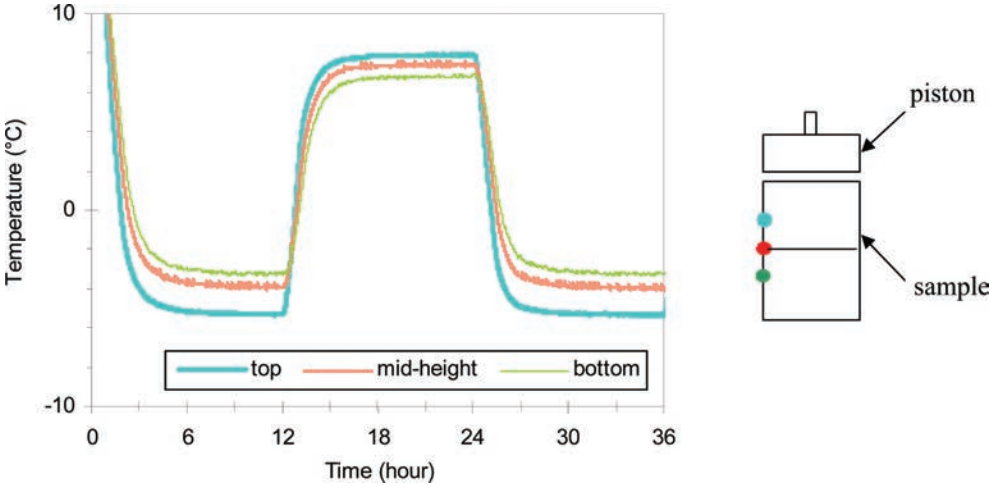

Figure 2. Left evolution of temperature with time recorded during a test by sensors positioned at different heights of a specimen. Right location of temperature gauges.

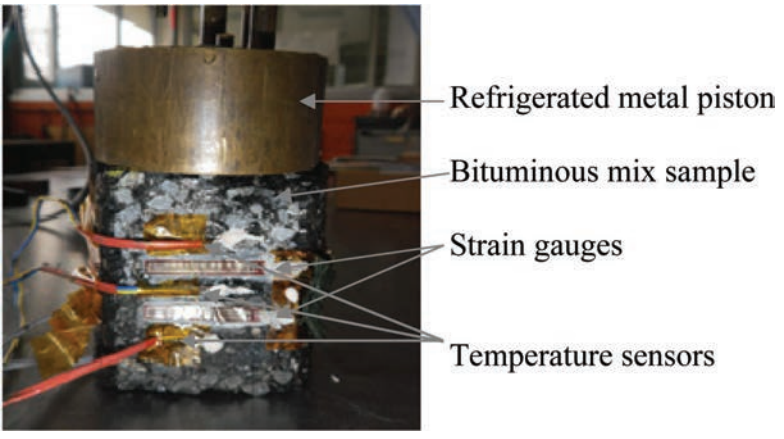

Figure 3. Temperature sensors and gauges mounted on a bituminous mix sample with a cut face.

at mid-height and from +5 °C to –3.5 °C in the lower part. The range of variation in the lower part is smaller because of the influence of the boundary condition at the bottom. Preliminary measurements performed at the edge and at heart of the specimen showing non significant differences, temperature at the edge of the sample was taken as reference, as shown in Figure 2.

2.3.2 *Radial strain measurement*

Strain measurements are made using gauges of length 30 mm and a self-temperature compensated method. A strain gauge in a half bridge circuit configuration is indeed utilized to evaluate deformation of the specimen. The temperature compensation is done using a similar sensor mounted on a rod of silicate of titanium, whose deformation can be considered as independent from temperature variations.

The sample is cut as shown in Figure 3, to provide a plane surface to paste easily sensors and avoid border effects of the confection mould. The gauges are placed horizontally to measure radial strain. Gauges placed horizontally are better suited to capture sharp events occurring at the freezing front than those placed in the vertical direction (i.e. the propagation direction of the front) which average over their height the phenomena observed (as it was made in [3]). As shown in Figure 3 the temperature sensors are placed as close as possible of the strain gauges to accurately perform the temperature compensation. In the case of a two-layer sample, two strain gauges are mounted near the interface on both sides of it to highlight a possible differential behavior.

The validation of experimental measurements was carried out using a steel alloy sample of known thermal coefficient. It showed a good correlation between theoretical calculations of contraction/expansion and measured thermally compensated strain subjected to temperature cycles.

3 RESULTS OF THE FROST/THAW TESTS

3.1 *Homogeneous samples*

Figure 4 shows the response in terms of strain of the dry and partially saturated homogeneous samples when subjected to frost/thaw cycles. The temperature at the location of the strain gauge (mi-height of the sample) is also plotted in this figure.

During a cycle, the deformation of the dry asphalt concrete varies almost proportionally with its temperature showing that the asphalt concrete mostly verifies the usual law of thermal deformation. Figure 5 shows also that under the test conditions of free deformation (except for the weight of the piston and the sample) a remaining creep component in extension after

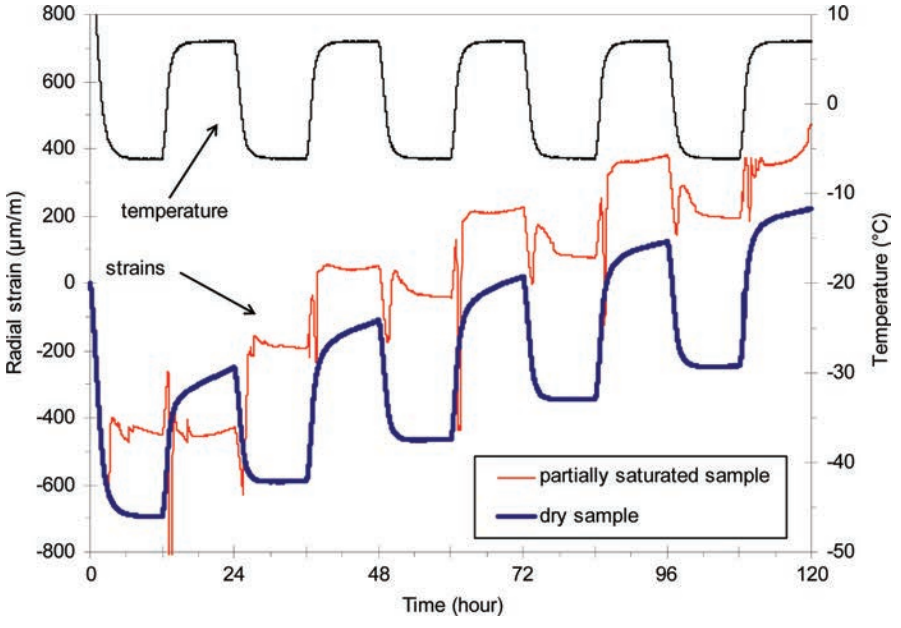

Figure 4. Radial strain measured during frost/thaw cycles applied to a dry and a partially saturated homogeneous sample of asphalt concrete (Convention: extension is in the upward direction on the graph).

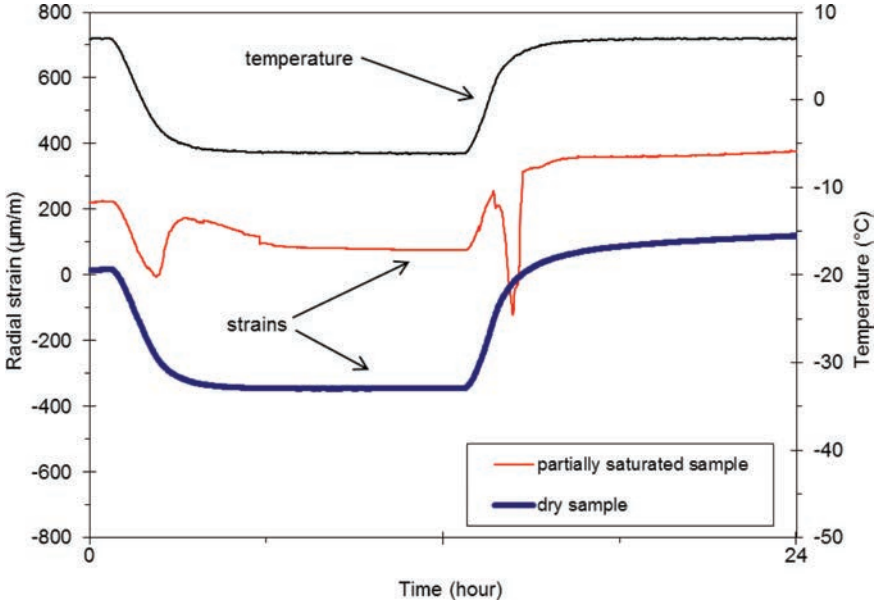

Figure 5. Close up view of radial strain measured during frost/thaw cycles applied to a dry and a partially saturated homogeneous sample of asphalt concrete.

each cycle, which in turn leads to a progressive swelling of the sample by cumulative effect. However this phenomenon is considered of secondary importance for our purpose and its explanation is not addressed here. The computation of the average thermal coefficient, $\alpha = \Delta\varepsilon_r / \Delta T$, between the two plateau temperatures of a same cycle yields a value of the order of 30.10–6/°C which is in accordance with values found in literature [4], [5], [6].

Concerning the partially saturated specimen, the response of the material is way more complex. In particular, we notice peaks of deformation (either in the upward or downward directions) each time the measure of temperature goes through zero at the location of the radial gauge. At this time, if the temperature is decreasing then the material undergoes a sharp extension which can be undoubtedly attributed to the dilatation of water within the porosity of the asphalt concrete during the phase change from liquid to solid (for recall the volume expansion of liquid water to ice is 9%).

If the temperature is increasing the material undergoes a large phase of contraction followed shortly after by a phase of expansion of similar amplitude probably due to the inverse transformation of water from solid to liquid and its decrease of volume. These successive contraction and expansion phases occurring in a short time may result from a negative pressure effect (as compared to the atmospheric pressure) of the newly melt water, followed by a readjustment of the air/liquid water pressures to the atmospheric pressure. More details about the response of partially saturated homogeneous specimens to frost/thaw cycles are given in Mauduit et al. (2014) [7]. Part of the tests not related here also shows that as expected the frost/thaw effect increases with the degree of saturation or still with the water content.

3.2 *Two-layer samples*

The two-layer sample tests are performed in order to approach the case of a multilayer bituminous pavement composed of mixes of different porosity separated by a coat layer. In dry conditions, results obtained but not shown here, are qualitatively similar to those obtained for homogeneous samples. However, the situation is quite different for the partially saturated two-layer samples as shown in Figure 6.

The upper part of the sample (ϕ = 11%) exhibits a behavior similar to that of the homogeneous wet sample of same porosity already shown in section 3.1, with even greater positive (swelling) and negative jumps induced by frost/thaw effects. Besides, the lower part of the sample shows a behavior close to that of a dry material probably due to the relatively small water content. Nonetheless a small frost/thaw effect is still present. Thus, the two-layer samples under wet conditions exhibit a complex response characterized by significant opposite strain evolutions at some times. These differential strains

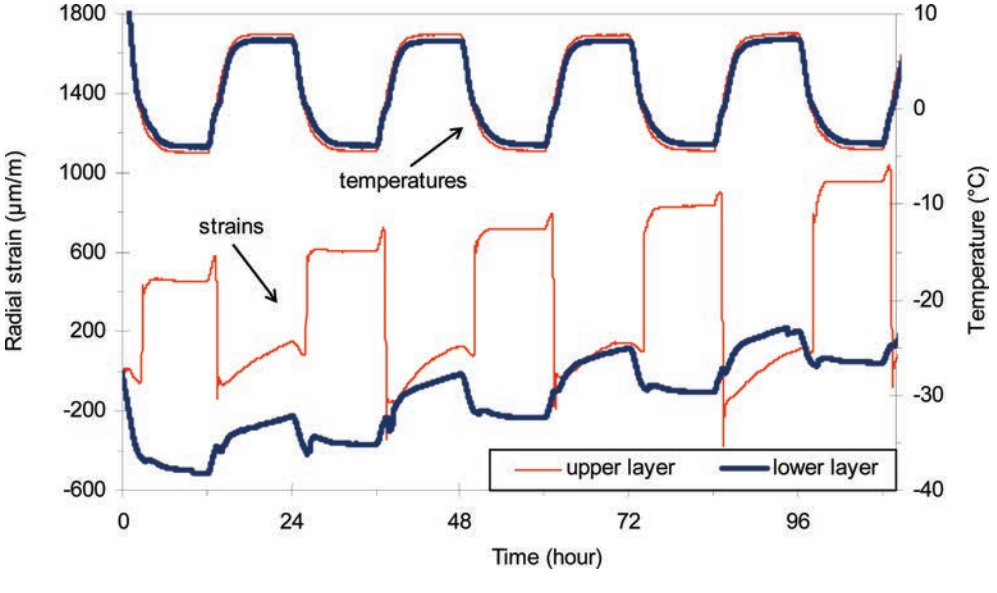

Figure 6. Graph of radial deformations of partially saturated two-layer sample.

probably induce high stress levels in the sample which however cannot be evaluated from these tests.

4 COMPLEX MODULUS TESTS

The previous tests have shown the significant effect of frost/thaw on strain. Additional tests are presented in this section to illustrate the effect of frost on the stiffness of asphalt concrete. Here the specimen are frozen prior to the beginning of the tests and then temperature is increased step-by-step (see Table 2). The impact of multiple freeze-thaw cycles on the possible damage of the samples is not addressed here.

Complex modulus tests (NF EN 12697-26 A1) are performed on asphalt concrete trapezoidal samples under dry and then partially saturated (~70%) conditions. The void content of the specimens tested is between 7 and 8%. The tests are run for the cross-conditions of temperature and loading frequency of Table 2.

The typical results obtained are presented in the Cole-Cole diagram which plots the imaginary part of the complex modulus as a function of the real part. Figure 7 shows this diagram obtained for a given sample under dry and then wet conditions. With regards to the dry condition, the curve clearly shows continuity at the junction between the isotherms, as usually observed for bituminous materials. This feature is classically reflected through the equivalence principle between time (or frequency) and temperature.

For the wet sample, the curve is superimposed with that of the dry condition in the domain of the positive or nil test temperatures. In the absence of stripping, this shows that

Table 2. Temperature and frequency conditions for complex modulus tests.

Temperature (°C)	–20	–10	–5	0	10	15	20	30		
Frequency (Hz)	1	2	3	5	10	15	20	25	30	40

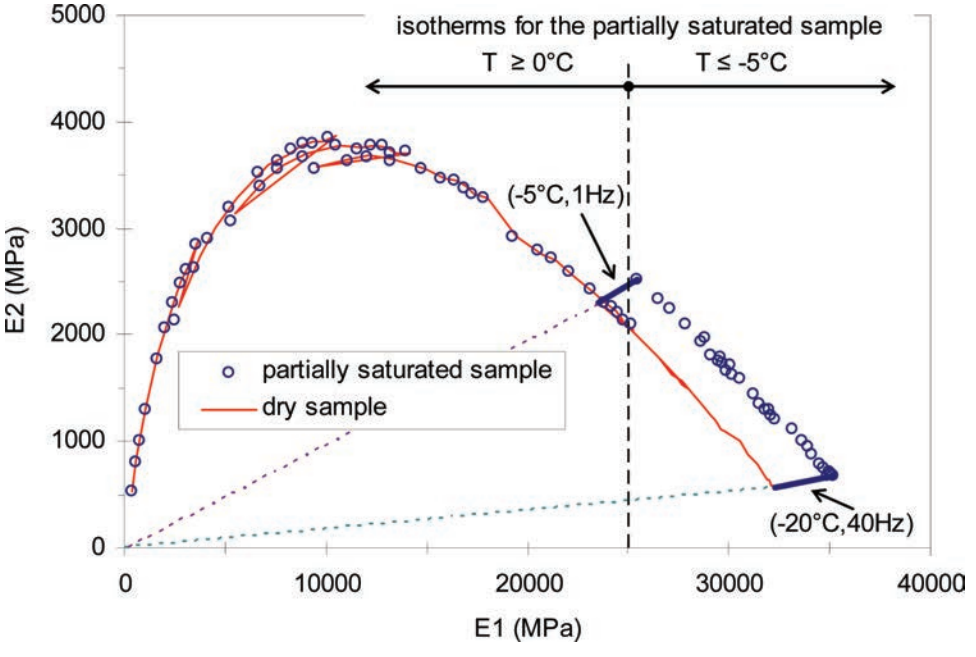

Figure 7. Cole-Cole diagram for the dry and partially saturated (70%) samples. Thick segments link points obtained for dry and wet conditions at the same temperature and frequency.

the viscoelastic behavior of the material is not affected by the present partial saturation in liquid water. Besides, the isotherms at temperature equal to or lower than −5 °C also show continuity at their junction but clearly exhibit another trend as if we were in the presence of a stiffer material. As shown by the thick segments in Figure 7, the complex modulus curve for wet condition looks homothetic to that for dry condition with a coefficient around 110%. This shows another effect of the change of pore water to ice, which is akin to an increase of the "granular" part (solid phase) of the mix.

5 CONCLUSION

The sudden disorders observed on pavements during some last winters made us investigate the freeze/thaw effect on bituminous mixes under wet conditions. Freeze/thaw tests (without external loading), performed on partially saturated bituminous samples, have shown significant swelling and contraction effects at the frost/thaw front. These effects appear to be function of the volumetric water content (ϕS_w). Besides, complex modulus test have shown a stiffening effect due the change of the pore water into ice.

Now it is believed that such effects can be at the origin of the sudden *in-situ* disorders observed on pavements, probably due to strong differential strains and self-stress developing in the asphalt layers at the frost front.

To deepen the understanding of the phenomenon and to be able to make practical recommendations to avoid these disorders, we plan further work to answer the following questions among others:

- Can the aforementioned effects be responsible of high stress levels in pavements able to break materials or interfaces?
- Is there a threshold of porosity under which the frost/thaw effect becomes negligible for wet conditions?
- Can cryosuction contribute to saturation of bituminous concrete as observed in some soils?
- Aside from the sudden occurrence of the aforementioned disorders, how do multiple freeze-thaw events damage asphalt materials and pavement structures?

Determination of discrete retardation spectra of asphalt binders using Modified Windowing Method

Yiren Sun, Jingyun Chen, Jiayin Liu & Hui Xu
School of Transportation and Logistics, Dalian University of Technology, Dalian, China

ABSTRACT: This paper describes a recursive algorithm termed the Modified Windowing Method (MWM) to fit Prony series models to creep data. The proposed method can generate discrete retardation spectra from test data without producing negative spectrum lines. The original Windowing Method (WM) assumes the equilibrium compliance of the Prony series representation to be equal to the largest data point. In that case, some errors may be introduced in calculation of spectrum lines from the data that do not cover the equilibrium region. In contrast to the WM, the MWM provides a more appropriate estimated value for the equilibrium compliance by fitting a straight line to the data in the last modelling window on the logarithmic time scale, thus resulting in a better fit. The effectiveness of the MWM was demonstrated through a numerical example in which the two algorithms were both applied to data read from a mathematical model for creep compliance. Finally, the MWM was applied to the Bending Beam Rheometer (BBR) data for determining the discrete retardation spectra of three asphalt binders.

Keywords: Asphalt binder, viscoelasticity, creep test, Prony series, retardation spectra

1 INTRODUCTION

Asphalt provides viscoelastic properties for asphalt mixtures used in pavement structures. Therefore, it is useful to investigate Linear Viscoelastic (LVE) responses of asphalt binders under different loads for performance prediction of asphalt pavements. In linear viscoelasticity, a discrete retardation spectrum which contains complete information on linear viscoelasticity is usually used to describe retardation behavior of viscoelastic materials, since the related retardation functions such as creep compliance, storage compliance and loss compliance can be easily calculated from it. Determination of a discrete retardation spectrum is essentially a procedure of fitting generalized Voigt model response to retardation data. The generalized Voigt model response can be mathematically described by a Prony series. The Prony series coefficients that a fit produces must be positive because spring stiffnesses should be positive ones. Many authors presented their fitting procedures of determining discrete retardation spectra using the Prony series [1–5]. Among these methods, the Windowing Method (WM) described by Emri and Tschoegl is a good approach that does not generate negative spectrum lines.

The WM is pretty effective for the data that cover all the three regions: the glassy region, the transition region and the equilibrium (or rubbery) region. However, due to the laboratory instrument limits or the material nature, one frequently cannot obtain such data. For example, the Bending Beam Rheometer (BBR) data obtained at low temperatures do not cover the equilibrium region. In that case, the WM may introduce some errors in calculation of the spectrum lines, since the method assumes the equilibrium compliance of the Prony series representation to be equal to the largest data point. To overcome this shortcoming, this paper presents a Modified Windowing Method (MWM), which provides a more appropriate value for equilibrium compliance in terms of the characteristic properties of the exponential

kernel functions. The effectiveness of this method was demonstrated through data read from a mathematical model. Finally, the MWM was applied to the BBR test data for determining the discrete retardation spectra of three asphalt binders.

2 BBR TEST DATA

Three asphalt binders were chosen for the purpose of this study. Two of these binders are unmodified, AH-90 and AH-70 (penetration grade). Another one is a Rubber Modified Asphalt (RMA) mixed with the AH-70 and Crumb Rubber Modifier (CRM). The CRM particle size is 80-mesh and the CRM content is 20% by weight of the basic binder. The specification parameters of penetration (at 25°C, 100 g, 5 s) and softening point for the three binders are presented in Table 1. The BBR was used to access creep data. For the AH-90, the tests were conducted at four different temperature levels: –6, –12, –18 and –24°C, while for the AH-70 and RMA, at –12, –18, –24 and –30°C. From the BBR test, the deflection at the midspan of the asphalt beam, $\delta(t)$, can be obtained. The creep stiffness, $S(t)$, and the creep compliance, $D(t)$, can be calculated as follows

$$S(t) = \frac{1}{D(t)} = \frac{Pl^3}{4bh^3\delta(t)} \tag{1}$$

where P is the applied constant load, 980 mN, b is the width of the asphalt beam, 12.7 mm, h is the thickness of the asphalt beam, 6.35 mm and l is the span length, 101.6 mm. Figure 1 presents the creep compliance data for the AH-90 at different temperatures.

Asphalt binder in LVE range is known to be thermorheologically simple and, as such, the Time-Temperature Superposition Principle (TTSP) can be employed to construct the master curve of the creep compliance. For asphalt binder in LVE range, the effects of temperature, T, and loading duration, t, can be combined into the reduced time, t_r, according to the TTSP. The reduced time is defined as follows

$$t_r = \frac{t}{\alpha_T} \tag{2}$$

Table 1. Asphalt binder properties.

Asphalt	Penetration (dmm)	Softening point (°C)
AH-90	87	46
AH-70	71	48
RMA	43	63

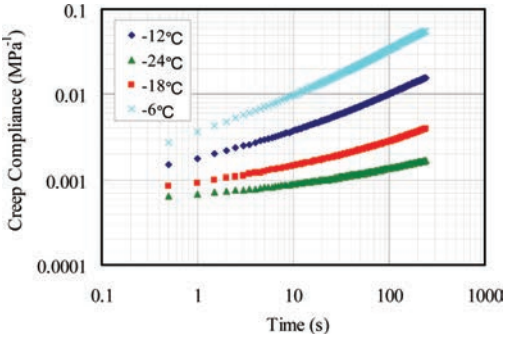

Figure 1. Creep compliance data for the AH-90 at different temperatures.

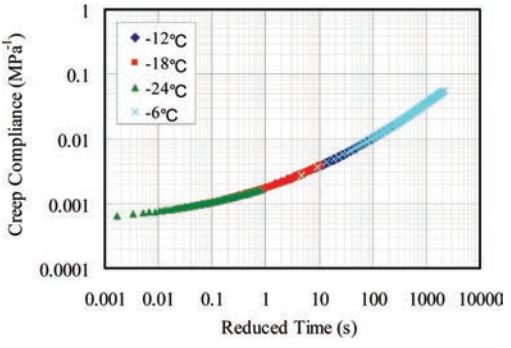

Figure 2. Master curve of creep compliance for the AH-90 at –12°C.

where α_T is the time-temperature shift factor. α_T can be employed to horizontally shift the test results measured at different temperatures to a preselected reference temperature, T_0, to form a smooth master curve. The relationship between creep compliance at reference temperature and that at test temperature is given by

$$D(T,t) = D(T_0,t_r) \tag{3}$$

Figure 2 presents the master curve of creep compliance for the AH-90 at the reference temperature of –12°C.

3 MECHANICAL MODEL

The generalized Voigt model is usually used to describe the creep behavior of LVE materials. The Prony series derived from the generalized Voigt model has the following form

$$D(t) = D_g + \sum_{i=1}^{N} D_i\left(1 - e^{-t/\tau_i}\right) + \frac{t}{\eta_0} = D_e - \sum_{i=1}^{N} D_i e^{-t/\tau_i} + \frac{t}{\eta_0} \tag{4a}$$

$$D_e = D_g + \sum_{i=1}^{N} D_i \tag{4b}$$

where η_0 is the zero-shear viscosity, D_g is the instantaneous (or glassy) compliance, D_e is the equilibrium (or rubbery) compliance, D_i are the retardation strengths, τ_i are the retardation times and (D_i, τ_i) is the discrete retardation spectrum. In this paper, the asphalt binders at low temperatures are assumed to behave as a LVE solid, and thus η_0 is set to ∞.

4 FITTING PROCEDURE

4.1 *Windowing Method*

To eliminate the negative spectrum lines and the oscillations that a fit produces, Emri and Tschoegl proposed a recursive computer algorithm referred as to the Windowing Method (WM) by using the characteristic properties of the exponential kernel functions. The method is based on the fact that a single Prony term exp(-t/τ) is only significantly time-dependent in the interval of one decade that contains the time constant, τ, whereas, outside the interval, it behaves like a unit step function. This interval of one decade is defined as the modelling window. By means of the exactly defined test data within each modelling window, the corresponding spectrum line can be determined. A set of equally

spaced retardation times needs to be preselected. Several key equations of the WM are summarized as follows:

At first, the creep data and the spectrum strengths are normalized, respectively

$$\hat{d}(t_j) = \frac{d(t_j)}{\max d(t_j) - \min d(t_j)} \tag{5}$$

$$\hat{d}_k = D_k \Big/ \sum_{i=1}^{N} D_i \tag{6}$$

The normalized creep compliance can be expressed as

$$\hat{d}(t_j) = \max \hat{d}(t_j) - \sum_{i=1}^{N} \hat{d}_i e^{-t_j/\tau_i} \tag{7}$$

Then, the absolute errors, Δ_j, between the data points and the normalized creep compliance are introduced and the sum of squares of Δ_j is formed with M function values in the modelling window

$$f_k = \sum_{j=1}^{M} \Delta_j^2 = \sum_{j=1}^{M} \left[\hat{d}(t_j) - \max \hat{d}(t_j) + \sum_{i=1}^{k-1} \hat{d}_i e^{-t_j/\tau_i} + \hat{d}_k e^{-t_j/\tau_k} + \sum_{i=k+1}^{N} \hat{d}_i e^{-t_j/\tau_i} \right]^2 \tag{8}$$

Minimizing the above error function according to $\partial f_k / \partial \hat{d}_k = 0$ leads to

$$\hat{d}_k = -\frac{\sum_{j=1}^{M} \left[\hat{d}(t_j) - \max \hat{d}(t_j) + \sum_{i=1}^{k-1} \hat{d}_i e^{-t_j/\tau_i} + \sum_{i=k+1}^{N} \hat{d}_i e^{-t_j/\tau_i} \right] e^{-t_j/\tau_k}}{\sum_{j=1}^{M} e^{-2t_j/\tau_k}} \tag{9}$$

The computation begins with the Nth spectrum line, that is, the one related to the largest retardation time, τ_N. In the first sweep, all the spectrum strengths are set to zero. In the succeeding sweeps, all positive strength values are saved and negative ones are set again to zero. The iteration is terminated when the difference between the previously found and the newly computed spectrum lines is smaller than a preset criterion. Finally, the unknown spectrum strengths, D_i can be calculated from the normalized ones.

4.2 *Modified Windowing Method*

For the data that do not cover the equilibrium region, such as the BBR data, the WM may introduce some errors in calculation of the spectrum lines. This is because the method is based

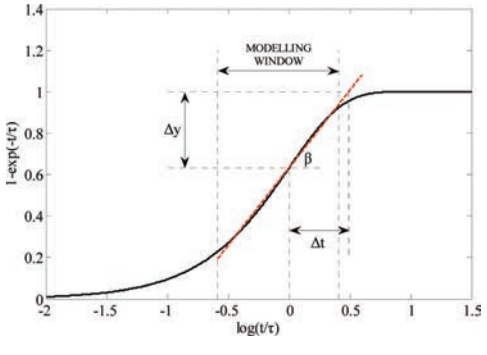

Figure 3. Graph of (1-exp(-t/τ)).

on the assumption that the equilibrium compliance of the Prony series representation is equal to the largest data point that, however, is not at the equilibrium stage. In order to overcome this shortcoming, a Modified Windowing Method (MWM) is proposed in this paper.

The MWM is still based on the characteristic properties of the exponential kernel functions. For creep compliance, the graph of (1-exp(-t/τ)) on the logarithmic time scale can make it easier to comprehend the method, represented in Figure 3. It is readily seen that (1-exp(-t/τ)) behaves like a straight line in the modelling window and a unit step function outside the window. Thus, the function value of (1-exp(-t/τ)) at the equilibrium stage can be estimated by adding $\Delta y = \beta\Delta t$ to the function value at $t = \tau$, where Δt is about 0.5. According to these properties of (1-exp(-t/τ)), the MWM sets the time associated with the last data point to the last retardation time, τ_N. The other retardation times are equally spaced before τ_N on the logarithmic time scale. The slope, β, is calculated by fitting a straight line to the data in the last modelling window. In the MWM, the equilibrium compliance is modified by replacing $\max \hat{d}(t_j)$ (see Eq. (7)) with $(\max \hat{d}(t_j)\ \beta\Delta t)$, which leads to a better fit to the creep data. It is worth noting that the MWM can also be used to identify discrete relaxation spectra from relaxation data.

5 RESULTS AND DISCUSSION

Since any true spectrum of test data is unknown, only the approximation to the true spectrum can be obtained. The success of a spectral identification is evaluated by comparing the original test data with those reconstructed from the identification [1]. To demonstrate the effectiveness of the MWM, both the WM and the MWM were applied to the identification of data read from a mathematical model for creep compliance because the spectrum of the model is known. The mathematical model is randomly given by

$$D(t) = 2 - 0.22e^{-t/1} - 0.46e^{-t/10} - 0.32e^{-t/100} \tag{10}$$

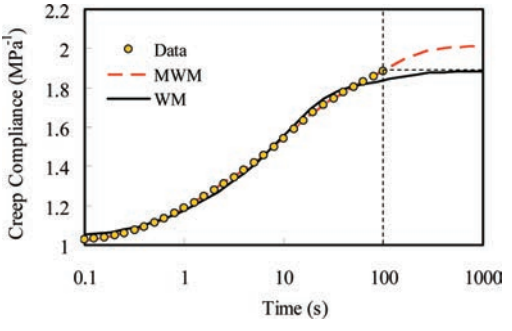

Figure 4. Fitting curves for two different methods.

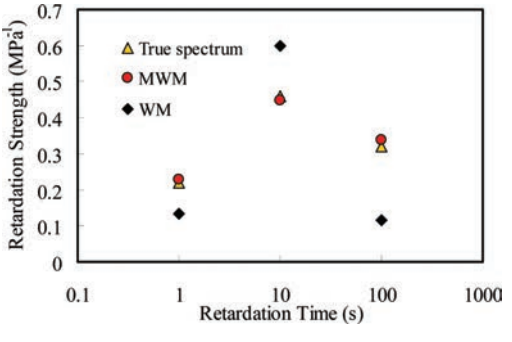

Figure 5. Discrete retardation spectra for two different methods.

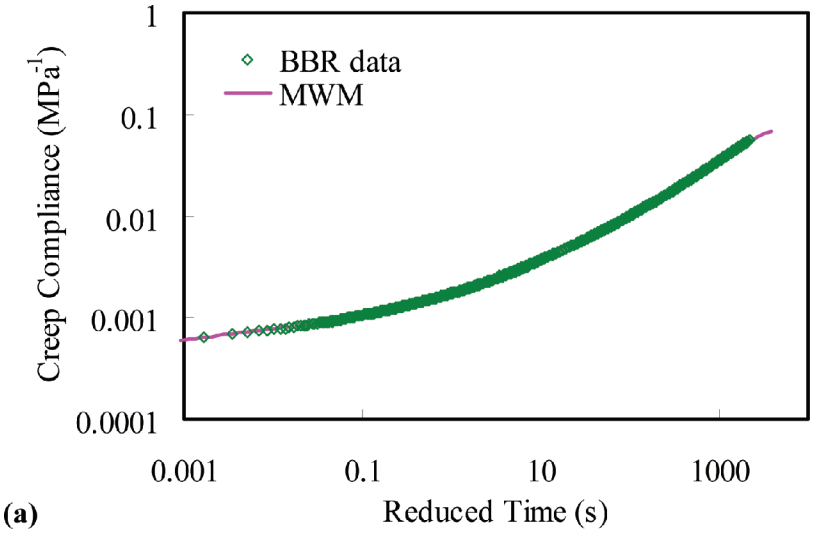

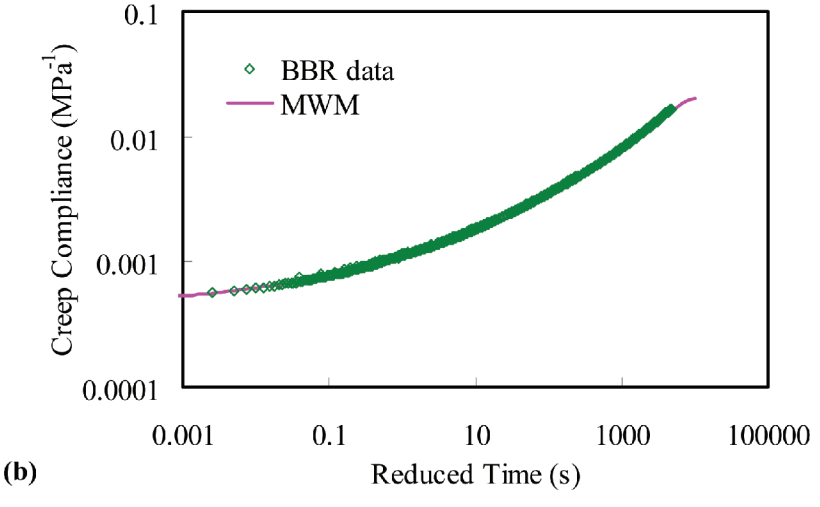

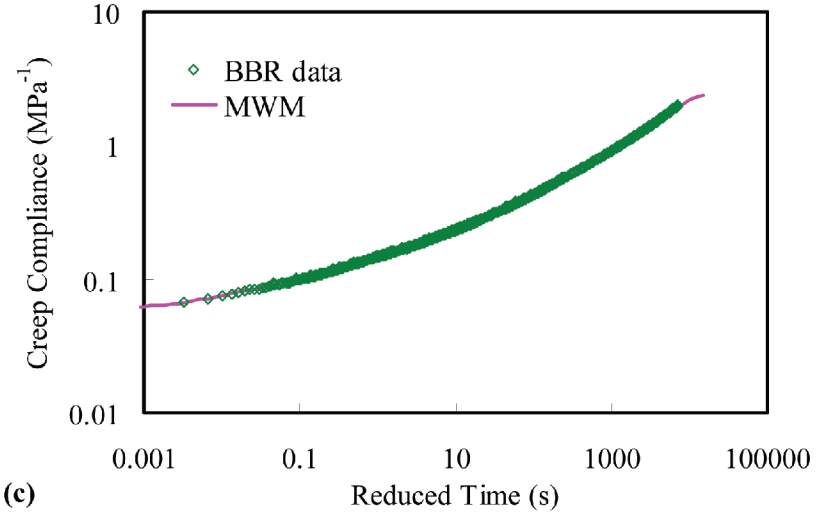

Figure 6. Fitting curve for BBR data by the MWM: (a) AH-90; (b) AH-70; (c) RMA.

Table 2. Discrete retardation spectra.

AH-90		AH-70		RMA	
τ_i (s)	D_i (MPa^{-1})	τ_i (s)	D_i (MPa^{-1})	τ_i (s)	D_i (MPa^{-1})
2.22e-3	2.02e-4	4.80e-3	9.25e-5	7.20e-3	1.57e-2
2.22e-2	8.74e-5	4.80e-2	9.93e-5	7.20e-2	2.20e-2
2.22e-1	5.05e-4	4.80e-1	3.43e-4	7.20e-1	5.06e-2
2.22e+0	5.98e-4	4.80e+0	4.65e-4	7.20e+0	6.94e-2
2.22e+1	3.46e-3	4.80e+1	1.47e-3	7.20e+1	1.92e-1
2.22e+2	4.57e-3	4.80e+2	2.37e-3	7.20e+2	3.66e-1
2.22e+3	7.05e-2	4.80e+3	1.71e-2	7.20e+3	1.85e+0

Ten data points per time decade were produced from Eq. (10), equally spaced between $-1 \le \log t \le 2$, and not covering the equilibrium region. According to the true spectrum of the mathematic model, the retardation times were preselected as 1, 10 and 100 s. Figures 4 and 5 show the fitting curves and the discrete retardation spectra for the two different methods, respectively.

It can be clearly seen from Figure 4 that the MWM yielded a better fit than the WM did. The WM forced the equilibrium compliance to equal the largest data point and this made the fitting curve have to reach equilibrium value that was equal to the largest data, thus leading to the deviation from the data. Unlike the WM, the MWM provided a modified creep compliance value in accordance with the developing trend of the data by fitting a straight line to the data in the last modelling window. Hence, the curve from the MWM fitted the data better. Figure 5 shows that the spectrum from the WM oscillates around the true spectrum while the spectrum from the MWM is very close to the true spectrum. This is also due to the inappropriate assumption that the equilibrium compliance is equal to the largest data point.

Based on the above theory, the MWM can be applied to the BBR data for determining the discrete retardation spectra. The reference temperatures for the AH-90, AH-70 and RMA are –12, –18 and –18°C, respectively. The fitting curves are shown in Figure 6, and the discrete retardation spectra are tabulated in Table 2. The results show that the MWM can well identify the discrete retardation spectra of the asphalt binders at low temperatures. Once the discrete retardation spectrum is determined, the related retardation functions, such as creep compliance, storage compliance and loss compliance are automatically established. In addition, the discrete relaxation spectrum which is usually used to describe the relaxation behavior of viscoelastic material can be obtained through various interconversion methods, which are well documented in the literature [6, 7]. These discrete retardation or relaxation spectra can be effectively and efficiently used for numerical analysis with techniques such as the finite element method.

6 CONCLUSIONS

A recursive algorithm termed the MWM was presented to determine the discrete retardation spectra of the creep data that do not cover the equilibrium region. The original WM assumes the equilibrium compliance of the Prony series representation to be equal to the largest data point, which may introduce some errors in calculation of the spectrum lines from such data. The MWM provides a more appropriate estimated value of the equilibrium compliance to overcome this shortcoming by fitting a straight line to the data within the last modelling window on the logarithmic time scale. The modified value of the equilibrium compliance results in close agreement with the test data and enhances the fitting accuracy. The effectiveness of the method was demonstrated through the data read from a mathematical model. The discrete retardation spectra of three asphalt binders were successfully determined by applying the MWM to the BBR test data.

DAsphalt—Innovative asphalt mix for PPP projects with increased lifetime

Sivapatham Pahirangan & Norbert Simmleit
TPA GmbH, Competence Centre of Strabag S.E. for Construction Material, Cologne, Germany

ABSTRACT: In the scope of the Private Public Partnership projects or build and maintenance project, the construction company can apply their knowledge, experience and competence in the form of the technical innovation to reduce the construction and maintenance costs. Hence, in this study asphalt material with long lifetime and low maintenance cost shall be developed. Therefore, several asphalt materials for base course, binder course and wearing course with different grading and binder types have been produced and tested in the laboratory of TPA, Cologne, Germany. The gained test results show, that the mechanical property and performance behaviour of asphalt mix can be improved significantly through optimization of mix composition. Hence, in this study the newly developed asphalt material DAsphalt (Deutsche Asphalt) has been selected for a highway construction with a contract: build and maintenance for a concession period of 23 years or design load of 50 Mio. 10-t ESAL by the international construction company STRABAG. The test result of analytical pavement design method show that the layer thickness of asphalt pavement with newly developed innovative asphalt DAsphalt can be reduced up to 10 cm compared to the conventional asphalt construction (thickness of 28 cm) according to German empirical design guide.

1 INTRODUCTION

The current economic crisis encourage the public authorities to establish joint ventures with private partners, because the budget of public authorities resources for infrastructure projects runs short and the budget has to be adjusted. This form of relationship is called Public Private Partnership (PPP). Additionally the number of projects: Building and Maintenance construction (B&M project) are also increasing. However, the PPP and B&M projects approaches are not new and have been successfully implemented for a number of years worldwide.

Moreover, the rising long-distance heavy traffic volumes stress pavement constructions enormously. To face this challenge only new technologies and product innovations can offer the solution. In the scope of PPP and B&M projects, the construction company can apply their knowledge, experience and competence to provide smoothen infrastructure with long lifetime and low maintenance cost. In comparison to traditional type of projects, in the scope of the PPP and B&M projects, the Private companies mostly bring private investment, build and maintain the infrastructure within tendered budget and period agreed with the public authorities. Due to, the private company has to take the full responsibility and risks involved through the lifetime for a given project. Furthermore the construction company will also form a crucial element of lifecycle analysis, by enabling the comparison of costs and benefits of different pavement construction and rehabilitation strategies. Therefore, PPP and B&M projects will provide new opportunities to reach high efficiency through speedy completion, cost-effectiveness and innovation at the infrastructure projects.

In common the construction and maintenance cost of infrastructure project can average up to 45% of the total project amount. Thus, the reduction of construction and maintenance costs can contribute significantly for cost effectiveness. Hence, in the scope of this study asphalt pavement with low construction and low maintenance cost for defined lifetime shall be developed. As a result, asphalt pavement with lower asphalt layer thickness in combination with long lifetime compare to reference asphalt according to German Standard has to be designed. These greater demands on asphalt pavements with long lifetime and low life cycle costs leads properly to the development of innovative asphalt mixes.

According to the tender document of building and maintenance project (B&M project) of motorway A 31, Section Gescher, the asphalt pavement construction can be calculated by means of analytical pavement design guide RDO Asphalt 09 [1]. Thereby the selected pavement shall be able to bear a load cycle of 50 Mio. 10 t-ESAL during the lifetime of 23 years. As result, the international construction company STRABAG decided to apply innovative asphalt mixes with high lifetime and low construction costs as well as low maintenance expense [2]. Due to, in this study adequate asphalt pavement base course mix, asphalt binder course mix and asphalt wearing course mix shall be developed. The efficiency of optimized asphalt mixes have been determined by means of analytical pavement design method with respect to the determined performance properties of newly developed asphalt mixes in comparison to reference asphalt pavement construction corresponding to German Standard [3, 4].

Finally, an economic feasibility study has been undertaken to calculate the life cycle cost of newly developed asphalt pavement construction in comparison to the reference asphalt pavement construction corresponding to German Standard.

2 ANALYTICAL ASPHALT PAVEMENT DESIGN

2.1 *Analytical pavement design*

Worldwide several pavement design methods are available to calculate the thickness of asphalt pavement construction and maintenance treatments. But the design methods differ from country to country according to their own requirements and Standards. Generally the methods are mostly based on linear elastic theory and can be used to calculate stresses, strains and deformations at critical locations of flexible pavement structures. In this study, an analytical pavement design method (Pavement Design Tool: PaDesTo) with respect to German analytical pavement design guide RDO Asphalt 09 [1] based on Multi-Layer Theory has been used.

2.2 *Pavement design criteria*

The crucial asphalt properties are the resistance against permanent deformation, low temperature performance, resistance against fatigue, ageing and adhesion between binder and aggregate. The criterion of pavement design has to be selected in relation to expected deterioration mechanisms according to climatic effect and traffic volume, so that low life cycle costs occur. Because of the complexity of deterioration mechanism caused by several loading, it is not very easy to take into account all the asphalt properties. The classical pavement design criteria are the fatigue at the bottom of the asphalt base layer, and the structural rutting originating in the granular layer and/or subgrade. But most important for flexible pavements are permanent deformation and cracking initiating at the surface [5]. For this paper following deterioration mechanisms were taken into account as design criteria:

- resistance rutting (asphalt surface layer and asphalt binder layer),
- resistance against fatigue (at the bottom of asphalt base layer) and
- resistance against deformation (granular layer and subgrade).

2.3 *Mechanical and performance characteristics of material*

As well known, asphalt is an elasto-viscous material and its behaviour changes with temperature. Due to, the mechanical properties of the asphalt layer varies regarding the temperature of the asphalt. As consequence, the asphalt tends at higher temperature (>35 °C) to deform and at medium as well as at lower temperature range (below 0 °C) to crack. Thus, the temperature of asphalt during the service time has to be considered as exactly as possible.

The stiffness modulus characterizes the stiffness of asphalt mixtures and indirectly also performance properties. The bearing capacity of asphalt layers increase with increasing stiffness. Consequently the thicknesses of pavement constructions with high stiffness asphalt can be reduced compared to pavement constructions with lower stiffness asphalt. The resulting strain and stress at the position of interest for relevant temperature can be calculated with respect to the mechanical properties of asphalt. In addition, the resistance against rutting at high temperatures can be estimated by means of temperature dependent stiffness: the higher the stiffness at high temperatures the higher the resistance against permanent deformation.

Furthermore, the performance characteristics of asphalt mixture used: permanent deformation (rutting) and fatigue line were considered by means of behaviour models derived from the laboratory test results of the wheel tracking test and dynamic indirect tensile test (fatigue line). The characteristics for unbounded granular layer and subgrade will be considered by means of bearing capacity and layer thickness. In addition the adequate Poisson ratios for asphalt and unbounded material have been selected.

3 ASPHALT MIX DESIGN

Several asphalt materials for asphalt base course, binder course and wearing course with the target to improve the mechanical properties and performance behaviour have been produced and tested. Thereby the composition and binder used for respective asphalt variants have been systematically selected.

For asphalt base course several grading in combination with high/low amount of mastix with hard and soft pen bitumen to improve the bearing capacity and fatigue resistance has been systematically selected compared to the conventional base layer mix according to German Standard. It is well known, that the rutting occurs because of high lateral shear in the depth of the 4 cm and 10 cm. Due to, in this range an asphalt layer with high stiffness at high temperature and high resistance against rutting shall be placed. As consequence the mix design for asphalt binder layer has to be optimised to improve the stiffness and rutting resistance compared to the conventional binder layer mix for highways used in Germany. Asphalt wearing course shall bring resistance against rutting and cracking initiating at the surface as well as grip. With respect to these requirements Stone Mastic Asphalt (SMA) with a polymer modified binder PmB 25/55-55A for asphalt wearing course has been selected. The bitumen for SMA has been selected with respect to the asphalt behaviour at higher and lower temperatures.

Three different asphalt mix-types with several optimizations were produced after European Standard EN 12108-1. As bitumen pen graded conventional bitumen and polymer modified bitumen in combination with additives were used.

4 LABORATORY TESTS

Several asphalt material have been tested in this study, but in this paper only the variant of the selected asphalt mixes for respective layer with a long lifetime has been compared to the conventional variant. The test results of following asphalt types will be discussed for respective layers.

- stone mastic asphalt, surface course with polymer modified bitumen [SMA 8S],
- asphalt concrete, binder course with PmB 25/55-55A (conventional variant) and PmB 10/40-65A + Additive (optimised variant with special bitumen) [AC 16 BS] and

- Asphalt concrete, conventional asphalt base layer [AC 22 TS + 50% RA] and modified asphalt base course mix: **DA**sphalt 22 TS + 40% RA with special bitumen.

The design of stone mastix asphalt has been not change compared to the German Standard. To characterize the binders, conventional and performance oriented binder test were conducted according to respective European Standard. The results are listed in Table 1. The test results of polymer modified bitumen PmB 25/55-55A and 10/40-65A + Additive indicate on hard bitumen with a high viscosity compared to the other binders. As consequence the asphalts with this bitumen will show high stiffness modulus and resistance against deformation.

The determined stiffness after EN 12697-26 (indirect tensile test) show that the asphalt base course mix DAsphalt 22 TS and asphalt binder course mix AC 16 BS + PmB 10/40–65A have significantly high stiffness compared to conventional variant at lower and higher temperatures, see Figures 1 and 2. This high stiffness increases the bearing capacity of asphalt construction and will result in lower strain at the bottom of the asphalt layer compared to the conventional variant. The briefing of the stiffness can be taken from the Table 2.

4.1 *Fatigue test*

The fatigue tests for asphalt base course material have been carried out after EN 12697-24 by means of the dynamic indirect tensile fatigue test. Different specimens are loaded with different stress levels. The number of load cycles to failure N_f have been plotted versus the corresponding initial strain on a log-log scale. Fatigue line can be generated for each asphalt

base course variant. In Figure 3 the fatigue line of conventional (AC 22 TS) and modified (DAsphalt 22 TS) asphalt base course mixes are displayed. The coefficient of fatigue line equation will be considered as material parameter for the analytical pavement design method, Table 3. The modified asphalt base course mix (DAsphalt 22 TS) show significant improvement of fatigue behaviour compared to the conventional variant.

4.2 *Permanent deformation (rutting)*

Worldwide numerous test methods and mixture response parameters to characterize rutting are exiting. In this work the resistance against rutting was determined by means of the wheel-tracking test according to the European Standards EN 12697-22. This method has been widely adopted as a straightforward method to evaluate rutting. The stone mastix asphalt mixture-slabs and asphalt binder mixture-slabs were tested in a tempered device at 60 °C using a rubber wheel. The slabs are loaded for 20 000 passes and the rut depth is the result of two simultaneously tested slabs. The determined test results of asphalt binder layer mixes are displayed in Figure 4. The test result of stone mastix asphalt is not displayed, because only one variant has been considered in this study.

The progression of rut depth clearly show the influence of the binder used. The variant with PmB 25/55-55A has higher rut depth compared to the variant with PmB 10/40-65A + Additive. The test result of variant with PmB 25/55-55A show also high resistance against

rutting. But, by means of improvement of rutting resistance of optimised asphalt binder mix compared to the conventional binder with PmB 25/55-55A the lifetime of asphalt binder layer shall be increased. Thus, the asphalt binder mix has been optimised with a high viscosity binder PmB 10/40-65A in combination with additives to improve the workability. The gained rut depth shows an improvement of rutting resistance. Due to, the lifetime of asphalt binder will increase. As consequence the maintenance can be reduced.

5 DAsphalt FOR BUILDING AND MAINTENANCE PROJECT OF MOTORWAY A 31

According to tender document of project motorway A 31, Section Gescher with building and maintenance construction contract, the selected asphalt pavement construction shall be able to bear a load cycle of 50 Mio. 10 t-ESAL during the lifetime of 23 years. As result, the international construction company STRABAG decided to apply asphalt mixes with high mechanical and performance properties with the target of increase of lifetime and reduce of the construction as well as maintenance costs. Due to, in this study developed innovative asphalt base course mix DAsphalt 22 TS and asphalt binder course mix AC 16 BS + PmB 10/40-65A with additives have been selected. The suitability of the selected asphalt pavement thickness shall be proofed by analytical pavement design guide RDO Asphalt 09 with respect to the selected traffic and climatic loading.

5.1 *Traffic loading*

The design method (RDO Asphalt 09 [1]) consider up to 11 different axle-load categories in combination with the frequency of the specified different axle-load categories. For the each category of the axle load the resulting stresses and strain at the affected location can be calculated according to RDO Asphalt 09. Only, by this way the effect of each single load on fatigue can be exactly considered. In this B&M project axle-load categories in combination with selected frequency of a high way has been considered, see Figure 5.

5.2 *Climatic condition*

According to RDO Asphalt 09 [1] 13 surface temperature in combination with the frequency of the specified value subject to the project location can be considered. For this B&M project the surface temperature, displayed in Figure 6 has been considered. For each position of interest the asphalt temperature can be determined based on considered surface temperature. Finally, for each combination of temperature frequency (13*) and axle load category (11*), the resulting strain and stress at interested position can be calculated.

5.3 *Asphalt thickness calculation*

The necessary layer thickness of asphalt pavement on the basis of prognosticated traffic loading, climatic conditions, material parameter and layer positioning has been calculated. The considered material parameters for analytical pavement design are displayed in chapter 4. The frequency of axle-load category and surface temperature considered can be taken from the Figure 5 and 6. The analytical pavement calculation show, that an asphalt pavement with

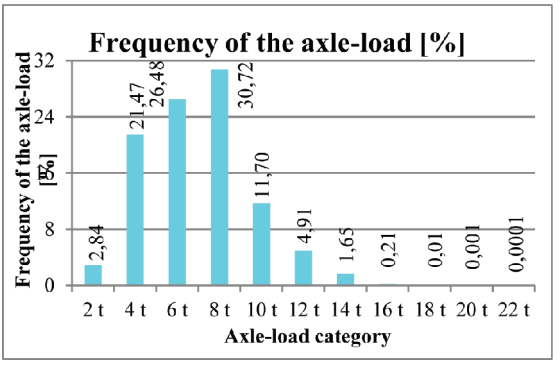

Figure 5. Frequency of the axle-load category.

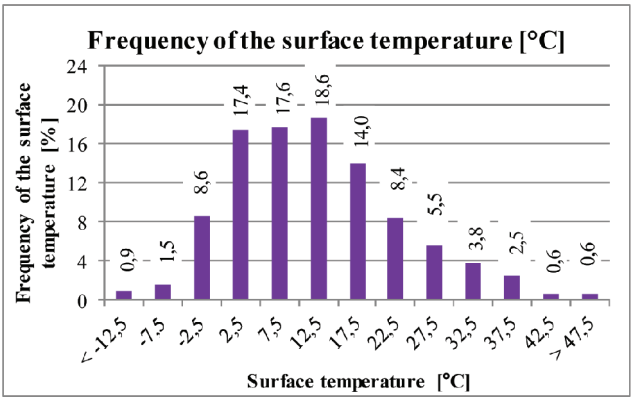

Figure 6. Frequency of surface temperature.

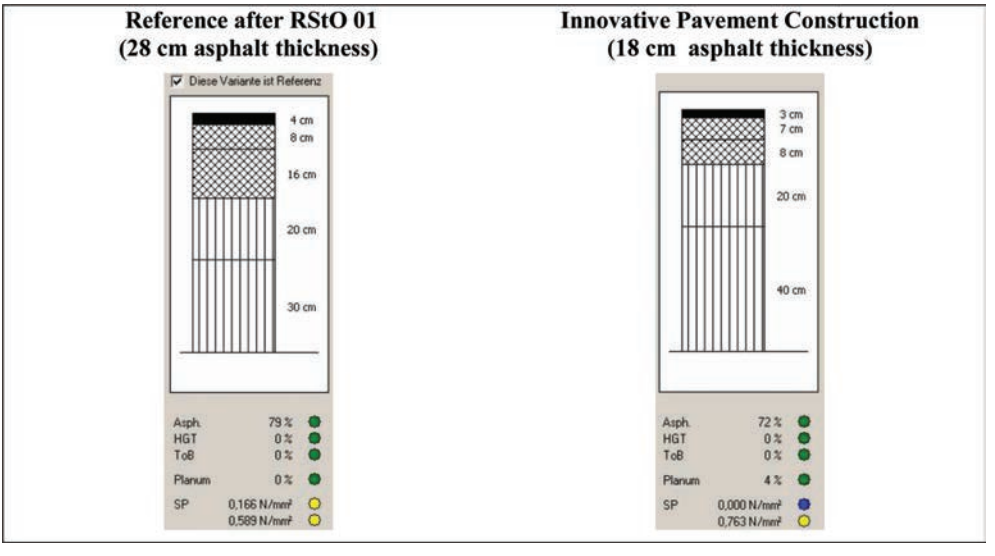

Figure 7. Comparison of conventional and innovative asphalt pavement.

layer thicknesses of 18 cm (DAsphalt 22 TS: 8 cm, AC 16 BS with 10/40-65A with additive: 7 cm and stone mastix asphalt SMA 8S: 3 cm) can be applied for the prognosticated load cycle of 50 Mio. 10-t ESAL.

According to Germany design guide [RStO 01] asphalt pavement thickness of 28 cm with conventional asphalt mixes (AC 22 TS: 16 cm, AC 16 BS: 8 cm and SMA 8S: 4 cm) has to be placed for prognosticated design load. The gained result of this study show, that the thickness of asphalt pavement can be significantly reduced in the case of use of newly developed innovative asphalt.

In addition, a rehabilitation of binder layer for an estimated traffic volume of 50 Mio. 10-t-ESAL within a lifetime of 25 years will not be necessary. According to the experience of selected stone mastix asphalt in Germany, the asphalt wearing course SMA 8S has to be completely changed one time during the concession period of 23 years. The economic feasibility study show that developed innovative asphalt pavement has a better cost effectiveness compared to the conventional asphalt pavement of German empirical design guide RStO 01 [2]. Based on this innovative knowledge the construction company STRABAG

selected this asphalt pavement concept to place at above mentioned B&M project with a thickness of 19 cm.

For validation the material parameter determined in the laboratory during this study, drill cores on systematically selected construction area, built on several days of a year has been taken and tested in the laboratory. The gained test results of analytical pavement design by means of material parameter determined on drill cores confirm that the calculated asphalt thicknesses of 18 cm is adequate to bear the prognosticated design loads of 50 Mio. ESAL.

6 SUMMARY

The calculated results show that the thickness of newly developed asphalt pavement can be reduced up to 10 cm compared to the asphalt pavement according to German empirical design guide for a design load of 50 Mio. 10-t ESAL. In addition, maintenance effort compared to the reference variant can be significantly reduced and the rehabilitation of binder layer will not be necessary. The international construction company STRABAG selected this innovative asphalt pavement for a construction of build and maintenance project of a highway in Germany for a concession period of 23 years. In addition, the validation of test result determined on the laboratory produced Specimen has been carried out by means of determination of material parameter on drill cores, sampled at several position of construction paved on different days. The gained test result of analytical pavement design method confirm with low deviances the test results determined at the Specimen produced in the laboratory. In addition, it shows that the selected asphalt pavement thickness of 18 cm is adequate to bear the prognosticated design load without to rehabilitation of asphalt base and binder course.

ABSTRACT: This study presents data which supports that the Superpave Gyratory Compactor (SGC) can be used as a suitable means of compacting unbound material. The SGC was utilized to test unbound material used by the Federal Aviation Administration (FAA) for the base and subbase layer for airport pavements at the National Airport Pavement Test Facility (NAPTF). Three different materials were tested using the SGC, namely the P-154, P-209 and DGA. This paper focuses solely on P-154 and P-209. The P-154 and DGA have been used as subbase layers and P-209 for the base layer at the NAPTF for various construction cycles. The results from the SGC have been compared to field compaction and trafficking data obtained from the NAPTF. It is evident that the SGC can be used as a suitable predictor of field performance due to construction compaction and possibly trafficking. The SGC better simulates field compaction due to the contribution of both shear and vertical work. Energy measurements have also been used to determine the dependence of material type on the compactive effort required. The micro-mechanics behind compaction has been examined and has been found to be due to attrition and abrasion of the aggregate.

Keywords: compaction; superpave gyratory compactor; airport pavements

1 INTRODUCTION

With the introduction of larger planes, such as the Airbus A380, which weighs approximately 1.3 million pounds (0.6 million kg), the FAA is testing airport pavements under heavy aircraft loading at the National Airport Pavement Test Facility (NAPTF) in Atlantic City, NJ, USA. The NAPTF located at the FAA William J. Hughes Technical Center, Atlantic City International Airport, New Jersey, USA opened for testing on April 12, 1999 as a joint venture between the FAA and the Boeing Company. The test facility consists of an indoor simulated runway 274 m (900 ft) long by 18.3 m (60 ft) wide. The test strips are constructed using techniques typical for runway construction. Instrumentation is installed in the test strip to monitor responses in the subbase and subgrade due to repeated trafficking. A test vehicle is used to simulate the field trafficking of aircraft weighing up to 1.3 million pounds. As a result of the heavy aircraft loading, the FAA found that the subbase layer compacted past the maximum Modified Proctor Density [1] during the simulated trafficking with very little crushing of the material.

The NAPTF Construction Cycle 5 (CC5) is the most recent construction cycle of interest. The test pavement of CC5 is comprised of 4 flexible pavement test items, namely LFC1, LFC2, LFC3 and LFC4, constructed over a low strength subgrade known as DuPont Clay. CC5 is utilized to study the effects of various gear configurations as well as subbase material depth and quality on the flexible pavement's performance. Test items LFC-1 and LFC-4 were constructed with 34 inches of subbase material. On the other hand, LFC-2 and LFC-3 have 38 inches of subbase material. The granular subbase material is comprised of two different materials including crushed quarry screenings, P-154, and Densely Graded Aggregate (DGA). Additionally, 8 inches of P-209 crushed stone base was placed on the subbase and topped off with a 5-inch thick asphaltic concrete surface layer [2].

1.1 *Superpave gyratory compactor*

In order to understand the compaction and shear flow characteristics of the subbase layer during construction and trafficking, the subbase material was compacted in the Superpave Gyratory Compactor (SGC) at various stress levels and moisture contents. To operate the SGC, a sample is placed in the mold, which is inserted in the machine. Compaction occurs due to the pressure from the ram and the kneading action provided by the revolving angle. The SGC records the height of the ram head at each gyration during the compaction process [3]. By transferring the height data from the SGC to a computer and combining the height of the sample at a given gyration with the known diameter of the mold, the volume of the sample at a given time in the compaction process can be determined. Because the weight and volume of the sample are known, the density of the sample can be determined at any gyration level during the compaction process.

1.2 *Pressure distribution analyzer*

To find the energy input in the SGC during compaction, a Pressure Distribution Analyzer (PDA) was placed in the SGC mold. The PDA has three load cells that are placed 120 degrees from each other at equal radial distances. The PDA is started on a delayed cycle, so that it can be unplugged from the computer, and placed in the mold before the test starts. It then collects the load data and stores it until the user transfers the data to the computer after the test.

The SGC inputs both a vertical component and a shear component of work due to the gyration of the mold. Vertical work, w_v is computed from:

$$w_v = PA\Delta h \tag{1}$$

where P is the pressure of the hydraulic ram, A is the cross-sectional area of the sample (28.27 in^2) and h is the height of the sample. The second component of the energy is the shear work, w_s, which is:

$$W_S = \frac{4Pe\theta}{Ah} \tag{2}$$

where e is the eccentricity and θ is the tilt angle (1.25 degrees). All other variables are the same as in Eq. (1).

2 PREVIOUS INVESTIGATIONS

There have been investigations into the possibility of using a SGC to simulate the compaction and lifecycle of unbound soils commonly used for roads and airport runways/taxiways. Many studies have started their testing based on the standards set for testing asphalt, due to the SGC's origin as a device for testing the compaction and life of asphalt mixes [4]. One such study performed at Montana State University [5] focused on varying only the pressure

and moisture content of the soils. Four different soil types were investigated with AASHTO Classifications of A-1-a (gravel), A-3 (sand), A-4 (silt), and A-7-6 (clay). The pressure was varied from 200 kPa to 600 kPa in 100 kPa increments and the moisture content was varied from dry to saturated for each soil. Comparison of the testing data showed that dry density vs. moisture content curves were found to be very similar to Standard and Modified Proctor tests, despite the differences between the compaction mechanism used by the SGC and the Proctor tests. Two observations were evident from these series of tests. Granular soils were more affected by the SGC because the gyrations create shear work that overcome interlock. The variables that have the most significant impact on the final dry density of granular soils were found to be the moisture content and the number of gyrations [5].

3 SGC TESTING PARAMETERS

The SGC allows several parameters to be changed prior to testing: confining pressure, gyration angle, rate of gyration, and number of gyrations per test. Initial testing parameters were adopted from standards for testing asphalt. Using AASHTO design standard T 312-04 [6] as a baseline, the following testing parameters were established. Confining pressure was set at 600 kPa, 800 kPa, or 1000 kPa due to the high pressure environment expected under heavy aircraft loads. The angle of gyration and gyration rate were held constant at 1.25 degrees and 30 gyrations per minute, respectively. The number of gyrations per test was most commonly 800 gyrations; however 1600 and 3200 gyration tests were also conducted.

4 RESULTS

4.1 *SGC compaction results*

A database was compiled for analysis by conducting tests on P-154, P-209, and DGA; the subbase and base materials used for construction at the NAPTF. Due to length constraints this article will focus on P-154 and P-209; however, P-209 and DGA yielded similar compaction characteristics.

To get a baseline of comparison for the SGC compaction tests, Modified Proctor tests, ASTM D1557-07 [1], at different moisture contents were performed. Different sample sizes were used to simulate the different lift heights in the field. 3000 g and 5000 g translate to 4 inch and 6 inch lift height respectively. At approximately the same water content, the 3000 g sample after 800 gyrations reached a higher density than the 5000 g sample at 800 gyrations. It was determined from the data that the compacted height of the 3000 g sample was approximately 8 cm as opposed to the 13 cm height obtained with 5000 g sample. Therefore, during construction, smaller lift heights would create a more compacted soil resulting in a runway/taxiway less prone to failure. Figure 1 show the results of the SGC tests relative to the Modified Proctor density curve. Compaction in the SGC resulted in final dry densities much higher than the Modified Proctor Density at lower moisture contents.

The testing procedures used above on the P-154 were repeated for P-209. Once again, before any SGC tests were run on the P-209 material, Modified Proctor tests [1] were performed on the P-209 to obtain the optimum moisture content and maximum Modified Proctor density. However, 56 blows per layer and a larger mold, 0.075 cubic feet of volume, were used due to the larger aggregate size.

As testing data was compiled, it was apparent that the tests displayed repeatability. Results showed that displacement and density for all tests at respective moisture contents and pressures had a tolerance of approximately 1–2 percent. The P-209 showed a significant increase in displacement and density with increases in moisture content, as illustrated in Figure 2. The increase in confining pressure did not significantly change compaction density. Similar to the P-154 results, the densities achieved by the compaction of P-209 in the SGC were greater than those achieved by the Modified Proctor at a moisture content dry of optimum.

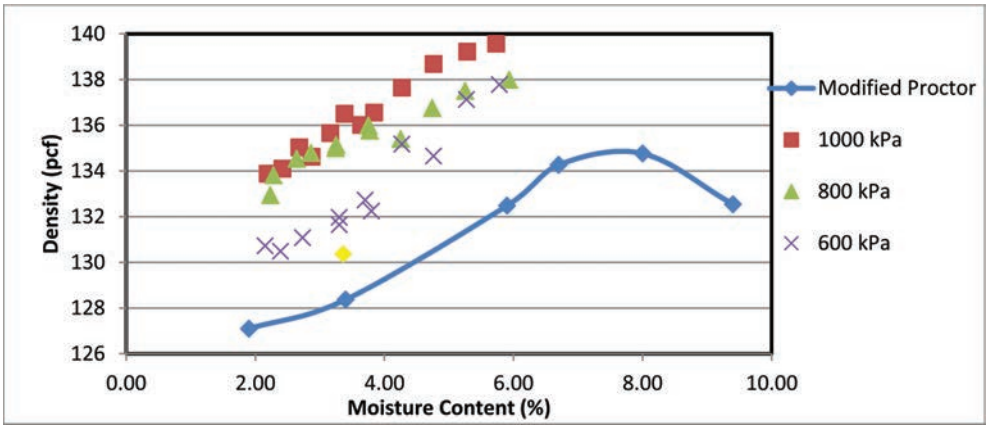

Figure 1. Evaluation of P-154 results below OMC.

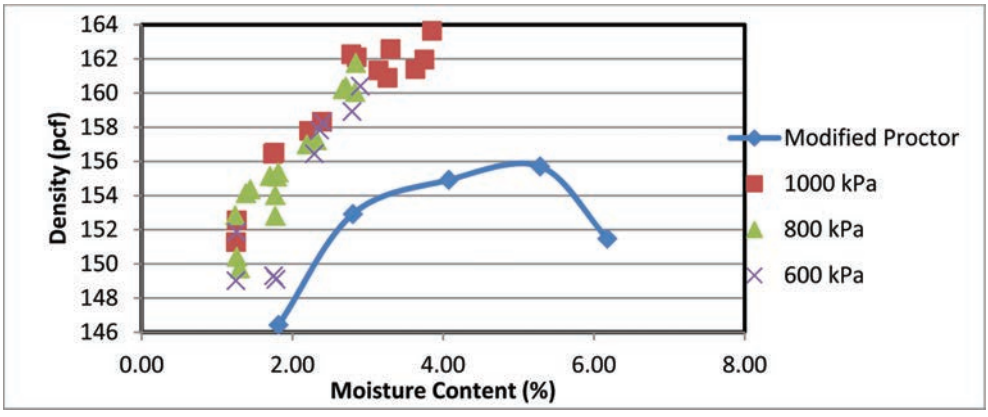

Figure 2. Evaluation of P-209 SGC results below OMC.

4.2 *Field compaction data compared to SGC compaction data*

Throughout the construction of CC5 at the NAPTF, dry density along with the number of roller passes required to reach that density was recorded. The primary compactor used for the preparation of the subbase material is a pneumatic tire roller, which was configured to weigh 205.5 kN giving it a ground contact pressure per wheel ranging from 345 kPa to 965 kPa depending on the tire pressure [7]. A drum roller was also used on the subbase during construction, which used a 2.13-m wide single-drum vibratory compactor with an operating weight of 117.5 kN and centrifugal force of 256 kN. Each roller makes passes until the maximum achievable density has been reached. As with the gyratory compactor, the material will eventually reach a point where additional passes will no longer increase the density. The density obtained in the field was obtained using either a nuclear density gauge or a sand cone, described in ASTM D6938 and ASTM D1556 [8,9]. These densities were then compared to densities achieved in the SGC by converting them into percentages of the Maximum Modified Proctor Density. These comparisons can be seen for P-154 and P-209 in Figures 3 and 4 respectively.

The results show that SGC is capable of achieving densities that the rollers achieve during field compaction. The ratio of passes of roller:SGC gyrations to achieve similar densities are approximately 1:2 and 1:10 for P-154 and P-209 respectively. Increase in ratio is most likely the result of P-209 having a denser gradation than P-154 which requires more gyrations to rearrange the material into a denser formation.

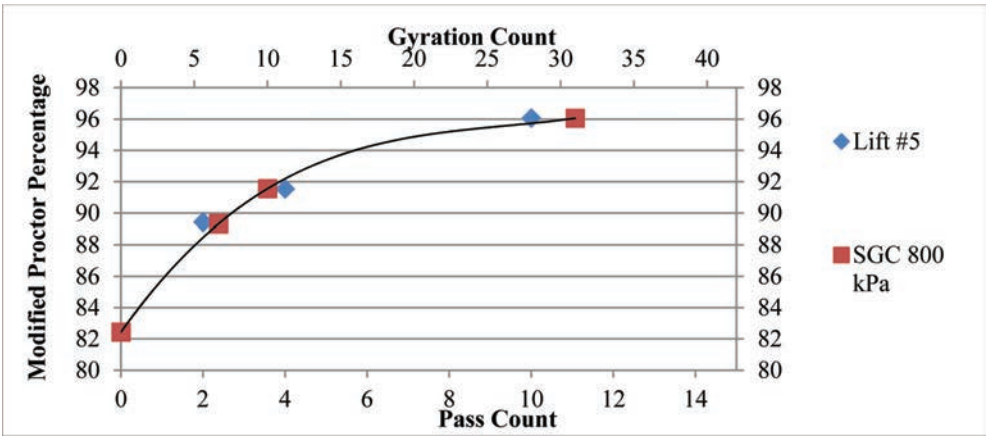

Figure 3. P-154 density to construction correlation.

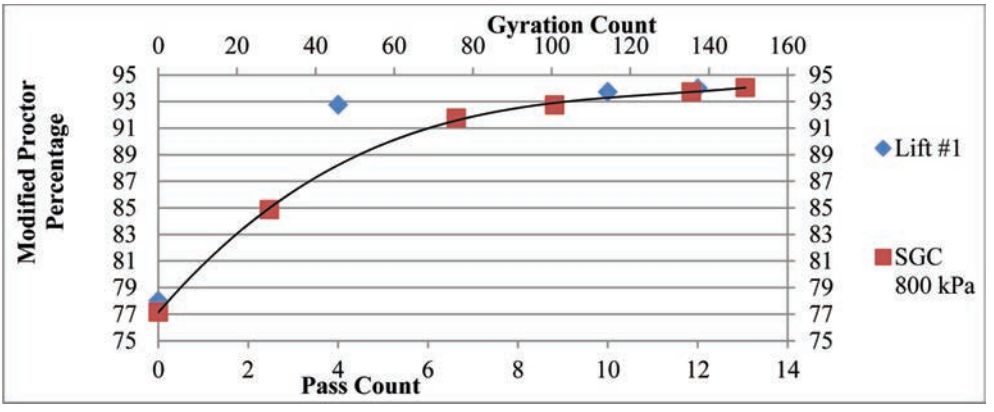

Figure 4. P-209 density to construction correlation.

4.3 *Energy measurements*

Since the SGC output includes height vs. gyration, the energy per gyration and the total energy were calculated using the data from the PDA. All energy measurements were completed at 600 kPa due to the PDA's limited load capacity. A constant 800 gyrations was also used. For the first 10 gyrations of each test the shear work was zeroed. The shear work was zeroed in order to eliminate discrepancies in the data and allow for a standard at which the PDA was leveled and not jammed against the mold. They were also zeroed because the first 10 gyrations were mostly vertical work.

Figure 5 shows the total work for P-154. As can be seen in Figure 5, as moisture content increases the sum of the total work (Fig. 5) at 800 gyrations decreases. The major component of the total work is shear work and is not shown here separately. These results are as expected because as more water is added, it is easier to compact the sample due to better lubrication of aggregate particles reducing inteparticle friction.

Similar tests were performed on P-209 and the energy results are displayed in Figure 6. The energy measurements for P-209 do not display a clear trend as was the case for P-154. This may be a result of the larger gradation of P-209. Though there is no clear trend for P-209, it appears that there is more energy input into the P-209 sample than the P-154. This is likely a result of the more uniform gradation of P-209 requiring more energy to compact because of the better aggregate interlock. The SGC mold may not be large enough to produce a

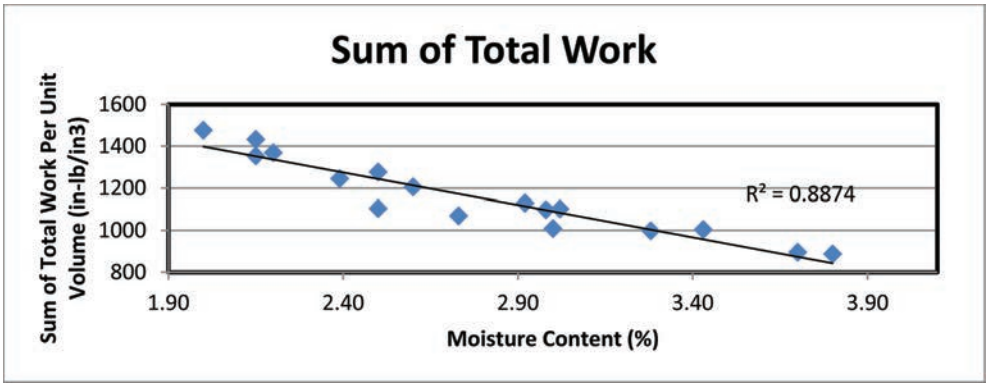

Figure 5. P-154 energy measurements.

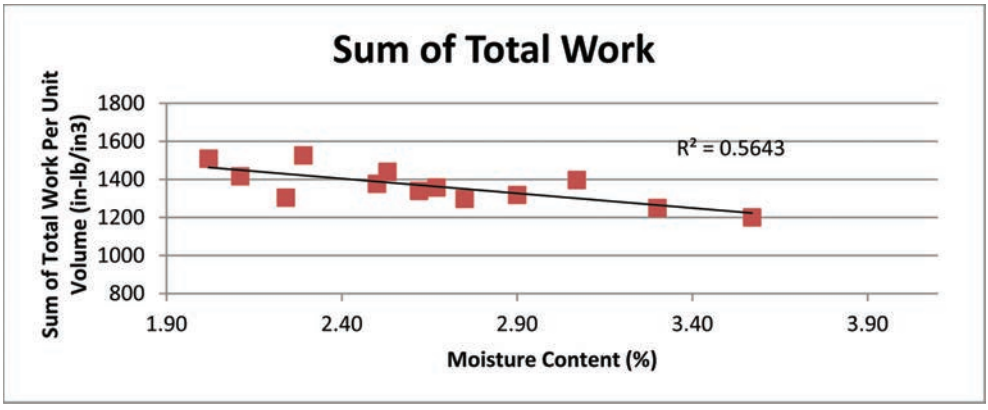

Figure 6. P-209 energy measurements.

representative sample. More tests are planned to confirm the energy measurements for P-209. P-209 does show a trend similar to P-154 in that the major component of the work done is a result of shear work and that the total work at 800 gyrations decreases as the moisture content is increased.

A comparison of the cumulative energy measurements in the SGC was also completed. The vertical work on each material at similar moisture content was developed. Only one plot is displayed below in Figure 7 because the trend is very similar for each moisture content. The vertical work is very high for the first 50 gyrations and eventually becomes almost negligible. This shows that most of the work completed in the first 50 gyrations is vertical work.

A similar comparison was made comparing the cumulative shear work for each gyration. Comparisons were made at 2.50, and 3.00 percent moisture content. The results of this analysis are displayed below in Figures 7 and 8 for 2.5% and 3% moisture content respectively. It can be seen that there is usually a significant difference in the shear energy between P-154 and P-209. Typically P-154 has much lower shear energy per gyration result than P-209. This is likely because P-154's poorer gradation makes it easier to compact than P-209. The difference in energy is greater at higher moisture contents.

Table 1 shows the average number of gyrations needed to reach a specific density range. This table is a summary of all the data that has been accrued throughout the project. It also shows that dry density values higher than the Maximum Modified Proctor Density are possible at relatively low moisture contents with increased compactive effort.

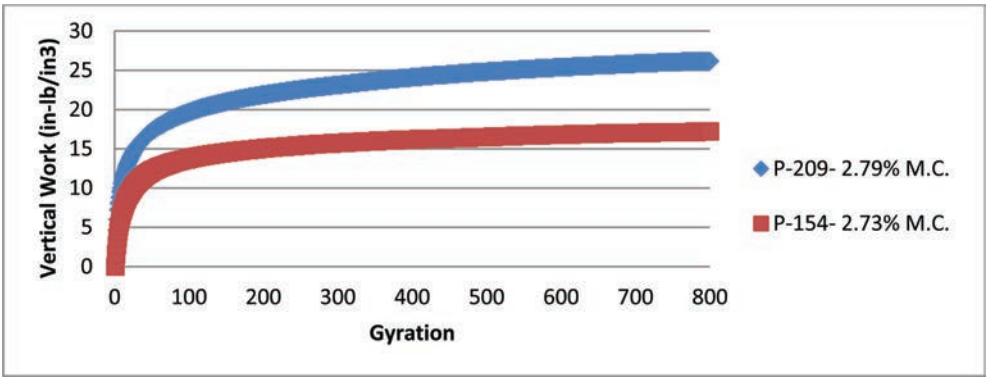

Figure 7. Cumulative vertical work per gyration at 2.75% M.C. for P-154 and P-209.

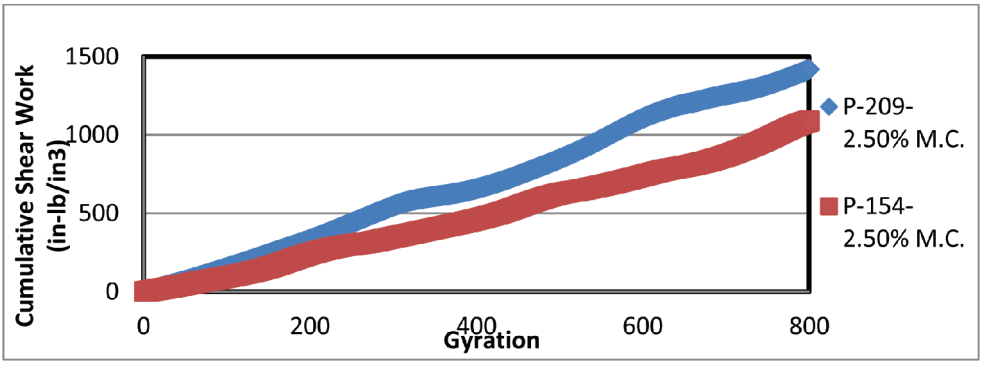

Figure 8. Shear work per gyration of P-154 and P-209 at 2.50% MC.

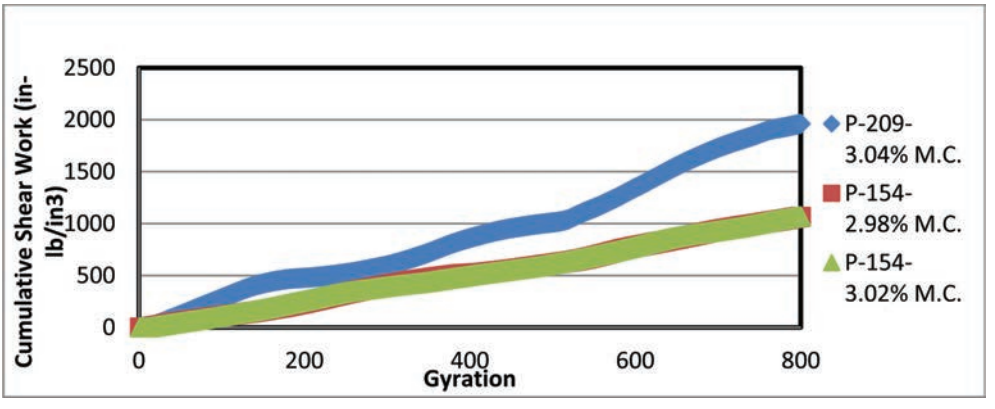

Figure 9. Cumulative shear work per gyration of P-154 and P-209 at 3.00% MC.

Table 1 also shows that as the applied pressure decreases, the number of gyrations to reach the target density is largely a function of the moisture content and it shows a more rapid increase in the number of gyrations required when pressure is decreased from 800 kPa to 600 kPa rather than from 1000 kPa to 800 kPa. This would seem to imply that increase in pressure beyond a certain threshold is not really beneficial for field compaction.

Table 1. Effect of pressure and moisture content on number of gyrations required to achieve target density for P-154.

Pressure (kPa)	1000	800	600	1000	800	600	1000	800	600	1000	800	600
Average moisture (%)	2–2.5	2–2.5	2–2.5	2.5–3	2.5–3	2.5–3	3–3.5	3–3.5	3–3.5	3.5–4	3.5–4	3.5–4
No. of tests	2	2	2	2	2	2	2	2	2	2	2	2
% max mod. Proctor	*Average number of gyrations*											
80–85%	2	2	4	2	3	4	2	4	6	3	4	6
85–90%	8	7	17	8	11	19	8	11	19	9	10	18
90–95%	39	43	131	32	44	123	30	42	107	33	37	93
95–100%	433	438	517	397	436	508	249	396	493	242	283	480
>100%	–	–	–	771	–	–	626	762	–	616	654	–

Table 2. Effect of pressure and moisture content on number of gyrations required to achieve target density for P-209.

Pressure (kPa)	1000	1000	800	800	600	600
Moisture (%)	2.0–2.5	2.5–3.0	2.0–2.5	2.5–3.0	2.0–2.5	2.5–3.0
No. of tests	2	2	3	3	3	3
% maximum mod. proctor	*Average number of gyrations*					
80–85%	29	11	20	15	19	17
85–90%	84	34	72	52	70	59
90–95%	273.5	124	299	196	308	237
95–100%	612	499	643	556	653	591
100–105%	–	–	–	–	–	–

Table 2 shows the results for P-209 and as can be seen, the number of gyrations required to achieve 100% Maximum Modified Proctor Density is larger than that for P-154. It is also to be noted that the effect of pressure is not as pronounced on the P-209 as the P-154.

In order to determine the mechanism contributing to compaction as well as assess crushing during compaction, gradation analyses were performed on virgin P-154 and P-209 as well as compacted P-154 and P-209. A wash-sieve was completed for each test to acquire an accurate representation of the fine material. The gradation analysis is not shown here but there was a movement of the grain size distribution of the materials to a finer gradation at all sieves sizes indicating that the mechanism of compaction was a combination of attrition, abrasion and fracture.

There are other means of analyzing breakage of material during compaction. For instance, the P-209 material had a much larger gradation than the P-154 material; consequently, it lent itself well to a flat and elongated particle test, described in ASTM D4791. This testing was useful in determining the change in particle morphology characteristics due to compaction. The analyses showed a decrease in flat and elongated particles for the compacted material. This backs the theory that fracture was also a method of compaction during compaction. Additionally, the fracture produced sharp edges that were easily broken by attrition or rounded by abrasion.

5 CONCLUSIONS

The SGC is capable of achieving densities greater than the maximum dry densities determined by modified proctor tests. These higher densities more closely resemble the densities

achieved in the field during construction and aircraft trafficking. Energy analysis has also shown that shear work is the main contributor to the advanced densification achieved in the SGC and is most likely why field results show densification due to trafficking much higher than the theoretical maximum dry densities. The SGC has proven to be a better option for predicting material behavior in the field than the modified proctor. The SGC could even replace expensive full scale testing once a reliable method for recording energy during field compaction is determined.

Including asphalt cooling and rolling regimes in laboratory compaction procedures

Frank R. Bijleveld & André G. Dorée
Department of Construction Management and Engineering, University of Twente, Enschede, The Netherlands

ABSTRACT: Given the various changes occurring in the asphalt construction industry, improved process and quality control is becoming essential. The significance of appropriate rolling and compaction for the quality of asphalt is widely acknowledged and vital for improved process control. But what constitutes appropriate rolling and what are appropriate instructions for operators? Existing laboratory procedures generate a single compaction temperature based on binder viscosity. However, in practice, roller operators choose various windows in terms of both time and temperature for compaction activities. This makes it difficult to design the compaction process and give proper instructions to operators.

This research project has aimed to (1) develop laboratory compaction procedures that take account of asphalt cooling during compaction and (2) determine the effects of different compaction strategies on the asphalt quality. Field compaction processes for two mixtures, an AC 16 base/bind and SMA 11 surf, were simulated in the laboratory using different temperature windows and applying different rolling regimes using a slab compactor and a 2.5 ton roller to produce 500 mm square slabs. The resultant densities and Indirect Tensile Strengths (dry and retained) were assessed based on 16 cores drilled from each slab.

The experimental results show that it can be important to design rolling strategies within clearly defined temperature windows. If an SMA 11 surf is compacted outside the optimal temperature window, or using a sub-optimal rolling strategy, the density may drop by 30 kg/m^3 and the Indirect Tensile Strength fall by up to 10%. Such experimental results are vital if one is to design appropriate rolling regimes and give appropriate instructions to roller operators. Also, the results can help to close the gap between field processes and laboratory compaction techniques. Overall, the results reflect a valuable step in the quest toward improved process and quality control.

Keywords: Asphalt temperature, cooling, compaction, density, Indirect Tensile Strength

1 INTRODUCTION

The final stage of the asphalt road construction process remains a grey area when it comes to quality control. Although substantial research effort is put into creating a mix with the desired characteristics, the actual compaction sequence, once this is delivered to a site, primarily depends on the experience and gut feelings of the roller operators. This unknown element in quality control is of increasing concern to contractors. The search is on for properly validated compaction procedures because significant changes are occurring in the asphalt construction industry that result in new roles for agencies (clients) and contractors. In particular, agencies are shifting toward service-level agreements with lengthy guarantee periods. With these new roles and contracts, contractors are directly confronted with any quality shortcomings that appear during the guarantee period. As such, it is important for contractors to professionalize their operations and improve process and quality control during construction. The current asphalt construction process is mainly based on experience and craftsmanship, and

is still mostly carried out without the use of high-tech instruments to monitor key process parameters, and little research effort has been put into the systematic mapping and analysis of construction processes [1]. Therefore, contractors have little knowledge of what actually transpired during construction and how the operations were carried out. It is therefore near impossible to relate the operations to quality parameters, to identify poor and good practices, and thus also to improve process control.

In the current technological age, various technologies are being developed to make construction processes explicit in real-time by both geodetic companies (Trimble, Topcon) and machine manufacturers (Bomag, Wirtgen, Ammann, Dynapac, Caterpiller). Using modern technologies, it becomes possible to make the construction processes explicit and systematically monitor, map, and analyze on-site processes. Several studies have demonstrated, using these technologies, that there is significant variability in both construction processes and key parameters [1–4]. To reduce this variability, it is essential to change from the current experience-based working methods toward a more method-based working. To enhance this change, it is vital to design and specify the optimum construction process before actual construction. However, it is difficult to relate the various construction processes to quality parameters in field projects given the many changing variables. Ideally, one would like to design the construction process in advance within the laboratory. However, procedures to design on-site construction processes within the laboratory are lacking and thus there remains a lack of appropriate instructions for operators. If the process could be designed in advance in the laboratory, better instructions could be provided for on-site operators.

This paper focuses on the compaction process in the laboratory (a process which on-site uses rollers). The existing laboratory compaction procedures mainly generate a single optimum compaction temperature based on binder viscosity. However, in practice, roller operators use a range of time and temperature windows for compaction (observed using GPS tracking and on-site measurements). This paper proposes a procedure to accommodate asphalt cooling and compaction rolling regimes in laboratory compaction procedures. The paper starts with a literature review of research addressing asphalt compaction, followed by the objectives and approach followed in this research. Next, the compaction procedures and materials used will be described, followed by the experimental results. The paper concludes by addressing the implications of the findings for the asphalt industry and considering opportunities for future research.

2 LITERATURE ASPHALT COMPACTION

2.1 *Asphalt compaction*

An extensive literature review by Miller [1] concludes that the majority of the literature deals with the characteristics of asphalt from the perspective of a construction material and that only about 5% of the asphalt-related journals deal with asphalt laying and compaction operations. Further, in this small research area, the studies have been conducted in separate niche areas such as ‘temperature variability’, ‘temperature segregation’, and ‘compaction problems’. Nevertheless, this literature [1,5,6] has identified two important facets within the construction process that are important for the final quality of the asphalt pavement: (1) compaction operations; and (2) the asphalt temperature during these compaction operations.

First, there are the compaction operations: inadequate compaction in vital areas of the road section can lead to premature failure. Roller operators have a limited window of opportunity to carry out their operations if they are to reach a certain quality level [7–12]. They have to take into account a number of factors including the temperature of the existing surface, the initial material temperature, the thickness of the layer, and the weather conditions. Further, the operators have to perform their tasks under frequently changing site conditions involving wind, rain, and layer thickness [1,7,8]. This all contributes to compaction being a complex task.

The second facet is the temperature of the asphalt mixture during the paving and compaction phase. In the asphalt paving industry, both researchers and practitioners recognize that the temperature of the asphalt mixture during compaction is an important determinant of the final quality of the pavement [1,7,12–17]. Some authors suggest that compaction should be completed in a specific temperature range such as between 90 °C and 100 °C [13] or have specified either maximum temperatures of about 130 °C [18] or minimum temperatures between 70 and 80 °C [19, 20]. If the material temperature is too low during compaction, the bitumen can no longer lubricate the mixture resulting in an open surface. If the temperature is too high, the binder is too fluid and the resulting aggregate structure is weak as the roller loads will simply displace or "shove" the material rather than compact it, cracks may originate behind the rollers, and the rollers sink into the mixture. Kari [10] describes these minimum and maximum temperatures as understressed and overstressed situations.

Traditionally, the optimal compaction temperature has been determined by plotting log-viscosity vs. log-temperature, and the ideal compaction temperature coincided with a bitumen viscosity of 1.7 poise [21]. Subsequently, Jordan and Thomas [22] and Luoma et al. [23] developed tools to predict a temperature window, and the starting and ending temperatures at which to compact. Later, Chadbourn et al. [7] and Timm et al. [12] developed Windows-based computer programs (PaveCool, Calcool, and Multicool) that produced solutions that predicted the pavement cooling phenomenon and suggested starting and stopping times for compaction. The main problem with these methods is that they are based on viscosity and density rather than final quality characteristics such as resistance against fatigue, rutting, and cracking. Decker [24] argues that determining the compaction temperature through viscosity-temperature plots is no longer appropriate with more viscous bitumens since these can have a higher compaction temperature leaving insufficient time to compact the mixture. Similarly, Bahia et al. [25] showed that these traditional approaches indicated unreasonably high temperatures for modified asphalts.

In conclusion, the compaction process and the temperature during this process are key determinants of the final quality of the pavement. However, how the density and mechanical properties of the pavement are influenced by the various operational compaction strategies remains unclear.

2.2 *Simulation of field compaction in the laboratory*

Several studies have shown that conventional laboratory compactors, such as Marshall compactors, vibratory compactors, and gyratory (kneading) compactors, do not truly simulate the compaction in the field. In the last decade, a new type of compactor has entered the laboratory asphalt compaction market—the rolling compactor (EN 12697-33)—that produces relatively large slabs. The principle of these compactors is a segmented roller that moves back and forth across the mixture in a mold to produce relatively large slabs, often 500 mm by 500 mm.

From various studies, it has become clear that rolling compaction is closest to field compaction [26–30]. Also, the instrument can be pre-heated and can produce several test samples at the same time, and this diminishes variability between subsequent tests. The University of Wuppertal has conducted research so as to be better able to simulate, in the laboratory, field compaction and more accurately simulate pre-compaction [28]. These new laboratory compactors are available on the international market. Companies in Europe, including BPS Wennigsen and Infratest Testing Systems in Germany (who have sold 66 machines worldwide since 2006) have developed several compactors as has IPC Global based in Australia. However, less research effort has been put into determining relationships from an operational (process) perspective related to the final mechanical properties of the asphalt mixture. As a result of these studies and developments, we believe that rolling compaction has now reached a stage where it can play an important role in simulating the field compaction process, and with that in the design of improved compaction procedures. The next section discusses the objectives of this research and the approach followed.

3 OBJECTIVES AND APPROACH

The objectives of this research were: (1) to develop laboratory-scale compaction procedures that include asphalt cooling; (2) to develop laboratory procedures to imitate actual rolling regimes with various rollers; and (3) to compare the compaction procedures used in various laboratories using different compaction methods. Overall, the aim was to improve understanding of operational strategies and narrow the gap between field compaction and compaction in the laboratory. The objective of this paper is to demonstrate the merits of the developed compaction procedures and the range of experimental results when the compaction procedures were varied.

To achieve the objectives, three experiments were designed and conducted. In these experiments, some elements of the compaction process were varied and quality parameters were determined. More specifically, the temperature window and the roller types used for compaction were varied (the independent variables) and the quality of the finished product was determined in terms of density and Indirect Tensile Strength (ITS) (the dependent variables).

The 'temperature window' variable warrants further explanation. From the literature review, it is clear that the traditional approach to specifying the compaction temperature from laboratory tests results in a single compaction temperature based on viscosity whereas, during field compaction, subsequent roller passes are made while the asphalt mixture cools, resulting in a temperature window. Timm et al. [12] put forward the idea that there is an ideal window of temperatures in which to compact the asphalt mixture and, if this is met, then it is highly likely that the desired mechanical characteristics will be achieved. Depending on the cooling rate of the asphalt mixture, this also means that there is an optimal time window in which to compact. If the asphalt mixture is compacted outside these windows, the asphalt mixture will be understressed (if the mixture is compacted at too low temperatures) or overstressed (if the temperatures are too high). Figure 1, which shows schematically the temperature of the mixture as a function of time, illustrates these conditions.

4 MATERIALS AND COMPACTION PROCEDURES

The experiments were conducted using two asphalt mixtures, namely an AC16 base/bind and an SMA 11 surf. These mixtures were chosen since the AC 16 base/bind is a frequently used asphalt mixture under less than ideal circumstances in the Netherlands and the SMA 11 surf is known to be a critical mixture in terms of compaction. Both mixtures were made without incorporating Recycled Asphalt (RAP) in order to increase the homogeneity of the mixtures. All the materials were ordered as a single batch to decrease the risk of excessive variability in the raw materials. The compositions of the two asphalt mixtures are shown in Table 1. These mixtures were then compacted using two different compaction methods, namely a Slab Compactor (SC) and small 2.5 ton Roller Compactor (RC) to create 500 mm squared slabs—shown in Figure 2.

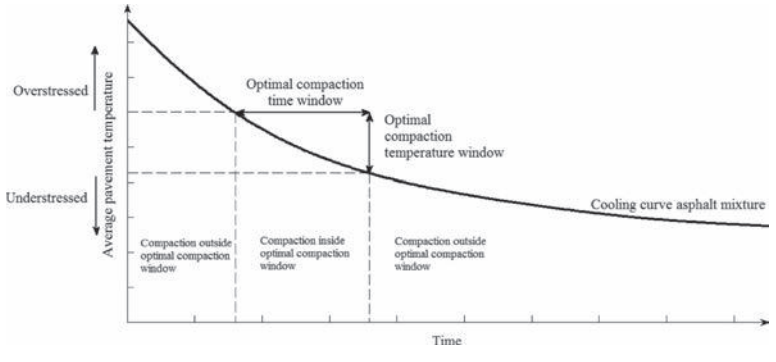

Figure 1. Compaction window (based on Timm et al. [12]).

Table 1. Composition asphalt mixtures.

Material	AC 16 base/bind	SMA 11 surf
Bestone 4/8	–	30.9%
Bestone 8/11	–	47.3%
Granite 2/8	22.7%	–
Granite 8/16	35.0%	–
Sand	35.8%	12.0%
Wigras 40 K (filler)	6.5%	9.8%
Bitumen 40/60	4.5%	–
Bitumen 70/100	–	7.0%

Figure 2. Slab compactor (left) and 2.5 ton roller (right).

Three experiments were designed and conducted: (1) varying the temperature window for the AC 16 base/bind mixture using both compaction methods, (2) varying the temperature window for the SMA 11 surf mixture using both compaction methods, and (3) varying the rolling regime for the SMA 11 surf mixture using only the slab compactor. The specified compaction procedures are shown in Table 2. In total, 47 slabs were produced in four laboratories from which 752 cores were extracted and analyzed.

The steps (i.e. the procedure) conducted in the experiments were as follows:

1. Mixing the raw materials. This involved heating the bitumen and aggregate to 170 °C. First, the aggregate, sand and filler were put in the mixer, these were mixed for 15 seconds, then the bitumen was added and mixed for 3 minutes.
2. Compacting the asphalt mixture using the slab compactor or the 2.5 ton roller. First, the asphalt mixture was pre-compacted to 90% of the target density (simulating screed compaction). Then the 4–5 rolling phases shown in Table 2 were simulated (also based on procedures from Mollenhauer [31]).
   a. To ensure the roller passes were carried out at the intended temperatures, thermocouples were placed in the asphalt mixture at the bottom and middle of the height through the slab. In practice, there was little difference between these two temperatures so the slabs can be considered homogenous in terms of temperature.
   b. The loads applied by the slab compactor were calculated based on the Dutch roller factor, which is calculated by the load of the roller divided by the product of the width and the square of the diameter of the roller. A force of 14 kN was used to simulate a tandem roller, and a force of 25 kN to simulate a three-drum roller.
3. Drilling and removing cores from the slab. Sixteen cores with a diameter 100 mm were extracted from each slab according to a standard drilling scheme.
4. Determining the dimensions and densities of the drilled cores. The dimensions of the cores was measured four times using a digital rod and the density was determined by a procedure based on Archimedes' Law.

Table 2. Design of the compaction procedures.

Experiment 1: AC 16 base/bind		
Procedure 1: 10 slabs	Procedure 2: 3 slabs	Procedure 3: 2 slabs
5 tandem passes at 150 °C	5 tandem passes at 120 °C	5 tandem passes at 120 °C
5 tandem passes at 115 °C	5 tandem passes at 100 °C	5 tandem passes at 80 °C
5 tandem passes at 90 °C	5 tandem passes at 80 °C	5 tandem passes at 60 °C
5 tandem passes at 70 °C	5 tandem passes at 60 °C	5 tandem passes at 40 °C
Experiment 2: SMA 11 surf		
Procedure 1: 12 slabs	Procedure 2: 12 slabs	
5 tandem passes at 150 °C	5 tandem passes at 120 °C	
5 tandem passes at 115 °C	5 tandem passes at 100 °C	
5 tandem passes at 90 °C	5 tandem passes at 80 °C	
5 tandem passes at 70 °C	5 tandem passes at 60 °C	
5 tandem passes at 50 °C	5 tandem passes at 40 °C	
Experiment 3: SMA 11 surf		
Procedure 1: 3 slabs	Procedure 2: 3 slabs	Procedure 3: 2 slabs
5 three-drum passes at 150 °C	5 tandem passes at 150 °C	5 tandem passes at 150 °C
5 three-drum passes at 115 °C	5 tandem passes at 115 °C	5 tandem passes at 115 °C
5 three-drum passes at 90 °C	5 tandem passes at 90 °C	5 tandem passes at 90 °C
5 tandem passes at 70 °C	5 three-drum passes at 70 °C	5 tandem passes at 70 °C
5 tandem passes at 50 °C	5 three-drum passes at 50 °C	5 tandem passes at 50 °C

5. Polishing the cores: The AC16 base/bind slabs were compacted to a thickness of 80 mm and polished to a depth of 60 mm for testing. The SMA 11 surf slabs were compacted to 60 mm and polished to 50 mm for testing.
6. Determining the dimensions and densities of the polished cores. As in Step 4, the dimensions were measured four times using a digital rod and the density was determined using Archimedes' Law.
7. Conditioning of the polished cores: Eight cores were conditioned in air at 15 °C for 72 hours (further called dry cores) and eight cores were conditioned in a water bath at 5 °C for 72 hours (further called retained cores).
8. Conducting ITS tests: ITS tests were conducted according to EN-12697–23. The ITS tests determine the peak load (P_{max}), the Indirect Tensile Strength (ITS), the work of fracture (W_f), and the fracture energy (G_f). The fracture energy was calculated according to the RILEM TC 50-FMC specification (1985). The work of fracture (W_f) was computed as the area under the load(P)—displacement(u) curve, and the fracture energy (G_f) was calculated by dividing the work of fracture by the ligament area (the product of the diameter (D) and the height (H) of the specimen).

5 EXPERIMENTAL RESULTS

Three experiments were conducted in four different laboratories. These laboratories are here numbered 1 to 4, and in 1 and 2 the mixtures were compacted using a Slab Compactor (SC) and in 3 and 4 the mixtures were compacted using a 2.5 ton Roller Compactor (RC). From each compacted slab, 16 cores were extracted and analyzed. The following aspects were assessed in detail: (1) layer thickness progression during compaction; (2) density before and after polishing; and (3) indirect tensile strength.

5.1 *Experiment 1: Varying temperature window—AC 16 base/bind*

The progression in the layer thickness during compaction is automatically determined when using a slab compactor and determined using a theodolite in the laboratories using a 2.5 ton roller. The progression in layer thickness using the slab compactors (laboratories 1 and 2) showed a consistent trend as shown in Figure 3: During pre-compaction, the layer thickness decreased by around 3–4 mm. In the first three roller phases, the layer thickness decreased by 0.1–0.6 mm in each phase. Following this, in the final phase, the layer thickness increased slightly (0.2–0.3 mm). These results are similar to the results of Faheem et al. [32] who also found that density does not always increase as the temperature falls, as we saw in the last compaction phase in our testing. In contrast, the changes in the layer thickness using the 2.5 ton roller (laboratories 3 and 4) were much more variable and no trend could be discerned.

Next, the densities of the extracted asphalt cores were determined. With this mixture, no significant differences in density were observed for a given procedure undertaken in different temperature windows. However, differences in density were observed between the two compaction methods and between the laboratories. The average slab density compacted with the slab compactors was 2296 kg/m^3, whereas the average density of slabs compacted with the 2.5 ton roller was 2339 kg/m^3. Also, the average density of slabs compacted with the same roller procedure was 2301 kg/m^3 in one laboratory and 2371 kg/m^3 in the other. The density variability within a slab was also analyzed and the variation within a slab was of a similar order. The average difference between the minimum and maximum densities within a slab was 53 kg/m^3.

Finally, the results of the ITS tests, presented as fracture energy (G_f) values in Figure 4, were considered. We concluded that there were large differences between ITS results for slabs compacted using the same procedure—both from slab to slab and from lab to lab. For the

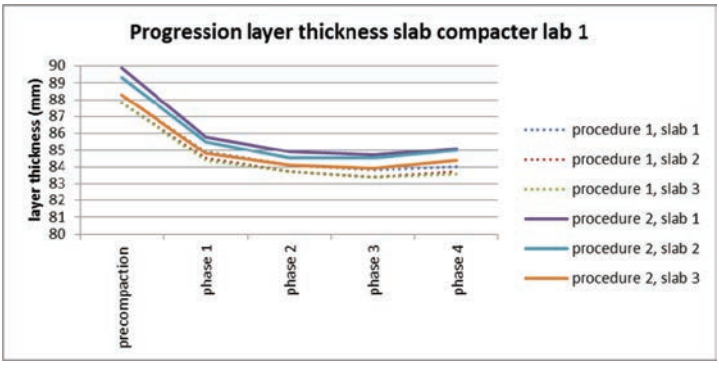

Figure 3. Progress in the layer thickness using the slab compactor.

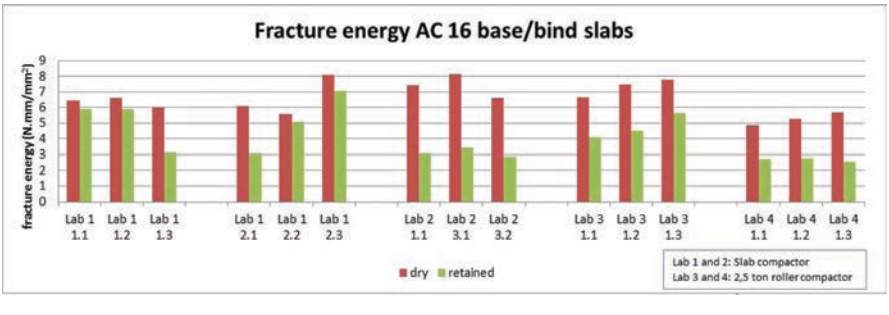

Figure 4. Average fracture energy values AC 16 base/bind slabs.
*The coding indicates the procedure (1st number) and the slab number (2nd number).

dry samples, G_f values ranged from 4.9 to 8.2 Nmm/mm^2. Given this high variability from one slab to another, it was not possible to determine a relationship between the different compaction procedures. Further, it is apparent that the retained ITS values of the slabs compacted in laboratories 2 (SC) and 4 (RC) are relatively low compared to those in the other two laboratories (by 1.97 Nmm/mm^2 on average). As a consequence, the ratio between the dry and retained values (ITSR) are relatively low in laboratories 1 (SC) and 3 (RC), and overall show a wide range (41–91%).

5.2 *Experiment 2: Varying temperature window SMA 11*

SMA 11 surf slabs were compacted in two different temperature windows, namely at 150-115-90-70-50 °C (Procedure 1), and at 120-100-80-60-40 °C (Procedure 2). Five roller passes with a tandem roller (Hamm DV70) were carried out in each of the five rolling phases.

Again, the progression in layer thickness during compaction was more consistent using the slab compactor than the 2.5 ton roller. Using the slab compactor it was possible to compact slabs with a maximum difference in layer thickness of 2.5 mm (59,7–62,2 mm). Using the 2.5 ton roller, the differences in thickness were much more variable (58,9–65,3 mm).

From an analysis of the progression in layer thickness, it seems that Procedure 2 was less successful in achieving the desired layer thickness than Procedure 1. This is also reflected in the final densities of the extracted cores. Although all the cores show a compaction degree of 100 to 102%, the densities of the cores compacted using Procedure 2 are approximately 30 kg/m^3 lower than those produced using Procedure 1. As with the AC16 base/bind mixture, the variability in density within a slab was high. Differences between the minimum and maximum densities in a slab were as high as 80 kg/m^3. However, the cores extracted from the central area of the slabs were much more consistent with the maximum difference between the minimum and maximum densities within a slab being 25 kg/m^3.

ITS tests were performed on the extracted and polished cores. Even when the largest differences in density were discounted (by selecting the middle cores of the slabs), there still seems to be a difference in ITS values between the cores compacted using the two procedures. The ITS values from the cores compacted according to Procedure 1 vary from 0.91–1.09 MPa, and using Procedure 2 from 1.01–1.20 MPa. The average ITS of the cores compacted using Procedure 2 was 0.11 MPa (≈10%) higher than the ITS of those compacted using Procedure 1. We then looked for a relationship between the density and the ITS of the cores. No relationship was found between the ITS and the density, for the obtained density range (2330 to 2370 kg/m^3).

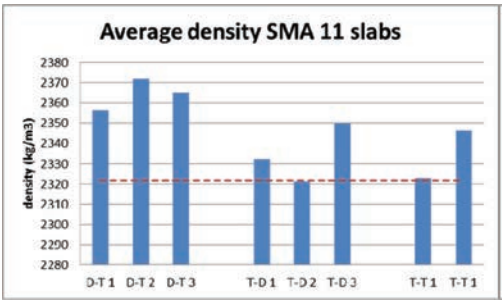
5.3 *Experiment 3: Varying roller regime SMA 11*

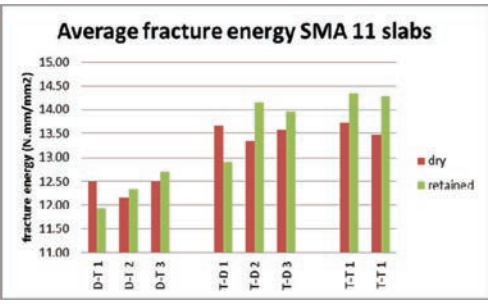
In Experiment 3, SMA 11 surf slabs were compacted following three different roller regimes, namely using a three-drum roller and then a tandem roller (further called D-T), using a tandem roller and then a three-drum roller (further called T-D), and using a tandem roller, followed by a second tandem roller (further called T-T). In all cases, compaction took place in five phases at temperatures of 150–115–90–70–50 °C with five roller passes in each phase.

The successive changes in layer thickness show that the D-T rolling regime results in a much faster reduction in slab thickness than in the slabs compacted using the T-D and the T-T rolling regimes.

Following the procedure, next cores were extracted and analyzed. All the slabs achieved the target density or higher densities. However, the cores compacted using the D-T rolling regime were denser than both the target density and the ones produced using the other rolling regimes. The average density of the cores compacted using the D-T rolling regime were about 30 kg/m^3 higher than those produced in the other regimes (see Fig. 5). Again, the variability within a slab was high, although the densities in the middle part of a slab were rather constant with the difference between the minimum and maximum densities no more than 25 kg/m^3.

ITS tests were then performed to complete the experiment. With the largest differences in density being discounted by selecting only the middle cores of the slabs, there seems to be a





Figures 5 and 6. Average density. Average fracture energy.
*D and T indicate the roller type (three-drum (D) and tandem (T)) and the numbers correspond to the slab number.

relationship between ITS and the rolling regime. The ITS of the cores compacted using the D-T rolling regime were about 10% lower than the cores compacted using the other rolling regimes (see Fig. 6). A possible explanation is that the three-drum roller is too heavy and so creates micro-cracks at the high temperature of 150 °C. However, this hypothesis needs to be confirmed or rejected in other laboratories.

6 DISCUSSION AND FUTURE RESEARCH

Although we have succeeded in simulating the asphalt cooling process in laboratory compaction procedures, there are still various points to address. First, we have seen that there is still significant variability in both density and Indirect Tensile Strength (ITS) within the asphalt slabs. As such, the procedures need to be improved to reduce the variability in density. Possibly, this could be achieved by automating the filling of the mold with the asphalt mixture related to the pre-compaction of the paver. Further, the variability in ITS values has a strong influence on the ratio between the dry and retained values (ITSR), and this makes the ITSR an even more unreliable parameter for use in analysis and comparison. A final concern is that the ITS test may not be sufficient to observe differences between slabs that were compacted within different temperature windows. In future research it may therefore be valuable to test cores using other mechanical tests such as the triaxial test or the four-point bending test. Also, additional research could usefully be devoted to further experimenting with different roller regimes, and specifically with more critical mixtures when it comes to compaction, such as thin surfaces. In case of using asphalt mixtures with multiple aggregate sources, it may be better to evaluate the air voids rather than the density. Further, more extreme loads could be tried to determine when micro-cracks due to roller loads may arise. We also plan to explore other variables in the compaction process, such as the timing of the first roller pass and the effect of roller speed, and to determine the effects of additional roller passes once the target density is achieved.

Finally, it is important to validate the experimental results obtained in the laboratory with field experiments. Therefore, further research effort is planned that involves designing a field experiment in which a rolling strategy will be given to roller operators and its implementation monitored using GPS equipment. Following this, the rolling process will be closely simulated in the laboratory and the resulting mechanical properties compared.

7 CONCLUSIONS

The significance of appropriate rolling and compaction for road quality is widely acknowledged and improved process and quality control are vital. However, procedures to design

or specify compaction processes are lacking and thus also methods to provide appropriate instructions for roller operators. Existing laboratory procedures generate a single 'ideal' compaction temperature based on the binder viscosity, while in practice roller operators have to select and work within windows based on time and temperature. This paper has described initial work to include asphalt cooling and rolling regimes in laboratory compaction procedures. Typical field compaction processes for an AC 16 base/bind and for an SMA 11 surf were simulated in the laboratory within different temperature windows by applying specified rolling regimes using a slab compactor and a 2.5 ton roller. In this initial stage, we succeeded in imitating, in the laboratory, field compaction processes in terms of temperature windows and rolling regimes. By following a standard procedure, it was possible to conduct roller passes at various temperatures and so compact the asphalt within a specified temperature window.

Using the AC16 base/bind, three temperature compaction windows were experimented with: from 140 down to 70 °C, 120–60 °C, and 120–40 °C. None of these tests suggested a significant and consistent relationship between temperature window and final density and Indirect Tensile Strength. Similarly, two temperature windows were used with the SMA 11 surf mixture, from 150 °C down to 50 °C and 120–40 °C. With this mixture, the slabs compacted in the cooler temperature window were less dense, typically by 30 kg/m^3. When the differences in density were discounted, the slabs compacted in the lower temperature window have Indirect Tensile Strengths (ITS) that are about 10% higher. In a final set of experiments, the rolling regime for the SMA 11 surf was varied. Three regimes were tested: (1) first a three-drum roller and then a tandem roller, (2) first a tandem roller and then a three-drum roller, and finally (3) two successive tandem rollers after each other. The slabs compacted using the first roller regime with a three-drum roller followed by a tandem roller were about 30 kg/m^3 higher in density. However, the ITS of the slabs compacted using this roller regime were about 10% lower.

The results demonstrate that it is certainly important to specify rolling strategies based on temperature windows that depend on the asphalt mixture. If an SMA 11 surf is compacted outside the optimal temperature window, or using a sub-optimal rolling strategy, the density may drop by 30 kg/m^3 and the Indirect Tensile Strength by up to 10%. These experimental results could help in designing appropriate rolling regimes and providing better instructions to roller operators. The results reflect a step forward in diminishing the gap between field and laboratory compaction outcomes. Further research effort will be put into verifying the results under in-situ conditions. Overall, the results are a valuable step in the quest for improved process and quality control.

ACKNOWLEDGEMENTS

This research would not have been possible without the cooperation provided within the ASPARi network. We would especially like to acknowledge the eleven contractors for the opportunity to conduct research at their construction sites and in their laboratories.

ABSTRACT: Hong Kong (HK) is currently developing a new flexible pavement design standard with the goal of building long-life pavement in the future. Long-life pavement is expected to last for at least 40 years without major structural damage. The design of long-life flexible pavement has been traditionally focused on structural design, in particular the control of tensile strain at the bottom of Asphalt Concrete (AC) layer and compressive strain at the top of subgrade. Changes of fundamental asphalt binder properties and performance due to its oxidative aging throughout the pavement structure often receive little attention. However, understanding the evolution of asphalt binder properties is critically important for long-life pavement design. It not only affects the load-induced mechanistic responses of the flexible pavement system, but also the fracture and cracking potentials of the binder *per se*. In this study, AC samples were taken from a heavily trafficked road in HK that has been in service for 36 years with only being periodically resurfaced. The cores were cut into six slices and asphalt binders were extracted and recovered for the analysis of their aging characteristics by using Gel Permeation Chromatography (GPC), Fourier Transform Infrared spectroscopy (FTIR), and Dynamic Shear Rheometer (DSR). The analysis results indicate that oxidative aging penetrates deep into the asphalt pavement layers, but there are variations in the extent of aging. In general, asphalt binder is severely aged at different depths, but at certain locations it exhibits less aging. The causes of the aging variations need to be further researched.

Keywords: long-life pavement, oxidative aging, Gel Permeation Chromatography, Fourier Transform Infrared spectroscopy, Dynamic Shear Rheometer

1 INTRODUCTION

From highway agencies' perspectives, the goal of road planning, construction, and maintenance is to maximize the value of road investment. This is often equivalent to minimizing the total amount of the agencies' construction and maintenance costs and road travelers' usage costs in the life-cycle of the planned road. For heavily trafficked roads, the social costs of road closure for reconstruction are so high that a long-life pavement is often desired. For instance, in the United Kingdom (UK), 40 years of pavement design life are believed to be the most economical for truck roads including motorways [1]. These pavements, referred to as long-life pavements, are constructed with thick bound layers built upon good foundations

and are expected to maintain their structural integrity in 40 years if the surface distress can be timely treated [1]. In the United States (US), a similar concept is placed under the name of "perpetual pavement" [2], which is expected to last longer than 50 years without structural rehabilitation or reconstruction. Hong Kong (HK) is not only the most densely populated city in the world, but also heavily relies on logistics and transportation as one of its key industries. Road closure for reconstruction always incurs significant economic, social and environmental impacts. Therefore, the highway agency in HK is pursuing a long-life pavement design strategy for new road construction and upgrading its existing major roads to long-life capacity when opportunities for rehabilitation or reconstruction arise.

The development of long-life pavement has been traditionally focused on structural design, particularly on controlling tensile strain at the bottom of Asphalt Concrete (AC) layer and compressive strain at the top of subgrade [3,4]. It is believed that if the two strains are small enough, cumulative fatigue and permanent deformation damage will not likely occur at the bottom of AC layer and at the top of subgrade layer, respectively. Monismith and Long [4] further suggest that tensile strain at the bottom of AC layer be no greater than 60 με and the vertical strain at the top of subgrade be limited to 200 με. A survey conducted by New Mexico Department of Transportation (DOT) in the US suggest that 70 με limiting tensile strain is the most commonly used value among the state DOTs for perpetual pavement design [5]. If the magnitudes and configurations of traffic loads, climate conditions, and material properties are provided, a proper combination of thickness and mixture types can be designed to meet the limiting tensile or compressive strain requirements based on well-established mechanistic analysis procedures. For instance, the design can be conveniently carried out by following the procedure in the Mechanistic-Empirical Pavement Design Guide (ME-PDG) [6].

However, as an organic material, bitumen in AC will likely undergo significant changes during its long service life. The most noticeable change is oxidative aging. As bitumen ages, its stiffness will increase and its ductility will decrease, making it susceptible to embrittlement and cracking. Although such changes are closely related to the mechanistic behaviors and performance of bituminous mixture, they often receive little attention in long-life pavement design. Particularly missing appear to be the following aspects:

- To what extent will the asphalt binder be oxidatively aged throughout the AC layers?
- How will the oxidative aging change the properties and performance of asphalt binder?
- How will the property changes of the binder affect the mechanistic property change of the mixture?

Oxidative aging causes asphalt hardening and concurrently increases the stiffness of AC. Although this may be beneficial to control permanent deformation, age hardening will cause pavement embrittlement, which leads to the development of distresses including cracking, fracture, or raveling. Early studies suggest that asphalt pavement aging primarily occurs at pavement surface (about one or one-half inches), below which there is little change in oxidative aging [7]. Using 134 data points from three roads of 43 test sections, Mirza and Witczak [8] demonstrated a clear decay of aging with AC pavement depth. For instance, the changes in relative viscosity (ratio of viscosity of the hardened asphalt to the original asphalt viscosity) at 25 °C decreases from 14.39 at the surface to 5.54 at the lowest layer (38–44 mm), and the changes in relative viscosity at 135 °C decrease from 2.25 at the surface to 1.56 at a lower layer (19–25.4 mm). These findings are widely cited and have significant impacts on academic research and engineering practices. They are also adopted in the global aging model of the Mechanistic-Empirical Pavement Design Guide (ME-PDG). However, a recent study argues that asphalt aging may not be only limited to pavement surface [9]. Using asphalt pavement cores from Texas and Minnesota, Al-Azri et al [9] found that oxidative aging "relentless" penetrates into deeper asphalt layers. However, some of the cores used in the study were obtained from the Long-Term Pavement Performance (LTPP) material reference library in Texas. The cores were stored in warehouse without air conditioning for more than 10 years. "Further aging" of the extracted cores may likely occur. In a more recent Ph.D. study, Han [10], supervised by Glover, reported aging of asphalt extracted from seven sites. The study developed an oxidation rate model and compared the predicted oxidation rate with measured bulk

oxidation rate from the sample cores. However, the variation of oxidation rate with pavement depth is not reported, and the study recommended that additional data to be included for model calibration and validation.

The change of asphalt binder aging with time and pavement depth has great implications on long-life pavements. If asphalt binder indeed ages very little at greater depth, i.e., beyond 40 mm, highway agencies can always periodically mill and resurface the wearing course of the long-life pavement and preserve the load-carrying base layers. Thus, the goal of "long life" or "perpetual" can be achieved. However, the application of the findings from the existing aging studies to long-life asphalt pavement suffers three major drawbacks. First, the reported asphalt pavements in the existing studies were typically not "old" enough to be even close to the "long-life" pavement standard. The pavements included in the study by Coons and Wrights [7] ranged from 1 to 13 years, and the oldest pavement cited in their paper was 19 years. Second, asphalt pavements in the existing studies were not as thick as that typically designed for long-life pavements. In the Mirza and Witczak [8] study, the maximum pavement depth examined was up to 44 mm. It is not uncommon that the total AC depth of a long-life pavement exceeds 250 mm. In the study reported by Han [10], only one thick pavement was used, but the cores taken from the project were only 1–2 years old. Third, the cores used in the existing studies were limited to a few locations primarily from Texas, with a few from Minnesota. As a result, the effects of intense precipitation and high humidity combined with long period of high temperature are not included. Therefore, the findings may not well represent long-life pavement behaviors in a subtropical climate such as HK.

2 RESEARCH BACKGROUND AND METHODOLOGY

2.1 *Research background*

This paper is based on a study to analyze sample cores taken from Tuen Mun Road in HK. Tuen Mun Road, with a total of six lanes, is one of the most heavily trafficked expressways in HK. The first phase (3 lanes in eastbound) of the road was open to traffic in 1977, while the second phase was open a few years later. The AC layers of the road consist of 40 mm Wearing Course (WC), 60 mm Base Course (BC), and 150 mm roadbase (RB). Since the completion of the road, several resurfacings have been performed in various locations and the most recent resurfacing on the tested section was conducted in November, 2006, but the BC and RB have never been replaced. Therefore, the asphalt materials in BC and RB are 36 years old. The general conditions of the road at a distressed section and a non-distressed section are shown in Figure 1. As can be seen, except for some fatigue cracks of low to medium severity in the wheelpath of the first section, the overall conditions of the road are reasonably good. It is confident that the road can last for another 4 years to literally meet the "long-life" pavement definition [11]. Therefore, this road was selected to study the characteristics of binder aging. It is expected that the findings will help improve future long-life pavement design, construction, and maintenance practices.

Figure 1. General conditions of Tuen Mun Rd (left: distressed section, right: non-distressed section).

A total of 36 sample cores were initially taken from this road. The majority of the cores were in intact conditions, as shown in Figure 2a and b. These cores were stored in an indoor environment for about one year before being tested for Indirect Tensile Stiffness Modulus (ITSM), Indirect Tensile Fatigue (IDF), binder extraction and size extraction chromatograph (SEC, or Gel Permeation Chromatography, GPC), and dynamic modulus test using Simple Performance Tester (SPT). In performing the tests, we found that the cores exhibit much greater stiffness than todays' asphalt mixtures that use the same mix design. In addition, we found that the proportion of large molecules in RB is greater than that in BC or WC. It appears that age hardening has a great impact on the conditions of the 36 year old samples. To avoid the possible impact of further aging in air on the bottom of the cores, which might have been always exposed in a low oxygen environment in the field, a second batch of six cores were taken from the road (Fig. 2c). Meticulous efforts were taken to reduce the chance of the samples to further contact air during sample preparation and binder extraction. The analysis below is primarily based on four samples from the second batch of cores.

2.2 *Bitumen sample preparation*

Immediately after the 250 mm cores were taken from the road, they were placed in glass jars that were subsequently filled with nitrogen gas and sealed to preclude further contact with air (Fig. 3c). These cores were then cut into six slices, including the OGFC layer, WC, BC, and

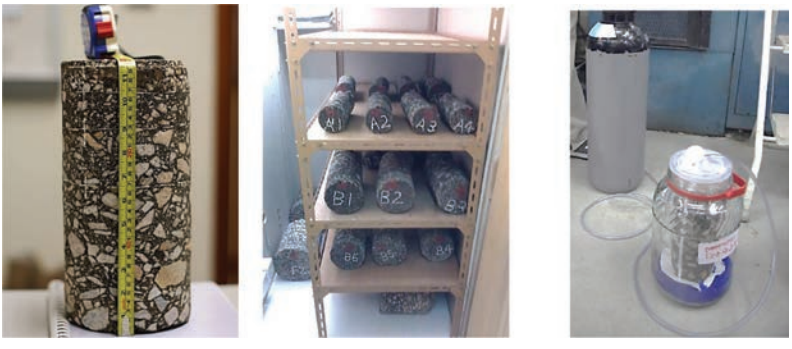

Figure 2. Photos of samples cores used in this study. 2a. Conditions of cores. 2b. Cores stored in the lab. 2c. Core stored in a glass jar filled with nitrogen.

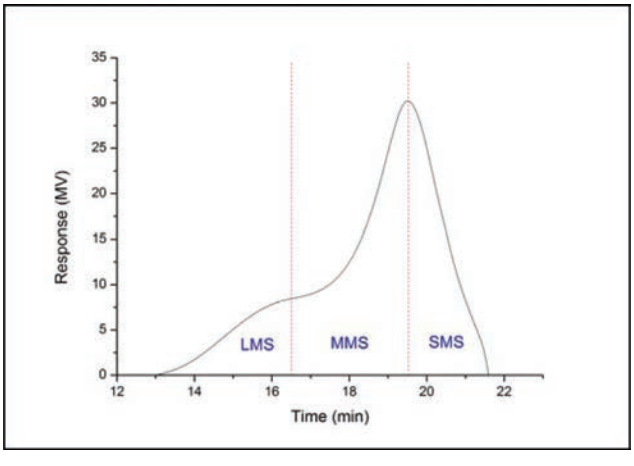

Figure 3. Typical GPC chromatogram.

three slices of RB. The OGFC slice was not used for further analysis. The separated cores were placed back into the glass jars with silica gel to absorb residual water used in the cutting process, refilled with nitrogen, tightly sealed, and stored in an air-conditioned environment.

After the majority of water from the sliced cores was removed (by observing the color change of silicon gels), they were taken out from the glass jars and broken into small pieces by hammer. Bitumen from these small pieces of samples was extracted by using an extraction unit bowl according to the ASTM standard D2171/D2172M-11. The solvent used for extraction was dichloromethane. To ensure that the fine particles were thoroughly removed, the extracted bitumen solution was further clarified in a sample tube centrifuge machine according to the European Standard EN 12697-3:2005. During the centrifuging process, a small amount of silica gel passing a 0.063 mm sieve was added to the solution to further remove the residual water. Asphalt binder was recovered from the clarified solution by using a rotary evaporator by following the European Standard EN 12697-3:2005. To ensure that the solvent was thoroughly removed during the rotary evaporation, the extracted bitumen was examined by Fourier Transform Infrared Spectroscopy (FTIR). A lack of peak at the infrared band of 1265 cm^{-1} in the FTIR spectrum indicates the total evaporation of the solvent. After the bitumen was recovered from the rotary evaporation, it was stored in a jar, refilled with nitrogen, and placed in refrigerator for further analysis.

2.3 *Test methods*

The focus of this study was to test and evaluate the extent of aging of asphalt binder extracted at different depth of the asphalt pavement. The chemical components of these specimens were analyzed by using the Attenuated Total Refraction (ATR) mode of FTIR and GPC. The rheological properties of the specimens were tested by using a Dynamic Shear Rheometer (DSR). FTIR and GPC testes were tested on four groups, each including three slices of RB, BC and WC, whereas DSR tests were performed on one group of the specimens.

In measuring FTIR spectra, scanning was performed in the middle infrared region (MIR, 400–4000 cm^{-1}). Duplicate measurements were conducted on each binder specimen to ensure the consistency of the measurements. However, only one spectrum was chosen from each specimen for further analysis because the duplicate measurements match each other very well.

Waters GPC equipment with 1515 isocratic HPLC pump and 2414 refractometer detector was used in the study for chromatographic analysis. A series of two columns (Styragel Column, HR3, 5 μm, 7.8 mm × 300 mm; Styragel Column, HR4, 5 μm, 7.8 mm × 300 mm) were used for detecting the molecular weight of 1000 to 500000. The mobile phase was tetrahydrofuran (THF) and the flow rate was maintained at 1 ml/min. About 100 mg samples was dissolved into 10 ml THF at room temperature and filtered through a 0.22 m membrane prior to injection. Each sample of 25 μl was injected into the system. The test took twenty-five minutes to complete and each test was repeated twice.

DSR tests were conducted under the controlled stress model and the strain levels were chosen to be in the linear viscoelastic range (0.05% at 40 °C or lower and 0.1% at 46 °C or higher). Both 8 mm plate with 2 mm gap, 25 mm plate with 1 mm gap, and 25 mm plate with 0.5 mm gap were attempted. The data used for constructing master curves was obtained by using the 8 mm plate with 2 mm gap. The temperature of the tests ranges from 10 °C to 70 °C with an equal increase of 12 °C, and frequency ranges from 0.1 Hz to 30 Hz. Due to the size limit of the paper, the master curves are not presented.

3 RESULTS AND DISCUSSION

3.1 *GPC test results*

A typical chromatogram of the extracted asphalt binder is illustrated in Figure 3. The chromatograms are equally divided into 13 slices according to the retention time [12]. The slices from 1 to 5 correspond to asphalt constituents of Large Molecular Size (LMS), the slices

from 6 to 9 correspond to Medium Molecular Size (MMS), and slices from 10 to 13 correspond to small molecular size [12]. It was concluded by several studies that the proportions of LMS correlate with the extent of aging of the binders [13–15].

The percent areas of the chromatograms corresponding to the LMS, MMS, and SMS of the different samples are calculated and shown in Table 1. The percentages reveal the relative proportions of molecules of different sizes.

The paired t-test was used to compare the average difference between the asphalt binder extracted from RB3 and that from BC and RB1. Pairwise comparisons were made for binders extracted from the same core. The test results are shown in Table 2. The results show that, on average, that the bottom lifts have a higher percentage of large molecules. However, the test results are not statistically significant. There is no strong evidence that asphalts in BC or RB1 were aged less than that in RB3.

3.2 *Analysis of FTIR spectra*

Infrared spectrometry has been widely used to study asphalt oxidation [e.g., 16–19]. The carbonyl functional group (C = O) is shown to be the major product of asphalt oxidation [16–19]. For the same asphalt, carbonyl content grows linearly with oxygen uptake, although the growth rate may vary between different asphalt [20]. A commonly used indicator of oxidative

C6	RB2	18.4	48.7	32.9
C6	RB3	16.4	51.6	31.9

Table 2. The results of paired-t test between RB3 and the other two middle layers.

Difference	Average difference	Std. dev.	t-value	p-value (tail)
RB3-BC	1.45	1.841195	1.5751	>0.05
RB3-RB1	0.967	1.5275	1.0961	>0.05

aging is the "carbonyl area," which is the integrated area under the absorbance peaks of IR spectrum from 1650 cm^{-1} to1820 cm^{-1}. Two indexes were used in this study to characterize the extent of oxidative aging based on FTIR results: the ratio between the absorbance peak height at about 1695 cm^{-1} (C = O band) to that at about 1455 cm^{-1} (saturated C-C band) [21] and the ratio between absorbance peak areas at these two peaks, as illustrated in Figure 4.

The ratios between the absorbance peak height at about 1695 cm^{-1} and that at about 1455 cm^{-1} and the ratios between absorbance peak areas at these two peaks were calculated and shown in Figure 5 and Figure 6, respectively.

Several observations can be made from Figures 5 and 6: 1) the oxidative aging of the asphalt in WC is the least severe, 2) the oxidative aging of asphalt in BC appears to be less severe than those in RB lifts, 3) the absorbance peak height ratios and peak area ratios are generally consistent. The paired-t tests of the absorbance peak area ratios are shown in Table 3.

Table 3 shows that there are no statistically significant differences in FTIR absorbance peak area ratios between the bottom lift and the BC layer, but the difference between the

Table 4. DSR parameters used to calculate DSR function and ductility.

Lift	δ	G* (MPa)	G′ (MPa)	η′ (MPa)	DSR func. (MPa)	Derived duc. (cm)
WC	59.66	693600	350378	59860	0.00102544	4.75
BC	44.63	1009747	718639	70933	0.00364036	2.72
RB1	36.43	2833500	2279879	168252	0.01544660	1.44
RB2	38.69	1829833	1428275	114382	0.00891736	1.83
RB3	38.86	1601588	1247127	100487	0.00773897	1.95

bottom lift (RB3) and top lift (RB1) of the same RB layer is significant. It appears that the asphalt at the top of the RB layer aged more.

3.3 *Reological properties of recovered binder*

The recovered binders from one of the samples (sample no. C5) were tested for reological properties by a DSR. It has been long recognized that the durability of asphalt binder is well related to its ductility, particular ductility at the temperature level of about 15 °C and with an elongation rate of 1 cm/min [22–24]. Ruan et al. [25] found that if an asphalt binder's ductility is less than 10 cm, the ductility tested at the above temperature and loading condition correlates well to a rheological parameter G′/(η′/G′), namely DSR function. The η′ and G′ are measured at 44.7 °C and 10 rad/s using a DSR and are converted to those at 15 °C and 0.005 rad/s. It is further recommended the use of ductility of about 3 cm at 15 °C, 1 cm/min (with DSR function value > 0.003 MPa/s) as the threshold for binder failure and ductility of 5 cm under the same condition (DSR function value > 0.0009 MPa/s) as the threshold for pavement cracking [25]. The DSR function values, estimated ductility, and

other relevant parameters for sample C5 are calculated and shown in Table 4. The data show that the derived ductility values at 15 °C and 1 cm/min of all the RB binders have reached "failure" status, whereas the ductility of the WC binder researches to a "critical" condition. The data indicates that binders in the three lifts of the RB are all severely aged, and extent of aging is slightly higher than that in BC.

4 SUMMARY AND CONCLUSION

Four sample cores were taken from wheelpath and non-wheelpath of one of the most heavily trafficked roads in HK that have served for 36 years without reconstruction or rehabilitation. Each sample was cut into different slices to study the variation of binder aging along the pavement depth. Meticulous efforts were taken to prevent further aging of asphalt binder during coring, storage, and binder extraction. The extracted binders were tested by GPC, FTIR, and DSR. The GPC test results show that the percentage of large molecules of the asphalts in the bottom of RB layer and in the BC layer is not significantly different. The absorbance peak height ratios between the C = O and C–C band, however, show that the asphalt in the bottom lift of the RB layer aged more than that in the top lift of the RB layer. DSR tests on one of the samples show that the derived ductility values of the three binders from RB are lower than that from BC, which is lower than that from WC. This implies that the extent of aging does not necessarily decrease with pavement depth. These results indicate that oxidative aging penetrates deep into the long-life AC layers. More samples are needed in the future to make a more decisive conclusion. In addition, a further investigation of the factors affecting the aging variations may assist the improvement of design, construction, and maintenance practices to prevent the detrimental effects of oxidative aging shortening the longevity of the long-life asphalt pavement.

ABSTRACT: The Kansas Department of Transportation (KDOT) instrumented four perpetual pavement sections with stress and strain gauges to investigate the suitability of perpetual pavement concept. Pavement response measurements under known vehicle load at three different speeds were performed on seven occasions. Falling-Weight Deflectometer (FWD) first-sensor (center) deflections were normalized and corrected to 20 °C temperature based on measured mid-depth pavement temperature. FWD deflection data were also used to back-calculate layer moduli. Dynamic modulus tests were done in the laboratory. The results show no clear trend of an increase or a decrease in stress, strain, center deflection, and back-calculated AC layer modulus with time at the early age. There is a decrease in stress and strain with an increase in traffic speed. A change in speed from 64 km/h to 32 km/h has a higher impact on the stress and strain than a change in speed from 96 km/h to 64 km/h for thicker sections and vice versa for thinner section. The assumed endurance limit of 70 microstrain was exceeded in the thinnest section. The effect of high temperature on stress and strain is more pronounced at the lower traffic speed and on the thinner section. Laboratory dynamic modulus is higher than the back-calculated modulus.

Keywords: mechanistic responses; perpetual pavement; FWD deflection; back-calculated modulus; dynamic modulus; endurance limit

1 INTRODUCTION

Increasing traffic volumes and heavy vehicle loads have led to the accelerated wear of pavement structures resulting in increased maintenance and rehabilitation expenditures. These trends, along with the desire for a longer lasting transportation infrastructure, have resulted in the need for extending asphalt pavement life from 20 to 50 years or more. The asphalt paving industry responded to this need by introducing the concept of perpetual pavements, which has been gaining momentum nationally and internationally (1). Perpetual pavement concept leads to pavement structures that crack only at the surface, and would need repair only at the surface. This failure mode leads to a significant monetary savings for the repair, rehabilitation, and reconstruction of these pavements (2).

Structural capacities of flexible pavements are determined from surface deflection measurements. Measured deflections by Falling-Weight Deflectometer (FWD) must be corrected to a standard load and to a predefined environmental condition. The most critical environmental factor affecting deflections in flexible pavements is the temperature of the Asphalt Concrete (AC) layer (3–5). Thus pavement deflection data must be adjusted to a reference temperature (6).

The main objective of the study was to investigate the mechanistic responses i.e. stresses, strains, and surface deflections of the perpetual pavement sections in Kansas.

2 TEST SECTIONS

The Kansas Department of Transportation (KDOT) developed a field trial to investigate the suitability of perpetual pavement concept for Kansas highway pavements. The experiment involved design and construction of four thick pavement structures on a new alignment of US-75 near Sabetha, Kansas. The design layer thicknesses were close to those recommended by the KDOT's structural design method for flexible pavements based on the 1993 American Association of State Highway and Transportation Officials (AASHTO) Pavement Design Guide (7). The Kansas Asphalt Pavement Association (KAPA) provided the thickness designs for Sections 1, 2, and 3. Section 4 was designed by KDOT. Sections 1 and 3 have the same thickness, but a softer binder was used in the base asphalt mix (PG 64-22 instead of PG 70-22), and a richer and more ductile Superpave Mix (SM) was used in the bottom lift of the base layer for Section 3. Section 2 is the thinnest section (total HMA thickness of 288 mm). Table 1 shows the pavement structures (2).

The test sections were constructed on a fill and each is approximately 390 m long with approximately 150 m transition zones in between them. The embankment on all four pavement sections was brought to grade and the top 150 mm of the soil were stabilized with 6% hydrated lime (by weight). The project was completed and the sections were opened to traffic at the beginning of November 2005 (8). The sections carried about 850,000 Equivalent Single Axle Load (ESAL) until summer 2013.

To verify the approach of designing perpetual pavements based on an endurance strain limit, all four pavements were instrumented with gauges for measuring tensile strains at the bottom of the asphalt base layers. A Geokon stress cell was also placed at the center of the outside wheel path to measure the stress at the top of the lime-treated subgrade (8).

3 DATA COLLECTION

3.1 *Stress and strain*

Pavement response measurements under known vehicle load were performed on seven occasions between July 2005 and October 2007, before and after the pavement sections were opened to traffic. In each occasion, the same single-axle dump truck owned by KDOT was used as the loading vehicle. According to the Federal Highway Administration (FHWA) vehicle classification system, this truck is a class 5 vehicle. On each section, three sets of five

5/1/2007	21.9	21.7	22.3	21.8

Note: Measurements were not performed on Section 3 on 8/1/2006.

passes of the loading vehicle were performed. Five passes each were performed with the truck passing at about 32 km/h (20 mph), 64 km/h (40 mph) and 96 km/h (60 mph), in order to determine the effect of vehicle speed on the pavement responses (8).

3.2 *Pavement temperature and deflection*

The thermocouple of a temperature gauge was lowered in the holes drilled in the Hot-Mix Asphalt (HMA) layers and filled with oil to measure the temperature at the mid-depth of each HMA layer. Oil was used as the heat transfer fluid to prevent evaporative cooling and freezing. Table 2 shows weighted average of measured mid-depth pavement temperature for each section. For all sessions, the temperature in the surface layers was the lowest in Section 1 and highest in Section 4. This happened since the response measurements were done on Sections 1 and 2 in the morning, on Section 3 around noon, and on Section 4 in the early afternoon (2).

FWD deflection data were collected at 15 m (50 ft) intervals. Measured mid-depth temperature was used to correct normalized FWD first-sensor (center) deflection data and back-calculated moduli to a standard temperature of 20°C (68°F).

4 DATA ANALYSIS

4.1 *Center deflection temperature correction*

Chen *et al.* (6) developed a universal temperature-correction equation for deflection of flexible pavements in Texas using an optimization technique based on the concept of minimum least-square difference between the target values and the predicted results. Eq. (1) has been used to correct normalized center deflection to 20°C temperature in this study.

$$W^1_{T_w} = W^1_{T_c}\left(\frac{1.0823^{-0.0098\times t}}{0.8631}\right) \times T_w^{0.8316} \times T_d^{-0.8419} \quad (1)$$

where $W^1_{T_w}$ = deflection adjusted to temperature T_w (mm); $W^1_{T_c}$ = deflection measured in the field (mm); t = thickness of the pavement (mm); T_d = mid-depth pavement temperature at time of FWD data collection (°C); and T_w = temperature to which deflection is adjusted (°C).

4.2 *Back-calculated modulus temperature correction*

Back-calculation was done using multilayered linear-elastic theory. The moduli of thin surface layers or layers "sandwiched" between the layers are usually difficult to obtain since surface deflections are often insensitive to changes in these layer moduli (9). In this study, all pavement sections were modeled as three-layer systems by combining all HMA layers into

one layer. EVERCALC was used to back-calculate layer moduli (10). It uses an iterative approach to find a set of moduli that would provide a calculated deflection basin closest to the measured deflection basin as characterized by the Root-Mean-Square (RMS) error (11).

Chen *et al.* (6) has developed Eq. (2) based on deflections from intact locations. Eq. (2) has been used to correct back-calculated modulus to 20 °C based on measured mid-depth pavement temperature.

$$E_{T_W} = \frac{E_{T_C}}{\left[\left(1.8T_W + 32\right)^{2.4462} \times \left(1.8T_C + 32\right)^{-2.4462}\right]} \quad (2)$$

where E_{T_W} = adjusted modulus of elasticity at T_W (MPa); E_{T_C} = measured modulus of elasticity at T_C (MPa); T_W = temperature to which the modulus of elasticity is adjusted (°C); and T_C = mid-depth temperature at the time of FWD data collection (°C).

4.3 *Laboratory dynamic modulus test*

Dynamic modulus samples were prepared from the mixtures mixed in the laboratory and compacted by the Superpave Gyratory Compactor (SGC). The 150-mm-diameter SGC-compacted samples were then cored in the laboratory to get 100-mm-diameter dynamic modulus test samples. Dynamic modulus tests were conducted using a Universal Testing Machine (UTM-25). Details have been published somewhere else (12).

5 RESULTS AND DISCUSSIONS

Because of installation issues, the strain results showed some inconsistency in Section 3. Thus, data from Section 3 were not used in this study.

5.1 *Stress and strains*

Stress and strain data from all seven measurement sessions have been analyzed in this study. The first two measurements were made before the sections were opened to traffic. All stress and strain data were corrected to 20 °C based on measured mid-depth pavement temperature. The result showed a decrease in stress and strain with an increase in traffic speed. The result also showed no clear trend as to whether there is an increase or a decrease in stress and strain with time. This may be due to the short time span over which data were collected.

Percent decrease in average stress on the top of subgrade, average longitudinal and transverse strain at the bottom of HMA due to an increase in speed from 32 km/h to 64 km/h and 64 km/h to 96 km/h, respectively, has been calculated. The results showed that a change in speed from 64 km/h to 32 km/h has a higher impact on the stress and strain than a change in speed from 96 km/h to 64 km/h for thicker sections (Sections 1 and 4) and vice versa for thinner section (Section 2). The results were not included for brevity.

The effect of traffic speed, offset (lateral wander), and age on stress and strain has been investigated in greater detail by using scatter plots. Results from Section 1 were not included for brevity.

5.1.1 *Stress on the top of subgrade*

Figure 1 shows stress on the top of lime-treated subgrade for Section 2. Sessions 3 and 5 data show consistency whereas session 6 shows more variation at all speeds. Offset (lateral wander) does not have significant effect on the magnitude of the stress. It is not clear whether there is an increase or a decrease in stress on the top of subgrade with time.

Figure 2 shows the stresses at the top of lime-treated subgrade for Section 4. Data from Sessions 3 and 5 are consistent and they are the smallest in magnitude. In general, data from Sessions 1 and 2 show more variation and higher in magnitude. It should be noted that

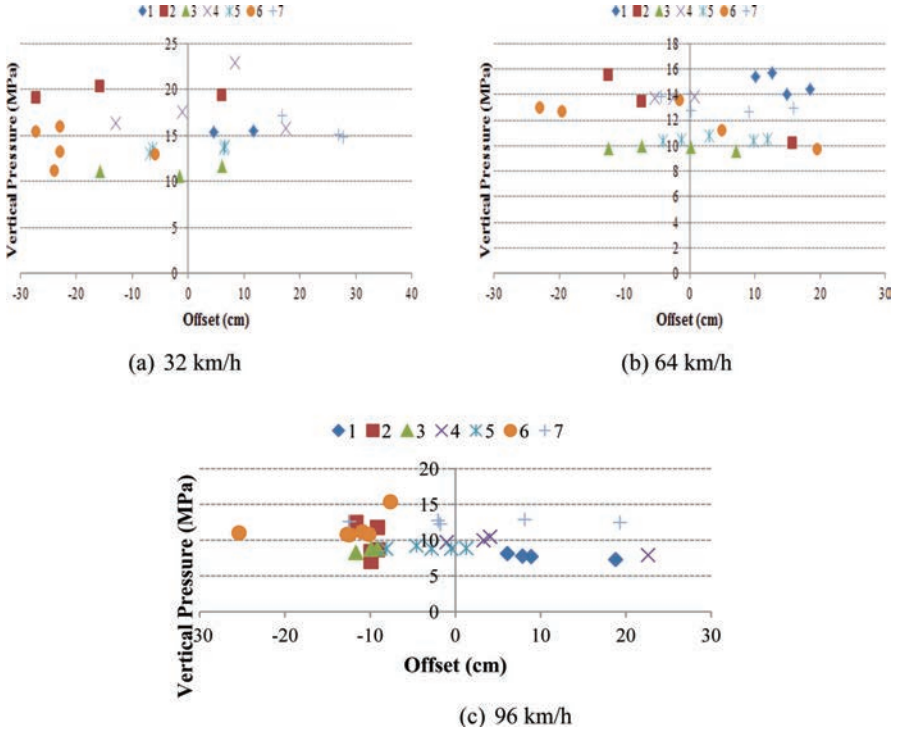

Figure 1. Vertical stresses on the top of subgrade during different sessions in section 2.
Note: 1 = 7/14/05; 2 = 9/29/05; 3 = 4/13/06; 4 = 8/1/06; 5 = 10/13/06; 6 = 5/1/07; and 7 = 10/5/07.

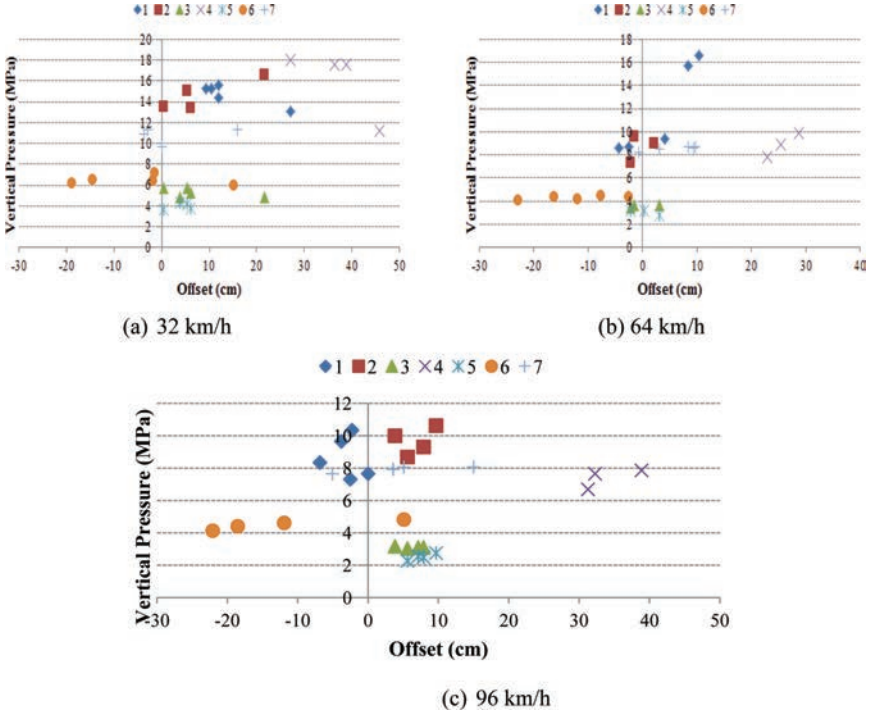

Figure 2. Vertical stresses at the top of subgrade during different sessions in section 4.

Sessions 1 and 2 were conducted before the section was open to traffic. Offset (lateral wander) does not have significant effect on stress magnitude. It is not clear whether there is an increase or a decrease in stress at the top of lime-treated subgrade with time.

5.1.2 *Longitudinal strain*

Figure 3 shows longitudinal strain at the bottom of HMA for Section 2. Longitudinal strain data were not collected at 32 km/h during session 2. Most data were collected at negative offset (lateral wander). Session 1 data show the highest variation at 64 km/h and 96 km/h speeds whereas session 4 data show the highest variation at 32 km/h speed. Session 4 data show the highest longitudinal strain at 32 km/h and two of the readings are greater than the endurance limit of 70 microstrain. This may be due to high pavement temperature during this session and the thinness of the section. Temperature effect may be more pronounced at lower traffic speed. Data from all sessions are consistent at 64 km/h and 96 km/h except Session 1 data. Offset (lateral wander) does not have significant effect on the magnitude of the strain. It is not clear whether there is an increase or a decrease in longitudinal strain at the bottom of HMA with time.

Figure 4 shows longitudinal strain at the bottom of HMA for Section 4. Most of the data were collected at negative offset (lateral wander). Session 1 data show the highest variation at 64 km/h. Session 4 data are on the higher side at 32 km/h and on the lower side at 64 km/h and 96 km/h. High temperature effect may be more pronounced at lower traffic speed. There is

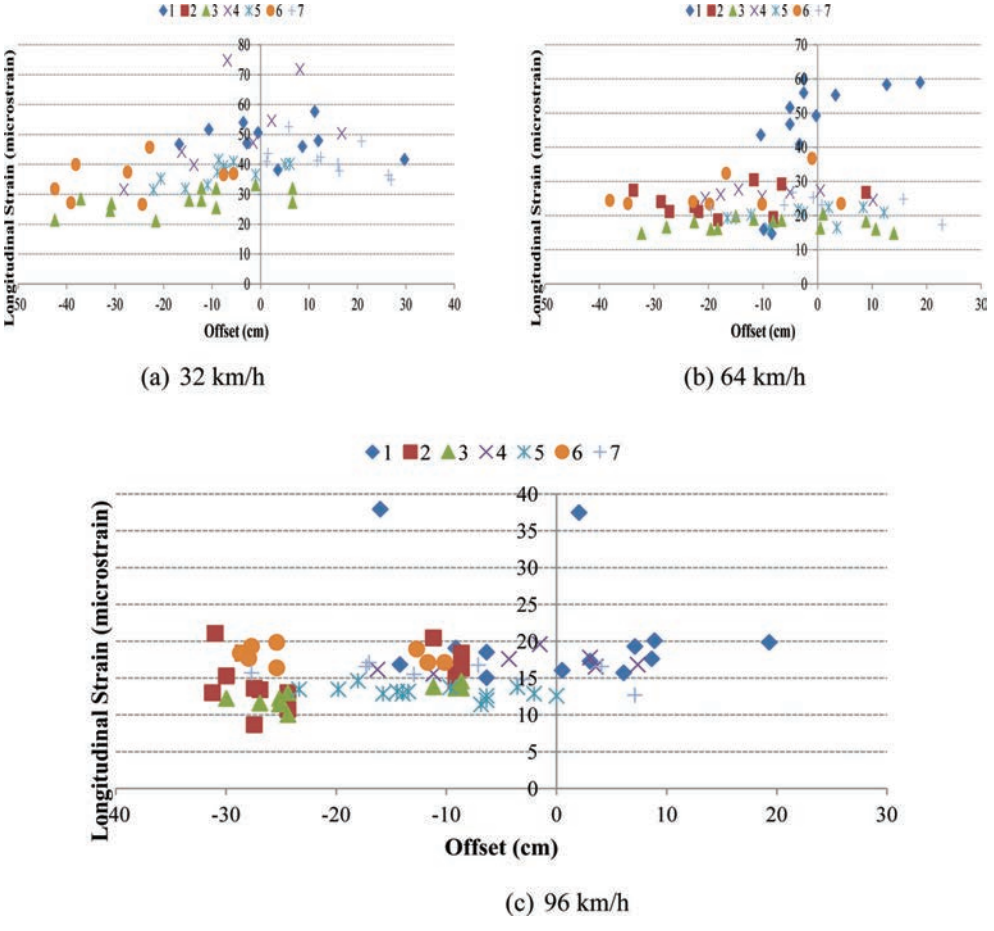

Figure 3. Longitudinal strains at the bottom of HMA during different sessions in section 2.

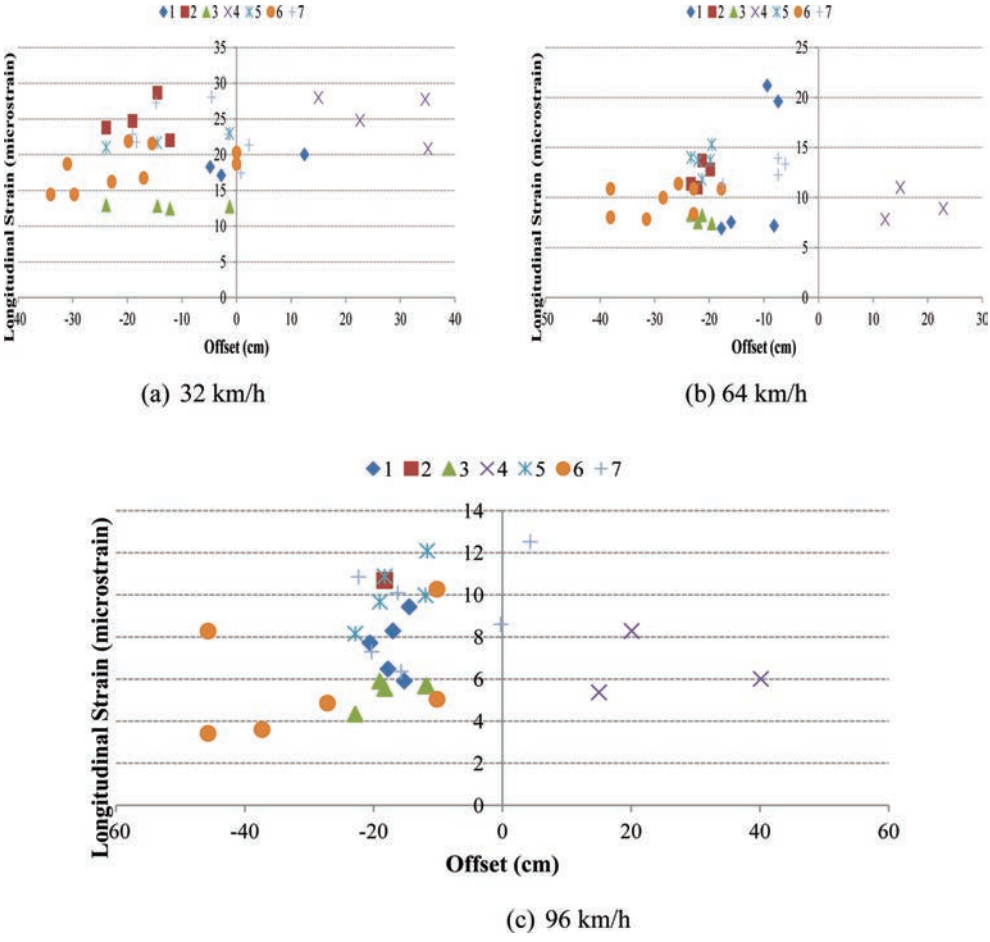

Figure 4. Longitudinal strains at the bottom of HMA during different sessions in section 4.

more variation in Section 4 at 64 km/h and 96 km/h as compared to other sections. This may be due to high pavement temperature in Section 4 during all sessions. Offset (lateral wander) does not have significant effect on the magnitude of the strain. It is not clear whether there is an increase or a decrease in longitudinal strain at the bottom of HMA with time.

5.1.3 *Transverse strain*

Figure 5 shows transverse strain at the bottom of HMA for Section 2. Transverse strain data were not collected at 32 km/h during session 2. A significant number of transverse strain readings show values greater than an endurance limit of 70 microstrain. This may be due to the thickness of the section, which is the thinnest. Transverse strain during session 4 is on the higher side at 32 km/h and on the lower side at 96 km/h. High temperature effect may be more pronounced at lower traffic speed. There is an increase in transverse strain due to temperature and age in general. Offset (lateral wander) does not have significant effect on the magnitude of the strain.

Figure 6 shows transverse strain at the bottom of HMA for Section 4. All readings are less than the endurance limit even though Section 4 was tested at higher temperature than Section 2 during all sessions. This clearly shows the effect of pavement thickness on strain. Transverse strain during session 4 is not the highest though the data were taken at the highest temperature. This shows pavement temperature has more pronounced effect on strains for thinner sections. Transverse strains before the section was opened to traffic are higher at all temperatures.

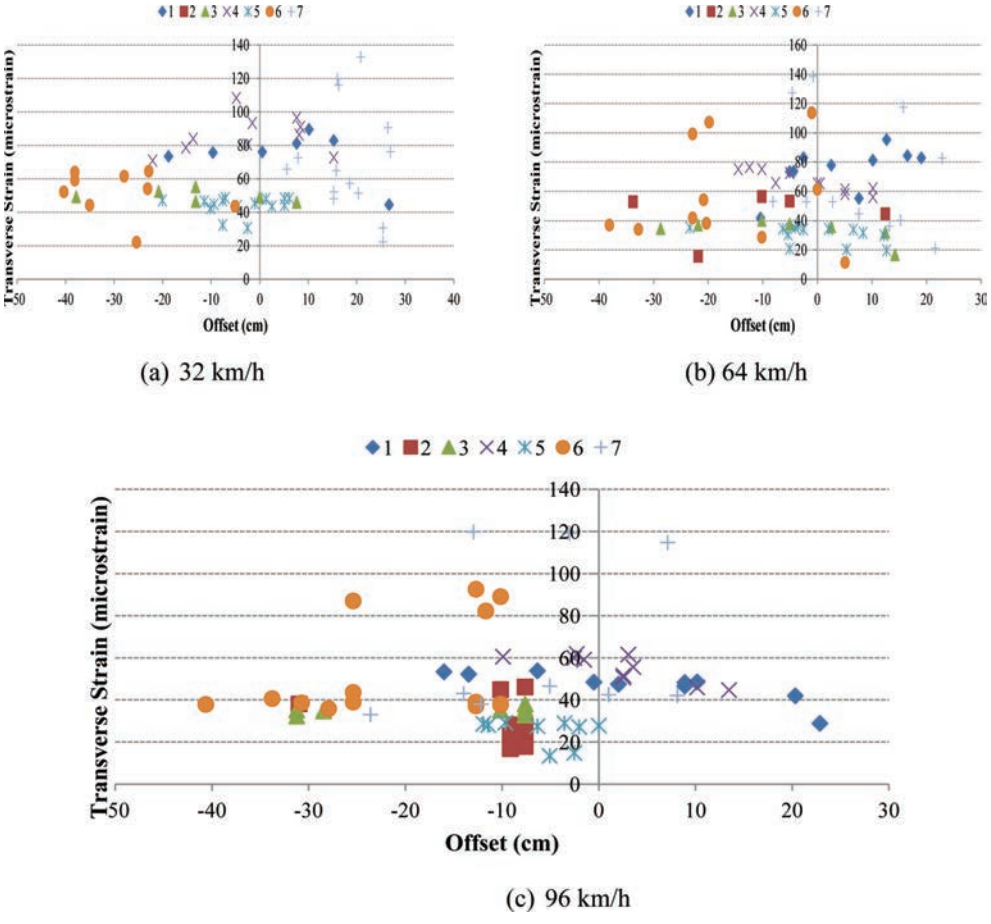

Figure 5. Transverse strains at the bottom of HMA during different sessions in section 2.

5.2 *Center deflection and back-calculated asphalt modulus*

FWD deflection data were not collected during session 1. FWD deflection data were collected on different dates than stress, strain, and pavement temperature data during session 6. As a result, FWD deflection data from only five sessions were analyzed. Center deflection data from Station 1 of Section 1 were normalized to a 40-kN load and then corrected to 20 °C using Eq. (1) based on measured mid-depth pavement temperature in Table 2. Table 3(a) shows the center deflection and biases. As shown in Table 2, mid-depth pavement temperature was the lowest and highest in October 2006 and August 2006, respectively. Center deflections from the two sessions are the first and second highest. This shows that both very low and very high temperature have significant impact on center deflection of the pavement. Biases were calculated using the first center deflection as a reference. The bias varies from –25.6 to 26.0 micron and –21.3% to 21.7%. There is no clear trend whether there is an increase or a decrease in center deflection with time.

EVERCALC was used to back-calculate layer moduli. Eq. (2) was used to correct back-calculated asphalt modulus to 0 °C based on the measured mid-depth pavement temperature in Table 2. Table 3(b) shows the biases calculated using laboratory dynamic modulus at 20 °C and 25 Hz as a reference. Frequency of 25 Hz was selected as a reference since it is the closest to the frequency of FWD deflection measurement and it is reasonable to compare measured and back-calculated moduli at this frequency. Bias varies from –50.6%

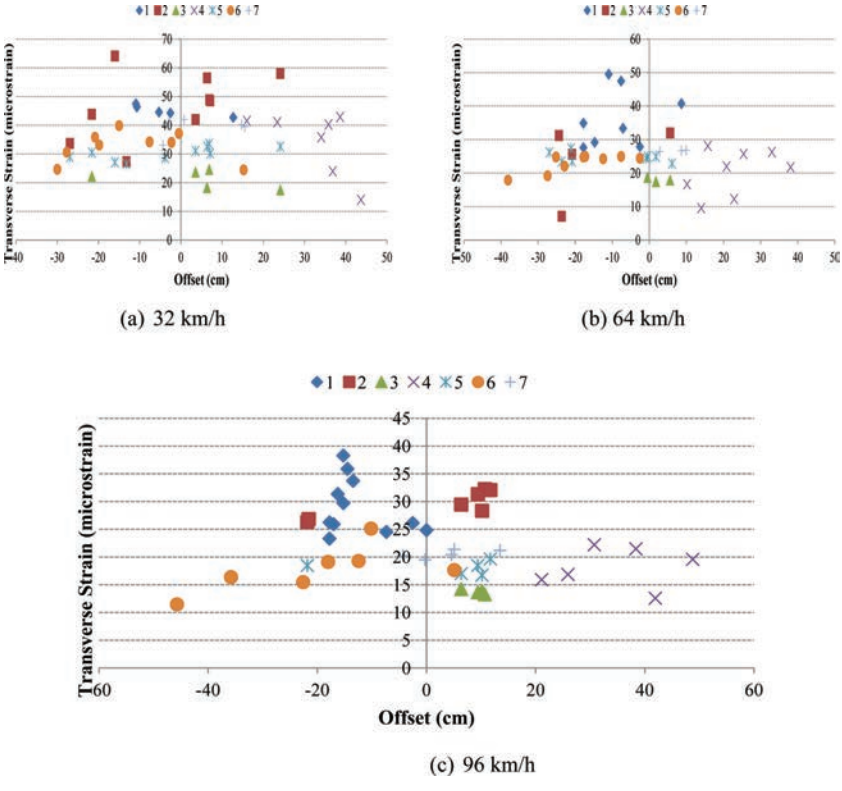

Figure 6. Transverse strains at the bottom of HMA during different sessions in section 4.

Table 3. Effect of aging on center deflection and back-calculated modulus.

Variable	FWD deflection data collection date				
	9/29/2005	4/13/2006	8/1/2006	10/13/2006	10/5/2007
(a) Center deflection					
d_0 (μm)	120.1	107.0	126.8	146.1	94.5
Bias (μm)	–	–13.1	6.7	26.0	–25.6
Bias (%)	–	–10.9	5.6	21.7	–21.3
(b) Back-calculated modulus relative to measured dynamic modulus of 9513.5 MPa					
Modulus (MPa)	6547.9	5990.3	4843.8	4703.8	7618.7
Bias (MPa)	–2965.3	–3523.0	–4669.4	–4809.4	–1894.6
Bias (%)	–31.2	–37.0	–49.1	–50.6	–19.9
(c) Back-calculated modulus relative to session 1 modulus of 6547.9 MPa					
Modulus (MPa)	6547.9	5990.3	4843.8	4703.8	7618.7
Bias (MPa)	–	–557.6	–1704.1	–1844.1	1070.7
Bias (%)	–	–8.5	–26.0	–28.2	16.4

to –19.9%. This shows that the laboratory dynamic modulus is higher than the back-calculated moduli.

Table 3(c) shows biases calculated relative to the first back-calculated modulus. The percent bias varies from –28.2 to 16.4. Back-calculated modulus is the largest for the last data collection session. This can be due to asphalt concrete hardening due to aging and/or other factors such as test temperature.

6 CONCLUSIONS

Based on this study, the following conclusions can be made:

- There is no clear trend whether there is an increase or a decrease in stress, strain, surface deflection, and back-calculated modulus with age for Kansas perpetual pavement test sections. This may be due to the short time span of data collection (two years) from the first to the last session.
- There is a decrease in stress and strain with an increase in traffic speed.
- A change in speed from 64 km/h to 32 km/h has a higher impact on the stress and strain than a change in speed from 96 km/h to 64 km/h for thicker sections and vice versa for thinner section.
- Endurance limit of 70 microstrain was exceeded in the thinnest section (288 mm total HMA thickness), which carried about 850,000 ESALs so far.
- The effect of high temperature on stress and strain is more pronounced at lower traffic speed and on the thinner section.
- Both very low and very high temperatures have significant impact on the center deflection.
- Laboratory dynamic modulus is higher than the back-calculated modulus.

ABSTRACT: Research carried out between 2001 and 2007 identified that: (i) there were likely to be economic benefits from development of road surfacing materials with a service life in excess of 30 years (Long Life Surfacing), and; (ii) laboratory and accelerated load testing of two materials (Epoxy Asphalt and High Performance Cementitious Materials) with the potential to fulfil these requirements could be successfully laid in pilot scale trials and performance verification tests satisfied the target (high) performance for the design mixtures.

This paper describes the planning, executing and monitoring of a full scale trial of Epoxy Asphalt in the UK, to demonstrate that the performance envisaged from the laboratory and accelerated testing would hold true within the period of the trial under real traffic and environmental conditions. Additional aims included to develop construction methods, optimise mixtures and increase contractor experience levels.

The trial was successfully completed and has now been monitored for one year. The target service life is at least twice as long as that typically expected from surfacings generally used in road pavements and involves higher initial expense, but aims to avoid major maintenance costs over the lifetime of the pavement, generate overall savings and be environmentally more sustainable.

Keywords: asphalt modifiers; field performance; innovation; perpetual pavements; sustainability

1 INTRODUCTION

In recent years, road pavements in developed countries have been subject to massively increased traffic loading, to a level that may compromise the longevity and serviceability of the pavement. In addition, other issues such as traffic congestion, road user charging, whole life cost and sustainable construction have placed greater pressure on road administrators to provide users with more robust road networks, with a reduced maintenance frequency and less interruption to traffic. In this context, 'Long Life Pavements', with a prolonged service life, are seen as particularly desirable for heavily trafficked roads and have been shown to be achievable for the subsurface layers. However, the surface layer or wearing course, which is critical for safe and comfortable driving, remains the Achilles' heel of the concept.

Against this background, since 2001, the UK has been involved in a joint research project on Economic Evaluation of Long Life Pavements, in collaboration with a number of national institutions under the umbrella of the Organisation for Economic Co-operation and

Development/European Conference of Ministers of Transport (OECD/ECMT). Phase I of this project, carried out between 2001–2003, identified that there were likely to be economic benefits from development of road surfacing materials with a service life in excess of 30 years (Long Life Surfacing), [1]. Phase II of the project (now called Long Life Surfaces for Busy Roads and prepared under the aegis of the Joint OECD/ITF (International Transport Forum) Transport Research Centre), carried out between 2004 and 2007, comprised laboratory and accelerated load testing of two materials (Epoxy Asphalt and High Performance Cementitious Materials) identified as having the potential to fulfil the requirement of Phase I [2]. The present paper summarises the work done in the United Kingdom in Phase III of the project; to plan, execute and monitor full scale trials of the optimum epoxy asphalt mixture design formulation that had been developed in earlier stages of the project. Specifically, monitoring results up to 12 months are provided from a field trial completed on the A390 Trunk Road in the South West of England.

2 EPOXY ASHPALT

Epoxy asphalt surfacing systems are not new; they have been used on a number of major bridges around the world. Excellent performance has been recorded, most notably on the San Mateo-Hayward Bridge, where epoxy asphalt surfacing has been in service for more than 45 years without failure [3]. Due to its superior resistance to aircaft fuel and jet-blast, the material has also been used on a number of military airfields in the USA [4]. Prior to the current project, the main use of epoxy asphalt in the UK in recent times had been on a limited number of steel bridge decks (Erskine and Humber), where the design was based on Hot Rolled Asphalt. To the authors' knowledge, epoxy asphalt surface course has not been used to any significant degree for highway surfacing. However, as part of the current project, successful trials of epoxy modified Open Graded Porous Asphalt were carried out on State Highway 1 in Christchurch, New Zealand in 2007 [5].

Due in large part to its thermosetting nature, past experience suggests that epoxy asphalt production has to be carefully controlled in order to optimise the curing profile for the local conditions, and to ensure satisfactory production, transport, laying and compaction. Furthermore, this material also requires a sound (stiff) substrate and good weather during construction.

The mixture design developed for this project was based on a generic surface course system that is widely used for the surfacing of major road networks around the world, namely Stone Mastic Asphalt (SMA). Essentially, the design of the epoxy asphalt SMA material was similar to that of conventional SMA, with the subsititution of a slightly increased quantity of the epoxy binder components, in place of the standard binder. Full details have been reported elsewhere [2, 6, 7].

3 OBJECTIVES AND SCOPE OF PHASE III TRIALS

The overall objective of the field trials was to demonstrate that the performance envisaged from the laboratory and accelerated testing would hold true within the period of the trial under real traffic and environmental conditions. Additional aims were to develop construction methods, optimise mixtures, and increase contractor experience levels.

In the UK, the Highways Agency (HA), an executive agency of the Department of Transport with responsibility for operating, maintaining and improving the Strategic Road Network in England, provided support to Scott Wilson (now URS) to assist in the organisation of the full scale epoxy asphalt trial. The scope of the support also encompassed monitoring performance over time, and relevant in situ and laboratory tests, the latter on cores extracted from the trial section.

It was intended that the epoxy asphalt would be laid as a 30 mm or 40 mm thick SMA surface course as a like-for-like and cost neutral replacement for the originally specified material;

the benefit to the road owner permitting the trial was that its life would be expected to be at least as long as that of the traditional material. The Phase I study identified an expected life for conventional SMA surface course ranging from 5 to 15 years, depending particularly on incidence of studded tyre use and level of traffic. 10 years was selected as the average expected life to be used for the economic evaluation [1], although it should be noted that EAPA quotes lives ranging from 16 to 25 years where SMA is used on secondary roads [8].

Mixture designs had been trialled in Phase II for 0/14 mm and 0/10 mm SMA for use in 40 or 30 mm lifts, respectively. From a practical perspective, the aggregate grading and binder content are effectively identical to those for conventional material, and the manufacture, transport, laying, rolling and aftercare for the epoxy asphalt SMA is carried out in a similar manner to that for conventional material. However, the thermosetting nature of the product necessitates special consideration in the plant, and for this reason, Colas, who have many years experience in manufacturing and laying epoxy asphalt, were involved at an early stage. The material requires a good quality substrate, and in practice could be laid over a new high performance base/binder course material such as EME, or a good quality residual material, where, for example, the old surfacing has been planed out because of surface (non-structural) deterioration.

4 TRIAL INSTALLATION

The UK Trial Site is located in Threemilestone, on Lane 1 (L1) of the A390 inbound carriageway towards Truro, in the South West of England. The trial encompasses an area approximately 110 metres long by 3.65 metres wide where approximately 40 tonnes of 10 mm nominal size epoxy asphalt SMA trial material was laid 30 mm thick; a comparable length and volume of control material was laid immediately afterwards.

The traffic data for this section of the A390, factored up to January 2012 from a 2006 traffic count, indicate an AADT of 29100 vehicles, with 830 (3%) Heavy Class Vehicles (HCV) of gross weight > 7500 kg and 1100 (4%) Medium Class Vehicles (MCV) of gross weight 3500–7500 kg. The pavement construction is flexible with a full depth asphalt construction ranging in thickness from 312 to 390 mm. The surfacing was due for replacement in 2012 due to surface deterioration (predominantly crazing and fretting, with poor profile due to patch reinstatement) but the substrate was considered to be sound. The logistical, practical and procurement issues were resolved in two meetings involving URS, Colas and the local authority (Cornwall County Council, CCC) held on 11 January and 30 March, and the material sourcing, production and laying of the road trial was successfully completed on Saturday 28 April 2012.

As the specific requirements of the site necessitated a 30 mm thick surfacing layer, it was decided that 10 mm nominal maximum aggregate size was more appropriate, rather than 14 mm as used in the Phase II work. After planing out the original surfacing and before laying the trial and control material, Colbond 50 polymer modified bond coat was applied to the planed surface at a nominal spread rate of 0.7 litres/m^2 (equivalent to 0.35 kg residual binder/m^2) and left until clearly 'broken' before laying the new surfacing. The trial proceeded without incident, apart from minor difficulty related to the paving of the 4th load, which was delayed in traffic between the quarry and the site, leading to a minor surface blemish where the paver stopped moving forward. Full details of the mixture design, plant trials, modification to the bitumen delivery system for the two part epoxy asphalt binder, and the particular trial specification criteria for materials, transport, laying and compaction of the epoxy asphalt, have been provided elsewhere [7].

The early life traffickability of epoxy modified SMA is the subject of ongoing research, but, for the trial, L1 was closed to traffic until Monday night (30 April 2012), when the Traffic Management was lifted. In order to monitor the quality control and 'strength' development of the manufactured product, and so that they could advise when it was appropriate to open to traffic, Colas produced specimens for Marshall testing, to BS EN 12697-34 [9]. The requirements were a minimum stability and maximum flow of 5 kN and 4 mm, respectively, after

24 hours curing at ambient temperature, and 30 kN and 7 mm, respectively, after 20 hours curing at 120°C.

5 MONITORING

5.1 *Scope*

The requirements for assessment, testing and monitoring of the epoxy asphalt field trials, established by the OECD/ITF steering group in July 2009, involved monitoring before, during and after the trial, the latter including monitoring at early age and after 1 year in service. Accordingly, two visits were made to the site: (i) an initial monitoring visit on the night of 09 May 2012, 11 days after the material was laid and 9 days after the trial section was re-opened to traffic, and; (ii) a final, 12 month, visit on 30 April 2013.

On both occasions, the monitoring work was done under a partial lane closure from 19.00 onwards, with L1 closed to traffic over the trial and control sections, and all inbound Truro traffic using L2. The work carried out comprised the following:

- Photographic record of visual condition
- Longitudinal profile, in accordance with Volume 1 of the Manual of Contract Documents for Highways Works (MCHW1) Clause 702, Table 7/2 [10]
- Surface macro-texture by volumetric patch method as described in BS EN 13036-1 [11] and BS 594987, Clause 8.2, [12], (with additional tests across full width of lane)
- Falling Weight Deflectometer (FWD) testing, broadly to the requirements of HD 29/08 (Volume 7 of the UK Design Manual of Roads and Bridges (DMRB7) [13])
- Coring, to establish depth of bound material and to recover samples for materials testing.

In the event, the weather during the initial visit was very poor (heavy rain), and the initial surface macro-texture could not be determined. A noise assessment was also planned but local topography and proximity of dwellings made this impractical.

5.2 *Visual and surface characteristics*

Visually, the surface appearance of the epoxy asphalt test section was indistinguishable from that of the control section (although see below) and from conventional SMA. Also, there had been no discernible change in appearance between the initial and 12 month visits. The longitudinal profile complied with the requirements of MCHW1 Clause 702, Table 7/2 [10], and the results from the two visits were essentially similar, indicating no change with time; two 7 mm irregularities found in the epoxy asphalt test section were on the joints at the beginning (0 m) and end (110 m) of the section respectively, and are a reflection of the site situation rather than a failure to achieve a consistent profile. These surface irregularities at the beginning and end of the test section can be detected when travelling over the test section by car, as can the location (around Chainage 80) where the surface profile was influenced by the paver coming to a halt between the 3rd and 4th loads of epoxy asphalt material. However, in the latter case, any impact on ride quality was not reflected in the surface regularity assessment.

The surface macro-texture data at 12 months show that the mean texture depth for the trial and control sections (set of 10 measurements) were both 1.1 mm. These values comply with the current UK requirements [10] for thin surface course systems for lower speed roads ($\geq$ 1.0 mm (average per 1000 m section); $\geq$ 0.9 mm (average per set of 10 measurements)).

5.3 *FWD testing*

The FWD testing was done at 2 m centres in two lines running longitudinally from Chainage 0 to 220 m, in the NearSide Wheel Track (NSWT) and Lane Centre (LC), at contact pressures of 700, 850 and 1000 kPa. The NSWT tests were offset by 1 m from the LC tests, and similarly offset from the cores (see below) where applicable.

The primary purpose of the FWD testing was to establish that the pavement was structurally competent in both the trial and control areas, and that the trial and control pavements were essentially similar. A detailed summary of the testing is beyond the scope of this paper. However, in overview, the analysed FWD data show that the asphalt stiffnesses were generally low throughout (it is possible that this may in part be a reflection of variable bond between asphalt layers influencing the back analysis) and the foundation stiffnesses were indicative of good performance throughout. Although there was some individual variation, overall the structural assessment of the site carried out using the FWD confirmed broadly similar performance in the trial and control areas.

5.4 *Coring and laboratory testing*

For both visits, twenty number 100 mm diameter cores were taken, evenly spaced along the centre of L1, ten in the epoxy asphalt test material and ten in the control material. Selected cores were drilled to full depth, revealing an asphalt construction comprising 6 to 8 discernible layers, typically:

- new SMA surface course, overlying;
- 2–3 layers of asphalt concrete, overlying;
- 1–2 layers of hot rolled asphalt, overlying;
- 1–2 layers of asphalt concrete.

The full depth of asphalt ranged from 312 mm to 390 mm, and was generally found to be slightly thicker in the test section (370–390 mm) than in the control section (312–350 mm). The full depth cores showed some lack of bond in their lower layers; the depth to the first layer showing lack of bond ranged from 111 to 240 mm, measured from the top of the pavement. Generally, the cores revealed a relatively thick asphalt construction encompassing several different material types, typical of a structure that has developed over time as new material has been laid over existing.

In order to provide baseline data on the mechanical and volumetric properties of the trial and control material, and to assess any change in mechanical properties occurring over time, a selection of the extracted cores from each section and from each visit was subjected to a bespoke programme of storage and testing. Thus the cores from the Final Visit, after 12 months curing in situ, were tested as soon as possible after extraction, while the cores extracted from the Initial Visit were stored at laboratory ambient temperature (20°C), after extraction from the road, until required for testing.

The testing carried out comprised bulk and maximum density, and calculated air voids, to BS EN 12697 Parts 5, 6 and 8 [14, 15, 16], Indirect Tensile Stiffness Modulus (ITSM) to BS EN 12697 Part 26 [17] and Indirect Tensile Splitting Strength (ITST) to BS EN 12697 Part 23 [18]. The indirect tensile stiffness and strength data are important parameters to assess likely pavement material performance over time, and are particularly useful here to illustrate the special properties of epoxy asphalt. A summary of the key mechanical property data from these two tests is presented below.

Figure 1 shows the mean stiffness data at 0, 20 and 30ºC, for in situ cured cores tested after 13 months (similar results were obtained with laboratory cured cores, tested one month after production). Figure 1 shows that the stiffness of epoxy asphalt is higher than that of the control mixture, regardless of the test temperature. At 20°C and 30°C, the stiffness of the epoxy asphalt is significantly higher than that of the control, which is likely to be beneficial with respect to the rutting potential of asphalt mixtures. Indeed, the dramatically improved deformation resistance of epoxy modified mixtures, compared with that of standard material, has been demonstrated in earlier work [6]. In addition, the result indicated that there is a strong exponential relationship between the stiffness and temperature for both mixtures.

The changes in stiffness (ITSM) over time for the epoxy modified and control mixtures are shown in Figure 2, for laboratory cured cores tested at 20ºC. It can be seen that the stiffness of the epoxy asphalt mixture is significantly greater than the control mixture at all ages. Furthermore, the stiffness of the latter remains at a constant (and relatively low) level

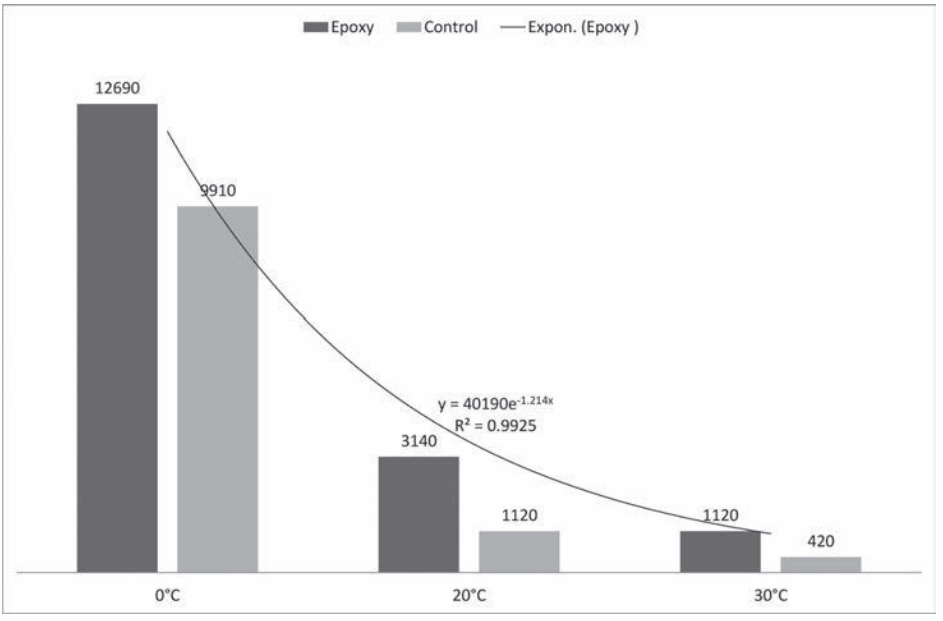

Figure 1. Mean stiffness (ITSM) data at three temperatures, performed on in situ cured cores, 13 months after production.

	1 Month	3 Month	6 Month	9 Month	13 Month
Epoxy	2850	5660	6220	6900	8240
Control	1050	1550	1770	1910	1790

Figure 2. Mean stiffness (ITSM) data at 20°C, performed on laboratory cured cores, at various ages after production.

between 6 and 13 months, whereas the stiffness of the epoxy modified mixture continues to rise throughout the period of monitoring.

Finally, Table 1 summarises the results of tensile strength (ITST) tests performed on laboratory and in situ cured cores. A direct comparison of the results of laboratory cured cores shows that the strength of the epoxy asphalt mixture increased by 50% between one and

Table 1. Mean tensile strength (ITST) data at 20°C at various ages after production.

	Mean ITST (MPa) at 20°C		
	Laboratory cured cores		In situ cured cores
Material	1 month	13 month	13 month
Epoxy	1.6	2.4	2.0
Control	0.6	0.6	0.8

Figure 3. Epoxy asphalt trial section after 12 months trafficking (2013).

13 months, while the strength of the control mixture did not experience any change. The in situ results also indicate that the strength of the epoxy modified mixture is substantially higher than that of the control.

In comparison with earlier results generated during Phase II of this project [2, 6], it is noteworthy that the laboratory cured stiffness at 20ºC of the field cores is substantially lower (8240 MPa after 13 months compared with 13400 MPa after 60 days). The reason for this difference is unexplained, but the slightly reduced stiffness of the field cores may be beneficial in the long term, as discussed further below.

6 CURRENT CONDITION OF THE ROAD

Figure 3 shows the condition of the epoxy asphalt trial section (Lane 1 in the photograph below) after 12 months trafficking.

Feedback received from CCC reveals the following:

1. Data from: routine SCANNER measurements (traffic-speed surveys of the network, using the Surface Condition Assessment of the National NEtwork of Roads (SCANNER) system, to determine rut depth, texture, profile and cracking, carried out according to the

User Guide and Specifications published by the UK Roads Board (2011), [19]), completed on 31 May 2012, and; SCRIM measurements (in-service skid resistance using a Sideway-force Coefficient Routine Investigation Machine (SCRIM), carried out according to HD 28/04 of DMRB7, [20]), completed on 06 July 2012; reveal that the surface has so far not shown any indication of change since it was opened to traffic.

2. Personal feedback from CCC staff who drive this section of road frequently is that nothing registers apart from the section where the paver stood for a period (see section 4 above), and even here there has been no sign of change since the road was opened to traffic.

7 CONCLUDING DISCUSSION

In earlier phases of this OECD/ITF research project, Long Life Surfaces for Busy Roads, an economic appraisal had demonstrated the likely benefits from development of road surfacing materials with a service life in excess of 30 years, which were subsequently characterised in laboratory and accelerated load testing of two candidate materials (Epoxy Asphalt and High Performance Cementitious Materials). The present report summarises the work done in the United Kingdom in Phase III of the research project; specifically, to plan, execute and monitor full scale trials of the optimum epoxy asphalt mixture design formulation that had been developed in the earlier stages of this project.

The site in question was located on a heavily trafficked section of the A390 inbound carriageway toward Truro, where the surfacing required replacement due to surface deterioration but the substrate was considered to be sound. The epoxy asphalt mixture design was a 10 mm nominal size SMA material, incorporating epoxy binder, which was laid 30 mm thick over 110 m of Lane 1 of the carriageway. A comparable 10 mm nominal size SMA control material, incorporating 50 penetration grade binder, was laid over the succeeding 110 m. Both the epoxy asphalt and control material were manufactured, transported and laid using conventional plant, generally without incident. Full details of the field trial installation have been published elsewhere [7].

Data from two monitoring visits over the first year of service and feedback from CCC indicates good performance to date, with comparable surface characteristics (regularity and texture) on the trial and control sections and no indication of change since the trial site was opened to traffic. In one location in the final quarter of the epoxy asphalt section, there are some surface blemishes which occurred as a result of an unforeseen break in the paving operation (delivery lorry delayed in traffic). However, although this is visible to the naked eye and detectable when driving over the site in a vehicle, the surface regularity complies with the current UK requirements. A structural assessment of the site carried out using the FWD has confirmed broadly similar performance in the trial and control areas. Testing of cores extracted from the site and subsequently stored in the laboratory, indicate that the epoxy asphalt material has substantially greater stiffness and tensile strength than the control material. The mean stiffness at 20°C of the epoxy asphalt has increased from 2850 MPa at 1 month to 8240 MPa at 13 months, compared with a comparable change for the control material from 1050 MPa to 1790 MPa. In addition, the mean tensile strength of epoxy asphalt has increased from 1.6 MPa at 1 month to 2.4 MPa at 13 months, whereas the control mixture has shown no change in strength over time and a much lower absolute value (0.6 MPa).

The primary objective of the field trials was to demonstrate that the performance envisaged from the laboratory and accelerated testing would hold true within the period of the trial under real traffic and environmental conditions. To date, this objective has been comfortably met, although, as noted in section 5, the stiffness of the epoxy modified mixtures are generally lower than previously determined in the laboratory [2, 6]. However, the stiffness is still comfortably in excess of that of standard surfacing mixtures, with consequent benefits for predicted life, and a slightly lower stiffness may be no bad thing to help mitigate any potential for cracking. Secondary objectives were to develop construction methods, optimise mixtures and increase contractor experience levels. It is certainly the case that the field trial has successfully demonstrated that the full-scale manufacture and construction of an

epoxy modified SMA surfacing can be accomplished with standard plant and equipment, and with only very minor changes to practice. In terms of increasing contractor experience levels and optimising mixtures, it is likely that this will only come with increased uptake of the concept. From the present research, obvious targets for mixture optimisation would include extending the workability window, improved knowledge of how curing temperature influences early traffickability and ultimate mechanical properties, and making best use of the potential to manufacture and lay epoxy modified mixtures at lower temperature than conventional material.

The economic case for long life surfacing of the type described in this paper depends on achieving a service life at least twice as long as that typically expected from asphalt surfacing currently used in road pavements. As an example, the expected life of 'conventional' Stone Mastic Asphalt (SMA) surface courses popularly used in Europe and North America were reported to range between 5 and 15 years [1]. Clearly, the current trial has a long way to go before a life of 30 years can be demonstrated, but early signs are encouraging. Although the envisaged monitoring of the field trial has now been completed, CCC has kindly agreed to supply future routine SCANNER and SCRIM data as they become available; this will be recorded for potential future use.

A long life surfacing is an essential requirement for the advanced and affordable transport infrastructure envisaged by the Forever Open Road (FOR) concept, which aims to bring together the best of what we have today with the best of what's to come. Long lasting overlays as part of durable and integrated pavements are one of the key research and innovation themes of FOR, to produce an affordable road for a society that cannot afford the closure of roads [21].

It is of course recognised that the additional cost and marginally increased construction complications will mitigate against the use of such material for many conventional applications. However, as traffic levels continue to rise, and in certain network 'hot spots' where any loss of serviceability is unacceptable, the justification for longer life surfacing materials can only increase.

Fulton Hogan, Christchurch, New Zealand

ABSTRACT: The NZ Transport Agency's (NZTA) has been developing an epoxy-modified Open-Graded Porous Asphalt (OGPA) with the aim of creating a low-maintenance long-life (>30 years) low noise surfacing material.

The New Zealand laboratory studies and field trials form part of a larger collaborative research programme conducted under the auspices of the OECD/ECMT (European Conference of Ministers of Transport) Joint Transport Research Centre, focused on the economic evaluation of long-life pavements.

Investigations into the cohesive properties and oxidation resistance of an acid-cured, epoxy-modified OGPA were undertaken in the laboratory. The initial trials at the NZTA's Canterbury Accelerated Pavement Testing Indoor Facility (CAPTIF) demonstrated the practicality of the project.

A field trial constructed on State Highway 1 in Christchurch in December 2007 demonstrated that full-scale manufacture and construction using the epoxy OGPA, could be undertaken without any significant modification to plant or operating procedures in a normal surfacing operation. The trial has been in place for 6 years and is performing well.

The original 2007 work has been optimised for cost, manufacture and construction. Test sections were placed on the Christchurch Southern Motorway in 2012 and this paper reports the optimisation and findings on manufacture and construction of the 2012 test sections.

Keywords: CAPTIF, long life surfaces, epoxy-modified open graded porous asphalt

1 INTRODUCTION

This paper discusses laboratory investigations and a trial of Epoxy Modified bitumen OGPA (EMOGPA) on the Christchurch Southern Motorway in November 2012. Concentrations of EMOGPA from 25% to 100% were studied and the results compared with conventional OGPA [1].

Economic analysis shows that 25% EMOGPA is a sound investment and has the potential to significantly reduce the NZTA's surfacing budget. Adopting 25% EMOPGA would in the long term reduce the NZTA resurfacing budget to 1/6 of its current level, or alternatively provide the ability to apply a far greater volume of noise reducing surfaces within the current OGPA budget level. These figures are based on a 40 year life for EMOGPA which is considered conservative (e.g. the epoxy asphalt on the San Francisco Bay Bridge, with 25,000 vehicles per lane per day is 40 years old and still performing satisfactorily). Laboratory studies predict much longer lives [2].

The epoxy modified bitumen concept was originally developed by Shell Oil in the 1960's. Commercially available epoxy bitumen is a two part system consisting of specially formulated

epoxy resin and a hardener-bitumen blend. As with standard epoxy materials the two components are mixed just prior to use and curing takes place over time. Epoxy modified bitumen is significantly different from common, rapid curing epoxy materials such as those used in adhesives or in high-grip surfacing formulations.

Epoxy modified bitumen uses a slow acid-curing chemistry so that it can be handled and applied at high temperatures (100–150°C) without excessive curing. Like other epoxy materials, epoxy modified bitumen is thermosetting (i.e. it will not melt once cured) but differs significantly from many other epoxies in that it cures to a flexible rubbery consistency at room temperature rather than a brittle 'glass'. Chemical changes on curing and oxidation of epoxy bitumen have been studied as part of the overall research programme [3].

The formulation of commercially available epoxy bitumens is proprietary but the product typically consists of about 20% wt epoxy resin and hardener and 80% of, an approximately, 80 pen bitumen.

Epoxy modified bitumen technology has been improved significantly since its first introduction and has found a niche application in providing very long life asphalt surfacings for high deflection bridge decks ([4],[5],[6]). The Bay Bridge in San Francisco for example was surfaced with epoxy asphalt in 1976–77 which is still in service today (35 years later) carrying 27,000 vehicles per lane per day [7]. Epoxy asphalts are characterised by a high modulus, fatigue resistance, resistance to permanent deformation (rutting) and damage from fuels and oil ([8],[9],[10]).

Recently the potential benefits of the application of epoxy modified bitumen in asphalts for general road surfacing applications have been demonstrated through an OECD project involving research agencies in New Zealand, Europe and the USA ([11],[12]). Research funded by the NZTA formed part of the OECD project and focused on Epoxy Modified bitumen Open Graded Porous Asphalts (EMOGPA). EMOGPA was found to offer the potential for open-graded porous asphalt with lifetimes in the field well in excess of 30 years compared with an average life of 7.5 years the NZTA achieves for standard OGPA. The work resulted in successful full scale trials being constructed on CAPTIF ([3],[13]) and on the State Highway 1, the Main North Road in Christchurch in 2007 ([2],[14]). Several related research projects have been completed since that time, further demonstrating the potential benefits of epoxy OGPA performance and in particular the potential for reducing costs by diluting commercially available epoxy binder with standard bitumen [2].

In general epoxy modified asphalts have been found to have very high strength, fatigue resistance and resistance to oxidative degradation. The only drawback with the material from an engineering perspective is the fact that curing limits the handling time available for manufacture and construction (about 60–90 minutes). Manufacture of epoxy asphalt is straightforward with only minor modifications needed to the asphalt plant to allow in line blending of the epoxy components (before entering the drum). No changes to plant or procedures are needed to lay the mix.

This paper deals with an additional EMOGPA trial constructed on the Christchurch Southern Motorway in November 2012 carried out in collaboration with Fulton Hogan Ltd. Laboratory investigations on durability and curing rate of the trial mixes are also reported together with suggested changes to the New Zealand Transport Agency (NZTA) P/11 specification needed to accommodate EMOGPA.

2 PROJECT DESIGN

2.1 *Object and research outline*

The object of the project was to gain further experience with large scale manufacture and construction with EMOGPA and to provide a further site for evaluation of performance over time for mixes that had been optimised for cost and performance. Sections of various EMOGPA materials were laid on the Christchurch southern motorway, sample of the mixes were tested in the laboratory for durability and curing rate. A brief cost analysis of EMOPA was also conducted.

2.2 *Trial sections*

Four different OGPA materials with the same mix design and binder content, but different binders, were laid:

- 100% EMOGPA (using the epoxy bitumen as specified by the supplier)
- 50% EMOGPA (50/50 blend of epoxy bitumen diluted with standard 80–100 penetration grade)
- 25% EMOGPA (25/75 blend of epoxy bitumen diluted with standard 80–100 penetration grade)
- Control (using 80–100 penetration grade bitumen).

2.3 *Materials test methods*

2.3.1 *Trial materials and test specimens*

The epoxy bitumen (supplied by ChemCo Systems Ltd, California) is a two-part product that is blended just before use. Part A (used at 14.6% by weight) consists of an epoxy resin formed from epichlorhydrin and bisphenol-A. Part B type V (85.4%) consists of a fatty acid curing agent in approximately 80 penetration grade bitumen. The product is free from solvents.

The bitumen used for all control mixtures was 80–100 penetration grade bitumen, manufactured from Middle Eastern crudes, comprising both air-blown and butane-precipitated material, and conforming to the NZTA M/1:2007 specification.

The same, nominal 20% air void OGPA mix design conforming to the NZTA P/11 OGPA specification [15] was used for all trial sections (see Table 1).

For all mixes, 100 mm diameter specimens were prepared in the Fulton Hogan Laboratory on the day of the trial by compaction (50 blows per side) in a Marshall Hammer, according to ASTM D6926 [16]. The average air voids of the specimens used, measured according to ASTM D3203-05 [17] are given in Table 1. These specimens were used in laboratory studies of durability and low temperature curing at Opus Research.

2.3.2 *Laboratory prepared specimens for specification development*

For the work reported in section 4.3 (specification development) additional specimens were prepared using the same mix design, aggregates and binders as used in the field trial work. The control mixtures using 80–100 bitumen were manufactured at a temperature of 125°C. The epoxy bitumen mixtures were made with parts A and B heated to 90°C and 125°C respectively, and blended just before addition to the aggregate, held at 125°C. The epoxy bitumen mixtures were held at 125°C for 45 minutes before compaction in the Marshall hammer (50 blows per side).

Further specimens were made using another mix design with different aggregates (Winstones Quarry, Wellington) but the same binders. The grading for these specimens is given in Table 2.

Specimens were subjected to the durability test procedure specified in NZTA P/11 (NZTA T/13). This involves oxidation at 80°C for 72 hours under an air pressure of 2069 kPa (300 psi).

2.3.3 *Durability studies*

Compacted mix specimens were oxidised by heating in a forced draft oven at 85 ± 1°C. The sides of specimens were wrapped in a silicone release paper to prevent slumping and were

Table 1. EMOGPA grading for field trial (typical).

13.2	9.5	4.75	2.36	0.075		
95	38	16	11.4	3.6	4.5	20.7 ± 0.4

Table 2. Additional EMOGPA grading for specification development work (typical).

Passing (%) sieve size (mm)					Bitumen content (%)	Air voids % (±95% CL)
13.2	9.5	4.75	2.36	0.075		
99.8	95	22.6	16.8	3.2	5.5	22.2 ± 1.1

supported on solid steel trays. The position of the specimens in the oven was interchanged periodically to minimise effects due to temperature variations in the oven. The specimens were inverted approximately weekly to minimise bitumen drainage, although some minor drainage was observed.

The specimens were aged for 40 days which corresponds to approximately 7–8 years in the field [2].

2.3.4 *Cantabro test procedure*

Mixture abrasion resistance and cohesion was measured using the Cantabro Test. The test procedure and detailed specifications for the equipment are given in APRG 18 [18], which is in turn based on the Los Angeles abrasion test described in AS 1141.234 [19]. In this test, cylinders of compacted mix (100 mm diameter and 50–70 mm high) are brought to a temperature of 25 ± 0.5°C in an incubator and then tumbled in a steel drum (maintained at 25 ± 3°C) for 300 revolutions at 30rpm. The mass of aggregate lost from the specimen through abrasion is recorded as a percentage of the original mass. Specimens tested as part of the durability study were tested at 10 ± 2°C to provide more stringent conditions and for comparison with earlier work [2].

Measurements of 'zero' time specimens (i.e. uncured or unoxidised) were made within 24–48 hours of manufacture. At least four hours (usually overnight) were allowed for specimens to stabilise at the test temperature. The test machine was enclosed in a large cabinet through which temperature-controlled air from a refrigeration/heating unit was circulated.

The Cantabro Test results presented are the mean percentage losses of 4–8 replicates. The error in the mean test results reported was 14% (mean 95% confidence limit).

2.3.5 *Indirect Tensile Modulus (ITM)*

ITM measurements were conducted on a 5 kN test frame (Model UTM-5, IPC Australia Ltd) at 25°C, according to AS 2891.13.1 [20]. This procedure employs a recovered horizontal strain of 50 micro strain (με), a rise time (90%) of 0.04 seconds and a pulse repetition of 3.0 seconds. A Poisson's ratio of 0.35 was assumed. The moduli of 'zero' time specimens (i.e. uncured or unoxidised) were measured within 24–48 hours after manufacture. At least four hours were allowed for specimens to stabilise at the test temperature. The ITM results presented were the mean of 4 replicates. Based on a large number of previous tests the precision of the test results was ±17% (95% confidence limits).

2.3.6 *Curing at 'ambient' temperatures*

Specimens of mix from the road trial were kept in a constant temperature chamber at 23°C and 43% humidity. The sides of the specimens were wrapped with silicone release paper (baking paper) to prevent slumping. The IDT of the specimens was measured periodically at 25°C as described above (section 2.3.5).

3 ROAD TRIAL CONSTRUCTION

3.1 *EMOGPA manufacture*

The EMOGPA mixes were manufactured at the Fulton Hogan asphalt plant in Miners Road Christchurch which is a continuous drum plant with a mixing box. Aggregate is heated to the

desired temperature in a rotating drum before entering a "mixing box" into which bitumen is feed at the desired rate. Mixing is achieved by two rotating mixing arms in the box. The box is not separately heated.

Part A (the less viscous component) was heated to 85°C in a small tank, whilst Part B was decanted from the 200 L drums in which it was supplied into a bitumen distributor truck and maintained at 125°C. Part A was pumped into the main bitumen line (through which Part B travelled). Part A and B proportions were controlled by previously calibrated mass flow meters.

For the 25% and 50% EMOGPA mixes the epoxy bitumen Part B was diluted with the appropriate amount of 80/100 bitumen in a load cell controlled blend tank at Lyttelton and loaded into a small trailer tanker and towed to site.

3.2 *Trial construction*

The trial was constructed on the Christchurch southern motorway duplication in November 2012. Each EMOGPA trial section was about 210 m (100 tonnes) it was laid 40 mm deep and constructed in the west bound left hand lane. The 100% EMOGPA was laid first (starting at the eastern end of the Lincoln road overpass) followed by a control section then the 50% EMOGPA. The 25% section was laid on the westbound lane on 5 November 2012.

All sections were constructed over 125 mm of dense asphalt mix (NZTA AC14) on top of 200 mm of 3.5% cement stabilised basecourse (see Fig. 1). The dense asphalt was laid approximately 2 weeks before the trial; a tack coat of 70% CRS 80/100 emulsion was applied.

The EMOGPA was laid using standard operating procedures and paving equipment. The travel time to the site was approximately 45–60 minutes and trucks typically waited for no more than 15 minutes before unloading into the paver. Air temperatures during construction were about 20°C and the surface temperatures before laying were around 30°C.

The target manufacturing temperature for the control OGPA was 135°C and 120°C for the EMOGPA, however this was exceeded in the case of the 50% material. The mix temperature leaving the paver was 107–110°C for the 100% and 25% EMOGPA but about 10–12°C higher for the 50% material. This error resulted from the plant still being hot from the previous run manufacturing the control mix so that when switching to the short run of 50% EMOGPA the initial manufacturing temperature was too high. The higher mix temperature resulted in some 'dull' discoloured areas (but without segregation) of the 50% EMOGPA section.

Figure 1. Trial pavement structure. Upper most layer is the final OGPA surfacing.

Rolling with steel drum vibrating rollers began generally within a few minutes of paving which resulted in some pick up of mix on the roller especially in the case of the 50% section which had been manufactured at a higher temperature than the other EMOGPA's. Pick-up was avoided simply by letting the mix cool before further rolling or in the case of the 50% EMOGPA site cooling with a water cart. The viscosity of the epoxy bitumen is substantially lower than that of 80–100 bitumen when first mixed and takes time to build. Pick-up observed when rolling was attempted at temperatures above about 70°C; below 50°C no pick-up was observed but rolling of ridges etc. was still easily achieved even at 45°C. The 25% EMOGPA was the easiest to lay and was similar in handling to the conventional OGPA.

3.3 *Initial trial site monitoring*

Water permeability, rutting and friction were measured on the shoulder and outer wheel path of each site about 3 months after construction. Water permeability was measured according to the method given in NZTA P23 notes: 2005 appendix A. method, friction using a British Pendulum tester [21] and rut depth using a straight edge and wedge (Fulton Hogan internal method 2013).

The results show permeabilities to be similar for all sections with the exception of the shoulder on the control site which shows a very wide range of values, the reason for which is not clear.

Friction values were higher on the shoulders than the wheel path in all cases but all four sections gave similar results. In the wheel path the 100% EMOGPA site was slightly higher than the other sections but the difference was not statistically significant.

None of the sections showed any indications of rutting. A visual assessment found all of the sections to be in good condition. The discolouration on the 50% site was still apparent but less pronounced.

4 LABORATORY STUDIES

4.1 *Durability*

Earlier work predicts that EMOGPA should have very long lifetimes in the field [2]. To provide further evidence of the improved durability of EMOGPA compared to standard OGPA mix specimens were oven aged as described in section 2.3.3 and 2.3.4. Results are shown in Figure 2. As the specimens had to be packed and shipped to the testing laboratory the initial ('t = 0') results presented were obtained on specimens that had been at ambient temperature (15–20°C) for 10 days.

The results show that mass loss increases as the epoxy bitumen content decreases, this is consistent with earlier work [2]. The absolute value of the mass losses of the control specimens was higher than observed in earlier work and probably relates to differences in mix design. Even when tested at 25°C control mix specimens lost substantially more mass than is typical for most OGPAs.

The difference between the mean mass loss of the 25% epoxy bitumen EMOGPA specimens (64%) and the controls (84%) was statistically significant at the 95% confidence level.

The 100% specimens showed a decrease in mass loss after oxidation which has been noted previously and can be ascribed to the increased strength due to the curing (crosslinking) process outweighing any effects due to oxidation.

4.2 *Curing at ambient temperature*

Specimens were maintained at 23°C to study the rate of 'strength' (modulus) increase at near ambient temperatures. In previous work on ambient cure specimens were exposed outdoors near the trial site but this procedure was not practical in the current case. Results are shown in Figure 3.

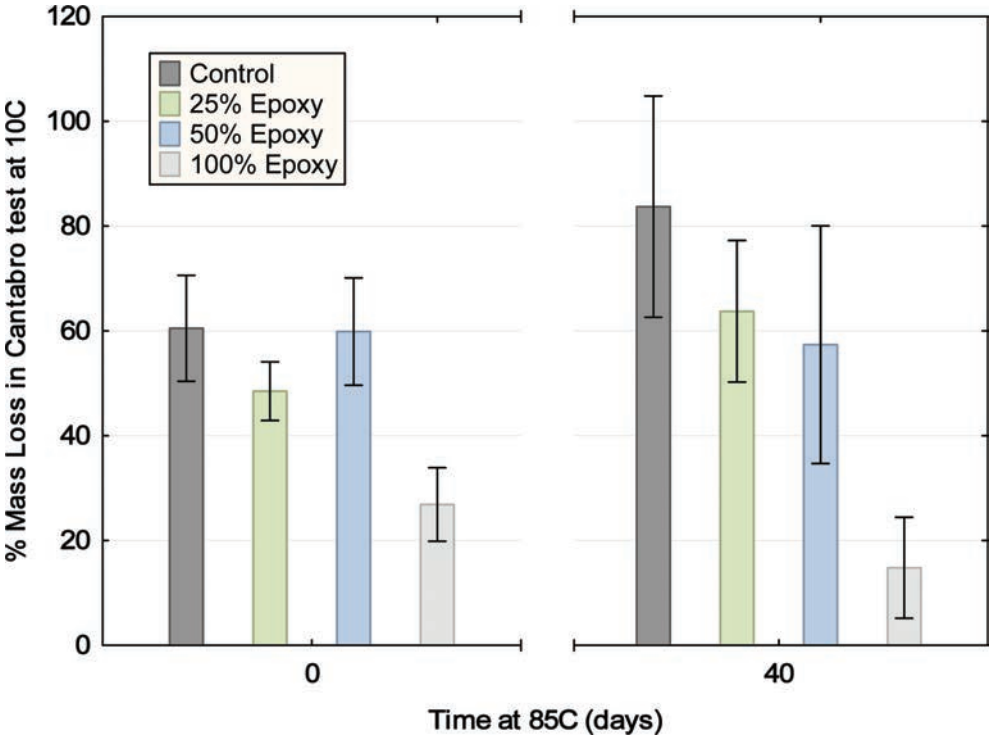

Figure 2. Cantabro test mass losses at 10°C before and after oxidation at 85°C for 40 days.

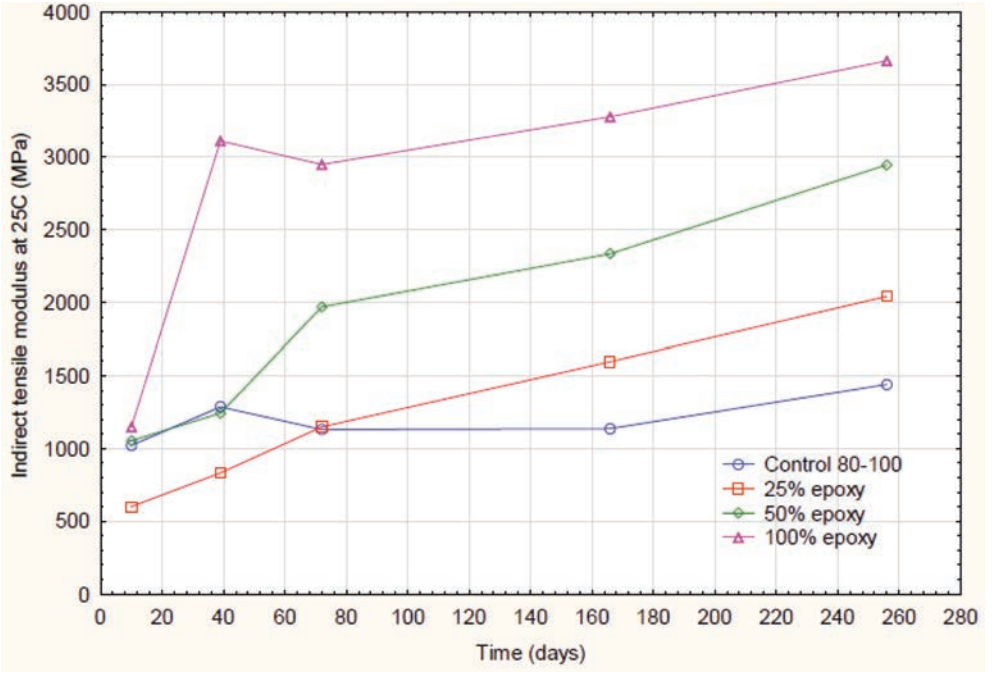

Figure 3. Change in IDT (measured at 25°C) after curing at 23°C.

The control specimens show effectively no net increase in modulus after 160 days. The 25% and 50% EMOGPA specimens show a similar rate of increase in modulus although the initial value of the 50% material is higher perhaps as a result of the (accidentally) higher manufacturing temperature and faster curing. The viscosity of the epoxy bitumen is lower than that of the control 80/100 on first mixing so that both 25% and 50% specimens would be expected to have lower initial moduli than the control. The viscosity of the 100% material should also be lower than that of the other three binders but the higher initial modulus probably is as a result of the faster curing rate of that binder. As noted above the specimens had been transported and stored at ambient temperature for 10 days before the initial measurements were made.

The 100% EMOGPA shows a rapid increase after 40 days but little change thereafter.

4.3 *Specification development*

The NZTA P/11 specification was not written with products such as EMOGPA in mind. In order for epoxy modified products to be specified some criterion that relates either to the chemical composition, enhanced durability of the material or the strength gain through curing needs to be developed. Chemical analysis requires specialist techniques that are generally not readily available in the industry so a physical property measurement is desirable.

For specification purposes a simple measurement of curing rate, in terms of the increase in indirect tensile modulus, at near ambient temperature would be sufficient to confirm the presence of epoxy modified bitumen (see Fig. 3). The drawback of low temperature curing is that the time required to obtain unambiguous results is quite long, 30–40 days. However low temperature ageing does highlight the difference between epoxy materials and standard OGPA more clearly than ageing at higher temperatures, where bitumen oxidation, resulting in hardening of standard mixes, becomes more significant.

5 COST-BENEFITS OF EMOGPA

A long term economic analysis looking at just Agency costs was undertaken on the 25% EMOPGA to determine if it was economically viable to use it. To calculate a mix cost per square meter in place, it was assumed that the binder content of the mix was 5.0%, the compacted mix was laid 40 mm thick and had an air void content of 20% giving a bulk density of 2.015 t m^{-3}. This resulted in an estimated increase in initial cost of \$NZ 6/m^2 for the 25% EMOPGA, this being the cost of more expensive binder. The rates for the conventional OGPA were very low due to the size of the Christchurch Southern Motorway contract and peer review suggests that they were likely a result of front loading the contract rates to improve the contractor's cash flow. Despite this the economic analysis proved very attractive.

Economic analysis using a 6% discount rate over a 40 year analysis period shows the OGPA with an 8 year life has a Present Worth of Costs 2.4 times higher than the 25% EMOGPA with a 40 year life.

There is a financial risk if the material does not perform as well as expected—however this is minor as a 40 year economic analysis at a 6% discount rate shows the 25% EMOGPA only needs an 11 years life to have the same Present Worth of Costs as an OGPA with an 8 year life. The Economic Indicator (EI) for the project was reviewed. The EI being the change in Present Worth of Costs over the change in Initial Cost, it was very favourable at 4.7 and only requires a 14 year life for the 25% EMOGPA to reach an EI of 1.

6 CONCLUSIONS

The trial confirmed earlier trials in that it successfully demonstrated that epoxy modified OGPA can be manufactured and placed without any significant changes to practice. The

25% EMOGPA was the easiest to lay of the EMOPGA materials with similar handling to standard OGPA. Its conventional strength eliminates the risk to plant and pavers of material setting hard if equipment breakdowns occur. The superior oxidation resistance will result in extremely long life when placed in mainline applications where skid resistance issues do not dominate life.

Durability studies using oven ageing at 85°C confirmed earlier work that showed EMOGPA should have a much greater resistance to oxidation than standard OGPA. The effectiveness of the epoxy bitumen modification both in durability and rate of curing reduces as the percentage level is decreased. As in previous work there appears only a small difference between the 25% and 50% modified materials.

A simple procedure based on the rate of curing at near ambient temperatures could be used in a specification to check for the presence of epoxy modified bitumen and potentially as a measure of the concentration present.

With an Economic Indicator of 4.7 the economic case for using 25% EMOGPA is compelling purely on Agency costs alone. These calculations assume a lifetime of at least 40 years for the EMOGPA. Evidence from laboratory studies and practical application of dense epoxy asphalt mixes overseas demonstrates that lives in excess of 40 years lives are easily obtainable. EMOGPA thus has the potential in the long term to reduce the NZTA's current OPGA surfacing budget to 1/6 of its current value, or alternatively provide the ability to far greater volume of noise reducing surfaces at the current OGPA budget level.

A performance-based Pavement Management System for the road network of Montreal city—a conceptual framework

Md Shohel Reza Amin & Luis E. Amador-Jiménez
Department of Building, Civil and Environmental Engineering, Concordia University, Montreal, Canada

ABSTRACT: Arterial roads of Montreal city, mostly constructed in 1950's, are at an advanced state of deterioration and need major rehabilitation, upgrading, or even reconstruction. City of Montreal has allocated over $1.6 billion for road infrastructure in its 2012–2014 Three-year Capital Work Program. This investment can be wasted without proper infrastructure asset management system. The current practice of mill and asphalt overlay method by City of Montreal to rehabilitate the pavement is inadequate to repair potholes, fatigue and cracking. A performance-based pavement management system can predict the response and performance of pavement under actual dynamic traffic loads. As of today, implementations of Pavement Management Systems (PMS) are dedicated to achieve optimal levels of condition under budget restrictions. Other important objectives (e.g. mobility, safety, accessibility and social cost), along with investments to upgrade and expand the network, are normally left outside the modelling. This paper presents a conceptual framework of a dynamic PMS for the road network of Montreal City. This dynamic PMS will manage continuous aggregate behaviour of transportation system and can solve optimization problems of pavement management at any time interval.

Keywords: Pavement Management System, dynamic, performance modelling, optimization

1 INTRODUCTION

The pavement management systems is an approach that incorporates the economic assessment of trade-offs between competing alternatives [1, 2, 3]. Historically, pavement management tools such as PAVER and HDM3 [4] were based on cost-benefit analysis incapable of trading-off decisions across asset types and modes of transportation [5]. The adaptation of linear programming and other heuristic optimization techniques for asset management came to address most of these issues [6, 7]. These techniques are capable of finding the optimal path to take full advantage of cost-effectiveness of individual treatments, associated with individual asset elements, and the benefits of advancing or deferring a certain treatment [1, 8]. However, the economic impact of multiple strategies (i.e., rehabilitation versus capital investments) has not yet been addressed for safety, pavement condition, congestion, pollution and social cost. The perception of congestion combined with pavement condition, highway capacity, accessibility, financial incentives, personal safety, and to a lesser degree environmental responsibility impacts personal choices of modes, routes and links [9]. Periodic incorporation of choice models into the Pavement Management System (PMS) will not only render it more tractable mathematically and more consistent with most growth-theory frameworks and distribution models, but also provide a better way of depicting on-going aggregate behaviour and a more satisfactory PMS [9].

The objective of this paper is to outline a conceptual framework of a pavement management system for the road network of Montreal City incorporating dynamic states of land use, traffic volumes, design capacities, and pavement conditions of arterial roads. Most of the arterial roads of Montreal city are constructed in 1950's and are at an advanced state of dete-

rioration. The commonly cited factors of this advanced state of deterioration are improper maintenance, low priority on infrastructure maintenance, inadequate funding, and the use of poor materials in the original construction. The City council seems to focus more on improving patching technology and execution, which don't appear to survive beyond two to five years. Moreover, the investments of City of Montreal on road system have increased more than 560% since 2001. The Three-year Capital Works Program (TCWP) 2012–2014 allocated over $130 million for maintaining and upgrading the city's roads, including $2.5 million that will be used solely for minor bridge and tunnel repairs [10]. A performance-based PMS can predict the response and performance of pavement under actual dynamic traffic loads, and can ensure cost effective scheduling of maintenance and rehabilitation operations.

2 MEASUREMENT OF THE ROAD INFRASTRUCTURE PRODUCTIVITY

The pavement investment policies face important policy questions regarding the uses of pavement maintenance and rehabilitation (M&R) funds such as: What is the optimal level of pavement M&R funding? How can the need for this level of M&R funding be validated persuasively? What choices of M&R sections in the current budget period would most effectively move pavement conditions toward an optimal level in the long-term? [11] There is a wide range of options to achieve a appropriate investment policy. They are: construction with a low initial cost followed by frequent low cost strengthening by overlays, construction of high quality pavements with higher initial costs but lower future maintenances costs, and construction of higher strength initial pavement followed by frequent thin overlays [12, 13, 14]. The first option is applicable when initial capital is limited but a steady flow of maintenance funds are available, however, the second and third options are supported by optimization and design studies.

The productivity of a road infrastructure needs to be understood before developing the optimization and design studies for pavement investment strategies. There is no universally accepted methodology to measure the productivity of a road infrastructure probably because of the lack of methodological consensus and the complexity of the hierarchical characteristics of many sub-systems within the road infrastructure system [15]. The development of cost efficiency analysis methods and methods for analysing deterioration, maintenance and renewal under a budget constraint is necessary [15]. An economic optimization model, with given budget constraints, can differentiate different maintenance scenarios while identifying optimal actions and scheduling schemes [15].

The economic optimization model for PMS consists of pavement deterioration model; user cost model; and construction, maintenance and rehabilitation cost model under possible budgets constraints [11]. Life-Cycle Cost Analysis (LCCA), which is associated with the evaluation of an asset with a definite life expectancy, is an appropriate economic optimization model to examine the subsequent maintenance works on the pavement [12].

3 STUDIES ON LIFE-CYCLE COST ANALYSIS (LCCA)

LCCA is a tool to assess total cost of M&R operations, to distinguish between alternatives, and to provide a basis for identifying trade-offs related to alternatives [16]. LCCA for PMS have been applied in a number of studies [4, 17]. Uddin et al. [17] describe a LCCA program developed for the Pennsylvania Department of Transportation (DOT). The program economically evaluates a range of strategies for design and rehabilitation of road pavements. However, the pavement deterioration algorithm is somehow simplistic [17].

Haas and Hudson [2] suggest a pavement management working system, including pavement deterioration prediction, decision optimization and feedback, and minimum serviceability index. The minimum serviceability index can be computed by Markov Decision Process (MDP) which may also minimize the long-term maintenance costs [18]. Kher and Cook [19] describe the Program Analysis of Rehabilitation System (PARS) model developed by the

Ontario Ministry of Transportation and Communication. The application of maintenance treatments and action timings can also be optimized by MDP [18].

The Texas Transportation Institute has developed optimization models to allocating M&R funds and other resources among highway districts. Under the budget constraints, the models attempt to maintain the quality of the road segments to some pre-specified level [18]. The use of a MDP would take a different approach to optimization since the specified quality of road segments would be calculated in determining the optimal (minimum cost) maintenance policy; an optimum (minimum) budget would then be computed [18]. Scullion and Stein [20] use the pavement deterioration matrices in planning M&R needs, however, the threshold levels of pavement deterioration for taking certain maintenance actions are determined exogenously [18].

Artman and Liebman [21] develop a dynamic optimization programming to schedule the rehabilitation projects of the airfield pavement. The rehabilitation projects are scheduled by maximizing the area under a utility-weighted Pavement Condition (PCR) versus time curve. The optimization programming is somehow similar to MDP; however, it uses the maximization of utility function of pavement condition rather than minimization of cost measures. Another drawback of this method is that the PCR prediction is based on the regression analysis, which does not include current or recent pavement condition data [18].

The discussion of the above-mentioned studies explains that the optimization of PMS can better be addressed by MDP, as it results in optimal solution of preventive maintenance strategies depending on the pavement conditions. The conventional MDP applies an infinite horizon probabilistic Dynamic Programming (DP) to solve the optimization problems in which LCCA is performed on the basis of long-term behaviour of the pavement structure [22].

The applications of MDP for optimization problems of PMS are justifies by various studies. Golabi et al. [23] determine the implications of implementing MDP for the Arizona DOT. Golabi et al. [23] identify that a total of $40 million was saved from the road preservation budget because of applying MDP optimization method. The Arizona MDP model applies two-steps linear programming to get a steady-state solution. A set of steady state maintenance actions was calculated to minimize the expected long-term average costs. If a road was found to be in a particular state, there was a specified probability that a particular maintenance action would be taken. Golabi et al. [23] argue that the PMS has provided a 'defensible procedure for preparing one-year and five-year budgets' and has helped to 'justify the revenue requests before oversight legislative committees.' However, the maintenance policy was found to be stationary, and random and long-term performance standards were not included [18].

Carnahan et al. [24] develop MDP model for optimal decision-making capability of PAVER, which is a PMS developed by the U.S. Army Corps of Engineers Construction Engineering Research Laboratory (CERL). Unlike Arizona MDP model, this model incorporates pavement data as a Pavement Condition Rating (PCR) based inventory at a single point in time. A transition matrix is developed to identify a Markov chain for each pavement type [18]. Feighan et al. [25] also employed dynamic programming in conjunction with a Markov chain probability-based prediction model to obtain minimum cost maintenance strategies over a given LCCA period.

4 PAVEMENT PERFORMANCE MODELLING

The appropriate and effective pavement performance models are the foundation for the long-term analysis of PMS. The performance models calculate the future condition of the pavement based on which PMS optimizes several maintenance treatments in the long-term maintenance process. The performance models have significant features in the PMS such as (1) the performance prediction models are used when the prioritization of maintenance treatments is required for each segments of road network [26], (2) the models enable the transportation agencies to estimate long-range investment requirement during the life-span of the pavement [26], (3) the models also estimate the consequences of budget allocation for maintenance treatments of a particular road segment on the future pavement condition

of that road segment [26], (4) the models can be applied for life-cycle economic evaluation of the pavement as they relate the pavement exposure variables to pavement deteriorations in the performance indicators [26], (5) many components of PMS such as pavement structural design, maintenance treatment strategies, and priority programming are directly related to the output of the Pavement Performance Prediction (PPP) models [27].

The PPP models should be selected carefully; otherwise they may make the highway system costly and may cause optimal pavement design and selection of optimal rehabilitation strategies and timing of projects impossible [28, 29]. Early PMS did not have PPP models rather they evaluated only the current pavement conditions. Later, simplified PPP models, usually based on the engineering opinions on the expected design life of different M&R actions, were introduced by considering age of the pavement as the only predictive variable [30]. The PPP modelling is explicitly complicated as it is very difficult to estimate incorporating a large number of parameters of pavement performance. A variety of approaches can be used to predict pavement performance such as regression [31, 32], survivor curves [33], latent variable models [34], mechanistic models [35] and Markov chain probabilistic models [36].

Probabilistic models recently have received considerable attention from pavement engineers and researchers. Typically, a probabilistic model is represented by the Markov transition process, which is a knowledge-based expert decision model for the prediction of pavement deterioration [27]. Knowing the 'before' condition' or state of pavement in probabilistic form, one can employ the Markov process to predict the 'after' state, again in probabilistic forms, for as many time steps as are desired [26]. The major challenge, facing the existing stochastic pavement performance models, includes difficulties in establishing Transition Probability Matrices (TPMs).

TPMs are estimated using a non-linear programming approach. The objective function of TPMs is to maximize the absolute distance between the actual PCR versus age data points and the predicted PCR for the corresponding age generated by the Markov chain [25]. The assumption is that the pavement condition will not drop by more than one state in a single year. Thus, the pavement will either stay in its current state or transit to the next lowest state in one year. The probability transition matrix has a diagonal structure. The pavement condition cannot transit from this state unless repair action is performed [25].

Several studies [26, 37] applies empirical-mechanistic pavement performance model to calculate PCR. George, et al. [26] executes various regression analyses to develop empirical-mechanistic performance model for the highways in Mississippi based on the pavement condition data during the period of 1986–1988. Several different models were constructed and evaluated. The evaluation was based on rational formulation and behaviour of the model and on its statistical parameters. Exponential and power functions of both concave and convex shapes are identified as statistically significant. The best-fit models for the performance prediction (PCR_t) of flexible pavement with no overlay (Equation 1), flexible pavement with overlay (Equation 2) and composite pavement (Equation 3) are given below [26]:

$$PCR_t = 90 - a[\exp(t^b) - 1]\log\left[\frac{ESAL}{SN^c}\right] \forall a = 0.6349;\ b = 0.4203;\ C = 2.7062 \tag{1}$$

$$PCR_t = 90 - a[\exp(t^b) - 1]\log\left[\frac{ESAL}{SN^c \times T}\right] \forall a = 0.8122;\ b = 0.3390;\ C = 0.8082 \tag{2}$$

$$PCR_t = 90 - a[\exp\left(\left(\frac{t}{T}\right)^b\right) - 1]\log[ESAL] \forall a = 1.7661;\ b = 0.2826 \tag{3}$$

The prediction models recognize the yearly *ESAL* and Structural Number (*SN*) are of only minor importance, while age (t) being the most important factor of pavement performance modelling. George, et al. [26] argue that *ESAL* would be the weakest link in the cumulative traffic computation because several questionable input parameters (e.g. traffic count, the growth factor, the truck factor) are associated with the *ESAL* estimation. George, et al. [26] apply the same argument for the exclusion of the environmental loads which include thermal effects, subgrade movements in expansive clays if applicable, freeze-thaw effects, and bitumen

aging. George, et al. [26] find out that computational accuracy along with the direct influence of *SN* and asphalt concrete thickness (*T*) on the mechanistic parameters (e.g. stress, strain and deflection) is the reason for its significance in the performance model [26].

Lee, et al. [52] develops the Present Serviceability Rating (PSR) of flexible pavements as a function of structural number, age, and cumulative equivalent single-axle loads (Equation 4).

$$\log_{10}(4.5 - PSR) = 1.1550 - 1.8720 \times \log_{10} SN + 0.3499 \times \log_{10} t + 0.3385 \times \log_{10} ESAL \quad (4)$$

Smadi and Maze [37] determine the Pavement Condition (PCR) for the Iowa Interstate 80 based on the 10 years traffic data. The performance curve of PCR is assumed to be a function of only the total number of 18 kip Equivalent Single-Axle Loads (*ESAL*s) that the pavement has experienced (Equation 5) [37]:

$$PCR = 100 - a(ESAL), \text{ a is constant depends on surface type} \quad (5)$$

Traffic volumes, which are transferred into *ESAL*s, can be calculated for each road link by applying four-step transportation modelling—trip production, trip distribution, modal split and choice analysis, and traffic assignment. Trip production is performed by relating the number or frequency of trips to the characteristics of the individuals, of the zone, and of the transportation network. Discrete choice models use disaggregate household or individual level data (personal, household, zonal and transportation network characteristics) to estimate the probability with which any household or individual will make trips. The outcome can then be aggregated to predict the number of trips produced.

Trip distribution models (e.g. growth factor models and gravity models) are used to predict spatial pattern of trips or other flows between origins and destinations. Modal choice model estimation and application is done to predict the zonal shares of trips by mode. The Multinomial Logit (MNL) model relates the probability that a decision unit chooses a given alternative from a set of alternatives to the utility of these alternatives.

The traffic assignment models (All-or-Nothing, STOCH, Incremental, Capacity Restraint, User Equilibrium, Stochastic User Equilibrium, and System Optimum) predict the network flows that are associated with future planning scenarios, and generates estimates of the link travel times and related attributes that are basis for benefits estimation and air quality impacts. The traffic assignment model is also used to generate the estimates of network performance that are used in the mode choice and trip distribution stages of many models.

5 DYNAMIC PROGRAMMING PROCESS OF PMS

The dynamic programming process starts with the calculation of the routine maintenance cost for each state condition in every family (categorized based on the pavement characteristics e.g. type, structure, construction history, condition, use, and rank) in a particular year. Routine maintenance is not feasible if $R_{ijk} = 0$ or state condition $S_j \geq i$ for family *j*. For all feasible states, the cost of routine maintenance is obtained from $C_{ijk,N} = C_{ijk}$, where *k* is the maintenance alternatives [25]. The cost of all feasible maintenance alternatives for year *N–n* is given by Equation 6 [25].

$$C^*_{ijk,N-n} = C_{ijk} + \left[P^1_{ij} * C^1_{ij^1,N-n+1} + \left(1 - P_{ij^1 1}\right) * C^1_{2j^1,N-n+1} \right] * \frac{1}{(1+i^*)} \quad (6)$$

where P_{ij} is the Markov Transition probabilities for state *i* (1 … 10 states) of matrix *j* (1 … *m* families). C_{ijk} is the cost of applying treatment *k* (1 … *n* maintenance alternatives) to family *j* in state *i*. R_{ijk} is the feasibility indicator for alternative *k* when in state *i* of family *j*. $R_{ijk} = 1$ if maintenance alternative is feasible and 0 for infeasible alternative [25].

The first part (C_{ijk}), of the right side of Equation 6, is the immediate cost of routine maintenance in year *n*. The second part ($[P^1_{ij} * C^*_{ij^1,N-n+1} + (1 - P_{ij^1 1}) * C^*_{2j^1,N-n+1}] * 1/(1+i^*)$) is the

total expected cost to be incurred in the remaining years as a consequence of applying routine maintenance operations. This expected cost is obtained by identifying the probability of remaining in a given state and multiplying this probability by the expected cost of that state and then finding the associated probability of dropping a state if routine maintenance is applied and multiplying this by the expected cost of the lower state. This sum is then discounted by the effective interest rate, i^*, to calculate the present net value in the year $N–n$ [25].

The optimum maintenance strategy is then given by Equation 7 [25].

$$C^*_{ijk,N-n} = Min[C_{ij1,N-n}, Ci_{jk,N-n}] \text{ for all } k. \tag{7}$$

With the related optimal maintenance alternative to be performed for this (i,j) family or state combination in year $N–n$ being the choice of k that minimizes the cost in Equation 6. This backward recursion is performed for every successive year of the analysis period until the analysis for year 0, or stage N, is reached. [25].

5.1 *Road user costs of pavement management system*

The objective function of life-cycle cost optimization is not only to reduce the maintenance costs but also to reduce the user costs. The road user costs are defined as the consequences of the periodic M&R strategies of pavement section. Moreover, the vehicle, accident and time costs are directly associated with pavement condition deterioration. Vehicles costs for fuel, lubricants, tires, repairs and depreciation are proportionately related to the pavement surface condition. For example, fuel consumption is a function of vehicle's speed and the road geometry (mainly vertical upgrade and downgrade) [38]. Although an increase of *IRI* has very insignificant impact on fuel consumption and lubricant costs, the impact of rutting is high during the wet season. In rain, when the ruts are full of water, the rolling resistance increases as a function of water depth. The average water depth is a result of cross-fall, rut depth, precipitation levels and intensity, traffic volume, and the driver's behavior. The increase in rolling resistance gives an increase in fuel consumption when driving on wet surfaces [38]. However, repair costs of vehicles are related to *IRI* rather than rutting. For example, the roughness can affect 50% of repair costs for passenger cars and 25% for heavy goods vehicles in Norway road network [38].

The cost of travel time is a product of value of time and the time to travel a certain distance. Traveling time is a result of traveling speed, which is the function of speed limit, road width, and curvature. Speed limit, road width, and curvature generate a speed of 70 km/hr at an average roughness of 2.7 (*IRI*) [38].

The number of accidents within a road section is a product of various casual factors. The Transportation Association of Canada has categorized causal factors into three main groups: road geometry elements, environmental factors and human characteristics [39, 40]. De Leur and Sayed [41] categorized the causal factors into three generic groups such as exposure, consequences and probability. Exposure has been defined as the extent of exposure to road accidents by road users [39, 40]. Consequences can be expressed by the severity of road accidents and the probability was explained as the likelihood of accidents occurrence [39, 40]. Sayyadi et al. [40] identify several road geometrics, traffic and environmental characteristics as the causal factors of road accidents. These are: individual car accident percentage, vehicle's speed, intersections per kilometer, severity of horizontal and vertical alignment, length of the road section, Annual Average Daily Traffic (AADT), light condition, weather-surface condition, road cross-section characteristics, and shoulder and land width.

The objective function (Equation 8) is also to minimize societal cost under budget constraints (Equation 9) [11].

$$Min \sum_i \sum_j \sum_k w_{ik} (C^*_{ik,N-n} + U_{ik}) \forall \sum_i \sum_j \sum_k w_{ik} = 1 \tag{8}$$

$\sum_k w_{ik} \le \varepsilon_i (1+\phi)$ for all unacceptable i and $\sum_k w_{ik} \ge \varepsilon_i (1+\phi)$ for all acceptable i.

$$B(1-\Omega) \leq \sum_i \sum_j \sum_k w_{ik}(C^*_{ijk,N-n}) - \beta \leq B(1+\Omega) \quad (9)$$

where w_{ik} is the fraction of area of pavement in state i with action k applied, B is the budget constraint per year, β is the parametric analysis adjustment on budget constraint, Ω is the tolerance on budget constraint, ε_i is the condition constraint for state i, ϕ is the tolerance on condition constraints [11].

5.2 *Drawbacks of Markov Decision Process (MDP)*

The main drawback of MDP approach is that it does not accommodate budget constraints [42]. Another important drawback of this approach is that pavement sections have to be grouped into a large number of roughly homogeneous families based on pavement characteristics [43]. A large number of families mean fewer sample of pavement sections in each family, which compromises the reliability and validity of the Transition Probability Matrix (TPM) generated for each family [43]. There are equally large numbers of M&R treatments for each family of pavement sections. It is suggested that all pavement sections should be categorized into small numbers of families. As the MDP addresses the performance evaluation of the pavement section as a group, it is not possible to address the performance condition of individual pavement section. Similarly, the optimization programming of M&R strategies are determined for a group of pavement sections rather than an individual section under a given budget. Moreover, the optimization programming of M&R strategies are calculated from the steady-state probabilities. However, in reality, the pavements under a given maintenance policy usually takes many years to reach the steady state and the proportion of the pavements are changing year by year. Therefore, the use of steady-state probabilities in the optimization objective function does not fully reflect reality, especially when this transition period is very long [43].

5.3 *Project-based PMS—an alternative modelling approach*

The project-based modelling approach is based on the analysis of historical performance data stored in the database to develop model coefficients for individual pavement sections. For each individual section, the available historical performance data since the last rehabilitation or construction is analysed to determine the model that matches the observed performance of the section and thus predict the future performance. The cost effectiveness, later on, derived from the prediction performance curve. The pioneer of project-based optimization method for pavement M&R strategies and projects is Arizona DOT [43].

Thompson et al. [11] divide the Finnish highway network into six regional class sub-networks and propose individual optimization model for each of the sub-network group rather than for an individual road segment. Each model is classifed among four dimensions—bearing capacity, pavement defects, rutting, and pavement roughness.

The proposed models by Arizon DOT and Thompson et al. [11] solve the opitmization problem at an individual or group of pavement section, however, the deterioration uncertainty has not yet been resolved. The required budget should treat the uncertainty of deterioration carefully by incorporating stochastic characteristics of road data.

Butt et al. [44] introduce different duty cycles to allow the changes in traffic loads and maintenance polices over the pavement life. This nonhomogeneous Markov model divides the life of the pavement into different zones assuming a constant rate of deterioration for each of these zones. A homogeneous Markov chain and a separate TPM are developed for each zone. On the other hand, a nonhomogeneous Markov chain has been used for transition from one zone to another [44].

A research project titled 'Maintenance Cost Prediction for Road' under the Cooperative Research Centre (CRC) for Construction Innovation has also developed a method that takes into account the variability and uncertainties of road data in investment analysis [45].

Piyatrapoomi et al. [45] identify the variability parameters of the predicted budget, which includes rut depth, AADT, initial roughness and pavement strength [45]. The variability of these parameters was quantified by probability distributions, means and standard deviation for each category. The best fitted probability distribution functions (pdf) for International Roughness Index (IRI), rut depth, and AADT of the Queensland road network are Beta General, log normal and exponential distributions, respectively [45]. Piyatrapoomi et al. [45] apply Latin-hypercube sampling technique to simulate the variability of above-mentioned parameters.

The major drawback to practice project-based optimization is that the complexity of pavement management problems increases exponentially with the size of the problem. For example, the number of possible solutions for project-based optimization problems is M^T, where M is the number of maintenance actions to be considered and T is the number of years (or periods) in the analysis period. If the solution space size for a single section given a certain analysis period and number of available maintenance actions (project level) is C, the solution space size of the network problem, assuming S similar sections, is $\boldsymbol{C}^{\boldsymbol{S}}$. With the general project-level complexity, therefore, this equates to $(A^T)^{CS}$ [46].

Pilson et al. [46] propose a Genetic Algorithm (GA) optimization model to overcome this complexity. The GA optimization model considers each analysis period as a 'gene' and maintenance actions as 'allele' values. A chromosome represents a maintenance strategy for a particular period. The second step of GA optimization model is to measure the 'fitness' of the chromosomes [46]. However, the major drawback of GA optimization model for PMS is that the chromosome has one gene for each pavement section and each gene can take on any value from that section's efficient set. This decomposition of the network problem relies on the independence of the project-level problems, which is not theoretically acceptable for annual budgets [46].

The project-based PMS is still struggling with the large size of problems and solutions. Although we can solve this problem by GA optimization model, there is a decomposition problem of the independence of the project-based PMS. This is not suitable under an annual budget for the whole road network. Moreover, the above-mentioned models optimize the PMS by minimizing the cost, ignoring the maximization of pavement condition.

5.4 *Multicriteria pavement management system*

PMS should include the effect of M&R strategies on other road users such as residents in close proximity from the road, industrial settlements, trade centres, etc. [47]. The Action de Préparation, d'Accompagnement, et de Suivi (APAS) transport research project, funded by the European Commission, develop some indicators for the choice of transport projects using decision criteria optimization [48]. The indicators are developed through simplified Multicriteria Analysis (MCA) techniques such as Elimination et Choix Traduisant la Realité (ELECTRE III) [49, 50] and the Analytical Hierarchy Process (AHP) [51]. Highway Development and Management Tool (HDM-4) applies AHP method to integrate multicriteria factors with the PMS [47].

Cafiso et al. [47] identify ride comfort and environmental factors as the criteria of PMS along with agency costs and user costs. The ride comfort is defined as Ride Number (*RN*) values by National Cooperative Highway Research Program (NCHRP). Ride Number (*RN*) values for alternative k of the section j are obtained from *IRI* (m/km) through Equation 10. IRI_{jkn} equals to *IRI* for the alternative k of the section j at year N [47].

$$RN_{jk} = \frac{\sum_{n=1}^{N}\left(5 - 2.63 \times \log\frac{IRI_{jkn}}{0.343}\right)}{N} \tag{10}$$

The environment parameter for a road segment can be calculated by deriving Air Quality Index (AQI). AQI can be calculated by applying Equation 11 [47].

$$AQI_{jk} = \sum_n \frac{\sum_p E_{pjkn} \frac{1}{S_p}}{\sum_p \frac{1}{S_p}} \times AADT_{jn} \times \frac{L_j}{1000} \tag{11}$$

where AQI_{jk} = AQI for the alternative k of the section j; E_{pjkn} = emission value of the substance p for the alternative k of the section j at year n; $AADT_{jn}$ = average annual daily traffic for the section j at year n; L_j = length of the section j; S_p = concentration limits of a single substance p [47].

Socio-economic development parameter can have significant relation with the PMS. The residents, in close proximity to the invested road infrastructure, may achieve significant socio-economic benefits from the PMS strategies. The characteristics of development parameters of urban area can be demographic characteristics, economic characteristics, social and community characteristics, transportation facilities, urban services and facilities, and environmental characteristics.

Instead of project-based PMS, this paper proposes a PMS for different categories of road groups with different pavement performance curves for each group.

The objective functions of multicriteria PMS are given by Equation 12 and 13.

$$Min \sum_i \sum_j \sum_k w_{ik} (C^*_{ijk,N-n} + U_{ik}) \; \forall \sum_i \sum_k w_{ik} = 1 \tag{8}$$

$\sum_k w_{ik} \le \varepsilon_i (1+\phi)$ for all unacceptable i and $\sum_k w_{ik} \ge \varepsilon_i (1+\phi)$ for all acceptable i.

$$\text{Subject to: } \sum_{n=1}^{N} \sum_{i=1}^{I} L_i Q_{n,i} \ge (LOS) \sum_{i=1}^{I} L_i \tag{12}$$

$$Max \quad \sum_{n=1}^{N} \sum_{i=1}^{I} (W_i * L_i Q_{n,i} + W_2 * MCI_i) \tag{13}$$

$MCI_i = f$(comfort, environment, socio– economic development criteria)

$$\text{Subject to: } B(1-\Omega) \le \sum_i \sum_j \sum_k w_{ik} (C^*_{ijk,N-n}) - \beta \le B(1+\Omega) \tag{9}$$

where $Q_{n,i}$ = Condition Index for asset i on year n; MCI_i = multicriteria index for asset i, and W_1 and W_2 are the weights of the condition index and multicriteria index.

6 CONCLUSION

The pavement management systems incorporate the economic assessment of trade-offs between competing maintenance and rehabilitation alternatives. The conventional techniques are capable of finding the optimal path to take full advantage of cost-effectiveness of individual treatments, however, incapable of addressing safety, condition, congestion, pollution and social cost. The objective of this paper is to outline a conceptual framework of a Pavement Management System (PMS) for the road network of Montreal City.

This paper initially describes the life-cycle cost analysis as the economic optimization model for PMS. The methods of appropriate and effective pavement performance modelling are discussed as the pavement deterioration modelling is the foundation for the long-term analysis of PMS. The framework of Integrated Land Use and Transportation (ILUT) modelling, applying four-step transportation modelling, is explained to predict the future traffic volume during the life-cycle of pavement. ILUT modelling is discussed because the predicted traffic volumes of each segment of road network are transferred to Equivalent Single Axle Loads (*ESAL*s).

The proposed dynamic programming process of PMS points out the drawbacks of the Markov decision process of network-based PMS and is brokering the project-based PMS. The project-based PMS is still struggling with exponentially increasing size of problems and M&R solutions. This study proposes a PMS for different categories of road groups with different pavement performance curves for each group. This paper also proposes the incorporation of road user costs and socio-economic development of the residents (in close proximity to road infrastructure) along with agent costs in the PMS. This dynamic PMS will manage continuous aggregate behaviour of transportation system and can solve optimization problems of pavement management at any time interval.

Noise related to pavement preservation surfaces in NJ

John Hencken, Ed Haas, Mike Tulanowski & Thomas Bennert
Center for Advanced Infrastructure and Transportation (CAIT), NJ, USA

ABSTRACT: NJDOT is evaluating the benefits of pavement preservation surfaces and techniques for interstate rehabilitation as a method to increase pavement life while reducing overall cost. A preliminary noise evaluation was conducted at the tire/pavement interface to compare the alternative surfaces to existing in-service pavements as part of a trial study being conducted by the NJDOT. Pavement preservation surfaces provide a benefit in relation to the speed of construction, which reduces the time required for lane closures, increasing public acceptance. Micro-surfacing and chip-sealing were specifically identified as having the highest potential to be applicable at the interstate level. The outcome for the project is to determine an appropriate treatment to reduce oxidization and extend pavement life quickly for a relatively low cost, when a 2% distress level is identified.

Although the design, implementation, and overall properties are different for these pavements, each yielded high noise levels when they were initially paved. It was considered important to conduct measurements at various speeds because these surfaces are frequently used within residential areas. This paper examines the pavement preservation techniques and the related pavement noise measured using the On-Board Sound Intensity Method compared to more commonly used pavements for reference.

Keywords: Pavement preservation, asphalt, noise, OBSI

1 BACKGROUND

The New Jersey Pavement Management System (PMS) has proven to be a critical system to enable the NJDOT to maintain the statewide roadway network effectively. Pavement management systems maximize the return on investment for maintenance and rehabilitation of the statewide network. Pavement management also provides valuable data to legislators and the public to explain the status of the road network [1]. The PMS is also useful to identify areas that need maintenance and to establish minimum condition requirements [1]. The NJDOT is determined to rehabilitate the overall state network to 80% acceptable levels of PCI by 2021. To accomplish this goal they have concluded that pavement preservation and preventative maintenance needs to be conducted earlier in a pavement's lifespan to ensure that the currently acceptable sections remain that way. Micro-surfacing has been suggested as a cost effective method to reduce oxidative aging of an underlying pavement and return PCI to 100% [2]. As such, the state is conducting in-service test applications on various state-maintained roadways to determine how well the technique works. One concern that arises with the increase in use of micro-surface and other pavement preservation techniques is whether or not the new surfaces will provide similar noise properties to current in-service surfaces.

1.1 *Micro-surface*

A micro-surface is a pavement preservation technique that provides a new high friction surface and returns a pavement to 100% Pavement Condition Index (PCI) by applying a thin slurry seal directly on the existing pavement surface. It is utilized in areas that have high crash potential,

to cap pavements that are beginning to exhibit wear, and to increase ride quality on rutted surfaces [2]. It should resist compaction after the initial curing period, and exhibit a skid resistant texture throughout its service life [2]. Micro-surfacing has been utilized in New Jersey previous to this study on at least two roadway sections in 2002 on US-202 S and NJ-29 [3]. This previous micro-surface application was designated as a type III micro-surface which is recommended for use to obtain maximum skid resistance on heavily traveled pavements, to level the existing surface eliminating rutting, or simply to implement a new highly textured surface [2, 3]. The micro-surfaces evaluated in this project are type II, which are used primarily to fill surface voids such as cracks and to provide a durable wearing surface [2]. Micro surfacing can be considerably cheaper than milling and paving by utilizing it as a capping surface when the pavement begins to show distress providing an expected performance of 3–5 years on a high-volume facility [4].

1.2 *Asphalt rubber chip seal*

Chip sealing is an asphalt surface treatment in which an emulsified asphalt binder is applied to the asphalt pavement surface followed by the immediate application of aggregate chips that are rolled to maximize aggregate embedment [4]. By introducing rubber into the emulsification, the chip seal is expected to last longer than a conventional polymer modified mix. Chip seals are used as a wearing course on low volume roads to enhance friction performance, correct minor cracking, roughness, bleeding, and other minor surface distresses [4]. Since the material is cheap to produce, quick to install, and has worked for a variety of road surfaces in NJ, the DOT was interested to learn about the noise levels associated with the surface to determine if it would be a potential application for some of the larger state-maintained roadways. This will be especially important if the longevity of the chip seal is extended due to the use of modified binder and the introduction of rubber.

1.3 *Other pavement preservation surfaces*

This study focused on the implementation of the micro-surface test sections put in place by the NJDOT in November 2012 and the AR chip seal sections laid in October 2012, but it was considered important to include data collected on the other thin-lift surfaces in service throughout the state. There is a significantly comprehensive review of the most current preservation techniques in the Strategic Highway Research Program (SHRP2) renewal research papers, "Preservation Approaches for High-Traffic-Volume Roadways," [5], and the "Guidelines for the Preservation of High-Traffic-Volume Roadways," [4]. The SHRP2 study evaluated a variety of twelve different preservation treatments related to Hot Mix Asphalt (HMA) surfaced pavements that are already in use on high-traffic-volume roadways [5]. An Open-Graded Friction Course (OGFC) is a functional asphalt overlay designed with a uniformly graded aggregate [5]. Stone Mastic Asphalt (SMA) is hot-mix asphalt in which mineral filler is introduced to the bituminous asphalt binder creating a mastic binder mixed with highly angular, uniformly graded aggregate [5]. High Performance Thin Lift overlays are plant mixed HMAs that are placed at roughly 0.75″ to 1.5″ (19–38 mm) with polymer modified binders [5]. An ultrathin bonded wearing course is a thin layer of high quality aggregate which has a gap graded design placed between 0.375″ (9.5 mm) to 0.75″ (19 mm) thick over a polymer modified emulsified membrane; this application is referred to as Novachip. NJ has examples of each of these pavements that are in service and have been tested using OBSI previously. Any functional overlay that could be utilized as a thin-lift laid up to 1″ (25.4 mm) could be considered a pavement preservation technique even though it may undergo performance testing and standardization typical to a HMA mix.

2 NOISE TESTING

2.1 *Testing procedure*

The method utilized to measure the tire/pavement noise for this study was the OBSI method, which provides sound intensity levels measured in dBA [6]. The testing was conducted in

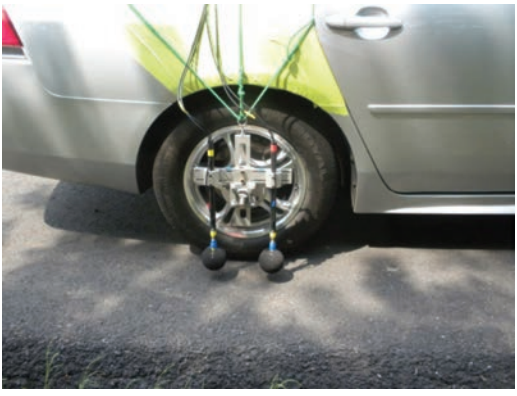

Figure 1. OBSI testing rig.

the right lane of each section to ensure equal comparisons for each section. The equipment utilized to measure the tire/pavement noise on the outside of the vehicle, shown in Figure 1, included four G.R.A.S. phase-matched free-field microphones and preamplifiers for the two probe systems.

The measurements were recorded over a 5.0 second measurement period at 60 mph (96.6 km/h). A minimum of three runs were completed to exceed the coherence, PI index, and run-to-run criteria outlined in AASHTO TP 76-12 [6].

2.2 *Analysis procedure*

The analysis of the measurements taken was completed in several separate processes using the following methods. Each test site was averaged together to get a representation for each material. A table and coinciding bar graph of overall material averages were compiled for each pavement to show the range of differences between each of the pavements tested. Secondly, one-third octave band frequency spectrum graphs were created for each site and averaged to represent each pavement section. The frequency graphs show the measured sound intensity levels along the one-third octave band spectrum, which is the typical frequency band used to show sound measurements for OBSI. Then comparisons were made between different materials. Typically, people are more sensitive to the higher frequencies between 2,000 and 4,000, and the less sensitive to lower frequencies [7].

3 RESULTS AND ANALYSIS

3.1 *Environmental conditions*

The environmental conditions throughout testing were similar for each of the sections, with the exception of the NJ Rt. 24 tested on November 12th, which had an almost 30°F warmer ambient temperature and 21.5°F warmer pavement temperature than the coldest test day, which was experienced on November 15th, at the I-287 test section. Table 1 below shows the ambient, tire, and pavement temperature recorded each test day. The ambient temperature was measured with a handheld Kestral© portable weather station, the pavement and tire temperatures were measured with infrared probes mounted on the OBSI rig.

3.2 *Mix designs*

The mix designs for the micro-surface were completed by Road Science™ and they fell within the specification for type II micro-surfaces outlined in the Recommended Performance Guideline for Micro-Surfacing [2]. Figure 2 shows the gradation chart for the mix, which

Table 1. Environmental and site conditions.

Road	Date tested	AADT	Ambient temp	Tire temp	Pavement temp	Elevation	Number of sites
I-287	11/15/2012	92,020	49.2	61.7	45.7	308	20
I-287	5/16/2013	92,020	68.8	80.2	63.6	308	20
NJ Rt. 24	11/12/2012	109,963	71.2	89	67.2	196	18
NJ Rt. 24	4/8/2013	109,963	78.7	109.1	98.4	145	18
NJ Rt. 133	11/30/2012	16,276	48.1	71.4	45.9	97	26
NJ Rt. 133	5/2/2013	16,276	68.6	98.4	106.9	101	26
NJ Rt. 206	12/6/2012	24,178	54.3	60.7	47.3	583	8
NJ Rt. 23	11/29/2012	2,064	41.4	62.6	47.4	836	8
River	10/8/2012	400	60.5	67.8	59	53	2

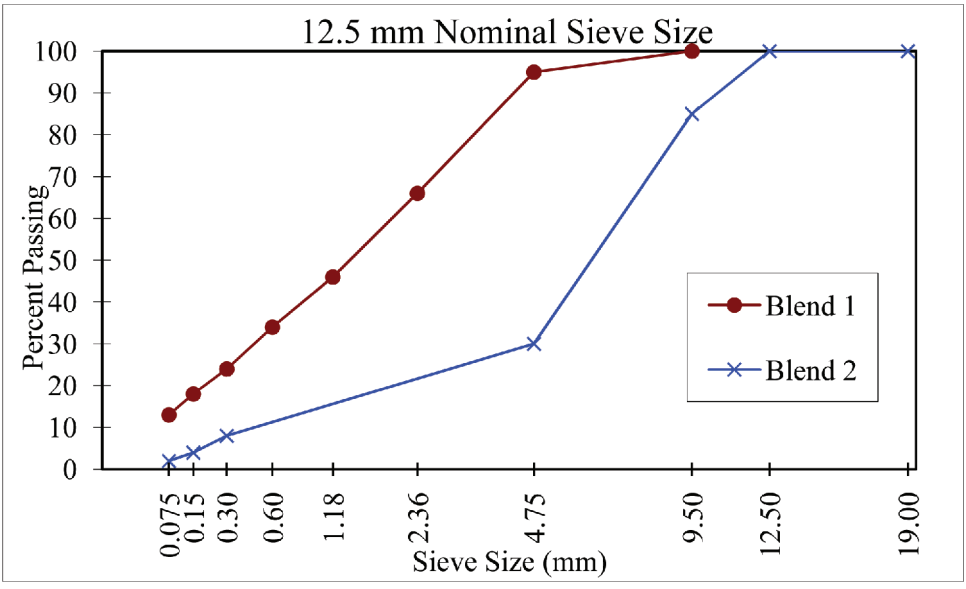

Figure 2. Type II micro-surface and AR chip seal mix gradation.

is labeled Blend 1. The aggregate source was Tilcon Inc. from Oxford, NJ which provided granite type II. The filler used was type I Portland Cement and the asphalt was CSS-1H latex modified MicroTekk™ provided by Road Science™ in Hammonton, NJ.

The AR Chip Seal utilized for this study was paved by the Branchburg Township municipal department, the aggregates were pre coated with PG64-22 by Stavola Inc. and stockpiled at the township complex. The AR binder PG58-28 was applied at a rate of 0.60 gal/yd^2 (0.003 L/m^2). The gradation for the AR Chip seal is shown in Figure 2, labeled Blend 2. An additional specification to screen off undersized material during the pre-coat was specified to allow the high binder content to permeate the mix.

3.3 *Noise levels*

The preliminary and secondary measured values for the micro surface sections on I-287 and NJ Rt. 133 are shown in Figure 3. It also shows the single measured value for AR chip seal tested on River Road in Branchburg Township for both the overall values and the one-third octave band spectrum. Unfortunately, a second test at 60 mph on the AR chip seal was not collected due to safety concerns.

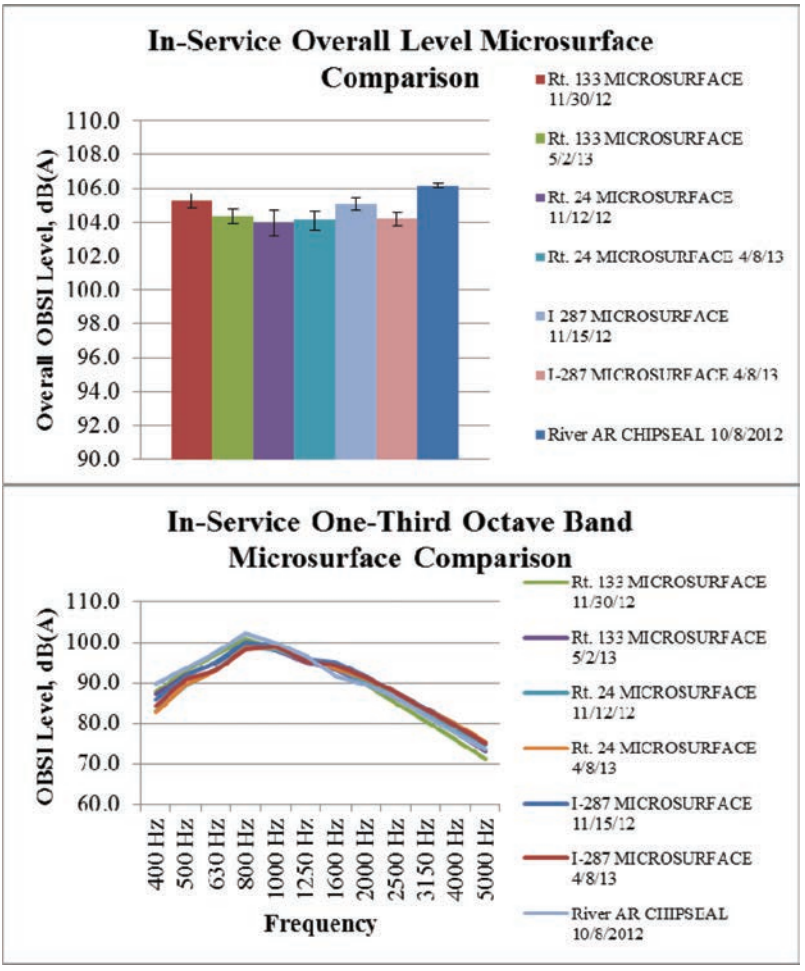

Figure 3. 60 mph (96.6 km/h) micro surface noise levels.

It is easy to see that the AR Chip seal is a loud surface at 60 mph (96.6 km/h). Since AR Chip seal would only be paved on low volume roads and would likely never see legal vehicle speeds as high as 60 mph (96.6 km/h). Initially the I-287 micro-surface had an overall level of 105.1 dBA with a standard deviation of 0.3 dBA. After half a year, the second measurement had an overall average of 104.2 dBA with a standard deviation of 0.4 dBA. The Rt. 24 micro-surface showed a maximum overall level measured at 104.7 dBA and a minimum recorded level at 102.6 dBA, which was a 2.1 dBA difference. The second round of testing measured an overall average of 104.1 dBA with a standard deviation of 0.6 which was similar to the original measured value. NJ Rt. 133 initially measured an average of 105.3 dBA with a standard deviation of 0.4 dBA. The second measurement date on that surface had an average of 104.4 dBA with a standard deviation of 0.4 dBA.

3.4 *Compiled results and external comparisons at 60 mph (96.6 km/h)*

Figure 5 shows the comparison of other in-service pavements throughout the state of NJ to compare noise levels experienced on different pavement surfaces and how those levels relate to the two pavement preservation surfaces measured here. The Novachip and HPTO surfaces would be directly considered pavement preservation surfaces, but AROGFC is shown as well. AROGFC is typically referred to as a quiet pavement, but as a functional

HMA overlay. In addition, a separate graph will relate overall values of other HMA surfaces typically found in NJ.

Figure 4 shows the overall and one-third octave band comparison of pavement preservation materials tested in NJ. The AROGFC measured the lowest on average around 100.0 dBA while the highest was the AR chip seal, which was an average of 106.2 dBA. From the spectral frequencies, the micro surface section was loud in the lower frequencies, which leads us to believe that because the micro-surface is not rolled it has a positive texture that increased the tread impact vibration. The chip seal was also loud in the low frequencies, which is due to the high texture related to that mix. The HPTO noise was also related to the properties of the mix gradation. The well graded small aggregate size mix with low air voids provided a smooth surface with decreased low frequency tread impact noise and louder high frequency noise due to more stick-slip interaction.

Figure 5 shows the comparison of micro-surface to typical HMA surfaces that are in service in NJ in addition to one Portland Cement Concrete (PCC). The micro surface was loud in overall decibel level and was only slightly quieter than the average PCC. It only differed from the PCC in the high end frequency range. The HPTO aligned well with the SMA and DGA, while the SMA was quieter in the low to mid frequencies. AROGFC remains the quietest in-service pavement in NJ, due to the attenuation of sound in the high air void mix.

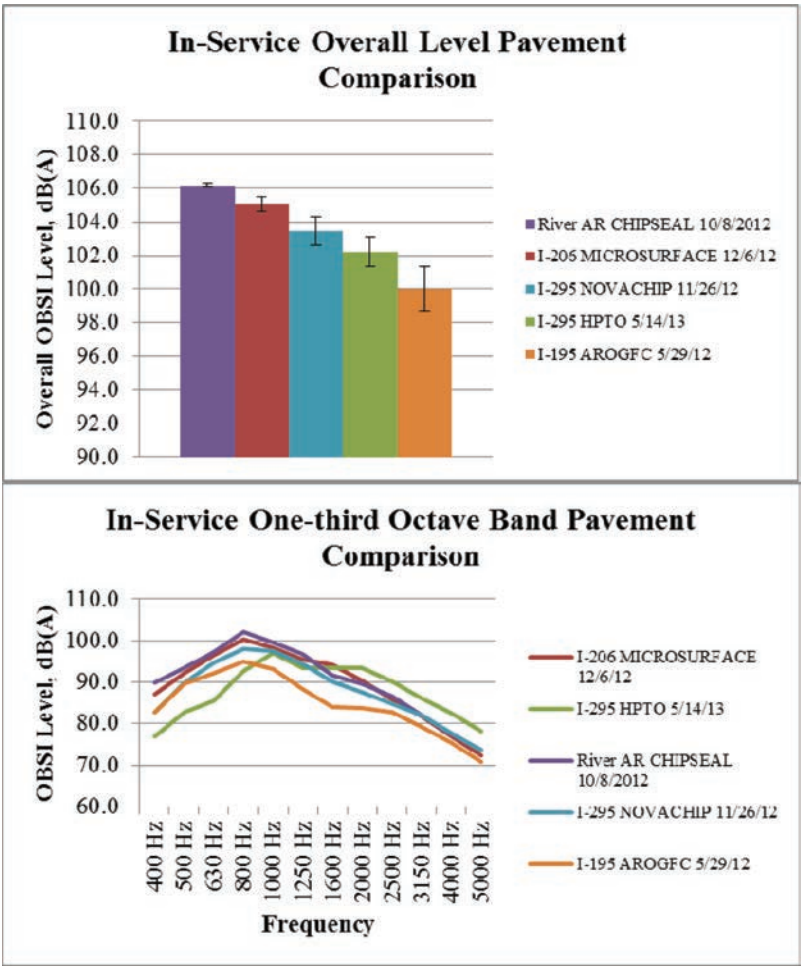

Figure 4. OBSI comparison of pavement preservation alternatives at 60 mph (96.6 km/h).

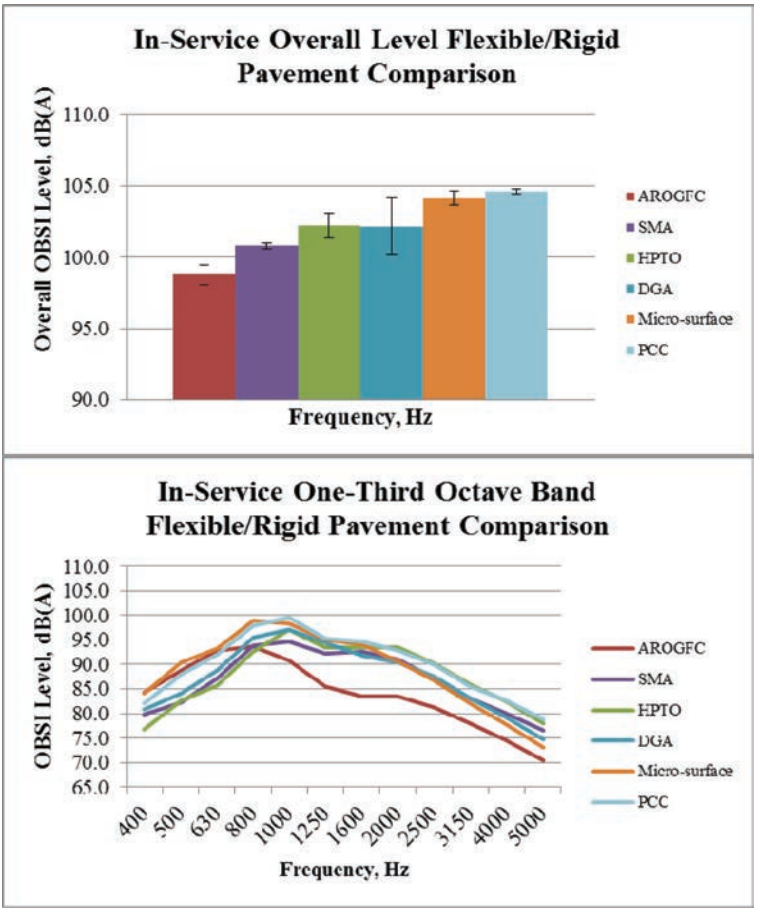

Figure 5. OBSI comparison of microsurface to convetional pavement at 60 mph (96.6 km/h).

4 CONCLUSIONS

4.1 *Noise analysis*

The NJDOT is interested to determine the noise levels for pavement preservation surfaces as they grow in popularity with the state PMS. The focus of the state is shifting to start using micro-surface as a pavement cap for pavements showing as little as 2% distress as measured by PCI. As the PMS switches from rehabilitative to preventative maintenance, the use of preservation techniques as a whole will continue to grow. Since the noise generated at the tire/pavement interface is closely related to the amount of overall traffic noise [8] it is important to understand how the state will be altering the environment for local constituents, especially when evaluating state-maintained arterial system.

Five micro surface sections and three AR chip seal sections were laid because of their low cost, speed of construction, and ease of application. Then these surfaces were noise tested and compared side by side to other pavement preservation techniques utilized throughout the state, namely HPTO, Novachip, and AROGFC. Finally, the micro-surface and AR chip seal were compared to other standard HMA mixes also in-service throughout the state including DGA, SMA, and PCC.

The micro-surface sections were tested initially in November 2012 purportedly a short time after they had been laid. All of the micro-surfaces measured similar values and provided similar one-third octave band spectrum results. The major trend was that the micro-surface seemed

to undergo some smoothing, that lowered the overall value by 1 dBA after a 6 month period except for one pavement measured on NJ Rt. 24, which is thought to have been paved at least 6 months prior to this study. Since the micro-surface on NJ Rt. 24 did not change between the two different tests and because both times it was measured at the lower value, it can also be presumed that after the initial 6 month break in period, the noise level would stabilize. Monitoring of these sections will continue in the future to determine how the acoustic longevity would perform, since there is still potential for more smoothing to occur, which may continue to decrease the overall level. They were a loud pavement option compared to the average DGA measured around 102 dBA, the SMA measured around 100 dBA, and the AROGFC measured around 99 dBA. As shown in Figure 5, it is notable that the micro-surface noise is more prevalent in the lower frequencies, so although the overall level is approaching that of a PCC, the micro-surface would not exhibit the high-frequency whine associated with concrete.

The AR chip seal pavement was tested at a variety of speeds which was useful for comparison purposes. It was tested one time at 60 mph (96.6 km/h) which was helpful for comparison to other pavements within the NJ noise database. Even though the measured value of 106.2 dBA at 60 mph (96.6 km/h) is very loud, the AR chip seal is not a very likely candidate for roads that allow high speeds.

The HPTO, due to its specific uniformly graded attribute of small aggregate, has an average overall noise level of 102.2 dBA, with prevalently loud high frequency noise. Similarly the Ultra-thin Bonded wearing course, or Novachip, has consistently measured an average of 103.5 dBA, which is louder than the HPTO. Since the HPTO, like Novachip, has specific structural uses and is required to undergo HMA performance testing similar to any other HMA, their use is still suggested when necessary.

There are factors other than noise to consider when choosing a pavement preservation surface including the safety associated with that surface, such as skid resistance and the reduction of splash and spray during wet weather. Cost and return on investment are also significant factors in pavement preservation technique selection. The general consensus in NJ is that as long as the new surface is not much more than 3 dBA louder than the original surface, which would be below the normal human perception threshold, it would still be considered acceptable. When there is a desire to specifically reduce noise, the data within this paper suggests that utilizing a thin AROGFC overlay may be the most beneficial option followed by an SMA. At this time in NJ, the SMA surfaces and AROGFC have shown similar longevity of life, but it would also be important to consider that future maintenance such as placing a micro-surface to reduce oxidation, would be applicable on an SMA surface, but not on an AROGFC.

Significance of non-load related distresses on airfield asphalt pavements: Review of 25 years of pavement management data

John F. Rushing, Jesse D. Doyle & Andrew Harrison
U.S. Army Engineer Research and Development Center, Vicksburg, MS, USA

ABSTRACT: Non-load related distresses are a major factor contributing to the need for maintenance and rehabilitation of Hot-Mix Asphalt (HMA) airfield pavements. By using pavement management system data, the quantity of these non-load related distresses can be determined. This paper summarizes data gleaned from the analysis of over 8 million square meters of HMA airfield pavement to identify the most significant types of surface distresses according to the Pavement Condition Index (PCI). These data represent 25 years of using the pavement management system, Micro PAVER, to determine the condition of U.S. Army airfield pavements. The quantity of longitudinal and transverse cracking, raveling and weathering, and block cracking was extracted from the database for various ages of pavements. In addition, the total percentage of non-load related distresses was identified for various ages of pavements. Findings from this analysis of existing data highlight the need for improved maintenance procedures to combat the need for maintenance and rehabilitation related to non-load distresses in HMA. The benefits of preventive maintenance are discussed, along with the need to monitor the application of various approaches using techniques employed by pavement management systems.

Keywords: pavement management, preventive maintenance, asphalt pavement, pavement distress, environmental damage

1 INTRODUCTION

Both airfield and highway pavements are designed to withstand the stresses exerted by wheel loads for a projected analysis period and traffic volume. The major difference in designing the two types of pavements is in the wheel load magnitudes and in the number of load repetitions anticipated during the design life. Highway pavements typically experience much higher traffic volumes during their service lifetimes than do airfield pavements. As such, highway pavement design requires a detailed analysis of the expected tensile strains at the bottom of the Hot Mix Asphalt (HMA) layer for fatigue consideration. On the other hand, airfield pavements are frequently designed with very thick base course layers compared to highway pavements to reduce stress on the subgrade under aircraft loadings. Traditional conservative design approaches for airfield pavements use a minimal thickness of HMA and often underestimate its structural capacity. In many cases, the HMA layer is in compression during loading, resulting in few occurrences of fatigue damage on airfield pavements. This conservatism generally results in few overall structural failures as long as traffic is limited to the design aircraft.

Most pavement distresses are caused by the interaction of traffic and environment effects, however they can be broadly categorized as primarily load (traffic) related or primarily non-load (environment, materials, construction) related. Many areas of typical airfields will experience limited or no direct aircraft wheel load applications and only occasional light vehicle traffic during their service life. As a consequence, non-load related distresses are the most frequent causes of airfield asphalt pavement damage. Climate, asphalt cement crude source, mixture variables,

and construction variables all contribute to the development of non-load related distresses [1]. Climate is a major contributor to distress formation in HMA. As the binder in the HMA ages, it becomes harder and more brittle, resulting in a less durable pavement. This change in the binder characteristics makes the pavement surface more likely to experience a loss of aggregate (weathering or raveling) or non-load associated cracking. Improper volumetric mixture proportions or poor construction techniques can exacerbate this mixture durability loss.

The U.S. Army Engineer Research and Development Center (ERDC) maintains a database containing information from Pavement Condition Index (PCI) surveys on U.S. Army airfields from 1986 to 2011. In 2011, the database contained information on over 8 million square meters of asphalt-surfaced airfield pavement. These pavement areas included runways, taxiways, and parking aprons. The database contains the most recent inspection data and includes a list of all distresses observed on the pavement surface. Data for asphalt concrete surfaces contained in this database were analyzed to determine the type, quantity, and magnitude of surface distresses. This paper presents findings from this analysis as well as implications for proactive pavement preservation and selection of durable asphalt paving materials.

2 PAVEMENT MANAGEMENT SYSTEM DATA ANALYSIS

The U.S. Army airfield pavement management database contains pavement surface distress data separated into three categories by the pavement management software Micro PAVER. These categories define distresses as primarily load-related, climate-related, or other-related. Primarily load-related distresses include alligator cracking and rutting. Primarily climate-related distresses include weathering/raveling, longitudinal and transverse cracking, and block cracking. Other-related distresses are relatively uncommon distresses such as bleeding, jet blast, and swelling. The analysis of this database is described in the following sections.

2.1 *Distribution of pavement age*

The pavements were first categorized according to their age before further analysis was conducted. Figure 1 shows the total area of asphalt-surfaced pavements in each age group. Figure 1 illustrates the unbalanced proportion of older asphalt-surfaced pavements in the database. The higher proportion of older pavements is likely attributed to two major factors.

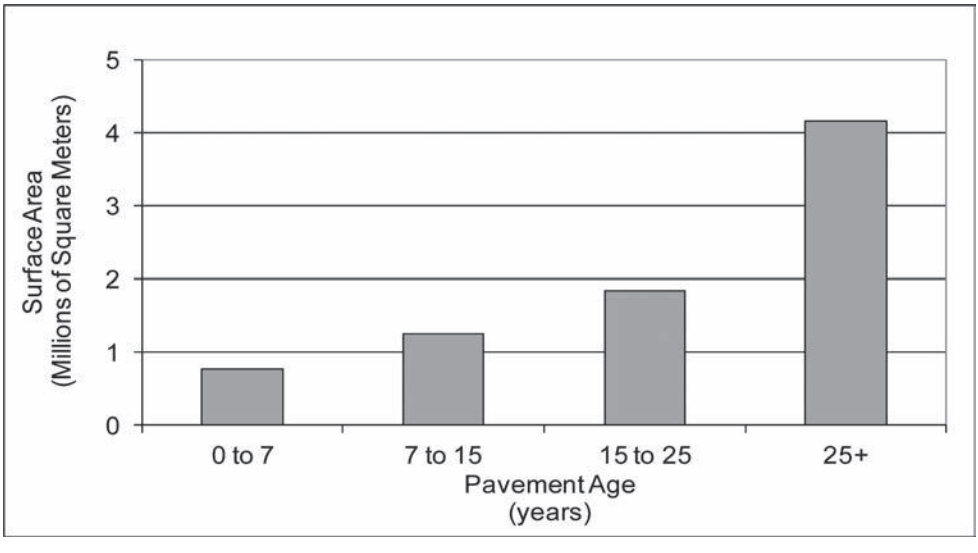

Figure 1. Distribution of pavement in database by age.

First, consolidation of forces and changes in mission requirements has reduced the need for pavement features at some installations. Therefore, the existing pavements have been allowed to age and deteriorate without maintenance and/or rehabilitation. Second, funding constraints have led to prioritization of maintenance projects, and non-essential pavement areas are often neglected. Maintenance funding problems have been realized by many transportation agencies, resulting in an enhanced awareness of the need to improve pavement management practices.

2.2 *Distribution of overall pavement condition*

The condition of the pavements in the database was denoted by the PCI. The PCI is an index from 0 to 100 used to describe the pavement condition through visual inspection [2]. This index only considers surface distresses. The PCI is determined by a cumulative reduction in points from 100 (no distresses) according to distress type and severity. Many transportation agencies use PCI to dictate threshold serviceability levels. The U.S. Army requir es runways, taxiways, and aprons to have minimum PCI values of 70, 60, and 55, respectively [3]. The PCI values reported in the database were computed by the Micro PAVER computer software [4]. Figure 2 shows the average PCI of the pavements in the database according to their age group.

The relative condition of the pavements follows a generally accepted trend. The initial condition of the pavement is expected to be 100 immediately after construction. The early years in the life of a pavement tend to reveal mix or construction deficiencies that result in small deductions in the PCI. Additional years of aging results in rapidly increasing deterioration, as evidenced by the reduction in the average PCI of those pavements greater than 15 years old (Fig. 2). The reduction in PCI is often enhanced because surface distresses allow rapid intrusion of moisture into the pavement system, often leading to additional distress formation. Moreover, the PCI rating system deducts more points as the distresses continue to become more severe. The deterioration of pavements with time is an expected phenomenon. Nearly all infrastructure systems require maintenance and rehabilitation to continue to perform at acceptable levels. The intention of this analysis is to enhance awareness of the nature of the deterioration in order to provide potential solutions for mitigation.

2.3 *Distribution of pavement distresses by type*

Figure 3 shows the relative percentage of each type of distress according to the pavement age. Pavements less than 7 years old have nearly equal proportions of load-related and non-load

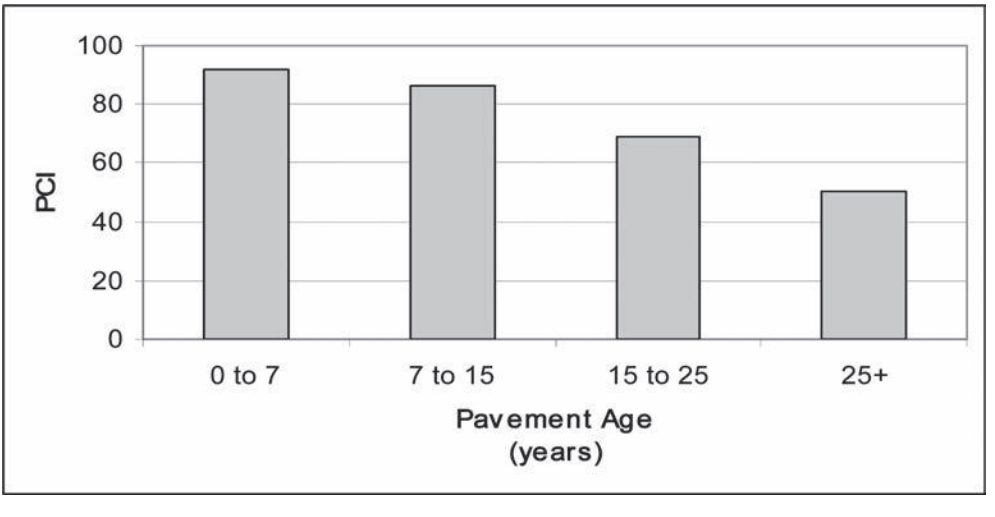

Figure 2. Average PCI of various pavement age groups in database.

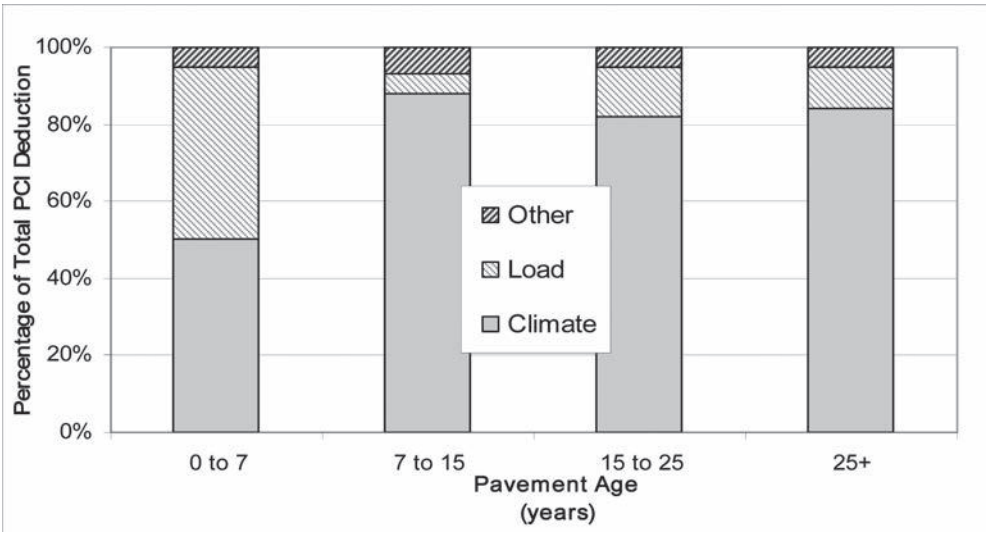

Figure 3. Distribution of PCI deduction factors for various pavement ages.

related distresses. The magnitude of both types of distresses is very low, as evidenced by the average PCI of 92 for these pavements shown in Figure 2. The distresses that do occur can likely be attributed to mixture or construction deficiencies or by external influences such as fuel or oil spillage. These early distresses tend to be minor in nature when adequate quality mixtures are properly placed.

Pavements from 7 to 15 years old had only 5 percent load-related PCI deductions. This range of age is when many of the pavements began to experience longitudinal and transverse cracking and raveling/weathering, and the reduction in PCI is mostly attributed to environmental factors. Pavements greater than 15 years old experience approximately 10 to 15 percent load-related distresses. The increased percentage of load-related distresses is likely caused by softening of the underlying pavement layers from increased moisture intrusion and from the reduction in load-distributing ability of the disintegrated HMA surface layer.

Overall, the data indicates the vast majority of distresses on airfield asphalt pavements are not load-related. Therefore, most of the maintenance and rehabilitation requirements are not caused by traffic volume and will be necessary even if the pavement is not used. Mitigating these types of distresses could result in substantial monetary savings when maintaining HMA pavements. Any maintenance procedure, whether preventive or corrective, must be performed in a timely manner to be effective. Pavement distresses left untreated tend to lead to accelerated deterioration and more expensive repair requirements. Implementing timely, practical maintenance programs is a necessity of a good pavement management system.

2.4 *Detailed analysis of climate-related distresses*

In order to further examine the formation and propagation of non-load related distresses in airfield asphalt pavements, the database was used to extract quantities of each distress type described as climate-related by Micro PAVER. These distresses included weathering/raveling, longitudinal and transverse cracking, and block cracking. The quantity and magnitude of each occurrence was tabulated to determine the overall percentage of the pavements with each distress and severity. Total distress quantities are extrapolated by Micro PAVER from the sample units surveyed during the pavement inspection.

Figure 4 shows the percent of the pavement area with low, medium, and high severity weathering/raveling. This type of distress existed on 0.4 and 7.4 percent of the pavement area from 0 to 7 and 7 to 15 years old, respectively. From 15 to 25 years, the pavements

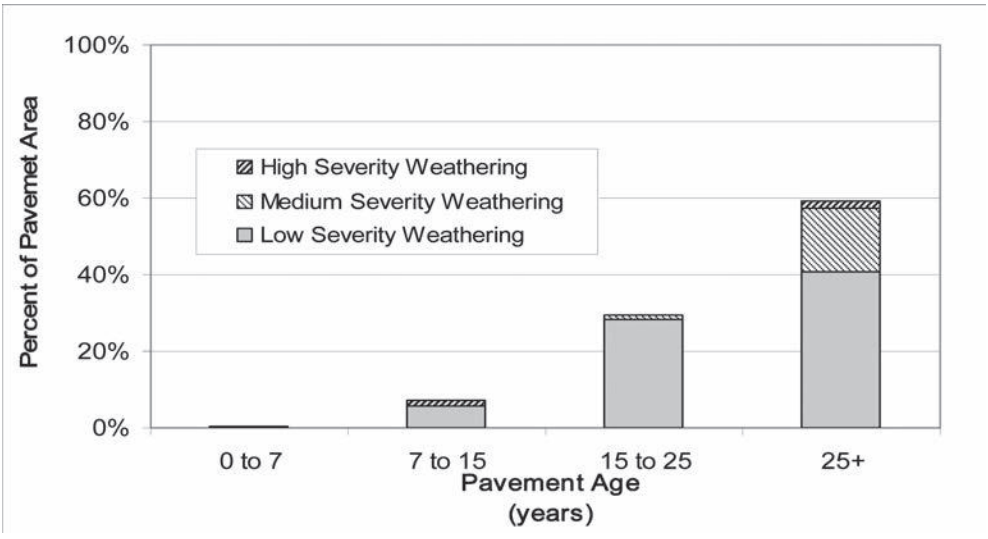

Figure 4. Percentage of pavements with weathering for various pavement ages.

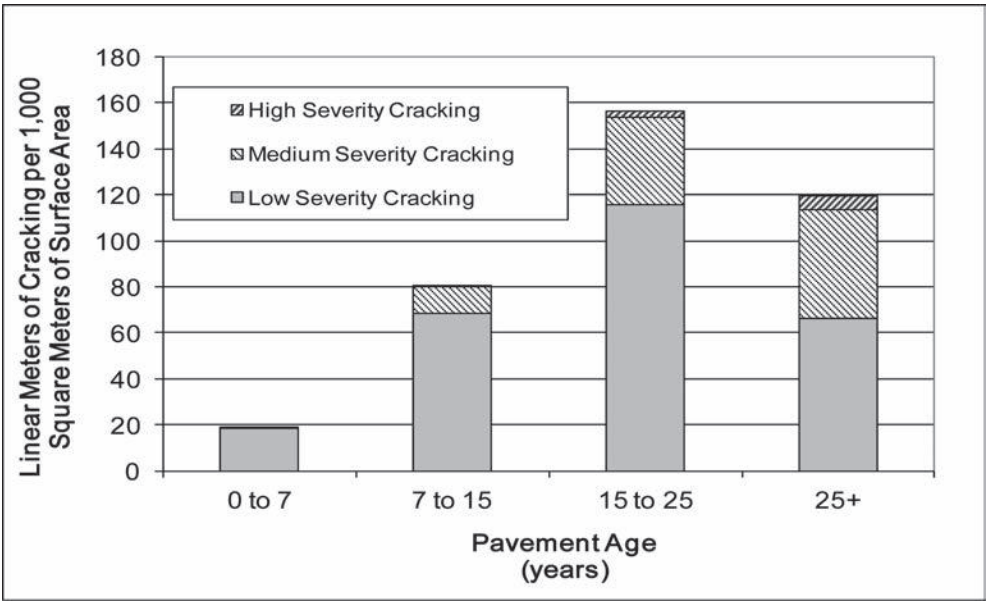

Figure 5. Quantity of longitudinal and transverse cracking for various pavement ages.

experienced weathering on nearly 30 percent of the surface area, and most of the weathering was low severity. After 25 years, a majority of the pavement surfaces was weathered, with an increasing percentage of medium and high severity conditions.

Figure 5 shows the quantity of low, medium, and high severity longitudinal and transverse cracking in the pavement. The quantity of cracking is shown as the number of linear meters of cracking per 1,000 square meters of pavement area. Pavements less than 7 years old experienced approximately 18 meters of linear cracking per 1,000 square meters of pavement area. This proportion would typically represent only a few minor cracks along the longitudinal construction joint or occasional small transverse cracks. Pavements between 7 and 15 years

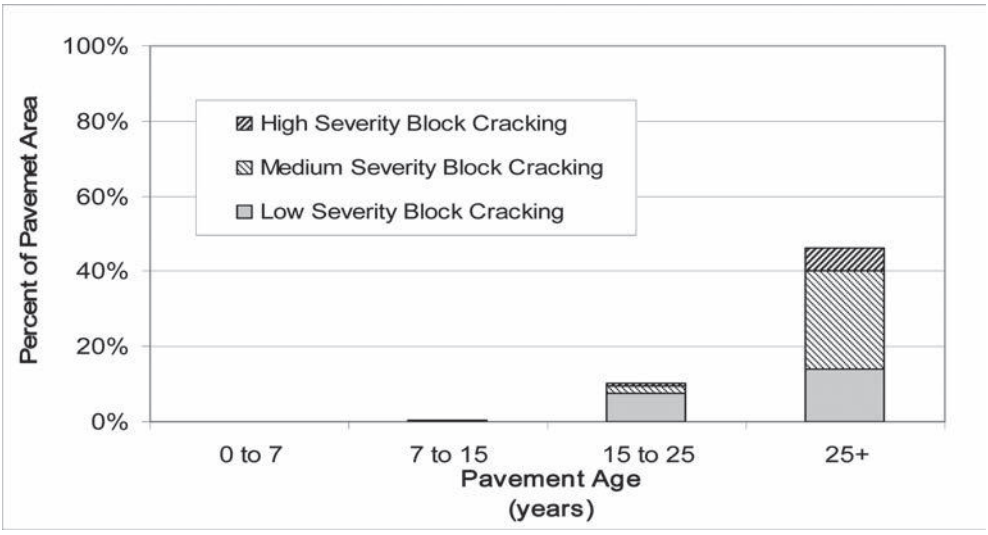

Figure 6. Percentage of pavements with block cracking for various pavement ages.

old experienced approximately 80 linear meters of cracking per 1,000 square meters of pavement area. A small percentage of the cracks were medium severity. This age range is when most pavements began to show visible evidence of cracking. The quantity of cracks likely represents short areas (1 to 5 meters) of cracking along the longitudinal construction joints and some uniformly-spaced transverse cracks. Pavements between 15 and 25 years contained approximately 155 linear meters of cracking per 1,000 square meters of pavement area. This age range is when the pavements begin to rapidly deteriorate. Both the quantity and severity of longitudinal and transverse cracks increases during this time. This increase is likely more significant than the data indicates, because much of the pavement area can be assumed to have received maintenance to fill medium-severity cracks. Additionally, some of the existing cracks begin to interconnect and create areas identified as block cracking. Pavements older than 25 years contained a higher number of medium- and high-severity cracks, indicating a failed asphalt concrete surface.

Figure 6 shows the percent of the pavement area with low, medium, and high severity block cracking. These percentages follow the same trends as the figure above displays. The percentage of the area containing block cracking exponentially increases with age. This correlation is expected because block cracking is the result of interconnecting longitudinal and transverse cracks. Very little block cracking exists in pavements less than 15 years old. Once block cracking is observed, the pavement appears to rapidly deteriorate. The rapid deterioration is likely caused by significant infiltration of water into the pavement system.

3 DATA IMPLICATIONS

3.1 *Pavement preservation*

An implication of the analysis of airfield pavement management data presented in this paper is the value of pavement preservation as a maintenance strategy. Pavement preservation is a concept that targets maintenance of pavement distresses early in the service life so that major rehabilitation is not required. This type of maintenance is often described as preventive maintenance. The rationale for preventive maintenance is that repetitive, low-cost treatments can improve a pavement's condition and reduce the life cycle cost compared to traditional rehabilitation methods that are usually delayed until the pavement is no longer serviceable. Preventive maintenance is particularly attractive for combating non-load related distresses,

because structural improvements to the pavement system are not required. The expectation with preventive maintenance is that pavement condition is maintained above the threshold where rapid deterioration begins to take place.

Transportation agencies are continually challenged with maintaining transportation assets and meeting growing traffic demands, often with reduced budgets. This realization has led to significant growth in the market for pavement preservation products during the past several years. A wide range of materials is currently available. Although the components of these materials vary drastically, the primary component is typically an organic compound that is compatible with asphalt cement. Many products are actually asphalt-cement based. The mechanism by which effective maintenance is achieved by these products is typically the same.

A frequent cause of non-load related distresses is aging of the binder in the asphalt concrete pavement. Binder aging processes include volatilization and oxidation which cause the binder to become stiffer, more brittle and less durable. The ability of the binder to hold aggregate in place is reduced, and the propensity of the asphalt concrete layer to crack in response to internal tensile stresses is increased. The visible effect of these changes is weathering or raveling of the pavement surface and the appearance of longitudinal and transverse cracking.

Preventive maintenance products target these distresses by one of two major methods. The first is that some products contain light oils and soft organic compounds that integrate with the binder in the pavement. The addition of these materials softens the aged binder and enhances flexibility and ductility. Although oxidation of the binder cannot be reversed, the addition of the new material reduces the detrimental effects and returns the mechanical properties of the binder to a condition more similar to its original placement.

The second major method of preventive maintenance is the addition of a sacrificial layer on the pavement surface. This layer can be a very thin spray-applied material or a thicker layer of aggregate and binder placed as slurry. Sacrificial layers seal the pavement, reducing the rate of oxygen and moisture intrusion. The layer itself is allowed to oxidize and deteriorate, protecting the underlying asphalt concrete. Reapplication or replacement of the sacrificial layer must be less expensive than milling and overlaying the existing asphalt concrete for this pavement preservation approach to be effective.

Pavement preservation requires more frequent maintenance than traditional rehabilitation approaches. The cost of these treatments is much lower, however. For example, traditional pavement management establishes a minimum condition index threshold value that a pavement must exceed to be considered serviceable. PCI is one example of a numerical pavement serviceability index scale [2]. Many transportation agencies use PCI to establish threshold serviceability values. Pavements with assessments that show the current condition above the threshold are not scheduled for maintenance. Action only takes place when the pavement condition falls below the threshold value. This type of pavement management is reactive in nature and requires significant funding to replace deteriorated pavements.

A preventive maintenance approach to pavement management includes routine recurring funding to maintain pavements in good condition. By doing this, the pavement condition index is sustained at a high level for many years without requiring major rehabilitation. Figure 7 illustrates the difference between preventive maintenance and traditional reactive rehabilitation.

The example of a pavement preservation approach illustrated in Figure 7 could be the use of a slurry seal on a pavement. The initial slurry seal should be placed early in the pavement life, while it is in good condition. This initial investment would maintain the pavement in good condition for several years until another slurry seal is required. If the cost of the slurry seal is approximately $2 per square meter, the total cost (not adjusted for inflation) of maintaining the pavement would be $4 per square meter over the analysis period. Assuming the alternative is a 2-inch mill and overlay, the cost of allowing deterioration to the threshold value is approximately $7 per square meter. The final pavement condition is similar, resulting in a net savings of $3 per square meter by using the preventive maintenance approach.

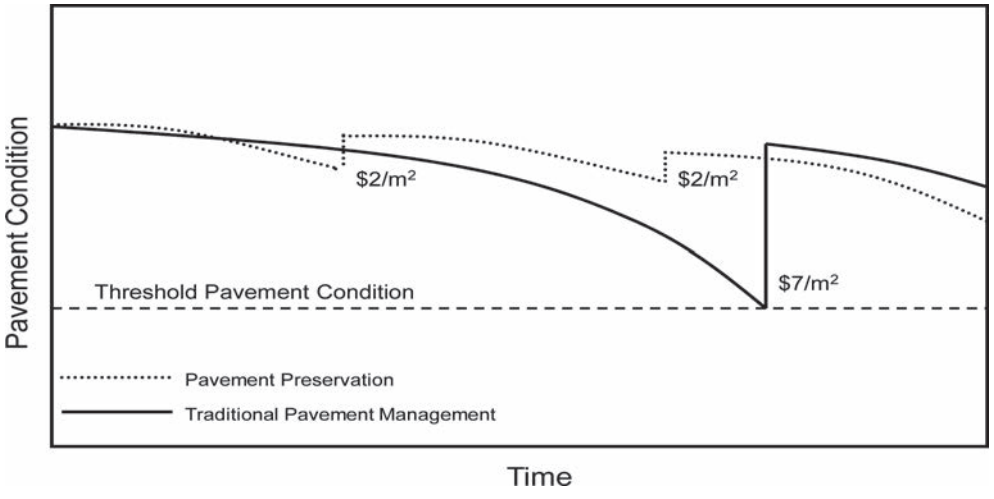

Figure 7. Typical pavement condition with time.

This type of cost analysis has been used to promote pavement preservation to many transportation agencies. The problems with the analysis are the number of variables affecting the true cost and the accuracy of the maintenance requirements. A true gage of the effectiveness of preventive maintenance is needed if there is to be a fundamental shift in the way pavements are maintained. The data presented in this paper provide a confident assessment of the condition of airfield asphalt pavements managed using a traditional rehabilitation approach. It is recognized that funding availability has a significant influence on the timing of maintenance and rehabilitation. However, the major trigger for initiating maintenance and rehabilitation has been a reaction to pavement degradation beyond the threshold values set by operational policy.

3.2 *Mixture materials selection*

An additional implication of the pavement management data analyzed in this paper is the value of selecting combinations of raw materials that result in the most durable possible pavements. Some mixtures are more prone to durability problems related to mixture aging that manifest themselves over time as climate-related distresses such as weathering/raveling and non-load associated cracking. Research has suggested that different aggregate types, binder grades, and volumetric properties have an effect on the durability potential of asphalt mixtures [5]. Furthermore, the compatibility of certain combinations of aggregate and asphalt binder can affect asphalt mixture durability over time [6]. For airfield pavements in particular, the ability to assess the long term durability potential of different asphalt mixtures during mixture design and construction is needed. Ideally, a mixture durability test method and associated conditioning protocol to simulate the effects of long term aging will be simple to perform and able to be used during mixture design and for quality control/quality assurance activities during construction. By selecting material combinations and mixtures with the best durability potential, pavement service life can be maximized. In combination with properly timed application of appropriate preventative maintenance techniques, airfield pavement life can be noticeably improved.

4 SUMMARY AND RECOMMENDATIONS

Data presented in Figure 2 shows that asphalt concrete pavements have an increasing rate of deterioration with time as indicated by PCI. This model of deterioration has been well

documented in literature. Figure 3 indicates that this deterioration is heavily influenced by non-load related factors, as indicated by the small percentage of load-related distresses throughout the life of the pavement. Figures 4–6 solidify the argument that rapid deterioration is attributed to non-load related distresses by showing the rapid increase in quantity and severity of these distresses over time.

A focused research effort is needed to strategically apply preventive maintenance techniques on airfield asphalt pavements in order to quantify the benefits of this pavement management approach. The research should evaluate several prevalent methods of pavement preservation. The cost associated with various treatment methods, as well as the changes in pavement condition with time, must be well documented. A standard condition index such as PCI is a reasonable method of quantifying the appearance of pavement distresses. An analysis period equal to the expected life of an unmaintained pavement will be required to develop the necessary confidence in the results. The documented pavement condition with age can be compared to the data presented in this paper to develop a relationship between the preventive maintenance technique and improvement in pavement condition over time. The costs of the preventive maintenance can be compared to the cost of rehabilitation to show if any financial savings can be achieved by using preventive maintenance. Without this type of data, pavement management personnel will continue to be bombarded by multiple product claims of enhanced performance shrouded in trappings of fiscal responsibility without any tangible evidence that the methods are valid. However, it is reasonable to expect that one or more types of products will prove to have the ability to reduce the rate of appearance of non-load associated distresses in asphalt pavements. Continued research on binder aging mechanisms will provide additional information leading to more successful mitigation techniques. Identifying these techniques and implementing timely preventive maintenance to mitigate the significance of non-load associated distresses as presented in this paper can lead to an enormous improvement in the overall condition of airfield asphalt pavements and reduction in the annual funding required to maintain pavements.

ABSTRACT: This paper presents an analysis of two recently developed models that relate pavement properties to vehicle rolling resistance and fuel consumption, as well as the sensitivity of each model to roughness, texture and future traffic predictions. The two models are the Vehicle Operating Cost model developed as part of the National Cooperative Highway Research Program (NCHRP) project 1–45 outlined in NCHRP report 720, and the model developed as part of an international collaboration, Models for rolling resistance In Road Infrastructure Asset Management systems (MIRIAM). Furthermore, several pavement related factors that contribute to vehicle rolling are discussed in this paper. It was found that the fuel consumption was highly sensitive to future traffic growth projections. Also, the pavement macrotexture can have a significant impact on excess fuel consumption of vehicles, particularly in the case that the MIRIAM model is used to calculate fuel consumption.

Keywords: Pavements; energy Consumption; rolling resistance; lifecycle assessment

1 INTRODUCTION

According to the Texas Transportation Institute (TTI), in 2011, congestion in the top U.S. urban areas resulted in an average of 19 gallons of excess fuel consumption per auto commuter per year [1]. Although it is expected to be significant, there is no similar figure assessing the wasted fuel due to the trillions of Vehicle Miles Travelled (VMT) over rough pavement sections that contribute to relatively high rolling resistance values. Rolling resistance is the mechanical energy loss by a tire moving a unit distance along the roadway, and is effected by both properties of the tire and of the pavement [2]. The energy that is lost comes directly from the power that is used to propel the vehicle, and as a consequence, more fuel must be

consumed to propel a vehicle over a pavement with higher rolling resistance. Evans et al. [2] reported that as much as 1/3 of the total energy that is available to the wheels can be expended to overcome the rolling resistance. Other factors that consume the energy used to propel the vehicle (the energy that makes it through to the driveline) are aerodynamic resistance and braking [3].

Evans et al. [2] measured the rolling resistance of several different tire types and reported that 0a 10 percent reduction in rolling resistance can lead to a 1 to 2 percent reduction in fuel consumption, with an average reduction of 1.1 percent. Schuring and Futamura [4] have shown that this relationship can be taken as linear. TIAX [5] reported that during highway driving, the 2 percent reduction in fuel consumption per 10 percent reduction in rolling resistance is expected, and the figure is closer to a 1 percent reduction during urban driving. Some estimations have shown that a 10 percent reduction in rolling resistance could save between 1 and 2 billion gallons of fuel annually (of 130 billion gallons currently consumed) among the passenger car fleet, assuming the driving habits used in the 2006 study [3]. Thus, it can be conclusively said that if the rolling resistance of a pavement were reduced, the vehicle fuel consumption along that pavement would also be reduced.

2 OBJECTIVE

The objective of this paper is to discuss the impact of pavement properties on vehicle rolling resistance, as well as present an analysis and comparison of current rolling resistance models. Two commonly used models to assess the additional vehicle fuel consumption due to rolling resistance will be compared, one model from the United States and one from Europe.

3 BACKGROUND

Many factors contribute to the fuel consumption of a vehicle, not the least of which is the interaction of the vehicle tire with the pavement surface. One of the earliest studies on the effects of road roughness on fuel consumption was performed in 1983 in Sweden at VTI (the Swedish National Road and Transportation Research Institute) [6]. The study evaluated 20 different roadway characteristics representing the full range of Swedish roads at speeds of 50, 60 and 70 km/h (30, 37 and 45 mph). Vehicle fuel consumption was found to be correlated best with short wave unevenness ($r = 0.91$), mega-texture ($r = 0.83$) and macro-texture ($r = 0.60$).

Mega-texture is generally defined as a pavement surface texture due to surface irregularities having a relative wavelength between 5 cm and 0.5 meters (2 in and 20 in) [7]. Pavement macro-texture is generally defined as a pavement surface texture having a relative wavelength between 0.5 mm and 50 mm (20 mils to 2 inches), and is a result of large aggregate particles in the mixture [7]. It is important to note that macro-texture plays an important role in pavement friction. The short wave unevenness range is close to the wavelength sensitivity range of the IRI which is between 1.2 to 30 m (4 to 100 ft) [8]. The following are pavement related factors that have been identified in past research as pertinent to consider during an analysis of the rolling resistance of the pavement [9, 10, 11]: macro-texture, pavement stiffness, roughness, rutting and the transversal slope of the pavement.

3.1 *Macro-texture*

Chatti and Zaabar [11] evaluated the effect of pavement macro-texture on fuel consumption, and determined that an increase in fuel consumption with increasing mean profile depth of the pavement was statistically significant at the 95 percent confidence level for lower speeds. Laganier and Lucas [12] found that macro-texture could lead to overconsumption of up to 5 percent from a base consumption of 0.7 l/km (0.3 gallons/mile). At high speeds, it is expected that aerodynamic resistances dominate the resistance forces, thus causing the

effect of macro-texture to be overshadowed. Conversely, Sandberg [6] found that the effect of macro-texture on fuel consumption was more defined at higher speed; though the author pointed to a possible cause of low speed driving having a lower correlation as poorly selected driving conditions.

The increase in fuel consumption as a function of the pavement macro-texture is dependent on the vehicle type, and is expected to be higher for heavy vehicles. According to Sandberg [13], the lower limit for expected effect of macro-texture on rolling resistance is a 2.5 percent increase in rolling resistance per unit increase of mean profile depth (in mm). Zaabar [14] reported that for trucks, an increase in mean profile depth from 0.5 mm (0.02 in) to 3 mm (0.12 in) is expected to result in an increase in fuel consumption between 1 and 1.6 percent. Hammarström et al. [15] used coast-down methods, or measurements of a vehicles velocity or acceleration while it is allowed to roll freely across a section of pavement, to measure the impact of pavement roughness, travel velocity and macro-texture on rolling resistance. The research proposed a set of equations to relate rolling resistance to macro-texture and roughness by comparing measurements taken during the research and theoretical models used to quantify the impact of each factor. The tests were conducted using a car, light truck and heavy truck. Some generalized results presented by Hammarström et al. [15] are that an increase in rolling resistance of 17 percent per unit of mean profile depth is expected for a starting speed of 50 km/h (30 mph) for the car, and an increase of 30 percent per unit of mean profile depth is expected for a starting speed of 90 km/h (55 mph) for the car. The results showed that if the total driving resistance is considered, an increase in mean profile depth from 0 to 1 mm (0.04 inches) at 50 km/h (30 mph) is expected to lead to an increase of driving resistance of 10.5 percent for the car. The researchers noted that more measurements would be required to obtain results for the trucks.

3.2 *Pavement stiffness*

Much of the research pertaining to the impact of pavement stiffness on rolling resistance has been derived from studies comparing asphalt concrete pavements to Portland cement concrete pavements. Taylor and Patten [16] conducted field tests using both cars and heavy trucks driven over asphalt concrete pavements and Portland cement concrete pavements in order to evaluate differences in fuel consumption for each case. The research also tested over multiple seasons and the trucks were subjected to multiple loading conditions. In most cases, the results of the research showed anywhere from a 1 percent to a 5 percent savings in fuel consumption when driving on concrete pavements. However, during many of the tests during summer days, the research indicated a fuel saving for composite pavements when compared to concrete pavements [16]. Although the test results indicated differences in fuel consumption with varying pavement stiffness, the developed models did not include surface wear and anomalies (e.g. potholes). Furthermore, other surface properties, such as tining of the concrete surface or texture of the pavement, were not accounted for in the study. Thus, the results of the study are not considered ideal for inclusion in an LCA of the use phase of the pavement.

Santero et al. [9] evaluated the impact that the pavement stiffness has on the fuel consumption of a vehicle travelling along the pavement by developing a mechanistic model. The researchers proposed a beam on elastic foundation as the model to describe the behaviour of the pavement subjected to a wheel load, and calibrated their model using data from the Long Term Pavement Performance (LTPP) database. The model indicated less fuel consumption over more stiff pavements, especially in the case of truck traffic. However, it is important to note that the model was developed in order to better understand the mechanisms that contribute to increasing rolling resistance with increased deflections, and field studies were not conducted to calibrate the model.

A follow up to the study by Santero et al. [9] was conducted that calibrated the model that was developed to describe pavement deflections, and scaling factors were developed for each of the inputs [17]. The calibration was conducted using additional sites from the LTPP database, and an example application of implementing the model into an LCA was conducted

using data from the Athena Institute. The results of the study indicated that for high volume roads, the Greenhouse Gas (GHG) emissions from the pavement-vehicle interaction can be greater than the GHG emissions from the materials and construction phases [17].

Whereas much research has been conducted on the differences in pavement type on rolling resistance, Wang et al. [18] pointed out that sufficiently validated models have yet to be developed to calculate the impact of pavement stiffness on fuel consumption and emissions. This is mainly a consequence of the experimental designs of the studies that compare asphalt pavements to concrete pavements. Although models were developed by Akbarian and Ulm [17] as well as Santero et al. [9] to quantify the impact of stiffness on fuel consumption, these models are generally considered first order attempts at understanding the mechanism of the pavement vehicle interaction, and are not yet sufficiently corroborated with field measurements to be used in a pavement LCA.

However, even in the absence of calibrated models, there is strong research demonstrating the differences in fuel consumption between asphalt and concrete pavements over certain conditions. Zaabar [14] showed that at 56 km/hr (35 mph) during summer conditions, there is a statistically significant difference between vehicle fuel consumption along apshalt and concrete pavements for trucks. The development of more accurate models in the future will facilitate the inclusion of pavement type, or pavement stiffness, into a pavement use phase LCA.

3.3 *Pavement roughness*

An early study on the impact of the pavement roughness on fuel consumption was conducted in 1983 in Sweden at VTI [6]. The difference in fuel consumption between smooth and rough pavement was around 4.5 percent [19]. Laganier and Lucas [12] found that pavement unevenness could lead to overconsumption of fuel of up to 6 percent from a base consumption of 0.7 l/km (0.3 gallons/mile). Laganier and Lucas [12] also calculated the power lost in the shock absorbers as a function of roughness level and found most loss occurs at wavelength between 1 m (3.3 feet) and 3.3 m (10.8 feet) which corresponds to the unevenness range as well as the most sensitive IRI range. According to Sandberg [13], the lower limit for expected effect of roughness on rolling resistance is a 0.8 percent increase in rolling resistance per unit increase of IRI (in m/km).

In the United States, WesTrack test results showed that rougher pavements result in increased fuel consumption of trucks [20]. Zhang et al. [21] used the WesTrack models in the LCA of an overlay system. One downfall of the WesTrack model was that it was developed for heavy trucks over a small variation of conditions. Zaabar [14] evaluated the impact of pavement roughness (in terms of IRI) on the change in fuel consumption, and used the data to calibrate HDM 4 prediction models.

Hammarström et al. [15] also measured the impact of pavement roughness on rolling resistance using coast-down measurements. The research found that for the car, an increase in rolling resistance of 1.8 percent per unit of IRI is expected for a starting speed of 50 km/h, and an increase of 6 percent per unit of IRI is expected for a starting speed of 90 km/h. The results for the car showed that if the total driving resistance is considered, an increase in mean profile depth from 0 to 1 at 50 km/h is expected to lead to an increase of driving resistance of 1.2 percent. The researchers noted that more measurements are required to obtain results for trucks.

Chatti and Zaabar [11] reported the results of calibrating the HDM 4 models for vehicle operating costs in the National Cooperative Highway Research Program (NCHRP) report 720. During this research, fuel consumption models as a function of pavement roughness for several vehicles and several speeds were calibrated. A vehicle operating cost modelling program was developed in the form of a spreadsheet tool by Chatti and Zaabar [11] as a part of the NCHRP project. Part of the spreadsheet output is the estimation of the additional fuel consumption as a function of the following variables; pavement roughness, mean texture depth, roadway grade, super-elevation, pavement type (i.e. asphalt vs. concrete), vehicle speed and air temperature.

3.4 *Rutting*

Rutting was one of the variables analysed in a VTI report aimed at using coast down measurements to determine the effect of the road surface conditions on rolling resistance [15]. However, rutting was not found to be significant on its own, and the researchers noted that the high correlation between rutting and the measured IRI may be good reason to leave rutting out of a generalized driving resistance model. The relationship between rutting and roughness has been demonstrated elsewhere [22], thus a separate factor relating rutting to rolling resistance would require rutting to be decoupled from the IRI effect if it was developed.

3.5 *Transverse slope*

The transverse slope of the pavement, sometimes known as the crossfall or crossslope of the pavement, has an impact on the side forces of the vehicle, which in turn affects the rolling resistance along the pavement [23]. Although this feature of the pavement is recognized to impact rolling resistance, similar to superelevation, no significant amount of research exists to quantify its effects. However, Chatti and Zaabar [11] included superelevation as a variable in the spreadsheet resulting from the NCHRP report 720, and it can be expected that the mechanism relating crossfall to rolling resistance behaves similar to the mechanism relating superelevation to rolling resistance.

4 ROLLING RESISTANCE MODELS

Two commonly used models relating pavement properties to rolling resistance and fuel consumption have been developed in recent years. One model was developed by Chatti and Zaabar [11] by calibrating the HDM 4 models for vehicle operating costs. The fuel consumption model was calibrated over several pavements in the state of Michigan using six different vehicles: a medium car, sport utility vehicle, van, light truck, and an articulated truck. The details of the model can be found in the NCHRP report 720 [11], along with a Microsoft Excel™ tool developed as part of the NCHRP project that can be used to estimate vehicle operating costs (as well as vehicle fuel consumption) given several conditions.

The second model was developed as part of an international collaboration, Models for rolling resistance In Road Infrastructure Asset Management systems (MIRIAM), and is described in detail in Hammarstom et al. [24]. The model was developed based on empirical results from coast down measurements in Sweden, and includes impacts of: pavement roughness, macrotexture, temperature, speed, horizontal curvature and the road grade. The model was developed for three vehicle types, a car, a heavy truck and a heavy truck with a trailer.

4.1 *Impact of pavement roughness on vehicle speed*

An important variable that must be considered when evaluating fuel consumption as a function of pavement properties is the impact of the pavement roughness on the average vehicle speed. Hammarstom et al. [24] investigated the impact of roughness on speed for European conditions. It is noted in Hammarstom et al. [24] that reducing roughness may have the effect of increasing vehicle fuel consumption due to a corresponding increase in average vehicle travel speed. Yu and Lu [25] investigated the relationship between roughness and speed and found that the average speed of a vehicle decreases 0.84 km/h for every increase in roughness of 1 m/km (0.0083 mph per every 1 in/mile). The data used in developing the relationship were taken from vehicles travelling along several pavement sections in California (both rigid and flexible pavements), and was limited to vehicles travelling between 80 and 145 km/hr (50 to 80 mph) to exclude times of congestion and vehicles that are potentially exceeding the speed limit by a significant amount.

5 ANALYSIS

In order to analyze and compare the two rolling resistance models, a baseline case of traffic was evaluated with the parameters shown in Table 1. The change in fuel consumption based on four variables will be evaluated: (1) the change in fuel consumption based on varying the roughness as a function of time, (2) the impact of the relationship between the reduction in average speed as a function of pavement roughness, (3) sensitivity to traffic growth, and (4) sensitivity to macrotexture. The relationship between roughness and average speed given by Yu and Lu [25] was included in the baseline calculations.

A second order polynomial was assumed for the roughness growth model which (with IRI given in units of in/mile) as $a*(x)^2 + b*(x) + c = IRI(x)$, where $IRI(x)$ is the value of the IRI in year x, c was set at 0.87 m/km (55 in/mile), b was set as 0.02 m/km/yr (1.23 in/mi/yr) and a was changed from the following values [0, 0.15, 0.3, 0.45, 0.6], with a value of a=0 chosen as the baseline case for roughness. This value is taken from McGhee and Gillespie [26] which reported a near constant growth in IRI of 0.02 m/km/yr (1.23 in/mi/yr) for a seven year time period for asphalt pavements in Virginia. The roughness growth over a ten year time frame can be seen in Figure 1 for each value of a. A ten year analysis period was evaluated, and the additional fuel consumption (i.e. the fuel consumption above the baseline case) was calculated per 1 km (0.62 miles) of pavement using the MIRIAM model [24] as well as the software that accompanied the NCHRP report 720 [11]. The results are shown in Figure 2.

It can be seen in Figure 2 that the NCHRP model is much more sensitive to the speed reduction due to an increase in IRI than the MIRIAM model. Although the models produce similar results, the highest amount of fuel consumption occurs when no speed reduction is taken into account and the NCHRP model is used. Conversely, the lowest amount of fuel

Table 1. Baseline case for evaluating the models.

Variable	Baseline value	Variable	Baseline value
Initial roughness	0.87 m/km (55 in/mile)	Traffic (AADT)	30,000
Temperature	20°C (68°F)	Traffic growth rate	3%
Horizontal curvature	0	Medium trucks	10%
Grade	0%	Articulated trucks	15%
Crossfall	0%	Speed	105 km/h (65 mph)
Macrotexture	0.5 mm (0.02 inches)	Pavement type	Flexible

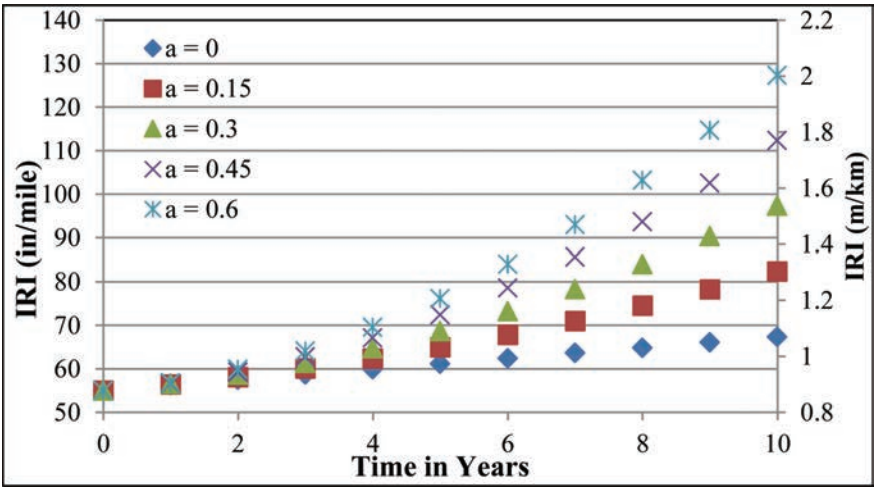

Figure 1. Roughness growth models.

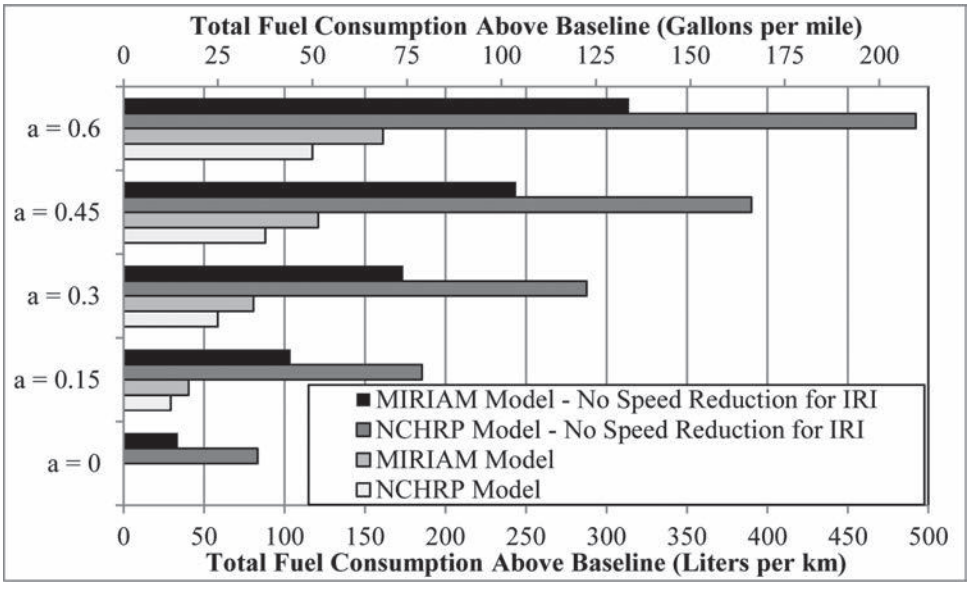

Figure 2. Fuel consumption above baseline case as a function of roughness.

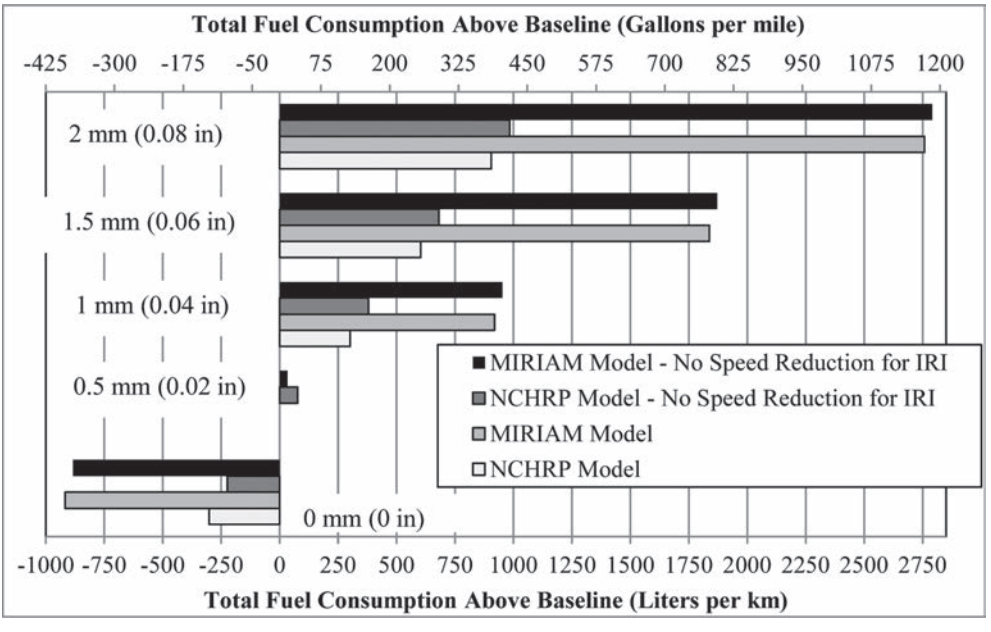

Figure 3. Fuel consumption above baseline case as a function of macrotexture.

consumption occurs with the NCHRP model when the speed reduction is taken into account. Next, the influence of macrotexture on the excess fuel consumption was calculated, assuming the baseline case of 0.5 mm (0.02 in), and a constant growth in roughness of 0.02 m/km/yr (1.23 in/mile/yr) per McGhee and Gillespie [26]. The results can be seen in Figure 3.

It can be seen in Figure 3 that the MIRIAM model is much more sensitive to changes in macrotexture than the NCHRP model. Also, the difference between the case where the speed reduces as a function of IRI and the case where no speed reduction is considered is nearly

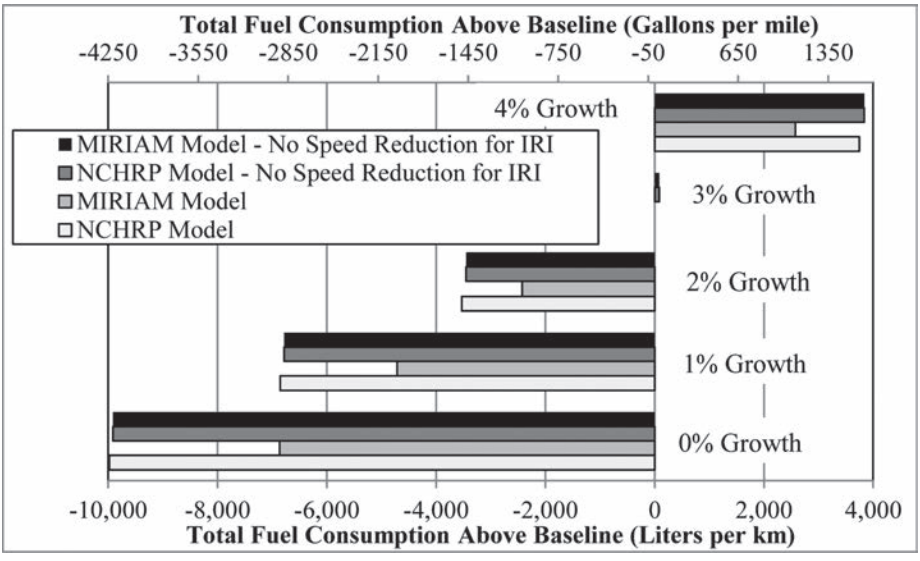

Figure 4. Fuel consumption above baseline case as a function of traffic growth.

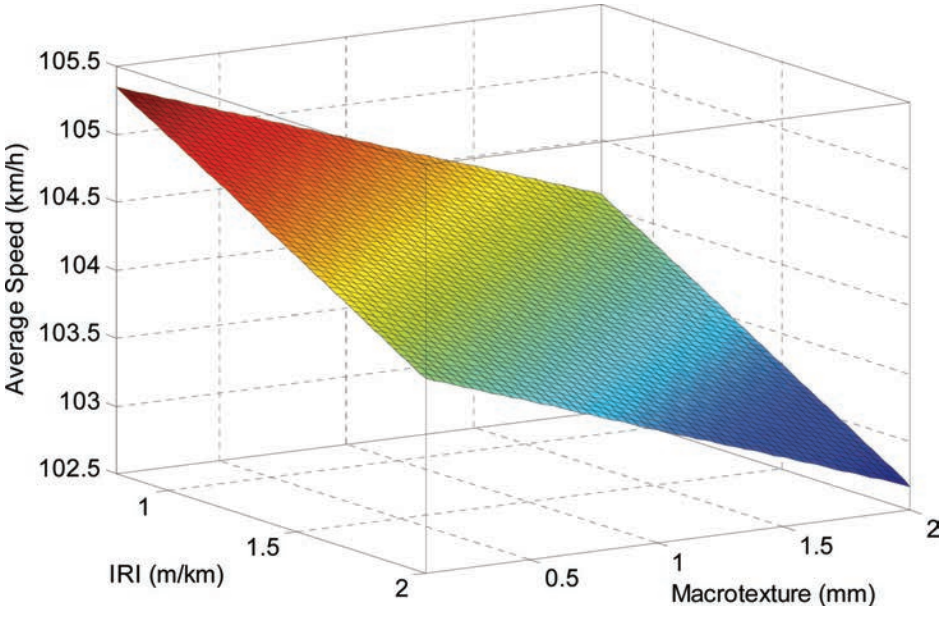

Figure 5. Surface for constant fuel consumption using the NCHRP model.

insignificant when compared to changes in the values for macrotexture. Finally, the influence of the traffic growth rate on the excess fuel consumption above the baseline case was evaluated, and the results can be seen in Figure 4.

Of the four variables analysed (IRI growth, macrotexture, speed reduction as a function of IRI, and traffic growth rate), it can be seen that the traffic growth rate most significantly impacts the excess fuel consumption. This seems to indicate that if a transportation agency has the goal of reducing fuel consumption within a pavement network, the most influential factor of the factors that were analysed is to reduce the number of vehicles travelling

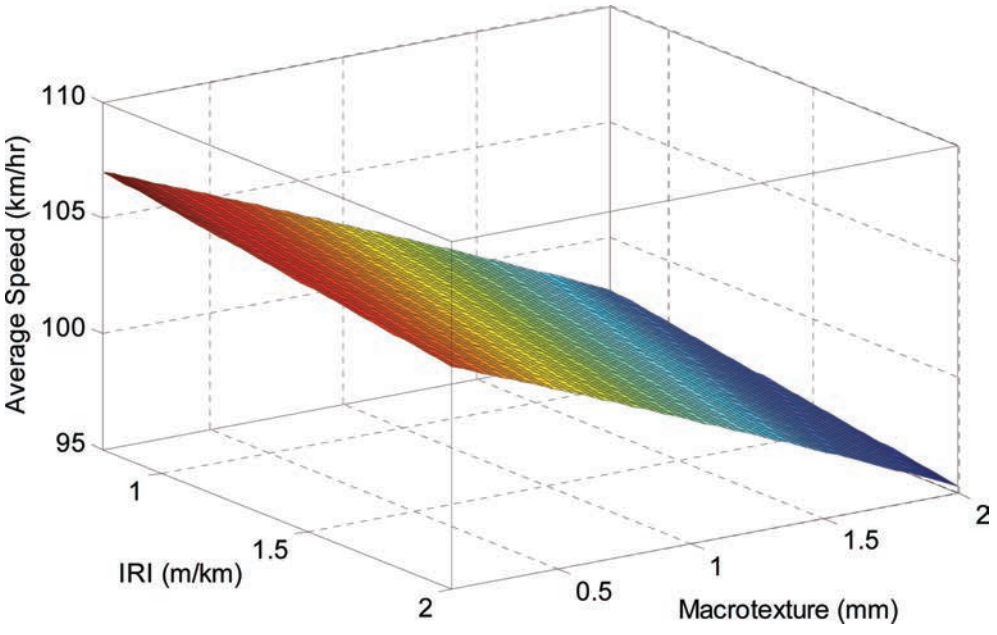

Figure 6. Surface for constant fuel consumption using the MIRIAM model.

in the network in future years. Second to the traffic growth rate is the macrotexture of the pavement. However, it is important to note that macro-texture plays an important role in pavement friction [7], as well as an important role in controlling pavement noise.

In order to better represent the sensitivity of the fuel consumption on the macrotexture, roughness and speed for each model, the three variables were plotted on the same figure for values that yield the same fuel consumption (Figs. 5 and 6). The value for fuel consumption chosen as the iso-plane was taken as the baseline case (defined in Table 1). One notable result is that the NCHRP model is more sensitive to changes in the average vehicle speed than the MIRIAM model (as seen by the smaller variation in speed in Fig. 5). Secondly, both models produce flat planar surfaces, as opposed to having curvature.

6 DISCUSSION AND CONCLUSIONS

Models that relate vehicle rolling resistance to pavement properties can prove to be a valuable resource for transportation agencies, particular when they are concerned with analysing such factors as the impact of excessive roughness on fuel consumption or the potential value of smoothness to road users. This paper presented two recently developed models, as well as an evaluation of their sensitivity to variables pavement roughness, pavement macrotexture and average vehicle speed. It is clearly shown that small variations in average speed can have a much more significant impact on the vehicle fuel consumption than the typical range of pavement roughness or macrotexture. Also, it was found that the total excess fuel consumption was highly sensitive to future traffic growth projections. Furthermore, the pavement macrotexture has a significantly higher impact on excess fuel consumption of vehicles than pavement roughness for both models analysed.

Physicochemical characteristics of RAP binder blends

Shin-Che Huang & Adam T. Pauli
Western Research Institute, Laramie, WY, USA

Qian Qin
GAF Materials, Ennis, TX, USA

ABSTRACT: Two chemically and physically different SHRP asphalts (AAA-1 and AAC-1) were mixed with 15 and 50 percent of extracted RAP binders, designated Manitoba and South Carolina. Several analytical techniques including dynamic shear rheometry, Automated Flocculation Titrimetry (AFT), and Differential Scanning Calorimetry (DSC) were used to characterize physical properties of the starting materials and RAP binder mixtures. Results indicate that different virgin binders interact differently with different RAP binders suggesting that PG grade adjustment is both asphalt and RAP binder dependent where certain virgin binders require higher PG grade adjustment compared to other blends. This finding is somewhat contradictory to what current literature recommends. Results obtained in the present study seem to suggest that knowledge of the stiffness of starting materials alone does not adequately explain observed differences in PG grade change. Rather, information of the composition, specifically asphaltene content, lends additional insight into observed differences in PG grades of virgin with RAP binder mixtures.

Keywords: RAP, physicochemical characteristic, rheology, compatibility, AFT

1 INTRODUCTION

The use of Recycled Asphalt Pavement (RAP) has become relatively common practice in most states as it is both an environmentally and economically attractive proposition. However, most highway agencies currently allow only low percentages of RAP-less than 25 percent by weight of aggregate even though specifications allow up to 30 percent. The reason is that recycled binders are less strain-tolerant and may be more susceptible to cracking under certain application. State agencies are concerned that the use of high RAP mixtures may adversely affect performance of asphalt pavements, ultimately resulting in higher maintenance and rehabilitation costs [1].

Some states have used RAP in Marshall mix designs with success [2–6]. Others have tried to use RAP in Superpave® mixture design [7–9]. Some highway agencies, when using low percentages of RAP, do not consider the aged asphalt in RAP in the total asphalt content and properties, and therefore, consider RAP as a "black rock". The question of whether RAP, at any percentage, should be considered as "black rock" has not been answered conclusively even after more than 30 years of application. The current Superpave® system does not provide any guidelines for characterizing asphalt binders extracted from RAP, nor are there any test procedures available for recycled hot-mix asphalts. Furthermore, the interaction between new and old asphalt binders in the mixtures containing RAP has not been studied extensively and the physico-chemical interaction is still not well understood.

It is essential to understand the fundamental properties of recycled asphalt binder as well as the interaction between the old binder in the recycled asphalt and the fresh binder in the new mix. The objective of this study is to investigate the interaction between fresh binders and RAP binders and how RAP binders influence physical properties of fresh binders.

2 EXPERIMENT DESIGN

Two RAP sources from Manitoba (Man) and South Carolina (SC) were used in this study. RAP binders were extracted from these two RAP sources by using 85% toluene/15% ethanol. The SHRP asphalts AAC-1 and AAA-1 were mixed with the extracted RAP binders at 15 and 50 percent for the aging study.

The rheological properties of unaged neat asphalts and laboratory aged asphalts and blends were measured using either a Rheometrics RDAII or an ARES rheometer. Data were obtained in the region of linear strain at frequencies of 0.1 to 100 radians per second and temperatures of –20, 0, 20, 40, 60, and 80°C using 25-mm, 8-mm, or 4-mm parallel plates with 1 mm, 2 mm or 1.75 mm sample gap. Master curves were constructed by using time-temperature superposition. The Christensen-Anderson model [10] was used to shift all temperatures to a reference temperature of 20°C. DSR measurements were used to calculate the PG grade of each binder including low temperature grades. The four binders AAA-1, AAC-1, Manitoba RAP binder, South Carolina RAP binder are graded as PG61-33, 69-33, 91-28, and 95-18. Note that Manitoba RAP represents "young" RAP and South Carolina RAP represents "old" RAP in this study.

The glass transition of RAP binder blends was measured on a TA instruments Q2000 differential scanning calorimeter. Temperature Modulated Differential Scanning Calorimetry (TMDSC) was used for this study in order to effectively separate the glass transition from other complex overlapped effects such as cold crystallization and enthalpy recovery. The limiting fictive temperature T_f' was determined from the reversing heat flow curve during the second heating scan at the average scanning rate of 2°C/min with modulation amplitude of 0.5°C every 80 seconds. T_f' was used as the glass transition temperature, T_g, since it has been widely accepted that T_f' is approximately equal to the glass transition temperature T_g obtained from the cooling scan at the same scan rate [11,12].

3 RESULTS AND DISCUSSIONS

The fresh binders were investigated to observe how their rheological properties change when they are mixed with RAP binders at different concentrations. Figure 1 shows typical complex modulus versus phase angle plot with respect to different RAP concentrations at reference temperature of 20°C. The important role of phase angle on the flow properties of asphalt materials has been extensively applied by several researchers [13–15]. The phase angle indicates the level of viscoelasticity in the asphalt. It is desirable to have a certain level of viscous flow behavior in an aged asphalt to provide the relaxation of stress. An asphalt exhibiting a higher strain to failure at the same stiffness is more resistant to thermal or fatigue cracking than an asphalt binder with a lower strain to failure at the same stiffness. In other words, it is reasonable to assume that the lower the phase angle at the same stiffness, the more susceptible asphalt becomes to fatigue cracking. The logarithm of the complex modulus and the phase angle are plotted for RAP blends at different contents, as shown in Figure 1. Surprisingly, a linear (R-Squared = 0.954) relationship between complex modulus and phase angle for all the RTFO-aged AAA-1, AAC-1, and their RAP blends is observed. This indicates that the changes in log stiffness are proportional to phase angle for RAP blends at all RAP concentrations. The results from the log G* versus phase angle plot suggest that this plot may be used as an alternative approach to characterize material's flow property or blending chart.

To evaluate how addition of RAP binders influence the PG grade system of fresh asphalts, the measurements obtained from dynamic shear rheometer including 4 mm plate were used to calculate both high and low temperature grades [16]. Figure 2 shows high and low temperature grades for RTFO-aged asphalt AAA-1 and its RAP blends with Manitoba RAP binder at different concentrations. As seen from Figure 2, the high temperature PG grade of RTFO-aged AAA-1 was increased from 61°C to 70°C with 15% Manitoba RAP binder and 78°C with 50% Manitoba RAP binder and up to 91°C with 100% Manitoba RAP binder. A linear regression on high temperature grades for RTFO-aged AAA-1 and its RAP blends

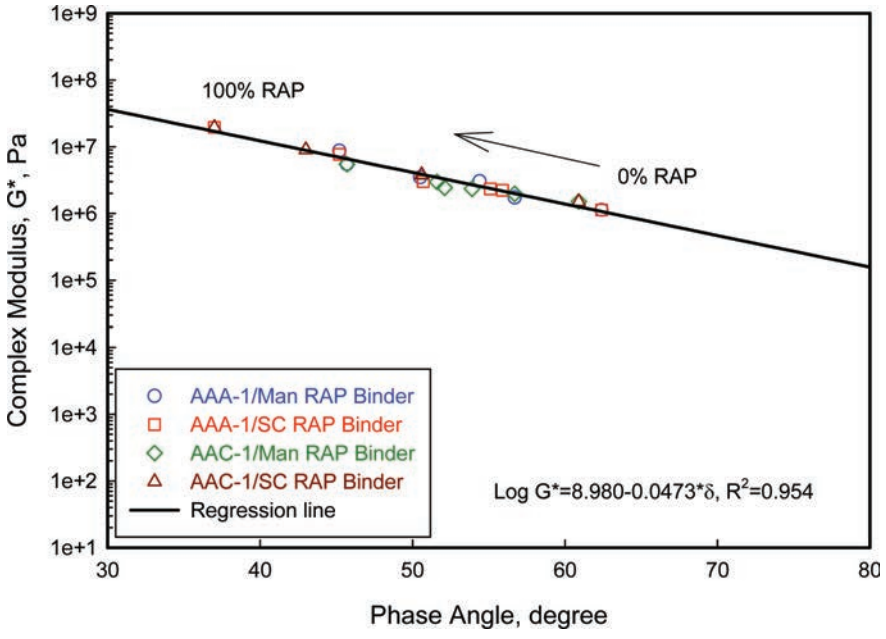

Figure 1. Complex modulus versus phase angle for aspahlts AAA-1, AAC-1 and their different concentrations of RAP binders.

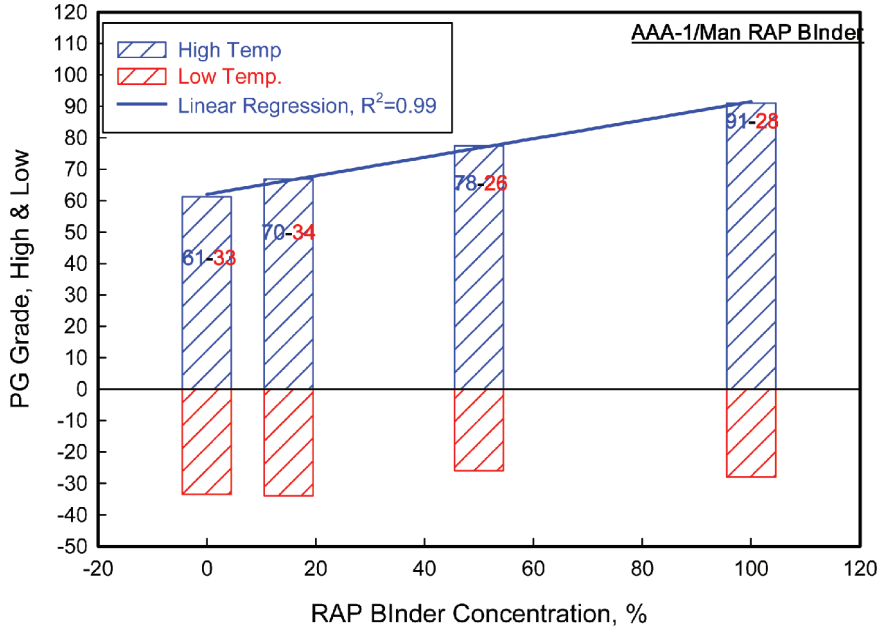

Figure 2. PG grades for RTFO-aged AAA-1 and its Manitoba RAP blend binders.

at different concentrations (0, 15, 50 and 100%) shows a linear relationship, R-squared of 0.99, between PG high temperature grade and RAP content. Further conversion indicates that the approximate changes of PG grade will be 3 PG grades when addition of 50 percent of Manitoba RAP binder is mixed into this particular asphalt (Fig. 2). A similar regression was also obtained for another RTFO-aged AAC-1 mixed with the same Manitoba RAP

binder at different concentrations and not shown in the paper. However, the result shows that the PG grade is changed to only one grade when 50 percent of RAP binder is mixed to this asphalt, RTFO-aged AAC-1. The same linear relationships are also observed on the other two blends of RTFO-aged AAA-1 and AAC-1 with South Carolina RAP binder and are not shown in the paper. The R-squared of these two blends are 0.91 and 0.91, respectively. Further conversion indicates that the PG grade needs to be adjusted up to 4 PG grades when 50 percent of South Carolina RAP binder is going to be mixed into the asphalts. The low temperature grade shows some scattering, however, the general trend still can be seen from Figure 2: addition of RAP binder into fresh asphalt increases its low temperature grade from –33 for RTFO-aged AAA-1 to –28 for the Manitoba RAP binder. Note that the Manitoba RAP binder was graded as PG91-28, and the South Carolina RAP binder was graded as PG95-18. These results indicate that different virgin binders interact differently with different RAP binders.

Asphalts, viewed by a majority of investigators as colloidal in nature, are derived from different crude sources. They are often classified as either gel-type (less compatible) or sol-type (more compatible) [17,18]. With "more" compatible asphalts, asphaltenes are usually lower in natural abundance and well dispersed or peptized by the maltene solvent phase. Compatible asphalts also exhibit "more" Newtonian-like flow properties, are more sensitive to temperature change, and generally are more ductile than less compatible asphalts. Conversely, "less" compatible asphalts, relatively speaking, will exhibit more of an elastic property, and hence, are less ductile than compatible asphalts. Based on this description of asphalt compatibility, asphaltene content is one type of measure of compatibility.

A convenient approach to characterize asphalt compatibility is by defining a state of dispersion of asphaltenes suspended in the maltene phase. Pauli [19, 20] considered Heithaus compatibility parameters utilizing an automated flocculation titrimetry test. This approach is thought to characterize the suspension-like colloidal stability of asphalt in the bulk phase [21–23]. Heithaus compatibility parameters have long been applied to quantify asphalt "molecular" compatibility, defined as the measure of mutual miscibility among molecular species present in an asphalt system. This is achieved by defining an equilibrium or steady state of a colloidal suspension, also referred to as the state of peptization [23]. Asphalts observed to be higher in values of compatibility parameters are generally designated sol-type asphalts while asphalts lower in these values are designated as gel-type. As a simple rule of thumb, in Figure 3 the asphaltene peptizability parameter p_a is shown to be proportional to the asphaltene content as $\chi_a \propto \phi = 1 - p_a$. Assuming that asphaltene content increases with addition of RAP, Figure 4 shows a logical trend in $\chi_a = f(\phi) = f(1 - p_a)$ and RAP content.

The limiting fictive temperature T_f', which is equivalent to the glass transition temperature T_g, is plotted against RAP concentration in Figures 5 and 6. The empirical Fox equation, as expressed in Equation (1), is used to fit the above mentioned experimental data.

$$Fox: \frac{1}{T_g} = \frac{w_1}{T_{g1}} + \frac{w_2}{T_{g2}} \tag{1}$$

where component 1 refers to the virgin binder and component 2 is the RAP binder; w is the weight fraction of the component.

As seen from Figure 5, the Fox equation can't satisfactorily describe T_g change of RTFO aged AAA-1 blends with either Manitoba RAP or South Carolina RAP (inset plot).

A similar trend is also found for RTFO aged AAC-1 blends with Manitoba or South Carolina RAP binders in Figure 6. The deviation of blends' T_g from the Fox equation is presumably due to the relative closeness in T_g for RTFO aged binder and RAP binder. Further, the possible inhomogeneity caused by the blending process in combination with small amount (~5 mg) of sample for DSC tests, might also contribute to the break-down of the Fox equation.

Results shown in Figures 5 and 6 indicate that T_g difference between fresh binders and RAP binders is relatively small with the largest difference of less than 10°C. Due to the lack of significant difference in T_g and the similarity in chemical structure of constituent components,

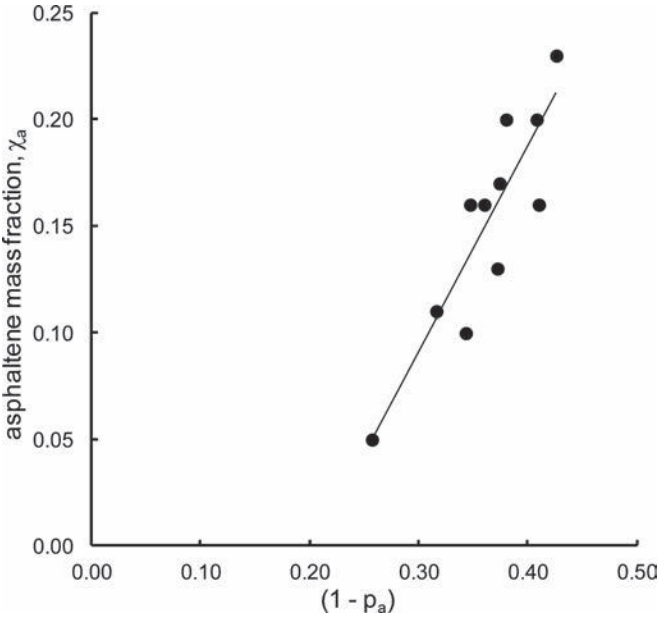

Figure 3. Correlation plot of asphaltene content to compatibility parameter p_a (data from Robertson et al. [24]).

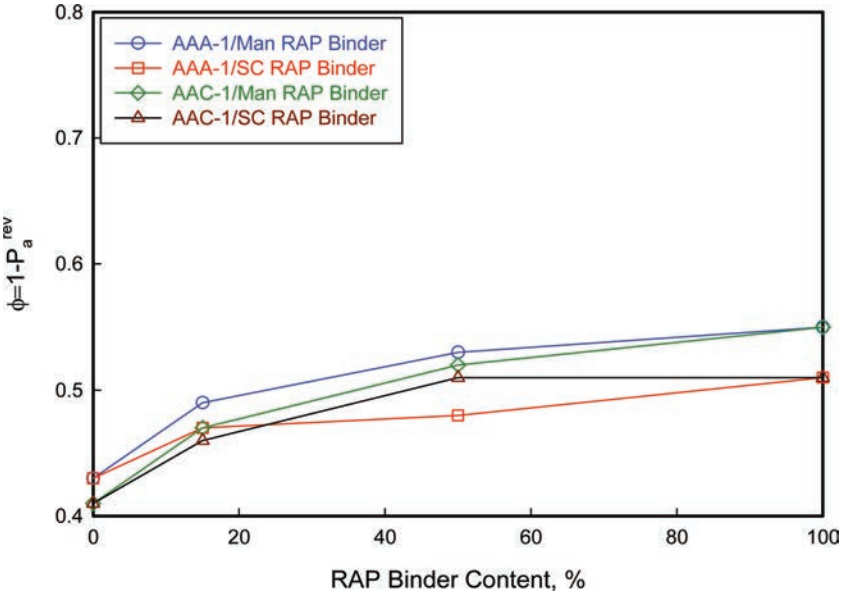

Figure 4. Asphaltene parameter $\phi = 1 - p_a$ plotted as a function of RAP content.

the severe incompatibility of those blends is not expected. As shown in Figure 7, the broadness of glass transition, as characterized by the temperature derivative of reversing heating capacity, remains unchanged for RTFO aged AAA-1/ Manitoba RAP blends. Similarly, no significant glass transition broadening is found for RTFO aged AAA-1/ South Carolina RAP blends, as shown in the inset of Figure 7.

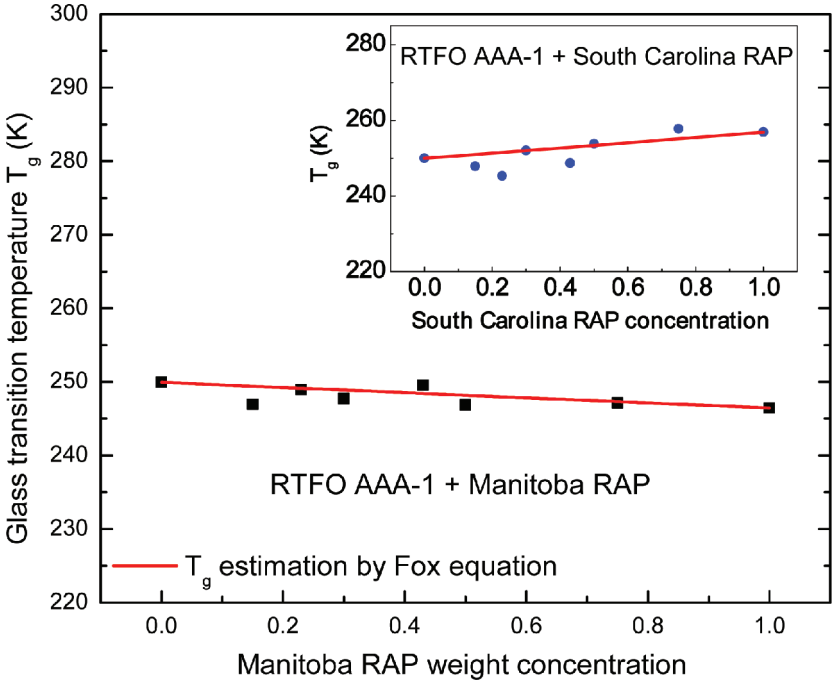

Figure 5. Glass transition temperatures of RTFO AAA-1/Manitoba RAP blends as a function of RAP concentration; the inset is for AAA-1/South Carolina RAP blends.

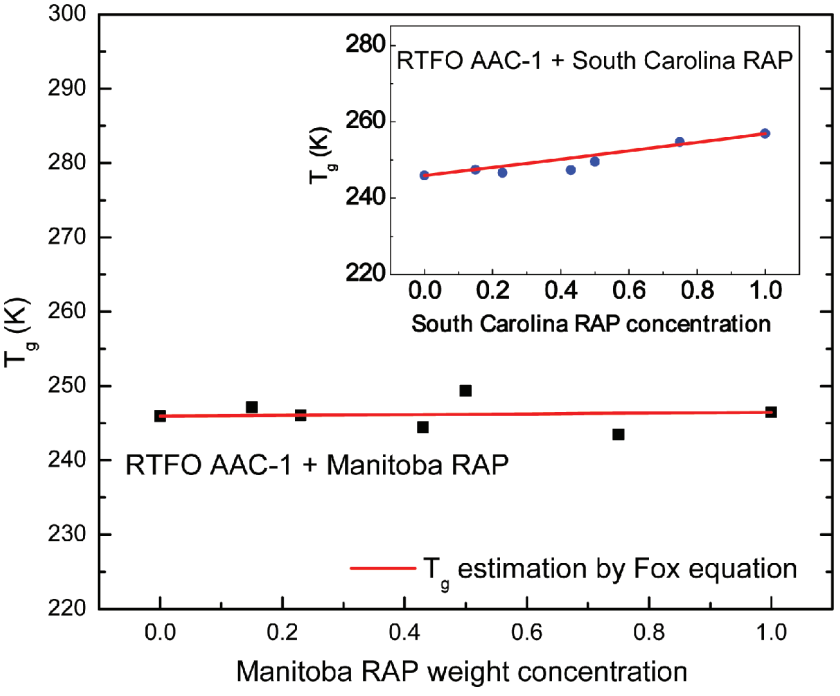

Figure 6. Composition dependence of glass transition temperatures for RTFO AAC-1/Manitoba RAP blends; the inset is for AAC-1/South Carolina RAP blends.

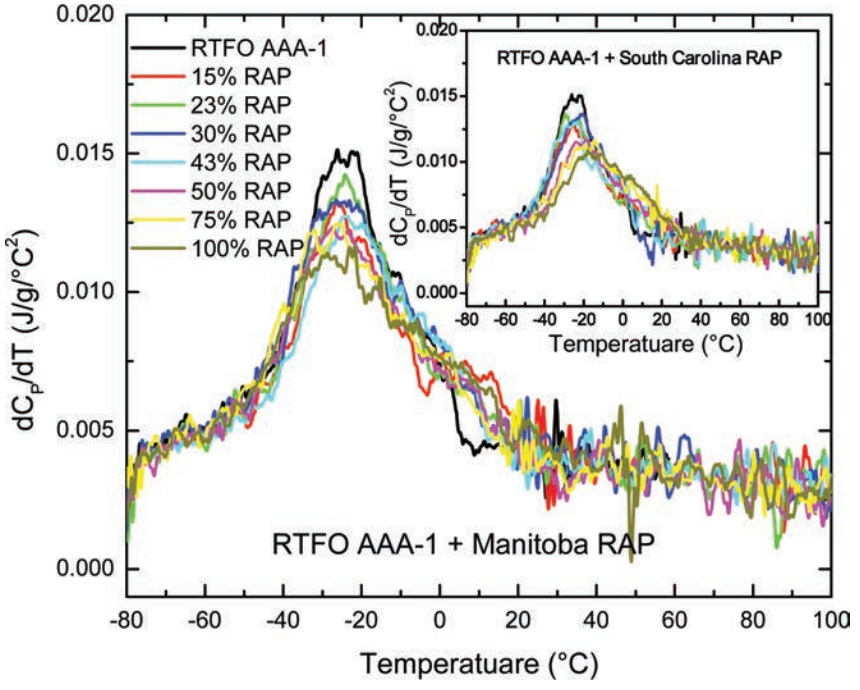

Figure 7. Glass transition broadness of RTFO AAA-1/Manitoba RAP blends; the inset is the same plot for AAA-1/ South Carolina RAP blends.

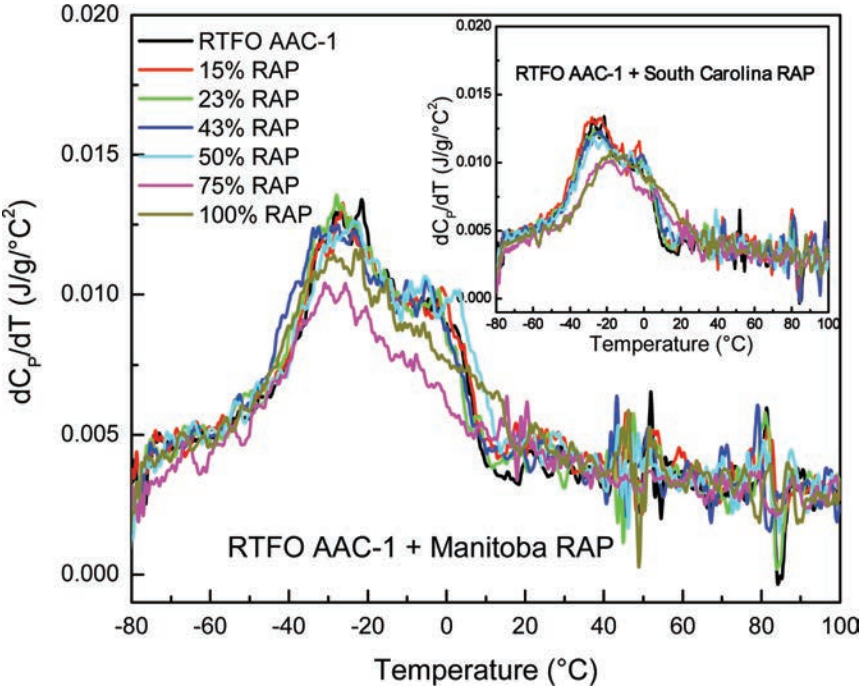

Figure 8. Glass transition broadness of RTFO AAC-1/Manitoba RAP blends; the inset is the same plot for AAC-1/ South Carolina RAP blends.

Figure 8 is the temperature derivative of reversing heat capacity of RTFO aged AAC-1/RAP blends. At RAP concentration of up to 50 percent, especially for South Carolina RAP, both the glass transition temperature and broadness is very close to RTFO aged AAC-1 binder. On the other hand, at 75 percent of RAP, the glass transition temperature and broadness is similar to that of RAP binders. These facts imply that the compatibility of RTFO aged AAC-1 with South Carolina RAP is not as good as RAP blends with RTFO aged AAA-1.

4 CONCLUSIONS

Two chemically and physically different asphalts were mixed with addition of 15 and 50 percent of extracted RAP binders, Manitoba and South Carolina. Several analytical techniques including dynamic shear rheometry, Automated Flocculation Titrimetry (AFT), and Differential Scanning Calorimetry (DSC) were used to measure physical properties of RAP binder blends.

The results indicate that different virgin binders interact with different RAP binders differently and the PG grade adjustment is asphalt and RAP binder dependent. Some asphalts require higher PG grade adjustments than the others. This finding is different from what the literature recommends [7]. The interaction between virgin binders and RAP binders contributes to different stiffening effects.

Temperature modulated DSC was used to investigate the thermal behavior of RAP binder blends. Due to the lack of sufficient difference in T_g and similarity in chemical structure of the binary components, the empirical blending equation can't reasonably describe the plasticization effect. No apparent broadening of glass transition is observed for all blends investigated. In comparison to RTFO aged AAC-1/RAP blends, RTFO aged AAA-1/RAP blends exhibit relative better compatibility.

ABSTRACT: It has been recognized that Polymer Modified Bitumens (PMB) have more potential for use in asphalt paving and can clearly demonstrate the value of their initial higher cost. To further assess sustainable benefits on heavy trafficked roads, test sections using various PMBs were built on highway E6 in Sweden during 2003–2006. The main objective of this paper is to study the aging and rheological properties of the binders used. A large number of cores were drilled and characterized with respect to stiffness, fatigue and permanent deformation. The binders (original, lab aged and recovered) were investigated extensively with rheological and chemical methods. It was found that PMBs, particularly SBS modified, demonstrate better rheological properties as compared to unmodified bitumens, even after several years in the field. These include higher strain recovery and lower non-recoverable compliance at high temperatures, and lower stiffness at low temperatures. For the SBS modified binders, good aging resistance was observed. The high resistance to aging for the SBS modified binders was also evident in the stiffness measurement made on asphalt field cores. Although significant differences have not yet been seen between the test sections (all the sections are in good condition after six years of traffic), the observed improvements for the modified binders are expected to be confirmed by a longer follow-up of the test road.

Keywords: test road; polymer modified bitumen; sustainability; aging; durability

1 INTRODUCTION

Over the years increased traffic volume and traffic loading along with a pressure of reducing material costs has created high performance requirement for asphalt pavements. In order to ensure pavement long-term durability, thus minimizing maintenance cost and conserving resources, proper selection of paving materials together with optimal mix and pavement design are of great importance. Numerous laboratory studies have shown beneficial effects of adding polymers to bitumen and using Polymer Modified Binders (PMB) in asphalt mixtures [1, 2]. Performance improvements are normally found with respect to permanent deformation (rutting), fatigue resistance and low temperature cracking, particularly for the modified binders with Styrene-Butadiene-Styrene copolymer (SBS). These improvements are also confirmed in full-scale tests using for example Heavy Vehicle Simulator (HVS) [3], and field trials, such as test sections in the Long Term Pavement Performance (LTPP) program in North America [4] and airfield runways [5]. The American LTPP study indicated that test sections with PMB mixtures had less fatigue cracking, thermal cracking and rutting compared to

conventional companion sections. Thus, the use of PMBs extends the service life of flexible pavements and HMA overlays [4].

In spite of recognized good performance, the application of PMB to asphalt paving has been quite limited in many countries probably because of higher initial cost. To determine whether it is cost-effective to use PMB and to assess its sustainable benefits on heavy trafficked roads under the Nordic conditions (long and cold winter time, use of studded tyres, etc.), a test road was built in Sweden during 2003–2006. The objective of constructing such a test road is also to validate if binder tests can quantity the functional properties of asphalt pavements. The test road is located in Geddeknippel—Kalsås, and was built as part of highway E6 north of Uddevalla where the Average Daily Traffic (ADT) was around ten thousand vehicles per day. The whole field trial consisted of five northbound and ten southbound sections. The northbound sections were only tested in the wearing course, whereas in the southbound sections various PMBs were tested in all asphalt layers, i.e. the wearing course, binder course and base course. The test road has been monitored continuously and a follow-up research was carried out. The research project includes field performance measurements, testing of asphalt cores, binder tests and evaluation, deterioration modeling, as well as Life Cycle Cost Analysis (LCCA). The present paper focuses on binder characterization with respect to aging and rheology. The binders used in the southbound test sections were studied.

2 MATERIALS, TEST SECTIONS AND FIELD SAMPLING

Table 1 shows the conventional properties of the binders selected for the test sections. The modified binders were produced using different polymers and different polymer concentrations. The 50/70-53 SBS, 50/100-75 SBS and 100/150-75 SBS contains 3, 4 and 6% SBS (by weight), respectively. In 50/70-53 EVA (ethylene vinyl acetate), the polymer content is 6%. All the modified binders are storage-stable according to the European standards EN 13399. Selection of the binders was based on intensive laboratory investigations on binder properties, and on asphalt mixture performance tests, including fatigue, permanent deformation (rutting), water sensitivity, and wear resistance, etc. [6, 7].

In the test road (southbound), two reference sections and eight sections with different binder combinations were built (Table 2). These sections were constructed in 2003/2004 by laying 100 mm base course (50 mm over-layer and 50 mm under-layer, both with hot-mix AG22) on a 80 mm unbound sub-base, and followed by 50 mm binder course of asphalt concrete ABb22. After about two years of traffic, 40 mm wearing course of stone mastic asphalt (ABS16) was applied to the binder course in September 2006. Detailed technical requirements for the used asphalt mixture types can be found in [8].

Field sampling was made in September 2010 when asphalt cores were drilled from two different positions—the wheel path (or under track) and between the tracks, denoted as UT and

Table 1. Binders used in the test road and their conventional properties.

Asphalt layers	Binder types*	Polymer % wt	Penetration, 1/mm	Softening point, °C
Wearing course	70/100	0	77	46
	50/100-75 SBS	4	58	98
Binder course	50/70	0	55	50
	50/70-53 SBS	3	58	58
	50/70-53 EVA	6	52	66
Base course	100/150	0	127	43
	160/220	0	190	38
	100/150-75 SBS	6	123	90

* Currently, 50/70-53 = 45/80-55; 50/100-75 = 40/100-75; 100/150-75 = 90/150-75.

Table 2. Test sections with various combinations of binders.*

Test sections	Ref 1	1a	1b	2a	2b	3a	3b	4a	4b	Ref 2
Wearing course	70/100	70/100	50/100-75 SBS			70/100				70/100
Binder course	50/70	50/70	50/70-53 EVA					50/70-53 SBS		50/70
Base course—over	100/150	100/150-75 SBS		100/150						100/150
Base course—under	100/150	100/150-75 SBS		100/150	160/220	160/220	100/150	160/220	100/150	100/150

* Currently, 50/70-53 = 45/80-55; 50/100-75 = 40/100-75; 100/150-75 = 90/150-75.

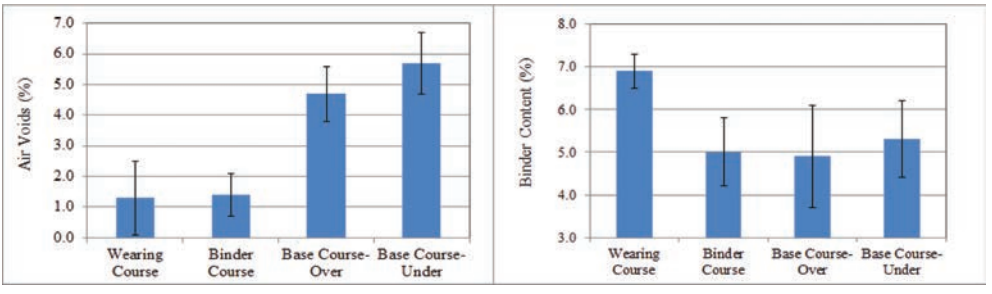

Figure 1. Binder contents and air void contents averaged for different asphalt layers.

BT, respectively. General analyses were conducted on the field cores with respect to binder contents and air void contents. The data averaged for different asphalt layers are compared in Figure 1.

3 CHARACTERIZATION OF BINDERS

Comprehensive tests were carried out on original binders, lab aged samples according to the Rolling Thin Film Oven Test (RTFOT, EN 12607-1) and the Pressure Aging Vessel (PAV, EN 14769), and recovered binders from the test sections. For binder extraction and recovery, the European standards EN 12697-1 and EN 12697-3 were followed. The solvent used was dichloromethane. Binder tests include penetration, fluorescence microscope (morphology), Gel Permeation Chromatography (GPC), Fourier Transform Infrared spectroscopy with Attenuated Total Reflectance (FTIR-ATR), and rheology with a Dynamic Shear Rheometer (DSR).

In the microscopic test, specimens were prepared by taking a drop of sample at 180°C on a glass plate, and morphologies measured at room temperature. The microscope used was Carl Zeiss Axioskop 40F1 equipped with a digital camera DP200.

GPC is a technique to determine molecular weights and molecular weight distribution. In this study, an Alliance 2690 Separation Module (Waters) with UV or refractive index detector was employed. Sample solutions of 0.4% were prepared using Tetrahydrofuran (THF). This solvent was also used as mobile phase.

In FTIR-ATR, a very small amount of bitumen sample was directly placed on an ATR crystal and IR reflection from the sample was detected. Spectra were recorded at wavelengths ranging from 500 to 4000 cm^{-1}. The compositional information was measured for polymers,

e.g. SBS at 966 cm^{-1} (butadiene) and 699 cm^{-1} (styrene), and for bitumen functional groups, such as carbonyl compounds at around 1700 cm^{-1} and aromaticity at about 1600 cm^{-1}.

With DSR, frequency sweeps (0.01 to 10 Hz) were performed at different temperatures ranging from 0 to 90°C, and Multiple Stress Creep and Recovery test (MSCR) according to ASTM D7405. Depending on test temperature, parallel plates of 25 mm in diameter and 1 mm in gap or 8 mm in diameter and 2 mm in gap were used.

3.1 *Morphology*

The morphologies of the modified binders measured at room temperature are presented in Figure 2. As expected, at a low concentration (3 or 4% by weight), the polymer exhibits dispersed phase in the binder. At a sufficiently high concentration of 6%, a continuous polymer phase is formed. The morphologies are also affected by aging. Apparently, in the studied binders of dispersed polymers, finer structures can be seen after the RTFOT-PAV. The polymer morphology may significantly influence the rheological properties of the binder [9, 10]. But for mixture performance, it is probably more important to know polymer structures in the mixture or mastics and to determine its structural impact. Further research on this aspect is needed.

3.2 *Retained penetration*

In assessing the age-hardening of bitumen or PMB over the time, an empirical parameter is retained penetration. It was found that after several years in the field, the modified binders used in the wearing course and base course generally showed higher retained penetration (i.e. less age-hardening) than the unmodified. The results are exemplified in Figure 3 for the binders extracted from the base course (AG22) which has been in the field for six years. On average, the degree of the age-hardening of 100/150-75 (SBS) is about half of that of bitumen 100/150 pen. This is probably due to polymer modification starting with soft bitumen and/or aged SBS acting as a softener in the bitumen. In the binder course, this effect was not seen for the binders modified by EVA or with a low concentration of SBS (3% by weight).

3.3 *Rheological properties*

From DSR frequency sweeps at different temperatures, complex moduli are plotted against phase angles. The so called black diagrams provide a method to check for the Time Temperature Superposition (TTS) principle and give information about chemical or structural changes during the rheological measurements. As exemplified in Figure 4, for the unmodified bitumens, no matter if aged or unaged, these curves are quite smooth, suggesting no structural changes during the rheological tests. On the other hand, it was not possible for the EVA

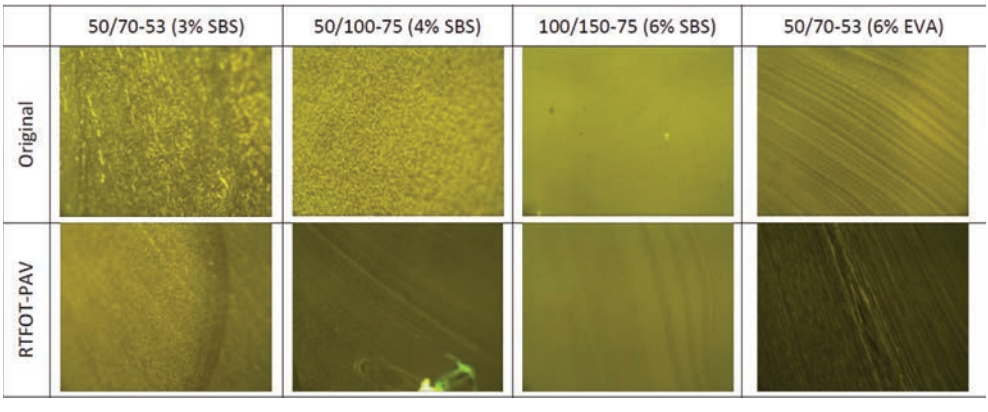

Figure 2. Morphologies of polymer modified binders (magnification 200×).

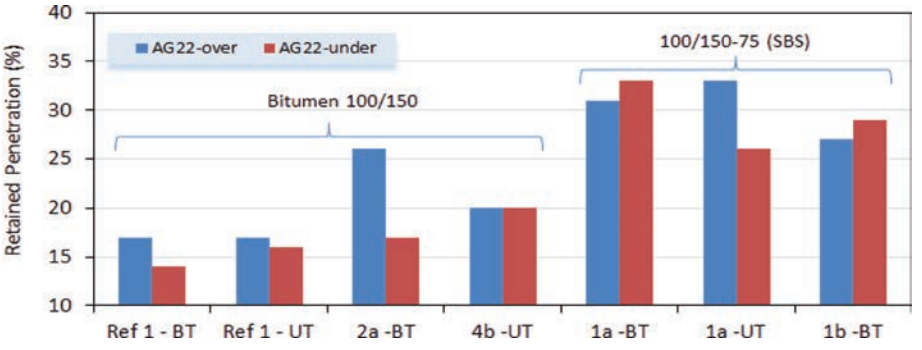

Figure 3. Retained penetration for the binders used in the base course (AG22).

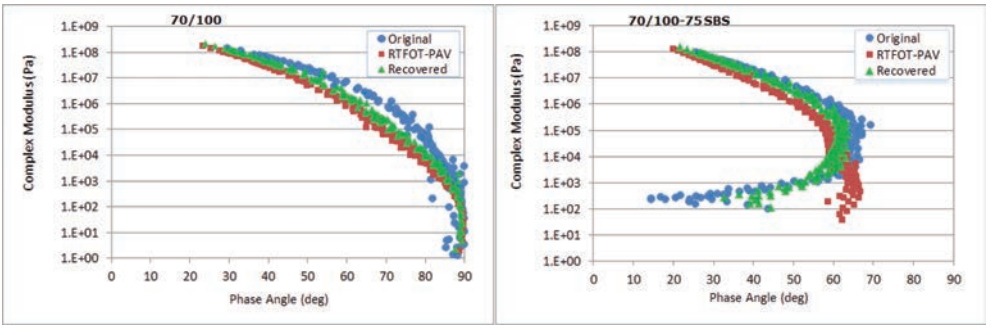

Figure 4. Complex modulus *vs* phase angle for different binders before and after aging.

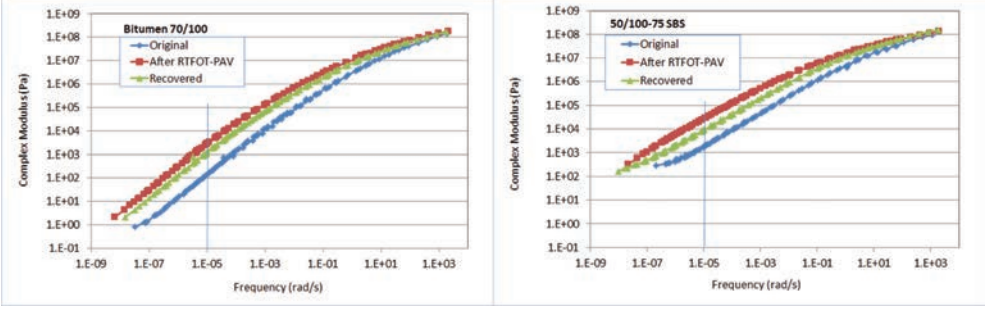

Figure 5. Complex modulus master curves at reference temperature 10°C.

modified binder to get a single smooth plot (figures are not shown). This is attributed to a phase change induced by the melting of the polymer. In the case of SBS modification, higher elasticity (lower phase angle) is very evident even at low complex moduli (at high temperatures and/or low frequencies), as well as after laboratory aging or several years in the field. This is beneficial when the resistance to permanent deformation is considered.

The DSR frequency—temperature sweeps are also used to construct master curves by applying the TTS principle [11]. Using master curves, bitumen rheological behavior and the effect of aging may be characterized over wider ranges of time or frequency at a specified temperature. Examples of the master curves of complex modulus are shown in Figure 5 for the binders used in the wearing course. For both the modified and unmodified binders, the transition to the glassy state can be seen at high frequency. The differences between the

binders, as well as the effect of aging, are more evident at low frequency range; the SBS modified binder exhibits significantly higher modulus than the pen bitumen, which is beneficial with respect to deformation resistance. For example, at a frequency of 1E-5 rad/s, the complex moduli of the modified binder are about 10 to 20 times higher than the unmodified bitumen, depending on if they are aged or not. In addition, the master curves of the recovered binders from the wearing course (4 years on the test road) lie between the original and RTFOT-PAV aged samples, implying the laboratory aging test predicts field aging quite well in this case.

To quantify the aging sensitivity of the different binders in the test road, it was intended to use aging index based on Zero Shear Viscosity (ZSV) measurements. Unfortunately it was not possible to precisely define ZSV for most of the modified binders. Instead, the complex viscosities measured at a low frequency of 0.001 Hz and at 60°C (LSV) are used to calculate the aging index (LSV of the extracted binders divided by that of the virgin samples). The averaged aging indices are: 6.77 for bitumen 70/100, 4.29 for bitumen 50/70, 5.05 for 50/70-53 EVA, 1.02 for 50/70-53 SBS, and 0.90 for 50/100-75 SBS. These data indicate that, of the binders used in the test sections, the SBS modified binders are the most resistant to aging. The high resistance to aging of the SBS modified binders is also confirmed by stiffness measurements on asphalt field cores; this will be shown later.

In the literature, several rheological parameters are used to assess binder rutting resistance. One test which can distinguish differences in the rutting potential is Multiple Stress Creep and Recovery test (MSCR) [12]. The measured parameters include strain recovery and non-recoverable compliance (Jnr). Typical examples of binder response to repeated loading are shown in Figure 6. Differences in strain recovery at 3.2 kPa and 60°C between the binders and the effect of aging are compared in Table 3. Obviously, the SBS modified binders show much higher strain recovery compared to others. Considering the effect of aging, the unmodified and EVA modified binders follow the same trend; the increased strain recovery for the aged and recovered samples is due to bitumen oxidation that makes the binders more elastic. In the case of SBS modification, aging may reduce binder strain recovery probably due to oxidation of the polymer. However, even after laboratory or field aging, the SBS modified binders still retain a higher level of strain recovery as compared to other binders.

Differences between the binders, as well as the effect of aging, are also evident when the non-recoverable compliances, Jnr 3200, are compared (see Table 3). Regardless of sample state (original, laboratory aged, or extracted from the test road), the polymer modified binders always show lower values of Jnr 3200 than the reference, suggesting higher rutting resistance for the modified binders.

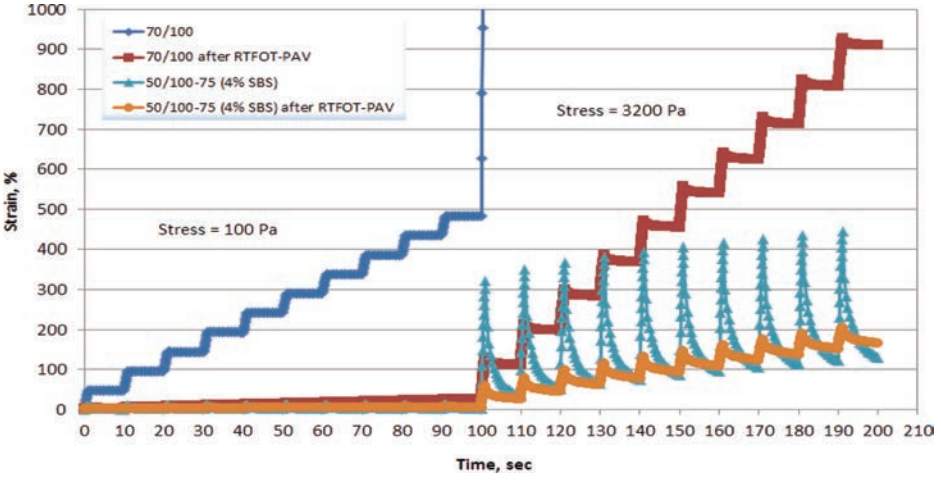

Figure 6. Strain response to repeated loading at 60°C for unmodified and SBS binders.

Table 3. Strain recovery and non-recoverable compliances (Jnr) measured at 60°C.

Asphalt layers	Binder types	Strain recovery, %			Jnr 3200, kPa^{-1}		
		Original	RTFOT-PAV	Recovered	Original	RTFOT-PAV	Recovered
Wearing course	70/100	0	16	5	5.16	0.28	0.69
	50/100-75 SBS	96	70	87	0.04	0.05	0.04
Binder course	50/70	0	13	6	3.55	0.41	0.84
	50/70-53 EVA	6	54	34	1.76	0.04	0.15
	50/70-53 SBS	47	51	32	1.00	0.09	0.34
Base course	100/150-75 SBS	99	90	78	0.01	0.08	0.34

MSCR tests were also carried out at 40°C for some test sections. Not surprisingly, differences between the binders became smaller as compared to the measurements at 60°C. For the unmodified and EVA modified binders, the strain recoveries increased to about 40 and 60%, respectively, while for the SBS modified binders, strain recoveries were more than 70%. In all cases, low values of Jnr were seen at 40°C (<0.03 kPa^{-1} at stress level of 3.2 kPa).

So far the above observation on binder rutting properties has not been validated by field measurement. All the test sections are in good conditions and very little rutting was observed.

Another aspect of particular importance to the Nordic countries is low temperature cracking. For the binders used in the surface layer, low temperature tests were performed according to Performance Grading (PG). It was found that 70/100 bitumen and 50/100-75 SBS were in a similar low temperature range of –22°C to –28°C. In addition, the critical cracking temperatures were determined in accordance with AASHTO PP42, and 70/100 bitumen and 50/100-75 SBS had –28.6°C and –29.1°C, respectively. The critical cracking temperatures are far below the lowest pavement temperature which is about –10°C.

For the binders recovered from the test sections, BBR tests were not performed due to limited amounts of samples. Instead, DSR with 8 mm parallel plate geometry was applied to measure binder stiffness (complex modulus) at –25°C. It was observed that at this low temperature and at 10 rad/s, the stiffness of the SBS modified binder was about 25% lower than that of the unmodified bitumen.

3.4 *Chemical analyses*

Using FTIR-ATR, the compositional information can be obtained directly on the binders without preparing a sample solution. Examples of the IR spectra are shown in Figure 7. To evaluate bitumen oxidation, IR absorbances are measured for oxygen-containing functional groups—carbonyl compounds at 1700 cm^{-1}, as well as aromaticity at 1600 cm^{-1}. As expected, the amount of the carbonyl compounds and aromaticity increase after laboratory aging (Fig. 8). However, for some test sections, the aromaticity and the carbonyl compounds measured for the recovered binders are lower compared to the original and lab aged samples. This could suggest that the functional groups are probably not completely extracted from asphalts, or there might be strong interactions between the bitumen and aggregates or fillers.

FTIR also showed that aging did not change EVA as reflected by more or less unchanged absorbance at 1241 cm^{-1} for the polymer. For the SBS modified binders, the butadiene signal at 966 cm^{-1} decreased slightly while the styrene at 699 cm^{-1} remained unchanged after aging (Fig. 7). Although the SBS polymers take part in chemical reactions and degradation of the polymers may occur during aging, the fragments formed are still kinds of polymer which are large enough to affect the binders in a beneficial way. It was shown by GPC that there were no significant changes in the contents of SBS polymer (and its fragments) after the laboratory aging or field aging.

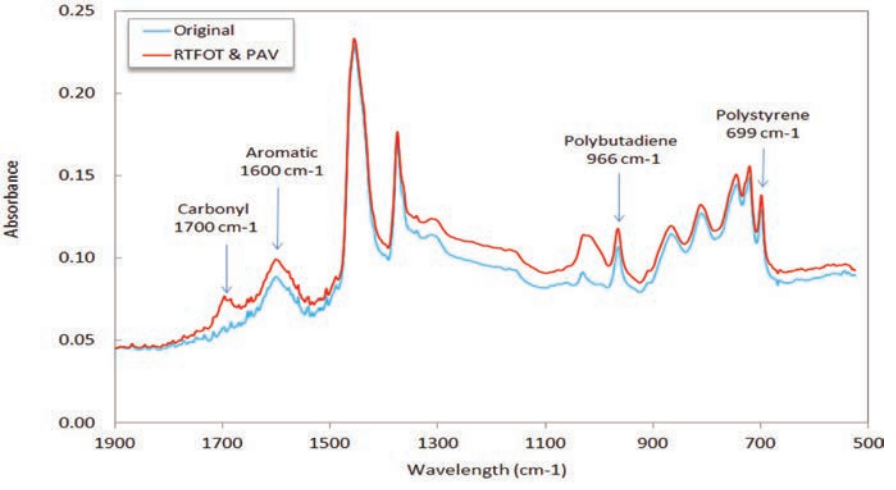

Figure 7. FTIR spectra of 50/100-75 SBS before and after aging.

Figure 8. Carbonyl compounds and aromaticity measured by FTIR-ATR.

4 MECHANICAL TESTS ON ASPHALT FIELD CORES

Several types of tests were performed on asphalt field cores, including stiffness measurement and repeated creep test. Based on stiffness results at 10°C, aging indices of the asphalt mixtures, defined as relative increase in stiffness modulus per year in percentage, are calculated. As shown in Figure 9, in both wearing course and binder course, the asphalt concretes made of the SBS-binders are less aged than those with other binders. This is in agreement with binder test results. Unexpectedly, in the base course, the mix with the SBS modified binder display a slightly higher aging index than the unmodified one. However, in spite of that, the SBS modified base course has shown better fatigue

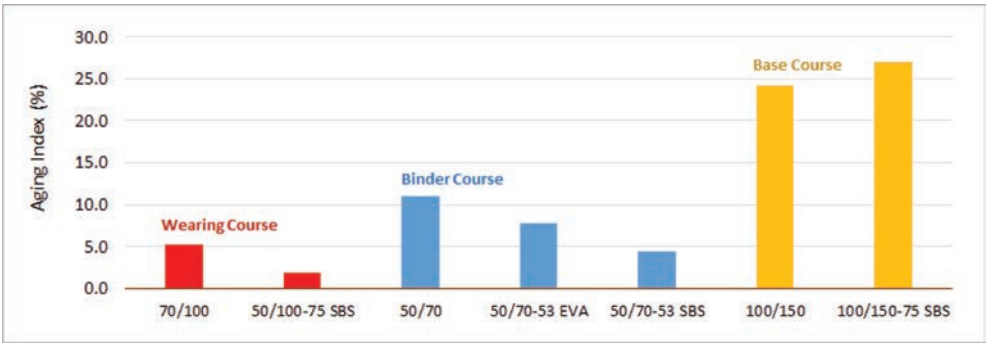

Figure 9. Aging indices of asphalt mixes at 10°C.

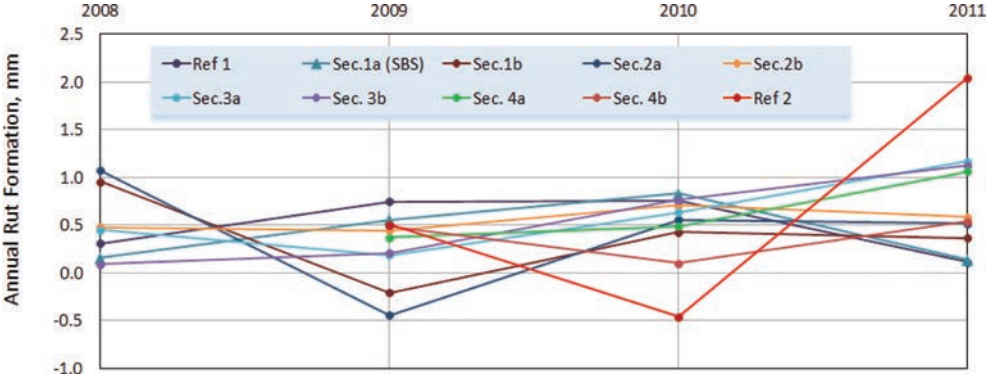

Figure 10. Annual rut formation of different test sections.

resistance than the conventional mix based on laboratory fatigue testing on field cores (data not shown).

Figure 9 also reveals that the aging of the base course mix is much higher than the wearing course and binder course mixes. Notice that in addition to the low binder content in the base course mix, the air voids content of the mix is about 5%; however in the wearing course and binder course, the air voids content is less than 2% (Fig. 1). An easier access to oxygen due to higher air voids combined with thinner binder layer (lower binder content) has caused a higher degree of aging for the base course mix.

5 FIELD PERFORMANCE OF THE TEST ROAD

The performance of the test road has been monitored since its opening to traffic. Annual field measurements and inspection show that all the sections are in good conditions. After 6 years traffic (2012), the rut depth measured on the wearing course was less than 7 mm, and rather small differences (about 2 mm) were found between the different sections. In Figure 10, the annual rutting in asphalt concrete layers estimated with Road Surface Tester (RST) between 2008 and 2011 is compared for different sections. In the estimation, wear rutting caused by studded tires is excluded. In addition to rutting, other deteriorations, such as stripping and low temperature cracking, have not been seen on the test road. To make definite comparisons on performance, a longer time of follow-up of the test road is obviously needed.

6 CONCLUSIONS

The polymer modified binders studied in this paper demonstrate better rheological properties than the unmodified bitumens, even after several years in the test road. These include higher strain recovery and lower non-recoverable compliance (Jnr) at high temperatures, and lower stiffness at low temperatures. For the SBS modified binders, good aging resistance is found. The high resistance to aging for the SBS modified binders is confirmed by stiffness measurements on asphalt field cores. The variation on binder rutting parameters (MSCR) has not yet been validated by the field performance of the test sections. So far, all the test sections are in good conditions and differences in rut depth are small. It is, however, believed that the improved binder properties should be beneficial to pavement performance. This is expected to be confirmed by a longer time of follow-up of the test road.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge Carl-Gösta Enocksson, The Swedish Transport Administration, for supporting this research. They would also like to thank their technical staffs, Orjan Otterstrom and Petri Uhlback (Nynas), and Hassan Hakim and Andreas Waldemarson (VTI), for laboratory assistance.

The low temperature characterization of bio-modified shingles

Daniel Oldham, Elham H. Fini & Albert Onochie
North Carolina A&T State University, Greensboro, NC, USA

ABSTRACT: With depleting natural resources and increasing material costs, the reusing of defective Roofing Shingles (RAS) has gained increasing attention. However, it has been noted that the use of aged asphalt materials can adversely affect low temperature performance shown both in the field through decreased pavement life and in the laboratory through the induction of micro-cracking. Another development in sustainable infrastructure is that of Bio-Modified Binder (BMB) particularly that derived from swine manure. The use of BMB in HMA has shown trends of increasing low temperature performance specifically in samples containing aged materials. In this paper, samples were subjected to dry air conditioning times of 0, 24, 48, and 72 hours to simulate low temperature field conditions. Through Bending Beam Rheometer (BBR) testing, stiffness showed a trend of being lower and m-values were higher in samples containing BMB in conditioned samples. Direct Tension Tester (DTT) results revealed congruent results; however, a drop in failure stress, strain, peak load, fracture energy, and ductility at 24 hour conditioning was observed to indicate micro-cracking as a discontinuity in results was observed.

Keywords: roofing shingles; swine manure; bio-binder; physical hardening; micro-cracking

1 INTRODUCTION

According to the American Society of Civil Engineer's 2013 Report Card for America's Infrastructure, America's highways received a grade performance of D with 32% of America's major roads in poor or mediocre condition. This in turn, cost US motorists, who are traveling on deficient pavement, approximately $67 billion a year in repairs to their vehicles [1]. One reason for the increase in deficient pavement, is that over the past 9 years, asphalt binder prices has risen 255% as a result of increasing crude petroleum prices and refining modifications that have resulted in a reduction of asphalt binders supply in the market. As a result, the maintenance of our nation's highways has become more costly and harder to manage [2–3]; therefore, it is essential for America's economic vitality to adopt more sustainable practices in the asphalt paving industry that would reduce material costs while improving pavement performance.

The use of recycled materials in asphalt pavement particularly that of Recycled Asphalt Shingles (RAS) has been well documented; RAS has been used in HMA for over 25 years as a means of economic value as well as landfill diversion. It is estimated that approximately 11 million tons of asphalt roofing shingles is discarded into landfills each year with 10 million tons being that of Post-Consumer Tear-Off Scrap Shingles (TOSS) and the remaining one million being Manufactured Waste Scrap Shingles (MWSS). This is equivalent to disposing approximately 5.8 million tons of useable mineral aggregates and nearly 3.1 million tons of reusable asphalt binder annually [4–5]; however, despite the potential benefits of utilizing such a vast resource, only approximately 10% of disposed roofing shingles are recycled for new pavement construction [6]. One of the reasons for strict limitation on RAS usage is the potential for adverse negative low temperature effects of the asphalt mixture. It has been shown that the low temperature grade of the base

binder increases approximately 1.9°C for every one percent increase in RAS usage in neat asphalt [4].

Previous research has indicated that low temperature performance of asphalt pavement is a key contributor to the overall performance of the asphalt pavement, particularly in cold regions. Nationally, this phenomenon cost various agencies approximately $45 billion dollars in expenditures in 2006 [3]. The main contributor to adverse low temperature properties has been that of high thermal stresses formed within the asphalt binder when the temperature drops suddenly. For this reason, the use of recycled materials in new pavement construction has been limited despite initial cost savings, better waste management practices and more sustainable development [4–7]. It has been well documented that the increase in high thermal stresses is due to the stiffer oxidized/aged binder added to the base binder upon introduction of recycled asphalt [8–12].

The use of recycled materials particularly the use of oxidized/aged binder such as Recycled Asphalt Pavement (RAP) and Recycled Asphalt Shingles (RAS) adversely affects low temperature performance of asphalt due to low-level interactions between the asphalt binder and the oxidized recycled binder; therefore, it is well documented that the use of wet processing can lead to significant improvements in overall pavement performance as well as consistency compared to dry processing [13–18]. In order to accommodate increased RAS percentages, wet processing of RAS was utilized for this paper [19]. However, the specimens are categorized as mastics rather than binders due to the addition of 85.5 μm size particles as well as the relatively high percentage of RAS introduced by weight of the shingles and base asphalt.

The presence of particles, in asphalt binder to form mastics, has been found to have a direct correlation and could be the sole contributor to premature failure of the overall asphalt mixture due to the particle's high surface area in the mix [20–24]. Other effects on the overall mixture from mastics can vary from air voids content, moisture sensitivity leading to stripping, as well as mixture stiffness resulting in increased brittleness [22–26]. Therefore, in order to increase sustainability, the use of bio based binder derived from swine manure was studied to determine if it's presence could alleviate the adverse effects from the RAS [27–29].

Swine manure based bio-binder is a newly developed technology with the potential of replacing petroleum based asphalt binder. Having been produced from swine manure, it offers considerable benefits both environmentally through being a best practice management solution and economically through a 70% reduction in production cost to that of petroleum based as well as improved profits for hog farmers [30–32].

This paper studies the low temperature properties of bio-binder in the presence of high percentages of recycled asphalt shingles (mixed by wet processing). In order to simulate actual low temperature field conditions, samples were conditioned in a freezer for 24 hours, 48 hours, and 72 hours at −18°C. Specimens were then tested using the Bending Beam Rheometer (BBR) and the Direct Tension Tester (DTT). The BBR was used to determine the m-value and stiffness for each of the blended samples while the DTT results were used to look at the blend's fracture energy, ductility, failure stress, failure stain, and peak load which are all indicators for thermal cracking resistance.

2 MATERIAL AND METHODS

2.1 *Asphalt roofing shingles*

For this project, Tear-Off Scrap Shingles (TOSS) were chosen and donated by S.T. Wooten's Quality Control lab located in Sanford, NC. Some states that allow RAS in new construction limit the selection to only that of Manufacture Waste Scrap Shingles (MWSS) due to it's consistency, separation from other Construction and Demolition (C&D) waste, and that it is considerably less aged than TOSS (7); therefore, this study investigates the feasibility of the application of high percentages of TOSS as the most severe scenario. The gradation of the shingles is given in Table 1.

Table 1. Recycled asphalt shingle gradation.

2.2 *Recycled Asphalt Shingle (RAS) modified mastic*

The base binder for the study was Superpave 64-22, which is commonly used across the United States. The 40% RAS particles with an average size of 85.5 μm by total binder mass was blended with the neat binder by means of a mechanical shear mixer rotating at approximately 450 rpm for 1 hour. There wasn't any extraction preformed on RAS particles since particles were added as is. Therefore, due to the large percentage of particles and to avoid segregation, the mastic was re-blended at 135°C for 5 minutes at 750 rpm prior to preparing each test specimen.

2.3 *Bio-binder production*

The bio-binder was produced by means of a thermochemical conversion of swine manure at the Swine Farm Unit at NC A&T. The processing begins with subjecting the manure to anaerobic atmosphere by purging the air 3 times by use of nitrogen gas. Once completed, the manure is heated to 300°C at which the temperature and pressure is maintained for a specified amount of time. After heating, the manure is cooled down to room temperature at which it is then removed from the reactor, separated by means of filtration, then finally undergoing a vacuum distillation.

2.4 *Bio-Modified Shingles (BMS) mastic*

The Bio-Modified Shingles (BMS) were the resultant of blending the 40% RAS mastic binder with 10% Bio-binder by mass. The mixing was conducted by means of a mechanical shear mixer rotating at 750 rpm for 30 minutes. Due to bio-binder specifications, the mixture temperature was reduced to 135°C due to the additive's ability to improve workability at lower temperatures, which also reduces excess aging.

2.5 *Sample conditioning*

For this paper, both DTT and BBR specimens were subjected to dry isothermal conditioning of −18°C to simulate the low temperature conditions in the field. Conditioning times were 0, 24, 48, and 72 hours to determine if a trend would be shown with increased conditioning time. Specimens were demolded in order to eliminate the influence of the molds as shown in Figure 1. All test specimens were still conditioned for 1 hour in the alcohol bath as stated by the respected ASTM standards; however, it is not considered in the conditioning time since it was not dry isothermal conditioning.

2.6 *Bending Beam Rheometer (BBR)*

In order to establish the low temperature performance of the modified binder, the BBR was used to determine flexural-creep stiffness and m-value parameters following AASHTO T 313.

Figure 1. DTT specimen preparation and testing.

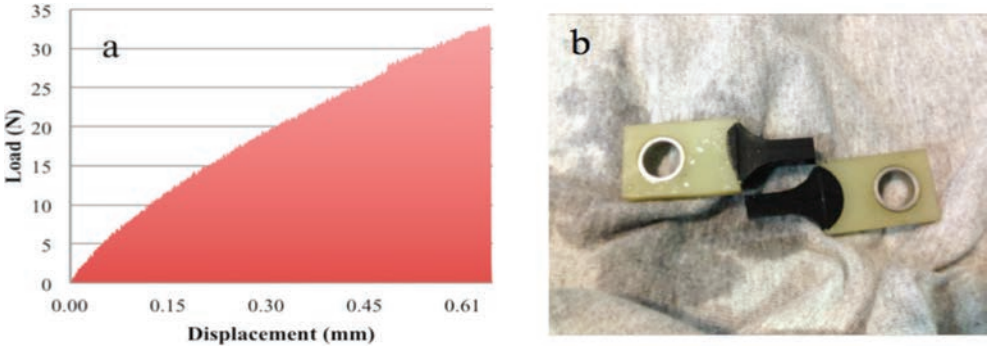

Figure 2. Load-displacement curve; (b) Fractured DTT specimen.

According to the Superpave™ specification, this test evaluates the binder's possible abilities of stress relaxation and thermal cracking. In this study, the testing temperature was –18°C with the stiffness and m-values recorded. Using Equation (1), the stiffness of the asphalt binder was calculated.

$$S(t) = \frac{PL^3}{4bh^3\delta(t)} \tag{1}$$

where:

P = applied constant load (100 g or 0.98 N)
L = distance between beam supports (102 mm)
b = beam width (12.7 mm)
h = beam thickness (6.25 mm)
$S(t)$ = asphalt binder stiffness at a specific time
$\delta(t)$ = deflection at a specific time

2.7 *Direct Tension Tester (DTT)*

The Direct Tension Test is typically used to determine the failure strain and failure stress of asphalt binders by means of direct tensile force using the Direct Tension Tester (DTT) apparatus developed by Interlaken Inc. Test specimens are prepared by pouring hot asphalt binder into a respected dog-bone shaped mold with two plastic end pieces. The two end pieces are also used to transfer the tensile load from the test machine to the asphalt binder. According to ASTM 6723-12, the rate at which the tensile is applied was approximately 1.00 mm/min. In this study, percent strain, stress, and load readings were recorded until the fracture failure was reached. The test must be conducted at temperatures where the specimens exhibit brittle behavior in order to capture fracture rather than ductile failure. For this paper, the testing temperature was –18°C which is 4 degrees above the low temperature grade of the PG 64-22 base binder.

Using load and displacement data collected during the DTT test, fracture energy was calculated using Equation (2) [27]. An example of the $A_{L\text{-}D\ Curve}$ and an image of DTT sample after fracture are shown in Figure 2.

$$\text{Fracture Energy} = \frac{\sum \text{Area}_{L-D.Curve}}{\text{Area}_{C.S.A}} \quad (2)$$

where:

$\text{Area}_{L\text{-}D.Curve}$: The area under the load—displacement curve (N*m)

$\text{Area}_{C.S.A}$: The cross section area at fracture (m^2)

3 DISCUSSION AND ANALYSIS

3.1 *BBR results*

It is evident from the trend discerned in Figure 3, that the longer the conditioning period in –18°C the stiffer the RAS samples. It was further observed that by conditioning the RAS samples for 24, 48 and 72 hours the creep stiffness increased by an average of 25%, 50% and 69% respectively from 0 hours conditioning.

As shown in Figure 3, the conditioning of BMS for 24, 48 and 72 hours increased stiffness by an average of 32% and 42% respectively. By observing the steady increase in creep stiffness with respect to the conditioning time and the constant temperature of –18°C, a phenomenon known as physical hardening was observed [33]. This phenomenon causes time dependent isothermal changes in specific volume and consequently changes in mechanical properties, though it has been noted that the effect of physical hardening is completely removed when the material is heated up to room temperatures [34]. This phenomenon occurs as a consequence of isothermal reduction of free volume at temperatures close to the glass transition temperature [35]. The effect of physical hardening is typically reflected in an increase in the stiffness values and a reduction of the stress relaxation capacity of the asphalt binder.

Figure 3 also indicates that the addition of 10% bio-binder reduced the RAS stiffness and a clear trend was observed as increased conditioning time lead to improved BMS sample performance over RAS. At 0 hours conditioning, the BMS reduced the stiffness by an average of

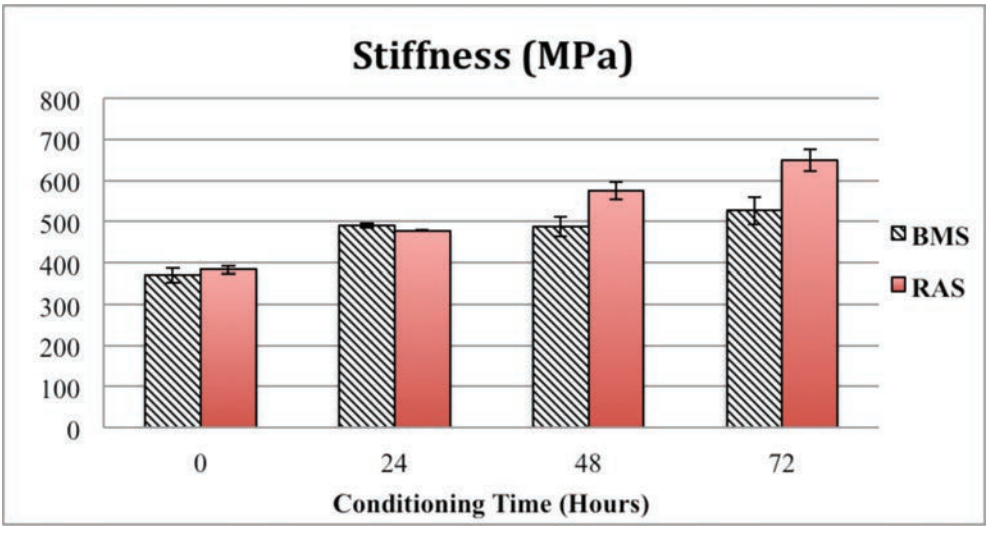

Figure 3. Time-dependent creep stiffness curves for 40% RAS.

4% at time 60 seconds and at 24 hours conditioning no reduction is clearly seen. Accounting for the little to no reduction in these two times would be the increased susceptibility of oxidative and thermal aging in BMS compared to the RAS samples. It can be seen that at 48 hours and 72 hours stiffness is reduced by an average of 18% and 23% respectively at time 60 seconds.

However, Figure 4 further demonstrates a clear trend of BMS performing better than RAS as the conditioning time was increased in that the m-values are constantly higher than the RAS specimens. At 0, 24, 48 and 72 hour conditioning, BMS saw an average increase in m-value of 4%, 5%, 15% and 16% respectively.

3.2 *DTT results*

The strain values were conducted using the DTT at a testing temperature of –18°C. As shown in Figure 5, as conditioning time increases, the failure strain decreases both in RAS

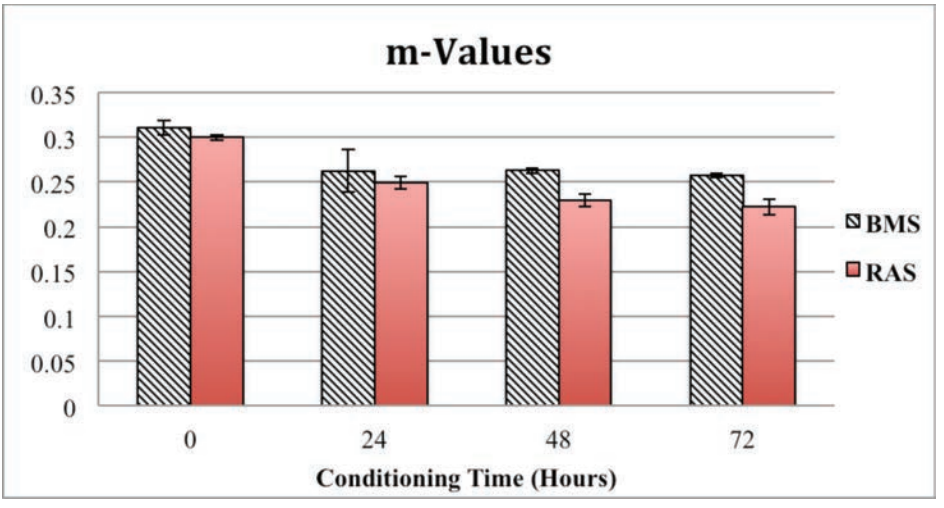

Figure 4. m-value results for BMS and RAS.

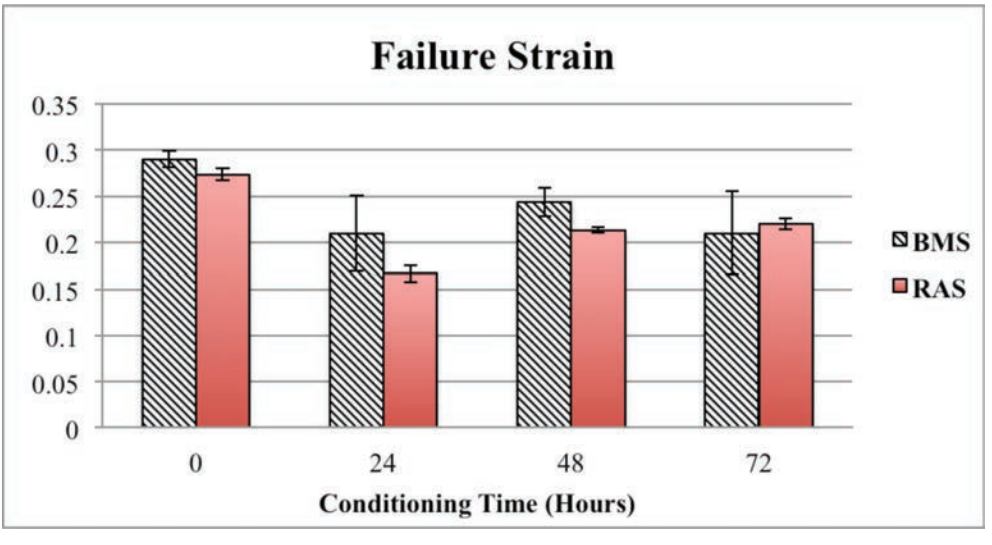

Figure 5. Failure strain for BMS and RAS samples.

and BMS samples. The strain findings as well as the stress findings in Figure 6 are both consistent with what was found in a prior mastic study which showed failure stain and stress to increase with increasing percentage of particles [36]. However, it is interesting to note that the strain value for both BMS and RAS dropped at 24 hour conditioning then proceeded to increase before declining again. When comparing the RAS and BMS, BMS had consistently higher Failure Strain values until 72 hour conditioning in which they were both relatively the same. This same trend was found for failure stress values as well in Figure 6 except that failure stress was consistently higher for all RAS samples compared to BMS, except for the 24 hour specimens, which indicates the material is stiffer due to the increase in stress.

The peak load is the maximum load placed on the specimen before fracture. As indicated from the failure stress and strain, the peak loads show a similar trend in Figure 7. Higher peak

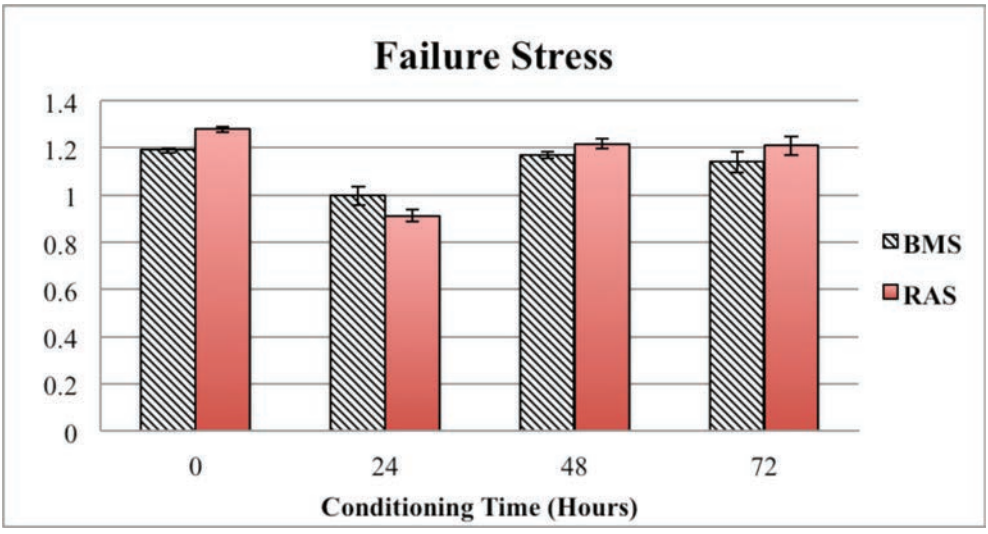

Figure 6. Failure stress of BMS and RAS samples.

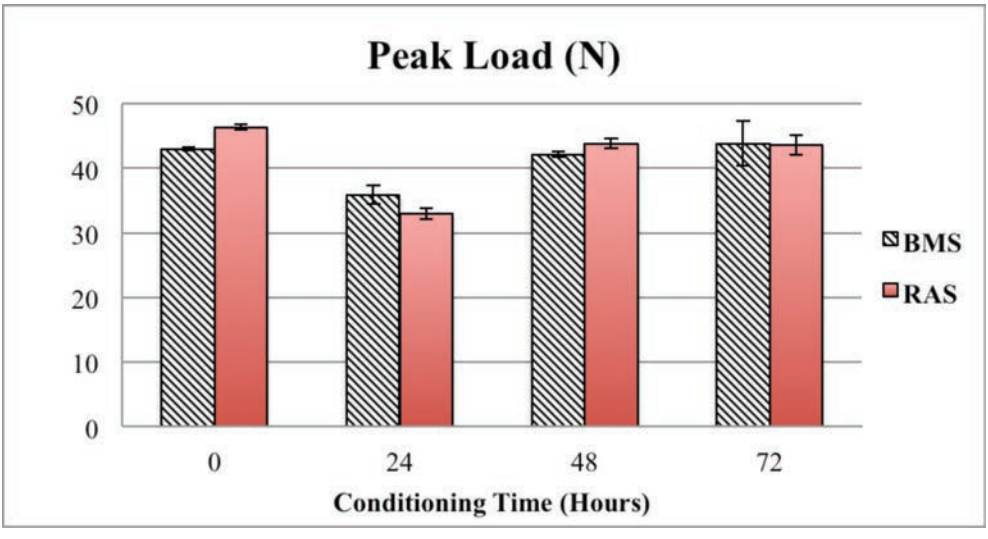

Figure 7. Peak loads of BMS and RAS samples.

loads have been related to more brittle materials. The peak loads for 0 and 48 hour RAS samples appear to be slightly higher, the 72 hour results being relatively the same, and the 24 hour samples indicate BMS as a higher peak load.

The fracture energy as calculated from Equation (2), is shown in Figure 8. From the results, it is shown that the BMS has higher fracture energy values compared to RAS except for 0 hours conditioning. It has been observed that materials with higher fracture energy values tend to have improved low temperature performance [27]. In Figure 9, ductility results show BMS with consistently higher values than RAS samples which also indicates RAS samples show more brittle behavior at low temperatures. The drop in performance could be attributed to the presence of micro cracking which has been indicated previously in sudden decreases in pavement performance during prolonged conditioning [37–38].

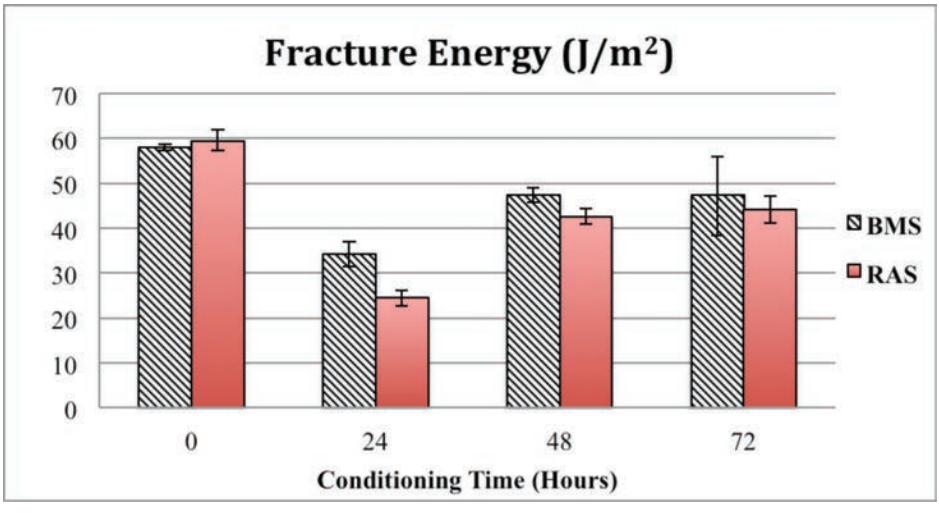

Figure 8. Fracture energy for BMS and RAS samples.

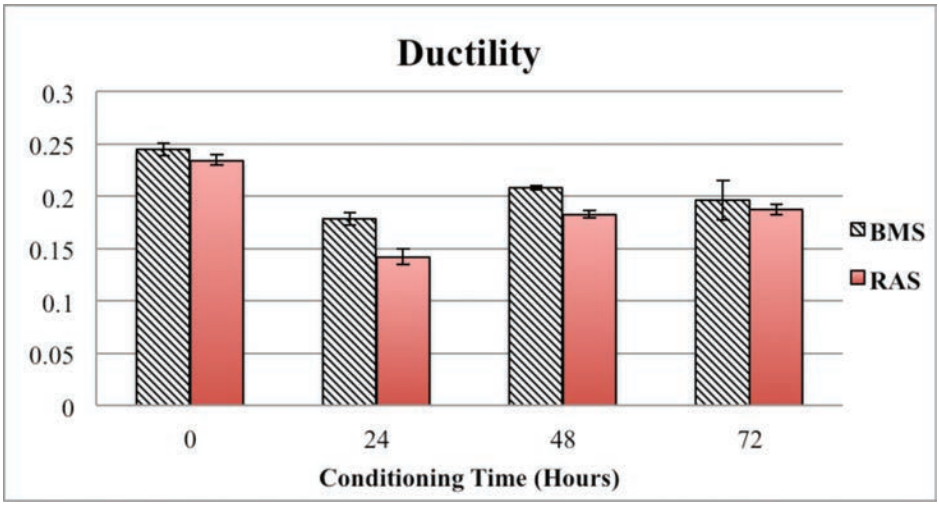

Figure 9. Ductility for BMS and RAS samples.

4 CONCLUSIONS

From these results, the follow conclusions were made:

- The performance of RAS based mastic samples was observed to have adverse low temperature effects compared to the neat binder.
- The performance of RAS samples was observed to have generally adverse low temperature performance as conditioning time increased.
- The performance of BMS samples was observed to have deteriorating low temperature performance similar to RAS samples; however, the presence of bio-binder showed trends of adverse low temperature performance mitigation.
- The RAS and BMS sample subjected to increasing increments of low temperature conditioning showed trends to physical hardening.
- The drop in performance observed in both BMS and RAS DTT samples subjected to 24 hour conditioning shows similar characteristics to the phenomena known as micro-cracking.

ABSTRACT: Due to the increasing needs for robust highway pavement structural monitoring tools with high accuracy and functionality, this paper introduces some preliminary outcomes from our research on developing an optical fiber based pavement behavior monitoring sensing system. The major content of this paper discusses the sensing system design concept and a novel optical fiber flexible encapsulation technique. The proposed sensing system integrates Fiber Bragg Grating (FBG) and Brillouin Optical Time Domain Analysis/ Reflectometry (BOTDA/R) techniques to ensure the large coverage and local high accurate monitoring. A new flexible encapsulation technique for optical fiber has been proposed to overcome the difficulties in withstanding the harsh working environment in pavement structures. Lab and field tests have also been carried out to study the effectiveness of the proposed flexible encapsulation method. It has been found that the proposed sensors has high survival rate (>75%) and are efficient for long term pavement structural behavior monitoring.

Keywords: Optical fiber, pavement structure, structural monitoring sensing system, encapsulation

1 INTRODUCTION

Roads, especially highways, are one of the most important parts of the nation's transportation infrastructure system. Their construction and service condition also influence traffic safety. Currently, China is entering a new era of rapidly building roads and expanding the highway system. The "national expressway network" of China [1] has planned to spend 300 billion dollars to finish the construction of the 7918 highway system within 30 years. However, the state of art in designing road structures still cannot fulfill the increasing requirements for long life and bearing heavy traffic. Research is needed to better understand the performance of road structures under different service conditions.

One of the key ways to assess the condition of road structures is through effective inspection, and therefore high accurate testing facilities are especially critical. According to the differences of testing location, road structure inspection technologies can be classified into two categories: lab test and field inspection. Comparing to field inspection, there are less restric-

tions (size, portability, etc.) to the test equipments for lab test and therefore high accurate data can be obtained. However, testing small road material samples in lab often cannot reflect their real working status. Due to technology limitation, road structure three dimensional stress fields are very hard to be simulated or measured. Zhou, et al. [2, 3] have designed an optical fiber based sensor trying to measure three dimensional strain field of road structures.

With the development of Non-Destructive Testing (NDT) technologies, more and more researches have been focused on using NDT instruments for pavement structure in-situ inspection. Falling weight deflectometers have been used to predict pavement structure elastic modulus [4]. Grote et al. [5] have used ground penetrating radar to detect damage and evaluate infiltration in layered pavement structures. Capacitance sounding technologies have also been adopted to measure the thickness of pavement structures. Although NDT instruments won't damage pavement structures during/after inspection, structural health information are obtained indirectly. Usually, complex inverse problems are needed to be solved in order to link the data with structural parameters, and therefore, the inspection accuracy is low. Besides, the inspection cost and small coverage are also the restrictions for large scale applications of NDT in pavement inspection.

Embedded sensors in pavement structures can provide real time pavement performance data with relatively high accuracy [6]. The harsh working environment and unique characteristics of pavement structures require the sensors to endure high temperature (up to 200°C), moisture, large compaction force, repeated heavy loading, etc., and have large coverage. Most of the traditional sensors for civil structures are not suitable for pavement structures [7]. The advantages of optical fiber sensors, such as small size, high accuracy, low cost, distributed large coverage, reliable durability, etc., make them the attractive choice for long term pavement health monitoring [8, 9]. However, bare optical fibers are vulnerable to shear stress, and therefore, encapsulation is needed before application. Due to the differences of material mechanical properties, the packaging material will increase the complexity of analyzing strain transfer from host material to the sensor core [10, 11]. For pavement materials with lower elastic modulus than optical fiber, this problem is more severe. Besides, the sensing system should be well designed in order to capture information of major damage modes (rutting, cracking, etc.) that distributed uncertainly [12–14].

The objective of our research is trying to develop a robust sensing system that can provide life cycle performance monitoring to in service pavement structures. The real time monitoring data then can be used for pavement structural health condition assessment and damage evolution pattern development. Currently, few references have been found related to using optical fiber sensors for pavement structural health monitoring except the works from our research group.

This paper will introduce some results from the preliminary study on optical fiber sensors for asphalt pavement performance monitoring. The sensing system design will firstly be discussed. A flexible encapsulation method for optical fiber will then be introduced. Lab and field tests have been carried out to evaluate the performance of the proposed sensors. A Fiber Bragg Grating (FBG) based curvature measurement sensor design as an alternative sensing method without encapsulation has also been introduced in the last part of the paper. The feasibility of the proposed design is discussed based on lab test results.

2 OPTICAL FIBER BASED SENSING SYSTEM DESIGN

2.1 *Introduction to optical fiber sensors*

As the most popular sensors with big application potential at the end of the 20th century, optical fiber sensors have many different types and their functions also differ a lot. FBG and Brillouin Optical Time Domain Analysis/Reflectometry (BOTDA/R) are the most typical optical fiber based sensing techniques [15]. Optical fiber gratings on a single-mode fiber are made by laterally exposing its core to a periodic pattern of intense ultraviolet light. FBG can measure strain of the optical fiber by detecting the change of Bragg wavelength transmitting in the fiber [16]. The low cost and almost absolute measurement are the distinguishing properties of FBG sensors. BOTDA/R is based on the fact that temperature or strain information received by an

optical fiber can be detected by the shift of Brillouin back scattering frequency. It can measure strain continuously in an optical fiber and therefore can measure the distribution of physical parameters over long distance [17]. Comparing to FBG sensing technique, the precision of BOTDA/R is lower, but BOTDA/R uses normal optical fiber as the strain sensor and therefore the sensor cost is much lower [18]. The BOTDA/R analyzer can detect strain along more than 30 km distance at one time to provide distributing measurement. The sensing system that will be introduced in this paper is also based on these two types of sensing techniques.

For FBG based sensors, it is investigated that the central wavelength of the reflected component satisfies the Bragg condition [19]:

$$\lambda = 2n\Lambda \tag{1}$$

where n is the effective index of refraction and Λ is the grating periodicity of the FBG.

Due to temperature and strain dependence of the parameters n and Λ, the wavelength of the reflected component will change as function of temperature and strain. The general expression for the strain of the sensor can be expressed as:

$$\varepsilon = \frac{1}{(1-P_e)}\left(\frac{\Delta\lambda_1}{\lambda_1} - \frac{\Delta\lambda_2}{\lambda_2}\right) \tag{2}$$

in which P_e is the optical elasticity coefficient. λ_1 is the Bragg wavelength of the grating experiencing both strain and temperature changes and λ_2 is the Bragg wavelength of the grating experiencing temperature changes only.

2.2 *Proposed sensing system design*

The proposed sensing system is designed to have multiple functions to fulfill the special requirements for pavement structural performance monitoring (Fig. 1). The sensor layout

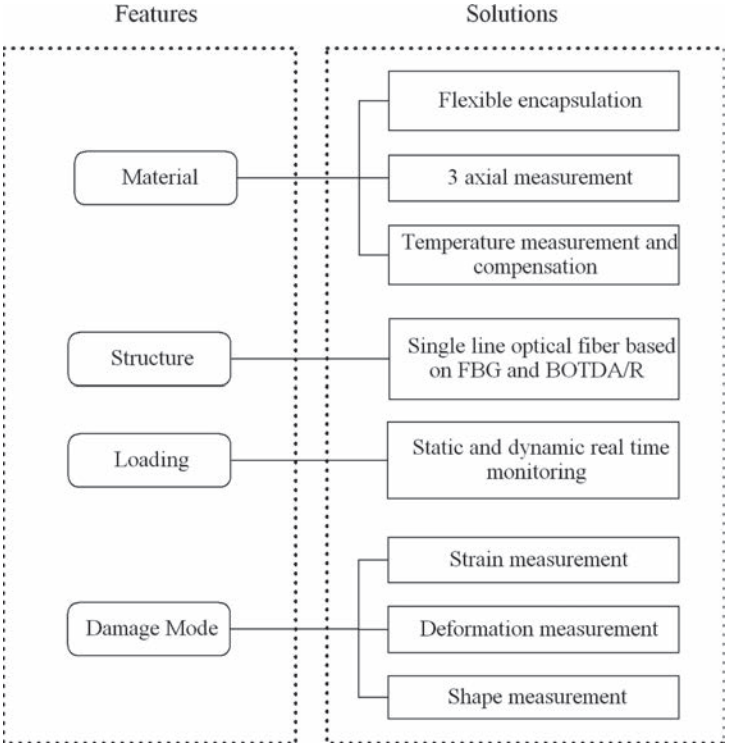

Figure 1. Major functions of the proposed sensing system.

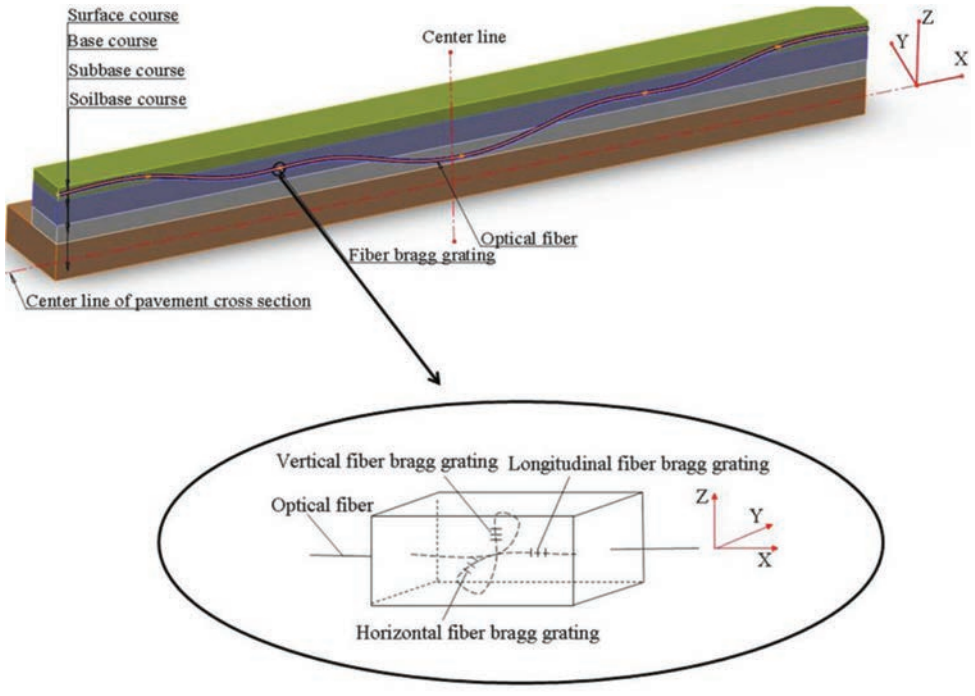

Figure 2. Proposed optical fiber based sensing system for multi-layered pavement structure.

diagram of the sensing system is shown as Figure 2. Firstly, the optical fiber sensors adopted by the system are packaged with flexible encapsulation. The bonding between the sensor core and pavement host materials is then enhanced and the strain transfer error will be reduced to some extent. Detailed encapsulating technique will be discussed in the latter section of this paper. Secondly, the FBG based sensors and BOTDA/R based sensors will both be used and sharing single line to ensure the local high accurate strain monitoring and long distance coverage. At particular interest point, the sensing line can be convoluted to provide three axial monitoring (Fig. 2). The entire sensing optical fiber line can be bent vertically at certain distance to cover all the layers of a pavement structure.

Thirdly, at each precise monitoring point, FBG temperature compensation sensor will be embedded simultaneously to measure the circumstance temperature and compensate temperature change introduced strain of the FBG based strain sensor. Since FBG sensors can provide low frequency dynamic measurement, both pavement structure static and dynamic real time performance data can be obtained under given loading condition. Besides, optical fiber shape measurement concept [20] can be adopted by this sensing system to measure bend and twist (curvature) of the sensor and therefore predict the deformation inside the pavement structure. Then the road subgrade settlement and its influence to pavement structure can be monitored. Pavement rutting information can also be obtained if the shape measurement happens at the surface layers of a pavement structure.

3 FLEXIBLE ENCAPSULATION DESIGN FOR OPTICAL FIBER SENSOR

Encapsulation of optical fiber is very important to protect the sensing element and ensure the strain transfer from host pavement material to the sensor core. Although cement concrete often has larger elastic modulus than asphalt concrete, the generated forces to the embedded sensor during the forming procedure are much less than that of asphalt concrete. The forming of cement concrete is a solidification process while the forming of asphalt concrete

pavement structure is a roller compaction process. During the compaction process, the movement of aggregates can generate large stress at the tips. Therefore the encapsulation must be strong enough to isolate the optical fiber sensor core from these destructive forces. However, the notable structural flexibility of the asphalt pavement (especially at high temperature) will make the rigid encapsulated sensor fail to obtain strain as the host pavement material deforming. Therefore, the encapsulation of the optical fiber sensor for asphalt pavement structure needs to be well designed to overcome these conflicts.

In this section, a flexible encapsulation technique for optical fiber will be introduced. Rough sensors based on the proposed encapsulation technique have been produced in lab.

3.1 *Design principle*

Armor for cables has been selected as the encapsulation material for the sensing element of the proposed sensor in this paper. It can bear strong compaction force, but bend freely. The structure of the sensor is shown in Figure 3. Two annuls made with epoxy resin are fixed at both sides of the FBG sensing element with design distance to increase the tension/compression strain transfer efficiency between the sensing element and the host material. The cable armors are also embedded into the annuluses but covered with a short rubber connection. Therefore, the modulus of the sensor in the axial direction will be increased within a limit.

To sustain the compaction induced large deformation and add damage information capturing capability, a precision spring has been attached beside the FBG sensing element. The transmission part of the optical fiber is also protected by the cable armor. The scale of the sensor can be adjusted by the distance between two annuluses. For BOTDA/R based sensor, the encapsulation of the optical fiber can use the same method, but much larger in length.

3.2 *Sensor calibration test*

All the sensors used in this paper were fabricated in lab. The axial elastic modulus of the proposed sensor was evaluated using a material testing machine and was found to be around 48 MPa. This value was much lower than the modulus of asphalt mixtures even at high temperature. Hence, the influence of the proposed sensor to the stress field of the host material can be ignored.

The precision of FBG sensors for strain measurement is high and can often be treated as absolute measurement. The influence of the precision spring to whole accuracy of the sensor has been tested in lab. Figure 4 show the tension test data of a FBG connected with a precision spring. The result show good linearity of the proposed sensor assembly. The total displacement of the sensor assembly has also been measured. The FBG received half the strain value of the total sensor, which fit well with the calculation based on the modulus of the precision spring and that of the optical fiber. The FBG can bear more than 10000 με before break.

3.3 *Sensor assembly field tests*

A mini test track has been constructed on a vacant lot to evaluate the performance of the proposed sensors. The length of the pavement structure is about 10 m and its width is around

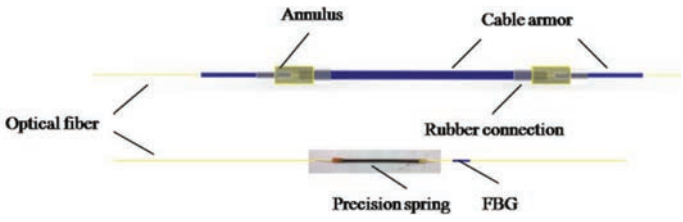

Figure 3. Proposed optical fiber assembly diagram.

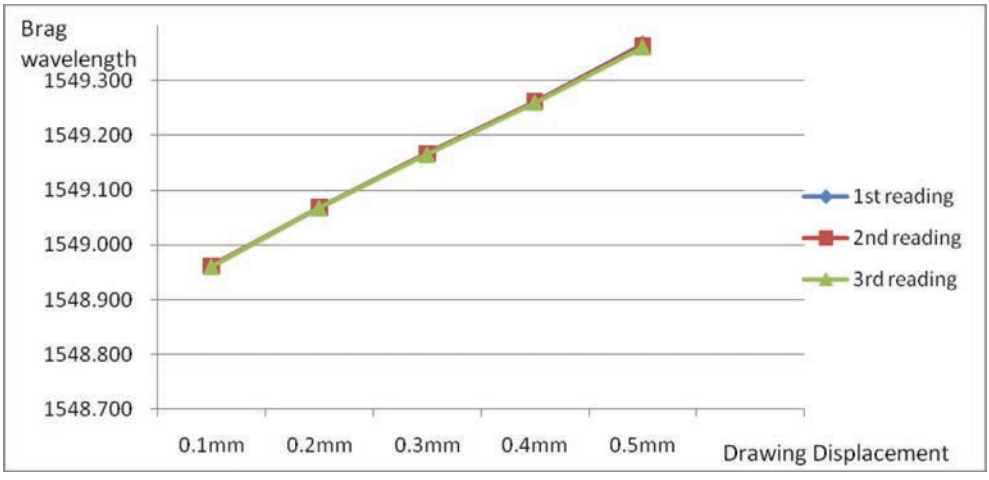

Figure 4. Tension test data of a FBG connected with a precision spring.

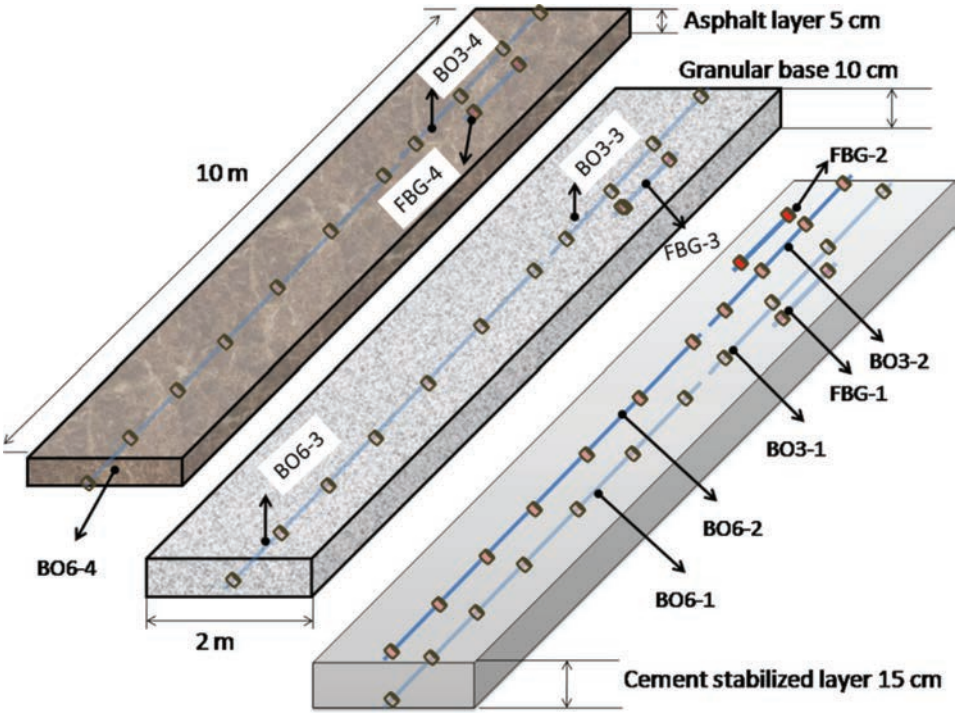

Figure 5. Sensor arrangement in pavement structure.

2 m. The pavement structure is simply composed of three layers. They are the asphalt layer, granular base and cement stabilized layer from top down and the ground is made up of hard rock. Their layer arrangement is shown in Figure 5. To make the structure stable, the width of each layer is increasing with depth.

Both FBG and BOTDA/R based sensors have been embedded into the pavement structure during construction directly. The gauge length of the FBG based sensor is 0.25 m and that of the BOTDA/R based sensor is 1 m. The optical fiber length of the FBG based sensor is shorter than the sensor used in lab calibration. Based on the length difference, it can be calcu-

lated that the actual strain of the whole FBG based sensor is around 1.2 times larger than the reading of the FBG. The sensor arrangement can be seen in Figure 5. Another FBG based temperature compensation sensor has also been embedded in the surface asphalt pavement layer. The sensing element in the temperature compensation sensor is in its free state and also protected by the armor for cables. Therefore the data of other strain sensors minus the strain data from the temperature compensation are the stain data caused only by external forces.

Since paver was not used in the pavement construction and there were no lateral restrictions to the structure during construction, the pavement construction materials have been flattened only by a road roller. The pavement construction material moved more than that during the real highway construction, and therefore the compaction forces to the sensors were also larger. Nonetheless, 75% of the sensors were in good condition.

3.4 *Data collection and analysis*

The strain data of all the intact sensors during eight whole days have been collected. Due to the large compaction displacement, most of the BOTDA/R based sensors were wrinkled. It made the data from BOTDA/R based sensors unreliable. The embedding technology for BOTDA/R based sensor should be improved in the future. Therefore this paper will only discuss the data from FBG based sensors.

The FBG based sensor FBG-1 in the cement stabilized layer was damaged. The data from other FBG based sensors are shown in Figures 6–9. It has been raining in Aug. 21 and Aug. 28, and it was cloudy in Aug. 26. From Figure 6 it can be seen that the temperature induced strain reading can be up to 250 με during a day. The temperature induced strain reading is not the actual strain, and therefore will not be influenced by the spring. For the deformation induced strain, the spring will make it smaller in reading. The data from FBG-2, FBG-3 and FBG-4 show that the temperature changing patterns are different in these three layers. The highest temperature appeared around 13:30–14:20 in the asphalt layer. The highest temperature in the granular base was after 15:00 and the temperature varying range was much lower than that of the asphalt layer and the cement stabilized layer. The highest temperature of the cement stabilized layer appeared after 16:00 and dropped gradually after 18:00.

Figure 6 shows that the temperature differences among Aug. 23, Aug. 27 and Aug. 29 are not obvious. However, the strain reading in Aug. 23 is obviously higher than that in Aug. 27 and Aug. 29 in the cement stabilized layer (Fig. 7). The lower strain reading in Aug. 29 was due to the rain in Aug. 28. There was no rainy day between Aug. 22 and Aug. 27. The strain difference between Aug. 23 and Aug. 27 is caused by the air shrinkage effect. Considering the function of the precision spring, the air shrinkage should be between 32–76 με. The cor-

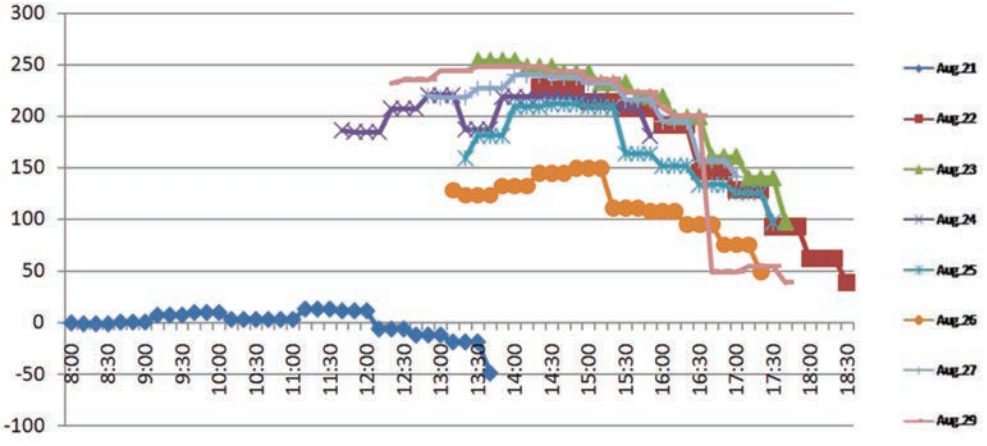

Figure 6. Strain reading from temperature compensation sensor.

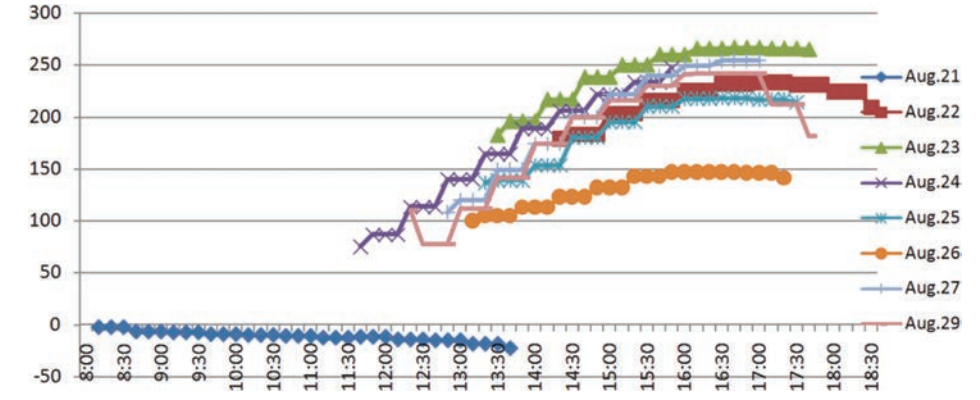

Figure 7. Strain reading from FBG-2.

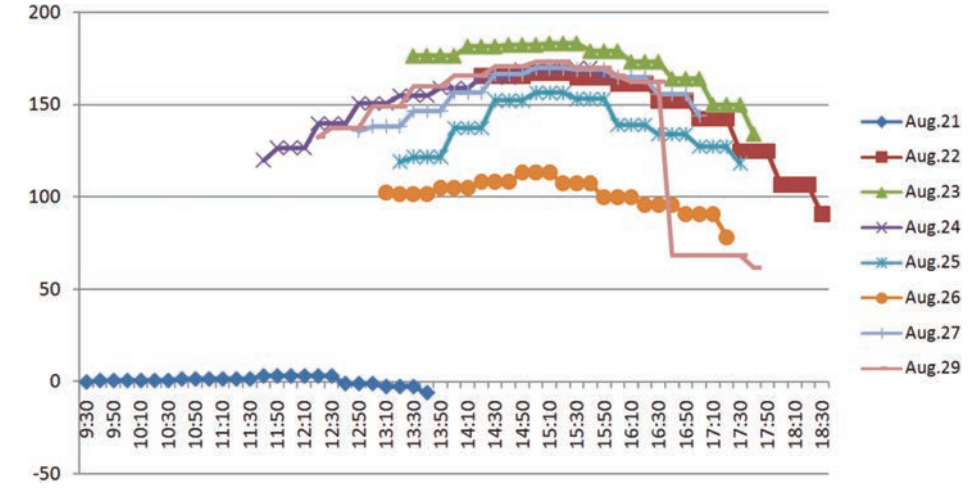

Figure 8. Strain reading from FBG-3.

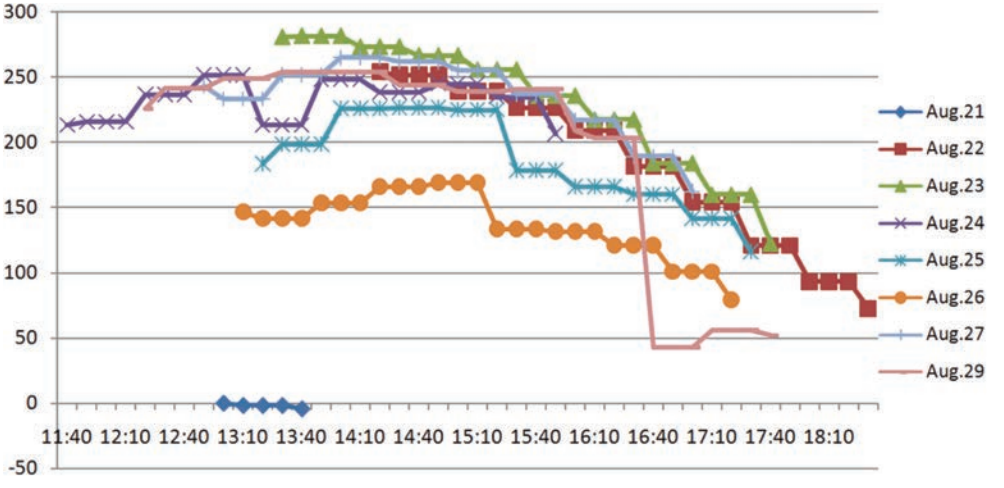

Figure 9. Strain reading from FBG 4.

responding lab test gave the shrinkage of about 68 με between the third day and the seventh day, which is close to the data from the FBG based sensors.

One of the shortages of this field test is that temperature compensation sensors have not been embedded into all the layers of the pavement structure. This makes the analysis of the material shrinkage strain of the lower layers difficult. Therefore only the data of the asphalt layer with temperature compensation will be discussed more in depth in this paper.

Figures 10–12 shows the strain readings from the FBG-4 and temperature compensation sensor minus the strain reading picked at 14:20 in Aug. 22 of each corresponding sensor.

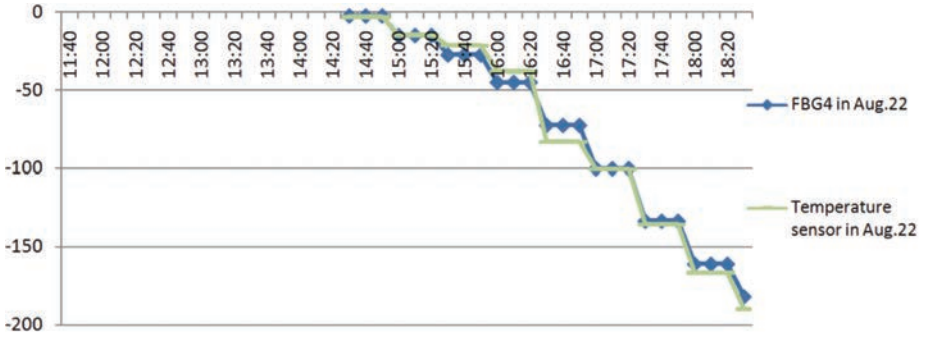

Figure 10. Comparison of data from sensors in asphalt layer.

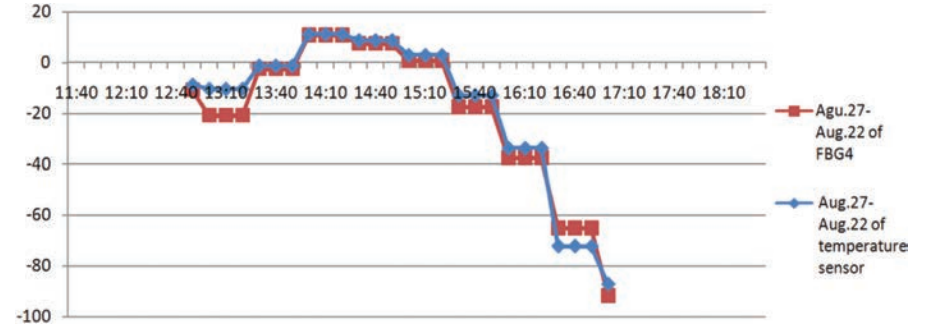

Figure 11. Comparison of data from sensors in asphalt layer of Aug. 27.

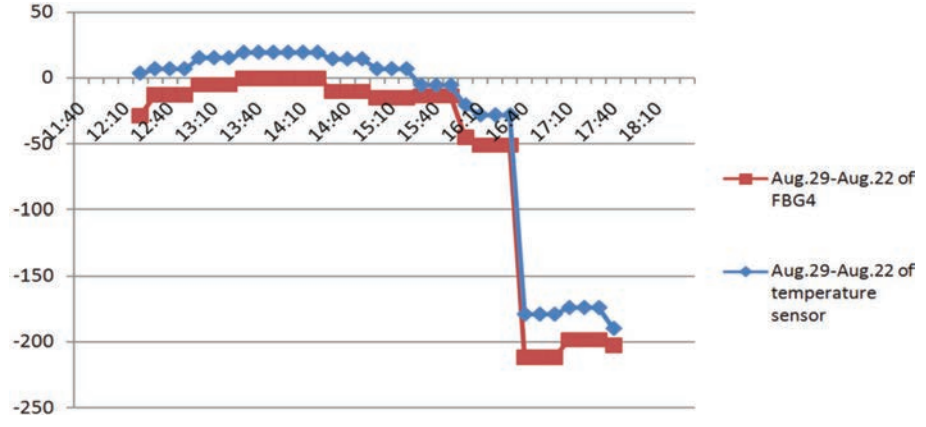

Figure 12. Comparison of data from sensors in asphalt layer of Aug. 29.

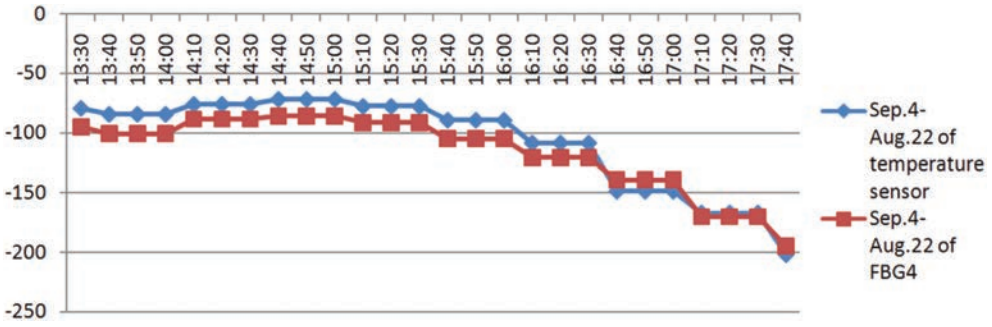

Figure 13. Comparison of data from sensors in asphalt layer of Sep. 4.

It can be notice that even after 5 days, the strain data of Aug. 27 of the two sensors are all most the same (Fig. 11). However, after a rainy day of Aug. 28, obvious strain difference can be noticed in Aug. 29 (Fig. 12). One of the conclusions can be deduced is that the asphalt layer has not shrinked during a short time in sunny days, but after a rainy day, the asphalt layer deformed for about 120 με. Another set of data have been collected in Sep. 4 and the comparison data in Figure 13 also show the same deformation strain. This permanent strain may be caused by the rain induced granular base material movement.

The field test has proved the high survival rate of the proposed encapsulation method. The collected data show the sensitivity of the FBG based sensors in strain monitoring. The sensors are efficient in pavement material shrinkage monitoring. The survival from the large compaction displacements and strain sensitiveness also prove the feasibility of the proposed sensors in pavement life cycle performance and damage monitoring.

4 CONCLUSIONS AND DISCUSSIONS

This paper introduces an optical fiber based pavement monitoring sensing system design. Special features of pavement structures are first summarized. Due to the complexity of pavement structural monitoring and few available references, the system should be well designed and should take into the consideration of these special features.

A new flexible encapsulation method for both FBG and BOTDA/R based sensors has been introduced. Lab and field tests have been carried out to study the feasibility of the proposed sensors. The sensors with flexible encapsulation show high "survival rate" after installation. The field test data also proves the potential of using optical fiber based sensors for pavement structure shrinkage monitoring and life cycle performance monitoring in a wide range.

Since the works present in this paper are only the preliminary results from the relative researches, many design concepts and operation procedures could be improved. The strain transfer error between the sensor core and pavement host materials will be studied in the future. However, the current results already show the feasibility and prospect of the proposed sensing system.

ABSTRACT: The project 'CO_2 emission reduction by exploitation of rolling resistance modeling of pavements' (COOEE) was started in 2011 to establish a scientific background for development of novel pavement types and asset management solutions that minimize the rolling resistance for cars and trucks, the purpose being to reduce CO_2 emission from the transport sector.

In summer 2012, three different test sections were constructed on a highway located near Vordingborg, Denmark, in order to verify the respective Rolling Resistances; the main purpose was to develop and design new surface layers with reduced Rolling Resistance coefficient that could improve energy efficiency of the roads. In particular, two new types of Split Mastic Asphalt (SMA) were developed and compared to a reference one; both mixtures have a relatively small maximum grain-size, 6 mm and 8 mm, respectively. Surface measurements such as Skid Resistance and Mean Depth Profile were appropriately verified in order to fulfill these essential texture values. Samples were taken and studied in the laboratory to analyze the volumetric characteristics. Rolling resistance measurements have shown that both new SMAs have a reduced Rolling Resistance compared to the traditional one.

1 INTRODUCTION

In recent years, the stabilization of greenhouse emission is one of most important instruments in order to avoid global climate change. Carbon dioxide (CO_2), generated from various sectors, is identified as one of key greenhouse gases to control. In 2004 in the United States, transportation as a whole accounted for approximately 33% of CO_2 emissions, of which 80% came from cars and trucks traveling on the roadway system [1]. In Denmark, these percentages were confirmed; in fact in 2006 the carbon dioxide emission was 52.5 million tons, of which the transport sector contributed with 16 million ton. In order to reduce these emissions, policy makers are primarily pushing for more efficient vehicles and the development of alternative fuels [2]. The European Union adopted in 2009 sets of mandatory emission reduction targets for new cars.

The Cooee project, aiming to design an overall more environmentally friendly road infrastructure, approaches the goal of reducing vehicle CO_2 emission by centering the attention to the road pavement characteristics. It focuses on establishing a scientific background for

development of novel pavements types and asset management solutions that minimize the rolling resistance for cars and trucks, thus improving the pavement energy efficiency.

Rolling resistance, together with wind drag and transmission losses, influences the need for motor power and resulting emissions. The influence of road surface properties, such as macrotexture and unevenness, on rolling resistance and fuel consumption is an important factor to consider when determining the coating of a road surface [3]. Surface texture and unevenness create vibrations in the tires and suspension. These vibrations reduce energy efficiency of motion because the shock absorbers and the tires are absorbing this energy, thus improving passenger comfort and reducing vehicle vibrations. Therefore, surface texture influences fuel consumption by inducing these vibrations. Microtexture affects the energy lost due to wear and small scale contact on the tires.

2 BACKGROUND

Over the years, many different studies have been conducted on the influence of road surface texture on the tire rolling resistance. Deraad [4] was—in 1978—among the first to show that road surface texture can significantly influence the rolling resistance losses. Data collected from laboratory tire dynamometer tests and outdoor tests, conducted on various types of paved public road, indicated that tire rolling resistance losses increase as road surface texture increases. Moreover, he focused on the point of the test surface adopted and how this can affect the results.

In 1980, the Wisconsin Department of Transportation conducted a local field study that sought to define the relation between automobile fuel consumption and pavement roughness. Five pavement sections, representing a wide range of roughness, were travelled by three different automobiles. For these pavements, roughness was expressed in terms of serviceability index, as measured by Wisconsin's electronic road meter. The collected data showed a very modest increase in fuel consumption as pavement roughness increased [5].

X.P. Lu [6], following a theoretical approach, introduces a linear model for evaluating the influence of pavement surface roughness on rolling resistance. Du Plessis et al. [7] show that rolling resistance losses, related with the road surface characteristics, are dependent from the mass of the vehicle. Surface texture was found not to be significant in determining rolling resistance for trucks with high pressures and hard rubber types associated with commercial vehicle tires. Sandberg [8], in order to improve the study of the tire-road interaction, introduced a more complete characterization of the pavement surfaces. In particular he defined macrotexture, microtexture, megatexture and unevenness characteristics, successively adopted by ISO 13473-1, and measured the respective induced fuel consumptions.

Delanne [9] compared the influence of different surface dressing on light vehicle fuel consumption on paved roads. The collected data have shown that unevenness and macrotexture can influence fuel consumption respectively up to 6% and 5%.

In 2004, Beuving [10] compared the impact of pavement surface characteristics on fuel consumption. The obtained results confirmed that different textures of road surfaces influence fuel consumption for passenger cars by up to 10%. No differences in fuel consumption were recorded between asphalt and concrete road surfaces for passenger cars. However, an important influence of the pavement surface roughness on the fuel consumption has been proven. Rolling resistance of a tire on concrete or asphalt pavements with the same profile or texture should be practically identical [11].

In 2009, the MIRIAM project was started with the intention to provide the road asset management systems of an integrated methodology for improved control of road transport CO_2 emissions related to road pavement conditions [12]. At the moment, a wide scatter of results are found and there is still much confusion and uncertainty about how large the influence actually is [3]. Moreover, the precision of the measurement systems are often in the same order of magnitude as the measured values, hence data may be highly affected by measurement noise. In any case, further research is needed to optimize pavement texture for rolling resistance without sacrificing friction and safety.

3 OBJECTIVE

The Danish Cooee project is based on the idea of providing a sustainable and environmentally friendly road infrastructure maintenance and design. The purpose is to develop new material types, creating a basic insight in wear and aging of asphalt pavement and fundamental research on the interface between the vehicle tire and the pavement surface.

The main objective of the present paper is to evaluate how different types of surface layer of a road pavement can condition the energy efficiency of the pavement itself. In particular, the Rolling Resistance of a pavement structure with different Split Mastic Asphalts (SMA) was studied. Rolling resistance is a fundamental property of the asphalt mix, traditionally neglected during mix and pavement design, which could represent the key a sensible reduction of the traffic CO_2 emission.

4 EXPERIMENTAL PROGRAM DESCRIPTION

The experimental program can be divided in four different phases.

- Laboratory mix design;
- Field sections construction (Fig. 1);
- Description of the volumetric and surface properties of field mixes;
- Analysis of the rolling resistance.

The asphalt mixtures were designed by NCC Roads A/S. Volumetric characterization was completed in order to optimize the laying and compaction of three different wearing courses. In particular, two new SMAs, with maximum grain-size respectively of 8 and 6 mm (SMA 8, SMA 6), were compared to a traditional SMA 0–8 mm (Reference).

The pavement section, selected for the rolling resistance analysis, was the Main Road 619 near Vordingborg, Denmark. The entire pavement section is 1.5 km which were paved with 500 m of each asphalt mixture type. A constant thickness was compacted over the same pavement structure with all the studied SMAs as part of a traditional maintenance replacement of the wearing course. Cores from each section were analyzed in order to verify the volumetric characteristics such as layer thickness and voids content. The binder content measurements were collected from the production plant and verified on samples taken from the paver machine. The surface texture of the three different pavement sections was characterized measuring the Mean Profile Depth (MPD) and the Skid Resistance. After material and field characterization, the study of the Rolling Resistance of the mixtures was carried out using the TUG trailer with three different reference tires.

Figure 1. Field section activities (a), SMA 8 (b), SMA 6 (c).

5 MATERIALS AND TEST DEVICE DESCRIPTION

5.1 *Mix design*

The new SMAs were studied in order to obtain dense and durable surface structure. To achieve these characteristics and reducing relative movement between the stone aggregates of the mixes, the mastic component of SMA 8 and 6 were appropriately optimized. Different aggregates and filler types were examined together with the desired Polymer Modified Binder. The aggregate types were: Hyperit and Jelsa from Norway and Ronne from Denmark. Abrasion and Adhesion Resistance of the aggregates were verified with standard procedures (EN 1097-2, EN 12697-11). The fillers, once combined as represented in Table 1, were mixed with the three different aggregates and the adopted asphalt binder and tested by using Tumbler Abrasion test (EN 12274-7).

The results showed that F3 has a rather bad strength compared to those obtained with the two different limestone fillers (F1, F2), independently of the adopted aggregates source. F1 and F2 fillers gave comparable results. Based on the location of the desired real test section, F1 filler was chosen and blended with Danish aggregates, Ronne.

The binder content was chosen to achieve approximately 4% of average voids. Based on the adopted mix designs, target voids and trial productions on the asphalt plant, the bitumen content for both SMA 8 and 6 was 7.5%. The binder content of the reference mixture was 6.9%.

5.2 *Volumetric and surface characteristics of the mixtures in the field*

Before studying the Rolling Resistance of the three designed mixtures, they were characterized verifying their volumetric and surface properties in the field. Surface properties in particular are directly related with the texture of the mixture and consequently with the rolling resistance itself [13].

With regard to the volumetric properties, a total of 6 specimens for each mixture were cored from the pavement section. For each specimen, the layer thickness and the voids content were verified according to EN 12697-8, see Table 2.

The field surface characteristics were measured as MPD and Skid Resistance respectively following the ISO 13473-1 and the CEN/TS 15901-5, see Table 2.

Table 1. Asphalt mixtures properties.

Fillers type	Portland cement [%][1]	Limestone filler A [%][1]	Limestone filler F [%][1]	Aggregates filler [%][1]
F1	20	45	0	35
F2	20	0	45	35
F3	0	0	0	100

[1]By mass of total filler.

Table 2. Asphalt mixtures properties.

	Volumetric characteristics				Wearing characteristics			
	Layer thickness		Voids content		MPD		Skid resistance	
Materials	Average [cm]	St. Deviation [cm]	Average [%]	St. Deviation [%]	Average [mm]	St. Deviation [mm]	Average [–]	St. Deviation [–]
Reference	2.9	0.2	5,1	1,4	0.77	0.06	0.65	0.05
SMA 8	2.4	0.4	4.4	2.2	0.75	0.07	0.64	0.06
SMA 6	2.0	0.3	8.2	0.7	0.72	0.06	0.70	0.05

No significant variations in surface characteristics were measured. In terms of percentage of voids, the SMA 6 reaches a lower degree of compaction compared to the Reference and SMA 8.

5.3 *Rolling resistance device description*

The Trailer (TR) method was adopted to describe the Rolling Resistance. It was chosen to use the TUG trailer (Fig. 2), developed by the Technical University of Gdansk (TUG) due its repeatability of results and correlation with MPD. At the moment no standard or common practice has been published for measurement of rolling resistance properties of pavements [13].

Figure 3 represents the measurment principle. The horizonal arm (1) connect the front and rear suspension. The load (6) is provided by arm (2) that has a common rotation axis with arm (1). The arm (4) connects the rear end of the arm (1) to the test wheel hub. Foucault currents electromagnetic brake suppresses the undesirable vibrations of the vertical arm (4) that may be induced during tests. Inflation pressure in the test wheel is maintained by remote controlled release valve and pressure sensor. During tests, the vertical arm (4) is pulled from the test wheel where the rolling resistance force acts. A laser sensor, installed on arm (1) and sending the laser beam towards arm (4), measures the deflection rate. Rolling Resistance Coefficient (RR), expressed by Eq. (1), is defined as a ratio of rolling resistance force P_f and vertical load F_z measured by the respective load cells.

$$\mathrm{RR} = \frac{P_f}{F_z} \tag{1}$$

Figure 2. The tire/road Rolling Resistance measurement TUG trailer.

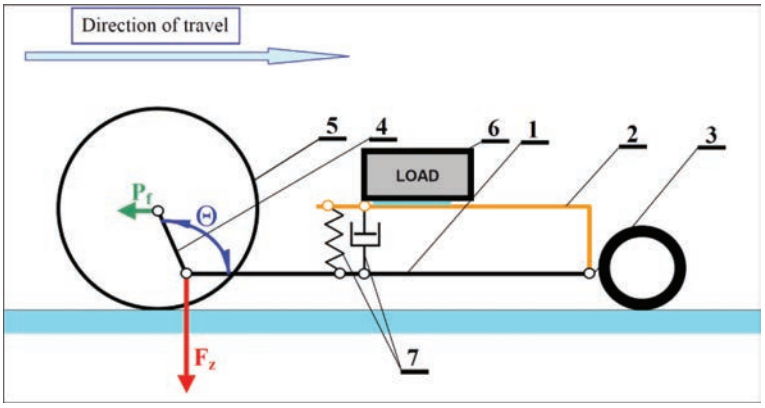

Figure 3. The TUG trailer measurement principle.

Figure 4. Types of tire used for Rolling Resistance measurement.

Table 3. Tires characteristics.

Tire	SRTT	AAV4	MCEN
Size	225/60R16	195R14C	225/60R16
Construction	Tread: 1 polyester + 2 steel Sidewalls: 1 polyester	Tread: 1 nylon + 2 steel + 2 polyester Sidewalls: 2 polyester	Tread: 1 polyester + 2 steel + 1 polyamid Sidewall: 1 polyester
Max load [kG]	730	950/900	750
Max inflation [kPa]	240	450	350
Hardness [Sh]	65	62	63

The position of arm (1) in relation to the road surface is monitored by two laser sensors.

The trailer is equipped with a device that eliminates influence of factors such as road inclination and longitudinal acceleration.

Three tires were adopted and compared for the measurement of the RR values (Fig. 4 and Table 3). The SRTT ("Standard Reference Test Tire") is specified in ASTM F2393 as a reference tire for various purposes. The AAV4, light truck tire, is a tire tested and found to classify pavements (for noise) in roughly the same way as a selection of regular heavy truck tires do. The smallest dimension for this series of tires, SRTT, fits on large passenger cars. The MCEN tire was used by TUG from the time when they started to make RR measurements, and has been kept for the purpose of providing a link to old measurements [12].

Before testing, the test tires were warmed-up long enough to stabilize the inflation pressure.

6 RESULTS ANALYSIS

For each pavement section and type of tire, three passes were completed. Air and pavement surface temperatures were respectively of 12°C and 16°C. Table 4 summarizes the average adopted speed for each test section and tire type. The differences between those, being relatively small, do not affect the Rolling Resistance measurement [13].

Figures 5–7 summarize all results.

The Standard Deviation between the three RR measurements obtained at the same longitudinal coordinate of the same test section was calculated for all the studied cases. The averages of these, expressed in percentage (referred to the mean of the corresponding of RR coefficients), are summarized in Table 5. No significant variations were detected within the three passes on the same longitudinal coordinate. The percentage of the standard deviation between the three passes of the TUG trailer with same tire type does not exceed 1.7%. These confirm the reliability of the data collected from all the test sections.

Table 4. Average speed during Rolling Resistance measurement.

	Av. Speed [km/h]		
Materials	SSRT	AAV4	MCEN
Reference	78.50	78.76	79.48
SMA 8	78.93	79.52	79.92
SMA 6	77.75	78.38	78.73

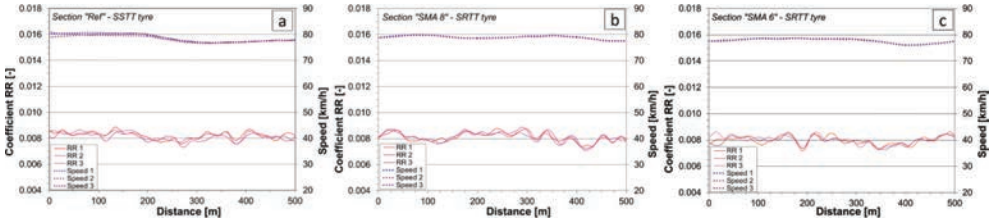

Figure 5. Coefficient of Rolling Resistance vs distance with SRTT tire.

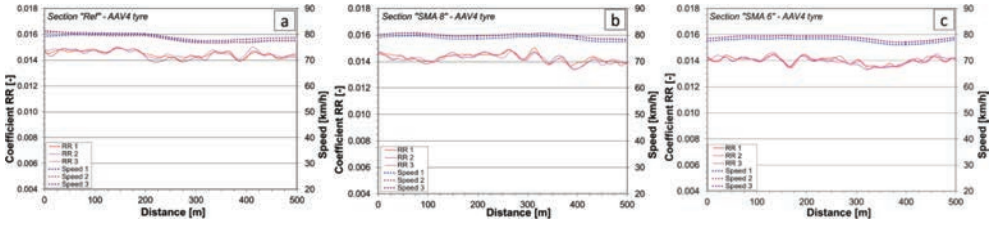

Figure 6. Coefficient of Rolling Resistance vs distance with AAV4 tire.

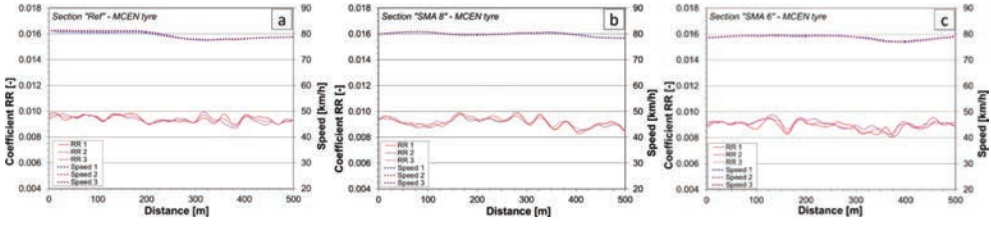

Figure 7. Coefficient of Rolling Resistance vs distance with MCEN tire.

With regard to the average Rolling Resistance Coefficients (Ave. RR) measured with the three different types of tire on each entire section, the collected results confirm the presence of dependence from the aggregates gradation (Table 6 and Fig. 5). The highest average RR Coefficient was measured with the Reference mixture while the lowest with SMA 6.

The differences between the average Coefficient RR are shown in Table 7. The Standard Deviations of the RR coefficients of two different wearing courses (Table 6) are generally higher than the respective difference between the average RR coefficients (Table 7). The two exceptions are the differences between the Reference and SMA 6 mixture with AAV4 and MCEN tires.

Even if differences between the RR measurements of the three test sections are not statistically significant in all the studied cases; it is possible to show a trend between the three

studied mixes, confirmed with all the adopted tires. The SMAs developed for this research exhibit reduced Rolling resistance compared to the Reference mix. In particular, SMA 6 appears to satisfy the goal of the research project. All the adopted tires were capable to detect the differences between the pavement sections even if the MCEN tire seems more susceptible, compared to the other, to register it (Table 5).

7 CONCLUSIONS

Road maintenance is a fundamental aspect to consider in pavement management, not only for the safety and comfort of the driver and for preserving the pavement structure, but even in perspective of optimizing the energy efficiency of the pavement itself during its service life. CO_2 emissions, related to the Rolling Resistance, are dependent on vehicle's weight and tire, but also on pavement surface properties and conditions. The Cooee project is based on the idea of optimizing pavement surface characteristics and developing new material types. Creating a basic insight in wear and aging properties of asphalt pavement and fundamental research on the interaction between vehicle tire and pavement surface, it is the hypothesis that it is possible to reduce the Rolling Resistance of the pavement itself, thus improving its energy efficiency.

The present paper highlights the importance to characterize the Rolling Resistance of the asphalt mixtures. In particular, this property was analysed for three different SMAs; two of these were appropriately developed with maximum gradation size respectively of 8 mm (SMA 8) and 6 mm (SMA 6). The reference mixture was a 0–8 mm SMA (Reference). Three different test sections were studied and the TUG trailer was used for the RR measurements.

The preliminary conclusions drawn from this investigation are:

- The mix design of a Split Mastic Asphalt can be optimized to reduce Rolling Resistance of the mixture itself. This is not only related to the maximum dimension of the adopted aggregates, but is even dependent of the mastic properties. A reduction in the maximum dimension of the aggregates amplifies the positive contribution in terms Rolling Resistance;
- Volumetric characteristics of the wearing course, like layer thickness and voids content, do not seem to influence the Rolling Resistance response of the pavement. However, a deeper analysis focused on these aspects is suggested;
- Rolling resistance coefficient may be correlated with texture characteristics of the surface layer such as MPD ad Skid Resistance;
- The Rolling Resistance measurement depends on the type of adopted tire; MCEN seems more sensitive to measure the differences between the studied mixtures.

Rolling resistance should be considered during mix design of surface layers, combined with traditional procedures, in order to achieve mechanical resistance, safety standards and high-energy efficiency.

Design alternative comparison system for pavements

Dragos Andrei
Civil Engineering Department, California State Polytechnic University, Pomona, CA, USA

ABSTRACT: While there are several sustainability rating systems available for pavements, their immediate use in the design phase of a project is somewhat difficult. These rating systems are fairly complex and some of them require the services of a third party, for a fee, or the expertise of certified individuals to evaluate and certify projects. Designers looking for sustainable pavement rehabilitation solutions on smaller projects and with limited budgets may not have the time and resources to use these existing rating systems. This paper describes the development of a simple, fast and convenient system that can be used to compare different design and rehabilitation alternatives based on their sustainability features. Four components are included in the analysis: materials, construction methods, surface properties and cost effectiveness. Colors are used to emphasize the sustainable aspects of a given alternative.

Keywords: sustainability; rating system; pavement design; pavement rehabilitation

1 INTRODUCTION

In recent years, the civil engineering community has become more receptive to sustainability and sustainable design. Many rating systems have been developed to encourage and reward the use of sustainable practices in civil engineering design [1]. Some of the most known "green" rating systems are the ones used by the Leadership in Energy and Environmental Design or LEED program [2]. In the LEED rating systems, sustainable practices are rewarded with credits and more credits will earn a higher LEED certification. Different rating systems have been developed to evaluate: buildings, retail developments, schools, home and neighborhoods.

Specific to pavements, LEED includes a range of applicable credits falling in the following major categories:

- Storm water management—and the recommended use of porous pavements
- Heat island effect reduction—and the recommended use of pavement surfaces with high Surface Reflective Index (SRI)
- Recycled content in infrastructure—and the recommended use of recyclable materials
- Construction waste management—and the recommendation to divert recyclable materials from disposal

Many other credits are included in LEED, for example for providing bike lanes, carpool lanes, building "walkable" streets, etc. However, pavement engineers are mostly concerned with the technologies and materials used to construct, maintain or rehabilitate a pavement structure and many times have little say in the geometric aspects of the design or rehabilitation.

Another very successful rating system used in the United States is Greenroads [3]. This rating system was developed specifically for roadways and transportation infrastructure. Projects have to meet eleven requirements to be eligible for certification:

- Environmental review process
- Lifecycle cost analysis

- Lifecycle inventory
- Quality control plan
- Noise mitigation plan
- Waste management plan
- Pollution prevention plan
- Low impact development
- Pavement management system
- Site maintenance plan
- Educational outreach

In addition, projects receive points for using sustainable practices. More points will result in a higher level of certification.

Both rating systems described above require registration and documentation of a project before it can be certified. Also, the systems are fairly complex because they take into account not only the environmental implications of a project but also the social and economic aspects of the proposed design.

In the United States, pavement engineers are most often confronted with the rehabilitation of existing pavements rather than new construction. In California for example, 81% of roads are managed by cities and counties. According to a recent study, the overall condition of these roads is "at risk" and continues to deteriorate [4]. In other words, these pavements are in need of maintenance and rehabilitation. The same study found that the funding available for maintenance and rehabilitation is only about a third of what is needed to prevent further deterioration. As a result, rehabilitation projects are often limited to restoring the structural and functional properties of the pavement and do not include any improvements such as widening or landscaping that could add more sustainable features to a project.

On such projects it may be impractical to use some of the existing rating systems which seem to be more appropriate for projects with larger budgets and greater publicity. "Green Up" is a comparison system that can be used to compare possible rehabilitation alternatives in terms of sustainability. Although the proposed system cannot be used to certify or rate projects, its purpose is to offer the designer a quick look at the sustainable aspects of different design alternatives and the choice to learn more about sustainable pavement rehabilitation options.

2 "GREEN UP" COMPARISON SYSTEM

2.1 *Methodology*

In developing the methodology, the intent was to provide pavement engineers with a tool that is easy to use and quick to provide results. To keep things simple, "Green Up" includes only design variables specific to structural pavement design:

- The choice of materials and thickness
- The choice of maintenance and rehabilitation strategies
- Surface properties such as permeability, surface reflectivity, and noise;
- Cost effectiveness

The number of inputs was minimized to ensure that users can enter the information for one design alternative in a matter of minutes. Once the information is entered, a software application is used to produce a graphic made of colored areas to convey a quick summary of the sustainability features of a project, as illustrated in Figure 1.

The image produced by the software resembles the three sides of a cube. The left side of the cube is reserved for materials. The colored areas indicate different categories of materials and their thickness. The right side of the cube is reserved for technologies. Colors are used differentiate between different technologies based on their carbon footprint and energy consumption. The areas reflect the volume of work specific to each category

Figure 1. Color coded image generated with the green up system.

of technologies. Finally, the surface or top face of the cube is divided into four diamonds which indicate:

- Surface permeability (the water drop symbol)
- Surface reflectivity (the sun symbol)
- Tire-pavement noise (the speaker symbol)
- Life cycle cost (the heart symbol)

The four diamonds will change colors depending on how these four aspects of sustainability are being addressed.

Note that there is no overall rating or numerical index associated to one design alternative. The purpose of the proposed system is not to rank alternatives but to allow engineers to identify and compare key sustainability features of different pavement rehabilitation alternatives.

Comparing different design alternatives is easily achieved by producing similar graphical representations for two or more alternatives and then comparing them visually. More green indicates more sustainable design, materials and construction. More red is an indication of the opposite. Colors like Green-Yellow, Yellow and Orange are used to represent materials and technologies in between the two extremes:

- Green = Sustainable
- Red = Not Sustainable

2.2 *Material categories*

"Green Up" divides materials into 5 major categories which are described in Table 1.

The ranking and categories described in Table 1 are based on engineering judgment. At the top of the sustainability scale are pavement materials recycled in place. Recycling makes perfect sense from a sustainability point of view. When recycling can be performed in place, the need to transport materials to and from the job site is minimized or eliminated. In addition, the owner agency will spend less on new materials by making use of the materials they already paid for in the past, when the pavement was originally built.

Table 1. Material categories.

Category	Color code	Description	Examples
Recycled in-place	Green Color	This category ranks highest on the sustainability scale. It includes materials recycled or reused in place, i.e. transportation to/from the job site is not required.	Asphalt concrete recycled in place, soil stabilization, Rubblized Concrete Pavement (RCP)
Recycled import (alternative materials)	Light Green Color	This category ranks second on the sustainability scale. It includes materials stockpiled offsite that will be incorporated into the pavement. It also includes materials that are byproducts of other industrial processes.	Reclaimed Asphalt Pavement (RAP), Recycled Asphalt Shingles (RAS), crumb tire rubber, Recycled Concrete Aggregate (RCA), blast furnace slag, fly ash, etc.
Recyclable export	Yellow Color	This category ranks third on the sustainability scale. It includes materials that will be removed from the road but can be stockpiled for future use in pavement projects or other civil engineering applications.	RAP, RCA, RCP, reinforcing steel
Virgin import	Orange Color	This category ranks fourth on the sustainability scale. It includes virgin materials.	Asphalt cement, asphalt emulsion, portland cement, lime, virgin aggregate, interlayers, and other materials or additives that are not recycled/reused products
Non-recyclable export (waste)	Red Color	The fifth and last category is reserved for materials that will be transported to a landfill with very little chances of reusing/ recycling.	RAP contaminated with fines or other deleterious materials, damaged concrete pavement, etc.

Transporting construction materials requires the use of fossil fuels and results in the production of green house gases. Heavy truck traffic also contributes to the accumulation of damage on the pavements that carry these trucks from aggregate quarries to asphalt and concrete plants, to job sites, to storage areas or landfills. The larger the amount of materials imported or exported from a project, the larger the amount of fossil fuel used, greenhouse gas emissions produced and damage caused to existing pavements.

To produce the left side of the Green Up cube, the volume of material(s) falling into each of the five categories is first determined. Then, parallelograms that correspond in thickness to the volume of material(s) in a certain category are drawn. The obtained image is a rough representation of the thickness of material in each category.

2.3 *Technology categories*

A similar approach is used to generate the right face of the Green Up cube. This time, technologies are ranked in terms of energy consumption and Greenhouse Gas (GHG) emissions. Starting from the findings of a 2003 Colas report [5], the Green Up systems uses four categories to differentiate between technologies in terms of energy consumption and greenhouse gas emissions. These categories are described in Table 2.

Table 2. Technology categories.

Category	Color code	Description	Examples
Cold	Green Color	Manufacturing and construction processes that make use of very little heat/energy and therefore generate very little emissions compared to other processes.	CIR, CCPR, FDR
Warm	Yellow Color	Manufacturing and construction processes derived from hot processes but where the mixing and compaction temperatures can be lowered with the addition of warm mix additive.	WMA
Hot	Orange Color	Manufacturing and construction processes that require considerable heating of materials	HMA, HIR
Big foot	Red Color	The manufacturing of portland cement and steel has a significantly higher carbon footprint than other binders used in construction. For this reason, concrete pavement falls in this fourth category.	Plain PCC, reinforced PCC

2.4 *Surface properties*

Besides materials and technologies, there are several key aspects specific to the surface of the pavement that can be related to sustainability.

2.4.1 *Porosity*

Porosity or the ability of the pavement surface to allow rain water to drain through the pavement surface and infiltrate into soil. Three categories are proposed:

- Porous (Green Color)
- Impervious (Red Color)
- Not Applicable (Gray Color)

Several types of pavement surfaces can be porous: pervious concrete, porous asphalt concrete and some types of interlocking concrete pavers.

2.4.2 *Surface reflectivity*

Surface reflectivity will influence the rate of cooling of the pavement after being exposed to sunlight during the day. In urban areas, pavements that take longer to cool down contribute to the so called "heat island" effect which contributes to increased energy costs and greenhouse gas emissions. To take into account surface reflectivity, pavement surfaces are divided into the following broad categories:

- Cool (Green Color): for pavements with high surface reflectivity
- Hot (Red Color): for pavements with low surface reflectivity
- Not Applicable (Gray Color): for pavements in rural areas or other scenarios where the heat island effect is not of interest.

2.4.3 *Noise*

Noise generated at the tire-pavement interface is a known source of noise pollution, especially in urban areas. The use of certain surface materials can minimize noise and thus improve the overall sustainability of the design. The following categories are defined as far as noise:

- Quiet (Green Color): where surface materials or treatments are planned to reduce noise
- Noisy (Red Color): where the materials/technologies used do not reduce noise
- Not Applicable (Gray Color): for pavements where tire-pavement noise is not a nuisance.

Noise can be reduced by using an open-graded friction course, rubberized asphalt concrete or by diamond grinding portland cement concrete.

Table 3. Cost efficiency categories.

Life	Temporary	Normal	Long-Life	Perpetual
High Cost	Very Poor	Poor	Fair	Saver
Moderate Cost	Poor	Fair	Saver	Super Saver
Low Cost	Fair	Saver	Super Saver	Excellent

2.5 *Life and cost analysis*

The last element included in the Green Up comparison system is the cost of the strategy over the life of the pavement. Life and cost considerations are included to encourage designers to think long term and to plan and include in the cost of the proposed solution both the initial construction cost and the cost of future maintenance and rehabilitation activities.

Based on the expected service life of a pavement the following categories are identified:

- Perpetual: where the design recommendations together with future maintenance and rehabilitation recommendations ensure that the pavement could be maintained in service indefinitely. For practical purposes, perpetual pavements should last more than three generations or 75 years.
- Long Life: these are pavements that are designed to last more than two generations or 50 years.
- Normal: traditionally, flexible pavements are designed for 20 years life; rigid pavements for 40 years. These pavements will fall under the Normal category.
- Temporary: these are design alternatives that will extend the life of the pavement for less than 20 years.

To compare design alternatives in terms of cost, the total cost that will likely be incurred over the life of the pavement is divided by the number of years the pavement will be in service. The total cost includes the following basic elements:

- The cost of initial construction and the resulting life extension in years
- The estimated cost of preventive maintenance and the frequency
- The estimated cost of reactive maintenance and the frequency
- The estimated cost of subsequent rehabilitation and the resulting life extension

Based on the calculated yearly life cycle cost, a proposed rehabilitation scenario may fall into one of the following cost categories:

- High Cost
- Moderate Cost
- Low Cost

Based on the categories defined for pavement life and cost, Table 3 is used to determine the Cost Efficiency category of a given design alternative.

The lower-central diamond on the surface of the Green Up cube will take the color shown in Table 3 to indicate the sustainability of the solution based on life and cost considerations.

2.6 *Green up software*

It would be impractical and time consuming to generate the color-coded images specific to each design alternative manually. A software application has been developed for Windows PC's and it will be made available for download online.

3 "GREEN UP" EXAMPLE

In California's urban areas, many cities use the "mill and fill" approach to rehabilitate their pavements. Typically, 50 to 75 mm (2 to 3 inches) of the existing asphalt concrete is removed

and replaced with new hot mix asphalt overlay. Milling is required because the final elevations of the pavement surface have to align with the existing concrete curb and gutter structures. This solution is also traditionally included in pavement management programs and the multi-year plans produced by pavement management software. However, it should be noted that the mill and fill method only removes distress at the surface of the pavement thus leaving the pavement susceptible to reflective cracking after only a few years of service.

A different approach is to recycle the existing asphalt Concrete in Place (CIR) and cap it with a thinner hot mix overlay. In order to maintain the same surface elevations, milling will also be required to make room for the hot mix overlay. The CIR layer will provide support for the HMA overlay and possibly delay or prevent the propagation of cracks from the original asphalt concrete to the surface. This strategy will likely result in a longer life extension. Also, this alternative makes better use of the materials already available at the site. How do the two alternatives compare in terms of sustainability? The Green Up system and software was used to compare the following two possible design alternatives:

1. Mill and Fill scenario:
   a. Mill 75 mm (3 inches)
   b. HMA Overlay 75 mm (3 inches)
2. Mill, CIR and Fill scenario:
   a. Mill 38 mm (1.5 inches)
   b. CIR 75 mm (3 inches)
   c. HMA Overlay 38 mm (1.5 inches)

Table 4. Green up inputs.

Input	Scenario 1: Mill and Fill	Scenario 2: Mill, CIR, Fill
Milling thickness	75 mm (3 inches)	38 mm (1.5 inches)
How much of the removed material will be reused on the project	0%	0%
How much of the removed material will be recyclable export (such as RAP)	90%	90%
How much of the removed material will be taken to a land fill (waste)	10%	10%
CIR thickness	–	75 mm (3 inches)
Percent recycling agent	–	3.5%
Percent recycling additive	–	0.5%
Percent water	–	3%
HMA thickness	75 mm (3 inches)	38 mm (1.5 inches)
Asphalt content	5%	5%
RAP	25%	25%
Crumb rubber	0%	0%
Surface drainage	Impervious	Impervious
Surface reflectivity	Low	Low
Noise	Noisy	Noisy
Initial rehabilitation		
Cost per unit area	$20/m^2 ($20/SY)	$20/m^2 ($20/SY)
Life extension	10 years	15 years
Preventive maintenance		
Cost per unit area	$2/m^2 ($2/SY)	$2/m^2 ($2/SY)
Frequency	Every 4 years	Every 4 years
Reactive maintenance		
Cost per unit area	$3/m^2 ($3/SY)	$3/m^2 ($3/SY)
Frequency	Every 6 years	Every 6 years
Subsequent rehabilitation		
Cost per unit area	$20/m^2 ($20/SY)	$20/m^2 ($20/SY)
Life extension	10 years	15 years
Cost level	Moderate	Moderate

The inputs required to use the software for this specific analysis are summarized in Table 4. The values used are typical for Southern California urban areas. The calculated values used to draw the Green Up cube images are summarized in Table 5. Figure 2 shows the two images side by side.

As shown in Figure 2, the two scenarios are similar in terms of surface properties: impervious, low reflectivity and noisy. Hence the red color for the top three diamonds. In terms of life and cost, both scenarios fall in the "Fair" category which corresponds to Moderate cost and 20 to 50 years design life (see Table 3).

The left side of the Green Up cube however tells a different story. The Mill and Fill scenario shows an almost 50/50 distribution of virgin material and recyclable export material. Also visible are lower proportions of recyclable import and waste. In comparison, the Mill, CIR and Fill scenario shows that almost half of the materials are recycled in place. The remaining materials consist of virgin material and recyclable export plus very little recyclable import and waste.

The right side of the cube shows that half of the materials in the Mill and Fill scenario are processed with a Cold technology while the other half uses a Hot technology. In comparison,

Table 5. Green up calculated paramteres.

Output	Scenario 1: Mill and Fill	Scenario 2: Mill, CIR, Fill
Thickness of materials		
Recycled in place	–	73 mm (2.88")
Recycled import	19 mm (0.75")	9.5 mm (0.375")
Recyclable export	68.5 mm (2.7")	34 mm (1.35")
Virgin import	57 mm (2.25")	31.5 mm (1.245")
Waste	8 mm (0.3")	4 mm (0.15")
Thickness of materials processed by		
Cold technology	75 mm (3")	114 mm (4.5")
Warm technology	–	
Hot technology	75 mm (3")	38 mm (1.5")
Big foot technology	–	
Service life	20 years	30 years
Yearly cost	$3/m^2/Year	$2.34/m^2/Year

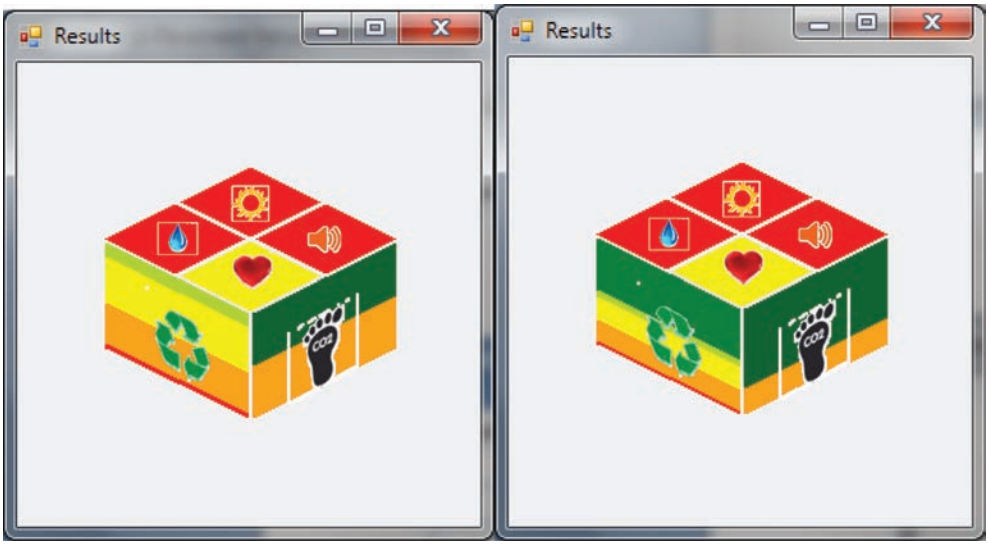

Figure 2. Green up cube for Mill and Fill Scenario 1 (left) and for Mill, CIR, Fill Scenario 2 (right).

75% of materials are processed with a Cold technology in the Mill, CIR and Fill scenario and only 25% with the Hot technology.

Is one approach more sustainable than the other? Could we get even more "green" in the picture? As mentioned before, a computer program was developed to facilitate the use of the system. To encourage users to learn more about sustainable pavement practices, many of windows that make the user interface are provided with a button labeled "Green Up." The Green Up button is a gateway to more information about sustainable pavement rehabilitation practices. Clicking on the button users can access websites and links with more information about a specific subject, such as pervious pavements for example.

4 CONCLUSIONS

The Green Up system provides design professionals with a method of comparing pavement rehabilitation alternatives in terms of four key sustainability features:

- Materials: based on the concept that material reusing and recycling is a sustainable practice;
- Technologies: based on the concept that reducing green house gas emissions and energy consumption is a sustainable practice;
- Surface properties such as:
  - Permeability: the ability to reduce the amount of storm water runoff;
  - Surface reflectivity: the ability to minimize the heat island effect;
  - Noise: and the ability to reduce noise pollution;
- Life and cost: based on the assumption that pavement rehabilitation solutions that cost less and result in a longer life extension are more sustainable.

Before using the Green Up system, designers should use the standards and methods appropriate to their project and jurisdiction to design pavements that are safe, smooth, and economically viable. After producing several design alternatives, the Green Up system can be used to compare and improve the proposed design in terms of sustainability.

The Green Up system was designed to be fast and simple. It limits the amount of information that needs to be provided by the user in an effort to minimize the amount of time needed to use the system. When time and resources are available, designers are encouraged to also use one of the more comprehensive sustainability rating systems such as Greenroads.

Technical Research Institute, Maeda Road Construction Co., Ltd., Oobatake, Tsuchiura, Ibaraki, Japan

ABSTRACT: In Japan, bagged cold asphalt repair materials are usually used for repairing pavements. They are not as strong as hot asphalt mixtures and are therefore mainly used for the temporary rehabilitation of lightly trafficked roads. In recent years, various highly durable cold mixtures have also been developed, but none match up to the quality of hot asphalt mixtures. Representative problems caused by cold mixtures include rutting and aggregate scattering, particularly immediately after traffic release and during the summer, as well as the limited use in rain or on wet areas.

To solve these problems, we developed a curing, reactive, highly durable, cold asphalt repair material used with a water activating system, which boasts quality equivalent to or higher than hot asphalt mixtures. Presently, the product is used widely throughout Japan, with more than 300,000 bags shipped annually. This paper discusses details of the background of the development and efforts made to put it to practical application.

Keywords: cold asphalt mixture, high durability, the bag, all weather, long preservation

1 INTRODUCTION

Bagged cold asphalt repair materials (cold asphalt mixtures) are used for different purposes such as repair of potholes and bumps in pavements making paving work easy and storage stability high. However, because their strength development is slow compared to hot asphalt mixtures (hot mix asphalt concrete) and durability is also poorer, cold asphalt mixtures are mainly used for the temporary rehabilitation of lightly trafficked roads. Meanwhile, the recent years have seen efforts being made to improve the durability of cold asphalt mixtures in the aim to apply them for the repair of roads with relatively heavy traffic, as well as for mid- and long-term temporary and permanent rehabilitation works. This has led to the development of various highly durable products. Unfortunately, the strength, development time, and durability of cold asphalt mixtures have yet to reach the level of hot mix asphalt concrete, and frequently cause damages such as rutting and aggregate scattering immediately after paving work and during summer. There are also limits to the use of cold asphalt mixtures in paving work during rain or when the repaired area becomes wet.

To solve these problems, we developed an all-weather highly durable cold asphalt mixture [1] which can be used for paving work even in rain and at wet areas while demonstrating the same strength as hot mix asphalt concrete, and put the innovative product to commercial application.

This paper discusses the properties of the mixture, scope of application, and some examples of paving work.

2 CONVENTIONAL COLD ASPHALT MIXTURES

Lubricating oil is combined to produce cut-back asphalt to ensure workability of the conventional cold asphalt mixture at cold temperatures (in the range of temperatures at which the mixture asphalt is used). After paving, the lubricating oil volatilizes, and the mixture is able to undergo strength development. However, as volatilization takes time (from several days to several months), some repaired areas may be damaged soon after the paving work, or even several months after the repair, particularly during summer, because the lubricating oil near the paved surface volatilizes but that inside remains. In addition, when paving work is carried out in the rain or in water puddles, the water causes the durability of the mixture to be reduced as well as the lubricating oil to leach out, resulting in many cases of paving problems, and creating environmental issues.

3 OUTLINE OF MIXTURE

3.1 *Mechanism of strength development*

Figure 1 shows the mechanism of strength development of the cold asphalt mixture. By coating the asphalt surface with special non-petroleum lubricating oil, workability in normal temperature can be ensured. In addition, by spraying water after laying down asphalt (before rolling), the special lubricating oil, reaction assisting material, and water chemically react and harden, and the mixture undergoes strength development.

As the special lubricating oil and asphalt have very good compatibility and products made of the special lubricating oil have the same or more strength than asphalt at service temperatures, the mixture can acquire high durability equivalent to or above hot mix asphalt concrete. Furthermore, as the speed of the chemical reaction is faster than the volatilization of the lubricating oil, the strength development of the mixture is also fast, promising early traffic release after the paving work.

3.2 *Manufacturing method of mixture*

This mixture can be manufactured using the same method as normal hot mix asphalt concrete. However, it should be noted that the mixing temperature of the mixture must be above 110°C because the chemical reaction of the lubricating oil initiates with the slightest amount of water, which may cause the mixture to harden due to the residual moisture in the aggregate.

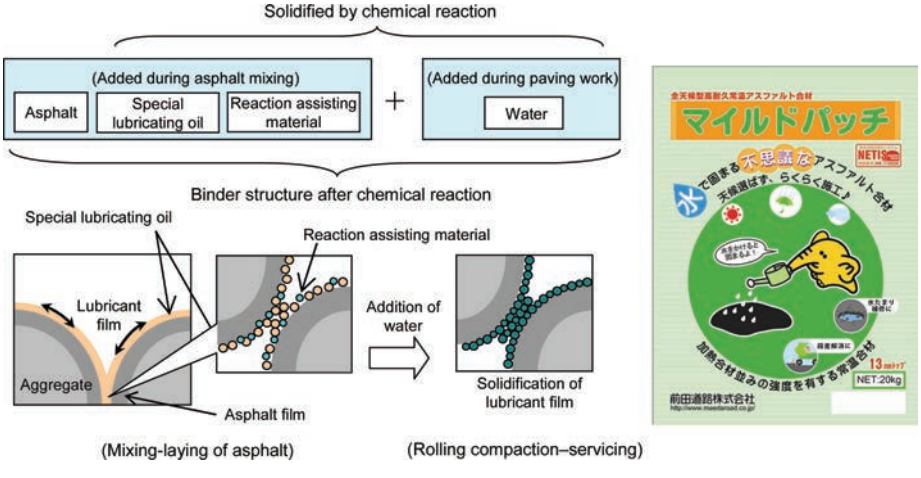

Figure 1. Hardening mechanism.

3.3 *Mixture types*

In fact the aggregate particle size is not specified and various particle sizes are used. Although the dense grade with maximum aggregate particle size of 13 mm is the major type. The product series provides a range of particle sizes to meet different needs. However, the porous type has lower strength compared to the continuous grading type because the binder serves as spot glue, and is thus difficult to use for places where rest steering and torsional effects of tires are frequent. We are therefore currently investigating the application of the mixture as repair material for porous asphalt pavements (drainage pavement).

3.4 *Deciding the binder content*

To determine the binder amount (total of asphalt and special lubricating oil) of the mixture, the tentative binder amount is calculated using the heat mixing method equation (1) described in the Manual for Asphalt Pavement [2] issued by the Japan Road Association, then test mixing is carried out at the calculated binder amount to evaluate the state of the mixture, based on which the binder amount is adjusted and decided. For better adhesiveness to the existing pavement, slightly more binder is included compared to hot mix asphalt concrete.

$$\text{Binder content (\%)} = 0.023a + 0.065b + 0.130c + 0.11d + 1.13 \quad (1)$$

where
a: weight percentage (%) of residue in a 2.36 mm sieve from the aggregate used
b: weight percentage (%) of residue in a 0.3 mm sieve after passing through a 2.36 mm filter
c: weight percentage (%) of residue in a 0.075 mm sieve after passing through a 0.3 mm filter
d: weight percentage (%) of portion passing through a 0.075 mm sieve.

4 INDOOR EVALUATION TEST

4.1 *Properties of mixture*

As there is no prescribed evaluation method for bagged cold asphalt mixtures, Marshall stability and Wheel Tracking (WT), general evaluation methods for asphalt mixtures, were used for the process. The test temperatures were 20°C (in comparison with other cold asphalt mixtures) and 60°C (in comparison with hot mix asphalt concrete).

1. Comparison with other cold asphalt mixtures
   To evaluate the mixture strength immediately after paving and after placing the road in service, Marshall stability test was conducted at normal temperature one hour after preparing the test samples. Given that the cold asphalt mixtures for comparison were of the lubricating oil volatilization type, test samples were cured at 60°C for seven days to completely volatilize the lubricating oil, after which normal temperature Marshall stability and normal temperature WT test were carried out. General type and highly durable type were used as the cold asphalt mixtures for comparison.

   Figures 2 and 3 show the results. This mixture was found to have stability of more than ten-fold that of the general type in the initial stage and three- to seven-fold that of the highly durable type. It was also confirmed that even when the road was placed in service, the mixture had very high strength compared to the other two cold asphalt mixtures for both Marshall stability and dynamic stability.
2. Comparison with hot mix asphalt concrete
   To compare properties of this mixture with those of hot-mix mixtures, normal temperature (60°C), Marshall and WT test were conducted. Taking the particle size of the hot mix asphalt concrete to be the same as that of this mixture, straight asphalt 60/80 binder was used.

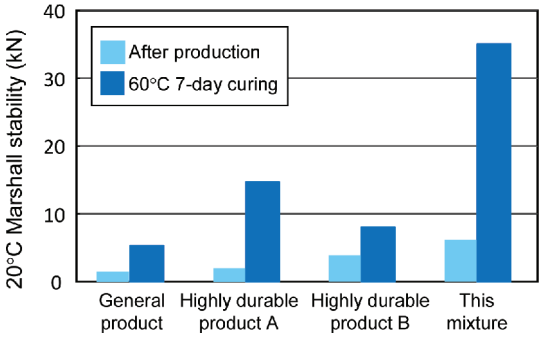

Figure 2. Marshall test results (20°C).

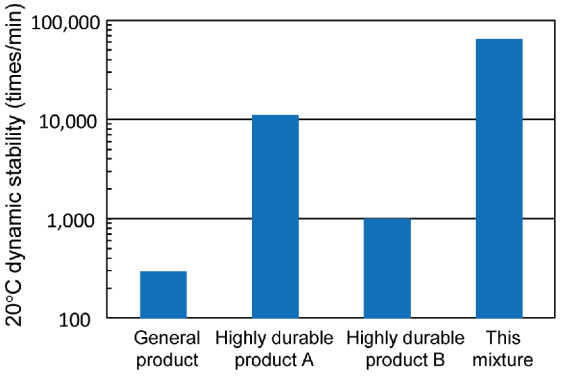

Figure 3. WT test results (20°C).

Table 1 shows the results. This mixture indicated values equivalent or above the hot-mix mixture, confirming that this mixture has the same strength as hot-mix mixtures even though it is a bagged cold asphalt mixture.

4.2 *Strength development*

This material develops strength not by the volatilization of the lubricating oil but by chemical reaction. As its chemical reaction time is faster than volatilization time, strength development of this mixture is faster than that of normal cold asphalt mixtures, suggesting that quick traffic release can be expected.

1. Initial strength of mixtures
   The speed of strength development of this mixture was verified by normal temperature Marshall test. Figure 4 shows the test result. The strength of the mixture increases with time, confirming that the strength of the mixture was higher than the general type (20°C, 7-day curing) 30 minutes after sample preparation, and higher than highly durable products (20°C, 7-day curing) one hour after.
2. Durability immediately after paving work
   To verify the strength of this mixture immediately after paving work, a car was driven over the road immediately after pothole repair (Photo 1), and the road surface profile before and after the tires had run over the road were measured (Photo 2). Tables 2 and 3 show the test conditions and results. Rutting is less compared to the general type and highly durable type, indicating that the mixture has superior initial durability. In addition, there were no cracks caused by aggregate scattering or displacement.

Table 1. Properties of mixture.

Item	Test value		Specification*
	This mixture	Hot mix asphalt concrete	
Marshall stability (kN)	9.2	9.8	≥ 4.9 kN
Dynamic stability (times/mm)	6,000	500	–

Item	Details
Paving work	
Paving scale	Approx. 0.15 m^2 (t = 50 mm)
Rolling compaction method	Harden by stepping with foot
Running vehicle	
Vehicle used	Passenger car (Tire ground contact pressure: 0.37 N/mm^2)
No. of runs (running time)	10 times (within 3 minutes from completion of paving work)
Road surface profile measuring device	MRP (multi-load profiler)

Table 3. Rut depth.

Type	Rut depth (mm)
This mixture	2.7
General product	5.1
Highly-durable product	4.0

Table 4. Paving method and mixture properties in low temperatures.

Compaction temperature (°C)	Density (g/cm^3)	Compaction degree compared with 20°C (%)	Workability (handling)	Marshall stability at 20°C (kN)	
				3-hour curing	7-day curing
20	2.342	100	Good	10.5	≥30
0	2.314	98.8	Good	9.7	≥30
–10	2.300	98.2	Good	9.5	≥30

Table 5. Storage stability verification results.

Type of bag	Sealing method	Hardening rate of mixture in bag (%)			
		1 month	2 months	3 months	6 months
Conventional type	Stitching by sewing	0	20	70	100
Dedicated type		0	0	50	80

4.3 *Workability in low temperatures*

Table 4 shows the results of verifying workability of this mixture in low temperatures. Evaluation was carried out by normal temperature Marshall test and handling during work.

In this study, the mixture temperature was decreased to the paving temperature (0, –10°C), so the compaction density was slightly lower than when paving was carried out at 20°C. However, there was essentially no drop in workability and mixture strength, confirming that there is no sharp decrease in durability even in paving at low temperatures.

As the freezing of the sprayed water during paving can cause inadequate compaction, there is a need to carry out compaction quickly. Compaction density can also be improved by placing the mixture inside before use to adjust its temperature to around 20°C.

4.4 *Storage stability*

As this mixture develops strength by adding water and it can start reacting gradually even with the slightest amount of water such as moisture in the air, etc., ideally the mixture should be stored in such a way that all entry of humidity, etc. is shut off. Table 5 shows the results of verifying storage stability. When bags used for storing general cold asphalt mixtures are sealed by stitching with a sewing machine, hardening started one to two months after storage. However, with storage bags with better humidity prevention and waterproofing performance are used, it was confirmed that sealing the bags by thermal compression to increase airtightness enabled storage for six months. In addition, workability and properties of a mixture which had been stored for six months were checked, and it was found that conditions were good and not different from mixtures just manufactured.

5 PAVING PROCESS

The paving process with this mixture is the same as normal cold asphalt mixtures other than the spraying of water before compaction. The following describes the paving process using pothole repair as an example.

5.1 *Pouring and spreading the mixture*

The required amount is poured over the area to be paved. The shrinkage allowance is about 30%.The paved area can be wet. Although scattering of emulsion is not required, it is still performed as necessary because it improves durability. The mixture is then spread as done with normal cold asphalt mixtures, however, efforts must be made to prevent the coarse aggregate from concentrating in one place as this causes aggregate scattering.

5.2 *Water spraying*

Water must always be sprayed before rolling. As shown in Photo 3, water is sprayed using a plastic bottle, watering can, etc. over the whole surface evenly. The amount of water to be sprayed is 1 per bag of mixture (20 kg), and can be slightly more or less than this. However, more will not cause any problems, but inadequate spraying can delay strength development.

5.3 *Rolling*

Rolling was carried out promptly after water spraying. As shown in Photo 4, compaction by stepping with the foot is adequate. Durability is better when rolling machines such as plate, etc. are used. If rolling is delayed, reaction with the mixture progresses, resulting in paving problems. For this reason, rolling need to be carried out promptly.

Photo 3. Water spraying.

Photo 4. Rolling compaction.

5.4 *Traffic release*

In small-scale paving work such as repair of potholes, etc., traffic release may be possible after completion of the paving work. However, curing may need to be carried out for about one to two hours when large cars are scheduled to frequently run over the areas where torsional effects of tires occur or at large areas of paving work.

6 EXAMPLES OF APPLICATION

6.1 *Restoration work after earthquake*

This mixture was used for repairing potholes (Photo 5) that had formed on roads in Miyagi Prefecture during the Great East Japan Earthquake. Conditions remain good even after two years from paving.

6.2 *Restoration work after north Kyushu heavy rain disaster*

As shown in Photo 6, a torrential downpour which occurred in the northern part of Kyushu in July 2012 severely damaged roads in Fukuoka Prefecture. This mixture was used in restoration work to repair the roads (Photo 7). More than 100 bags (containing 20 kg) were used.

6.3 *Application to sites with torsional effect (exit/entrance of distribution center)*

Photo 8 shows the repair situation at the entrance/exit of a distribution center. There is an area showing torsional effect of large-vehicles. Repairs had been carried out several times but

Photo 5. Restoration after earthquake.

Photo 6. Damage situation.

Photo 7. Urgent repair situation.

Photo 8. Repaired state at entrance/exit of distribution.

the area quickly became damaged again after each repair. When it was repaired using this mixture which has high durability, good serviceability was confirmed.

7 SUMMARY OF RESULTS

This mixture has the following features:

- Although it is a bagged cold asphalt mixture, it has the same durability as hot mix asphalt concrete.
- Strength development is via chemical reaction and is thus faster than volatile cold asphalt mixtures, enabling early traffic release.
- Paving is possible even in rain and subzero temperatures.
- Applicable to all particle sizes. (However, the porous type is limited to sidewalks.)
- Can be stored for a long time (about 6 months).
- Paving method is the same as conventional cold asphalt mixtures except for water spraying. No special paving machine is required.

8 NEW ENDEAVORS

This mixture can be applied for various purposes using techniques developed for it. Some new methods of use are introduced below.

8.1 *Use as normal hot mix asphalt concrete*

As this mixture does not need to be bagged and sealed immediately and can be used as long as it is on the day it was made (about 12 hours from production), it can be used as normal hot mix asphalt concrete. In addition, the workable temperature can be set freely by changing the amount of special lubricating oil added, thereby allowing use for the following purposes.

1. Use for small-scale repairs and several locations in one day
   By setting the workable temperature low (about 50–90°C), the mixture can be used cold. This means that when small-scale repairs are required at several locations in one day, mixtures delivered in the morning can be used even in the evening. Thus no mixtures are wasted and there is no need to go all the way to the manufacturing plant to obtain more stock when it runs out.
2. Application to warm-mix asphalt and improved workability asphalt mixtures
   As the manufacturing temperature of the mixture can be decreased to 110°C (temperature at which the residual water in the aggregate becomes more or less zero), it can be reduced by about 50°C for normal mixtures and by about 70°C for modified mixtures. This enables CO_2 emissions to be cut, work environment of employees to be improved (prevent heat stroke), and traffic to be released early due to the fast chemical reaction of the special lubricating oil. By setting the shipment temperature the same as normal temperature, the mixture can also be used as an improved workability mixture in paving work where temperature drops of the mixture are anticipated such as winter.
3. Transportable over long distances
   Normally, hot mix asphalt concrete should be used within two hours from shipment due to decrease in temperature. This is difficult in areas without asphalt mixing plants in the vicinity. In such cases, paving problems tend to occur easily, and this may cause early damage of pavements. This mixture is also useful for resolving this problem and is suitable for long distance transportation.

8.2 *Stockpile mixture bagged in flexible container*

This mixture needs to be sealed in an airtight bag for long term storage as it starts to react even with the moisture in the atmosphere. Small amounts such as 20 kg can be sealed in

airtight bags but large amounts like 1t are difficult and cannot be stored over long periods of time. Since mixtures harden as a result of the mixture and chemical reaction of the special lubricating oil, reaction assisting material, and water, as long as one of these is not present, the mixture can be stored semi-permanently. Consequently, by manufacturing the mixture without adding the reaction assisting material, then transporting the mixture to the site of use and mixing in the reaction assisting material just before paving work as shown in Photo 9, large amounts can be stored in flexible container bags, etc. This method not only enables asphalt paving in regions that do not have mixing plants such as remote islands, but also allows the mixture to be brought to disaster sites from afar and to be stored there. This is considered a technique useful for the restoration work after earthquake disasters.

Currently, kneading and paving tests are being conducted to verify the serviceability of this technique. A simple device for mixing reaction assisting material on site is also being developed in the aim to put it to practical application.

8.3 *Decolorizing*

This mixture can also be applied to decolorizing binders, as well as fieldstone and bagged colored cold asphalt mixtures (Photo 10, 11). Presently, durability and weather resistance are being verified. Applications such as repair material for fieldstone and colored pavements, small-scale pavements such as parks, and normal households are being considered.

Photo 9. Stockpile materials bagged in flexible container.

Photo 10. Application to natural stone pavement.

Photo 11. Application to colored pavement.

9 CONCLUSION

This mixture is a new type of cold asphalt mixture with sharply improved strength development and durability during the winter and summer, which has been the challenge of conventional cold asphalt mixtures.

In the future, efforts will be made to further increase the scope of application such as use as decolorizing agent of natural color pavements and color pavement, and application as repair material of porous asphalt pavements, etc.

Asphalt Pavements – Kim (Ed)

Effect of moisture on asphalt mastic tensile properties at ambient temperature

Alex K. Apeagyei, James R.A. Grenfell & Gordon Airey
Nottingham Transportation Engineering Centre, Department of Civil Engineering, University of Nottingham, University Park, Nottingham, UK

ABSTRACT: The purpose of this study was to investigate moisture absorption characteristics and their impact on tensile properties of asphalt mastics subjected to long-term soaking under ambient conditions (20°C and 50% relative humidity). The objective was to better understand the moisture damage phenomenon by providing suitable material inputs that can be used for numerical simulation. Understanding the effect of moisture on the mechanical properties of the asphalt mastics investigated is of utmost importance because they are commonly used in the construction of open-graded asphalt mixtures. The experimental approach adopted for studying the effect of moisture on mechanical properties of asphalt mastics consisted of exposing initially dry samples to moisture under controlled temperature and relative humidity, recording the moisture uptake until equilibrium using an ultra-sensitive balance, and then drying back and performing mechanical testing at multiple levels of saturation (moisture contents). The mechanical tests were all conducted at 20°C using a loading rate of 20 mm/min on dog-bone shaped samples. Using this approach, it was possible to identify the reversible and irreversible moisture absorption and its effects on mechanical properties. Moisture absorption of up to 0.4 wt% was observed and was largely recoverable upon drying for most of the mastics tested. The results suggest that the degradation of mastic tensile properties associated with moisture absorption is partially recovered upon drying. The effect of moisture conditioning on mastics appears to be aggregate type dependent as higher degradation in stiffness response was observed in the granite mastics than in the limestone mastics. Tensile strength in moisture saturated mastics was generally lower than in drier samples and was largely recoverable upon specimen drying. The failure mode in all the mastics considered were ductile which suggests that at the temperature and loading rate employed, the effect of moisture on failure mode is minimal. Aggregate type can accentuate the influence of moisture on tensile properties of asphalt mastics.

Keywords: asphalt mastic; moisture absorption; stress-strain relationship; tensile strength; moisture damage

1 INTRODUCTION

From a micro-mechanical point of view, asphalt mastic comprising of bitumen, fine aggregate and mineral filler can be considered as one of the two key components of conventional asphalt mixtures. The second component is mineral aggregate. In this case, the mastic, not the bitumen, may be considered as the adhesive that binds the aggregates together. The adhesive bond at the asphalt mastic-aggregate interface and/or the cohesion within the bulk mastic controls the mechanical properties of asphalt mixtures. However, both adhesive and cohesive properties of asphalt mastic can be susceptible to the detrimental effects of moisture in a phenomenon known as moisture induced damage [1]. Moisture damage can lead to significant degradation of mechanical properties and is generally recognized as one of the most important factors that influence long-term durability of asphalt pavements [1–10].

Most damage in asphalt mixtures involves extremely complex mechanisms that are not completely understood yet. Recent attempts aimed at better understanding the mechanisms of moisture damage have involved two main approaches: the application surface energy methods based on physico-chemical properties and the application of finite element techniques for simulating the moisture damage [3–9]. In both approaches, fundamental physical and material properties are required as inputs that are currently not routinely available. Critical input parameters for the FE approach, which is the focus of this study, include the bulk mastic tensile properties of asphalt mastics and the effect of moisture on the same. The second important FE input material property is related to the influence of moisture on interfacial bonds is beyond the scope of this paper.

Asphalt mastic show sensitivity to moisture due to physico-chemical interactions between water molecules and some polar groups found in bitumen and mineral aggregates (aggregates and fillers). This sensitivity is also a function of the mineralogical composition of aggregates and mineral fillers. The latter controls both moisture uptake and diffusion properties that are fundamental input parameters many numerical simulation models for moisture damage. Through the application of Fick's laws of diffusion [11] the amount of moisture transport through asphalt mastic can be modelled as a function of time and the results used to relate moisture content to damage. A simple but useful approach for studying the effect of moisture on mechanical properties of asphalt mastics consists of exposing an initially dry sample to moisture under controlled temperature and Relative Humidity (RH), recording the moisture uptake until equilibrium using an ultra-sensitive balance, and then drying back and performing mechanical testing at multiple degrees of saturation (moisture contents). Using this approach, it is possible to identify the reversible and irreversible moisture absorption and its effects on mechanical properties. Almost all currently available testing protocols for evaluating moisture damage assumes moisture induced damage in asphalt mixtures is irreversible or fail to consider the possibility reversible moisture induced-damage. On the basis of this assumption, if asphalt mastic is exposed to moisture for long period of time, permanent damage should be expected. As this paper will demonstrate, this supposition may not be the case for certain asphalt mixtures.

This study reports on an investigation of the effects of moisture on tensile properties of asphalt mastics under accelerated moisture conditioning regimes in the laboratory. Tensile properties are evaluated from controlled strain loading at ambient temperatures. The observed tensile response of asphalt mastic to moisture exposure is rationalized based on physico-chemical analysis in conjunction petrographic data from a Mineral Liberation Analyser (MLA).

2 MATERIALS AND METHODS

2.1 *Aggregates properties*

Four asphalt mastics (LALF, LAGF, GALF and GAGF) containing different fine aggregate and mineral filler types were used. Combination of the two fine aggregates and two fillers types yielded the four different mastics. Materials passing the 1.00 mm sieve but retained on 0.125 mm sieve were considered as fine aggregates while the mineral filler was defined as material passing the 0.063 mm sieve. The aggregates and mineral fillers differed in terms of their petrological type (granite or limestone), mineralogical compositions, surface characteristics and specific gravities. The mineralogical compositions of the aggregates were characterized using a Mineral Liberation Analyzer (FEI Quanta 600 SEM). The device combines an automated Scanning Electron Microscope and multiple Energy Dispersive X-ray detectors with state-of-the-art analysis software to produce quantitative mineralogy measurements. The results were used to identify key mineral phases and their possible influence on the moisture-induced asphalt mastic tensile property degradation. Figure 1 shows the mineralogical composition of the aggregates obtained from the Mineral Liberation Analyzer. The results show that the mineral compositions of the granite and limestone aggregates are significantly different in

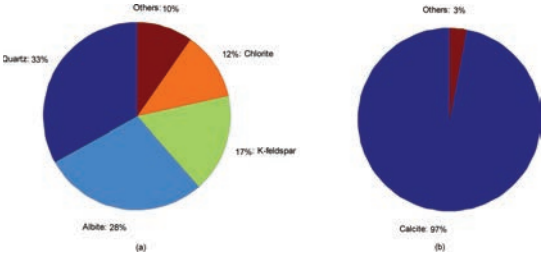

Figure 1. Petrographic type and mineral composition of aggregates and fillers. K-feldspar = potassium-dominant feldspar. a) Granite. b) Limestone.

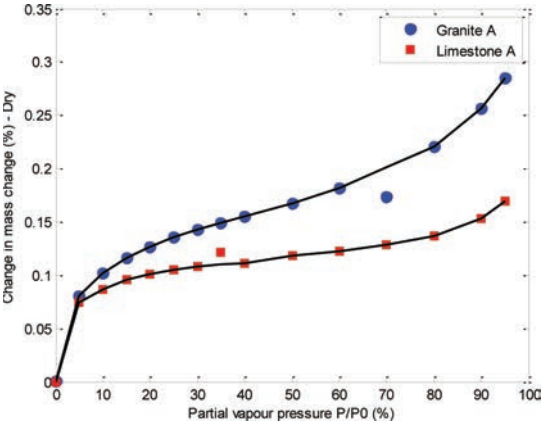

Figure 2. Octane sorption isotherms for aggregates (1.18 mm size fraction) used for fabricating mastics. The higher the absorption the more porous is the aggregate.

terms of the number and amount of mineral phases present. While the granites were made up of a large number of different dominant mineral phases (quartz, albite, potassium-dominant feldspar, and chlorite), the limestone consisted of predominantly (about 97%) calcite.

The aggregates for the mastics were mechanically sieved in the laboratory to obtain only materials passing the 1-mm sieve and retained on 0.125-mm sieve (fine aggregate). In addition to the fine aggregates, limestone and granite mineral fillers satisfying BS EN 1097-7-2008 were used. Again, the choice of the mineral fillers was made to quantify the effect, if any, of different types of fillers used in asphalt mixtures.

Surface characteristics such as porosity, specific surface area, and surface free energy, are key physico-chemical properties of aggregates that influence the adhesion between materials. The physico-chemical properties of samples of the aggregates were characterized using a Dynamic Sorption Device (DVS Advantage), with octane as a probe, to generate a series of sorption isotherms (Fig. 2). The absorption of octane was higher in the granite than in the limestone suggesting the former is more porous than the latter. Also, as can be seen in Figure 2, the isotherms are similar to type II isotherms. Therefore, the BET specific surface area for the 1.18 mm aggregate was calculated giving a value of 3.49 m^2/g and 2.57 m^2/g, respectively, for the granite and the limestone. Additional detailed characterization of the physico-chemical properties of the aggregates are provided elsewhere [5, 6]. From this study, the total SFE of the granite and limestone was reported as 353 and 223 mJ/m^2, respectively.

The specific gravities of the aggregates and mineral fillers were not significantly different. They were 2.663, 2.720, 2.626 and 2.680, respectively, for the Limestone Aggregate (LA), Limestone Filler (LF), Granite Aggregate (GA) and Granite Filler (GF).

2.2 *Asphalt mastics*

The same 40/60 penetration grade bitumen (40/60 pen) was used in the manufacture of all the four asphalt mastics examined. The bitumen is typical of those that are commonly used for asphalt mixture production in the UK with a reported total surface free energy of about 31 mJ/m^2 [5–6]. The proportion of the constituent components (fine aggregate, mineral filler, bitumen) of the mastics used was 50:25:25 by weight of mixture or about 36:18:46 by volume. These proportions were chosen to mimic mastic mix design typically used in open-graded friction course asphalt mixtures in The Netherlands [8]. The mastics were produced by combining the dried aggregates and molten bitumen using a Hobart mechanical mixer at a mixing temperature of 185°C. The mastics were then put in quart tins and stored in temperature controlled (20°C, 50% RH) conditions until testing. The bulk specific gravity of the mastics was estimated to be approximately 1.917.

2.3 *Specimen fabrication*

Mastic specimens shaped in the form of a dog-bone with dimensions of 17.75 mm at the middle, 21 mm at the top, and 62 mm tall (Fig. 3), was used to determine the cohesive tensile properties of the mastics. The dog-bone shaped nature of the mastic specimens required custom-made stainless stress moulds to be procured. In addition stainless steel rings measuring 21 mm diameter by 5 mm high were used for gripping the specimens. The average dry weight of each mastic specimens (excluding the two steel rings) was about 30 g. Similar specimen configurations have been used to measure tensile strength of mastic in the past [8]. The dog-bone shaped specimens were fabricated by pouring molten mastic (135°C–140°C) in the steel mold with any form of compactive effort applied.

2.4 *Moisture conditioning*

Schematic of the moisture conditioning test set-up is shown in Figure 4. Special mats were made to cradle the fragile dog-bone shaped specimens to ensure that damage to the specimen were kept to a minimum during the rather long conditioning time (over 200 days of absorption and desorption) required. Moisture uptake during soaking (absorption) and during drying (desorption) was captured at regular intervals using an ultra-sensitive microbalance with a 0.1 μg resolution. It should be noted that while the specimens were fully submerged (and therefore diffusion of moisture into the mastic occurred through all exposed surfaces) during the absorption stage, moisture flow during the drying (desorption) stage was restrained to occur only at the ends of the mastics by covering the middle portion of the specimens with

plastic sheeting. This was to ensure that moisture was always present at the most critical location (middle of the specimen) during mechanical testing at all saturation levels. Similar approach was used by Kringos et al., 2011 [8]. Moisture uptake was computed as the ratio of moisture uptake at given conditioning time to the weight of the dry mastic.

2.5 *Tensile testing*

Figure 5 shows the details of the test set-up developed for examining the effect of moisture on tensile properties of asphalt mastics. The same Instron machine with a load cell of 5 kN were used for both set-ups. In both cases, the test specimens were attached to the Intron machine through mechanical wedge-action grips via two custom-made steel loading rings. The applied loading rate of 20 mm/min was also the same for the cohesive and adhesive strength test sets. A single testing temperature of 20°C was used. An additional feature for cohesive strength test was the use of a video gauge capable monitoring both the transverse and longitudinal strains using virtual targets (speckle patterns) that enable accurate stress-strain characteristics of the mastic to be made in a non-obstructive manner.

2.5.1 *Mastic cohesive tensile properties*

The samples were mechanically tested after four different moisture conditioning regimes: 1) dry samples stored under ambient conditions (20°C and 50% RH) for about 112 days, 2) after 112 days of soaking, 3) 112 days of soaking followed by about 30 days of partial

drying and 4) 112 days of soaking followed by 112 days of partial drying. To obtain the partially dried samples, samples of the 112 moisture conditioned specimens were covered with plastic on all sides except the two ends so that water can evaporate from the ends only. The applied load and the resulting cross-head displacement were monitored continuously by software connected to the Instron machine. The results were used to determine both stiffness and tensile strength of the mastics as a function of moisture conditioning and moisture absorption.

3 RESULTS AND DISCUSSION

3.1 *Mastic cohesive tensile properties*

A key objective for conducting the cohesive tensile testing on the mastics was to examine the effect of absorbed moisture on the bulk mastic properties. Bulk asphalt mastic properties of interest included stress-strain behaviour (load versus cross-head displacement), ultimate tensile strength (cohesive strength) and strain at ultimate strength. It was anticipated that the relationship between mastic properties and moisture absorption profiles could be used as inputs into a finite element model for simulating moisture damage in asphalt mixtures.

3.1.1 *Mastic moisture absorption profiles*

For each of the four mastic types considered, at least 6 replicate specimens were tested to determine their moisture absorption and desorption characteristics. The results are depicted in Figure 6 where differences in the rate and amount of moisture absorbed or desorbed could be seen depending on aggregate type. The amount and rate of moisture absorbed was higher in mastics containing limestone aggregates than that in granite aggregate mastics for the conditioning period of up to 112 days considered in this study. More than 80% of moisture uptake occurred during the first 50 days of the 112-day conditioning period for the limestone mastics compared with just over 20% for the granite mastics over the same period. This suggests moisture absorption in the limestone mastics appear to be approaching 'equilibrium' after 112 days of soaking. On the contrary, for the mastics containing granite aggregates, it appears that equilibrium could not be reached after 112 days of soaking in 20°C water. However, the lack of a plateau in the moisture uptake profiles suggests none of the mastics

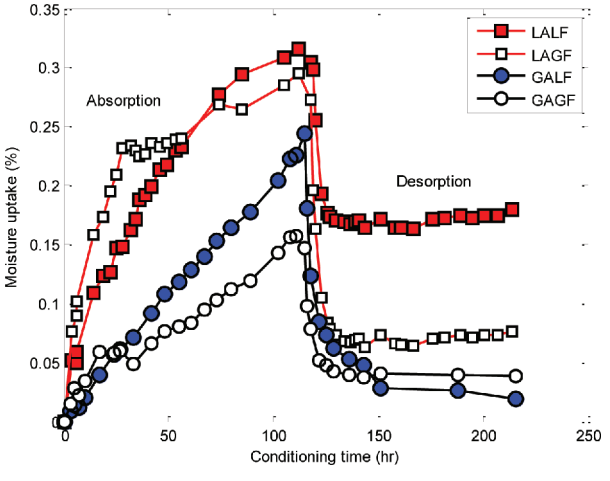

Figure 6. Moisture absorption and desorption profiles for asphalt mastics. Moisture uptake profile during absorption was obtained by soaking in water at 20°C. Desorption profile was obtained by drying partially covered specimens at 20C and 50% relative humidity. LA = limestone aggregate; LF = limestone filler; GA = granite aggregate; GF = granite filler.

achieved true equilibrium moisture after 112 days of moisture conditioning at 20°C. The four mastics tested were nominally similar except the type of aggregates and mineral fillers used. Therefore, any differences in moisture absorption could be attributed to physico-chemical properties of the aggregates and fillers.

Even though the absorption and desorption profiles shown in Figure 6 cannot be compared directly because desorption was constrained to occur only in one direction while absorption occurred in all directions, a key feature of the desorption profile was that it occurred at a relatively faster rate than absorption. For 3 out of the 4 mastics considered, it took less than 20 days to reach the residual moisture content of 0.025 to 0.05% (about 20% of peak uptake value) while it took over 110 days for each mastic to reach the pseudo-peak value.

3.1.2 *Effect of moisture conditioning on mastic stress-strain relationship*

Like many polymeric materials, asphalt mixtures can absorb moisture with time during moisture conditioning. A key effect of the presence of moisture on asphalt mixtures is the degradation of mechanical properties associated with moisture conditioning time. For dense-graded asphalt mixtures, stiffness degradation of up to 80% of unconditioned sample stiffness is possible. It was therefore anticipated that conditioning asphalt mastic in water at 20°C for up 110 days would induce significant measurable degradation in tensile properties. To test the hypothesis, mastic samples were soaked in water for about 112 days and then dried. Tensile strength tests were conducted after specified periods of drying including 0 days, 33 days and 112 days. The effect of absorbed water on the stress-strain behaviour of mastics dog-bone specimens as a function of conditioning regime (drying time) is depicted in Figure 7. In majority of the mastics, the longer drying times the higher the load-displacement (stiffness) curve plots; peak load for mastics conditioned dried for 112 days were always higher than those dried for 0 days. The results suggest that the degradation of mastic stiffness associated with moisture absorption is partially recovered upon drying. The effect of moisture conditioning on mastics appears to be aggregate type

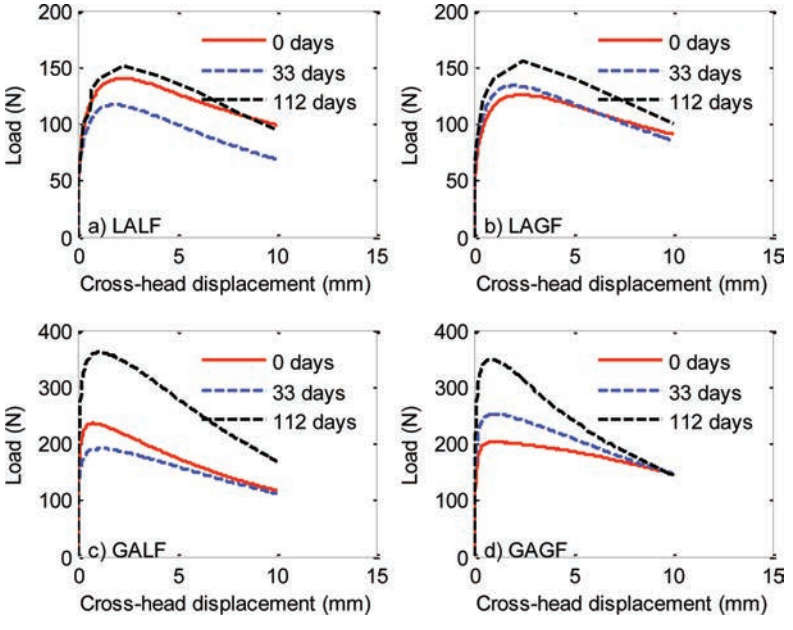

Figure 7. Effect of wetting and drying on asphalt mastics stress-strain response at 20C and 20 mm/min loading rate. All specimens were conditioned in water at 20°C for about 112 days before been dried for 0, 33 or 112 days for testing. Mixtures dried for 112 days contained the least amount of moisture while mixtures labelled 0 days were the wettest.

dependent as higher degradation in stiffness response was observed in the granite mastics than in the limestone mastics.

3.1.3 *Effect of moisture on mastic ultimate strength*

From the load versus longitudinal displacement plots (similar to those depicted in Fig. 7) for each mastic type, ultimate tensile strength values were computed as the ratio of the peak load to cross-sectional area of the neck of the dog-bone specimen. The results are summarized in

Table 1. Effect of moisture on tensile properties of asphalt mastics.

Exposure conditions	Moisture uptake (%)	Tensile strength (MPa)	Strain at ultimate strength (%)	Failure mode
LALF				
112 days in water at 20°C	0.315	0.62 ± 0.17	3.90 ± 0.45	Ductile
Then dry at 20°C 50% RH for 33 days	0.165	0.52 ± 0.04	4.14 ± 0.96	Ductile
Then dry at 20°C 50% RH for 112 days	0.180	0.59 ± 0.11	3.70 ± 0.30	Ductile
LAGF				
112 days in water at 20°C	0.295	0.70 ± 0.220	4.04 ± 0.40	Ductile
Then dry at 20°C 50% RH for 33 days	0.063	0.53 ± 0.10	3.54 ± 0.08	Ductile
Then dry at 20°C 50% RH for 112 days	0.077	0.65 ± 0.03	4.14 ± 1.04	Ductile
GALF				
112 days in water at 20°C	0.244	0.83 ± 0.12	1.76 ± 0.39	Ductile
Then dry at 20°C 50% RH for 33 days	0.029	0.66 ± 0.11	1.75 ± 0.16	Ductile
Then dry at 20°C 50% RH for 112 days	0.019	1.14 ± 0.02	1.90 ± 0.08	Ductile
GAGF				
112 days in water at 20°C	0.157	0.76 ± 0.12	1.85 ± 0.17	Ductile
Then dry at 20°C 50% RH for 33 days	0.041	0.86 ± 0.05	1.72 ± 0.31	Ductile
Then dry at 20°C 50% RH for 112 days	0.039	1.16 ± 0.10	1.71 ± 0.23	Ductile

RH = relative humidity.

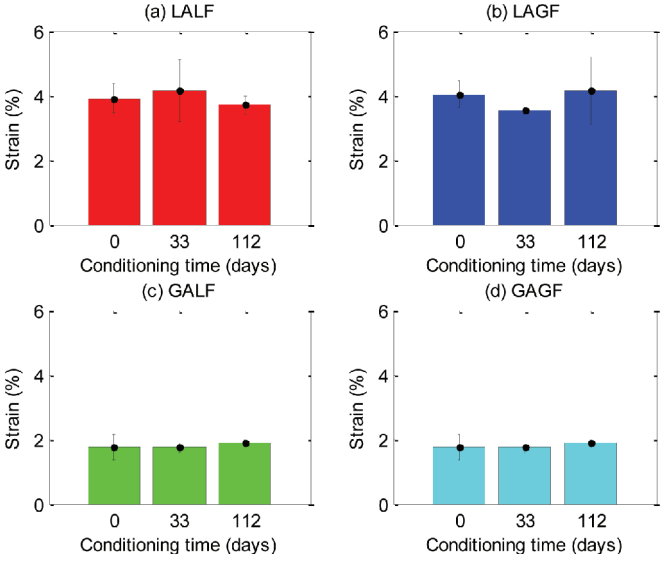

Figure 8. Strain at peak stress. Conditioning time is the number of drying days after specimens have been moisture conditioned for about 112 days in water at 20°C.

Table 1. They show that tensile strength in saturated (wetter) mastics is generally lower than in drier samples. The results also show that tensile strength in moisture saturated mastics largely recover upon drying. The failure mode in all the mastics considered were ductile which suggests at the temperature and loading rate employed, the effect on moisture on failure mode is minimal. It can be seen in Table 1 that aggregate type can accentuate the influence of moisture on tensile properties of asphalt mastics. Recovered tensile strength was generally higher in granite mastics than in limestone mastics. Also the strain at peak strength was significantly higher in limestone mastics compared with granite mastics under similar testing conditions (Fig. 8).

4 CONCLUSIONS

The objective of this paper was to investigate the effect of moisture on the tensile properties of asphalt mastics. The following conclusions were reached based on the data presented in the paper:

- Differences in the rate and amount of moisture absorption in mastics could be attributed in part to physico-chemical properties of the constituent aggregates and fillers.
- The rate of moisture absorption in asphalt mastics is significantly lower than the rate of moisture desorption. For most of the mastic studied, moisture absorption was about 80% recoverable.
- For moisture-conditioned asphalt mastics, the longer drying times the higher the stiffness. The results suggest that the degradation of mastic tensile properties associated with moisture absorption is partially recovered upon drying.
- The effect of moisture conditioning on mastics appears to be aggregate type dependent as higher degradation in stiffness response was observed in the granite mastics than in the limestone mastics.
- Tensile strength in moisture saturated mastics is generally lower than in drier samples and is largely recoverable upon specimen drying.
- The failure mode in all the mastics considered were ductile which suggests at the temperature and loading rate employed, the effect of moisture on failure mode is minimal.
- Aggregate type can accentuate the influence of moisture on tensile properties of asphalt mastics.
- Recovered tensile strength was higher and strain at peak strength significantly lower in granite mastics compared to limestone mastics under the conditions investigated in this study.

This study offers insight into the practical and measurable consequences to asphalt concrete caused by moisture damage and the often overlooked recoverable tensile properties associated with the phenomenon. The concept of recoverable tensile strength after a drying period maybe analogous to the micro-damage healing effect often associated with fatigue cracking models. Proper implementation of these concepts could offer important improvements to moisture damage models. Further studies aimed at understanding what factors influence reversible moisture-induced damage in asphalt mixtures is recommended.

Triaxial Cyclic Compression Testing of hot mix asphalt with cyclic confining pressure

Bernhard Hofko, Markus Hospodka & Ronald Blab
Research Center of Road Engineering, Institute of Transportation, Vienna University of Technology, Vienna, Austria

ABSTRACT: Permanent deformation in terms of rutting is a major deterioration mode of bituminous bound pavements. The Triaxial Cyclic Compression Test (TCCT) is a scientifically accepted and standardized test method to assess the resistance to permanent deformation. In most cases, TCCT is carried out with cyclic axial loading and constant confining pressure. In road pavements dynamic traffic loading due to passing tires leads to dynamic confining pressures. Thus, to bring the TCCT closer to reality, within the study presented in this paper, the radial response and its phase lag to axial loading in standard TCCTs is measured and an enhanced TCCT with cyclic confining pressure which takes into account the viscoelastic material response in terms of radial phase lag to axial loading is introduced. In a subsequent test program TCCTs with various confining pressure amplitudes are run on an AC 11 70/100 and results from standard and enhanced TCCTs are analyzed and compared in terms of resistance to permanent deformation. It is shown that the resistance to permanent deformation increases significantly when the viscoelastic material response is taken into account in the TCCTs with cyclic confining pressure.

Keywords: triaxial testing; permanent deformation; viscoelasticity; hot mix asphalt; cyclic confining pressure

1 INTRODUCTION

Besides low-temperature and fatigue cracking, permanent deformation at elevated temperature is a third major distress mode of bituminous bound pavements. Permanent deformation or rutting occurs especially as transverse profile deformations within the wheel paths but can also be seen as longitudinal profile irregularities [1]. Rutting is an important deterioration mode since it affects the comfort and safety of road users. Thus, various test methods have been developed to address the permanent deformation behavior of Hot Mix Asphalt (HMA). A commonly used test method to assess the permanent deformation behavior of HMA is the Triaxial Cyclic Compression Test (TCCT) with a well-defined external stress state. Research in this field in the 1970s and 1980s [2–5] was a major source for developing a European standard for TCCTs EN 12697-25 [6]. Recent studies show the importance of taking into account triaxial behavior with confining pressure [7–12]. In the standard TCCT according to EN 12697-25 cylindrical specimens are stressed by a cyclic axial loading in the compressive domain to simulate traffic loading by passing tires. The axial loading can either be shaped as a sinusoidal function or a block-impulse. The confining pressure can either be held constant or cyclic without giving more specific information in the standard. However, most laboratories that have integrated the TCCT on HMA into their test procedures use constant confining pressure, especially since the test control gets even more complex with two independent cyclic loadings.

Research on TCCT with cyclic confining pressure was mainly carried out in the area of unbound granular materials [13–26]. While earlier studies [e.g. 14] did not find significant

differences in the deformation behavior of unbound material for tests with constant and cyclic confining pressure, more recent studies [e.g. 17] showed that differences in permanent deformation occur depending on the ratio of the axial and radial stress amplitude.

The main difference between testing of unbound granular materials and bituminous bound materials (e.g. HMA) is that due to the viscoelastic nature of bituminous bound materials the phase lag between axial loading and radial response ($\phi_{ax,rad}$) must be analyzed and used for cyclic confining pressure to address the viscoelastic material response correctly [18] showed by finite element simulation of a pavement under a passing tire that cyclic axial loading leads to cyclic radial confining pressure within the pavement structure. Thus, the present practice of testing HMA specimens with constant confining pressure is a simplification. Only a small number of studies that work with the TCCT on HMA [19,20] have been carried out with cyclic confining pressure. The mentioned studies set a constant phase lag between axial loading and radial response of 36° for all tested materials at all temperatures and frequencies. Knowing that HMA shows a temperature and frequency dependent viscoelastic behavior, it is questionable whether this constant radial phase lag is correct for all materials, temperatures and frequencies.

2 OBJECTIVES AND APPROACH

Since the standard TCCT with constant confining pressure does not represent the state of stress in a pavement structure and the phase lag between axial loading and radial response for TCCTs given in literature do not match the common understanding of the theory of viscoelasticity [21] that viscoelastic material properties change with temperature and frequency, the main objectives of this study are to measure the radial phase lag $\phi_{ax,rad}$ between axial loading and radial response accurately and to incorporate cyclic confining pressure with a well-defined phase lag $\phi_{ax,rad}$ to have a more realistic simulation in the TCCT. Results from TCCTs with constant and cyclic confining pressure shall be compared exemplarily for an AC 11 70/100. To reach the objectives, the following approach is taken:

- Carry out standard TCCTs with constant confining pressure, record and analyze the phase lag between axial loading and radial response $\phi_{ax,rad}$ with high precision.
- Use the obtained data for the radial phase lag in the further course to incorporate it in an enhanced TCCT with cyclic confining pressure that thus takes into account the viscoelastic material response.
- Carry out a test series with the enhanced TCCT with a variation of the amplitude of the cyclic confining pressure to study the impact of the stress deviator on the permanent deformation behavior.
- Analyze, compare and interpret results of standard and enhanced TCCTs exemplarily run on an AC 11 70/100.

Thus, the main goal of this study is to lay the basis for an improved test procedure to address the permanent deformation behavior of HMA. Different from former studies the test will incorporate the actual (measured) radial phase lag of the material to take into account the viscoelastic behavior of HMA. The test can be employed in the future for a more efficient and realistic mix design optimization.

3 TEST EQUIPMENT

The equipment employed for this study consists of:

- a test machine with two circuits, one hydraulic circuit for axial loading including a load cell and a pneumatically driven device for application of static and cyclic confining pressure including a pressure cell,
- a temperature chamber to control the test temperature,

- a triaxial cell, and
- displacement sensors to record axial and radial deformation.

To realize cyclic confining pressures at high frequencies (3 Hz), a new device (see Fig. 1) has been developed that based on pneumatics where compressed air is used to activate a stiff membrane. The membrane can be described as a high-end shock absorber also used in Heavy Goods Vehicles (HGVs). It works as a pressure transmitter since it is filled with water and connected to the triaxial cell. The actual control mechanism is a valve that controls the air pressure on the membrane. The more compressed air is put onto the membrane the more water is pressed into the cell. Since the cell is filled with water and the system is water-tight, the pressure within the cell is changed by the volume of water pressed into the cell from the membrane. The triaxial cell is equipped with a pressure gauge. The gauge not only records the pressure, it is also connected to the control unit of the test machine. The control unit drives the valve in the pneumatic device according to the signal of the gauge to reach the target pressure given by the user. An additional Linear Variable Differential Transducer (LVDT) below the membrane records the position of the membrane and is a safety device to keep the membrane within safe operation limits.

For the measurement of radial strain, strain gauges are attached directly to the surface of the specimens (see Fig. 2). One 150 mm strain gauge is laid tightly around the circumference at half height and glued at both of its ends to the specimen. Usually strain gauges are attached to an object over its complete length in order to transfer strain from the object in tension and compression. Since the stiffness of HMA specimens especially at elevated temperatures (in this case 50°C) is significantly lower than the stiffness of the adhesive, gluing the strain gauges over the complete length would prevent any deformation within this area. The method used in this study to attach only the end parts of the strain gauge to the

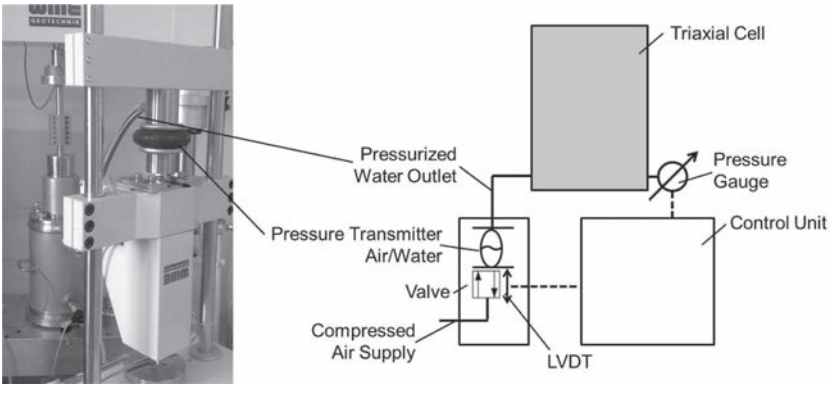

Figure 1. Principle of the pneumatic device to apply cyclic confining pressure.

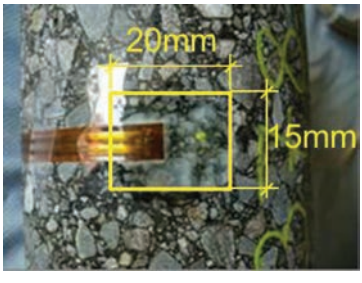

Figure 2. End of a strain gauge glued to an HMA specimen.

specimen is sufficient since radial deformation will only be positive in a purely compressive test. A study in [22] compares readings from strain gauges attached only at their end parts to readings from LVDTs and confirms correct measurements of strain gauges in the tensile domain. Figure 2 shows a detail of a strain gauge attached to an HMA specimen. The figure also contains information on the exact size (15 × 20 mm) of the glued area. To ensure that the glued area was the same for every specimen, the area was defined by marking its edges with adhesive tape prior to gluing the strain gauge.

4 MATERIALS AND TEST PROGRAM

4.1 *Materials*

For the present study an asphalt concrete with a maximum nominal aggregate size of 11 mm (AC 11) was used. The coarse aggregate used for the mixes is a porphyrite (specific gravity: 2830 kg/m³), the filler is powdered limestone (specific gravity: 2700 kg/m³). The binder is an unmodified bitumen 70/100 pen. The main characteristics of the binder are presented in the table in Figure 3. The optimum binder content according to Marshall is 5.3% by mass which was used for the mix. The target void content was set to 3.0% by volume. The grading curve is shown in Figure 3. The diagram also contains upper and lower limits for AC 11 mixes according to the national standard ON B 3580-1 [22]. The maximum density of the mix was determined to be 2564.0 kg/m³.

4.2 *Specimen preparation*

The complete process of specimen preparation from mixing and compaction to coring and cutting was carried out in accordance to the respective European Standards (EN). The mix was produced in a reverse-rotation compulsory mixer according to EN 12697-35 [24]. The mix drum as well as the mixing device are heated to ensure correct mix and compaction temperatures. Subsequent to the mixing process the material is compacted in a segment roller compactor according to EN 12697-33 [25]. Slabs compacted by the device have a base area of 50 × 26 cm and a variable height of up to 22 cm. The radius of the segment of 55 cm corresponds to the size of standard roller compactors used in the field.

The slabs were compacted to a target height of 13.0 cm in a displacement-controlled way. The complete slab was compacted in two layers hot on hot. Single-layered compaction leads to a large scatter of the density between upper and lower parts of the slab [26]. Since the maximum density is known as well as the target content of air voids, the target unit weight can be derived. The target unit weight and the target volume of the slab define the necessary mass of the material for compaction.

Parameter	70/100

Mixing Temperature [°C]	160
Compaction Temperature [°C]	135 - 160

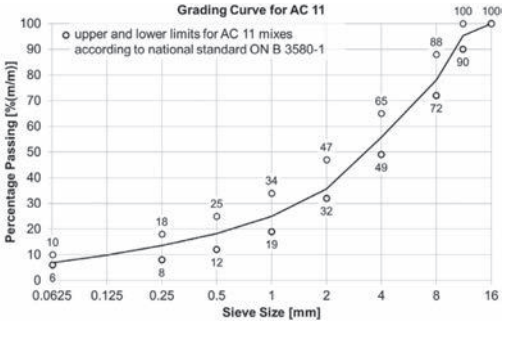

Figure 3. Main characteristics of the binder (left) and grading curve of AC 11 (right).

Table 1. Test program.

	Test conditions	$\sigma_{ax,l}$ [kPa]	$\sigma_{ax,u}$ [kPa]	$\sigma_{rad,l}$ [kPa]	$\sigma_{rad,u}$ [kPa]
Standard	50°C, 3 Hz, 25,000 load	150	750	150	150
Enhanced	cycles	150	750	150	250
		150	750	150	300
		150	750	150	350

From each slab, four specimens were cored out with a diameter of 100 mm. The obtained specimens were then cut to a height of 200 mm. Before the specimens were finally tested they were stored at the test temperature for at least 4 h but no longer than 7 h.

4.3 *Test program*

The test temperature was set to 50°C, the sinusoidal test frequency was set to 3 Hz. All tests were run for 25,000 load cycles. To introduce an enhanced TCCT with cyclic confining pressure, the radial phase lag $\phi_{ax,rad}$ between axial loading and radial deformation was determined in standard TCCTs. To study the impact of the amplitude of the confining pressure, enhanced TCCTs were carried out at three different amplitudes on three specimens for each amplitude. Table 1 shows the layout of the test program. The table presents the lower and upper value of the axial stress ($\sigma_{ax,l}$ and $\sigma_{ax,u}$) and the radial confining stress ($\sigma_{rad,l}$ and $\sigma_{rad,u}$). The lowest radial stress amplitude (i.e. the difference between upper and lower stress value) is 50 kPa, the other two are set to be 75 kPa and 100 kPa.

5 DATA EVALUATION

For the analysis of the periodic (sinusoidal) component of the test data a regression analysis was employed with the following function:

$$f(t) = a_1 + a_2 \cdot \sin(2\pi \cdot f \cdot t + a_3) + a_4 \cdot t \tag{1}$$

$f(t)$ Regression function of the periodic component of test data
a_1 Vertical offset of the regression function
a_2 Amplitude of the regression function
a_3 Phase lag of the regression function
a_4 Gradient of the linear term of the regression function
f Frequency [Hz]
t Time [s]

For the regression analysis the test data is split into individual sets of three oscillations. For each of these sets a regression analysis with the function shown above is carried out. The reason to take three oscillations for each analysis is to achieve a more robust and stable evaluation routine. The sum of square errors between test data and approximation function is aimed to become a minimum by systematically varying the parameters of the function. The quality of the approximation is described by the coefficient of determination R^2. If R^2 is below 0.95, the oscillation set is omitted from the subsequent data analysis since the deviation between approximation function and test data is considered too large. This regression is carried out for data from the axial load cell, the mean value of the two axial LDVTs, the data from the radial strain gauge and from the pressure cell recording confining pressure. The analytical functions of the periodic component are then used to calculate extreme values and from that the time lag between different sensor data to obtain phase lags between axial loading and radial deformation for all applied load cycles.

The non-periodic, axial deformation component for data from tests in the compressive domain can be described by a creep curve to assess the permanent deformation behavior.

To determine the permanent axial strain from the test data, the minimum axial strain value from the analysis of the periodic component of each load cycle is used to create the creep curve. Creep curves obtained from TCCTs according to EN 12697-25 can be divided into three different phases (Fig. 4):

- The primary phase (1): Within the first phase of a TCCT a certain amount of recompaction leads to decreasing slope of the curve with increasing number of load cycles.
- The secondary phase (2): The main phase of the TCCT is characterized by a quasi-constant slope of the curve.
- The third phase (3): Usually the standard TCCT does not reach this state where the deterioration of the specimen leads to an increase of the slope of the curve with increasing number of load cycles.

The axial strain is determined for the complete test and presented in a load-cycle-strain-diagram with linear scale for both axes. The secondary creep phase with a quasi-constant incline of the creep curve is approximated by the following linear function by using the method of least squares:

$$\varepsilon_{ax}(n) = A_1 + B_1 \cdot n \tag{2}$$

$\varepsilon_{ax}(n)$ Approximated function for permanent axial strain at the load cycle n [%]
A_1 Regression parameter describing the intersection of the approximation function with the y-axis (offset) [%]
B_1 Regression parameter describing the incline of the approximation function [%/load cycle]
n Load cycle

To define the secondary quasi-linear phase, the linear regression is used to approximate the creep curve starting between load cycles 1,000 and 20,000. If the coefficient of determination R^2 is below 0.98 for this range of load cycles, the lower load cycle limit for linear regression is increased in steps of 500 until R^2 is above 0.98. For all tests carried out in this study the load cycle range for the secondary phase was from load cycle 5,000 to 20,000.

The creep rate f_c is determined as the incline B_1 [%/load cycle] of the linear function in micrometers per meter (i.e. µstrain) per load cycle:

$$f_c = B_1 \cdot 10^4 \tag{3}$$

f_c is used to determine the resistance of a specimen to permanent deformation. The smaller its absolute value, the smaller is the increase of permanent deformation vs. load cycles.

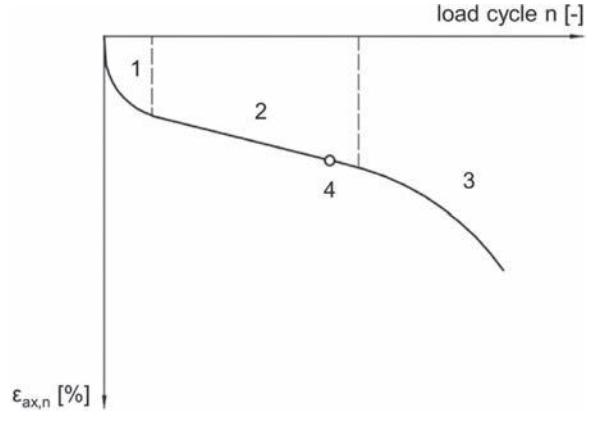

Figure 4. Example of a creep curve.

Thus, a smaller absolute value of f_c means that the resistance to permanent deformation is higher.

In addition the permanent deformation is also described by the total axial strain $\varepsilon_{ax,tot}$ after 10,000 load cycles. Since both, the axial and radial deformation is recorded for all tests, two strain components of the total axial strain, the volumetric and deviatoric strain component can be determined as follows: A cylindrical specimen shall have an initial height h_0, an initial diameter of d_0 and thus an initial volume of

$$V_0 = \frac{{d_0}^2 \pi}{4} \cdot h_0 \tag{4}$$

The change in height Δh_n and in diameter Δd_n with each load cycle n results in the volume

$$V(n) = \frac{\left(d_0 + \Delta d_n\right)^2 \pi}{4} \cdot \left(h_0 - \Delta h_n\right) \tag{5}$$

If the pure deviatoric part of the deformation (without any change in volume) shall be derived, $V(n)$ in the formula above has to be substituted by V_0 and solved for Δh_n which then becomes $\Delta h_{n,dev}$:

$$\Delta h_{n,dev}(n) = h_0 - \frac{V_0 \cdot 4}{\left(d_0 + \Delta d_n\right)^2 \cdot \pi} \tag{6}$$

This change in height can be converted to an axial strain component by dividing it by the initial height h_0. If the total axial strain is referred to as $\varepsilon_{ax,tot}$ then the deviatoric and volumetric strain component can be defined as follows:

$$\begin{aligned} \varepsilon_{ax,dev}(n) &= \frac{\Delta h_{n,dev}(n)}{h_0} \\ \varepsilon_{ax,vol}(n) &= \varepsilon_{ax,tot}(n) - \varepsilon_{ax,dev}(n) \end{aligned} \tag{7}$$

$\varepsilon_{ax,vol}$ volumetric part of the axial strain
$\varepsilon_{ax,dev}$ deviatoric part of the axial strain

6 RESULTS AND INTERPRETATION

6.1 *Analysis of phase lag $\phi_{ax,rad}$*

As a first step standard TCCTs with constant confining pressure were carried out on three specimens for the two mixes. Test data was evaluated in terms of phase lag $\phi_{ax,rad}$ between axial loading and radial deformation. Figure 8 presents an example of the evolution of $\phi_{ax,rad}$ vs. the number of load cycles for one specimen. For the evaluation of the phase lag, data from load cycle 500 on were considered since there is a strong change in the phase lag within the first 500 load cycles due to recompaction in the first phase of a TCCT. The grey lines show the actual test data, the black line the mean value of all data and the dashed black lines the 95% confidence interval. The confidence interval shows a scattering of around 6°.

For the further evaluation of $\phi_{ax,rad}$, data from the three single standard TCCTs were merged and statistically analyzed. Table 3 shows mean values of of $\phi_{ax,rad}$ as well as the 2.5% and 97.5% quantiles. The scattering of $\phi_{ax,rad}$ in terms of the 95% confidence interval is 12.8° for the tested mix AC 11 70/10. The mean value of $\phi_{ax,rad}$ serve as input values for the enhanced TCCTs to set the phase lag between axial loading and radial confining pressure and thus take into account the viscoelastic material response in the enhanced TCCT.

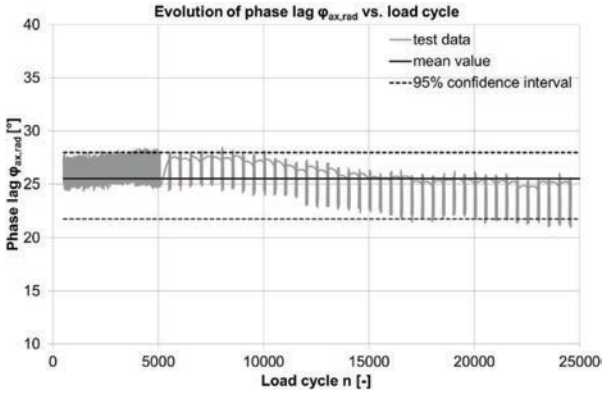

Figure 5. Evolution of phase lag between axial loading and radial deformation $\phi_{ax,rad}$ vs. number of load cycles for one specimen in standard TCCT (T_{test} = 50°C, f = 3 Hz, $\sigma_{ax,l}$ = 150 kPa, $\sigma_{ax,u}$ = 750 kPa, $\sigma_{rad,l} = \sigma_{rad,u}$ = 150 kPa).

Table 2. Phase lag $\phi_{ax,rad}$ derived from standard TCCTs (T_{test} = 50°C, f = 3 Hz, $\sigma_{ax,l}$ = 150 kPa, $\sigma_{ax,u}$ = 750 kPa, $\sigma_{rad,l} = \sigma_{rad,u}$ = 150 kPa).

97.5% quantile	27.6°

6.2 *Analysis of TCCTs with cyclic confining pressure*

Figure 9 gives an example of the recorded test data from an enhanced TCCT. It shows 3 oscillations of the axial stress on the top, the confining pressure in the middle and the resulting radial deformation on the bottom. The solid vertical line indicates a minimum of the axial loading, and the dashed line a minimum of the confining pressure. This demonstrates that the test machine is working correctly and the confining pressure actually lags behind the axial loading as set by the user. The extreme values of the confining pressure also coincide with the extreme values of the radial deformation. This shows that the chosen phase lag for the confining pressure taken from standard TCCTs is correct and accounts for the viscoelastic material response.

For the employed mix, three specimens were tested at each test condition. The air void content of the successfully tested specimens is listed in Table 3.

All tests were run at 50°C and 3 Hz for 25,000 load cycles and an axial stress amplitude of 150 kPa to 750 kPa. Different from the standard TCCT according to EN 12697-25 the radial stress amplitude is varied in three ranges. The test procedure starts from a hydrostatic state of stress on the low level where both the radial and axial stress are at the same level at 150 kPa. This pre-loading phase is held constant for 120 s. Then, the axial sinusoidal loading starts and with a well-defined time lag (i.e. the phase lag $\phi_{ax,rad}$) the confining pressure starts to oscillate sinusoidally as well. The stress applied to the specimen for each point in time t can be given as:

$$\sigma_{dev}(t) = \sigma_{ax,m} + \sigma_{ax,a} \cdot \sin(2\pi t) - [\sigma_{rad,m} + \sigma_{rad,a} \cdot \sin(2\pi t - \varphi_{ax,rad})] \quad (8)$$

σ_{dev} Stress deviator
$\sigma_{ax,m}$ Mean axial stress

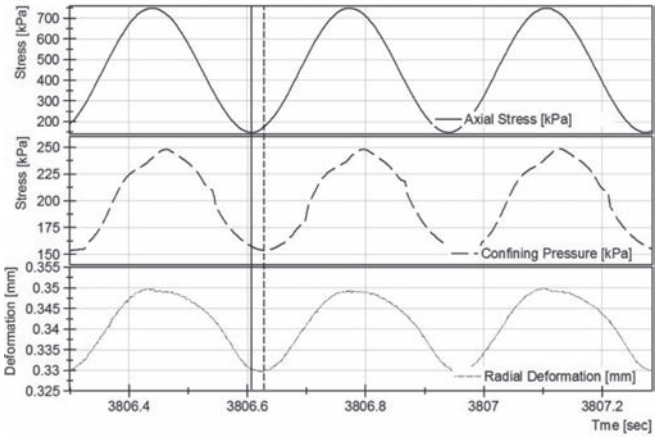

Figure 6. Example of recorded test data from enhanced TCCT for one specimen with cyclic confining pressure (T_{test} = 50°C, f = 3 Hz, $\sigma_{ax,l}$ = 150 kPa, $\sigma_{ax,u}$ = 750 kPa, $\sigma_{rad,l}$ = 150 kPa, $\sigma_{rad,u}$ = 250 kPa).

Specimen #2	2.8	2.7	–	3.0
Specimen #3	2.7	2.9	–	–
Mean value	2.9	3.0	2.7	3.3
Standard deviation	0.3	0.3	–	0.4

$\sigma_{ax,a}$ Axial stress amplitude
$\sigma_{rad,m}$ Mean radial stress
$\sigma_{rad,a}$ Radial stress amplitude

The expression above is also valid for standard TCCTs where the mean radial stress is set to 150 kPa and the radial stress amplitude is set to 0. One objective of the following investigation is to compare results from standard and enhanced TCCTs. To carry out this investigation, the stress applied on the specimen within one load cycle must be calculated to be able to compare different test conditions. Thus, equation (8) can be integrated over one oscillation period $T_p = 2\pi/f$, or since all tests were run at the same frequency over 2π. This number is equal to an impetus and is independent of the radial phase lag $\phi_{ax,rad}$. For the lowest radial stress amplitude from 150 kPa to 250 kPa a value of 500π results from the integration, for the medium amplitude of 450π and for the highest amplitude of 400π. The value for the standard TCCT with constant confining pressure is 600π.

For the enhanced TCCTs the phase lag between axial loading and radial confining pressure was set according to the results from standard TCCTs listed in Table 2. To check how well the given phase lag was controlled by the test machine throughout the test, the actual phase lag between axial loading and confining pressure was analyzed with regard to the time shift between both signals for each test and load cycle. Figure 7 shows these results for the three different test conditions. The diagrams show the mean value as well as the 95% confidence interval (light grey bar 2.5% quantile to MV, dark grey bar MV to 97.5% quantile) of the deviations between given and actual phase lag. At the lowest radial stress amplitude (Fig. 7 a)) all specimens were tested successfully. The worst deviation between given and actual phase lag is 9.6° or 5.3% (the basis is 180°). 97.5% of the test data show a lower deviation. At the

Figure 7. Phase lag between axial loading and radial confining pressure induced by the test machine vs. given value from the standard TCCTs with a confining pressure of 150 to 250 kPa (a), 150 to 300 kPa (b) and 150 to 350 kPa (c), (T_{test} = 50°C, f = 3 Hz, $\sigma_{ax,l}$ = 150 kPa, $\sigma_{ax,u}$ = 750 kPa).

second amplitude (150 kPa to 300 kPa, Fig. 7 b)) only one out of three tests ran successfully. The maximum deviation is similar to the tests with the lowest amplitude. Since the deviations were higher than expected, the test machine was optimized once more by adapting the PID (Proportional-Integral-Derivative) control of the pneumatic device responsible for the confining pressure. After this optimization the test series was continued. For the largest radial amplitude (150 kPa to 350 kPa, Fig. 7 c)) two specimens were tested successfully. The error of the actual to the given radial phase lag is below 2.7° or 1.5% in 97.5 out of 100 cases.

For the further analysis, it is of great interest, how the different radial amplitudes affect the results of TCCTs in terms of resistance to permanent deformation and if there are any differences between standard and enhanced TCCTs. For this reason, a number of diagrams compare the stress deviator to various parameters which describe the deformation behavior. The stress deviator multiplied by π is congruent to the impetus put into the specimen at each load cycle and thus a proper parameter to compare different test conditions. Each diagram in Figures 8 and 9 contains data from each single enhanced TCCT, highlighted in grey together with a linear regression. In addition, a 95% confidence interval was place around the linear regression. The confidence interval was derived by computing the relative error RE between each data point and the linear regression. In the following, the 2.5% and 97.5% quantiles were obtained for this relative error. These quantile values were then used to create the two confidence interval lines from the linear regression as follows:

$$f(x) = (a \cdot x + b) \cdot (1 + RE_{2.5\%})$$
$$f(x) = (a \cdot x + b) \cdot (1 + RE_{97.5\%}) \quad (9)$$

a slope of the linear regression
b Y-intercept of the linear regression
$RE_{2.5\%}$ 2.5% quantile of the relative error
$RE_{97.5\%}$ 97.5% quantile of the relative error

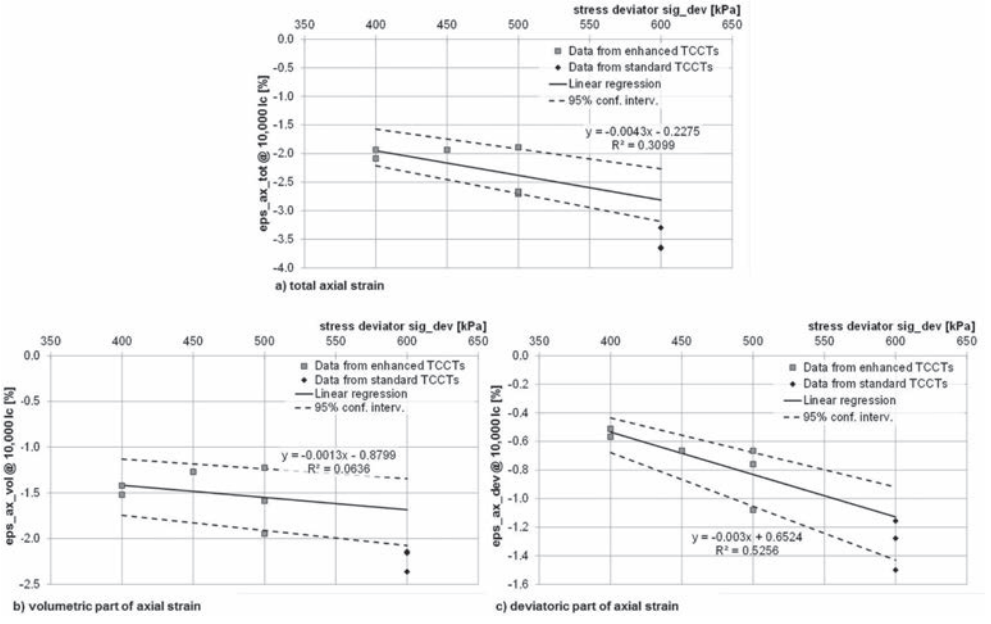

Figure 8. Total axial strain (a), volumetric axial strain (b) and deviatoric axial strain (c) at load cycle 10,000 in % at different stress deviators from standard and enhanced TCCTs (T_{test} = 50°C, f = 3 Hz).

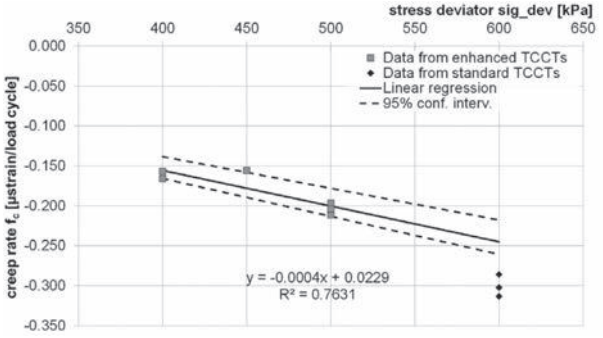

Figure 9. Creep rate f_c in µstrain/load cycle at different stress deviators from standard and enhanced TCCTs (T_{test} = 50°C, f = 3 Hz).

Data from standard TCCTs are also shown in the diagrams marked in black to compare enhanced TCCT to standard TCCT results.

Figure 8 shows a compilation of all test results from enhanced TCCTs in terms of axial strain at load cycle 10,000 vs. the stress deviator. Figure 8 a) shows the total axial strain. There is a decreasing trend with increasing stress deviator showing that a higher stress level leads to more deformation. Although the 95% confidence interval is quite large, the standard TCCT results in significantly more total axial strain (–3.5% vs. –2.8% from enhanced TCCTs) at comparable stress levels. Thus, specimens tested in the standard TCCT setup suffer 25% more axial strain than those tested under enhanced conditions at comparable stresses. This benefit of the enhanced TCCT can be explained by the fact that the viscoelastic material response of the material is taken into account by the radial phase lag. When the volumetric and deviatoric part of the axial strain are taken into consideration, it can be analyzed which strain component is affected by taking into consideration the viscoelastic material response.

Figure 8 b) and c) present the situation for the volumetric and deviatoric part of the axial strain. The scatter of results is quite large. It seems that the axial volumetric strain hardly depends on the stress level. This may be due to the high degree of compaction (3.0% by volume voids). The standard TCCTs (MV of $\varepsilon_{ax,vol}$ –2.2%) results in 32% more volumetric deformation than the prediction from enhanced TCCTs (–1.7%). From Figure 8 c) it is clear that the impact of the stress deviator on the deviatoric strain component is more significant. The standard TCCT results in a MV of $\varepsilon_{ax,dev}$ of –1.7% compared to a value of –1.3% from enhanced TCCT at the same stress level. The material exhibits 21% less deviatoric strain when tested with the enhanced test setup. It can therefore be stated that this mix reacts in a positive way (i.e. shows a better resistance to permanent deformation) when the viscoelastic material response is taken into account.

The same analysis is also provided for the creep rate f_c in Figure 9. The situation here is more significant since the scatter of results is less severe. The creep rate decreases with increasing stress deviator, showing—analogue to the total axial strain—that the material exhibits more permanent deformation when the stress level is increased. Again, it is obvious that the material contains a potential of better resistance to permanent deformation when the viscoelastic material response is considered in the TCCT. For the creep rate, standard TCCTs result in a MV of –0.301 µstrain/load cycle, enhanced TCCTs at the same stress level in a MV of –0.245 µstrain/load cycle (–19%).

7 SUMMARY AND OUTLOOK

Within the study presented in this paper cyclic confining pressure was introduced into the TCCT to simulate the state of stress that occurs in the field in a more realistic way. The results of standard and enhanced TCCTs are compared and interpreted. The main findings are summarized below:

- The pneumatic device developed for TCCTs with cyclic confining pressure was successfully employed in the study for the first time. After preliminary problems with the control of the target phase lag between axial loading and confining pressure (deviations of up to 9.6° between given and actual phase lag), a second optimization of the device was carried out. After that the error of the actual to given phase lag was around or below 4°. This is satisfactory when it is kept in mind that a scattering of $\phi_{ax,rad}$ of around 6° occurs when measured on specimens in standard TCCTs.
- An AC 11 70/100 was tested to show the impact of cyclic confining pressure with radial phase lag exemplarily. The total axial strain $\varepsilon_{ax,tot}$ after 10,000 load cycles decreases when the enhanced TCCT is compared to the standard TCCT with constant confining pressure at comparable stress levels. The tested mix suffers from 25% more axial strain in the standard TCCT.
- The volumetric strain component $\varepsilon_{ax,vol}$ is 32% higher in the standard TCCT and the deviatoric strain component $\varepsilon_{ax,dev}$ 21% higher in the standard TCCT. These findings can be explained by the fact that the viscoelastic material response is taken into consideration in the enhanced TCCT. This means that the maximum confining pressure is activated at the point of maximum radial deformation. Thus, the deviatoric strain component, which is the component responsible for changes in the shape of a specimen, decreases.
- The creep rate f_c is the benchmark parameter for the assessment of the resistance to permanent deformation in the European standard for production classification of HMA. The quality of a mix is defined by classes of the creep rate ($0.0 \le f_c < 0.2$, $0.2 \le f_c < 0.4$, $0.4 \le f_c < 0.6$, …). f_c decreased when specimens were tested in the enhanced TCCT. The tested mix shows a 19% lower creep rate compared to standard TCCT results.

Since only one mix was tested so far for this study, the significance of the findings is limited. Still, the potential of enhancing the TCCT not only by introducing cyclic confining pressure but especially by taking into consideration the viscoelastic material response with the radial phase lag $\phi_{ax,rad}$ for the cyclic confining pressure could be shown by the investigation.

Specimens tested in the enhanced TCCTs show a significantly higher resistance to permanent deformation. To create more findings and put the presented conclusions on a stronger basis, a future test program will take into account a variation of void content, gradation type and binder type and content of mixes. By expanding the test program, a sensitivity analysis will be carried out to quantify the impact of different mix design parameters on the ratio of results from standard vs. enhanced TCCT. Since the enhanced TCCT takes into account the viscoelastic material response and thus can be expected to simulate the field performance in a more realistic way, the larger test program will provide information on which mix design parameters have the largest impact on the performance and need to be taken into consideration for efficient mix design optimization.

ABSTRACT: To monitor field ageing of bitumen and hot mix asphalt closely, a test field has been constructed in September 2012. The test field consists of two mixes, an asphalt concrete with 11 mm maximum nominal aggregate size (AC 11) with an unmodified 70/100 pen and an SBS-modified PmB 45/80-65. Pavement temperature and weather conditions are recorded continuously. First HMA samples were taken from the test field after 6 and 12 months. The low-temperature performance by cooling (TSRST) and Tensile Strength Testing (UTST), as well as the viscoelastic behavior (dynamic modulus |E*| and phase lag φ) with temperature and frequency sweep are obtained. Results from unaged and field-aged specimens are compared. In addition, bitumen was extracted and recovered from HMA slabs to investigate field ageing. Penetration, Softening Point Ring & Ball, DSR tests with temperature and frequency sweep and BBR tests were run on fresh binder, lab-aged and field-aged samples.

This paper analyzes first data on the low-temperature behavior of binder and mixes. Significant differences start to occur after 12 months of field ageing on mix and binder level. A slight but non-significant adverse impact of double heating of the mix was found on the low-temperature behavior. Direct comparison of unmodified and SBS-modified mixes shows a 90% higher resistance to thermal cracking for the modified mix.

Keywords: field ageing; hot mix asphalt; performance based testing; low-temperature performance; master curve

1 INTRODUCTION

Bitumen as an organic material is subject to ageing due to thermal and atmospheric influences. When bitumen is used as a binder for hot mix asphalt as a paving material, its ageing can be divided into (a) short-term ageing during the mixing, transportation and compaction at the construction site and (b) long-term ageing in the field [1]. While short-term ageing is mostly affected by high temperatures during mix production within several minutes to hours, long-term ageing is a slow process taking several years. Ageing of bitumen leads to increased stiffness and brittleness of the material and has a major impact on the durability of pavement structures [2, 3]. Especially the low-temperature resistance to thermal cracking is reduced by bitumen ageing [4, 5].

While the process of short-term ageing of bitumen is well explained in literature by loss of volatiles and oxidation due to high temperatures and a large specific surface of the material while mixing [6], the mechanisms of long-term ageing are still subject to scientific

discussion [7–10]. The chemical mechanisms are not thoroughly understood yet and the influence of different possible ageing agents available in the atmosphere (e.g. oxygen, UV radiation, ozone, aqueous solutions) are not clear [11, 12].

Analogue uncertainties can be stated for lab methods to simulate ageing of bitumen and mixes. While the Rolling Thin Film Oven Test (RTFOT) is commonly used and seen as a capable tool to realistically simulate short-term ageing of bitumen, the Pressure Ageing Vessel (PAV) is also commonly used, but the question whether it simulates 1 year, 3 years or 5 to 10 years of field ageing has not been answered clearly [13–16]. Or rather, it depends strongly on bitumen, mix and location of the field ageing whether the PAV represents several months or several years of field aging. When it comes to methods to simulate ageing of HMA in the lab, various methods have been developed [17–20]. In all of them HMA specimens are stored at significantly higher temperatures than in the field to accelerate ageing. It is questionable from a chemical point of view whether the processes activated at elevated temperatures are the same as the processes occurring in field ageing.

Thus, a detailed investigation and long-term study of field ageing of HMA and bitumen is necessary to increase knowledge on the chemical processes and mechanical changes in binder and mix during field ageing, understand ageing mechanisms and improve existing methods to simulate long-term ageing of binder and mixes.

2 OBJECTIVES AND APPROACH

Since there is only a minor number of studies monitoring field ageing of bitumen and asphalt mixes over an extended period of time with short intervals between testing, the following objectives are aimed for in the on-going study of a test field laid in September 2012:

- Investigate the change in performance of binders and asphalt mixes due to field ageing versus time and depth (distance to the pavement surface)
- Link changes in the performance of bitumen due to ageing to changes in the performance of asphalt mixes
- Analyze the differences in ageing of unmodified and polymer-modified (styrene-butadiene-styrene SBS) binders
- Understand ageing mechanisms better by combining mechanical and chemical testing as well as multi-scale modeling
- Analyze the effect of winter maintenance (de-icing by applying NaCl) on ageing
- Employ results of the comprehensive investigations to optimize methods to simulate short- and long-term field ageing of binder and asphalt mixes in the lab.

To achieve these goals, the following approach is taken:

- Build a test field consisting of HMA slabs made from unmodified and SBS-modified binder.
- Install a weather station to monitor the most important meteorological data and thermal couples in various depths within the HMA slabs to monitor pavement temperature.
- Take slabs from the test field at predefined dates after construction. Cut and core HMA specimens from the slab to investigate mix performance. Extract binder from the mix to investigate binder performance by means of mechanical and chemical analysis.

This paper discusses first analyses on the effect of field ageing on the low-temperature performance of HMA with unmodified and SBS-modified binder, as well as the extracted binders themselves after 6 and 12 months of field ageing.

3 MATERIALS AND TEST PROGRAM

3.1 *Materials*

For the test field, two binders were used: An unmodified 70/100 pen (PG 58-22) and an SBS-modified PmB 45/80-65 (PG 76-22). To ensure comparability of the binders, the 70/100 pen

was the source for producing the PmB. The main characteristics of both binders are listed in Table 1.

An asphalt concrete with a maximum nominal aggregate size of 11 mm (AC 11) was used for the test field. The coarse aggregate used for the mix is a porphyrite, the filler is powdered limestone. The binder content was set to 5.4% by mass with a target void content of 7.0% by volume. The maximum density of the AC 11 70/100 was determined to be 2.594 kg/m³ and 2.566 kg/m³ for the AC 11 PmB 45/80-65. The grading curve is shown in Figure 1.

The mix for the test field was prepared in a commercial mixing plant with mixing temperatures of 160°C for the unmodified mix and 185°C for the modified mix, filled into bags of 25 kg and stored in the lab. In addition, samples of the fresh binders and the aggregates used for the mix were also taken and stored in the lab.

3.2 *Preparation of HMA slabs for the test field*

The test field consists of 72 single HMA slabs compacted in the lab. The reason for using lab compacted slabs instead of one uniformly compacted pavement prepared by a commercial compactor is mainly because a substantial amount (30 to 130 kg) of asphalt mix is taken every 3 to 6 months from the test field to monitor field ageing closely. Removing slabs from the test field is more efficient than taking up to 32 cores every 3 months.

For the preparation of the slabs, the plant-produced mix was pre-heated for 5 hours and compacted in a roller compactor according to EN 12697-33 [21] to slabs with dimensions $50 \times 26 \times 10$ cm. The radius of the roller segment of 55 cm corresponds to the size of standard roller compactors used in the field. The slabs were compacted with one lift.

3.3 *Test field*

The test field is located in Vienna, Austria (coordinates: 48.189866, 16.394048). The field can be divided into four parts: one section consists of AC 11 70/100, the other section of AC 11 PmB 45/80-65. In each of these sections, winter maintenance is simulated on one subsection by removing snow and spraying a 20% by mass NaCl brine on as needed. The other subsection is only taken care of in winter by removing any snow from the surface.

Table 1. Main characteristics (mean values) of binders.

Parameter	70/100 pen
Penetration [1/10 mm]	90.9
Softening point ring & ball [°C]	46.7
SHRP PG [°C]	58-22

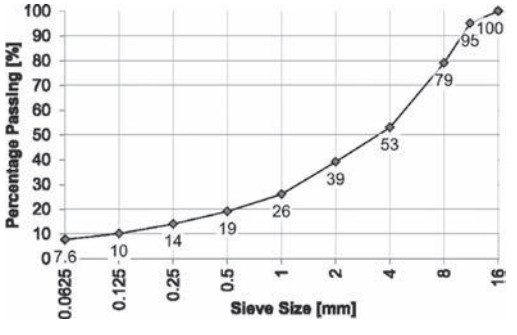

Figure 1. Grading curve of AC 11.

An aerial view of the test field is depicted in Figure 2a. Figure 2b shows a cross section of the test field. The slabs were laid on a drainage with a slope of 3%. The 1.0 cm joints between the slabs were filled with fine aggregates 0/2 mm and the joints were sealed by using hard bitumen 90/10 (5–15 1/10 mm penetration; 85°C–95°C softening point). Two slabs were instrumented with thermo couples in various pavement depths to monitor surface and pavement temperatures. One slab is situated in the section with winter maintenance, the other one in the section without winter maintenance. Figure 2c shows a profile of a slab with the position of the five thermo couples: One was situated in a groove on top of the slab and sealed with bitumen, the other four were put in depths of 1.25 cm, 3.75 cm, 6.25 cm and 8.75 cm. In addition a weather station in the vicinity of the test field records air temperature, humidity, precipitation, wind speed and direction and global solar radiation. All instruments record data with a rate of 6 values per hour (every 10 min).

As it can be seen from Figure 3 the test field is located on a non-trafficked part of the laboratory side. This means that the HMA is only exposed to loading due to weather and climate

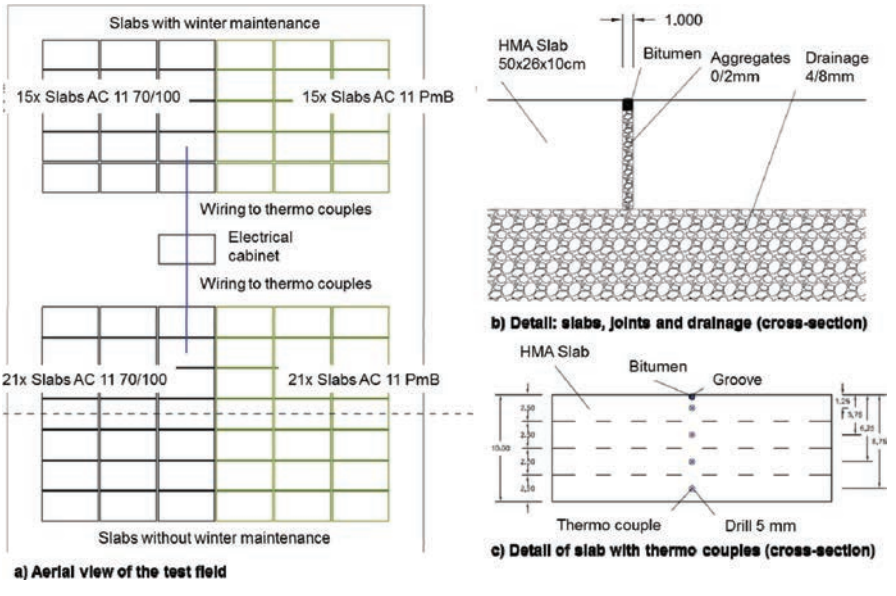

Figure 2. Details of the test field: a) aerial view, b) detail of slabs, joints and drainage, c) detail of instrumentation.

Figure 3. Photo of the test field with winter maintenance section (left), electric cabinet (center) and section without winter maintenance (right).

and no traffic loading or emissions from traffic are considered. Since the common understanding [6, 22] is that mainly climatic conditions (temperature, humidity, UV radiation) are responsible for bitumen ageing in the field, the lack of traffic on the test field is a minor setback. All slabs for the test field were produced in the lab in August and early September 2012 and the test field was laid on September 18th 2012. By June 2014 the test field will have been aged for 21 months.

Since no significant difference between slabs with and without winter maintenance can be found at this time, only data from slabs without simulated winter maintenance are taken into consideration.

3.4 *Specimen preparation for testing*

HMA specimens and bitumen samples are extracted from the test field at predefined dates after construction to monitor field ageing closely. For testing of the mix characteristics, the slabs with a height of 10 cm are cut into two halves to obtain HMA specimens from the upper and lower layer. Specimens are then obtained by coring and cutting, the dimension of the specimens as well as the bulk density is determined according to EN 12697-6 [23] and the void content according to EN 12697-8 [24].

For bitumen testing the slabs taken from the test field are cut into four layers with 2.5 cm each. For each layer, bitumen is extracted according to EN 12697-3 [32] with tetrachloroethylene (C_2Cl_4) as a solvent. The solvent-bitumen solution is distilled according to EN 12697-3 to recover the bitumen. The residual solvent in the recovered bitumen is determined by gravimetric analysis. Samples with a residual solvent content of larger than 0.5% by mass are discarded. By extracting one bitumen sample for each layer, ageing can not only be monitored versus time but also versus depth, i.e. distance to the surface.

3.5 *Test program*

Testing of HMA specimens consists of the following test methods:

- Thermal Stress Restrained Specimen Tests (TSRST) according to EN 12697-46 [25]. TSRST are carried out from an initial temperature of +10°C with a cooling rate of 10°C/h on prismatic specimens (50 × 50 × 200 mm). Results of TSRST are the cryogenic stress versus temperature $\sigma_{crack}(\tau)$ and the cracking temperature T_{crack} by triple determination.
- Uniaxial Tensile Stress Tests (UTST) according to EN 12697-46. UTST are run at temperatures of +5°C, –10°C and –25°C with a strain rate of 112.5 µstrain/sec. The tensile strength against temperature $\beta_t(\tau)$ is obtained from the test.
- The difference between cryogenic stress from TSRST and tensile strength from UTST gives the tensile strength reserve $\Delta\beta_t(\tau)$. It correlates to the stress that can be applied on a pavement by traffic loading in addition to the thermal stress at a certain temperature τ before failure [26].
- Direct Tension/Compression tests (DTC) are run at temperatures of –20°C, 0°C and +20°C and frequencies ranging from 0.1 Hz to 20 Hz according to EN 12697-26 [27]. From test data the norm of the complex modulus or dynamic modulus $|E^*|$ and the phase angle φ against temperature and frequency can be determined [28].

Table 2 gives an overview of the test program on HMA specimens. Since slabs for the test field were compacted in the lab from plant-produced mix (C_L000), the mix was heated twice for compaction. To compare the impact of double heating on short-term ageing, slabs were also produced from a lab-produced mix where fresh binder and aggregates were only heated once for compaction (C_F000). For slabs from the test field two series of specimens were obtained: one series from the upper 5 cm (upper layer UL) and one series from the lower 5 cm (lower layer LL). Up to now specimens from the lab-mixed slab, the plant-mixed slab and from the test field after 6 and 12 months have been tested. The paper contains results from low-temperature tests (TSRST, UTST).

Bitumen samples recovered from HMA will be subjected to various physico-chemical analytical techniques to supplement mechanical testing with a solid physico-chemical background. This holistic approach will provide the basis for the formulation of a new and enhanced ageing theory for bitumen. For mechanical testing the following methods are employed:

- Needle Penetration at 25°C according to EN 1426 [33]
- Softening Point Ring & Ball according to EN 1427 [34]
- Dynamic Shear Rheometer (DSR) tests with a temperature and frequency sweep according to EN 14770 [35]. At temperatures from −10°C to +30°C tests with the small plate (diameter: 8 mm) and a 2 mm gap are run, from +30°C to +80°C with the large plate (diameter: 25 mm) and a 1 mm gap. A frequency sweep between 0.1 Hz and 10 Hz is employed.
- Bending Beam Rheometer (BBR) tests according to EN 14771 [36] to assess the low-temperature behavior at −12°C, −18°C and −24°C.

Table 3 shows the test program for the binder samples. In addition to samples extracted from the test field, samples of the fresh binder (A), RTFOT-aged (B_LRTF) (according to EN 12607-1 [37]) and RTFOT + PAV-aged (C_LPAV) (according to EN 14769 [38]) binder are taken into account to compare lab to field ageing. Also, extracted samples from a lab-mix slab (C_L000), the plant-mix (B_F000) and the plant-mix slab (C_F000) are tested to investigate effects of double heating and compare lab to plant mixing. At this time all samples up to 12 months have been tested. This paper contains results from low-temperature testing (BBR) of the samples.

4 RESULTS AND DISCUSSION

4.1 *Weather data and pavement temperatures*

Since field ageing is crucially dependent on the climatic conditions of the test site, Figures 4 and 5 give details about the weather conditions from January 2013 to February 2014. The test field was constructed in September 2012, which is also the starting point for monitoring weather and pavement temperature. Due to malfunction of the data logger for the instrumentation, data is only available from the beginning of January 2013 on. Figure 4 shows a diagram with the temperature distribution of air, surface and pavement temperatures in various depths. On the right side in Figure 4, a table shows quantiles for the temperature distribution, as well as the absolute maximum and minimum of temperatures and the frequency by which certain temperatures were exceeded and undercut. The air temperature was below 0°C at around 12% of the time, and around 10% at the surface and in layer 1. Due to the thermal capacity of the material and the constant thermal flow from the subgrade, the frequency of lower temperatures decreases with lower layers to around 8% in layer 4. Although the air temperature did not exceed 40°C, the surface temperature of the test field was higher than 40°C in 9% of the time, and even exceeded 50°C (3%) and 60°C (0.4%). Even in layer 4, around 9 cm from the surface, the maximum temperature was 56.8°C.

Figure 5 shows the distribution of humidity (a) and precipitation [mm/24 h] (b) at the test site. In around 50% of the time the humidity is between 60% and 80%. No precipitation was recorded in 77% of the days, and a sum of 234 mm of rain was recorded between January 2013 and February 2014.

	Temperature [°C]					
Quantile [%]	Air Temperature	Surface Temperature	Layer 1 (1.25 cm)	Layer 2 (3.75 cm)	Layer 3 (6.25 cm)	Layer 4 (8.75 cm)

4.2 *Tests on HMA specimens*

4.2.1 *Cooling Tests (TSRST)*

According to the test program for HMA (Table 2), specimens were tested in TSRST before ageing (C_F000), after 6 months of ageing (C_F006) (after the first winter) and after the first year of ageing (C_F012). Since all slabs for field ageing were heated twice for mixing in the plant and then for compaction in the lab, additional slabs with identical mix design were produced completely in the lab by mixing fresh binder and aggregates in the lab and compacting it subsequently in the roller compacter. Thus, the binder was only heated once for the lab-mixed slab (C_L000). Differences between non-field aged plant-mixed slabs (C_F000) and non-field aged lab-mixed slabs (C_L000) show the impact of double heating on the performance of the HMA.

Figure 6a shows the air void distribution of AC 11 70/100 specimens tested in TSRST. The value given in the diagram is the mean value (MV), the bars show the 95% confidence interval based on the Standard Deviation (SD). Figure 6b shows the results of the statistical analysis of air void distribution. The numbers in the table give the significance according to the t-test [29]. The significance level was set to 5%. For values below 5% it is considered that the air void content differs significantly for the compared set of specimens. As it can be seen from Figure 6b, the specimens after 6 months of field ageing from the lower layer (C_F006_LL) are significantly different from all other specimens. This is in accordance with the data shown in Figure 6a. Thus, any differences in results from C_F006_LL may be due to differences in the volumetric composition of the specimens and will not be taken into consideration.

Figure 7 gives the results of TSRST for AC 11 70/100 specimens. The diagram shows the temperature at which the specimens fail due to cryogenic stress (T_{crack}) and the stress at cracking (σ_{crack}). Again, the given values represent the MV and the bars indicate the 95% confidence interval. As expected, the lab-mix (C_L000) produced better low-temperature behaviour than the plant-mix (C_F000) in terms of a 1.3°C lower T_{crack}. The results from 6-month field-aged specimens do not show large differences to the non-aged specimens. After 12 months of field ageing, the upper layer (C_F012_UL) seems to be affected stronger by ageing than the lower layer (C_F012_LL). The crack temperature on the UL is 2.6°C higher than on the LL. Interestingly enough, most of the field-aged specimens produce better low-temperature behaviour than the non-aged specimens from the plant-mix.

Table 4 presents results for the statistical analysis of TSRST results of AC 11 70/100. Again a significance level for the t-test of 5% is taken into consideration. Table 4a gives data for T_{crack}, Table 4b for σ_{crack}. The only significant difference can be found for T_{crack} between 12-month field aged specimens at the lower layer (C_F012_LL) and non-aged specimens (C_F000), as well as at the upper layer (C_F012_UL). It can be concluded from these results,

C_F012_LL						

that ageing starts to affect the low-temperature behavior significantly after a year of ageing. At this time, significant differences in terms of ageing time and distance of the material to the surface can be found. No significant differences were detected for σ_{crack}.

The same analysis as for the unmodified mix AC 11 70/100 is shown in the following for AC 11 PmB 45/80-65. Figure 8 shows data for the air void distribution of specimens for TSRST testing. As it can be seen from Figure 8b, the specimens after 12 months of field ageing from the upper layer (C_F012_UL) show significantly different air void distribution compared to all other specimens. Any differences found for these specimens will not be considered as significant since an influence of the air void content is possible.

Figure 9 shows results for the TSRST at specimens from the modified mix AC 11 PmB 45/80-65. Again, a small difference between lab- and plant-mix can be detected in terms of T_{crack}. The lab mix results in a 0.3°C lower crack temperature. All field-aged specimens show similar low-temperature behaviour compared to the non-aged specimens from the plant mix.

When the results for the polymer-modified mix (Fig. 9) are compared to the results of the non-modified mix (Fig. 7), the positive effect of the SBS modification on the low temperature behaviour becomes obvious. Since the SBS-modified binder can bear higher tensile stresses, the cracking temperature of the modified mix is about 8°C lower than of the non-modified mix.

Table 5 provides information on the significance of differences between the mixes for T_{crack} (a) and σ_{crack} (b). The statistically significant differences for 12-months field-aged specimens from the upper layer (C_F012_UL) cannot be taken into account since they also differ in their air-void content significantly from all other mixes. Specimens from the lower layer after 6 months of ageing (C_F006_LL) show a significantly better low-temperature performance than the non-field aged mix. Material that is further away from the surface is therefore not affected from ageing as much as material closer to the surface. The same can be said about the lower layer after 12 months of ageing (C_F012_LL).

4.2.2 *Combined analysis of cooling tests (TSRST) and Uniaxial Tensile Strength Tests (UTST)*

To explain the concept of combined analysis of TSRST and UTST, Figure 10 shows results of both tests for the plant-mixed (C_F000) AC 11 70/100 (a) and AC 11 PmB 45/80–65 (b). The diagrams contain data of the three single TSRST (light grey) and the MV of the TSRST (long dashed black line). The TSRST results give the thermally induced (cryogenic) stress versus temperature. In addition the single results (tensile strength) from UTST at different temperatures are shown by diamonds. The UTST results versus temperature are approximated by a quadratic function. The difference between UTST (tensile strength) and TSRST (cryogenic stress) is the tensile strength reserve ($\Delta\beta_t$), which is given by the small dashed black line. The higher the reserve is, the more stress additional to thermal stress can be applied to

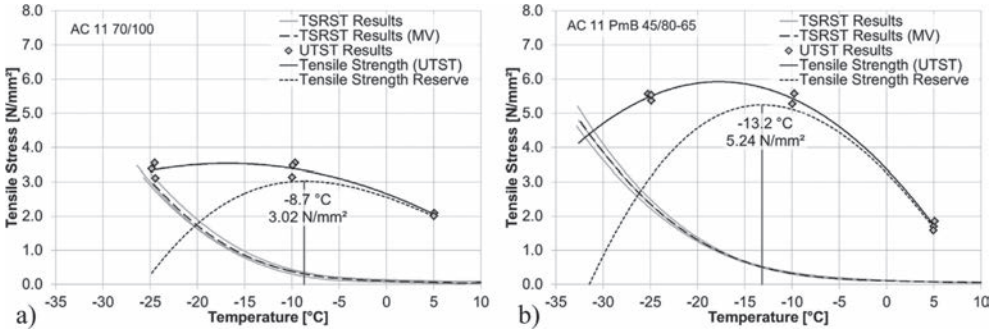

Figure 10. Combined results of TSRST and UTST for non-field aged (C_F000) AC 11 70/100 (a) and AC 11 PmB 45/80-65 (b).

the pavement (e.g. by traffic) before it fails due to cracking. The maximum strength reserve for the AC 11 70/100 occurs at –8.7°C and 3.0 N/mm² and at -13.2°C and 5.2 N/mm² for the AC 11 PmB 45/80-65 respectively. Thus, the modified mix shows a more than 70% higher maximum strength reserve. As another parameter to assess the resistance to thermal cracking the area between the x-axis and the tensile strength reserve curve from 0°C to the interception of the tensile strength reserve curve with the x-axis is introduced. This sums up the tensile strength reserve for the critical temperature range (< 0°C) to one single value. This Cumulative Tensile Strength Reserve (CTSR) is defined as follows:

$$\mathrm{CTSR} = \int_{\tau=I_{\Delta\beta t|x}}^{0°C} \Delta\beta_t \, d\tau = \int_{\tau=I_{\Delta\beta t|x}}^{0°C} \left(\beta_t(\tau) - \sigma_{cry}(\tau)\right) d\tau \qquad (1)$$

where

$I_{\Delta\beta t|x}$ left interception of $\Delta\beta_t$ with the x-axis ($\Delta\beta_t = 0$) in °C

$\beta_t(\tau)$ tensile strength from UTST as a function of temperature τ in N/mm²

$\sigma_{cry}(\tau)$ cryogenic stress from TSRST as a function of temperature τ in N/mm².

For the unmodified mix, CTSR comes to 59.8 N/mm²*°C and to 113.7 N/mm²*°C for the modified mix, which means a 90% higher resistance to thermal cracking for the modified mix. Since the mix design of both materials is the same, the higher resistance is due to the SBS-modification of the bitumen.

UTST were also carried out on specimens from the lab-mix (C_L000) to see differences between lab- and plant-mix (C_F000). In addition, UTST were run on specimens from slabs after 12 months of field ageing for upper and lower layers. Figure 11 presents results for the unmodified AC 11 70/100. Maximum tensile strength reserve and the temperature at which this maximum strength occurs are given in Figure 11a. The lab-mix indicates a 27% higher strength reserve at a 2.2°C lower temperature than the unaged plant-mix. Both values show that the low-temperature behavior is more favorable for the lab-mix. The results after 12 months of field ageing show only slight changes, the maximum strength reserve is around 10% higher for upper and lower layers compared to the unaged plant-mix.

Figure 11b compares the CTSR. Results are analogue to the maximum strength reserve. The lab-mix shows 31% better results than the plant mix. The 12-month field-aged specimens have a 10% higher CTSR.

Figure 12 shows the combined results of TSRST and UTST for the SBS-modified AC 11 PmB 45/80-65. The lab-mix shows a slightly better (+13%) performance in terms of maximum strength reserve (Fig. 12a) than the plant-mix. The 12-month field aged samples show a similar or slightly better performance than the non-aged mix as well. In terms of the CTSR (Fig. 12b), again, lab-mix and field-aged plant-mix show better results than the non-aged plant mix.

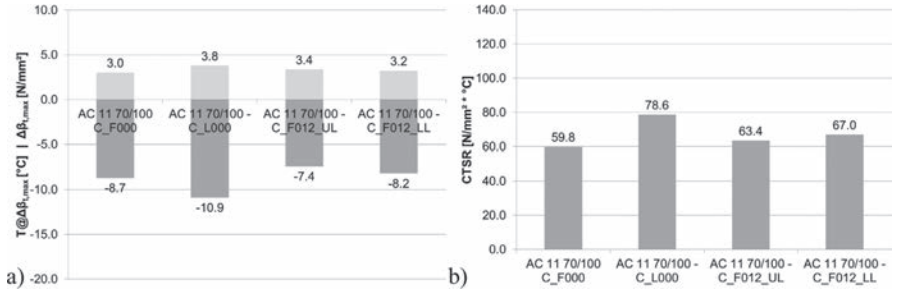

Figure 11. Combined results of TSRST and UTST of AC 11 70/100 for non-field aged slabs from plant mix (C_F000) and lab mix (C_L000) and after 12 months of field ageing for upper layer (C_F012_UL) and lower layer (C_F012_LL).

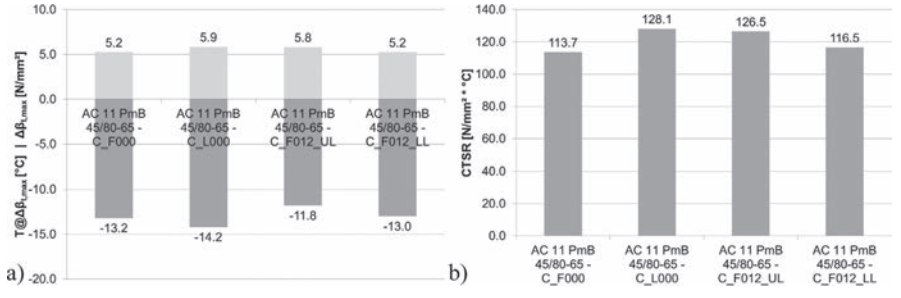

Figure 12. Combined results of TSRST and UTST of AC 11 PmB 45/80-65 for non-field aged slabs from plant mix (C_F000) and lab mix (C_L000) and after 12 months of field ageing for upper layer (C_F012_UL) and lower layer (C_F012_LL).

4.3 *Tests on binder samples*

To compare performance of the mixes to the performance of the binders, exact lower PGs were derived from Bending Beam Rheometer (BBR) testing according to the SHRP procedure. Therefore, the stiffness and the m-value of the binder were investigated after 60 s of testing versus test temperature. The temperature where the stiffness exceeds 300 MPa and the m-value falls below 0.3 was determined. The higher of both temperature values is taken to derive the lower PG by subtracting 10°C from the determined temperature value. The results are given in Figure 13a for the non-modified 70/100 and in Figure 13b for the SBS-modified PmB 45/80–65. The left three bars show the lower PG for the fresh, the RTFOT and the RTFOT+PAV aged binder, the middle four bars for the 6- and 12-month field-aged binders and the right three bars for binder samples extracted from different mix sources to compare lab- versus plant-mix. The results for the fresh and lab-aged samples are given as a reference.

When the non-aged binder from the plant mix (C_F000) is compared to the field-aged samples, it can be seen from both binder types, that the field-aged sample show only slightly worse lower PGs. In any case they cannot be seen as significant showing, that the first year of field ageing does not seem to have a crucial impact on the binder performance. Also, the differences between upper and lower layers of field aged samples do not differ strongly.

Different from the mix performance, where the benefit from SBS modification reflected in better low-temperature behavior, this cannot be stated for the binder performance to the same extent. In terms of lower PG, the SBS-modified binder results in only around 5% better values than the non-modified binder.

A better low-temperature binder performance can be found for the binder extracted from the once heated lab mix compared to binder extracted from the double heated plant mix for

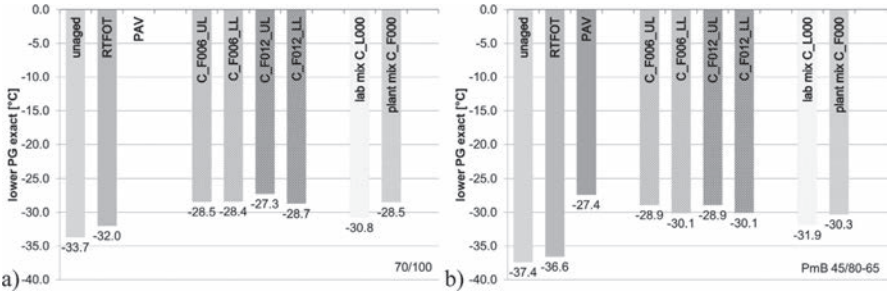

Figure 13. Exact lower PGs derived from BBR testing of binder samples from non-modified mix (AC 11 70/100) (a) and SBS-modified mix (AC 11 PmB 45/80-65) (b).

the non-modified 70/100 (Fig. 13a) where the lower PG is 2.3°C lower, as well as for the SBS-modified PmB 45/80-65 with a 1.6°C lower lower PG.

5 SUMMARY AND OUTLOOK

This paper contains first investigations on a test field to monitor field ageing of bitumen and HMA. The test field consists of 72 slabs ($50 \times 26 \times 10$ cm) from plant-mixed, lab-compacted HMA. Thermo couples and a weather station monitor pavement temperatures in various depths and most important climatic parameters. Two mixes (AC 11) are investigated: One mix is made from unmodified bitumen 70/100 pen, the other mix from PmB 45/80-65. The test field was constructed in September 2012. Thus, the material will have been aged for 21 months in June 2014. The focus of this paper is the low-temperature performance of field-aged mix and extracted binder after the first 12 months of field ageing in terms of cooling tests (TSRST) and tensile strength tests (UTST) for the mix and BBR tests for the binders.

All slabs for the test field were heated twice: once in the plant for mixing and another time in the lab for compacting (C_F000). To analyze the impact of double heating on ageing, slabs with lab-mixing and—compaction were produced for which the mix was only heated once (C_L000):

- Double-heated mixes (C_F000) resulted in a slightly worse low-temperature performance than lab-produced mixes made in the lab (C_L000). The non-modified mix showed a 1.3°C higher cracking temperature, the SBS-modified mix in a 0.3°C higher T_{crack}. These differences were not found to be significant.
- Combined analysis of TSRST and UTST in terms of maximum tensile strength reserve ($\Delta\beta_{t,max}$) and Cumulative Tensile Strength Reserve (CTSR) showed that the non-modified mix performed around 30% and the SBS-modified mix around 13% better when heated only once compared to double heating.
- The lower PG determined from BBR testing on the extracted binder from lab- and plant-mix confirmed the trends seen for the mix. Both binders show a better low-temperature performance, for the non-modified 70/100 the lower PG is 2.3°C lower when lab-mix is compared to plant-mix, for the SBS-modified PmB 45/80-65 it is 1.6°C lower.
- All analyzed data show that the effect of double heating is harsher on the non-modified binder with smaller impact on the SBS-modified binder.

The impact of field-ageing on the mix- and binder-performance was tested after 6 and 12 months of ageing:

- Regarding the cooling tests and resulting cracking temperatures, no significant difference were found after 6 months of field-ageing compared to non-aged samples for both mixes. Also, no difference between upper and lower layer was found after this period of ageing.

- After 12 months of field ageing, the difference in cracking temperature between upper and lower level is significantly different for the non-modified mix, the lower layer showing a 2.6°C lower (i.e. better) T_{crack}. Also, the difference between non-aged and 12-month field-aged lower layer results is significant for the non-modified mix. Interestingly enough, the lower layer after a year of ageing shows a better performance than the non-aged sample.
- Regarding the tensile strength reserve derived from combined analysis of TSRST and UTST only slight changes can be observed between non-aged and field-aged mixes with both binders. Interestingly enough, the low-temperature performance is 6% to 12% better for field-aged mixes. This is contradictory to the common understanding that the low-temperature performance decreases with increasing field ageing. Since the differences are rather small, no certain conclusions can be drawn from the results at this time. A better performance after one year of ageing could be linked to a stress relaxation phenomenon that occurs if the HMA slabs have time to rest after compaction. This is not the case for non-aged samples since they were tested around 5 days after production. Further investigation into this field have to be carried out to analysis this phenomenon in more details.

A direct comparison between non-modified and SBS-modified mix is sensible in this case since the mix design is the same for both mixes and the SBS-modified binder was produced from the same crude oil source as the non-modified binder. The benefit of SBS modification is obvious. The cracking temperature in TSRST is 8°C lower for the SBS-modified mix, the tensile strength reserve is 70% (maximum strength reserve) to 90% (cumulative strength reserve) higher. Interestingly enough, no significant differences can be seen in binder performance when comparing the lower PG derived from BBR testing.

Further results from Direct-Tension and Compression testing (DTC) on the mix and from traditional testing as well as DSR testing on the binder are still being analyzed. In addition, testing of specimens after 24, 36 and 60 months of field ageing is planned. Together with an in-depth analysis of bitumen samples extracted from the field-aged slabs, which will be analyzed by chemical methods, a better understanding of field aging is expected. Since winter maintenance is simulated on parts of the test field, the influence of de-icing by thawing salt will be investigated more closely in the further course of the study. The outcomes of this long-term study will help to optimize existing lab ageing methods for binder and mixes to simulate short- and long-term ageing in a more realistic way.

ABSTRACT: This paper presents the Advanced Shear Tester (AST) device capable of testing of 150 mm in diameter cylindrical samples in the shear mode. Samples can be either typical bi-layer pavement cores or solid gyratory compacted specimens. Validation of the AST design was performed on the Hot-Mix Asphalt (HMA) specimens prepared in laboratory conditions as well as cored from the asphalt pavement. For the comparison, the abbreviated triaxial test was conducted in order to determine the Mohr-Coulomb failure criterion of the HMA samples. The results demonstrated that monotonic strength tests in the AST device can be used to determine the Mohr-Coulomb failure envelope for solid HMA samples. Additionally, the AST can differentiate between different application rates of the interlayer bonding agent during the shear strength and shear fatigue tests. It was observed that the dissipated energy parameter from the fatigue testing is the most indicative of the application rate of the interlayer material.

Keywords: Asphalt pavements, shear properties, interlayer bond

1 INTRODUCTION

Proper bonding between different layers in the pavement structure provides an adequate bearing capacity of the entire structure and greatly influences its long term performance. Since the interlayer bonding is very important there has been numerous experimental procedures to examine the interface conditions. The first credited source for the HMA shear testing was Leutner [1]. Various modifications of this test have become standards in European countries and are used as interlayer performance measures [2]. The original procedure calls for a monotonic test on an unconfined asphalt specimen along its interlayer interface at a rate of 50 mm/min. Similar work reported by [3] emphasized the importance of the interface horizontal reaction modulus (K) and its relationship to shear stress and strain. Numerous studies since Leutner have developed new devices to look at the shear strength as means of optimizing interlayer bonding material (tack coat) in composite samples [4]–[10]. Further studies have explored unconfined shear tests as a means of differentiating or characterizing shear properties of the HMA [11]–[14]. Although, there is a large number of devices available, there is still a need to develop new protocols due to several important reasons discussed in details by [14]. Considering these issues, the Advanced Shear Tester (AST) was designed and manufactured. This paper presents only

selected aspects of the development effort so the specific emphasis was made on the following items:

– To present the design and main features of the AST,
– To report the validation process of the AST on the HMA samples.

2 ADVANCED SHEAR TESTER

The AST is an unique sample fixture that allows for the confined shear testing in the uniaxial load frame. The confinement load is applied via a system of sandwich plates connected by the specially selected four die springs (see Fig. 1). The initial confinement is set and then monitored by the in-line load cell. In terms of the shearing load, its history can be arbitrarily programmed by the closed-loop load frame system. It should be mentioned the AST allows for the bi-directional shear loading, i.e. a monotonic shear testing as well as bi-directional cyclic testing can be conducted. The AST was design with a relatively small foot-print and it can be placed in the 40 by 40 cm environmental chamber. However, all tests discussed in this paper were conducted at the room temperature (approx. 25°C) except for the cyclic tests that were performed at 35°C.

3 VALIDATION PROCESS

As the part of the development process, validation of the AST was performed on various HMA samples prepared both in the laboratory conditions as well as cored from the freshly

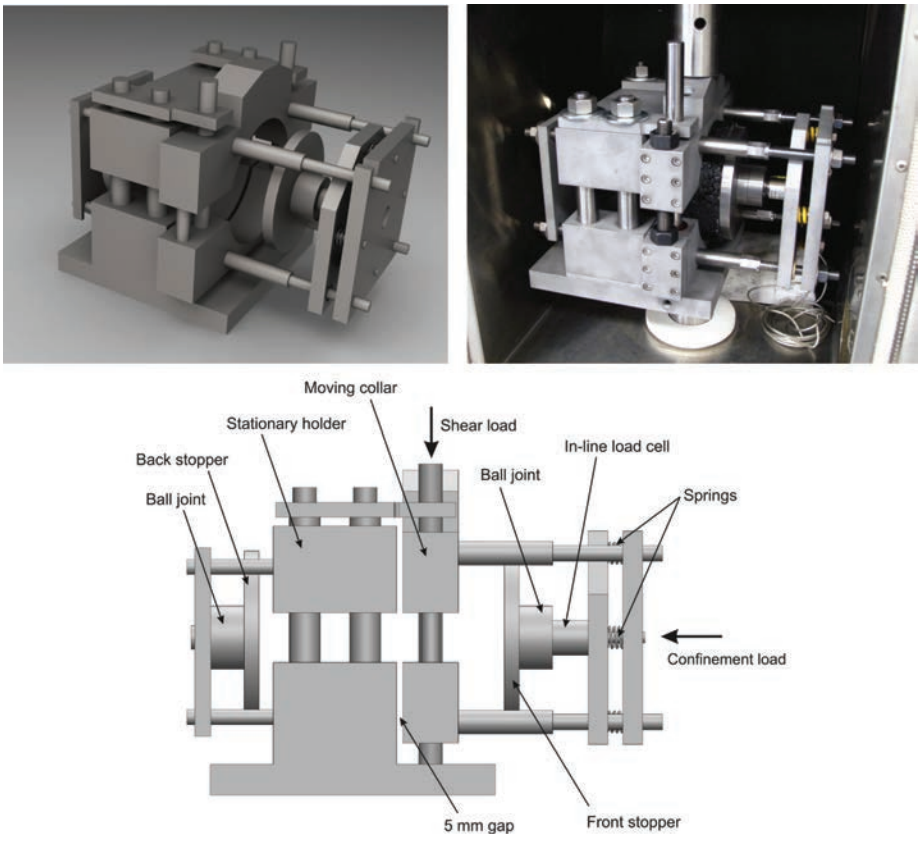

Figure 1. 3D model, image and schematics of the AST device.

constructed pavement section. The following paragraphs present the details on the materials/samples and experimental protocols.

3.1 *Experimental design—materials*

Validation effort comprised both laboratory- and field-prepared samples. In the laboratory, samples were prepared using gyratory compactor and two types of samples were used:

– Two (2) types of uniform samples that differed NMAS (9.5 mm and 12.5 mm).
– Four (4) types of bi-layer (composite) samples.

The laboratory composite specimens were fabricated in two steps. For 2 of the 4 treatments, the first 75 mm of compacted sample was left in the gyratory mold overnight to cure before an additional 75 mm layer was compacted on the top ("hot on cold"). The additional factor was the presences of a polymer-modified asphalt tack coat placed in between each level of the specimen as 50 g disk. For the other 2 treatments, the second layer was compacted immediately after the first layers were prepared ("hot on hot"). This difference was to simulate hot versus cold interfaces where either of those factors had tack coat present or absent.

The three field test sections had identical base and surface layers, both having 9.5 mm NMAS with varied amounts of tack coat at the interface. The control section was constructed without a tack coat, second treatment had a 'standard' tack coat application rate, 0.4 L/m^2 (0.1 gal/yd^2), and a third with a "heavy tack coat" application rate, 0.8 L/m^2 (0.2 gal/yd^2). The field effort amounted to 12 cores, 4 from each section (see Table 1) extracted using a 150 mm diameter diamond-impregnated coring bit. Tack coat application rates were verified by placing corrugated cardboard strips within the test sections and the weights were evaluated after a prolonged curing period.

3.2 *Experimental design—testing*

Uniform laboratory-prepared samples were examined in 3 experimental setups. Unconfined Compressive Strength (UCS) and Indirect Tensile strength (IDT) were used in order to construct Mohr-Coulomb (M-C) failure envelopes according to the abbreviated protocol for triaxial testing proposed by [15]. Uniform samples as well as composite samples were also tested in the AST in the simple shear mode (constant crosshead rate) (see Table 1 for experimental details). Additionally, composite field-prepared samples were examined in the AST under cyclic haversine loading (load-controlled). The loading amplitudes were set to 60% of the simple shear bond strength.

Table 1. Summary of validation effort.

Type	Treatment	# of replicates	Test performed
Uniform	9.5 mm NMAS	6	UCS[1], IDT[2],
	12.5 NMAS	5	AST (mono)[3]
Composite prepared in the laboratory	Hot on cold, w/o tack	6	AST (mono)[3]
	Hot on cold, w/tack	7	
	Hot on hot, w/o tack	7	
	Hot on hot, w/tack	7	
Composite cut from the field pavement section	No tack	4	AST (mono)[3]
	Normal tack	4	AST (cyclic)[4]
	Double tack	4	
Total HMA samples		50	

[1]UCS (unconfined compressive strength); 7.5 mm/min @25C.
[2]IDT (indirect tensile strength); 3.75 mm/min @25C.
[3]AST (mono) simple shear test in AST; 1 mm/min @25C; 1.5, 3 and 6 kN confining load.
[4]AST (cyclic) cyclic shear test in AST; 1 Hz w/0.7 s rest; @35C; 0.5 kN confining load; 14,400 cycles.

Table 1 presents a summary of all samples and corresponding treatments used in the HMA validation phase.

The results from the simple shear AST testing are reported on the M-C plane using shear stress at failure and corresponding normal stress. Additionally, as the alternative to the simple "shear strength" (i.e. shear load at failure over sample area), the mean peak (failure) stress parameter was determined using the following formula:

$$\sigma_m = \frac{\left(\tau_{peak} + \sigma_{peak}\right)}{2} \tag{1}$$

σ_m mean peak (failure) stress,
τ_{peak} shear stress at peak (failure),
σ_{peak} corresponding normal stress.

The results from the cyclic testing were reported in terms of two parameters:

1. Apparent secant modulus E_i and corresponding damage D_i.
2. Dissipated energy W_i.

Secant modulus E_i was defined as the ratio of the incremental increase in force and corresponding change in displacement during a loading part of a given fatigue cycle. Secant modulus E_i is a measure of material damage and it is typically used to plot damage D_i in the ith cycle as the fractional loss in the secant modulus from its initial value. The other parameter, dissipated energy W_i was calculated in each cycle as the area encompassed by the loop of experimental points in force-displacement space. After taking into consideration specimen geometry, the energy is expressed in J/m^2 and presented as a function of cycle number, similar to the dimensionless damage parameter D_i.

4 VALIDATION RESULTS

Figure 2 shows an example of two direct shear tests performed on 9.5 NMAS and 12.5 NMAS uniform GCS with 3 kN initial confinement load. The larger aggregate mix had a higher peak shear load and a higher residual shear load than the finer mix. Likewise, the confinement load monitored during the test increased significantly for the larger size mix. This was expected due to dilation of the larger aggregate particles on the shear interface that are forcing the sheared part to move further than the aggregate in the finer mix.

The results in Figure 3 display the average mean peak stress for each treatment of laboratory prepared specimens. It can be seen that the uniform specimens and cold specimens

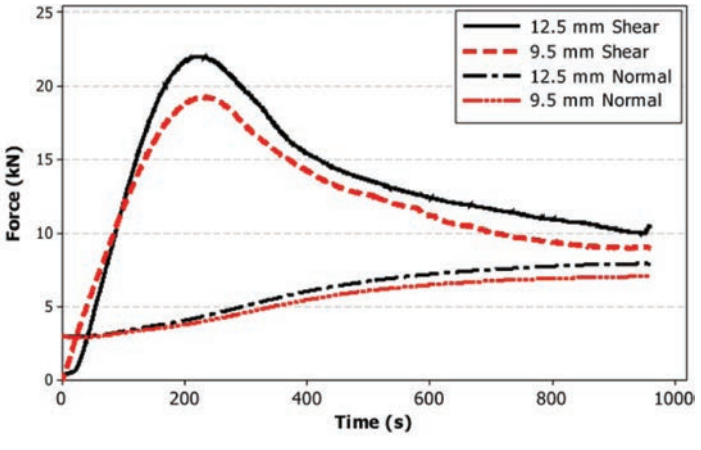

Figure 2. Typical force data measured in the AST.

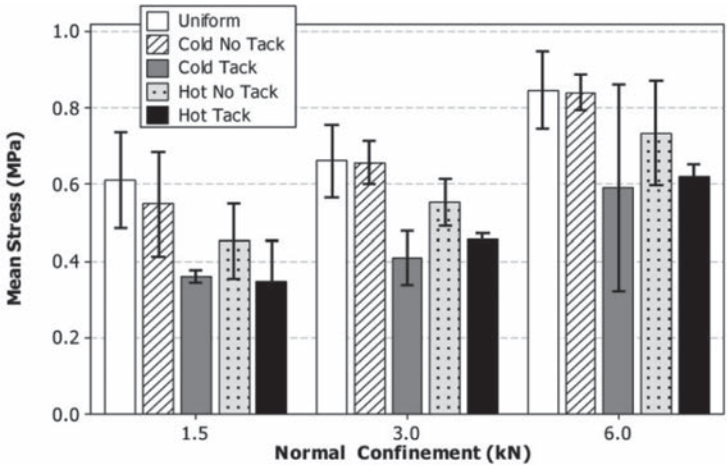

Figure 3. Mean peak stress for lab prepared samples (mean value and its 95% confidence interval).

Table 2. Summary of friction angle and cohesion for lab composite samples determined from AST.

Interface type	Friction angle (deg)	Cohesion (MPa)
Hot on cold, w/o tack	48.04	0.8827
Hot on cold, w/tack	40.81	0.4865
Hot on hot, w/o tack	50.47	0.6554
Hot on cold, w/tack	43.91	0.4708

Table 3. Summary of friction angle and cohesion for lab uniform samples determined from abbreviated 3-axial and AST.

	Friction angle (deg)	Cohesion (MPa)
Abbreviated 3-axial (UCS/IDT) (mean)	40.7	1.08
AST (mean and 95% confidence interval)	42.3 (13.8 to 57.5)	0.93 (0.76 to 1.11)

without tack produced similar results. Both treatments with the 50 g tack coat interface decreased the mean stress significantly which indicates the shear fixture is capable of differentiating between various interfaces. Table 2 provides a summary of friction angles and cohesion values for each interface type. It can be seen from the Table 2 that all four friction angles fall between 40 and 51 degrees. The cohesion followed no apparent pattern but, as suggested, was the most sensitive parameter. Analysis of Variance (ANOVA) for the means of each treatment was performed using Fisher Least Significance Difference (LSD). The LSD results support the expected outcome of the different treatments, i.e. hot and cold interfaces with tack coat had statistically equal mean peak stress values which would suggest the large amount of tack coat applied during fabrication would mask the effects of other parameters. The control specimens and the cold interface without tack coat were always statistically the same. The hot interface without tack was statistically different of the other treatments.

Table 3 shows the comparison of the M-C parameters (friction angle and cohesion) for the uniform GCS tested in the abbreviated 3-axial and the AST. It can be noticed that both protocols produced similar average values and observed variability in the AST should be further investigated in the larger experimental effort with various treatments.

Figure 4 indicates the mean stress at peak for the field-prepared samples. Statistical analysis showed that only the double tack coat group is different than the other two groups. Additionally, the values for the mean peak stress (and shear bond strength) obtained for the field samples were lower than corresponding values determined for the laboratory-prepared samples (shown in Fig. 3). Since the results from the simple shear testing were not sufficiently indicative of the tack coat application rate, the field samples were subjected to the cyclic loading in the AST fixture. It is believed that conceptually results from cyclic testing should translate the best to the actual field performance, especially under significant shear loads.

The evolution of the damage parameter as a function of cycle number for all three different interface treatments is presented in Figure 5. The results show similar trends in damage for all three types of interfaces. It seems that damage progresses at fairly constant rate for the "zero" interface whereas in case of the double tack coat" interface it accumulates quickly at the beginning of the fatigue testing and then levels out. The terminal values of the D_i parameters are similar and they are oscillating around 0.30 at 14,400 cycles.

Figure 6 shows the total accumulated dissipated energy from the cyclic testing in the AST. It can be easily observed that this parameter provides a clear distinction between different

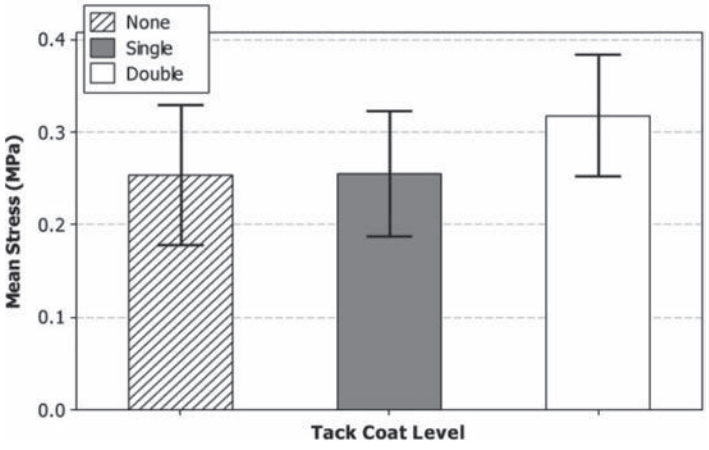

Figure 4. Mean peak stress for field composite samples (mean value and its 95% confidence interval).

interfaces. Since the fatigue results were obtained on single replicates, it needs further statistical verification but the large differences between total dissipated energies are very encouraging and are difficult to neglect. More research is planned to further examine these observations.

5 SUMMARY

The validation results reported in this paper show that the AST fixture can differentiate between various interlayer treatments as well as it can be used to examine shear properties of the solid samples. In particular, the results demonstrated that monotonic strength tests in the AST device can be used to determine the Mohr-Coulomb failure envelope for solid HMA samples. Additionally, the AST can differentiate between different application rates of the interlayer bonding agent during the shear strength and shear fatigue tests. It was observed that the dissipated energy parameter from the fatigue testing is the most indicative of the application rate of the interlayer material.

Although results presented in this paper were obtained on the limited number of samples, they are still encouraging and proved that the AST can be a valuable addition to the existing suite of the shear devices in the asphalt industry. More research is planned in order to further excel the capabilities of the AST and to employ it on larger experimental effort with diverse treatments.

ACKNOWLEDGEMENTS

The authors would like to thank University of Connecticut, Connecticut Department of Transportation and Tilcon CT, Inc. for supporting this study. The opinions and conclusions presented in this publication are not necessary of those entities and are only of its authors. The authors would like also to express a special appreciation to Prof. Andrew Drescher from the University of Minnesota for the valuable discussion and comments.

Effect of cooling rate on the thermo-volumetric, thermo-viscoelastic, and fracture properties of asphalt mixtures

Mohammad Zia Alavi & Elie Y. Hajj
University of Nevada, Reno, NV, USA

ABSTRACT: Thermal cracking of asphalt pavements has been known to be highly influenced by both the climatic conditions at the project location and the asphalt mixture properties. Hence, characterization of asphalt mixtures under thermal regimes is essential for appropriate selection of thermal crack resistant material. In this study thermo-volumetric, thermo-viscoelastic, and fracture properties of asphalt mixtures were evaluated by measurements of thermally induced stresses and strains under various cooling rates (2.5, 5, 10, and 17.5°C/hr). Dense-graded asphalt mixtures with two types of asphalt binders (unmodified and polymer-modified) were examined. Thermo-volumetric (i.e., coefficient of thermal contraction) and fracture properties were obtained directly from the thermal strain and thermal stress measurements, respectively. The thermo-viscoelastic properties at the viscous softening stage, viscous-glassy transition stage, glassy hardening stage, and crack initiation stage of the evaluated asphalt mixtures were determined from the evolution of the stiffness, i.e., modulus, as a function of temperature. The modulus was determined using the Boltzmann's superposition principle with the concurrent measurements of thermally induced stress and strain. The results showed that the fracture stress, fracture temperature, and thermo-viscoelastic properties of the evaluated mixtures were influenced by the applied cooling rate and the impact of cooling rate depended on the type of asphalt binder. The coefficient of thermal contraction was not significantly affected by the rate of cooling.

Keywords: Asphalt mixture, thermo-volumetric, thermo-viscoelastic, fracture, thermal stress, thermal strain, cooling rate

1 INTRODUCTION

The resistance of asphalt pavements to thermal cracking are generally influenced by asphalt mixture properties (e.g., thermal volumetric, viscoelastic, and fracture properties), environmental conditions (e.g., temperature, rate of cooling, pavement age), and pavement structure (e.g., interlayer characteristics) [1]. Therefore, an accurate characterization of asphalt mixtures is essential to appropriately model thermal cracking in asphalt pavements and/or in the selection of thermal cracking resistant mixtures. In the mechanistic-empirical design of flexible pavements, the frequency and amount of thermal cracking are estimated using the coefficient of thermal contraction, the relaxation modulus, and the tensile strength properties of the asphalt mixture.

The coefficient of thermal contraction of an asphalt mixture has been traditionally considered constant as a function of temperature within a reasonable range. It has been typically predicted for a given mixture from the volumetric coefficient of thermal contraction of the asphalt binder and aggregate [2]. However the dependency of the thermal coefficient of asphalt mixtures to temperature has been revealed by several researchers [3–7].

Although the direct approach for measuring relaxation modulus is theoretically sound, it is typically difficult to consistently run the test in the laboratory because of equipment control limitations. Therefore, the relaxation modulus is usually obtained by inter-conversion

from other viscoelastic functions, such as creep compliance or complex modulus, considering the materials must behave in the linear viscoelastic range [8–10].

In the case of the fracture properties of asphalt mixtures, several tests have been developed and used throughout the years such as single notch beam, SE(B) [11]; indirect tension, IDT [12]; semi-circular bend, SCB [13]; and the disc-shape compacted tension, DC(T) [14] tests. These tests provide the essential fracture mechanics properties, i.e., tensile strength and fracture energy, in order to characterize crack propagations in asphalt mixtures.

Overall, the aforementioned test methods utilize mechanical loading instead of thermally induced loading to determine the viscoelastic and fracture properties of asphalt mixtures at low temperatures. More precise designs of thermal crack resistant mixtures could be considered if the mixture properties were obtained by suitable thermally-induced loading conditions. Additionally, assuming the thermal coefficient of contraction constant at any temperature results in a thermally-induced strain that is linear at a constant cooling rate, which is contradictory to the basic properties of a viscoelastic material.

The Thermal Stress Restrained Specimen Test (TSRST), historically, was one of the few test methods which could describe the fundamental behavior of asphalt mixture under thermal loading. Relationships between the field cracking temperature and frequency have been observed with the results of the TSRST [15]. The original TSRST method is not in the current AASHTO standard methods. However, a European standard, EN 12697-46, for TSRST has been developed and is currently available [16].

In the earliest work done by Monismith et al. [17], an asphalt mixture beam was subjected to cooling at a rate of 4°C/hr. It was found that no thermal stress were developed in the specimen at the temperatures above 10°C and the measured stress was relatively small down to 0°C. Febb [18] used the TSRST to evaluate gap-graded asphalt mixtures with three cooling rates (5, 10, and 27°C/hr). It was observed that the fracture temperatures were independent of the cooling rate. Sugawara et al. [19] confirmed this finding by conducting the tests on beam specimens under different cooling rates (3, 6, 12, 18, 24, and 30°C/hr) and concluded that cooling rate does not significantly affect the fracture stress or temperature, if the rates were faster than 5°C/hr.

As a part of the Strategic Highway Research Program (SHRP), Jung and Vinson [1] were conducted extensive research on the effects of binder type, aggregate type, mixture air voids, aging levels, cooling rates, and specimen size on the low-temperature characteristics of asphalt mixture beams in the TSRST. All these factors were found to be significant. Correlations between cooling rate and TSRST results (i.e., fracture stress and temperature) were found to depend upon the asphalt binder type. Specimens with a stiffer binder exhibited no significant difference in fracture strength regardless of the applied cooling rate. For specimens containing softer binder, the fracture strengths were greater for faster cooling rates. For evaluated asphalt binder types, both the fracture and transition temperatures were warmer for higher cooling rates.

As part of the National Pooled Fund Study 776 [7], preliminary tests were conducted to evaluate the effect of cooling rate at 2 and 10°C/hr along with specimen shape, beam versus cylinder, on the TSRST. The study revealed that specimens subjected to the faster cooling rate had warmer fracture temperatures. However, the fracture stress did not follow the expected behavior, as it increased slightly with the decrease in the cooling rate. The specimen shape analysis observed that the cylindrical specimens had slightly lower fracture temperatures and higher fracture stresses when compared to beam specimens. Ultimately, the authors recommended additional studies to examine the effects of cooling rate and specimen geometry.

Tabatabaee et al. [20] evaluated the effect of cooling rate and physical hardening on the thermal build up stress and strain in asphalt mixtures. The stress and strain were measured continuously while conducting the test at various cooling rates and isothermal contraction periods (i.e., physical hardening). A slower increase in thermal stress was observed at lower cooling rates.

2 MOTIVATION AND OBJECTIVE

A new test method and associated analysis procedure has been recently introduced and used by the research group at the University of Nevada, Reno, in order to characterize

thermo-volumetric, thermo-viscoelastic, and fracture properties of asphalt mixtures [21, 22]. The calculation of these properties requires direct measurement, with good repeatability, of the thermally induced stress and strain. Therefore, improvements were applied to the conventional TSRST set up to increase the repeatability and to measure the thermal strain of asphalt mixtures from an unrestrained specimen. The enhanced set up is termed the Uniaxial Thermal Stress and Strain Test (UTSST). Details of the UTSST set up can be found in the literature [21, 22].

It is noted that the Asphalt Thermal Crack Analyser (ATCA) set-up has been simultaneously developed at University of Wisconsin, Madison which can also measure the thermal stress and strain while undergoing selected thermal history [23]. The results of the ATCA can also be analyzed in a similar fashion to the results of the UTSST. Ongoing collaborative research is being undertaken to standardize these test methods to analyze the low temperature cracking properties of asphalt mixtures as currently specified in a draft AASHTO standard procedure [24].

With the established test method and respective evaluation procedure, the effect of cooling rates on thermo-volumetric, thermo-viscoelastic, and fracture properties of asphalt mixtures will be evaluated in this study in an attempt to extend the previous knowledge which has been based solely on the fracture stress and temperature.

3 EXPERIMENTAL PLAN

Two types of dense graded asphalt mixture with nominal maximum aggregate size of 12.5-mm were evaluated in this study. The mixtures were fabricated using graded aggregate from the same local aggregate source, and two grades of asphalt binders: an unmodified PG64-22, and a Styrene-Butadiene-Styrene (SBS) modified PG64-28. The asphalt mixtures were designed following the Superpave volumetric mix design method, AASHTO M323, for a medium traffic level equivalent to 3–10 million ESALs. The binder content of mixtures with PG64-22 and PG64-28 were determined to be 5.8 and 5.5 percent by weight of total mix, respectively. After mixing, loose mixtures were subjected to short-term oven aging for 4 hours at 135 ± 3°C. The mixtures were then compacted using a Superpave gyratory compactor to a target air void of 8.0 ± 0.5%. Compacted samples were subjected to long-term oven aging for 5 days at 85°C in accordance with AASHTO R30. Specimens were long-term aged because thermal cracking is a long-term distress mode. Ultimately, two cylindrical specimens were cored from each Superpave compacted specimen perpendicular to the compaction direction (i.e., sideways), with a diameter of 57 mm and height of 135 ± 5 mm. This specimen geometry was found to improve the repeatability of thermal build up stress measurements significantly when compared to other geometries including traditional prismatic specimens, i.e., beams [25].

The mixtures were evaluated in the UTSST using four cooling rates of 2.5, 5, 10, and 17.5°C/hr and an initial equilibrium temperature of 20°C. The cooling rate of 2.5°C/hr is in the range of typically observed daily cooling rates in asphalt pavements [26]. The 10°C/hr is the commonly used cooling rate in the TSRST and the 17.5°C/hr was the fastest cooling rate that can be implemented in the laboratory. The 5°C/hr, according to the literature, was the cooling rate beyond which the fracture temperature and stress were not sensitive to the applied cooling rate [19].

It is noted that the TSRST is traditionally conducted by cooling from an initial temperature of 5°C, although the current European standard recommends 20°C as the initial equilibrium temperature. Asphalt mixture specimens must be conditioned at the initial temperature to reach thermal equilibrium before the start of the test. It should be noted that considerable physical hardening may happen to the asphalt mixture specimen if conditioned at 5°C. Moreover, the initial temperature of 20°C will provide the necessary data needed to examine the evolution of the asphalt mixture properties with temperature.

A total of two replicates for the restrained specimen were tested for each of the evaluated mixtures. In the case of thermal strain, the same unrestrained specimen was tested twice, once for each of the corresponding retrained specimen replicate tests.

4 METHODOLOGY

4.1 *Determination of thermo-volumetric properties*

The thermal contraction strain of the unrestrained specimen caused by the constant cooling rate is plotted against temperature; Figure 1. Then, the model proposed by Bahia et al. [27] and shown in Eq. (1) is fitted to the data.

$$\varepsilon_{th} = \frac{\Delta l}{l_0} = C + \alpha_g (T - T_g) + \ln\left\{\left[1 + e^{\frac{(T-T_g)}{R}}\right]^{R(\alpha_l - \alpha_g)}\right\} \quad (1)$$

where, $\Delta l/l_0$ is the relative change of length or thermal strain; C is intercept with no physical meaning; α_l and α_g are, respectively, the liquid and glassy coefficients of thermal contraction; T_g is glass transition temperature; and, R is the parameter representing the curvature between the two linear asymptotes. The glass transition temperature is determined at the intersection of the two linear portions of the curve in respect to the liquid and glassy coefficients of thermal contraction.

4.2 *Determination of thermo-viscoelastic and fracture properties*

The measured thermal build up stress can be related to the corresponding measured thermal build up strain using the uniaxial constitutive equation for linear viscoelastic materials, i.e., Boltzmann equation [9] as follows.

$$\sigma(t) = \int_0^t E_r(t - t') \frac{\partial \varepsilon(t')}{\partial t'} dt' \quad (2)$$

where, $E_r(t)$ is the relaxation modulus; $\sigma(t)$ is the thermal stress; $\varepsilon(t)$ is the thermal strain; and, t' is the variable of integration. In discrete form, the same Boltzmann equation can be written as:

$$\sigma(t_n) = \sum_{i=1}^{n} E(t_n - t_i) \times (\varepsilon(t_i) - \varepsilon(t_i - 1)) \quad (3)$$

where, n is the time index, and $\sigma(t_0)$ and $\varepsilon(t_0)$ are set to zero corresponding to initial test conditions. By considering the synchronized thermal stress and thermal strain, the modulus at each temperature can be derived from the discrete form of the Boltzmann constitutive equation as follows.

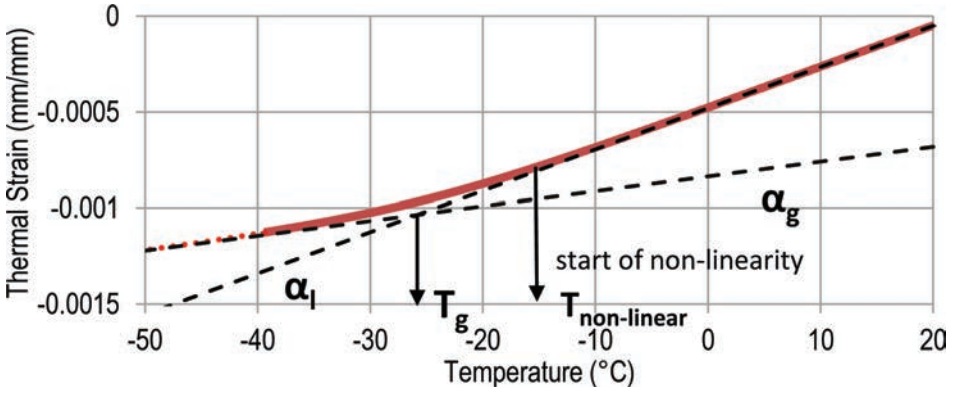

Figure 1. Determination of thermo-volumetric properties from thermal strain measurements.

$$E(T(t_n)) = \frac{(\sigma(t_{n+1}) - \sum_{i=2}^{n+1} E(t_{n+1} - t_i)(\varepsilon(t_i) - \varepsilon(t_{i-1})))}{\varepsilon(t_1)} \quad (4)$$

Figure 2a shows an example of the thermal stress and strain measurements for a typical asphalt mixture. Figure 2b illustrates the modulus curve determined from the thermal stress and strain measurements following Eq. (4).

Five characteristic stages describe the thermal behavior of the asphalt mixture as observed by changes in the stiffness, i.e., modulus, with temperature. These stages, briefly described as follows, can be identified mathematically by the second derivative of the relaxation modulus with respect to temperature [21, 22].

– **Viscous softening.** From this stage the relaxation modulus of the asphalt mixture increases rapidly, mostly in a linear fashion, with decreasing temperature (Fig. 2b). A considerable build up in thermal stresses is observed for temperatures colder than the viscous softening temperature.
– **Viscous-glassy transition.** At this stage the glassy properties of the material overcome the viscous properties (Fig. 2b).
– **Glassy hardening.** At this stage the relaxation property of the asphalt mixture mostly disappears and the material behavior becomes mainly glassy (Fig. 2b).

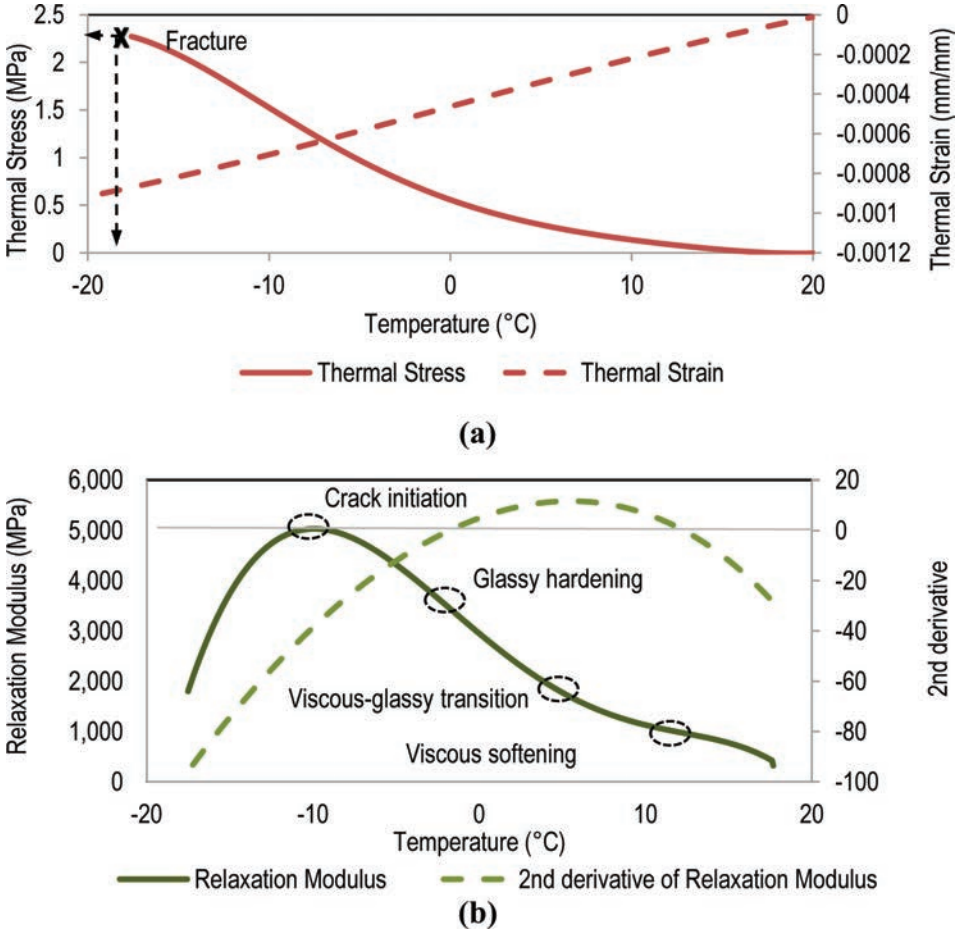

Figure 2. (a) measured thermal stress and strain; (b) calculated relaxation modulus and associated characteristic stages.

– **Crack initiation.** At this stage micro-cracks occur in the specimen due to the induced thermal stresses when the material behavior is glassy (Fig. 2b). Significant instantaneous decrease in the stiffness after this point can be related to the loss of specimen uniformity due to the initiation of micro-cracks.
– **Fracture.** At this stage a global failure occurs in the asphalt mixture specimen mainly due to the propagation of micro-cracks by the induced thermal stresses (Fig. 2a).

5 TEST RESULT AND DISCUSSION

Figure 3 shows the average thermal stress, percentage change in thermal stress, thermal strain, and modulus curves for the evaluated mixtures at the various cooling rates. Examining the data in Figure 3, the following general observations can be made:

– Thermal build up stresses were generally slightly higher for the faster cooling rates as observed for both PG64-22 and PG64-28 mixtures. The percent change in thermal stress for 5, 10, and 17.5°C/hr cooling rates compared to the thermal stress at 2.5°C/hr, are shown for both asphalt mixtures.
– The thermal stress was higher and started to build up at warmer temperatures for the PG64-22 mixture when compared to the PG64-28 mixture, regardless of the cooling rates. The polymer-modified PG64-28 mixture had higher potential for relaxation under cooling events which resulted in lower stress build up and reaching fracture at considerably colder temperatures.
– The change of thermal strain with temperature does not seem to be strongly affected by the cooling rates regardless of the binder type. Overall, the average percent differences in thermal strains at cooling rates of 5, 10, and 17.5°C/hr compared to the 2.5°C/hr were not less than 10% for both mixtures.
– The thermal strains for the PG64-22 and PG64-28 mixtures were generally similar in magnitude.
– The modulus at a given temperature was found to be higher for faster cooling rates, i.e., 10 and 17.5°C/hr. The lowest values for the modulus were observed at the cooling rate of 5°C/hr for both mixtures. The difference in modulus was more noticeable in the case of the PG64-22 mixture.
– The modulus of the PG64-22 mixture was higher than the PG64-28 mixture at temperatures between 20 to –15°C. However, the maximum observed modulus for the PG64-22 mixture was lower than that of the PG64-28 mixture. It should also be noted that, for the various cooling rates, the maximum modulus occurred at considerably colder temperatures in the case of the PG64-28 mixture as compared to the PG64-22 mixture. The substantial relaxation potential of the polymer-modified PG64-28 mixture provided the mixtures with the ability to tolerate colder temperatures before fracture.

5.1 *Effect of cooling rate on thermo-volumetric properties*

The thermo-volumetric properties of asphalt mixtures including liquid and glassy coefficient of thermal contraction, and glass transition temperature, where determined from fitting Eq. (1) to the thermal strain versus temperature data. In addition to these parameters, the temperatures at which the evolution of thermal strain with temperature deviates from linearity were determined and named, $T_{non\text{-}linear}$. This temperature may describe the initiation of glassy properties. The average values of these thermo-volumetric properties for various cooling rates are shown in Table 1. The following observations can be made:

– The glassy coefficients of thermal contraction, α_g, were at least 1.5 times smaller than the corresponding liquid coefficients of thermal contraction, α_l. This observation reveals that considering constant value for coefficient of thermal contraction, irrespective of temperature, may cause significant errors in the prediction of thermal build up stresses.

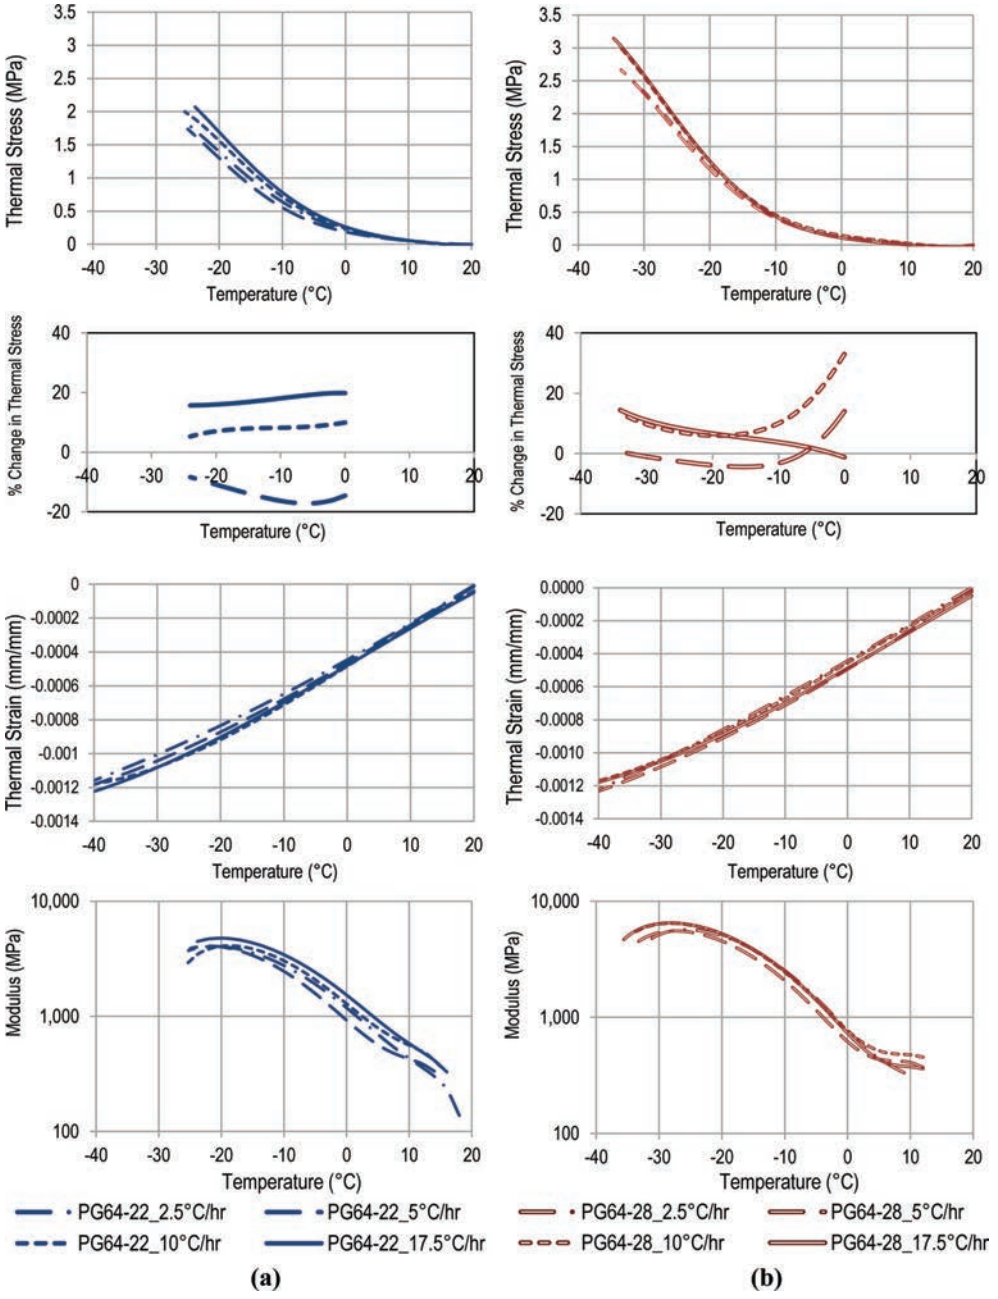

Figure 3. Thermal stress, percentage change in thermal stress, thermal strain, and modulus under various cooling rates for (a) PG64-22 Mixture; (b) PG64-28 Mixture.

- The liquid coefficients of thermal contraction, α_l, were not found to be affected by the evaluated cooling rates.
- The glassy coefficient of thermal contraction, α_g, slightly decreased with the increasing cooling rate except for the PG64-22 mixture at 17.5°C/hr.
- The glass transition temperatures, T_g, for both asphalt mixtures were found to be around –26 ± 1°C for various cooling rates.

Table 1. Thermo-volumetric properties of asphalt mixtures under various cooling rates.

Cooling rate (°C/hr)	α_l (1/°C)		α_g (1/°C)		T_g (°C)		$T_{non\text{-}linear}$ (°C)	
	PG64-22	PG64-28	PG64-22	PG64-28	PG64-22	PG64-28	PG64-22	PG64-28
2.5	2.26E-05	2.22E-05	1.06E-05	1.33E-05	–25	–25	–9	–14
5	2.35E-05	2.23E-05	1.02E-05	1.25E-05	–27	–24	–10	–14
10	2.37E-05	2.23E-05	6.48E-06	1.00E-05	–27	–27	–11	–15
17.5	2.15E-05	2.20E-05	7.55E-06	9.52E-06	–26	–27	–10	–15

– The deviation from the linear portion of thermal strain (i.e., $T_{non\text{-}linear}$) occurred at colder temperatures for the PG64-28 mixture (around 4°C colder on average). This temperature, $T_{non\text{-}linear}$, was not considerably affected by the cooling rate. The colder $T_{non\text{-}linear}$ for the polymer-modified PG64-28 mixture indicates a higher relaxation potential under thermal loadings.

5.2 *Effect of cooling rate on thermo-viscoelastic and fracture properties*

Table 2 summarizes the thermo-viscoelastic and fracture properties calculated for the individual replicates of the various evaluated mixtures and cooling rates.

5.2.1 *Thermo-viscoelastic properties*

Figure 4 shows the change in the average thermo-viscoelastic properties of the evaluated asphalt mixtures as a function of cooling rate. The following observations can be made:

– Based on Figure 4a, the viscous softening modulus of the PG64-22 and PG64-28 mixtures increased with the increase in cooling rate to reach a maximum value at 10°C/hr beyond which a decrease in the viscous softening modulus was observed. No considerable change in the viscous-glassy transition modulus as a function of the cooling rate was observed for both mixtures. The PG64-22 and PG64-28 mixtures exhibited different trends for the change in moduli at the glassy hardening and crack initiation stages as a function of cooling rates. The glassy hardening and crack initiation moduli of the PG64-22 mixture decreased with the increase in cooling rate up to the 10°C/hr, after which the moduli increased with the faster cooling rate. On the contrary, the glassy hardening and crack initiation moduli of the PG64-28 mixture increased with the increase in cooling rate up to 10°C/hr, after which a decrease in the moduli values was observed with the faster cooling rate.
– Based on Figure 4b, the viscous softening temperatures of both asphalt mixtures were not considerably affected by the change in the cooling rate. The effect of cooling rate appeared on the other thermo-viscoelastic stages. It was attractive to observed that the effect of cooling rate on these thermo-viscoelastic properties were different in respect to the mixture type. The PG64-22 mixture reached the viscous-glassy transition, glassy hardening, and crack initiation stages at warmer temperatures with the increase in cooling rate. On the other hand, the PG64-28 mixture exhibited colder temperatures for the various stages with the increase in cooling rate. Furthermore, it was observed that the glassy hardening temperatures which were obtained from the curvature of the relaxation modulus and the temperatures at which non-linearity occurs in the thermal strain measurements, $T_{non\text{-}linear}$, were relatively similar (Fig. 4c).

5.2.2 *Micro-crack and fracture properties*

Figure 5 shows the relationship between the cooling rate and average fracture properties of the asphalt mixtures. The following observations can be made.

– The effect of cooling rate on the fracture and crack-initiation stresses was mixture dependent. For the PG64-22 mixture, these stresses decreased with the increase in the cooling rate

Table 2. Thermo-viscoelastic and fracture properties of asphalt mixtures under various cooling rates.

*T. = Temperature, **St. = Stress, and + Mod. = Modulus

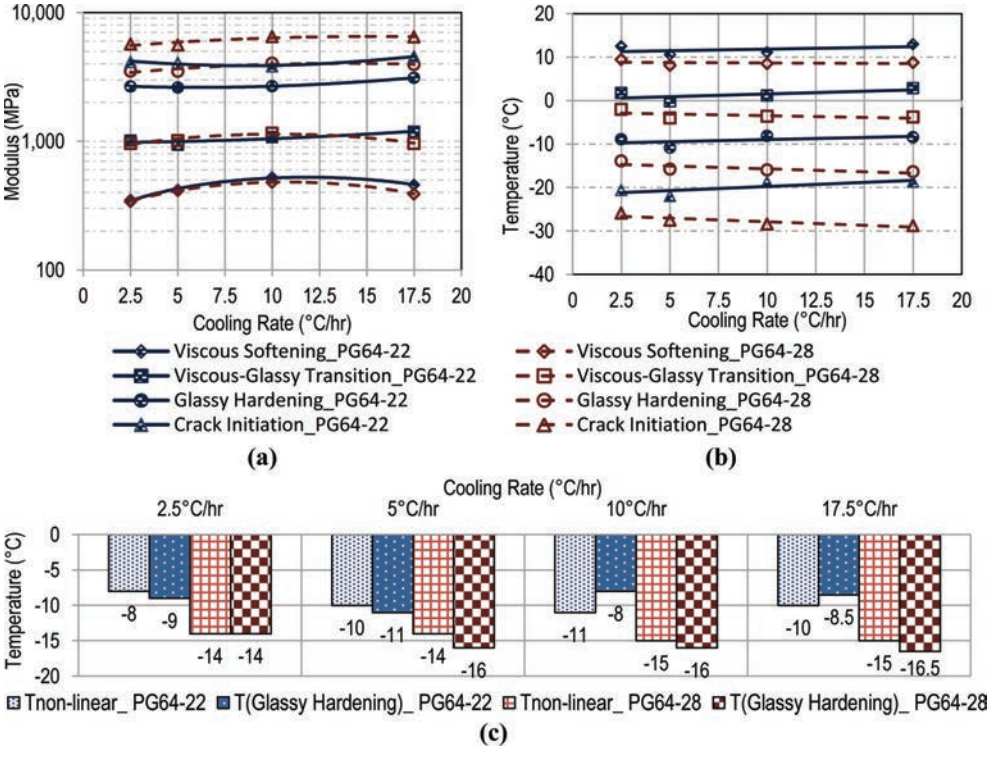

Figure 4. Thermo-viscoelastic properties of asphalt mixtures.

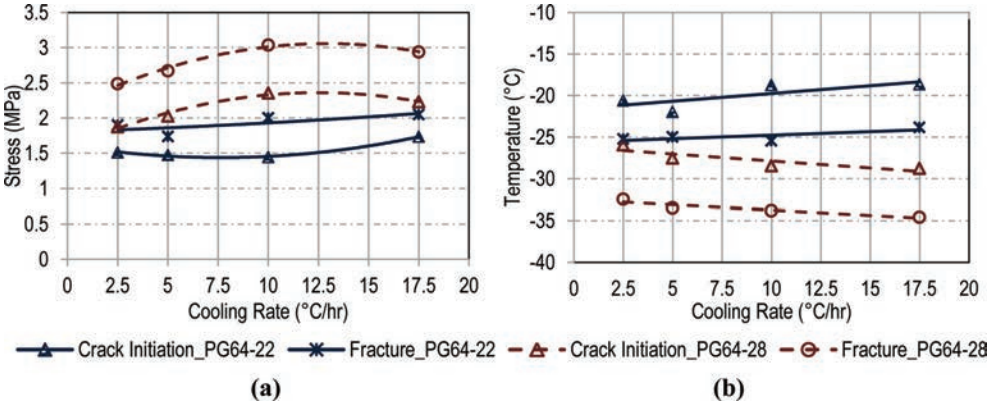

Figure 5. Fracture properties of asphalt mixtures.

up to 10°C/hr beyond which an increase in the stresses was observed for the 17.5°C/hr. Conversely, an increase in the fracture and crack initiation stresses was observed for the PG64-28 mixture with the increase in cooling rate up to 10°C/hr, beyond which the stress values decreased with the 17.5°C/hr.

– In the case of PG64-22 mixture, the fracture and crack initiation temperatures increased (i.e., warmer) with the increase in cooling rate. The opposite behavior was observed for the PG64-28 mixture.

– It is worth to note that in the case of both mixtures, the micro-crack temperatures obtained from the analysis of the modulus at various cooling rates were in the volumetric transition zone of the thermal strain between the liquid and glassy contraction.

Generally, the effect of cooling rate on the thermo-viscoelastic, crack initiation and fracture properties of asphalt mixture depended on the asphalt binder type, i.e., unmodified versus polymer-modified. A study covering additional asphalt binders would assist clarifying the impact of polymer-modification on the thermal behavior of asphalt mixtures.

6 SUMMARY AND RECOMMENDATIONS

In summary this paper evaluated the effect of cooling rate on the thermo-volumetric, thermo-viscoelastic, and fracture properties of two asphalt mixtures using a recently developed test method and analysis procedure at the University of Nevada, Reno. To measure such properties the thermal stress and strain of an asphalt mixture were measured from, respectively, restrained and unrestrained specimens using the Uniaxial Thermal Stress and Strain Test (UTSST), developed at the University of Nevada, Reno. The concurrent measurements of thermal stress and strain were obtained by cooling the specimen from an initial temperature of 20°C at a rate of 2.5, 5, 10, and 17.5°C/hr. In general, it was found that the cooling rate influenced the thermo-viscoelastic and, to a higher level, the fracture and crack-initiation properties of the mixtures. The effect of cooling rate on thermo-viscoelastic and fracture properties were found to depend on the asphalt binder property, i.e., unmodified versus polymer-modified. The effect of cooling rate on the thermo-volumetric property (i.e., coefficient of thermal contraction) was not found to be significant for the evaluated mixtures.

In summary the UTSST showed lower thermal stress build up, lower stiffness, and colder glassy hardening, crack initiation, and fracture temperatures for the PG64-28 asphalt mixtures. These observations can be related to the potential field performance of the asphalt mixture especially that the polymer-modified PG64-28 has historically been outperforming the performance of the unmodified PG64-22 asphalt binder in terms of thermal cracking in the state of Nevada.

The understanding of the characteristics of the asphalt mixture in terms of its thermo-volumetric, thermo-viscoelastic, and fracture properties is an important step toward improved mix designs of thermal crack resistant mixtures. It is recommended that the study be repeated to include asphalt mixtures with different binder sources, binder modifications, aggregate types, and recycled material, possibly with field performance history of the mixtures, to better understand their effect on the mixture resistance to thermal cracking.

ABSTRACT: The cavities under the asphalt pavement cause unexpected collapse accidents due to repeated traffic load or the influence of temperature. So, the early detection and rapidly repair of cavities under the pavement are essentially to ensure the safety of user. In the usual case, the cavity is often found around the underground structure. The mechanism of cavities under the pavement has been investigated from site to site based on ground conditions and influence of the underground structure. But the detail mechanism is not well known.

In this study, the tendency of cavities under the pavement caused by "The 2011 Great East Japan Earthquake" was investigated comprehensively. According to the damage pattern after the earthquake, it is often the case that the cavities caused by sand boils due to liquefaction, soil loss at the damaged underground pipe and compacting the loose ground. And the location of cavities is similar to the usual case. Moreover, non-distractive evaluation method of the specification of cavities under the pavement was examined. As the result, the validity of the survey method by use of both FWD and GPR to detect the particular cavity which is possible to reduce the safety of user was demonstrated.

Keywords: The 2011 Great East Japan Earthquake, cavities under the pavement, collapse, FWD, GPR

1 INTRODUCTION

The 2011 Great East Japan Earthquake Disaster claimed many lives and property, as well as causing enormous damage to infrastructure. Many cases of road damage were reported after the earthquake, including collapse, faulting, and impaired traffic function due to sand boils caused by liquefaction. Takeuchi [1] investigated the relationship between liquefaction and damage of pavement in the Tohoku region and pointed out that cavities may have formed under the pavement over a wide area. Cavities under the asphalt pavement can cause unexpected collapse accidents due to repeated traffic load, fluctuations in temperature, or other relevant influences. Therefore, it is essential to detect and repair cavities early to ensure the safety of user. However, as it is difficult to investigate entire disaster area in a short period of time after an earthquake, it is reasonable to prioritize investigation and repair area according to site condition, importance of route, risk for collapse accident due to cavities, and other relevant factors, similar to the medical concept of triage. In order to introduce this concept, the mechanism for forming cavities under the pavement should be clarified, and a simple

investigation method to immediately evaluate the possibility of existence of cavity under the pavement and the risk for collapse accident due to cavities should be developed.

Ordinarily, cavities under the pavement are usually investigated by visual inspection (patrol) or GPR (Ground Penetrating Radar). GPR is a non-destructive exploration technology used to detect a buried object or underground cavity based on the reflected travel time of an electromagnetic wave radiated into the ground. This investigation method allows planar or spatial detection of abnormal areas and also can estimate the specification and location of cavity roughly based on the characteristics of the reflected wave [2], [3]. However, as interpretation of the measurement data can be difficult in certain cases, it requires skill and experience to accurately detect the cavity under the pavement. On the other hand, in cases of an earthquake or other disaster where many cavities can be formed, quantitative evaluation of the risk for collapse accident due to the cavity, as well as the determination of existence of cavities, can be useful for planning investigation and repair strategy. When evaluating the risk for collapse accidents due to cavities, it is necessary to examine the influence of the cavity on the deformation of pavement using dynamical methods.

RWD (Rolling Wheel Deflectometer), TSD (Traffic Speed Deflectometer) and other mobile deflection measurement devices have been developed as dynamical non-destructive investigation methods to identify the continuous status of pavement [4–6]. However, as these testing methods cover a wide investigation area, application to a local abnormality (such as a cavity) has not yet been examined. Therefore, it is considered that the most practical investigation at present combines planar investigation, such as GPR investigation, with dynamical investigation at a fixed point, such as FWD (Falling Weight Deflectometer) test.

In this study, a questionnaire survey of local municipalities in the disaster area was conducted to identify the tendency of cavity under the pavement. Moreover reasonable investigating method for cavities after earthquakes using both GPR survey and FWD test is demonstrated.

2 OVERVIEW OF THE GREAT EAST JAPAN EARTHQUAKE DISASTER

The 2011 off the Pacific coast of Tohoku Earthquake occurred at 14:46 JST on March 11, with a magnitude of 9.0 (Mw)—the greatest observed in the history of Japan. As shown in Figure 1, strong earthquake motions were observed in a wide area extending from the

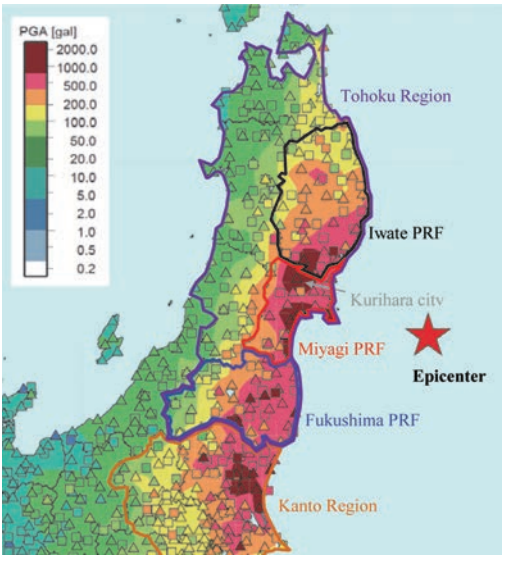

Figure 1. Epicenter and maximum acceleration distribution of the Tohoku earthquake (adapted from Fig. 1, p. 64, in reference [7]).

Tohoku to Kanto regions. According to strong motion seismogram published by the National Research Institute for Earth Science and Disaster Prevention [7], the maximum acceleration in this earthquake reached 2933 gal (in Kurihara City, Miyagi Prefecture) in terms of the three-component composition value, and acceleration exceeding 1G (980 gal) was recorded in some observation points along the Pacific coast. Although it is difficult to identify pavement damage directly caused by earthquake motions, the earthquake caused the road flooding associated with sedimentation (land subsidence) in some parts of coastal area.

Furthermore, the massive tsunami and liquefaction associated with the earthquake led to heavy loss of lives, property, and infrastructure. An investigation of trace of tsunami height reported that tsunami heights exceeded 10 m or higher, causing devastating damage to the coast of the Iwate, Miyagi, and Fukushima prefectures [8]. Reported road damage include stripping surface layer and washing away of blocks due to soil scour around and under pavement. In the Kanto region, liquefaction and sedimentation, sand boils, manholes floating occur in a wide area of reclaimed lands, rivers, and lakes [9], [10].

3 INVESTIGATION OF CAVITY FORMATION TENDENCIES

A questionnaire survey was conducted in the local municipalities affected by The 2011 Great East Japan Earthquake Disaster in order to investigate the occurrence tendency of cavities under the pavement after earthquakes. The questionnaire, which was implemented in November 2012, collected 62 responses from urban areas in the Kanto and Tohoku regions, which experienced particularly strong earthquake motions (as shown in Fig. 1). Questions in the survey concerned with the status of road damage, liquefaction around the affected loads, installation status of underground infrastructure (e.g. sewage pipes, subway systems, catchment basins, etc.), status of cavity investigation implementation, and so on. Figure 2 outlines the results of the survey.

According to the results of questionnaire, pavement damage caused by the Great East Japan Earthquake Disaster included collapse, faulting, manhole floating, and other forms of destruction, such as cracking and undulation. Many of the collapse occurred near sewage pipe, cross drainpipes, catchment basins, manholes, subway systems. Collapses occurred particularly frequently at open-cut construction sites, which indicate the difficulties of selection of backfilling material and compaction around the underground structure. There were 29 sites where sand boils and other traces of liquefaction were confirmed near the affected road, which indicates a strong cause-and-effect relationship between liquefaction and pavement damage. Within the scope of this survey, approximately 80% or more of the affected roads are influenced by underground infrastructure and nearby backfilling areas.

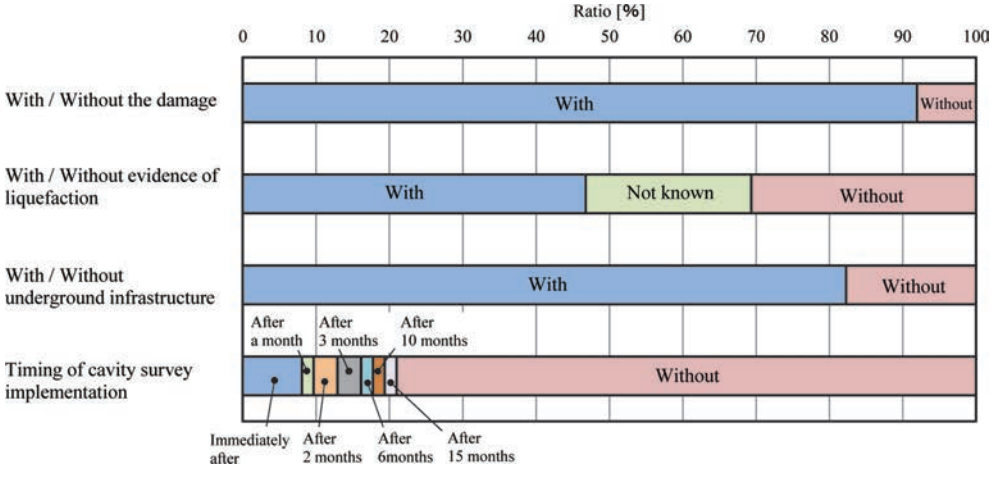

Figure 2. Results of the questionnaire survey.

Table 1. Cavity formation locations.

Categories	Sub-categories
Location where settlement occurred	/Site where the amount of settlement is great
	/Site where differential settlement occurred
	/Site where settlement continues
	/Site where looseness on the ground has been confirmed
Near underground infrastructure	/Around buried pipes (water and sewage pipes)
	/Around manholes
	/Around box culverts
	/Around subways (open-cut areas)

Timing of cavity survey implementation, as shown in Figure 2, refers to the timing of the implementation of underground radar exploration or other non-destructive investigations, and excludes visual inspection (patrol). Although approximately 20% of the municipalities had implemented cavity surveys by the time the questionnaire was conducted, respondents pointed out several implementation issues, including unclear the survey method and priority determining method for investigation routes, shortage of manpower, and economic matters (such as survey cost). Table 1 summarizes the locations of detected cavities. These patterns did not appear to differ significantly from ordinary occurrence tendencies of cavities.

4 CAVITY EVALUATION METHOD

For a common investigation of cavities under the pavement, a simplified survey is performed, consisting of visual inspection (patrol) and underground radar exploration. If the possibility of existence of the cavity under the pavement is suggested, a detailed survey such as a scope, drilling, open-cut, simplified dynamic cone penetration test, etc., is performed to confirm the presence of a cavity. When cavities exist under the pavement, possible appropriate approach (such as repair or progress observation) are determined based on the scale of the cavity, situation of the site, and other necessary factors. These procedures are highly effective at ensuring accurate identification of cavities and prevention of serious accidents. However, in a situation where many cavities may form under the pavement, such as during an earthquake or similar emergency, the possibility of collapse accident caused by cavities should be identified immediately. This requires supplementing conventional methods with a dynamical evaluation. Therefore, this study examines the applicability of a combined planar-dynamic method for detecting cavities, which uses GPR survey and FWD test.

GPR survey and FWD test were conducted at the pavement test field of the Public Works Research Institute shown in Photograph 1. Figure 3 shows the pavement composition and location of Styrofoam simulated cavities, which were buried in the granular base (M-30, layer thickness = 20 cm) and cement treated soil (CBR4%, layer thickness = 30 cm). The specifications of the simulated cavities, made of commercially available Styrofoam, are described in Table 2.

The GPR survey used a chirp radar exploration device (GROUNDSEER GN-01, manufactured by The Nippon Signal, Co., Ltd, with the frequency of 800 MHz) shown in Photograph 2. Measurements taken along the survey line (shown in Fig. 3) are displayed in Figure 4. The survey detected abnormal signals at the points where simulated cavities were buried. Although permittivity varies depending on materials, density, moisture content, etc., this study assumes the value of common asphalt permittivity. This assumption may have generated errors in depth measurement. But it is obvious that the relative position and size of cavities can be confirmed by the GPR survey results. This shows the GPR survey results are available for the determination of measurement points of FWD test.

FWD test was conducted by setting measurement points at 0.5 m intervals along the same survey line as the GPR survey. These intervals differ from actual survey intervals, as they are set to identify the relationship between cavity location and surface deflection. The magnitude of

Photograph 1. Pavement test field.

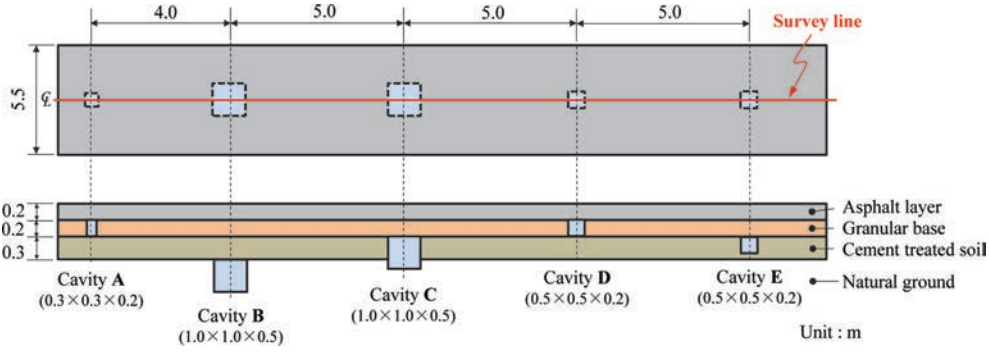

Figure 3. Pavement composition and cavity installation.

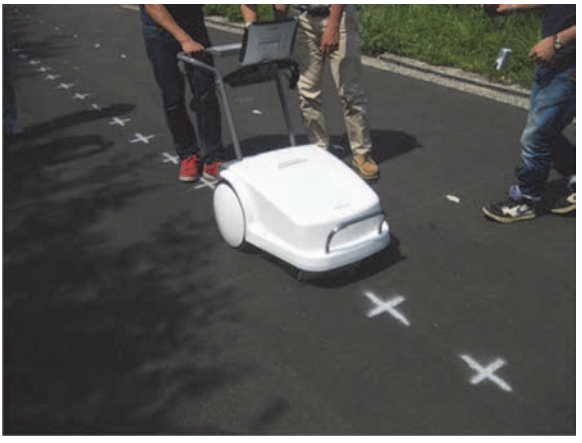
Table 2. Specifications and location of simulated cavities.

Cavity	Dimension [m]	Depth [m]		Remarks
		Upper	Lower	
A	0.3 × 0.3 × 0.2	0.2	0.4	Installed in granular base
B	1.0 × 1.0 × 0.5	0.7	1.2	Installed under cement treated soil
C	1.0 × 1.0 × 0.5	0.4	0.9	Installed in cement treated soil
D	0.5 × 0.5 × 0.2	0.2	0.4	Installed in granular base
E	0.5 × 0.5 × 0.2	0.4	0.6	Installed in cement treated soil

load was 49 kN. Figure 5 shows the deflection immediately below the loading plate (hereafter referred to as D_0 deflection) for each measurement point. By comparing D_0 deflection between Cavity A and D, and between Cavity C and E, it was observed that the surface deflection is large and the area where surface deflection affected by cavity is wide, as the cavity scale is large. Additionally, the comparison of D_0 deflection between Cavity B and C and between Cavity D and E showed that deflection is small and the area where surface deflection affected by cavity is wide, as the cavity location is deep. This suggests that dynamical surveys such as FWD test can discern the cavities which affect running of the vehicle or have a high risk of



Photograph 2. GPR survey apparatus.

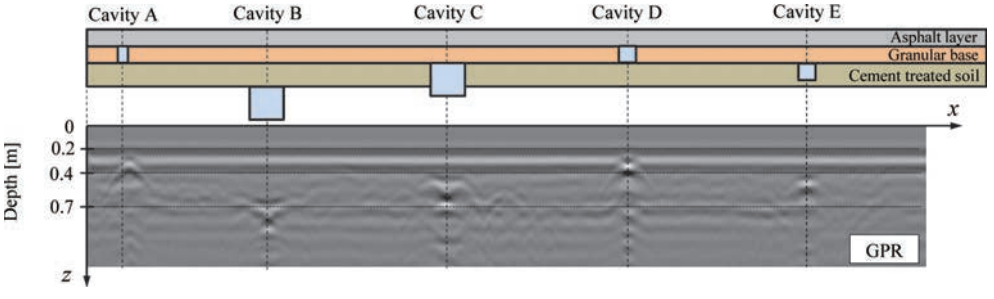


Figure 4. Results of the GPR survey.

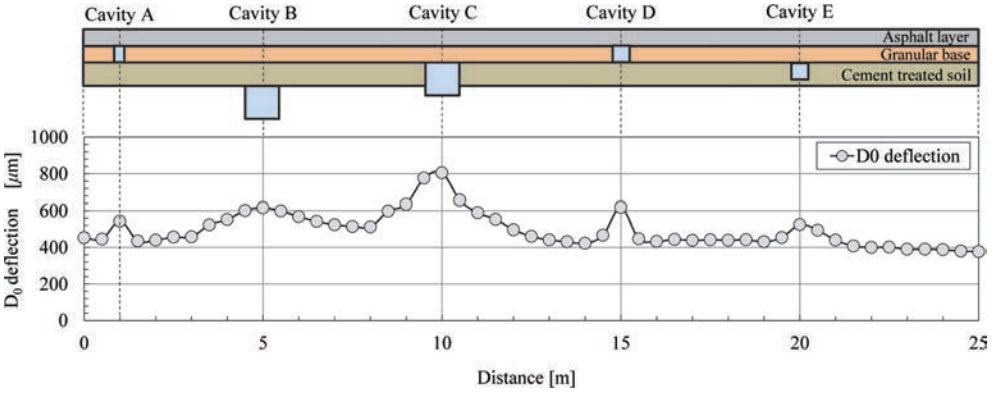

Figure 5. Results of FWD test.

collapse accident. As mentioned above, it is shown that the cavities under the pavement can be efficiently detected by combining the GPR survey with FWD test.

Finally, the evaluating method of the cavity under the pavement using the FWD test results was examined. As shown in Figure 5, when the load applied at the surface of pavement near the cavity, D_0 deflection increased. It indicated that the comparison between D_0 deflection for the sound part of same cross-section and the measurement value enable to detect cavities

under the pavement. However, D_0 deflection obtained from FWD test vary even the same cross-section due to the stiffness heterogeneity of each pavement layer, uneven layer thickness, loading conditions, etc. Therefore, it is reasonable to set the upper limit for confidence interval as the threshold of D_0 deflection using interval estimation of population mean value for samples of D_0 deflection in the sound section. The threshold of D_0 deflection is defined by the following equation.

$$D_{lim} = D_{0ave} + t_x \, SE \tag{1}$$

where,
D_{lim} : Threshold of the D_0 deflection
D_{0ave} : Average of the D_0 deflection for the sound section
SE : Standard error of sample
t_x : Factor corresponding to the reliability x% based on the distribution of t

An example of the cavity evaluation is shown below. First, FWD test was conducted at 12 points on sound parts with the same cross-section shown in Figure 3. The average value of D_0 deflection at the 12 points was 384 μm, with a variation coefficient of 5.6%. Next, the confidence intervals were calculated respectively for 3, 4, 6, 8, and 12 samples extracted from the D_0 deflection at the 12 points. As an example of these calculations, the upper limit for 99, 95 and 90% confidence interval are given in Table 3. Figure 6 compares D_0 deflection on the simulated cavities (Fig. 5), with the upper limit for 99% confidence interval with 12 samples, and the upper limit for 95% confidence interval with 3 samples. For example, when setting the upper limit for 95% confidence interval as the threshold (with 3 samples, shown with a green dashed line in the figure), the D_0 deflection of Cavities B and C exceed the threshold in a wide area. In comparison, setting the upper limit 99% confidence interval as the threshold (with 12 samples, shown with a red dashed line in the figure), all cavities exceed the threshold. Also, as this examination uses results for the test filed where pavement layer thickness and

Table 3. Upper limit of the confidence interval [μm].

Average [μm]	Standard deviation [μm]	Sample number	Reliability index [%]		
			99	95	90
384	22	12	403	398	395

compaction level were strictly controlled, the number of samples necessary for the evaluation and the method for setting the reliability are not to be discussed.

5 SUMMARY

In this study, a survey on pavement damage caused by the Great East Japan Earthquake Disaster was conducted in order to understand the occurrence tendency of cavity under the pavement after an earthquake. Additionally, non-distractive investigation method of cavities under the pavement using GPR and FWD test was examined. The major findings of this study are as described below.

1. Cavity formation patterns during earthquakes are similar to those under ordinary case.
2. The relative location and size of cavities can be confirmed by the GPR survey. This shows the GPR survey results are available for the determination of measurement points of FWD test.
3. From the results of FWD test for simulated cavities, it is confirmed that the D_0 deflection varies significantly by the location and size of cavities. This suggests that the risk for collapse accident due to cavities under the pavement can be estimated by dynamical method such as FWD test.
4. As mentioned above, it is shown that the cavities under the pavement can be efficiently detected by combining the GPR survey with FWD test.

In future research, we will evaluate the relationship between pavement composition, FWD deflection, and the risk of cavities based on collapse accident reports.

ACKNOWLEDGMENT

We would like to express our deepest gratitude to local municipal authorities for their extensive cooperation in the questionnaire survey, despite their busy disaster recovery schedule.

ABSTRACT: Performance of Permeable Friction Courses (PFCs) was evaluated over time and compared against other mixture types. Several pavement sections including Asphalt Rubber (AR) PFCs, Performance Graded (PG) PFCs, and dense-graded Hot Mix Asphalt (HMA) were monitored over a four-year period. On-site measurements included noise, drainability, texture, friction, and skid. The change of these variables with time as well as the influence of traffic, binder/mixture type, aggregate classification, and climatic region was evaluated. Accident data was also gathered and analysed on a more comprehensive number of pavement sections across the state of Texas.

Performance of PFCs over time was adequate. PFCs had lower overall noise levels when compared to HMA, and AR-PFCs were quieter than PG-PFCs. With regard to drainability, the water flow values had a tendency to increase early in the life of the pavement and remain relatively constant afterwards. PG-PFCs showed better drainability as compared to AR-PFCs. Texture for PFCs remained practically unchanged over time. Both AR- and PG-PFCs had superior texture and skid vs. HMA pavements. With regard to friction and skid, sections with lower quality aggregates had inferior values. The accident data indicated that PFCs reduce the number of accidents, injuries, and fatalities on roads in Texas.

Keywords: Permeable Friction Course, porous asphalt, field performance, non-destructive testing

1 INTRODUCTION

Permeable Friction Course pavements (PFCs) are being used as a pavement surface layer for reasons of safety, amenity, and environmental benefits. PFCs consist of a compacted permeable mixture of aggregate, asphalt binder, and additives mixed hot in a mixing plant. These pavements are designed to achieve good drainability and reduce the generation and propagation of traffic noise. PFCs also offer better ride quality, better vehicle handling, and the flexibility of application as a wearing surface over Portland Cement Concrete (PCC) or Hot Mix Asphalt (HMA). The usual percent Air Voids (AV) in PFCs is at least 18 percent. With such a high fraction of AV, PFCs are a superior pavement in wet weather due to reduced splash and spray and hydroplaning potential [1–5].

There are also some potential disadvantages associated with the use of PFCs related to the high fraction of AV that provides its benefits. Besides the decreased expected service life for PFCs (typically 6–10 years for PFCs vs. 12–15 years for HMA), loss of safety and functionality are important factors to consider. Functionality is defined as the ability of the pavement to maintain its beneficial characteristics with regard to increased drainabil-

ity and reduced tire/pavement noise. PFC functionality diminishes when dust and debris accumulate and clog the AV structure or when the pavement densifies under the effect of traffic loads. State agencies usually schedule preventive maintenance focused on cleaning the PFC pore structure and prolonging the advantages of the pavement surface. In the absence of cleaning activities, the initial permeability and noise reduction capacity are expected to decrease such that, at the end of the functional life at approximately 6–10 years (when the functional characteristics are lost), PFC behaves more like a conventional dense-graded HMA. In addition, the durability of PFCs is usually impacted by the onset and rapid progression of raveling [6].

Recent studies have explored the mix design, construction, maintenance, noise abatement, and winter maintenance issues of PFCs [7–9]. In this study, the performance of PFCs and other types of pavement surfaces was tracked over time to quantify changes in functionality and safety. Functionality included drainability and noise reduction effectiveness. Safety was measured in terms of texture, friction, skid resistance, and accident data. Additional information about this study can be found elsewhere [10].

2 EXPERIMENTAL DESIGN

In order to track the performance of PFCs over time and compare it against other types of mixtures, 28 pavement sections across different climatic zones in Texas were selected. The first 20 sections listed in Table 1 were tracked over a 4-year period (i.e., 2009–2012) and include four conventional dense-graded HMA pavement sections that served as reference, one Thin-Bonded PFC (TBPFC), and one Ultra-Thin-Bonded HMA (UTBHMA). Two types of asphalt binders were used in the PFC sections, Performance Graded (PG) and Asphalt Rubber (AR). TxDOT specifies a finer gradation and higher binder content for the AR-PFCs as compared to PG-PFCs [11]. The rest of the pavement sections (i.e., 21–28) were used as case studies. Details of all sections are listed in Table 1.

The non-destructive on-site field tests that were performed to monitor functionality and safety are listed in Table 2. Skid values were extracted from the Texas Department of Transportation (TxDOT) Pavement Management Information System (PMIS). An evaluation of the change in each variable with time was completed first, followed by an evaluation of the effect of traffic (except for noise), binder/mixture type, aggregate classification, and climate. In addition, accident data for each pavement section was obtained from the TxDOT Crash Records Information System (CRIS).

In order to quantify the effect of traffic, on-site tests were performed both On the Wheel Path (OWP) and Between the Wheel Paths (BWP). All testing was done on the right wheel path when facing the direction of travel. Testing BWP was done by placing the equipment near the estimated centerline of the wheel paths. On-site Water Flow Value (WFV), texture, and friction measurements were performed on three equally spaced subsections approximately 150 m apart. Testing OWP and BWP was done in all three subsections and the average of the measurements reported as the OWP or BWP result for that pavement section. One WFV measurement was performed OWP and BWP in each subsection unless there was a reason to believe the result was inaccurate due to localized bleeding or clogging. In the case of the Circular Track Meter (CTM), two replicate tests about 2 inches apart from each other were performed in each subsection. The average of the six replicate measurements was reported as the OWP or BWP texture for that pavement section. Friction was measured once in each subsection by placing the Dynamic Friction Tester (DFT) in the same spot where the first texture measurement was acquired.

For the noise measurements, two valid test runs were performed per sound intensity probe position (i.e., leading edge and trailing edge), and three replicate measurements were collected at each probe location and then averaged to obtain the overall noise level. Each measurement was averaged over a 5-second period, yielding test sections that, given the testing traveling speed of 97 kph, were approximately 130 m long.

3 PAVEMENT PERFORMANCE

The effect of time, traffic, binder/mixture type, aggregate classification, and climate was explored for the on-site field measurements. The climatic regions were defined based on annual precipitation, annual freezing index, and the number of wet days and freeze/thaw days to assign the TxDOT districts into five zones [12]. To assess the differences caused by time, traffic, and aggregate classification, a two-sample t-test was performed assuming equal variances, a two-tailed distribution, and a significance level of $\alpha = 0.05$. In the case of binder/mixture type and climate, an Analysis of Variance (ANOVA) and Tukey's Honest Significant Differences (HSD) test was performed to compare the effect of these factors on the on-site measurements. A summary of observed trends is presented in Table 3.

3.1 *Noise*

Even though an increase in noise levels was expected in PFCs since their acoustic benefit is thought to diminish due to AV clogging and mixture consolidation under traffic, the results of this study did not show a clear pattern of noise level increase with time; some PFC sections even showed lower noise levels with time. A possible explanation for the reduction in noise levels is the fact that two tire types with different aging conditions were used to perform the noise measurements. A correlation model was used to enable the comparison between different tire types but no adjustment was made to account for tire age [10]. The effect of other factors on noise is summarized in Table 3.

3.2 *Drainability*

WFVs were acquired only on PFC pavement sections since UTBHMA and dense-graded HMA pavement sections are essentially impervious. To identify the effect of traffic on drainability, researchers compared OWP vs. BWP measurements. The data for both measurements showed good correlation with the OWP WFVs being somewhat higher than the BWP WFVs (as expected). In addition, after a WFV of about 90 seconds, the correlation of BWP vs. OWP became weaker. Therefore, 90 seconds was established as the threshold to define draining PFCs vs. impervious ones. The effect of time on drainability is illustrated in Figure 1 for AR-PFCs and PG-PFCs after applying the 90-second impervious threshold criteria to the subsection measurements. Only OWP measurements are presented due to the strong

Table 3. Effects of various factors on the on-site field measurements.

	Factors				
Field test	Time	Traffic	Mix/binder type	Aggregate classification	Climate
Drainability, WFV	Initial increase, constant afterwards	No effect	AR-PFC higher than PG-PFC	No effect	WW: lowest DW: largest
Noise, dBA	No effect	–	AR-PFCs ~2 dBA quieter than PG-PFCs	–	M: most quiet WC: loudest
Texture, MPD	No effect except for sections with raveling or fog seal	OWP > BWP	AR-PFC = PG-PFC PFC > HMA	No effect	DC & DW: lowest WW: largest
Friction, FN	Increasing trend on AR-PFCs sections	BWP > OWP	No effect	SAC-B lowest FN	DC & DW: lowest WC: highest
Skid, SN	Effect on many sections	–	PFC > HMA	SAC-B lowest SN	DW: lowest WC: highest

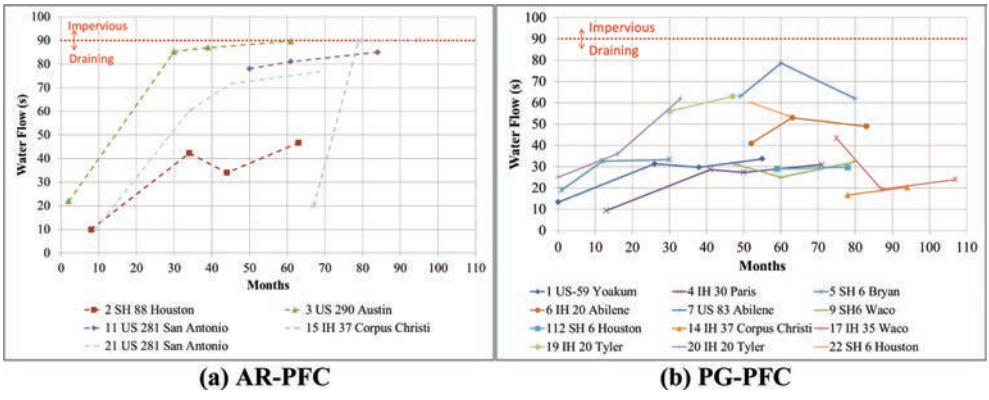

Figure 1. OWP drainability measurements with pavement life.

correlation between BWP and OWP values. In Figure 1, WFVs from five field sections (i.e., 1, 2, 3, 4, and 21) that were collected in 2007 soon after construction as part of a previous study are also included. All 2007 values were below 20 seconds.

Trends showed that WFVs tend to increase when the pavement is new and then remain relatively constant throughout the life of the pavement. For the PG-PFCs, after the initial increase in WFV, the drainability of more than one-third of the pavement sections remained constant at around 30 seconds (Fig. 1b). Conversely, the WFVs for three out of the five AR-PFC sections were close to or beyond the impervious threshold of 90 seconds. Therefore, it is likely that the AV structure of the AR-PFCs is more prone to clogging.

The effect of aggregate classification on drainability was also assessed. Some mixtures employed aggregates classified per TxDOT's Surface Aggregate Classification (SAC) system as SAC-A or SAC-B. More importantly, a few pavement sections used a combination of SAC-A and SAC-B aggregates. Aggregates classified as SAC-A consist of high-quality materials that are resistant to polishing and have higher soundness values as compared to aggregates classified as SAC-B. Some TxDOT districts have demonstrated concerns about combining SAC-A and SAC-B aggregates because they have observed crushing of the SAC-B aggregate under loading. For PFCs, this could translate into a loss in functionality (i.e., permeability and noise reduction). However, a statistical comparison of the WFVs obtained for the pavement sections with SAC-A, SAC-B, and combination of SAC-A/B aggregates showed no significant differences. The effect of the other factors on friction is summarized in Table 3.

3.3 *Texture*

Texture measurements were performed on all pavement sections in 2009, 2010, and 2012. The effect of traffic on texture was assessed by comparing OWP vs. BWP Mean Profile Depth (MPD) values. There was a strong correlation between the MPD values acquired OWP and BWP for both PFC and non-PFCs. For PFCs, the MPD values acquired BWP were slightly higher than the ones acquired OWP, which implies that texture BWP was somewhat larger than texture OWP. The change of texture with time is illustrated in Figure 2. All pavement sections with the exception of sections 14 and 15 in Corpus Christi show relatively flat texture trends. In the case of section 15, a fog seal was applied between the measurements performed in 2009 and 2010, causing the significant decrease in texture. For Section 14, the raveling experienced by the pavement towards the end of its service life more likely has caused the increase in texture. Sections 14 and 15 were considered extreme cases and excluded from the subsequent texture analysis. The effect of the other factors on texture is summarized in Table 3.

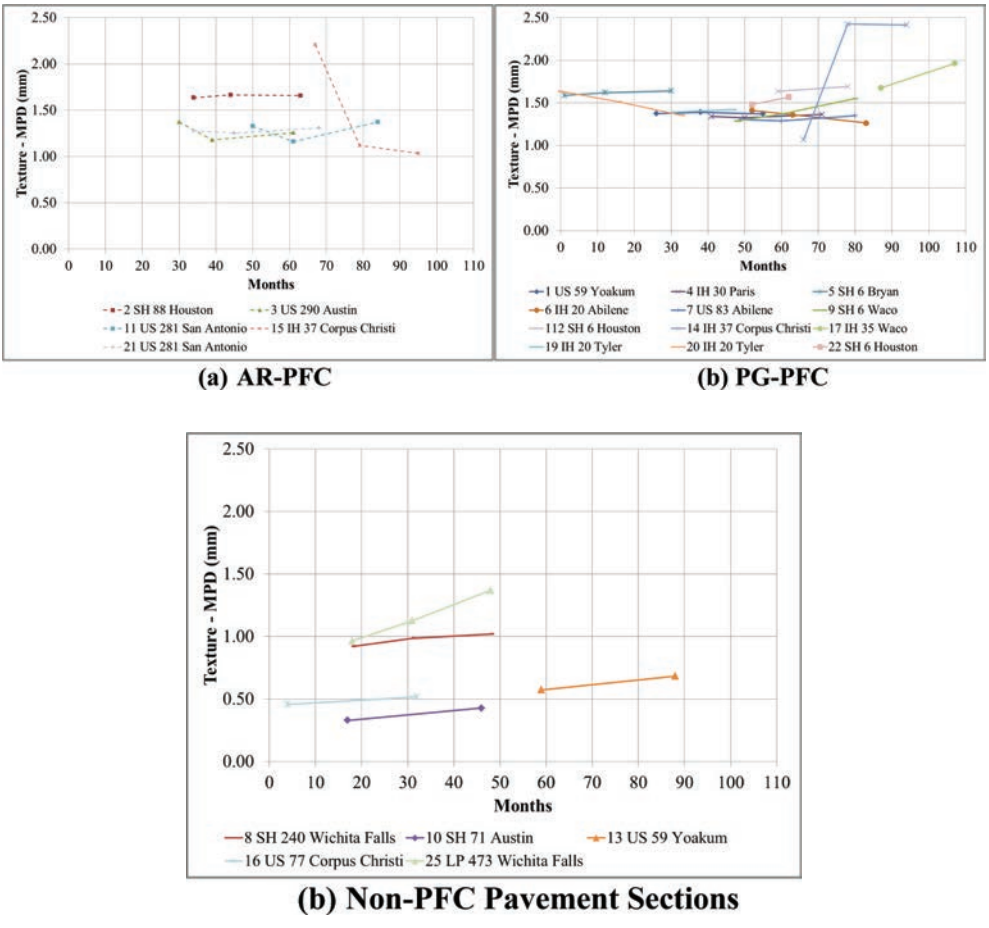

Figure 2. OWP texture measurements with pavement life.

3.4 *Friction*

The effect of traffic on friction was evaluated using OWP and BWP DFT measurements acquired at 60 kph. There was a strong correlation between the OWP and BWP values. The friction values were slightly higher BWP than OWP, especially for non-PFCs. The change in friction with time is illustrated in Figure 3. As previously mentioned, Section 14 experienced raveling, which could explain the significant increase in measured texture. Section 15, which was treated with a fog seal between 2009 and 2010, showed a decrease in friction, although not statistically significant. The significant increase in friction observed in pavement Section 20 is likely due to the fact that this pavement section was constructed just before the first measurement was acquired, and thus traffic likely wore down the asphalt binder at the surface of the pavement and the friction value increased. The effect of the other factors on friction is summarized in Table 3.

3.5 *Skid*

Skid Numbers (SNs) for the pavement sections were extracted from TxDOT's PMIS database. Not all values were available for all sections and/or all years. As compared to the other on-site field measurements, the SNs had more variability and did not follow a consistent trend. For some sections, the values increased; for others, the values decreased; and some others stayed

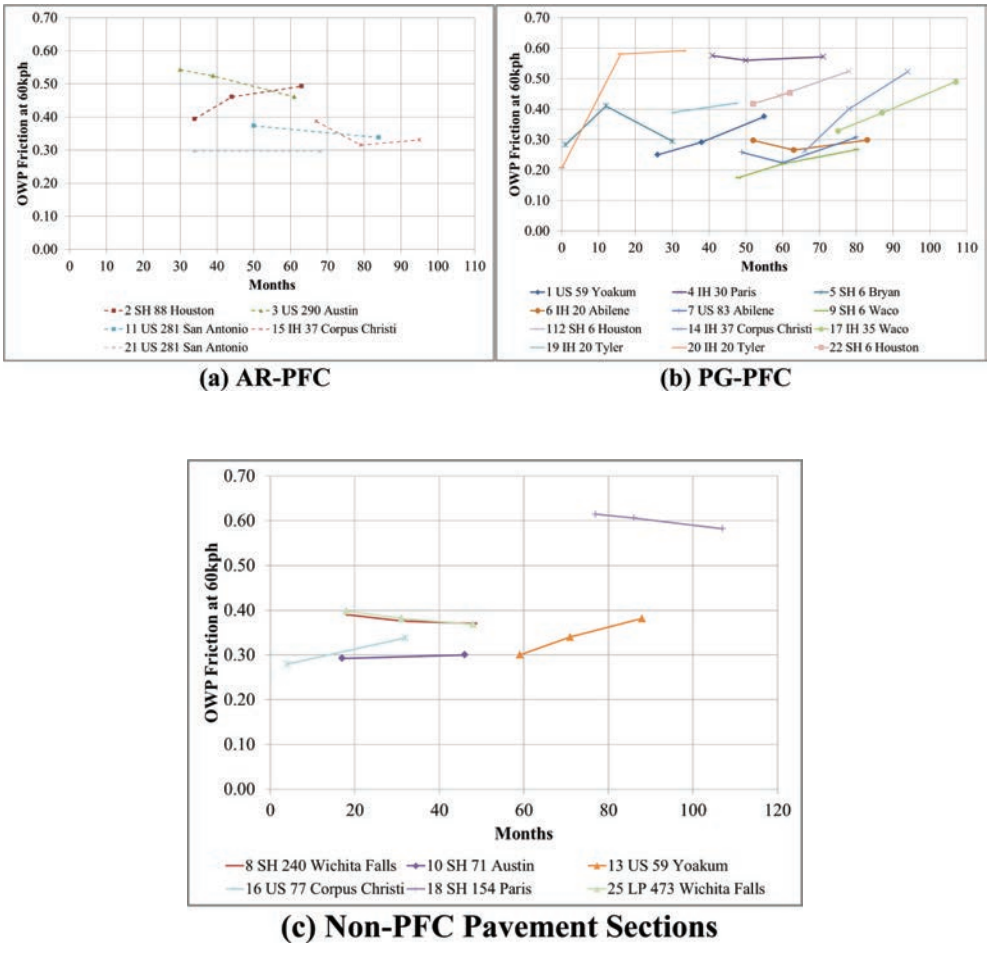

Figure 3. OWP friction measurements with pavement life.

constant. Several PFC pavement sections had statistically significant differences in their SNs with time.

The effect of binder/mixture type on SN was also evaluated. From the statistical results, it was apparent that AR-PFCs and PG-PFCs had higher SN values compared to both UTB-HMA and dense-graded HMA, with AR-PFCs having the largest SN values. When only PFCs and dense-graded HMA were included in the analysis, PFCs clustered together and were statistically different from HMA.

The effect of aggregate classification on SN was quantified as well. ANOVA and Tukey's HSD resulted in statistical significant differences between all aggregate classes (except in 2011 where SAC-A and SAC-A/B were statistically equivalent). Sections employing SAC-A aggregates had the highest SNs, while sections in which mixtures were comprised of only SAC-B aggregates had the lowest SNs. This confirms the friction observations that also showed that the sections with SAC-B aggregates had the lowest friction values as compared to the sections with SAC-A aggregates, which resulted in the largest friction values.

Finally, the effect of climate on SN showed significantly lower values in the Dry Warm (DW) climatic region, while the Wet Cold (WC) region had the highest SNs. The other climatic regions had values in between these two extremes.

3.6 *Accidents*

To investigate the wet weather safety of PFCs in Texas, accident rates under dry and wet conditions and the initial safety of PFC following construction were studied. At the onset, only the pavement sections included in this study were evaluated. However, since no significant trends were found, researchers decided to expand the dataset to include a larger sample of PFC constructed in Texas between 2003 and 2011. A total of 161 PFC projects constructed from 2003 were identified, providing a better platform to evaluate wet weather safety of PFC across Texas.

CRIS reports the weather condition at the time of the accident. Of the accidents reported, 84 percent occurred under clear or cloudy conditions and 14 percent occurred in rainy conditions with the balance occurring under windy, snowy, sleet, hail, or unknown conditions. CRIS also reports the road condition at the time of the accident, i.e., whether wet or dry. Of all the accidents, 78 percent occurred when the road was reportedly dry and 19 percent when wet. A breakdown of the accidents on the pavement sections by weather (i.e., clear/cloudy and rain) and road condition (i.e., dry surface and wet surface) with the relative proportion of the accidents that occurred under these conditions when the surface was a PFC as compared to dense-graded HMA provided a general indication that accidents on PFC were comparatively lower under rain and wet conditions.

To investigate the reported higher accidents on PFC immediately following pavement construction, an analysis of the accidents per lane mile on the PFC sections was made. Some research studies have reported similar observations claiming that apparently drivers take advantage of the reduced splash and spray on PFCs during rain events, driving faster at shorter following distances and causing more accidents [11, 13]. Results of this study showed a definite increase in the number of accidents that continued for three months following construction of the PFC pavement section. The increase in accidents was slight, however, in the order of about 0.0005 accidents per lane mile. Nonetheless, measures to improve safety right after construction should be considered.

4 CONCLUSIONS

The objective of this study was to evaluate the performance of Porous Friction Course pavements (PFCs) over time and compare them to other wearing surface pavement types. Field performance of several pavement sections including Asphalt Rubber (AR) PFCs, Performance Graded (PG) PFCs, Thin-Bonded PFCs (TBPFC), Ultra-Thin-Bonded Hot Mix Asphalt (UTBHMA), and dense-graded Hot Mix Asphalt (HMA) were monitored over a four-year period. Non-destructive on-site tests included noise measurements using On Board Sound Intensity (OBSI) measurement equipment, drainability following the Tex 246 F field water flow test procedure, Mean Profile Depth (MPD) using a Circular Track Meter (CTM), friction at 60 kph using a Dynamic Friction Tester (DFT), and skid that TxDOT collected using a skid trailer. The change of these performance variables with time as well as the influence of traffic, binder/mixture type, aggregate classification, and climatic region was evaluated. Accident data on a comprehensive number of PFC sections in the state was also gathered and analyzed.

Performance evaluation of PFCs over time demonstrated adequate performance. For drainability, PG-PFCs showed better performance as compared to AR-PFCs. In general, measurements in AR-PFCs were more variable than PG-PFCs. For PG-PFCs, the Water Flow Values (WFVs) had a tendency to increase early in the life of the pavement and remain relatively constant afterwards. A 90-second threshold was established to define pervious vs. impervious pavement sections after comparing the WFVs acquired On Wheel Path (OWP) vs. Between Wheel Path (BWP). All PG-PFCs were below the set threshold, while most of the AR PFCs were close to or above the 90-second limit. The classification of the aggregates per the Surface Aggregate Classification (SAC) system did not play a role with respect to WFVs, but climate had a significant effect. Apparently, the amount of

rainfall in a particular climatic region helped assure the continued drainability of PFCs, especially in warm climates.

There was a slight increase in OBSI noise levels with time, but the correlation was weak. The trend was observed only when all measurements were combined. When each pavement section was individually analyzed, no particular trend was observed, except for sections 9 and 14 where a substantial increase in noise levels was noted due to raveling. The binder/mixture type had a significant effect on noise levels with the statistical analysis showing a significant difference between the AR-PFCs (quieter) vs. the PG-PFCs. In addition, PFCs had lower overall noise levels when compared to dense-graded HMA reference sections, although not statistically significant. The climatic region proved to be a statistical significant factor as well.

With regard to the texture measurements, there was a strong correlation between the MPD values acquired OWP and BWP, with texture measured BWP being slightly larger than texture measured OWP. With time, the texture values remained practically unchanged. The two exceptions, where texture changed significantly, corresponded to a pavement section that was fog sealed and another one that exhibited significant amounts of raveling. Both AR- and PG-PFCs had statistical equivalent texture yet better texture than the dense-graded HMA pavement sections used as reference. Neither the aggregate classification nor the climatic region where the pavement sections were placed had a significant impact on texture. Pavement texture achieved soon after construction seemed to be more critical to performance over time.

Friction measurements acquired OWP vs. BWP also showed a strong correlation, with BWP friction values being slightly higher than OWP, especially for non-PFCs. With time, PG-PFCs demonstrated an upward trend in friction values, while AR-PFCs and non-PFCs show a flat or downward friction trend. Differences in binder/mixture type did not have an influence on friction. Aggregate classification, however, did play an important role. Pavement sections with SAC-B aggregates had statistically significantly lower friction values as compared to those pavement sections employing either SAC-A or SAC-A/B aggregates. The effect of climatic region on friction demonstrated that pavement sections in dry climates had lower friction values while pavement sections located in the WC climatic region had the highest friction.

With respect to Skid Number (SN) measurements, these seemed more variable and did not follow a consistent upward or downward trend with time. Similar to the texture observations, AR-PFCs and PG-PFCs had higher SN values compared to dense-graded HMA. Moreover, in line with the friction results, sections employing SAC-A aggregates had the highest SNs, while sections where mixtures were comprised of only SAC-B aggregates had the lowest SNs. Pavement sections in the DW climatic region had the lowest SNs, while pavement sections located in the WC regions had the highest SNs.

The analysis to investigate the safety of PFC under wet conditions included 161 PFC sections from across Texas constructed between 2003 and 2011. Accident rates on these sections were compared before and after construction of the PFC surface. To investigate the safety of PFC under wet conditions, the weather and surface conditions at the time of an accident as reported in CRIS was used. The data indicate that PFC indeed reduces the number of accidents, injuries, and fatalities on roads in Texas. Using the accident data as reported in CRIS, a slight but consistent increase in accidents on PFCs was observed immediately following construction of these surfaces. Therefore, it is recommended that the initial safety of PFC be addressed before opening the road to traffic.

Implementation of algorithms for asphalt moduli temperature correction

Christina Plati, Vasilis Papavasiliou, Andreas Loizos & Christina Tsaimou
Laboratory of Pavement Engineering, National Technical University of Athens (NTUA), Zografou, Athens, Greece

ABSTRACT: Determination of Asphalt Concrete (AC) moduli is a critical issue in terms of pavement evaluation. AC moduli are strongly influenced by temperature variations and thus, determination of AC moduli to a common reference temperature is a complex task. Temperature correction of AC moduli has occupied many researchers over the years yielding the development of multiple algorithms. The main focus of the current research is to evaluate and compare correction results from multiple algorithms and to highlight potential differentiations that occur from their implementation. For this purpose, a road experiment was conducted based on Non Destructive Testing (NDT) techniques, including the Falling Weight Deflectometer (FWD) and the Ground Penetrating Radar (GPR). AC moduli were determined from in situ measurements and corrected to 20 °C. The aim of the experiment was to examine variations between the corrected moduli and the reference values for a untrafficked pavement. AC corrected moduli were examined and analyzed by plotting charts and through statistical processes. Statistical and further analysis of the AC moduli showed that there were large discrepancies between corrected values and real values.

Keywords: temperature correction of moduli, algorithms, NDT techniques

1 INTRODUCTION

Determination of Asphalt Concrete (AC) moduli is critical for monitoring pavement performance and furthermore for gathering information for rehabilitation and maintenance strategies. AC moduli can be determined through laboratory tests or in-situ measurements. The latter can be determined through Non Destructive Testing (NDT) with the Falling Weight Deflectometer (FWD), which is a commonly utilized tool to quantify the response of a pavement structure to known loads.

The modulus of asphalt layers is strongly influenced by temperature conditions and this correlation explains the fact that AC moduli for the same pavement vary in accordance with the temperature within the body of the asphalt layers. Thus, a temperature correction of AC moduli to a reference temperature is required.

Temperature correction for AC backcalculated moduli has been intensively studied by researchers over the years resulting in the development of multiple unique algorithms. Ideally FWD testing should be performed at various temperatures, in order to develop an algorithm for the temperature sensitivity of AC moduli for the site under investigation. However, this is not feasible in most cases due to the fact that there is no control on temperature variations during the survey and there are strict time limitations imposed because of road closures [1]. For this reason, existing algorithms are commonly used for temperature correction of backcalculated AC moduli.

The objective of the current research is to investigate the problems that may potentially occur from the use of existing algorithms for the correction of AC backcalulated moduli. To achieve this goal, a road experiment was conducted that included the utilization of FWD and

Ground Penetrating Radar (GPR) measurements. Deflections from the FWD were measured at three different temperatures. For each measurement AC moduli were determined through a backcalculation approach. Backcalculated moduli were then corrected to the reference temperature utilizing multiple internationally known algorithms. The analysis concerns only backcalulated moduli determined from NDT data and not laboratory determined values.

2 STATE OF THE ART

Temperature correction of moduli has been addressed in multiple studies over the years and several algorithms have been developed. For some of these algorithms there is a limitation on the reference temperature, while others permit the use of any user-specified reference temperature. The most commonly used reference temperatures are those of 20 and 25 °C. In this research, AC backcalculated moduli are corrected to 20 °C by using algorithms based only on a reference temperature 20 °C or on any user-specified reference temperature. Moreover, backcalculated moduli were corrected based on the algorithms that require only temperature data. Potentially, algorithms that need laboratory data may be more accurate, however this requires laboratory test results, which is both time consuming and in some cases difficult to perform. Table 1 indicates the temperature correction algorithms used in this research in chronological order.

Indicatively, bellow are some comments and conclusions from the relative investigations performed for the development of the algorithms. The development of Baltzer and Jansen algorithms is based on FWD measurements. Moreover the use of equation 4(b) with T_{ref} = 20 °C should be limited to a narrow temperature-interval, while equation 4(c) can be used for a wider temperature-interval [5]. Ali and Lopez [7] developed a temperature correction algorithm for backcalculated AC moduli based on in-situ measurements. FWD measurements were also used for Chen et al. [9] algorithm. They conducted a comparison of AC corrected moduli from their algorithm with the relative ones from other algorithms and there was no close agreement. Lukanen et al. [10] used temperature and deflection data from Long Term Pavement Performance (LTPP) program's Seasonal Monitoring Program (SMP). They noted that the slope does have a correlation with the latitude of the site, which is expected to relate to the grading of the asphaltic cement used. In the English Highways Agency [13] report it is noted that where a layer is known to be severely cracked throughout its depth, temperature correction should not normally be applied.

Comparison of temperature correction results from different algorithms has occupied several researchers including Park and Kim [14] which concluded that no single model can cover a broad range of mixtures with different thermoviscoelastic properties. According to Chen et al. [9], comparisons with other reported temperature correction equations showed close agreement for deflection, but not for moduli. Similar results were also derived from the research done by Chang et al. [15] who concluded that the differences among studies were higher for modulus than those for deflection correction. The results of research done by Fernando et al. [16] indicate the importance of collecting data to evaluate the temperature dependency of a given mix. This may be accomplished by laboratory testing of cores or by collecting FWD data at different pavement temperatures.

It should be noted that at reference temperature of approximately 21 °C (Eq. (3, 6)) was assumed to be equal to the 20 °C, as the 1 °C variations will have limited impact on the results. Furthermore for the purposes of this research, in spite of the fact that implementation of some algorithms may require only laboratory estimated AC moduli, it was assumed that all algorithms can be used for correction of moduli from field measurements.

3 ROAD EXPERIMENT AND ANALYSIS OF RESULTS

For the evaluation of temperature correction algorithms a road experiment was conducted using NDT techniques. The experiment consisted of three FWD measurement sets over two

Table 1. Temperature correction algorithms.

1. Ullidtz [2]

$$\frac{E_{T_0}}{E_T} = \frac{1}{3.177 - 1.673(\log T)} \quad (1)$$

where: E_{T_0}, E_T are the asphalt moduli at temperatures of T_0 and T (°C) for $T > 1$ °C.

2. Jung [3]

$$ES = EAe^{kx(TA-TS)} \quad (2)$$

where: ES is the modulus of AC layer (MPa) at the standard temperature, EA is the modulus of AC layer (MPa) corresponding to the test temperature, TA is the mean pavement temperature (°C), TS is the standard temperature (°C) and k is the equation coefficient.

3. Johnson and Baus [4]

$$\frac{E_{std}}{E_{field}} = 10^{-0.0002175}(70^{1.886} - T^{1.886}) \quad (3)$$

where: E_{std} is the AC modulus at standard (reference) temperature, E_{field} is the AC modulus field temperature and, T is the measured temperature in °F. Reference temperature = 70 °F (21.1 °C).

4. Baltzer and Jansen [5]

$$E_{ref} = \frac{E_{ac}}{1 - 2\log\left(\frac{T_{ac}}{T_{ref}}\right)} \quad (4(a))$$

where: T_{ref} is the reference temperature (°C), E_{ref} is the reference AC modulus (MPa), T_{ac} is the AC temperature measured during the FWD test at a depth of 40 mm below the surface and, E_{ac} is the AC modulus from the backcalculation, Pa.

$$\frac{E_{ref}}{E_{AC}} = \frac{1}{1 - 2.2\log\left(\frac{T_{AC}}{T_{ref}}\right)} \quad (4(b))$$

where: E_{ref} is the reference Asphalt modulus, E_{AC} is the backcalculated asphalt modulus, T_{ref} is the reference temperature (°C) and, T_{AC} is the temperature at 1/3 of pavement thickness (°C)
10°C–30°C for $T_{ref} = 25$°C.

$$\lambda_E = 10^{m(T-20)} \quad (4(c))$$

where: T is the effective AC temperature at a depth of one-third of the AC layer in °C.
5°C–30°C

5. Kim et al. [6]

$$\frac{E_{68}}{E_T} = 10^{-0.0153(68-T)} \quad (5)$$

where: E_{68} is the asphalt modulus at temperature 68 °F (20 °C), E_T is the backcalculated asphalt modulus at temperature T and, T is the temperature at mid-depth of asphalt pavement (°F)
Reference temperature = 68 °F (20 °C).

6. Ali and Lopez [7]

$$C = e^{(0.03608145*T-0.75771)} \quad (6)$$

where: T is the pavement temperature at a point 25 mm below pavement surface
$T_{ref} = 21$°C.

7. Braun Intertec [8]

$$\frac{E_1}{E_2} = 10^{0.01*(T_2-T_1)} \quad (7)$$

where: E_1 is the modulus at temperature T_1 °F and, E_2 is the modulus at temperature T_2 °F.

(*Continued*)

Table 1. (*Continued*)

8. Chen et al. [9]	$E_{Tr} = \frac{E_T}{(1.8T_r + 32)^{2.4462} \times (1.8T + 32)^{-2.4462}}$ (8) where: E_{Tr} is the modulus corrected to a reference temperature of T_r (°C) and, E_T is the modulus determined from testing at a temperature of T (°C) For any user-specified reference temperature.
9. Lukanen et al. [10]	$ATAF = 10^{slope(T_r - T_m)}$ (9) where: ATAF is the Asphalt Temperature Adjustment Factor Slope is the slope of the Log Modulus versus Temperature curve, recommended as –0.0195 for the wheel path and –0.021 for mid-lane, T_r is the reference temperature (°C) and, T_m is the pavement temperature at mid-depth (°C).
10. Noureldin et al. [11]	Temperature corrected $E = E_{back}$ / Correction Factor (10) Correction Factor $= 1.0000008^{314432 - T^3}$ (10(a)) where: T is the mean temperature of asphalt concrete layer (°F) measured at the mid-depth of that layer or calculated using air and surface data.
11. English Highways Agency [12]	$E_{20} = E_T * 10^{(0.0003*(20-T)^2 - 0.022*(20-T))}$ (11) where: E_{20} is the stiffness at 20 °C, E_T is the stiffness at temperature T and, T is the temperature of the asphalt at the time of testing (measured at 100 mm depth), from 15 to 25 °C.
12. ELMOD [13]	$E = \exp(-0.04663 * (t - t_{ref})) * E_{ref}$ (12) where: E is the bituminous stiffness at temperature t and, E_{ref} is the bituminous stiffness at reference temperature t_{ref}.

periods along the same pavement section. The first period corresponds to FWD measurements conducted in November 2012 and the second to March 2013. Temperature measurements were conducted within the body of AC layers, at different depths, according to the needs for the application of the algorithms. The most common temperature required from the algorithms is the mid-depth temperature. Table 2 shows the recorded temperatures at mid-depth of AC layers during these three measurement sets. It should be noticed, that the test refers to mild conditions (Mediterranean climate).

The test pavement is 782 m in length and consists of 2 lanes per direction. This pavement was un-trafficked (traffic only during construction). Along the pavement 10 measurement sites were chosen. GPR measurements [13] and extracted cores were utilized in order to determine pavement layer thicknesses. From further analysis it was determined that the AC thickness is equal to 14 cm. Figure 1 shows the cross section of the test pavement (typical flexible pavement). AC moduli were backcalculated from in-situ data using ELMOD software, and temperature correction was applied to AC backcalculated moduli at reference temperature of 20 °C.

AC backcalculated moduli for measurement (c) are assumed to be approximately equal to the reference moduli for reference temperature 20 °C, as measured temperature differs little from reference temperature. Thus only the AC backcalculated moduli of measurements (a) and (b) are corrected.

The test was conducted in order to examine variations between corrected moduli and the reference values. The evaluation includes two basic steps: first is the comparison of corrected moduli of measurements (a) and (b) to the reference temperature of 20 °C with the relative backcalculated values of measurement (c), and secondly the comparison of corrected moduli between measurements (a) and (b).

Table 2. Measured temperatures at mid-depth of AC layers.

Measurements	Minimum temperature	Maximum temperature
(a)	13.1	13.8
(b)	28.5	29.2
(c)	21.3	22.1

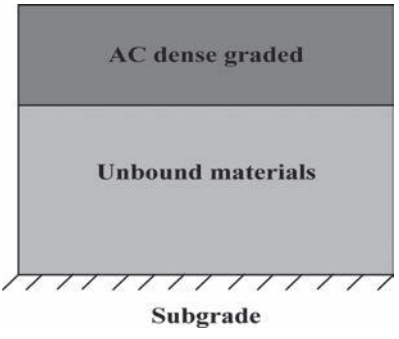

Figure 1. Cross section of the test pavement.

Figures 2 and 3 show indicatively the corrected moduli at 20 °C for each test site along the pavement for measurements (a) and (b), respectively. The bold black line illustrates the backcalculated moduli of measurement (c), i.e. the assumed reference moduli. AC corrected moduli at some sites in measurement (b) seem to be quite high, so for the purposes of this research the scale on the charts stops at 16,000 MPa. Furthermore the numeration in both charts is performed according to the algorithms numeration in Table 1.

Correction of the AC backcalculated moduli for measurement (a) was performed from a lower to a higher temperature, while correction for measurement (b) was performed from a higher temperature to a lower temperature. For measurement (a) corrected moduli seem to be underestimated in comparison with the reference values, while corrected moduli from measurement (b) are overestimated. Figures 2 and 3 also indicate that there is a large dispersion of values. In fact the deviation of some algorithms corrected moduli from the reference values is rather high.

In order to investigate the significance of the moduli values differences, the paired t-test was applied [17]. In particular, the paired t-test determined whether the corrected and the reference modulus differ from each other in a significant way. The paired t-test was applied for every two measurements. Application of the t-test between measurements (a)-(c) and (b)-(c) aims at the comparison of corrected moduli of each measurement with the reference values. T-test between measurements (a)-(b) was performed in order to examine the capability of each algorithm to result in the same or approximately the same corrected moduli regardless of the measured temperature each time. Table 3 illustrates the results of the t-test, where the symbols '√' and '–' mean that the null hypothesis is accepted or rejected, respectively.

Root Mean Square Percentage Error (RMSPE) values were calculated for corrected and reference moduli at T_{ref} = 20 °C. RMSPE is used on order to determine the percentage difference between calculated and measured values. In this case calculated values are corrected moduli and measured values are reference moduli. Table 4 summarizes RMSPE values.

Table 3 shows that the null hypothesis is rejected for almost all the algorithms. This indicates that the difference between corrected and reference moduli is significant. Thus, in general, significant variations appear to occur between corrected and reference moduli.

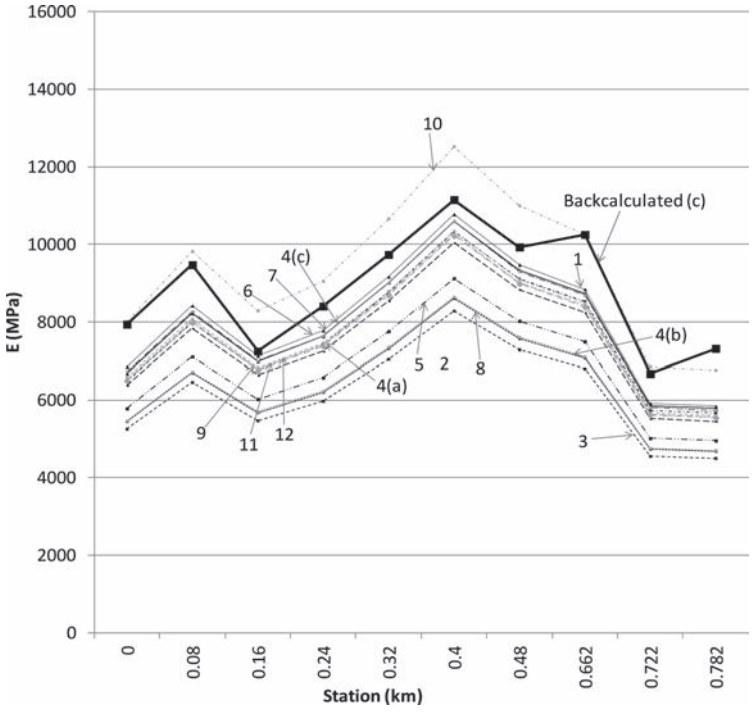

Figure 2. Backcalculated moduli for measurements (a), corrected to 20 °C.

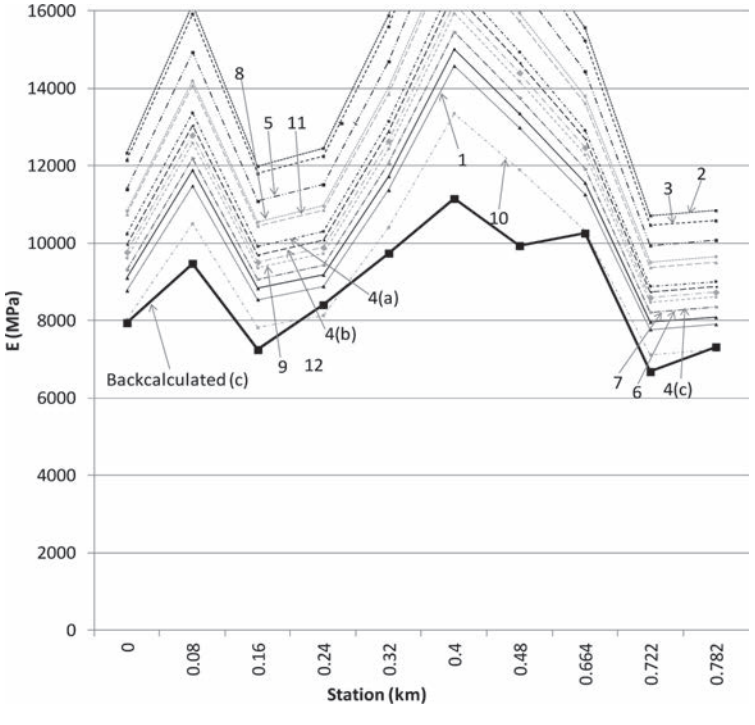

Figure 3. Backcalculated moduli for measurements (b), corrected to 20 °C.

Table 3. T-test for backcalculated and corrected moduli.

Algorithms	T-test (a)-(c)	(b)-(c)	(a)-(b)

Table 4. RMSPE for corrected and reference moduli at $T_{ref} = 20$ °C.

Algorithms	RMSPE (%) (a)-(c)	(b)-(c)
1. Ullidtz [2]	10.8	18.7
2. Jung [3]	27.9	63.7
3. Jonshon and Baus[4]	30.6	60.7
4. (a) Baltzer and Jansen [5]	14.1	36.1
4. (b) Baltzer and Jansen [5]	16.3	33.4
4. (c) Baltzer and Jansen [5]	12.2	25.4
5. Kim et al. [6]	23.7	51.7
6. Ali and Lopez [7]	12.0	22.1
7. Braun Intertec [8]	12.2	25.4
8. Chen et al. [9]	27.6	44.8
9. Lukanen et al. [10]	14.0	29.1
10. Noureldin et al. [11]	8.4	10.3
11. English Highways Agency [12]	14.6	43.2
12. ELMOD [13]	14.9	31.1

RMSPE values for measurement (a) (lower measured temperature than the reference value) seem to be lower that the respective ones for measurement (b) (higher measured temperature than the reference value). This may lead to the conclusion that algorithms have more sensitivity at higher temperatures.

In general, it could be stated that there is no close agreement between corrected and reference moduli, as well as between algorithms.

4 CONCLUSIONS

In this research temperature correction was performed on AC backcalculated moduli of a test pavement, where measurements at three different temperatures within the body of the

asphalt layer were conducted. Among the existing algorithms for temperature correction, algorithms that require only temperature data and can perform correction at 20 °C were implemented in order to correct backcalculated moduli to the reference temperature.

Statistical and further analysis of the results led to the conclusion that correction results are different from one algorithm to another. Furthermore, it is concluded that there are deviations between results of each algorithm for different temperatures, while all the algorithms show greater temperature sensitivity when the measured temperature is higher than the reference value.

Deviations of corrected moduli from reference values are larger for correction from a higher to a lower temperature than from a lower to a higher temperature in spite the fact that difference of measured and reference temperatures was approximately equal for both cases.

Based on the findings of the research it is believed that although algorithms with relative small deviation can be used for temperature correction, analysis results should be evaluated and utilized with caution. So, it is essential to expand the experiment and perform more tests examining other pavements, such as old pavements already trafficked, in order to result in final conclusions. Further research is needed.

Use of distributed fiber optic sensors to detect damage in a pavement

ABSTRACT: This paper presents the feasibility of damage detection in the asphalt pavements by embedded fiber optics as a new non-destructive inspection technique. The distributed fiber optic sensing technology called "Rayleigh technique" was used in this study. The main advantage of this technique is that it allows to measure strains over long length of fiber optic with a high spatial resolution, less than 1 cm. By comparing strain profiles measured at different time, we tried to link strain changes with the appearance of damage (cracking) in the pavement. This non destructive method was evaluated on the IFSTTAR accelerated pavement testing facility, in a bituminous pavement. In our experimentation, the optical fibers were placed at 7 cm depth, near the bottom of the asphalt layer. To accelerate damage, artificial cracks were initiated in the pavement and 500 000 loads were performed during the test. Optical fiber measurements were made at regular intervals and surface cracking of the pavement was surveyed. After some traffic, a significant increase of strains was detected by the optical fibers at different points in the pavement structure, before any cracking was visible at the surface. Later, cracks appeared in the zones where the strain profiles were modified, thus indicating a clear relationship between the increased strains and crack initiation. This first test confirms thus the possibility of using a distributed fiber optic sensor to detect crack initiation in a pavement.

Keywords: Distributed fiber optic sensor, asphalt concrete pavement, cracking, non-destructive inspection

1 TECHNOLOGY OF FIBER OPTIC SENSORS

The common definition of a fiber optic sensor, as found in Wikipedia *"is a sensor that uses optical fiber either as the sensing element ("intrinsic sensors"), or as a means of relaying signals from a remote sensor to the electronics that process the signals ("extrinsic sensors")"*. Today, the technologies of intrinsic fiber optic sensors offer interesting benefits when compared with traditional sensors. The main advantages are small size, electrically passive operation, electromagnetic immunity, flexibility, corrosion resistance, etc. Fiber optic sensors can be used to perform local or distributed measurements with precision in a wide range of strain and temperature. Moreover, the technologies of fiber optic sensors become more and more efficient and reliable. All these elements contribute to a growing interest in fiber optic sensors. Several fiber optic sensor technologies have already been used for structural health monitoring and surveillance with positive results. The most promising technology is the distributed sensing technique because in one acquisition, a lot of measurement points can be obtained along a long length of fiber optic (up to 2 km).

The "Rayleigh sensing technique" is one of the distributed fiber optic sensing techniques having the highest spatial resolution (less than 1 cm). It is sensitive to both strain and temperature. This distributed sensing technique is based on the measurement of the back-scattering of light by random fluctuations of the refractive index profile along the length of the optical fiber. A strain (or temperature) profile can be obtained from two successive measurements of the Rayleigh signal, one acquired at an initial state and the second one measured at time t. The typical accuracy of the Rayleigh sensing technique is better than ±1°C in temperature and ±1 μm in strain with a centimeter spatial resolution. This high spatial resolution of the strain profile measurements is one of the main advantages of the Rayleigh sensing technique. The idea, in this study, is to use the strain profile to detect cracks in pavements. If a crack occurs transversely to the fiber optic sensor, the strain transfer from the host material to the fiber optic will be modified locally. By comparing strain profiles measured at different times to detect strain changes along the fiber optic, internal damage (cracks) in the pavement should be detectable. This non destructive method was evaluated on the IFSTTAR accelerated pavement testing facility described below.

2 DESCRIPTION OF THE EXPERIMENTATION

2.1 *Accelerated pavement testing facility*

The pavement fatigue carrousel of IFSTTAR (Fig. 1) is a large scale circular outdoor facility, unique in Europe by its size (120 m length, 6 m width) and loading capabilities [1]:

- maximum loading speed 100 km/h,
- loading rate 1 million cycles per month,
- 4 arms equipped possibly with different wheel configurations,
- lateral wandering of the loads to reproduce real traffic.

Figure 1. Accelerated pavement testing facility of IFSTTAR.

Figure 2. Fiber optic cable used as distributed sensor and measurement system.

2.2 *Fiber optic sensors and measurement system*

Common fiber optic cables (containing one or more single mode optical fibers) of telecommunication systems can be used with the Rayleigh sensing technique. However, special fiber optic cables designed for sensing measurement must be used. Indeed, they must have high enough mechanical resistance (in tension, compression, shear, against crushing etc.) for safe handling and to withstand the stresses experienced during the pavement construction process. In our experimentation, we choose to use an optical fiber cable (Fig. 2) containing 6 fibers (only one fiber optic was used) protected by an epoxy overcoat and an hytrel jacket. This cable is robust enough to be embedded in asphalt layers and its small diameter of 2 mm minimizes its intrusivity in the pavement.

Concerning the measurement system, we used a commercial device called "Optical Backscatter Reflectometer" (Luna's OBR). Strain or temperature profiles can be obtained from two measurements of Rayleigh signal. The measurement range is approximately 70 m with a measurement time less than 10 s. So, this new technology is limited to static tests up to now. However, this sensing technique has already been tested successfully for damage detection in composites laminates [2], for crack detection in concrete [3 and 4] and for structural tests of wind turbine blade [5].

3 CONSTRUCTION OF THE PAVEMENT WITH THE FIBER OPTIC SENSOR

3.1 *Pavement structure and implementation of defects*

The tested pavement structure is a typical French low traffic pavement [6] consisting of 80 mm of high modulus asphalt, over a granular subbase (300 mm thick, 300 MPa of modulus), and a sandy subgrade soil with a bearing capacity of about 95 MPa.

To accelerate damage, artificial cracks were initiated in the pavement by the implementation of steel bars with different shapes (triangle, T shaped and flat) in the layer of asphalt. These bars were placed at the bottom of the asphalt layer, to initiate bottom-up cracking. (Figs. 3 and 4). All the steel bars were placed transversely to the wheel path axis as shown

Figure 3. Triangle steel bars and T shaped steel bars fixed in the UGM.

Figure 4. Implementation of a flat steel bar in the asphalt.

on Figure 5. The distance between two identical shape steel bars is approximately 40 cm. It was expected that a crack would initiate at an early stage and propagate transversely to the wheel path axis between the two steel bars of the same shape placed 40 cm apart.

3.2 *Implementation of the distributed fiber optic sensor*

The optical cable used as distributed fiber optic sensor was placed in wheel path axis of the pavement over a length of 8 m. In this configuration, we expected that cracks initiated by

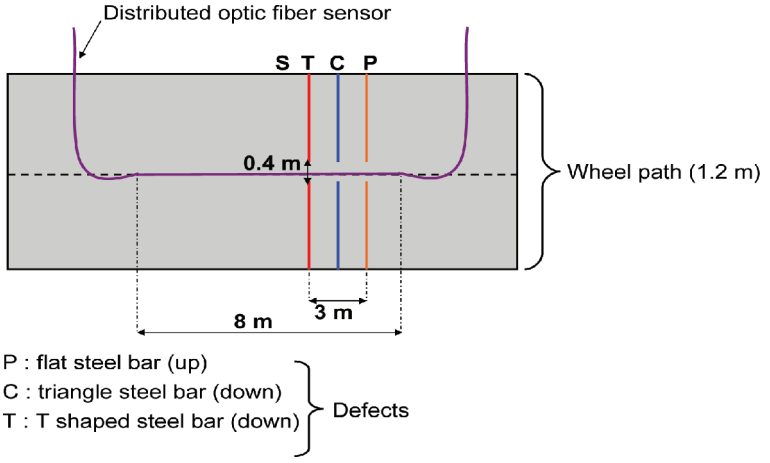

Figure 5. Plan of implementation of the steel bars and of the fiber optic cable.

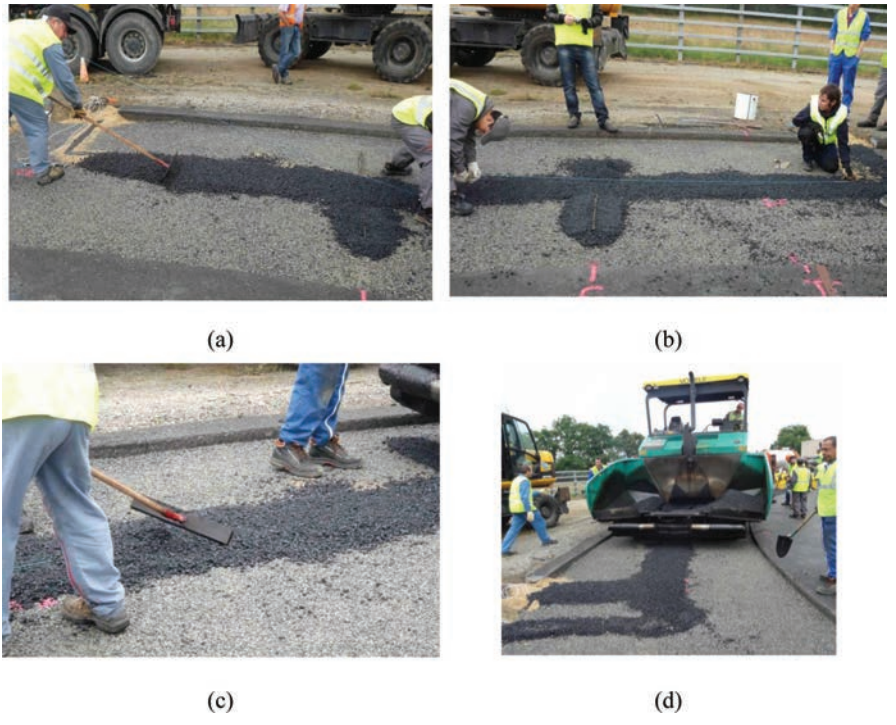

Figure 6. Steps of the process of integration of distributed fiber optic sensing in the asphalt layer.

the implementation of the steel bars would intersect the optical cable perpendicularly. The integration of the optical cable in the asphalt layer was performed in three steps. First, a thin layer of asphalt (about 10 mm thick) was placed manually on the UGM foundation and compacted (Fig. 6-a). Afterwards, the optical cable was put on this layer of asphalt in the wheel path axis (Fig. 6-b) and it was covered manually by a thin layer of asphalt (Fig. 6-c) to maintain it in place. Finally, a paver and compactor were used to place an asphalt layer of 80 mm (Fig. 6-d). By this process, the optical cable was integrated in the pavement at 70 mm depth, near the bottom of the asphalt layer.

It is worth to note that none of the optical cables put on the asphalt layer were damaged during the construction of the pavement. The optical cable chosen for this experimentation proved to be resistant enough to the high temperature of the asphalt mix (about 170°C) and to the compaction of the pavement layer by the paver and the compactor.

4 EXPERIMENTAL PROTOCOL

4.1 *Configuration of the pavement fatigue carrousel*

In our experimentation, the four arms of the pavement fatigue carrousel have been equipped with standard dual wheels, loaded at 65 kN (standard French equivalent axle load). The tires used are Dunlop 1200 R20 SP321, inflated at 850 kPa (Fig. 7). The loading speed was 6 rounds/minute (43 km/h). The lateral wandering was ±52.5 cm.

Two phases of loading were applied during the test. For the first 308 000 load cycles (from 9th August to 4th December 2013) the four arms of the fatigue carrousel have been equipped with standard dual wheels, loaded at 65 kN. For the next 221 00 load cycles (from 5th to 18th December 2013) the dual wheel loads were increased to 75 kN. At the end, 529 00 load cycles were applied on the structure.

4.2 *Fiber optic measurements*

It is important to note that two measurements of the Rayleigh signal are necessary to obtain a strain (or temperature) profile. It is similar as taking two pictures at different times and comparing them to find differences due to strain or temperature modifications along the fiber optic. Strain profiles are then relative measurements. All the strain profiles presented in this article were obtained from two successive measurements of the Rayleigh signal which were performed on the structure first with no load and then under the application of a static 65 kN load (one of the dual wheel axles of the carrousel) at different positions above the fiber optic sensor. Typically, a first measurement was made with the tires of the dual wheels of the carrousel placed outside the instrumented pavement section. Then, the tires were placed above the fiber optic at positions “P”, “C”, “T” and “S” successively (Fig. 5) and a new measurement was made at each position. This sequence of measurements was performed every 50 000 load cycles and surface cracking of the pavement was surveyed at the same time.

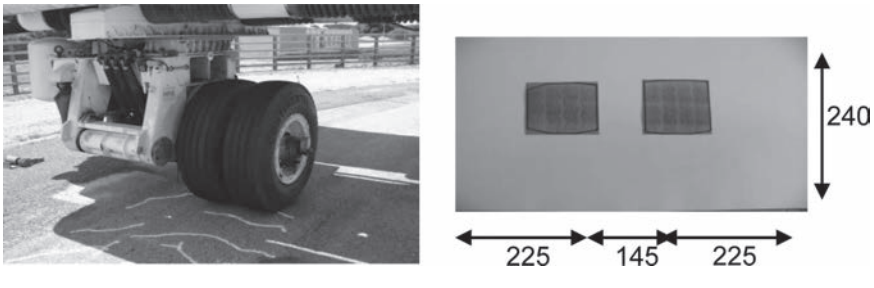

Figure 7. Dual wheel load and its dimensions in mm.

To summarize, a strain profile was obtained (for a given number of loads) from the comparison of the Rayleigh signals measured with a static load applied at each position i (i = "P", "C", "T", "S") of the test section, with the "reference signal" obtained without any load.

Moreover, it was necessary to take into account in the measurement procedure the viscoelastic behavior of the asphalt pavement. Due to viscoelasticity, when a static load was applied at a position i, the measured strain increased with time (creep phase). To reduce the dispersion of the strain profile measurements due to this effect, the same time interval was always kept between the application of the load and the Rayleigh signal measurement (one minute).

It is worth to note that the time between the optical measurements at the different positions was less than 20 minutes; so we can consider reasonably that the temperature did not change and neglect the influence of temperature in the analysis of the fiber optic measurements.

5 RESULTS AND DISCUSSION

Figures 8-a and 8-b show strain profiles measured at different numbers of load cycles, with a static load applied at the position "P" for the Rayleigh signal measurement. Until 300 000

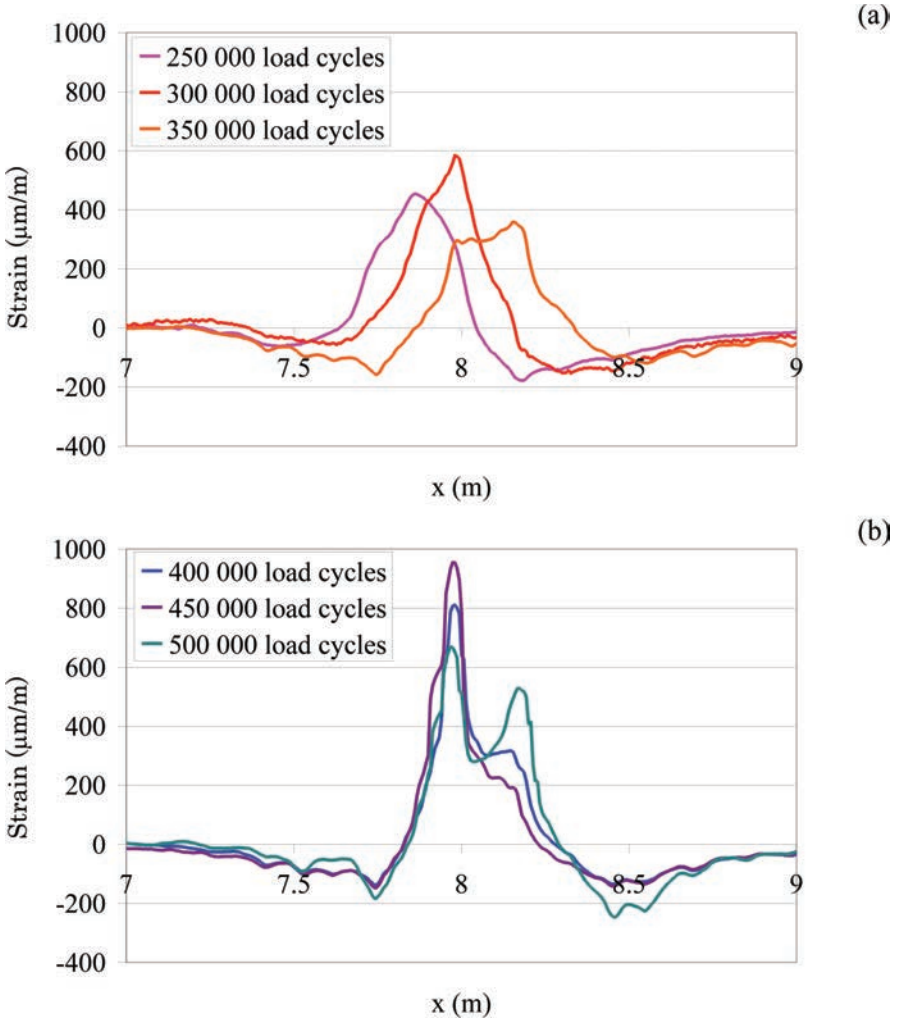

Figure 8. Strains measured at position "P" at different numbers of load cycles.

load cycles, the measured strain profiles are similar. They have the same shape, as shown in Figure 8-a. No significant change of width and maximum of the peak can be observed. The only difference is that the abscissa of the peaks are slightly shifted. It is due to the fact that the tire (the load) was not placed exactly at the same position for the different measurements. Moreover, no crack was detected on the pavement until 300 000 load cycles (see Figs. 9-a and 8-b). So, it seems logical enough to detect no change in the strain profile measurements.

The first cracks were detected on the surface of the pavement after 350 000 load cycles. They appeared at the ends of the steel bars placed in the pavement to initiate early cracks (Figs. 9-c and 9-d). The propagation of these cracks under further load cycles was surveyed. At the end of the test (500 000 load cycles), the cracks extended over the whole width of the pavement section and split (Fig. 9-e).

These observations were compared to the strain profile measurements obtained by the distributed fiber optic sensor embedded in the asphalt layer of the pavement. At 350 000 load cycles, just before the first crack appeared, the width of the peak of strain increased significantly in comparison with the previous measurements. At 400 000 and 450 000 loads cycles, the maximum of the peak continued to increase and finally the peak split into two new distinct peaks. This last measurement (at 500 000 load cycles) is particularly interesting because the two peaks of the strain profile could be unequivocally attributed to the two cracks observed at the surface of the pavement.

Similar results were obtained at the positions "C" and "T". The evolution of strain profiles at these positions was almost the same as obtained at position "P". These measurements were again consistent with observations of cracks at the surface of the pavement. In comparison, at position "S", where no crack was observed on the surface of the pavement, the shape and amplitude of the strain profiles remained almost identical until the end of the experiment (Figs. 10-a and 10-b).

All these results clearly demonstrate that distributed fiber optic sensor based on Rayleigh sensing technique could detect crack initiation and propagation by monitoring the shape of the strain profiles measured near the bottom of the pavement layer (in the longitudinal or transversal direction), at different times.

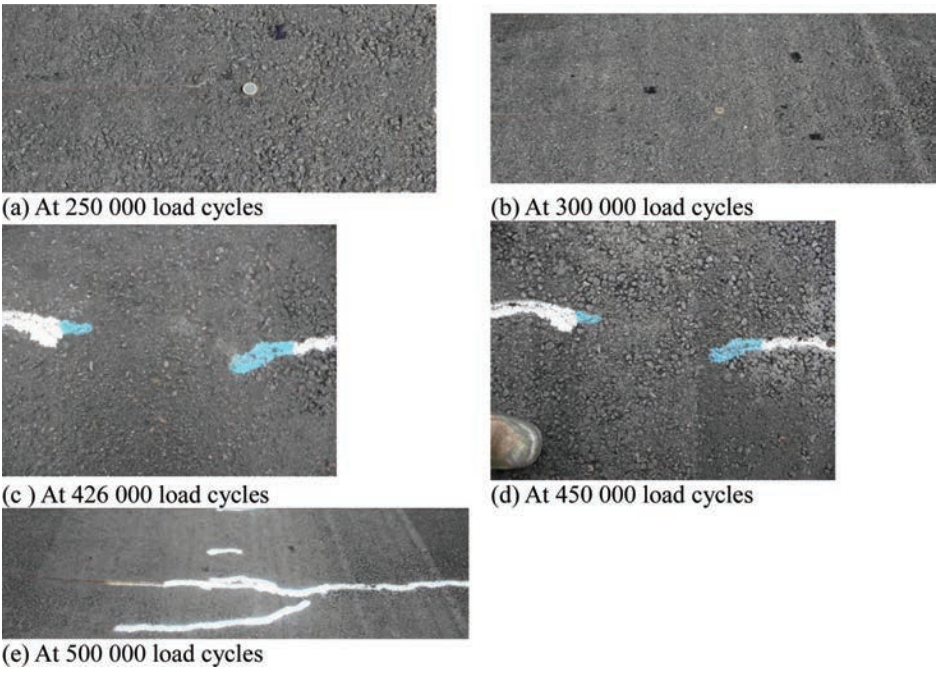

Figure 9. Evolution of cracking of the pavement structure at position "P".

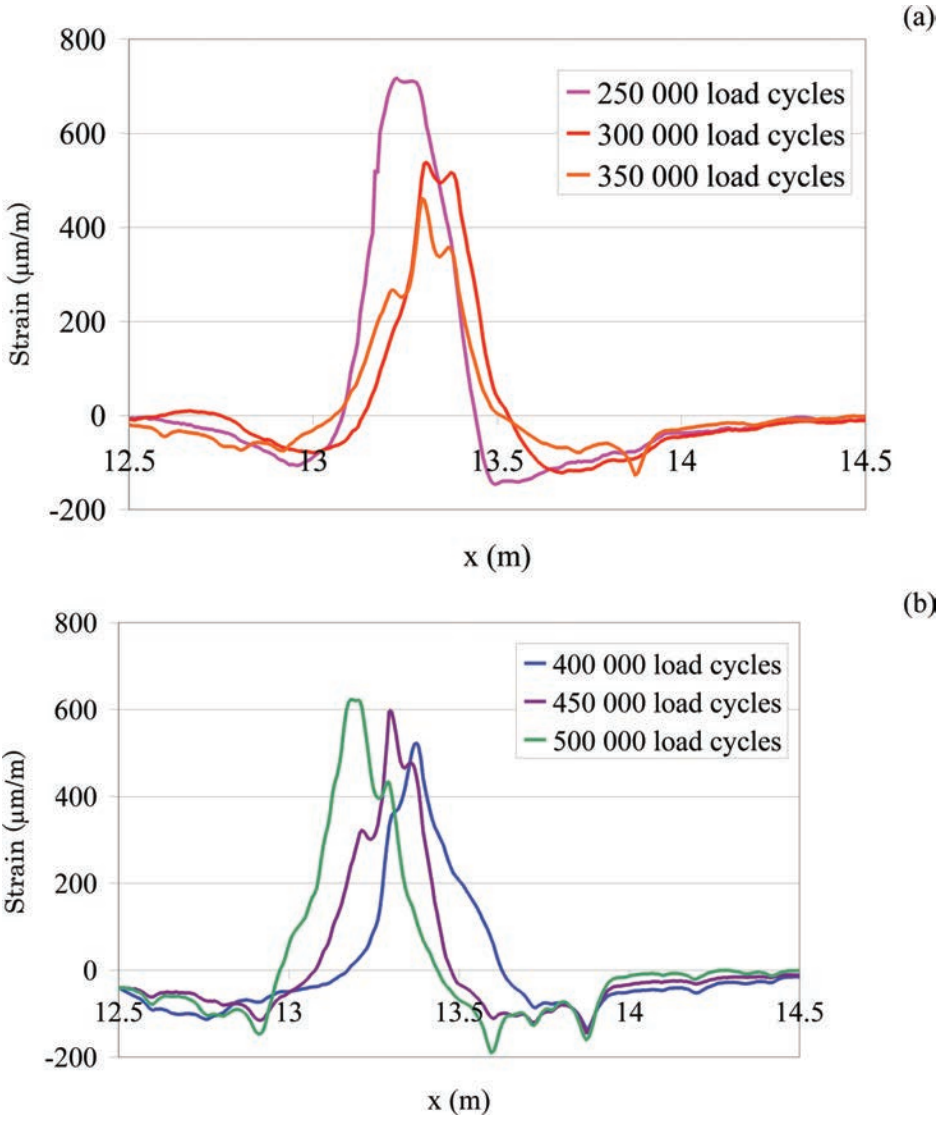

Figure 10. Strains measured at the position "S" at different load cycles.

Moreover, the experiment demonstrated the good resistance of the fiber optic sensor during construction and during traffic loading. In particular, it is worth to note that the transducer continued to respond well despite the cracking of the pavement structure.

6 CONCLUSION

A new non-destructive technique for the detection of cracking in asphalt pavements was tested at real scale on the pavement fatigue carrousel of IFSTTAR. The proposed method requires the embedment of a fiber optic cable in the pavement layer. This cable is used as a distributed sensor to obtain strain profiles by the Rayleigh sensing technique. The method is based on the comparison of the strain profiles measured at different time, after different levels of traffic.

In our study, we showed that significant changes of shape of the strain profiles could be directly linked to crack initiation and propagation. It is a promising result that confirms the possibility of using distributed fiber optic sensor to detect crack initiation in a pavement. The main originality and interest of this technique is the possibility to make continuous measurements, over relatively long distances (70 m with the equipment used in this study, but more with other techniques), with a high spatial resolution.

It is planned to continue to evaluate the efficiency of this technique. Indeed, the first results need to be confirmed for other pavement structures. Some additional tests will be performed on our pavement fatigue carrousel in the next months. A laboratory study is also planned, to carry out bending tests on pre-cracked asphalt plates, equipped with a continuous optical fiber. These tests, carried out in controlled conditions, should allow a better assessment of the sensitivity of the fiber to the presence of a crack in the asphalt, and of the influence of various parameters (loading time, temperature) on the results.

In perspective, we also study the feasibility of using distributed fiber optic sensor to detect cracks without the requirement of applying a load on the pavement. This solution would be a more efficient to monitor long lengths of pavements.

Evaluation of fatigue damage in asphalt pavement using FWD dissipated work

Kimio Maruyama & Masayuki Kumagai
Civil Engineering Research Institute for Cold Region, Toyohira-ku, Sapporo, Japan

ABSTRACT: The purpose of this study was to verify the relation between the secular changes in FWD dissipated work and fatigue damage, including the timing of fatigue cracking.

The FWD measurement data used in this study were acquired in research conducted from 1993 to 2007 at a national highway site. FWD dissipated work were calculated from the FWD load-deflection hysteresis loop. Investigation was made to determine whether there was correlation between fatigue cracking and FWD dissipated work. This study found the followings,

1. It was confirmed that dissipated work decreases with increases in the thickness of the asphalt mixture layer.
2. FWD dissipated work was found to show a tendency to increase with the occurrence of fatigue cracks.
3. A linear relationship on the double-logarithmic graph was found between FWD dissipated work and the number of wheel load passes.
4. FWD dissipated work is able to serve as a useful indicator in predicting the timing of fatigue failure.

Keywords: FWD, dissipated work, fatigue damage, fatigue failure, hysteresis loop

1 INTRODUCTION

In analyzing research data obtained by Falling-Weight Deflectometer (FWD), analysis based on the deflection amount or back-calculation of the elastic modulus have been commonly used; however, dissipated work has been proposed as an evaluation indicator. Dissipated work measured by FWD (hereinafter: FWD dissipated work), according to the literature, relates closely to pavement damage and pavement fatigue failure [1–3]; therefore, it is logical to expect dissipated work to relate closely to cumulative fatigue damage; however, the tendency for FWD dissipated work to change with time and the relation between FWD dissipated work and fatigue failure phenomena have not been fully verified on roads in service.

From 1993 to 2007, the authors continuously performed FWD measurements of deflection at the inner wheel path parts and between the wheel path parts on a specific site of a national highway, where asphalt pavements with eight different types of layer structures were constructed in the same lane. During the continuous investigation, fatigue cracks were detected in five of the eight layer structures. Therefore, this study was conducted with the aim of understanding secular changes in FWD dissipated work and of verifying how the secular changes relate to fatigue damage, including the timing of fatigue cracking.

2 RESEARCH METHOD

2.1 *FWD test method used at Bibi New Test Road*

The FWD measurement data used in this study were acquired in research conducted from 1993 to 2007 at a national highway site named Bibi New Test Road. The road has been in service since July 1990, when it was constructed. Since then, FWD measurements have been taken continuously at the Inner Wheel Paths (IWP) and Between the Wheel Paths (BWP) of the eight types of layer structures described in Figure 1. Table 1 shows the year and month of FWD measurement. The measurement was basically conducted in spring and autumn; however, in addition to then, it was conducted at various times of year with temperature differentials in the pavement. Additionally, 24-hour wheel load investigation has been conducted

on weekdays in autumn almost every year. The measurement has been conducted according to "the method of using a portable vehicle weight scale," described in the Pavement Research and Test Methods Handbook [4]. Table 1 also shows the cumulative number of 49 kN-equivalent wheel load that had been recorded until the time when the FWD measurements began.

During the continuous research, 5 of the 8 sections at the Bibi New Test Road were found to have fatigue cracks. In Section T1-1, Section A and Section T2-1, fatigue cracks occurred after 8.8 million wheel passes. In Section B, fatigue cracks occurred after 11,24 million wheel passes, and in Section T1-2, fatigue cracks occurred after 12,95 million wheel passes. Section T1-1 and Section A each had a 12-cm-thick asphalt mixture layer, and Section T2-1 and Section B each had a 15-cm-thick asphalt mixture layer. In addition, these sections had a course graded asphalt mixture type-B (poor content of asphalt type) at the bottom layer. Also, the Section T1-2 had a 12-cm-thick mixture layer and had a course graded asphalt mixture type-A (rich content of asphalt type) at the bottom layer. Fatigue cracks occurred in more than one of the layer structures; however, fatigue cracks were not detected in Section C, which had a 26-cm-thick asphalt layer, in Section D, which had a 35-cm-thick asphalt layer, or in Section T2-2, which had a dense-graded asphalt mixture layer at the bottom. It is assumed that differences in the thickness of the mixture layers and in fatigue resistance of the mixture at the bottom layers relate to the occurrence of fatigue cracks [5]. Investigation was made to determine whether there was correlation between fatigue cracking and FWD dissipated work.

2.2 *Definition of FWD dissipated work*

FWD dissipated work is defined as the area that is surrounded by the hysteresis loop on a time-series graph that plots measured load on the vertical axis and deflection on the horizontal axis, as shown in Figure 2. The work is considered to have dissipated into the asphalt layers, the subbase layers or the subgrade layers; furthermore, it is also considered to have dissipated into the rubber material or the rubber buffer under the FWD loading plate or as mechanical friction in the measuring device. Therefore, the FWD dissipated work is regarded as involving all the work that dissipated in all these portions. Accordingly, in light of accurately evaluating fatigue damage in asphalt pavement in line with the purpose of the present paper, it is ideal to start by quantitatively and separately grasping the work that has dissipated from each portion, then detect the amount of work that has dissipated into the asphalt layers, the subbase layers or the subgrade layers, and finally evaluate how the amount of work that dissipated relates to fatigue damage.

However, in light of the four viewpoints listed below, this study was conducted with the aim of specifically determining whether FWD dissipated work relates to fatigue crack phenomena in asphalt mixture layers.

1. No technique exists for determining how much of the FWD dissipated work has dissipated into each portion (e.g., the asphalt layer, the subbase layer, the subgrade layer, the rubber material, the rubber buffer under a FWD loading plate) or as mechanical friction in the measuring device.

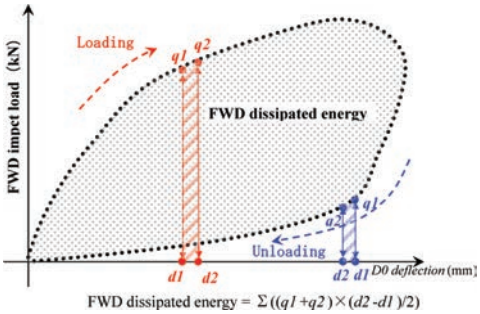

Figure 2. Calculating method of dissipated work.

2. The FWD data used in this study were obtained in the measurement test conducted with the same FWD testing machine on the same test day. Given that the testing machine produces the same discrepancies (e.g., from the rubber material and the rubber buffer under the FWD loading plate) for all the data, it was considered possible to attribute most of the differences in FWD dissipated work to the asphalt mixture layers, the subbase layers or the subgrade layers.
3. It is recognized that FWD dissipated work is always affected by the presence of an asphalt layer, since FWD dissipated work varies according to temperature and it changes depending on the asphalt layer structures such as thickness. In addition, it is thought that the degree of influence given by the subbase layers or the subgrade layers does not change much with temperature.
4. It is already known that there is a linear relationship on a double-logarithmic graph of the dissipated energy obtained by bending fatigue tests conducted in a laboratory versus the load applications to fatigue failures [6,7]. It was considered to be remarkably meaningful to verify whether there is a similar relation between FWD dissipated work and fatigue failure phenomenon in the mixture layers.

2.3 *Calculation method of FWD dissipated work*

Figure 2 and the following paragraph show the procedure for calculating FWD dissipated work from FWD time-series data.

The time-series data on loaded weight and deflection just below loading point was sampled at intervals of 0.002 seconds. FWD dissipated work, which is equivalent to the area surrounded by the hysteresis loop, was obtained by integrating the product of increase in deflection and change in load at every sampling, during the loading process and by sequentially subtracting the product of decrease in deflection and change in load during the unloading process at every sampling.

2.4 *Method of sorting temperature of asphalt mixture*

Since the properties of asphalt are known to be affected by the temperature, FWD dissipated work was also expected to be affected by pavement temperature; therefore, the values of the FWD dissipated work were sorted according to the temperature of asphalt mixture at the time of measurement. Temperature of pavement layer structure was measured by means of thermocouples buried in the four types of pavements of Section A, Section B, Section C and Section D, at the depth shown in Table 2. The temperature measurements for the asphalt layer, which correspond to the shaded parts in Table 2, were used to calculate the average temperature of the asphalt mixture layers by Formula (1).

$$t_{as} = \left((t_0 + t_1)h_1/2 + (t_1 + t_2)(h_2 - h_1)/2 + \cdots\cdots + (t_{n-1} - t_n)(h_n - h_{n-1})/2\right)h_n \quad (1)$$

3 RESULTS AND DISCUSSION

3.1 *Relation between pavement temperature and FWD dissipated work*

The relation between temperature of asphalt mixture layer and FWD dissipated work is plotted in Figures 3 and 4, according to the type of pavement layer structure. Figure 3 plots the results from a group of layer structures, namely Sections A, B, C and D, which have the asphalt layer designed according to a TA method in a Japanese standard way; however, each of these asphalt layers has a different thickness. Figure 4-a) plots the results from the a group of layer structures that have a 12-cm-thick asphalt mixture layer, but each of these bottom layers has a different type of mixture, and Figure 4-b) plots the results from a group of layer structures that have a 15-cm-thick mixture layer, but each of these bottom layers has a different type of mixture.

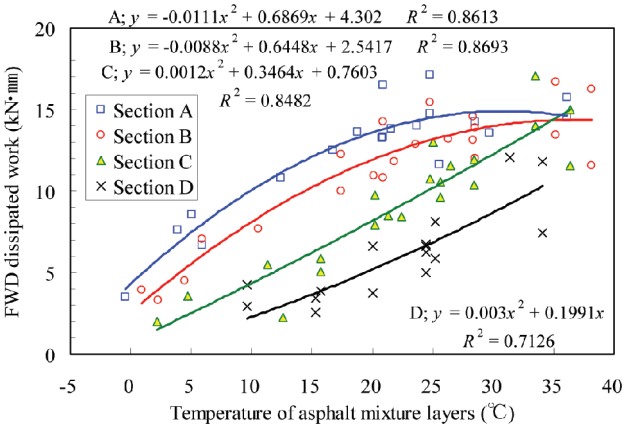

Figure 3. Relation between pavement temperature and FWD dissipated work (Sections A, B, C and D).

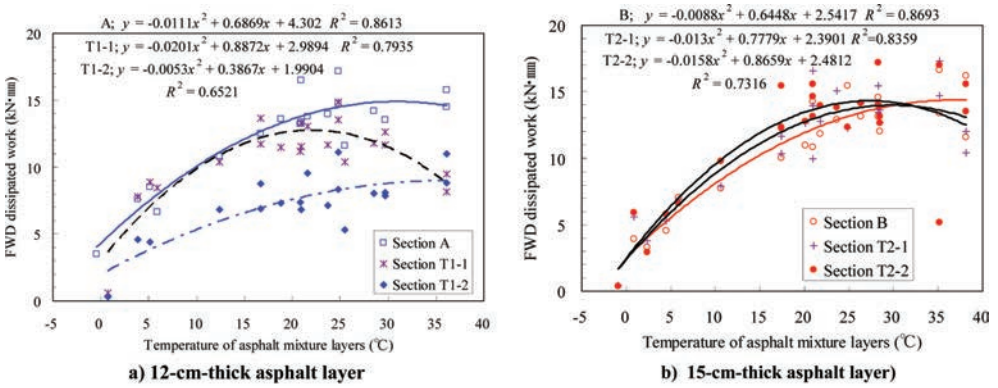

Figure 4. Relation between pavement temperature and FWD dissipated work.

First, Figure 3, Figure 4-a) and Figure 4-b) show that the FWD dissipated work increases with increase in temperature of asphalt mixture, when the pavement temperature was 25°C or lower, but the FWD dissipated work had a tendency to remain at the same level or lower when the pavement temperature was 25°C or higher. Further, Figure 3 shows that when the asphalt layers designed in a standard way according to the TA method differ in thickness from each other, the FWD dissipated work also differs. Figure 4-a) shows that the FWD dissipated work is smaller in Section T1-2, even though all the asphalt mixture layers have the same 12-cm thickness. In contrast, in Figure 4-b), differences in FWD dissipated work are not found among the pavement layer structures.

3.2 *Relation between the pavement layer structure and the FWD dissipated work*

3.2.1 *Relation between the thickness of asphalt layers and dissipated work*

The relation between the thickness of asphalt mixture layers and the FWD dissipated work is shown in Figure 5. In Figure 5, the values of FWD dissipated work calculated when the pavement temperature was 10°C, found from the regression equation for each pavement layer structure in Figure 3, Figure 4-a) and Figure 4-b), are plotted. Here, 10°C is used as a representative pavement temperature, since the average yearly pavement temperature of the Bibi New Test Road is approximately 10°C. A tendency for the dissipated work to decrease with increases in the asphalt mixture layer thickness is found here.

3.2.2 *Relation between asphalt mixture type of bottom layer and dissipated work*

Figure 6 show the relation between the asphalt mixture type of bottom layer and the dissipated work observed for Sections A, T1-1 and T1-2, and for Sections B, T2-1 and T2-2, in both of which the asphalt mixture layers have the same thickness but are made with different asphalt mixtures. In addition, the values in Figure 6 correspond to the values obtained when the pavement temperature was 10°C in the regression equation for each pavement layer structure shown Figures 3 and 4. The dissipated work in Section T1-2, whose bottom layers consisted of course graded asphalt mixture type-A (rich content of asphalt type), seems to be smaller when compared with the dissipated work in Section A and Section T1-1, whose bottom layers consisted of course graded asphalt mixture type-B (poor content of asphalt type). In contrast, the dissipated work in Section T2-2 is approximately the same as that of Section B or Section T2-1, whose bottom layers consisted of course graded asphalt mixture type-B (poor content of asphalt type). It is speculated that dissipated work would differ according to mixture type even if asphalt layers were of equal thickness; however, no specific tendency was identified.

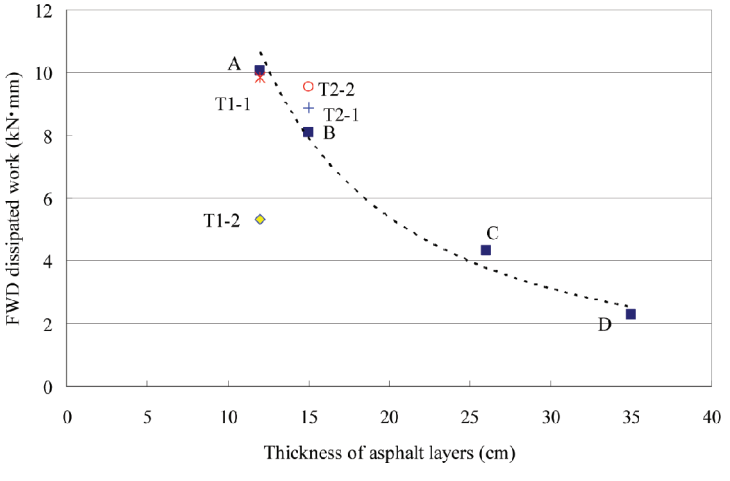

Figure 5. Thickness of asphalt layers and dissipated work (10°C).

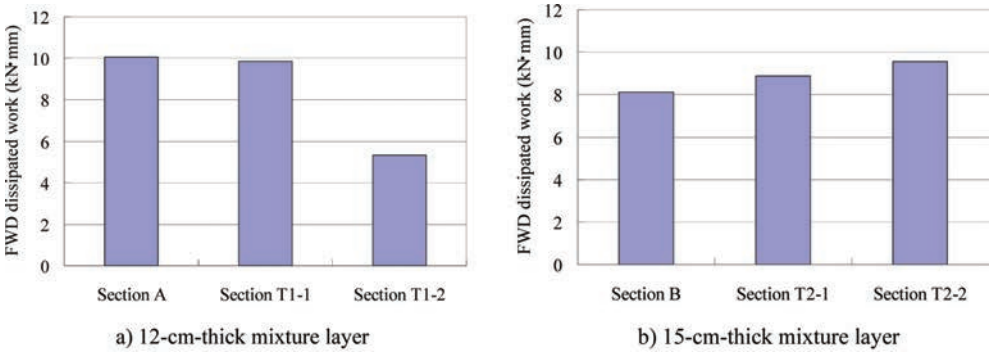

Figure 6. FWD dissipated work in layer structures (10°C).

3.2.3 *Change in dissipated work after the occurrence of cracks*

In Figure 7, the data group obtained from 1993 to 1995, when the pavement was still undamaged, the data group obtained around the time when fatigue cracks began to occur (October 2000 to October 2001) and the data group obtained around the time when reflection cracks began to occur after milling & overlay (July 2003 to June 2006) are plotted to clearly visualize the relationship between dissipated work and fatigue damage.

In Section A, the dissipated work at the IWP, which is directly affected by wheel load, has a tendency to deviate from the relation between asphalt temperature and dissipated work that was found before the layer structure was damaged, as the damage in the pavement increased. Also, in Section B, the dissipated work at the IWP, which is directly affected by load, has a tendency to deviate from the relation between mixture temperature and dissipated work that was found before the layer structure was damaged, as the damage in the pavement increased.

In contrast, in Section C and Section D, fatigue cracks did not occur during the investigation, and also during that time, secular change was not found in the relation between dissipated work and temperature.

From the above, it is speculated that the values of dissipated work show a tendency to be greater in damaged condition, where the accumulation of fatigue damage and the occurrence of fatigue cracks were found, than in sound condition.

3.2.4 *FWD dissipated work and the cumulative number of 49 kN-equivalent wheel load at the time of fatigue failure*

The relation between FWD dissipated work and the cumulative number of 49 kN-equivalent wheel load up to the occurrence of fatigue cracks, and the relation between the sum of FWD dissipated work and the cumulative number of 49 kN-equivalent wheel load up to the occurrence of fatigue cracks, were examined in the five pavement sections where fatigue cracks occurred (Sections A, T1-1, T1-2, B and T2-1). The results are shown in Figures 8 and 9. The dissipated work per FWD impact load in Figure 8 is defined as dissipated work from one-time FWD loading measurement at the pavement temperature of 10°C, which was obtained using the regression equations shown in Figures 3 and 4. The values of FWD dissipated work when the pavement temperature was 10°C were used as representative values, because the yearly average pavement temperature at the Bibi New Test Road is approximately 10°C. In addition, the total FWD dissipated work in Figure 9 is defined as the sum of dissipated work up to the time of fatigue crack occurrence, which is equivalent to the value obtained by multiplying the cumulative number of 49 kN-equivalent wheel load passes up to the occurrence of fatigue cracks, by the dissipated work per FWD impact load, on the assumption that "the dissipated work per FWD impact load ≒ dissipated work per 49 kN wheel load pass."

Moreover, fatigue crack generation was not found in Section C, Section D and Section T2-2 up to the present time; therefore, the expected cumulative number of 49 kN-equivalent wheel load up to the occurrence of fatigue cracks was calculated instead, using research

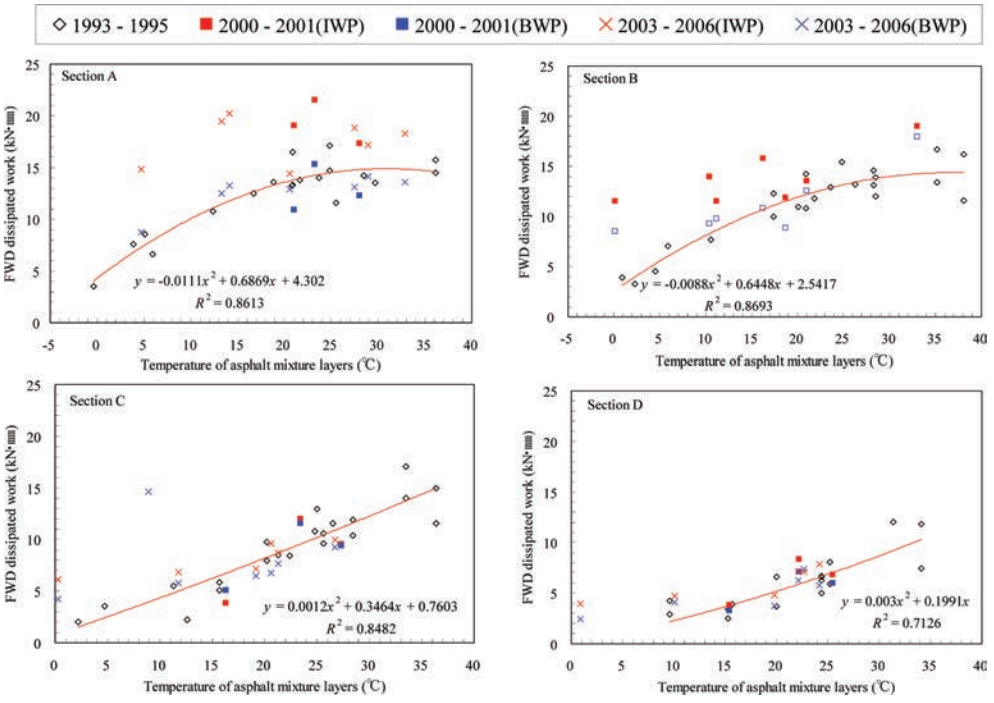

Figure 7. Change in FWD dissipated work after the occurrence of fatigue cracks.

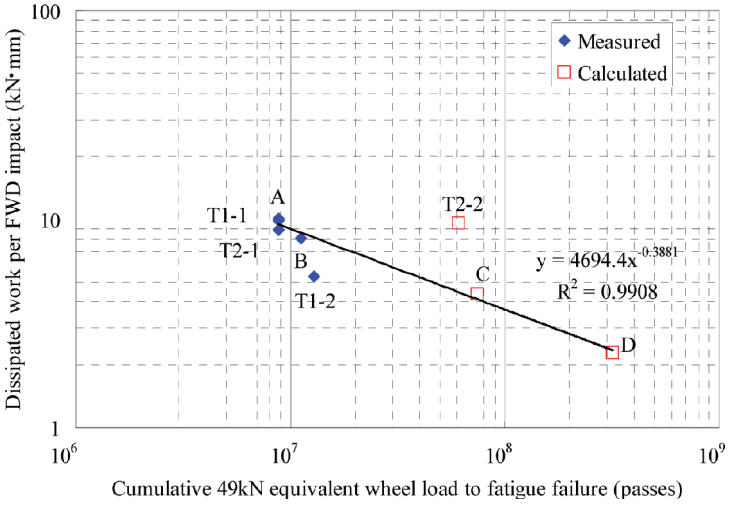

Figure 8. Relation between FWD dissipated work (10°C) and fatigue failure wheel load.

results [8] obtained by the authors, in order to predict how long it would take for fatigue failure to occur. The calculated values are plotted in Figures 8 and 9 as open square. In addition, regression lines for the data group taken from the layer structures (Sections A, B, C, D, T1-1 and T2-1), whose bottom layers consisted of course graded asphalt mixture type-B (poor content of asphalt type), are also plotted.

As shown in Figure 8, it is still difficult to identify a specific tendency only from the measured data on the pavement layer structures in which fatigue cracks were detected; however,

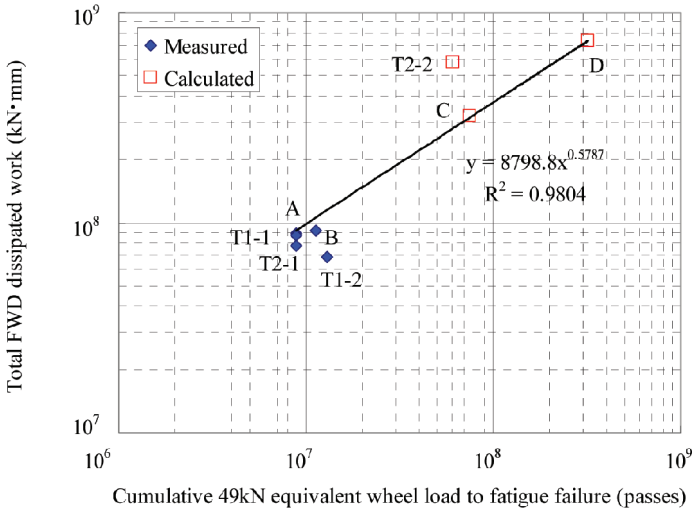

Figure 9. Relation between total dissipated work and fatigue failure wheel load.

when taking calculated values into consideration, it becomes obvious that there is a linear relationship between the dissipated work and the cumulative number of 49 kN-equivalent wheel load at the point of fatigue crack generation, in the double-logarithmic graph. Also, in Figure 9, a linear relationship in the double-logarithmic graph is found even between the total FWD dissipated work and the cumulative number of 49 kN-equivalent wheel load.

Himeno and Van Dijik have reported that there is a linear relationship on the double-logarithmic graph, between the number of fatigue failures and the values of dissipated energy obtained in laboratory bending fatigue tests [6,7]. From the obtained results, it is assumed that there is an analogous relation between FWD dissipated work and the timing of fatigue failures, and it is also assumed that FWD dissipated work is able to serve as a useful indicator in evaluating the fatigue damage of pavement.

However, as shown in Figures 8 and 9, the values for Section T1-2, whose bottom layers consisted of course graded asphalt mixture type-A (rich content of asphalt type), and the values for Section T2-2, whose bottom layers consisted of dense graded asphalt mixture, are plotted at a distance from the regression lines obtained from the values of the layer structures that have course graded asphalt mixture type-B (poor content of asphalt type) at the bottom layer; therefore, it is considered that the obtained data, including the data shown in Figures 8 and 9, do not yet allow a consistent conclusion to be drawn. As mentioned above, FWD dissipated work is able to serve as a useful indicator in predicting the timing of fatigue failure; however, it is considered that FWD dissipated work has to be further examined through data accumulated from various sites in the future.

4 CONCLUSIONS

The results of this study can be summarized as follows.

1. It was confirmed that dissipated work decreases with increases in the thickness of the asphalt mixture layer. In contrast, it was speculated that FWD dissipated work would differ by the type of asphalt mixture at the bottom layer. Expected results were obtained for the layer structure of Section T1-2; however, no significant difference was found in the results obtained from Section T2-2. Therefore, we recognize that we have not yet reached a satisfying conclusion through this verification.
2. FWD dissipated work was found to show a tendency to increase with the occurrence of fatigue cracks, compared with when it was in sound condition. It is assumed that fatigue

damage in pavement will be able to be evaluated by understanding the relation between the temperature of the mixture layer and FWD dissipated work at the time when pavement is in sound condition.

3. A linear relationship on the double-logarithmic graph was found between FWD dissipated work measured shortly after pavement construction and the number of 49 kN-equivalent wheel load passes on the pavement up to the point that the pavement suffered fatigue failure. A similar relation was also found to be associated with the total of the FWD dissipated work.
4. FWD dissipated work is able to serve as a useful indicator in predicting the timing of fatigue failure; however, it is considered that FWD dissipated work has to be further examined through data accumulated from various sites in the future.

ABSTRACT: In recent years, expressway authorities in Japan require an effective method for monitoring and measuring surface characteristics of their pavements. Against this background, we have introduced a mobile profiling system enabling real-time roughness data collection. The system uses two accelerometers fixed to a suspension system of any passenger and commercial vehicles to measure the International Roughness Index (IRI) based on a back-calculated profile. One of the advantages of this system is to capture the information of longitudinal profile features. However, since the measurement algorithm is optimized to compute the IRI in real-time, the back-calculated profile is distorted by the natural frequencies of suspension components. This study examines an estimation technique of a longitudinal true profile using the mobile profiling system by developing a reconstruction filter to attenuate the distortion in the spatial frequency domain by the Fast Fourier Transform (FFT) method. As the result of a validation experiment, the mobile profiling system using the reconstruction filter satisfies practical requirements as a profiler compared with a Class 1 measures. The result also indicates that the system basically has a capacity to measure the IRI in real-time, and the back-calculated profile is appropriate for the purpose.

Keywords: mobile profiling system, true profile, accelerometer, signal processing, International Roughness Index

1 INTRODUCTION

In recent years, expressway authorities in Japan require an effective method for monitoring and measuring surface characteristics of their pavements. Against this background, we have introduced a mobile profiling system enabling real-time roughness data collection. The system uses two accelerometers fixed to a suspension system of any passenger and commercial vehicles to measure the International Roughness Index (IRI) based on a back-calculated profile. One of the advantages of our system is the capability to capture the information of how the roughness deteriorates by means of longitudinal profile features. This study describes the real-time IRI measurement algorithm for the mobile profiling system. However, since the measurement algorithm is optimized to compute the IRI in real-time, the back-calculated profile is distorted by the natural frequencies of suspension components. This study examines an estimation technique of a longitudinal true profile using the mobile profiling system by developing a reconstruction filter to attenuate the distortion in the spatial frequency domain by the Fast Fourier Transform (FFT) method. Against the traditional pavement monitoring approaches based either on visual inspections or on laser profilers, the proposed system contributes to valid, quantitative, and economical monitoring activities for expressway pavements.

2 MEASUREMENT ALGORITHM OF THE MOBILE PROFILING SYSTEM

Since modern technologies for road surface condition survey with better sensors have been improved, a lot of profilers have been developed in various countries. Principle of our profiling system is based on the conventional Quarter-Car (QC) model used for calculating IRI. Therefore, two accelerometers are mounted at the sprung and unsprung mass of a vehicle. This chapter describes system configuration and measurement algorithm of the mobile profiling system.

2.1 *Overview of the Quarter-Car model*

The IRI is a mathematical model applied to a measured longitudinal road profile. The model simulates a QC model shown in Figure 1 that predicts the spatial derivative of suspension stroke in response to a profile using standard settings for speed and the vehicle properties depicted in the figure [1].

In Figure 1, V, m_u, m_s, k_t, k_s, and c_s denote vehicle forward speed, unsprung mass, sprung mass, tire spring rate, suspension spring rate, and suspension damping rate, respectively. The values called the Golden Car parameters are: = 80 (km/h), = 0.15, = 653 (1/s2), = 63.3 (1/s2), and = 6 (1/s2). The moving average baselength (B) is set to 250 mm as a standard aspect of the IRI calculation.

2.2 *Conception of the system development*

Nowadays, many approaches for measuring surface roughness have been developed. According to Sayers [2], the approaches can be grouped into the following four classifications on the basis of how directly their measures pertain to the IRI.

- Class 4—a roughness measure is not reproducible or stable with time, and can only be compared to IRI by subjective estimation,
- Class 3—a measure obtained from an RTRRMS is calibrated to the IRI scale by correlation with reference measures from a Class 1 or 2 system,
- Class 2—a profile-based method is used that is reproducible and stable with time, and that is calibrated independently of other roughness measuring instruments, and
- Class 1—a profile-based method similar to Class 2 is used. A profile-based measurement qualifies as a Class 1 measure if it is so accurate that further improvements in accuracy would not be apparent.

These classifications are attended with a conflict between accuracy and convenience on the roughness measurement. The more accurate the measurement, the convenience is sacrificed.

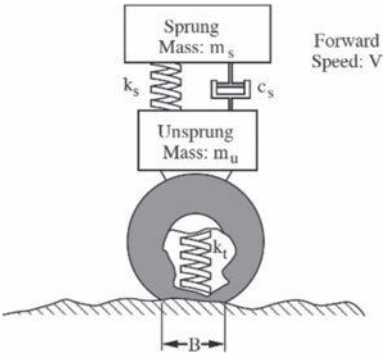

Figure 1. A schematic depiction of a Quarter-Car model.

The more convenient the measurement, on the contrary, the accuracy is impaired. The developed profiling system is intended to combine the accuracy of Class 2 and the convenience of Class 3. In other words, it can directly measure surface profiles using vehicle dynamic responses.

2.3 *System configuration and measurement algorithm*

The new profiling system can be mounted in any passenger and commercial vehicles. The system of the profiling system consists of two small accelerometers, a GPS (Global Positioning System) sensor, an amplifier, and an onboard laptop computer. A small GPS sensor is put on near the front window of the vehicle for measuring the vehicle traveling speed and location. An amplifier converts the strain of accelerometers into the electrical signal. An onboard computer records and displays the measurement results in real time.

The main feature in designing the mobile profiling system is measuring surface profiles using accelerometers. Using accelerometers contribute to save the installation costs over the use of laser sensors. Two small accelerometers are attached to the sprung and unsprung mass at a suspension system of a four-wheel vehicle. This instrumentation mechanically implements the quarter-car model used for the IRI simulation on a real car. Figure 2 shows the overview of roughness measurement algorithm of the mobile profiling system. The following sections describe the details of the algorithm.

2.3.1 *Acceleration measurement*

First, vertical accelerations of the sprung and unsprung masse (denoted by $\ddot{X}_s$ and $\ddot{X}_u$) are measured by using two accelerometers. The measurements are mathematically converted to the velocities and displacements of each mass by subsequent steps. Note that the two dots over a variable indicate a double derivative of the variable with respect to time.

2.3.2 *Pre-processing*

Second, as a pre-processing, the noise, trend, direct current excitation, and velocity dependence factors of vehicle vibrations are removed from $\ddot{X}_s$ and $\ddot{X}_u$ by use of digital filters. As the first step of this process, a Kalman filter is applied to detrend the measured acceleration. Then, as the second step, a narrow-bandpass filter removes the velocity dependence factors. As the final step, high frequency components over 30 Hz are removed by using a low-pass filter.

2.3.3 *Integration of acceleration data*

Third, $\ddot{X}_s$ and $\ddot{X}_u$ are integrated over time to calculate the velocities (denoted by $\dot{X}_s$ and $\dot{X}_u$ respectively) and the displacements (denoted by X_s and X_u respectively). Here, the dot over a variable indicates a time derivative of the variable.

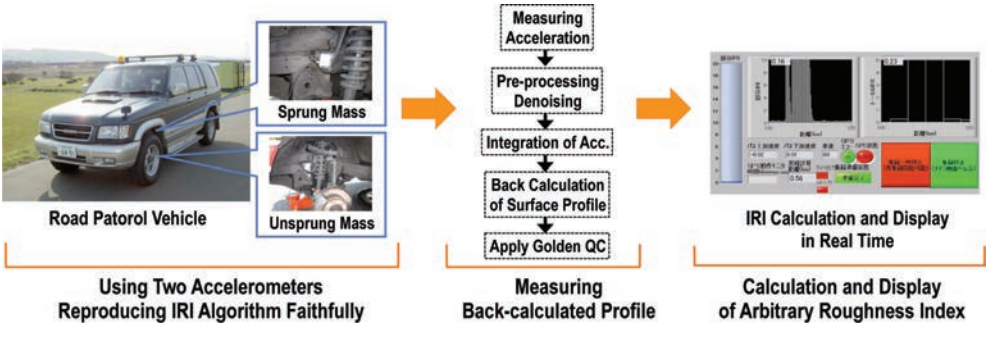

Figure 2. Overview of the measurement algorithm of the mobile profiling system.

2.3.4 *Back calculation of a surface profile*

Fourth, a longitudinal elevation profile denoted by X_p is calculated based on the back calculation of the equations related to motions of the mechanical suspension system which reproduces the quarter-car model. The equations of motions for the suspension system are described as follows:

$$m'_s\ddot{X}_s + c'_s(\dot{X}_s - \dot{X}_u) + k'_s(X_s - X_u) = 0 \tag{1}$$

$$m'_u\ddot{X}_u + c'_s(\dot{X}_u - \dot{X}_s) + k'_s(X_u - X_s) + k'_t X_u = k'_t X_p \tag{2}$$

Here, in the equations, a single prime for each coefficient indicates the value obtained from the survey vehicle.

2.3.5 *Golden Car simulation*

Fifth, the response of the Golden Car model to the measured profile X_p is simulated by use of the following equations.

$$m_s\ddot{x}_s + c_s(\dot{x}_s - \dot{x}_u) + k_s(x_s - x_u) = 0 \tag{3}$$

$$m_u\ddot{x}_u + c_s(\dot{x}_u - \dot{x}_s) + k_s(x_u - x_s) + k_t x_u = k_t X_p \tag{4}$$

Here, for the variables, a small letter "x" is used instead of the capital letter "X".

2.3.6 *IRI calculation*

Finally, IRI values for an arbitrary interval are computed by using the result of the Golden Car simulation regarding the slope profile. The IRI is an accumulation of the suspension stroke of the Golden Car in response to a slope profile, normalized by the travelled distance. Thus, the IRI represents average rectified slope, with units such as mm/m or m/km. The IRI over a number of profile samples (n) is as follows:

$$\mathrm{IRI} = \frac{1}{n}\sum_{i=1}^{n}\left|S_{s,i} - S_{u,i}\right| \tag{5}$$

Here, the motion variables x_s and x_u are redefined in terms of slope valuables S_s and S_u. Note that the feature of the developed profiling system is its ability to directly obtain surface profiles. Consequently this profiling system can calculate any other profile-based indices instead of the IRI.

3 METHOD OF LONGITUDINAL TRUE PROFILE ESTIMATION

3.1 *Overview of the true profile estimation*

The mobile profiling system calculates IRI based on back-calculated surface profile data by use of accelerometers. The measurement algorithm optimizes the back-calculated profile to compute IRI in real-time by the pre-processing (see Section 2.3.2). Figure 3 shows an example of profile measurements and Power Spectral Density (PSD) functions of surface elevation measured by Rod & Level of a Class 1 profiler and the mobile profiling system operated at 80 km/h. As shown in the figure, the mobile profiling system underestimates the PSD amplitudes with wavelengths of 14 and 1.5 m (Wave Number of 0.07 and 0.7 m^{-1}) corresponding to the natural frequencies of sprung and unsprung mass of a vehicle than Rod & Level. The other difference appears in a wavelength of 0.7 m (Wave Number of 1.5 m^{-1}) caused by the natural frequency of tire characteristics. Here, the precision of IRI measurements of the mobile profiling system is within 10% of the Rod & Level as shown in Figure 3. In the following part of this paper, we develop an estimation method of longitudinal true profiles that are compatible with Class 1 measurements by use of the mobile profiling system.

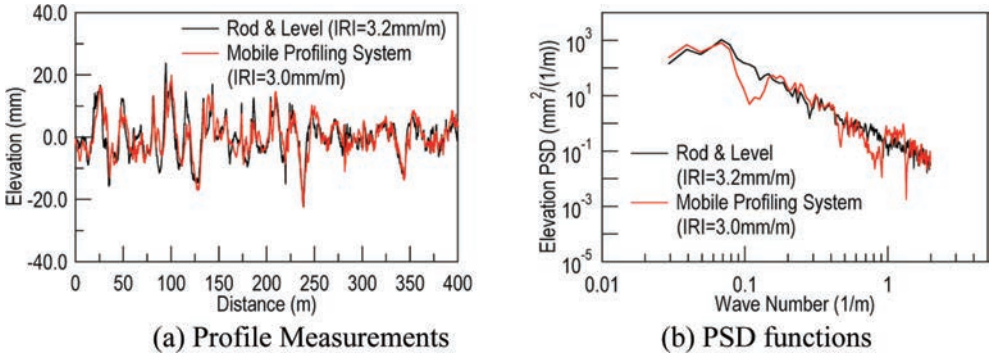

Figure 3. An example of profile measurements and PSD functions of surface elevation measured by Rod & Level and the mobile profiling system.

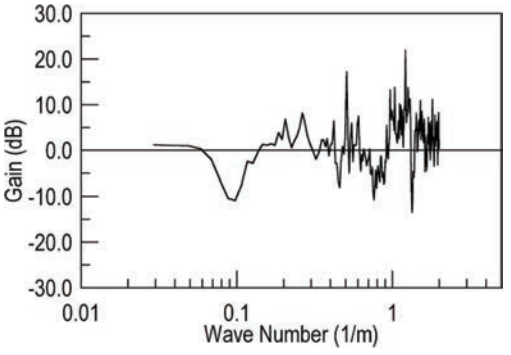

Figure 4. A wave number response of the mobile profiling system.

This chapter describes a reconstruction filter and its application to compensation of the underestimations.

3.2 *Development of a reconstruction filter*

The mobile profiling system functions as mechanical filters that have a wave number response optimized to the real-time IRI calculation. Figure 4 illustrates an example of the filter gain for profile elevation measured by Rod & Level. For the purpose of the true profile estimation, a reconstruction filter that has the inverse wave number response of Figure 4 is required. A reconstruction filter can be designed by computing a wave number response of the mobile profiling system to Rod & Level measurements. In this study, we develop a reconstruction filter on the basis of a Fast Fourier Transform (FFT) method that is performed in the spatial frequency domain. By using the FFT, convolution via the frequency domain can be faster than directly convolving the time domain signals. The final result is the same; only a more efficient algorithm has changed the number of calculations. For this reason, we use FFT convolution for the true profile estimation. Following are the detailed procedures for designing a reconstruction filter.

3.2.1 *Pre-filtering*

To remove the slope and very long undulations of road surfaces, measured profile data are filtered to limit the wavelengths to the range between 0.5 and 50-m which define the profile wavy characteristics in terms of pavement roughness by a 6th order Butterworth band-pass filter [3]. Profiles are resampled at an interval of 0.1 m for different sampling intervals in this process.

3.2.2 *Segmentation of measured profile data*

A related confusion of the FFT is the trade-off that must be made between wave number and distance resolution. The more accurately we want to measure the wave number content of a profile, the more samples we have to analyze in each frame of the FFT. Yet there is a cost to expanding the frame size—the larger the frame, the less we know about the temporal events that take place within that frame. A potential idea of applying the FFT to a very long profile is to split the profile sequence into several segments and then to average the segments at a certain overlap. By considering the trade-off between wave number and distance resolution for profile analyses, this process splits the profile data series into analytical segments of 1024 (= 2^{10}) with 50% overlap.

3.2.3 *Windowing*

The FFT algorithm assumes that the input profile data is an infinitely repeating periodic signal with the endpoints wrapping around. Thus, to the extent that the amplitude of the first point differs from the last point, the resulting frequency spectrum is likely to be distorted as result of this start point to endpoint discontinuity, which is so-called "edge effect". This can be overcome by "windowing" the data during the transformation. In this study, the hamming window function is used to attenuate the edge effects.

3.2.4 *Computation of a wave number response*

For this purpose, first, the profile data series of each segment are transformed into the spatial frequency domain by the FFT. Then, this process computes the PSD function of the transformed data series because the FFT produces a spectrum in complex form. Where the PSD functions of the profiles measured by Rod & Level and the mobile profiling system as $P_x(f)$ and $P_y(f)$, a wave number response $H(f)$ can be calculated by the following equation:

$$|H(f)| = \sqrt{P_y(f)/P_x(f)} \tag{6}$$

The gain can be expressed in a decibel unit as following:

$$|H(f)| = 10\log_{10}\left(P_y(f)/P_x(f)\right) \quad (dB) \tag{7}$$

Finally, a wave number response of the mobile profiling system can be obtained by averaging the responses for each analytical segment as shown in Figure 4.

3.2.5 *Design of a reconstruction filter*

A reconstruction filter is simply composed by the inverse factor of the wave number response shown in Figure 4 in the spatial frequency domain. Note that a reconstruction filter depends on the operated speed of the mobile profiling system.

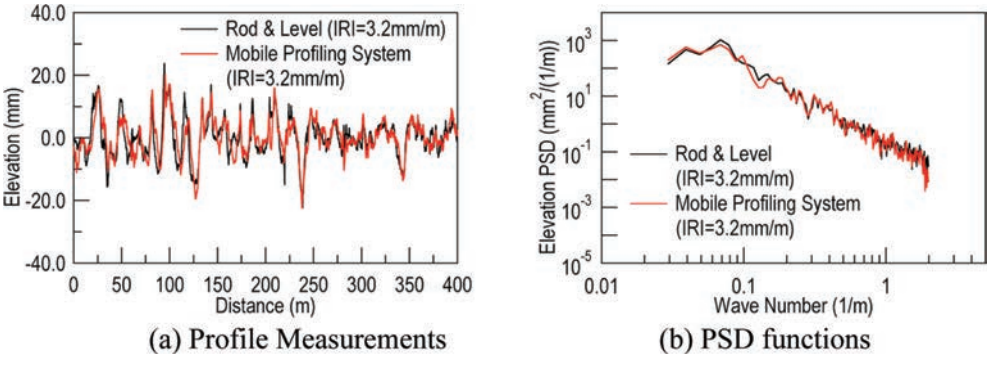

Figure 5. An example of true profile estimation result by use of the mobile profiling system.

3.3 *Estimation of a longitudinal true profile*

The basic idea of developing a reconstruction filter uses the principle of FFT-based digital filters that multiplication in the spatial frequency domain corresponds to convolution in the spatial domain. To estimate a true profile by use of the mobile profiling system, first, the measured profile data is transformed into the spatial frequency domain using the FFT, and then multiplied by the reconstruction filter developed by the previous section. Finally, the filtered data is transformed back into the spatial domain using the Inverse FFT (IFFT). Figure 5 shows an example of the estimation result of the true profile.

As shown in Figure 5, the reconstruction filtering process dramatically improves the profile measurement of the mobile profiling system compared with Rod & Level of a Class 1 measure. In the next chapter, we demonstrate the applicability of the true profile estimation regarding vehicle characteristics and operating speeds of the mobile profiling system.

4 VALIDATION EXPERIMENT OF THE TRUE PROFILE ESTIMATION

In this study, we performed a validation experiment of true profile estimation using the mobile profiling system. The experiment was carried out on an in-service expressway in Hokkaido, Japan.

4.1 *Measurement of surface profile data*

For the purpose of the validation experiment, a reference profile was manually measured by Rod & Level survey. At the same time, three different vehicles such as Sedan, SUV, and Van with the mobile profiling system recorded the relative profiles at three different speeds of 60, 80, and 100 km/h. The experimental section was 400 m long, and the profiles were sampled at an interval of 100 mm for the present study. Figure 6 shows an overview of the experimental site and the Rod & Level survey.

4.2 *Comparison of profile measurements*

This section verifies the accuracy of back-calculated profiles and true profile estimations using the mobile profiling system by comparing with the Rod & Level survey. For this purpose, average percentage errors of the PSD functions per octave-band are calculated for each measurement condition so as to quantify the discrepancy between two instruments. Table 1 summarizes the error of each back-calculated profile and true profile estimate. As shown in the table, the percentage errors are substantially decreased in the true profile estimations. Here, note that the acceptable error for longitudinal profile measurements in Japan is within 30% compared with Class 1 measures. Thus, the performance of the mobile profiling system

Figure 6. Overview of the experimental site and the Rod & Level survey.

Table 1. Profile measurement accuracy of the mobile profiling system.

Vehicle type	Operation speed (km/h)	Percentage error (%)	
		Back-calculation	True profile estimation
Sedan	60	47.6	7.9
	80	41.6	14.5
	100	37.2	11.3
SUV	60	46.9	7.4
	80	44.4	13.0
	100	38.5	10.6
Van	60	42.8	10.1
	80	54.1	17.8
	100	71.1	25.3

Table 2. IRI measurement accuracy of the mobile profiling system.

Vehicle type	Operation speed (km/h)	Percentage error (%)	
		Back-calculation	True profile estimation
Sedan	60	6.4	1.2
	80	14.0	0.1
	100	20.4	2.9
SUV	60	6.1	2.2
	80	7.0	0.6
	100	5.3	0.4
Van	60	8.7	4.0
	80	3.7	2.8
	100	4.9	5.8

satisfies the practical requirements as a profiler. This result indicates that the reconstruction filter is effective in estimating true profiles using the mobile profiling system.

4.3 *Effect on IRI measurements*

The mobile profiling system can originally reproduce IRI values within 10% error on average in real-tine. Table 2 shows the effect of the reconstruction filter on the IRI calculation. As shown in the table, the accuracy of the IRI measurement is slightly improved, but the change is not drastic. Therefore, the mobile profiling system basically has a capacity for measuring the IRI in real-time, and the back-calculated profile is appropriate regarding real-time IRI computation.

5 CONCLUSIONS

Today, expressway agencies in Japan require a proper method of monitoring the pavement roughness. This paper introduced a mobile profiling system for real-time monitoring of the IRI of expressways. The system uses two accelerometers fixed to a suspension system of any passenger and commercial vehicles to measure the IRI based on the back-calculated profile. The measurement algorithm of this system achieves both of the accuracy of Class 2 measures and the convenience of Class 3 measures. However, since the measurement algorithm is optimized to compute the IRI in real-time, the back-calculated profile is distorted by the natural frequencies of suspension components. This study also examined an estimation technique of a longitudinal true profile using the mobile profiling system based on the theory of

digital signal processing. For this purpose, we develop a reconstruction filter to attenuate the distortion in the spatial frequency domain by the FFT method. As the result of the validation experiment, the mobile profiling system using the reconstruction filter satisfies the practical requirements as a profiler of which percentage error is within 30% compared with a Class 1 measures. The result also indicated that the mobile profiling system basically has a capacity for measuring the IRI in real-time, and the back-calculated profile is appropriate for the purpose.

Kitami Institute of Technology, Kitami, Hokkaido, Japan

ABSTRACT: Although it is generally believed that road profile will improve after a repair paving project, it was revealed that this is not always true, judging from comparing IRI levels before and after repairing on 500 sections of the Japanese toll expressways. Some 30 percent having had IRI 2.0 m/km or lower showed higher IRIs after conventional milling and overlaying methods. To find out how to steadily obtain smoother road surface, octave band analysis was conducted to compare profile data before and after the repair between improved and unimproved sections.

As a result, it is recommended that rod-and-level survey is used, when road undulation or long wavelength profile needs to be corrected. It was also found that there was quite difference in post-repair riding quality on the sections that had been controlled by a veteran asphalt finishing operator and an inexperienced person, in spite of no visual differences in the repaired field. Thus it is concluded that octave band analysis can an excellent method of controlling road profile as it can effectively differentiate unseen quality on the roadway.

Keywords: IRI, repair paving project, octave band analysis, profile, survey

1 INTRODUCTION

Roughness quality in a repair paving project is inspected using a 3-meter-profilometer with its standard deviation value whose threshold is 1.3 mm. In a repair planning stage, International Roughness Index that relates riding quality [1] has been used on the nationwide toll expressways operated by three authorized companies, namely East, Central and West NEXCO in Japan.

Recently there has been an increasing claim that IRI is not improved after repair paving projects for the purpose of a better riding quality at NEXCO. Figures 1 and 2 report the situation at a local bureau, comparing IRI values before and after the repair. The five hundred 200 m-unit IRI data were collected on a left-sided truck lane in fiscal 2011 and 2012, covering several paving contractors. According to Figure 1, IRI was slightly reduced by the repair in average and standard deviation, while the peak values were not much changed. However, Figure 2 tells that some 30% of unit-sections are higher after the repair at the sites where pre-IRI is 2.0 or lower. Needless to say, all the projects sufficiently passed the current contract criteria of the 3-meter-profilometer's standard deviation.

It is unrealistic to prescribe a recoverable level for roughness, as it varies with various field conditions. However, a newly constructed level should be a bench mark. Figure 3 compares the above post-repair IRIs with those on four newly constructed roadways just before opening to traffic in fiscal 2004 through 2010. The shape of the new data group resembles that of the repair data group. This may suggest that profile improvement in the IRI ranges less than 2.0 is difficult with a common repair method.

This paper presents several findings in the course of studying an effective repair paving method that can practically improve road roughness. From the past studies, it was indicated

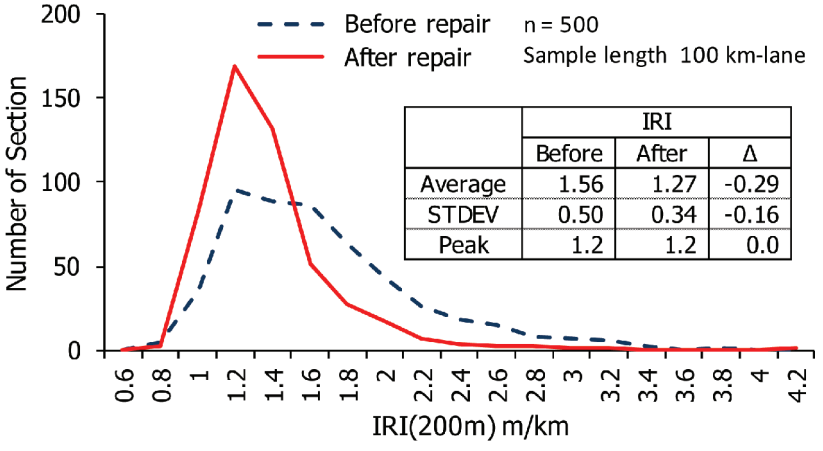

Figure 1. IRI histograms before and after repair at a local bureau.

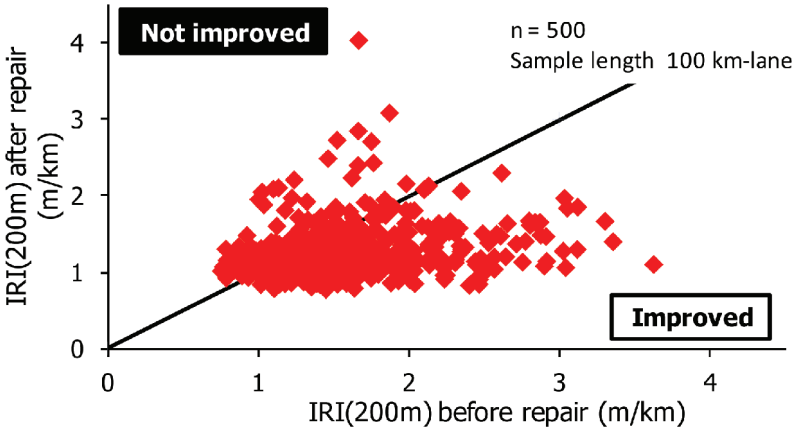

Figure 2. IRI distribution before and after repair at a local bureau.

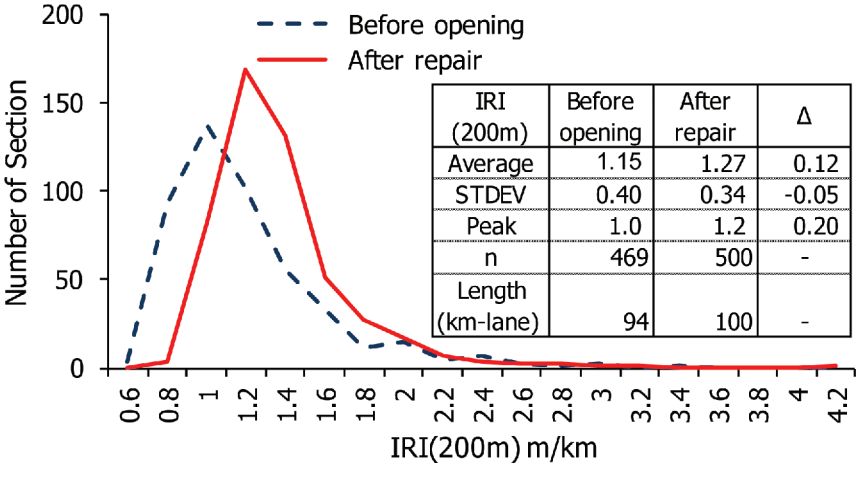

Figure 3. IRI histograms before opening and after repair at a local bureau.

that IRI is not suited for detecting irregular forms of road roughness. For understanding of localized defects, power spectral density [2], discrete Fourier transform [3], and wavelet transform [4,5] were introduced. However, these methods are too much academic to apply in the current contract procedures in Japan. In the study, octave band analysis which seems a much easier method was applied and comparison of profile data before and after several repair projects was conducted.

2 PAVEMENT REPAIR PROJECT

As a given condition in a pavement repair project, a road administrator is required to follow a traffic regulation issued by local police agency that is in charge of traffic safety in the community. The regulations are strict nationwide, due to a lack of road network system in Japan. Thus Japanese road operators and contractors are always struggling to secure safety in the field. For example, during milling and overlaying repair projects in many urban areas, only one lane closure is permitted and the closing hour for the lane is about 8 hours.

Table 1 lists typical repair projects for porous asphalt with measurements of longitudinal profile before and after rehabilitation. Project A adopts milling and overlaying two layers during a daytime 7 hours lane closure for damaged porous asphalt on an expressway nearby Tokyo. Project B repairs two layers by extending lane closure hours to 24 hours on a local route. Project C on another rural expressway strengthens the pavement structure by paving 14 cm thickness after milling 4 cm during an 8 hours daytime. Project A handles only one lane, while Project B and C repair two lanes by switching to the adjacent lane after the first.

Every 100 meter section's IRI data before and after repair among the three projects were plotted in Figure 4. Four sections out of 16 showed slightly higher IRI values after the repair.

Table 1. Typical repair Projects for porous asphalt on expressways.

	Project A	Project B	Project C
Repair method	Mill and overlay	Mill and overlay	Mill and overlay
Milling depth (cm)	4 + 6	4 + 6	4
Overlaying thickness (cm)	4 + 6	4 + 6	4 + 10
Repair month	September	October	November
Traffic regulation	6 hrs, one lane	24 hrs, one lane	8 hrs, one lane
Repair layers/day	2	1	1
Number of repair lanes	1	2	2

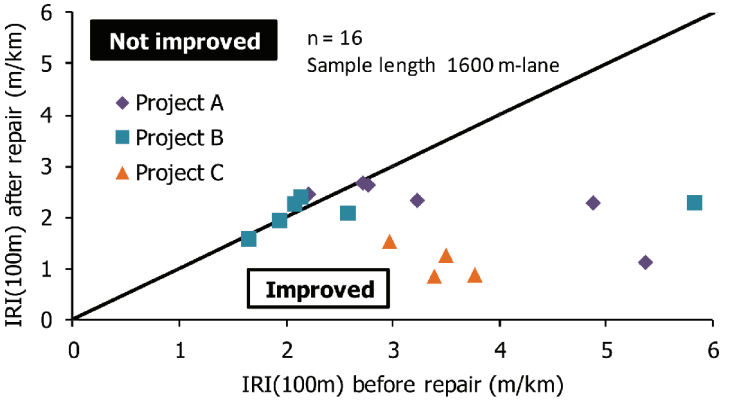

Figure 4. IRI distribution before and after repair at three projects.

The problematic sites were again observed at around 2.0. As naturally, Project C substantially improved the roughness, as it can best adjust the road profile by controlling the thicker thickness and on the neighbouring lane. Project A must be the toughest repair, since its allowable paving time was the shortest and only one lane is repaired. Although Project B had to deal with IRI levels around 2.0 in advance of repair, it covered two adjacent lanes, which is close to repair condition of Project C. A question arises here; "Was it really impossible in Project B to reduce the IRI values like in Project C?"

3 OCTAVE BAND ANALYSIS

Among six sections in Project B, three showed improvement in roughness after repair while the other three remained or increased IRI values. The most remarkable reduction in IRI was observed at its initial IRI level of 5.83. Because this worst site had suffered a slightly undulated roadway, rod-and-level survey was used as a pre-survey to correct the longitudinal profile. The other five adopted 10-meter-long-strings method to adjust milling depth.

3.1 *Band selection*

In order to find out how to steadily obtain smoother road surface, octave band analysis was conducted to compare profile data before and after the repair between 10-meter-long-strings and rod-and-level sections. In doing the octave band analysis, longitudinal profile of the selected sections was divided into nine bands, based on the known wave number response of the IRI quarter-car filter [6], as shown in Figure 5. Because IRI is mostly affected by octave band ranges No. 2 with wavelength of 51.2 m–25.6 m through No. 7 with 1.6 m-0.8 m, these 6 ranges will be focussed on hereafter.

3.2 *Pre-survey of profile*

Table 2 summarizes the comparison of a 100 meter's 10-meter-long-strings section and another 100 meter's rod-and-level survey section for each entailing octave band profile before and after the repair. Some surface distress types were also put down in the table.

All the post-repair octave band profiles in the latter section decreased more remarkably than in the former. This is quite understandable because the initial IRI value of 5.83 for the rod-and-level section diminished greatly to the post value of 2.29. However, it is noted

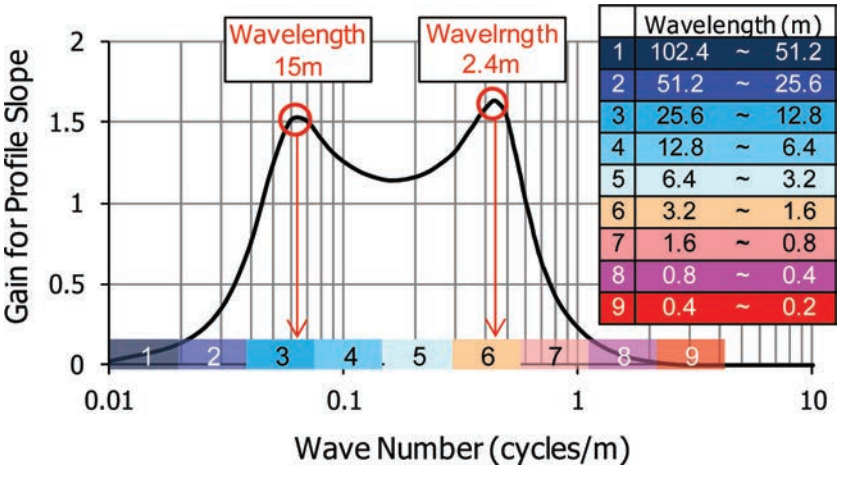

Figure 5. Wave number response of IRI quarter car filter [6].

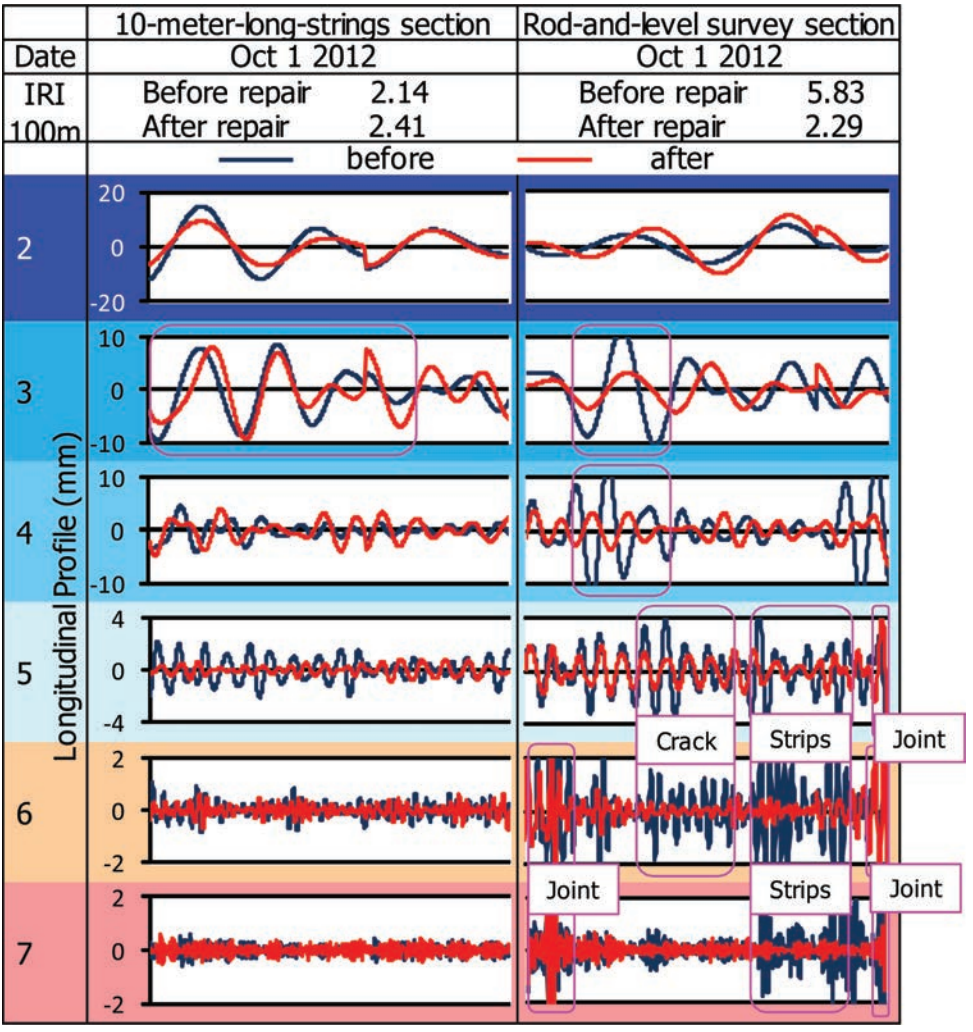
Table 2. Octave band profiles between pre-survey methods (Project B).



that portions of profiles on octave bands No. 3 and No. 4 were successfully improved in the rod-and-level, while those not well in the 10-meter-long-strings method. This probably indicates the limitation of the 10-meter intervals survey that cannot control road profile with its wavelength exceeding 10 meters. If rod-and-level survey had been adopted in the 10-meter-long-strings section, the post-repair IRI value would have been much lower than the initial value of 2.14.

It is also revealed that distress segments of cracking and stripping of aggregates that had emerged on octave bands No. 5 through No. 7 in the rod-and-level section were improved by the repair. This is quite reasonable, because the existing materials are replaced with new materials. At a site in Project A, however, it was confirmed that profiles on these octave bands will also be affected by the manipulation of asphalt finisher's screed during paving, which will be mentioned later. On the other hand, high profiles on adjacent bridge joints were unfortunately remained as there had been. This is because the joints were so damaged that the only new materials could not compensate for the adjacent profile.

From above findings, it was confirmed that octave bands No. 2 through No. 4 will capture undulation of road profile, while road surface distress can be explained by octave bands No. 5 through No. 7. Moreover, it is recommended that rod-and-level survey is used, when

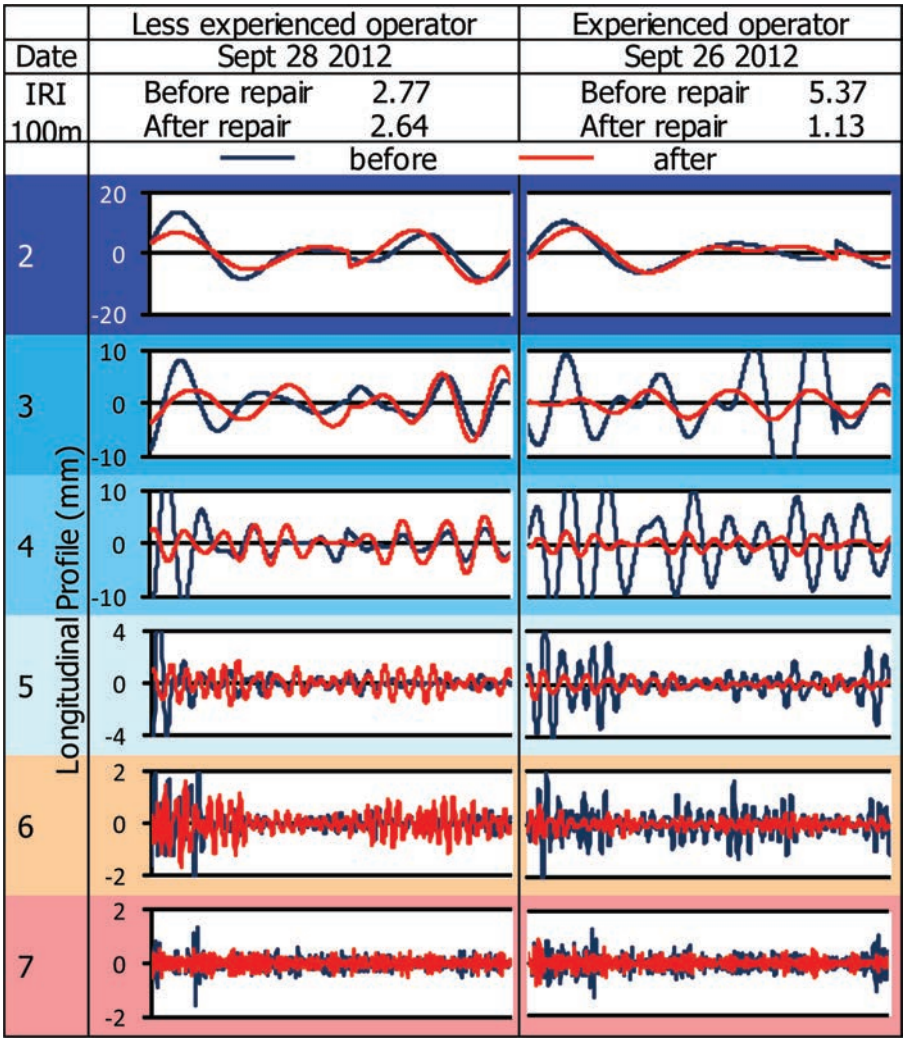
undulation or long wavelength profile that belongs to the former octave bands needs to be adjusted.

3.3 *Finishing operator*

There was a very interesting finding at Project A where the most difficult paving procedure was required. It was proved evident that roughness quality differs on sections paved by a well experienced finishing operator and a less experienced person. Table 3 supports the evidence.

As shown in the right side of Table 3, a drastic reduction in longitudinal profiles on octave bands No. 3 through No. 7 was observed on the section paved by a veteran operator. As a result, IRI was greatly improved from 5.37 to an initial opening level of 1.13. The two days later, when an inexperienced staff took replaced him on the continuing roadway section, there was not a clear improvement in profiles after the repairing. Judging from comparing the pre-profiles between the two sites, the veteran's part was more difficult to control the finishing machine, as the profiles acted up more in the entire octave bands. Moreover to be surprise, these sections were repaired without using rod-and-level survey or 10-meter-long-

Table 3. Octave band profiles between finishing operators (Project A).



strings methods, since there was not such visual abnormality in the roadway that nobody thought of the necessity of the pre-survey. As IRI indicates the post-IRI values, there is quite difference in riding quality on the two continuing sections, although there is no visual difference. This indicates the importance of so-called an artisan's technique, which is said to be impossible to write down in words for handing down to younger generations.

Although it is not yet revealed how the veteran achieved the profile improvement, it is at least confirmed that octave band analysis can clearly differentiate unseen quality on the roadway. The next challenge is to elucidate the veteran's technique that does not require a pre-survey. If this is well done on the analysis, road profile can be improved by controlling the existing octave band profiles to newly planned ones.

4 CONCLUSION

In the wake of an increasing claim that IRI is not improved after repair paving projects at NEXCO, investigation with five hundred 200 m-unit IRI data revealed that some 30% are higher after the repair at the sites where IRI before the repair is 2.0 or lower. In the course of pursuing a consistent repair method, octave band analysis was conducted to compare profile data between specific repair paving projects. Consequently, the followings were found.

1. Octave band ranges No. 2 through No. 4 with wavelength of 51.2 m to 6.4 m will capture undulation of road profile, while road surface distress can be explained by octave bands No. 5 through No. 7 with wavelength of 6.4 m to 0.8 m.
2. It is recommended that rod-and-level survey is used, when road undulation or long wavelength profile that belongs to the octave band ranges No. 2 through No. 4 needs to be corrected.
3. There was quite difference in post-repair riding quality on the sections that had been controlled by a veteran asphalt finishing operator and an inexperienced person, in spite of no visual differences in the repaired field.
4. It is concluded that octave band analysis can an excellent method of controlling road profile as it can effectively differentiate unseen quality on the roadway.
5. If a veteran's technique can be further grasped on the analysis, road profile can be steadily improved by controlling each existing octave band profile to a newly planned one.

ABSTRACT: Intelligent Compaction (IC) is defined as vibratory rollers with accelerometers mounted on the axle of drums, Real-Time Kinematic (RTK) or Virtual Reference System (VRS) Global Positioning System (GPS), and on-board computers that can display various roller operating settings on color-coded maps in real time. IC measurements include roller positions, number of passes, surface temperatures, and stiffness of the compacted materials. Asphalt in-place density, a common measurement for mix durability and performance, is influenced by many factors including material properties, environment, paving, and compaction. Based on the compaction history captured by IC, a stochastic method was developed to correlate the IC measurements to asphalt in-place density, either measured with nuclear density gauges or from cores. Between 2011 and 2014, the US Federal Highway Administration (FHWA) IC Phase II research team has planned nine (9) field projects around the US to validate and enhance the statistical correlation between IC measurements and asphalt in-place density. The validation data from the first three (3) sites show that the critical period of initial breakdown compaction is the most dominating factor to achieve desired density for a given support condition. A nonlinear stochastic model was developed to correlate the in-place density with IC measurements, including the stiffness of asphalt material and underneath layers, asphalt mat temperature, and roller vibration frequency/amplitude. Once the model is fully validated with data from all remaining sites, any IC system may utilize this stochastic method developed under this research to estimate asphalt in-place density in real time and use IC as a quality control tool to optimize asphalt density. Leveraging the IC geospatial data that cover one hundred percent of compacted area, IC can also be a truth metric for compaction uniformity. The ultimate goal of this research is to achieve compaction uniformity for long lasting pavement.

Keywords: asphalt, in-place density, paving, compaction, intelligent compaction, uniformity, performance

1 INTRODUCTION

Intelligent Compaction (IC) is defined as vibratory rollers with accelerometers mounted on the axle of drums, Real-Time Kinematic (RTK) or Virtual Reference System (VRS) Global Positioning System (GPS), infrared sensors, and on-board computers that can display various roller operating settings on color-coded maps in real time as displayed in Figure 1. IC measurements include roller positions, number of passes, mat surface temperatures, and stiffness of the compacted materials.

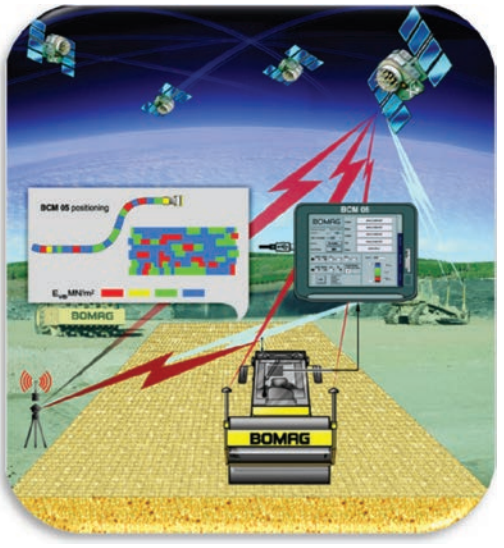

Figure 1. An illustration of intelligent compaction technology.

Asphalt in-place density, a common measurement for mix durability and performance, is influenced by many factors including material properties, environment, paving, and compaction. Based the compaction history captured by IC, a stochastic method was developed to correlate the IC measurements to asphalt in-place density, either measured with nuclear density gauges or from cores.

The Federal Highway Administration (FHWA) has been leading a national effort to advance the IC technology through a Transportation Pooled Funded (TPF) IC project (TPF-5(128)) with twelve (12) States participating and other subsequent projects. The scope of the FHWA/TPF IC project (FHWA-IC) was principally to conduct field demonstrations of the technologies in the twelve participating states on various material types including non-cohesive soils, cohesive soils, granular subbase, stabilized base, and asphalt materials and establish a knowledge base for further advancement and implementation of IC. Between 2007 and 2011, the FHWA IC research team has conducted fifteen field projects around the US to validate and enhance the statistical correlation between IC measurements and asphalt in-place density. The validation data show that the critical period of initial breakdown compaction is the most dominating factor to achieve a desired density.

The current IC technology outputs roller IC Measurement Values (ICMV) that relate to the stiffness of the underlying materials. On the other hand, density measurement is still commonly used for quality acceptance for most agencies and contractors as in-place densities often relate to long-term performance of asphalt or hot mix asphalt pavements. To accelerate the implementation of IC technology, it is essential to study the correlation between ICMV and asphalt core densities. In spite of the accomplishment of the FHWA/TPF IC projects, unsatisfactory correlation between ICMV and asphalt core density was observed from the initial IC field demonstration projects. This is due to many factors such as the differences in nature of measurements between ICMV and in-place densities, limited cores for being statistically significant, etc.

As a continuing effort under Phase II of the FHWA IC project, an extensive study is being conducted to assess the correlation between the IC measurements and asphalt core densities between 2011 and 2014. This work investigates the relationship between ICMV and core densities via extensive coring in order to establish a procedure to use IC as an acceptance tool for in-place asphalt densities.

In this paper, the preliminary results from the second phase of the FHWA IC study was reported based on the data collected from the first three of the nine field validation

sites (Utah, Florida, and Ohio). Nonlinear stochastic models were developed to correlate the in-place density with IC measurements, including the stiffness of asphalt material and underneath layers, asphalt mat temperature, and roller vibration frequency/amplitude. These stochastic models were screened and the optimal candidate model was selected. The selected stochastic model was firstly calibrated with a subset of the field data, and validated with the remaining data. Though still under development, the ultimate goal of this study is to evaluate whether IC technologies can be a reliable acceptance tool in addition to being a quality control tool. If it is a success, IC systems can incorporate the stochastic method developed under this research to estimate asphalt in-place density in real time and use IC as a quality assurance tool to optimize asphalt density during construction.

2 LITERATURE REVIEW

There are various efforts devoted to, though some partially, evaluate the potential benefits of intelligent compaction and relate ICMVs and other measurements to in-place field density. Past researches have shown poor or inconsistent correlations between ICMVs and asphalt core density, which could be due to factors such as the influences of the IC systems (e.g., vibration frequency and amplitudes) and pavement conditions (e.g., underlying layer stiffness). In summary, these factors include the following:

- Stiffness indexes derived from ICMVs of existing IC rollers represent an integral pavement structure with influence depths normally deeper than those by point test devices such as the nuclear density gauge. Therefore, these ICMVs are currently not yet decoupled to characterize individual layer stiffness.
- The current ICMVs for asphalt are tied to temperatures at test conditions instead of being normalized to a reference temperature. On the other hand, core density is independent of in-situ temperatures. Therefore, it would result in unsatisfactory correlation between ICMVs and core densities.
- Asphalt cores are normally taken after finishing rolling, while ICMVs are normally measured at breakdown or intermediate compaction. Therefore, there would be a gap of correlation created by the effects of intermediate and finishing rolling.

FHWA/TPF IC Study (2007 to 2011): The FHWA/TPF IC study was conducted between 2007 and 2011. Field demonstration projects are the major work under the FHWA-IC study. Key elements of the field demonstration include on-site training of TPF DOT and contractor personnel, comparison of IC roller technologies to traditional compaction equipment and practices, correlating IC roller measurements to in-situ spot test measurements, mapping the existing support to understand the influence of underlying layer support, selecting the appropriate machine operation parameters (e.g., speed, amplitude, frequency, etc.), and managing and analysing the IC and in-situ test data. Sixteen (16) IC field demonstration projects were performed for non-cohesive soils, cohesive soils, granular subbase, stabilized base, and asphalt materials. There were twelve (12) asphalt IC projects on various types of bases, overlay, and new construction under this study. HMA IC rollers from Bomag America, Inc. and Sakai America, Inc. were used during the above field demonstration.

The analysis results from FHWA-IC study have shown inconsistent correlations between ICMVs and nuclear density gauge (NG) densities. From the FHWA-IC study, ICMV generally increases with increasing density measurements by NG indicating that a higher stiffness corresponds with a greater material density. However, the correlation is often where the R^2 values ranges from 0.04 to 0.97. For the cases with more satisfactory correlation, it is often associated with larger number of in-place measurements on denser asphalt mixtures. On the other hand, cases associated with coarser mixtures such as the Stone Matrix Asphalt (SMA) in the Maryland demonstration often result in poor correlation. Therefore, consistent and repeatable NG measurements are the keys for improved correlation with ICMV. The analysis results from FHWA-IC study have also shown inconsistent correlations between ICMVs and asphalt core densities. The correlation reverses for some cases

such as the SMA overlay project in Maryland and new asphalt paving on the saturated base in Georgia.

As ICMV is potentially influenced by a number of factors, a multivariate analysis was conducted to include those factors as an attempt to improve the correlation under the FHWA-IC project (Xu et al. 2010; Chang et al. 2011). The factors included: ICMV from mapping the baseline structure, ICMVs during compaction of asphalt base courses, roller vibration frequencies, and asphalt surface temperatures during different stages of mapping and construction. The coefficients of determination, R^2, were improved for the multivariate linear regression compared to those from simple linear regression. For the Minnesota asphalt IC demonstration project, ICMVs from mapping the subbase as well as asphalt surface temperatures have shown significant effects on ICMVs during asphalt base course compaction. For the Wisconsin asphalt IC demonstration project, the most significant factors to the ICMVs during HMA compaction are: FWD deflections on the baseline structure, asphalt surface temperatures, and ICMVs from mapping the rubblized Portland Cement Concrete (PCC) subbase (Chang et al. 2011). Nonetheless, IC has been proven as practical tool for improving the quality control process through harmonization and standardization efforts in the US (Gallivan et al., 2011; Gallivan and Chang, 2012).

Highways for LIFE IACA Project (2008 to 2010): The Intelligent Asphalt Compaction Analyzer (IACA) is a device based on neural network technology to report the density of an asphalt pavement continuously in real time during its construction. The IACA uses a neural network to compare the vibrations of the vibratory compactor with known patterns of the vibrations and estimate the density/stiffness of the pavement. The IACA technology was developed and adapted for field study under the Highways for LIFE Technology Partnerships Program and Volvo Construction Engineering (Commuri 2009 and 2010). From this research, relatively high correlation was observed between IACA estimated density and NNG measurements. Also, similar observation was found between IACA estimated density and core and concluded that the IACA was a good tool for contractors' quality control operations. However, the IACA system is not ready for commercial production, and further independent verification study for acceptance is recommended.

Iowa DOT IC Study (2010): The Iowa Department of Transportation (Iowa DOT) Intelligent Compaction Research and Implementation was initiated in summer 2009. There was one asphalt IC field demonstration project conducted at the IA 218 asphalt overlay project under the Iowa Phase I IC research to evaluate Continuous Compaction Value (CCV) technology on the Sakai SW880 dual drum vibratory asphalt roller (White et al. 2010). The asphalt demonstration project under this study was performed to demonstrate mainly IC tracking capability for the asphalt surface temperatures and roller passes. Only qualitative analysis was performed to investigate the correlation between ICMV and core density by using approximate Geospatial references of test locations. Correlation between ICMV and core density showed a moderate correlation with linear regression R^2 equalling 0.4.

Wisconsin DOT HMA IC Study (2010): The Wisconsin Department of Transportation (WisDOT) conducted an asphalt overlay IC demonstration on US 45, during 2008–2009 (Quintus et al. 2010). The goals of this project were to help WisDOT evaluate the advantages and limitations of IC for achieving density, and to determine the material types and conditions that might cause inaccuracies in IC roller output concerning layer stiffness and other properties. Caterpillar, Bomag, and Sakai IC rollers were used for this study. However, the Caterpillar IC roller was not equipped with an accelerometer-based measurement system and the Bomag IC roller was not equipped with a GPS. The main findings identified the IC benefits including: 1) the IC roller's on-board display unit shows color-coded image to ensure adequate number of pass; 2) mapping stiffness of the underlying layer; and 3) IC response corresponds to laboratory measured resilient modulus, etc. For the asphalt IC, this research pointed out some issues including: 1) IC cannot prevent the intermediate or finish rollers from being operated in the temperature sensitive zone and reducing the density; 2) ICMV is heavily influenced by supporting layers; and 3) IC could not detect cold spots by stiffness measurements, etc. The major issue for this research is that only printed strip charts from the Bomag machines were used and no geospatial referenced data (i.e., GPS) were available for

a more precise geostatistical analysis. Therefore, results and conclusions from this study may not be supported with sufficient evidence.

Minnesota DOT HMA IC Studies (2001 to 2011): In 2001, a Minnesota Department of Transportation (MnDOT) study has shown that the thermal segregation affects the density. For example, profiles with the temperature difference below 25 °F (–3.8 °C) had 93% passing the density target, while those with the temperature difference higher than 25 °F (–3.8 °C) only had 50% passing the density target. In 2010, IC projects were conducted on TH 169 and TH 13. Results confirmed immediate IC benefits including: 1) map existing layers; 2) improve roller patterns; 3) improve roller operators' accountability; 4) improve density; 5) improve efficiency; and 6) increase information for QC/QA, etc. It pointed out that the influence depth varies dependent on the technology and site conditions. This study encouraged IC's use as a construction aid to reduce thermal segregation, and suggested to install retrofit systems on an entire roller train (Johnson 2010). In 2011, MnDOT conducted an asphalt IC study on an I-35 project with several IC retrofit systems on a break-down roller, an intermediate roller, and a finishing roller. The main goal was to track temperatures and roller passes, but there is no attempt to correlate ICMVs with in-place asphalt density.

NCHRP IDEA Project 145 (2013): An improved ICMV model was developed to decouple stiffness for each pavement layer to improve the correlation of ICMV and in-situ spot measurements under the National Cooperative Highway Research Program (NCHRP) Innovations Deserving Exploratory Analysis (IDEA) project 145 "Extraction of Layer Properties from Intelligent Compaction Data". This study used numerical Finite Element Method and Boundary Element Method (FEM/BEM) as a forward model for the roller-soils systems and trained a neural network based on the FEM/BEM results to produce a stochastic method for real-time back calculation to decouple the layer properties. The back calculation model was demonstrated for a two-layer soils system but not asphalt pavement systems. This back calculation model is influenced by IC measurement uncertainties and sensitivities of back calculation parameters (e.g., E1/E2, and d1/d2 or ratios of layer stiffness and thicknesses).

Normalizing ICMV to a Referenced Temperature: For asphalt compaction, an improved ICMV model is recommended to normalize ICMV to a referenced temperature. ICMV represents a relative stiffness of pavement materials during compaction at elevated temperatures. The asphalt stiffness is dependent on temperature, while the asphalt density is independent of temperature. During compaction, the ICMVs are associated with the asphalt surface temperature measurements. If the master curve of the asphalt mixture is known, the ICMV can be shifted along the curve to represent a value at a desired reference temperature.

Geospatial Analysis for ICMV: The geostatistical analysis of the ICMV is recommended to account for the influence of geospatial dependency in order to improve the correlation study. The commonly adopted linear regression analysis is based on the generalized regression without considering the effects of geographical dependency such as autocorrelation.

3 METHODOLOGY

3.1 *Technical framework*

The IC-density model is based on IC data and other in-situ density measurements. The model development makes use of statistical approaches. The IC data include IC Measurement Values (ICMV)—accelerometer-based measurements, vibration frequencies/amplitudes, and asphalt surface temperatures during compaction at vibratory mode during break-down and/or intermediate rolling. There are no ICMV for accelerometer-based measurements during static rolling. The densification is mainly achieved during vibratory compaction at elevated temperatures (during breakdown and intermediate rolling) while the increase of density due to static compaction (finishing rolling) is minimal, as displayed in Figure 2. However, different densification curves were observed in the field where the same equipment and materials were used with the proximity of tests (i.e., spatial differences). Therefore, the densification characteristic is very complex.

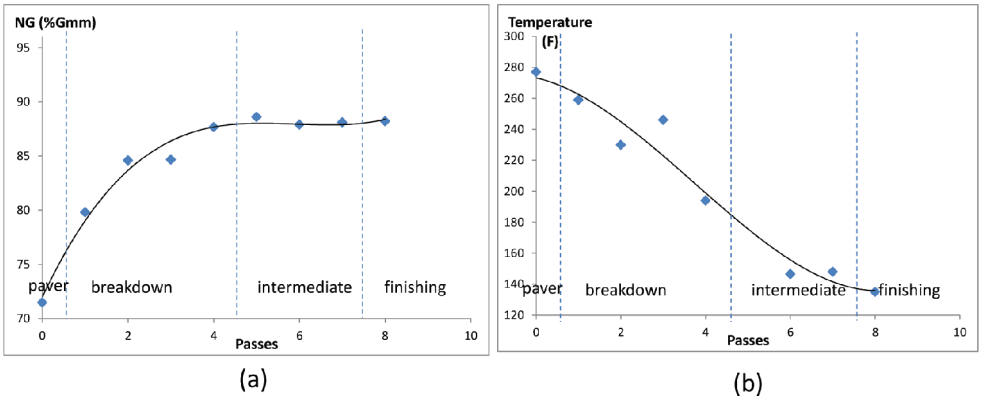

Figure 2. (a) Density growth and (b) temperature drops during compaction (FHWA IC demo in Maine, test point 1).

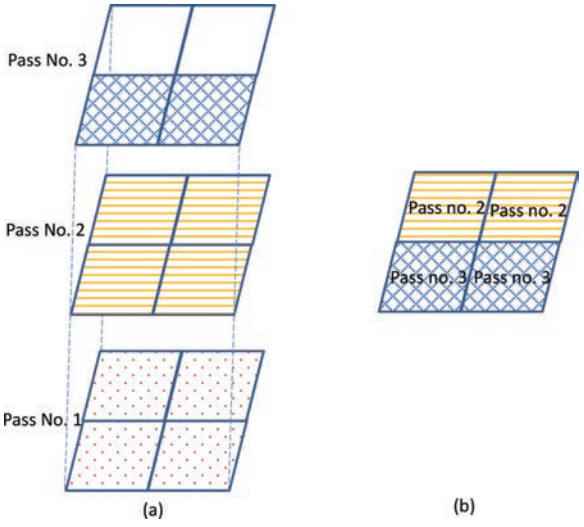

Figure 3. (a) Gridded all-passes IC data and (b) final coverage IC data.

The IC data, in terms of roller passes, include gridded all-passes data and final coverage data at 1 ft. (300 mm) by 1 ft. (300 mm) data meshes as displayed in Figure 3. The all-passes data include all IC measurements from every single roller pass at a given data mesh. The final coverage data include the last roller pass data. Currently, ICMV reflects the pavement layers up to 4 ft. (1.2 m) deep. ICMV is also categorized in two types: compaction indexes (e.g., CMV, HMV, and CCV) and stiffness/modulus values (Kb and Evib). Machine Drive Power (MDP) systems, which are not accelerometer-based, are not included in this study. Although there are researches on decoupling the ICMV, there are no prototype or commercial products available. The IC data analysis was conducted using the Veda software (Veda 2013) as displayed in Figure 4.

In addition to IC data, asphalt density measurements are normally conducted with NG as well as laboratory bulk density tests from field core samples in a calibration test strip. Under this study, NG data were collected after each IC roller pass at selected locations. Cores were then taken after the finishing rolling. NG measurements were also taken at the core locations prior to coring operation as displayed in Figure 5. Together, all the above IC measurements are tied with precise GPS measurements for density-IC model development.

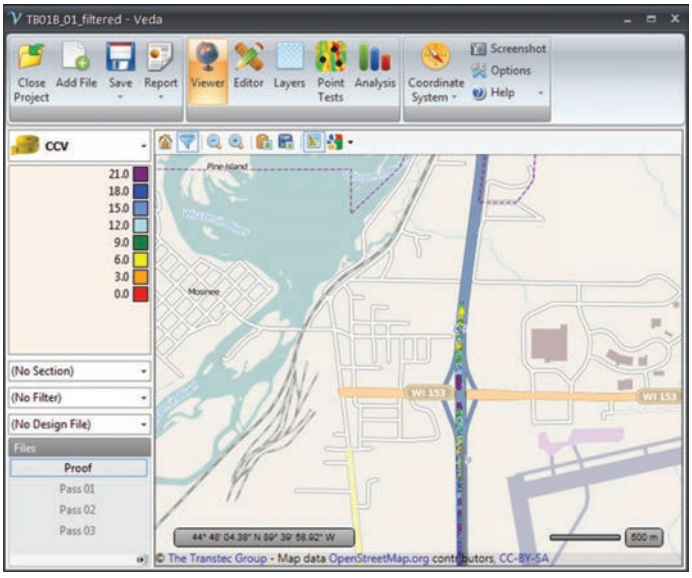

Figure 4. Veda software for IC data viewing and analysis (Veda 2013).

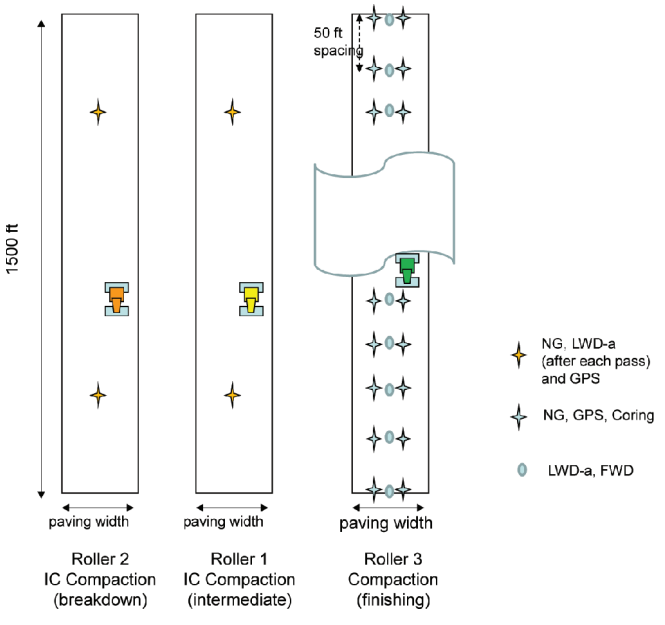

Figure 5. Calibration test strip with IC compaction and in-situ density measurements (FHWA IC demo in California, Test plan).

IC data and asphalt density measurements (using nuclear density gauge and cores) were collected in a calibration test strip. Both data were analysed using the Veda software and the results were extracted for the model development. IC data (ICMV, roller vibration frequencies/amplitudes, speeds, and asphalt surface temperatures) with respect to asphalt density measurements were extracted for both all-passes and final coverage data. Pass-by-pass data and portions of the final coverage data set were used to fit the IC-density model using the Excel Solver function. During the solving process, all unconstrained variables were made

positive and the evolutionary method was used to find a good solution to a reasonably well-scaled model. The fitted model was then validated using the remaining data set. The resulting model can then be used for the rest of the production compaction. The above IC-density model development framework is displayed in Figure 6.

The IC data capture compaction history including ICMV, surface temperatures, roller passes, vibration frequencies/amplitudes, roller speeds, etc. Although other factors can also influence in-place density (such as: nominal aggregate size to layer thickness ratios, aggregate shapes and gradation, binder and binder additives, reclaimed asphalt pavements, material transfer vehicles, pavers, etc.), the IC-density model is based on the IC data during breakdown and intermediate compaction in order to capture the most dominating factors, assuming the above factors being equal for a given lift at a given paving section. The data gap during static rolling (if IC is not equipped for the entire rolling train) would be considered as a random variable term fitted spatially with IC data and density measurements (including pass-by-pass data) in a calibration test strip. A simplification of the calibration process can be done by reducing the density measurements and coring. Therefore, the resulting IC-density model is locally calibrated for project-specific application in order to be a practical assurance tool for real-time in-place asphalt density prediction in the production compaction areas.

3.2 *IC Measurement Values (ICMV)*

The IC Measurement Values (ICMV) used in the US include Compaction Meter Value (CMV), Hamm Measurement Value (HMV), Compaction Control Value (CCV), vibration modulus (E_{VIB}), soil stiffness value (K_b), and Machine Drive Power (MDP). The Hamm Measurement Value (HMV) is identical to CMV. The K_b and MDP are not included in the second phase of the FHWA IC study due to the machine availability for asphalt IC.

Compaction Meter Value (CMV): CMV is a dimensionless compaction parameter developed by Geodynamik based on the phenomenon that different harmonic components of drum rebounds occur when compacting materials of different stiffness, displayed in Figure 7. CMV is influenced by roller dimensions, (i.e., drum diameter and weight) and roller operation parameters (e.g., frequency, amplitude, speed) (Sandström 1994).

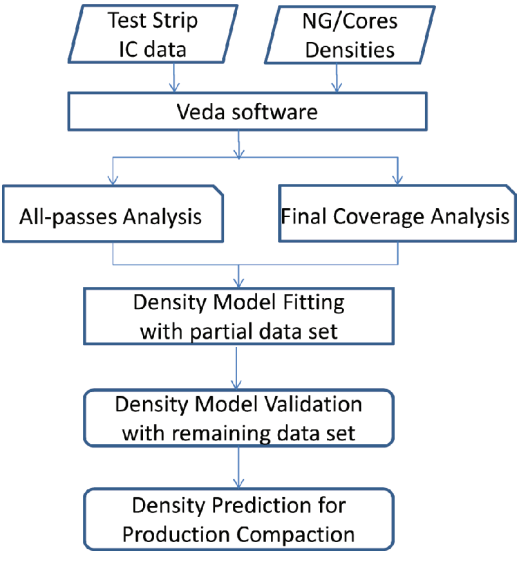

Figure 6. IC-density model development framework.

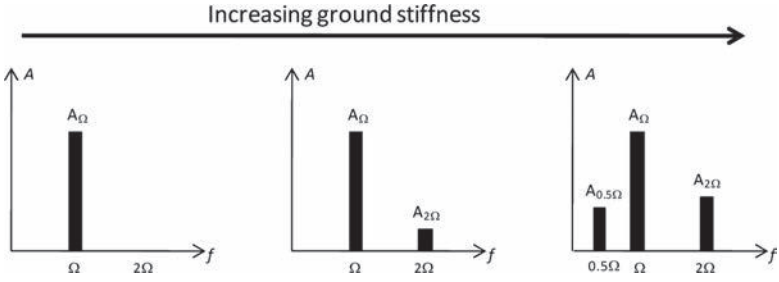

Figure 7. Changes in amplitudes of harmonics with increasing ground stiffness (Thurner and Sandström 1980).

CMV is calculated using Equation 1 (Sandström and Pettersson 2004).

$$CMV = C_1 \cdot \frac{A_{2\Omega}}{A_{\Omega}} \tag{1}$$

where
C_1: a constant (e.g., 300);
$A_{2\Omega}$: amplitude at the second order harmonic frequency;
A_{Ω}: amplitude at fundamental frequency.

The Geodynamik system also measures the Resonant Meter Value (RMV) which provides an indication of the drum behavior (e.g., continuous contact, partial uplift, double jump, rocking motion, and chaotic motion) and is calculated using Equation 2. Dynapac reports this value as Bouncing Value (BV). Under the drum jumping condition, the drum behavior affects the CMV measurements (Brandl and Adam 1997) and therefore must be interpreted in conjunction with the ICMV measurements (Vennapusa et al. 2010).

$$RMV = C_2 \cdot \frac{A_{0.5\Omega}}{A_{\Omega}} \tag{2}$$

where
C_2: a constant;
$A_{0.5\Omega}$: Acceleration at a sub-harmonic frequency caused by drum jumping movement (i.e., the drum skips every other cycle).

Dynapac uses a preselected threshold BV as an indicator of roller jumping to adjust the amplitude in compaction under the Auto-Feedback Control (AFC) mode. Similarly, Caterpillar uses RMV to adjust amplitude in compaction (White et al. 2008b). It was found that CMV increases monotonously with the stiffness of soil.

Compaction Control Value (CCV): CCV is developed by Sakai based on a similar concept that as the ground stiffness increases the roller drum starts to enter into a "jumping" motion which results in vibration accelerations at various frequency components displayed in Figure 8.

CCV is calculated using Equation 3.

$$CCV = \left[\frac{A_{0.5\Omega} + A_{1.5\Omega} + A_{2\Omega} + A_{2.5\Omega} + A_{3\Omega}}{A_{0.5\Omega} + A_{\Omega}} \right] \times 100 \tag{3}$$

where
$A_{1.5\Omega}, A_{2.5\Omega}$: amplitudes at sub-harmonic frequencies;
$A_{3\Omega}$: amplitude at the third order harmonic frequency.

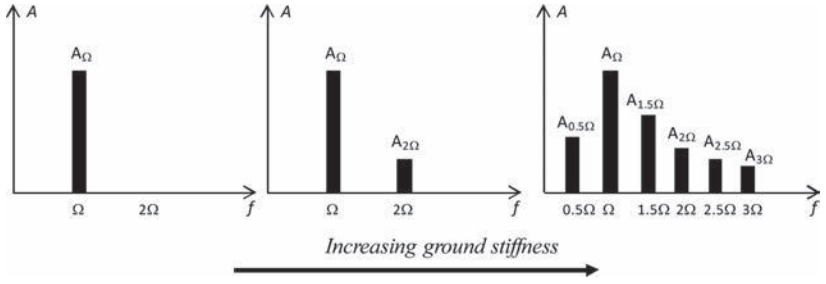

Figure 8. Changes in amplitude of spectrum with increasing ground stiffness (Scherocman et al. 2007).

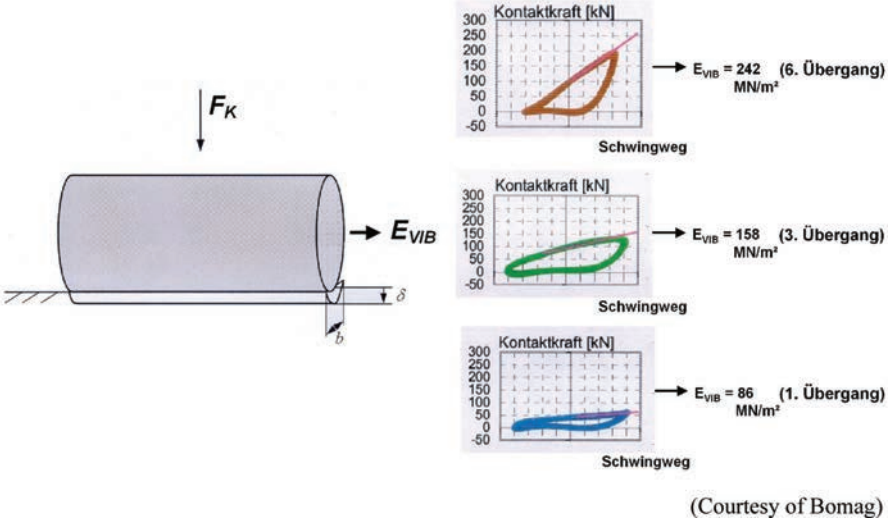

Figure 9. The drum-on-grade model and changes of slopes of the drum loading curves.

Vibratory modulus (E_{VIB}): Vibratory modulus (E_{VIB}) value is developed by Bomag based on the one-degree-of-freedom lumped parameter model and Lundeberg's theoretical solution for a rigid cylinder sitting on an elastic half-spaced earth, displayed in Figure 9 (Hertz 1895, Lundberg 1939, Kröber et al. 2001).

The E_{VIB} value is back-calculated using Equation 4. The E_{VIB} value is related to the modulus determined from a static plate load test (Krober 1998 and Krober et al. 2001).

$$z_d = \frac{(1-\eta^2)}{E_{VIB}} \cdot \frac{F_s}{L} \cdot \frac{2}{\pi} \cdot \left(1.8864 + \ln \frac{L}{W_d} \right) \tag{4}$$

where,
η: Poisson's ratio of the material;
L: length of the drum;
F_s: roller-soil interaction force;
W_d: contact width of the drum, $W_d = \sqrt{\frac{16}{\pi} \cdot \frac{R'(1-\eta^2)}{E_{VIB}} \cdot \frac{F_s}{L}}$
R': radius of the drum.

Correlation Studies: When performing regression analysis and model development between IC data and point test data (such as core densities), care shall be taken to understand the mechanism, footprints, and influence depths of different measurements displayed

in Figure 10. Depending on its weight and operational settings, a full size IC roller may measure up to 4 ft. (1.2 m) of influence depth with a 6 ft. (2 m) wide footprint.

3.3 *Decoupling of IC measurements*

ICMV is accelerometer-based under drum vibrating at around 20 Hz and the measured values are not decoupled or separated to represent individual pavement layers. The influence of underlying layers to the overall stiffness measurement can be simplified and modelled with Hook's law. The simplification is needed due to the short time frame of about 0.1 second (10 Hz) for the IC system to complete a computation cycle. A static two-layer single-degree freedom lumped system is displayed in Figure 11 and followed by the details of the model derivation for decoupling.

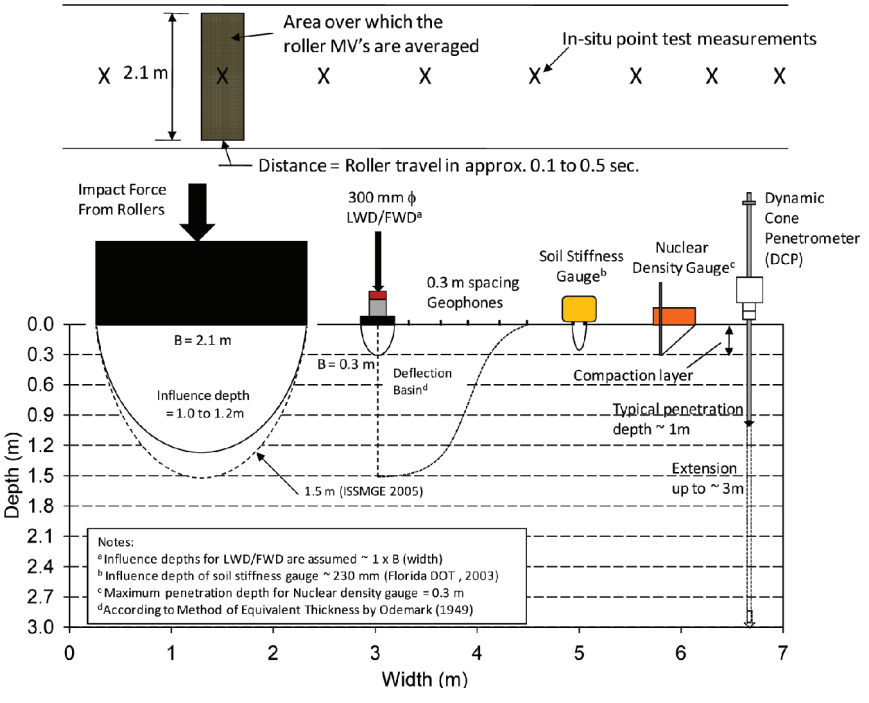

Figure 10. Influence depths for different measurements (White 2008).

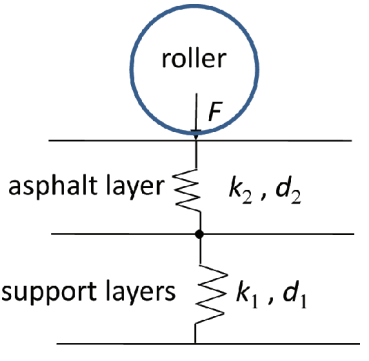

Figure 11. A static two-layer single-degree freedom lumped system under roller loading.

$$\begin{cases} F = k(d_1 + d_2) \\ F = k_1 d_1 \\ F = k_2 d_2 \end{cases} \tag{5}$$

where,
F: force exerted by the roller;
k: composite stiffness of the entire layer system;
k_1: stiffness of the support layers;
k_2: stiffness of the asphalt layer;
d_1: thickness of the base and underneath layers;
d_2: thickness of the asphalt layer.

The stiffness of the asphalt layer (k_2) can be derived as follows:

$$F = k\left[\frac{F}{k_1} + \frac{F}{k_2}\right] \tag{6}$$

$$k_2 = \frac{k \times k_1}{k_1 - k} \tag{7}$$

If the IC mapping data for the supporting layers of a two-layer system are available, the k_1 value can be determined. During the subsequent asphalt compaction, k value can be obtained at the same location as k_1. Therefore, the k_2 value for the top asphalt layer can be computed or re-coupled.

The above can also be extended to multi-layer linear elastic systems as follows:

$$\frac{1}{k} = \frac{1}{k_1} + \frac{1}{k_2} + \cdots + \frac{1}{k_n} \tag{8}$$

where,
k_n: stiffness of the top asphalt layer of a multilayer system.
$k_{i\ (i=1\ to\ n-1)}$: stiffness of the ith support layer of a multilayer system.

Therefore, the stiffness of the top asphalt layer can be solved as:

$$k_n = \frac{k k_1 k_2 \cdots k_{n-1}}{k_1 k_2 \cdots k_{n-1} - k k_2 k_3 \cdots k_{n-1} - \cdots - k k_1 k_2 \cdots k_{n-2} k_{n-1} - k k_1 k_2 \cdots k_{n-2}} \tag{9}$$

The above k values can be expressed in units or unitless based on the corresponding ICMV. With the above consideration in mind, regression analysis and model development between ICMV and core densities can be interpreted properly.

3.4 *Statistical approaches for IC-density model development*

Four (4) statistical models were considered during the development of the IC-density models, including Model I—multivariate linear model, Model II—multivariate nonlinear model, Model III—multivariate linear panel model, and Model IV—multivariate nonlinear panel model. Models III and IV were excluded after the initial screening study. The details of development for Models I and II using the SI units are described as follows.

3.4.1 *Model I—multivariate linear model*

A multivariate linear regression density model based on IC measurements can be expressed as follows:

$$\rho = B_0 + B_1 \cdot ICMV_a + B_2 \cdot W + B_3 \cdot T + B_4 \cdot f + B_4 \cdot Amp + B_5 \cdot ICMV_b + \epsilon \tag{10}$$

where,
ρ: asphalt density;
B_i: model intercept when $i = 0$ and coefficients when $i = 1$ to m, where m is total number of coefficients;
$ICMV_a$: ICMV during asphalt compaction;
W: roller weight;
T: asphalt surface temperature;
f: roller vibration frequency during asphalt compaction;
Amp: roller vibration amplitude during asphalt compaction;
$ICMV_b$: ICMV during base layer compaction or mapping;
$\in$: residual.

3.4.2 *Model II—multivariate nonlinear model*
A multivariate nonlinear IC-density model based on IC measurements can be expressed as follows:

$$\rho_n = \rho_0 + (G_{mm} - \rho_0) \times e^{-\left[\frac{a_1 \cdot k_{ac} + a_2 \cdot f + a_3 V + a_4 (T - T_r)}{n}\right]^{\beta}} + \Delta\rho_n \quad (11)$$

where,
ρ_n: density at pass count, n;
n: roller pass number;
ρ_0: density behind the paver;
a_1, a_2, a_3, a_4, and β: fitted parameters;
k_{ac}: asphalt stiffness expressed in ICMV;
f: roller vibration frequency during asphalt compaction;
V: roller speed;
T: asphalt surface temperatures;
T_r: a reference temperature;
$\Delta\rho_n$: difference between density at pass count, n, and the final density.

After the second screening process, Model II was selected to be used in the subsequent model calibration and field validation.

4 FIELD VALIDATION

The selected IC-density model was calibrated and validated using the field data from the first three (3) of the nine (9) field sites under Phase II of the FHWA IC project.

The Utah site is a project with asphalt overlay at US-89 in Lehi, UT. The test section for this study is approximately 3 miles (4.8 km) of US-89 conducted during nighttime paving. The project consisted of a mill-and-fill asphalt paving project with one lane in the northbound and southbound directions. 4 in. (100 mm) of the existing pavement were milled from the existing pavement prior to the asphalt overlay. The new layers include an asphalt base course (2.5 in. or 64 mm) and an SMA wearing course (1.5 in. or 38 mm) with a cross slope of 2%. The focus for this demonstration is the base course construction. Test Bed 02 that includes the coring section is located at the northbound of US-89. A Hamm IC roller was used at the breakdown position and a Sakai IC roller was used at the intermediate position.

The Florida site is located at I-95 in Brevard County, FL. The paving was operated on the outside lane behind construction barrels in two lifts between Stations 2432 and 2452 for 2,000 ft. (610 m) during night time. The project consisted of a mill-and-fill asphalt paving job for the travel lane in the northbound direction. Based on the core information of the existing pavement before paving, the average asphalt layer thickness is 7.81 in. (198 mm), and the base layer thickness is 7 in. (175 mm). The top 0.75 in. (19 mm) of existing friction course along with 3 in. (75 mm) of the existing structural layer for a total of 3.75 in. (95 mm) were milled off followed by two 1.5 in. (37 mm) lifts of HMA structural layer or base course. The bottom

Table 1. Description of IC field sites.

States	Location	Dates	Asphalt layer	IC rollers
Utah	US-89, Lehi, UT	August 6–9, 2012	2.5″ base course	Hamm, Sakai
Florida	I-95, Brevard, FL	October 15–18, 2012	1.5″ base course	Hamm, Sakai
Ohio	I-71, Morrow, OH	June 24–27, 2013	1.75″ base course	Hamm, Sakai

lift of the structural base course is the focus of this IC study. Test Bed 02 that includes the coring section is on the northbound travel lane of I-95. A Hamm IC roller was used at the breakdown position and a Sakai IC roller was used at the intermediate position.

The Ohio site is located at I-71 in Morrow County, OH. The paving was operated on the north lanes with traffic closure between junctions with SR 95 and Mt. Gilead-Fredericktown road during day time. The project consisted of a new asphalt construction for two 24ft. (7.3-m) wide sections and an inside shoulder in the northbound direction. The pavement layers are (from the bottom up): 6 to 8 in. (150 to 200 mm) 304 aggregate stone base, 10 in. (250 mm) 302 asphalt concrete base, 1.75 in. 19 mm intermediate course, and 1.5 in. 12.5 mm surface course. The 1.75 in. (45 mm) 19 mm intermediate course is the focus of this IC study. The Test Bed 02 location that includes the coring section is in the northbound direction of I-95. The Sakai IC roller was used as the breakdown roller with the front drum vibrating at the high frequency and low amplitude settings. The Hamm IC roller was used as the intermediate/finishing roller with the front drum vibrating at the high frequency and low amplitude settings.

4.1 *Density compaction curves and pass-by-pass IC data analysis*

The Nuclear density Gauge (NG) measurements after each roller pass were used to build density compaction curves that show the growth trend of asphalt densification. The main purpose of compaction curves is to identify the compaction characteristics for specific materials and roller(s) used in a paving project in order to determine the optimal rolling pattern. The NG measurements can also be correlated to ICMV to evaluate whether there is a linear relationship between the two.

The compaction curves and linear correlation for the Utah site are presented in Figure 12. The compaction curve from the breakdown compaction indicates a monotonic growth of densification. The temperature drop also follows a similar monotonic but reverse trend. The R^2 for the correlation between NG measurements and HMV from the breakdown compaction is 0.50 which is consistent with the observations by IC vendors.

The compaction curves and linear correlation for the Florida site are presented in Figure 13. The compaction curve indicates a rapid growth of densification during the breakdown compaction then levelling off during the intermediate compaction. The temperature drop also follows a similar but reverse trend. The R^2 for the correlation between NG measurements and CCV during the breakdown compaction is 0.97 while R^2 is 0.20 between the NG measurements and asphalt during the intermediate compaction. The significant difference between the two correlations is due to the nature of accelerometer-based ICMV that reflects the changes of internal aggregate structure or densification during breakdown compaction at elevated temperatures while the ICMV would reflect the hardening of asphalt binder during the cooling off stage of intermediate compaction.

The compaction curves and linear correlation for the Ohio site are presented in Figure 14. Three locations within a 100 ft. (30 m) section were surveyed. The compaction curves indicate different patterns even though the same equipment, materials, and compaction method were used. The temperature drop also follows a similar but reverse trend. At T1, the pattern of the compaction curve is similar to that from the Utah site, which is monotonic growth. At T2 and T3, the pattern is similar to that from the Florida site, which the density grows rapidly during the breakdown compaction then levels off during the intermediate compaction. Contrary to

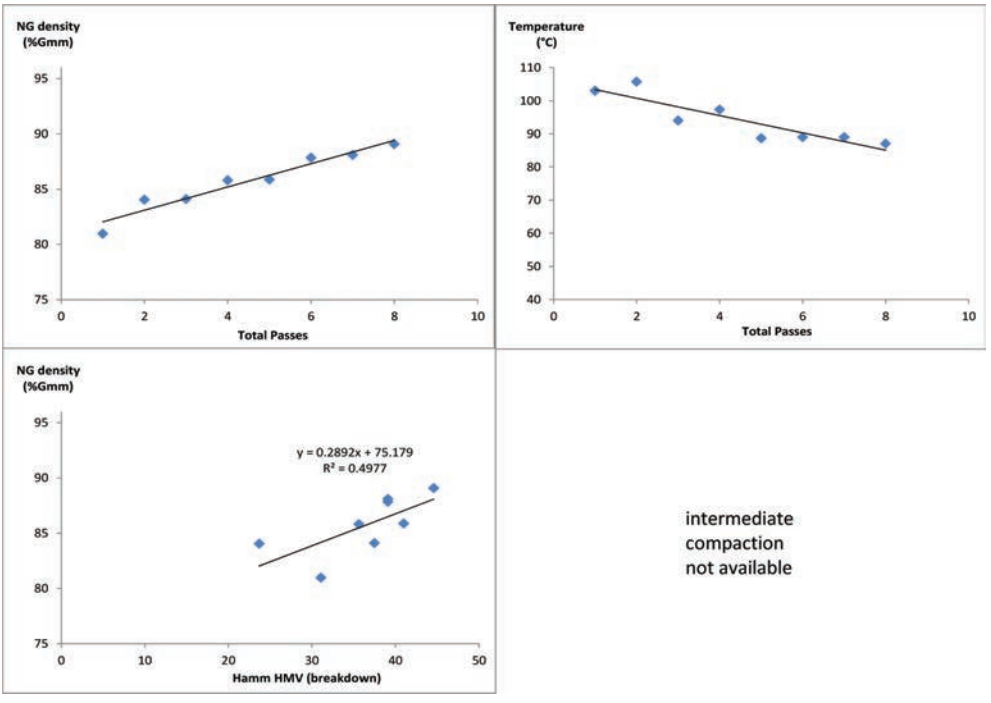

Figure 12. Compaction curves and linear correlation between NG measurements and Hamm HMV from breakdown compaction at a location in Test Bed 03 (UT site).

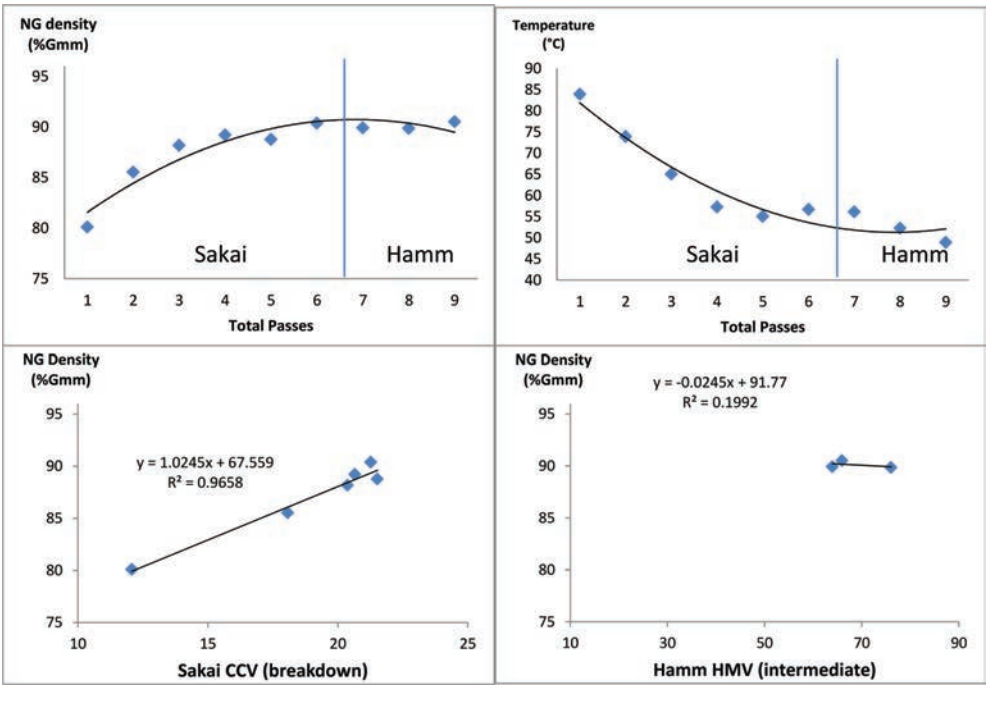

Figure 13. Compaction curves and linear correlation between NG measurements and Sakai CCV from breakdown compaction; and between NG measurements and Hamm HMV during intermediate compaction at a location in Test Bed 03 (FL site).

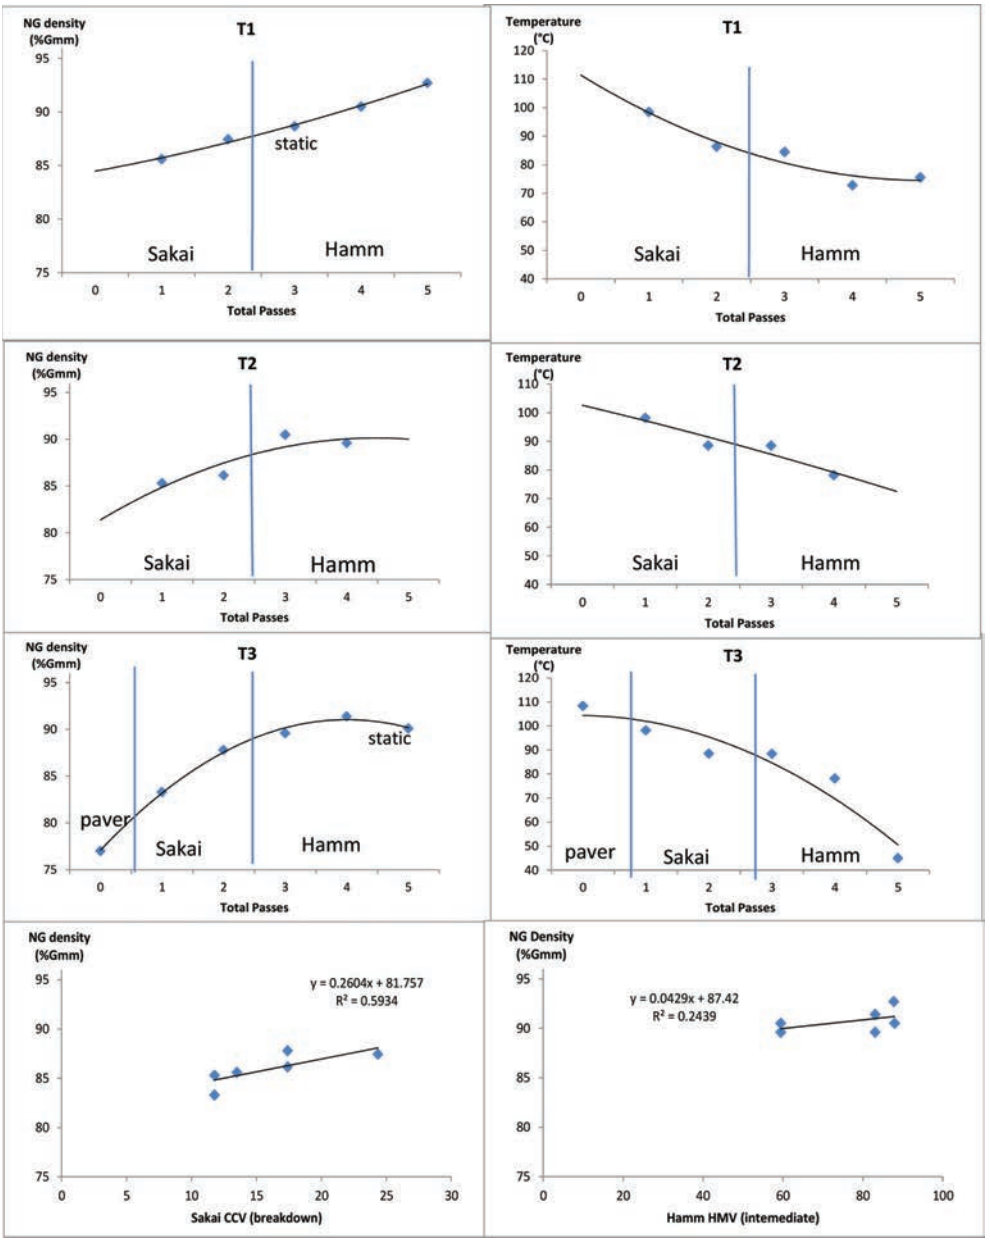

Figure 14. Compaction curves and linear correlation between NG measurements and Sakai CCV and Hamm HMV from breakdown and intermediate compaction at three locations in Test Bed 01 (OH site).

conventional belief that the optimal window for compaction is within higher temperatures, the comparison between T1 and T2/T3 present a different scenario. As the densification growth is slower within the breakdown compaction at T1, the densification continues during the intermediate compaction and eventually reaches higher density than these at T2 and T3. Therefore, compaction behavior is more complex than it was previously thought. This phenomenon also poses challenges to modelling efforts for predicting asphalt density. As for the ICMV-density relationship, The R^2 for the correlation between NG measurements and CCV during the breakdown compaction is 0.59, while it is 0.24 between the NG measurements and

HMV during the intermediate compaction. The comparison is consistent with that from the Florida site.

The above compaction curves and correlation analyses show that compaction characteristics may vary even within the same paving operation. It verifies the daily (or nightly) challenges that paving industry has been facing. It also calls for improved technology in order to achieve better quality control of consistent asphalt paving products. The above also shows that pass-by-pass ICMV and NG measurements are correlated well with R^2 from 0.49 to 0.97 during breakdown compaction. The correlation, however, is less satisfactory during intermediate compaction. It is postulated that ICMV during breakdown compaction reflects on the internal structure (or aggregate-to-aggregate contacts) of compacted mixture as the accelerometer-based measurements reflect the changes of the roller drum rebounds when the compacted materials stiffen due to aggregate re-arrangements. During intermediate compaction or later, the stiffening of compacted materials may be due to binder hardening while the density or internal aggregate structure stays mostly constant. Thus, the ICMV would be less correlated to densities at the later stages of compaction.

4.2 *Final coverage IC data vs. core density analysis*

There were sixty (60) cores taken during each field validation which is considered unprecedented and valuable for correlation study with IC. However, there may be a gap between what the IC measures and the final core results including any gains (further compaction) or loss (de-compaction) of density due to subsequent intermediate or finishing compaction. As postulated in the above pass-by-pass analysis, ICMV would be less correlated with density during later stages of compaction. The following analyses using the final coverage data present further such evidence.

The correlation of the final coverage IC data (i.e., last passes or final product data) and core density for the Utah site is presented in Figure 15. As expected, the correlation of ICMV with core density is poor during the latter stages of breakdown and intermediate compaction.

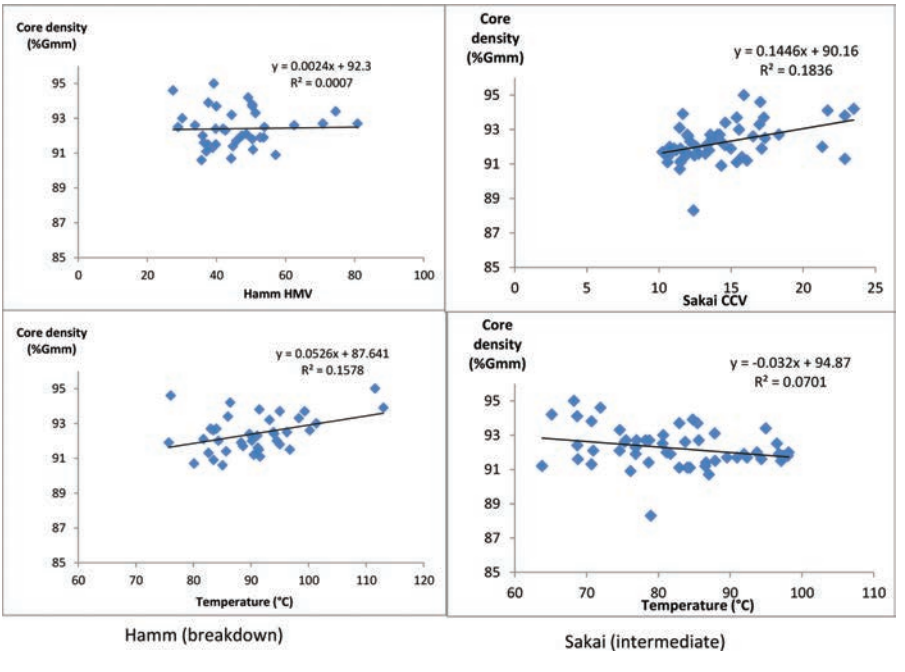

Figure 15. Core density data vs. Hamm HMV and Sakai CCV from breakdown and intermediate compaction in Test Bed 02 (UT site).

Even though there was no finishing compaction, the rolling patterns were erratic at Test Bed 02 which may pose issues for correlation. The erratic rolling patterns would produce non-uniform compaction, and thus density. As IC data were extracted within 6.6 ft. (2 m) diameter (i.e., approximately the full-size roller drum width) surrounding a core location and averaged for the processes, the averaged IC data may not be reflecting the density value of within a 4 in. (100 mm) diameter coring location.

The correlation of the final coverage IC data (i.e., last passes or final product data) and core density for the Florida site are presented in Figure 16. Similar to the Utah site, the correlation of ICMV with core density is poor during the latter stages of breakdown and intermediate compaction. The rolling patterns are also erratic at Test Bed 02.

The correlation of the final coverage IC data (i.e., last passes or final product data) and core density for the Ohio site are presented in Figure 17. Similar to the Utah and Florida sites, the correlation of ICMV with core density is poor during the latter stages of breakdown and intermediate compaction. There was no finishing compaction at Test Bed 02.

From the above observations, the correlation between final coverage IC data and the core density is poor. This is a different observation from the pass-by-pass analysis where ICMV does have good correlation with NG density measurements. Based on the NG-core density correlation analysis (not presented in this paper due to limited space), it can be deduced that ICMV measurements during breakdown compaction do reflect the actual in-place asphalt density. However, the final coverage IC measurements do not represent the eventual in-place density due to the measurements under cooler condition when binder stiffens in addition to the IC data averaging over a varied in-place density within the width of a roller drum.

4.3 *IC-density model validation*

The IC-model validation was conducted to explore the possibility of using such a model to overcome the limitation of the final coverage ICMV to correlate to in-place asphalt density.

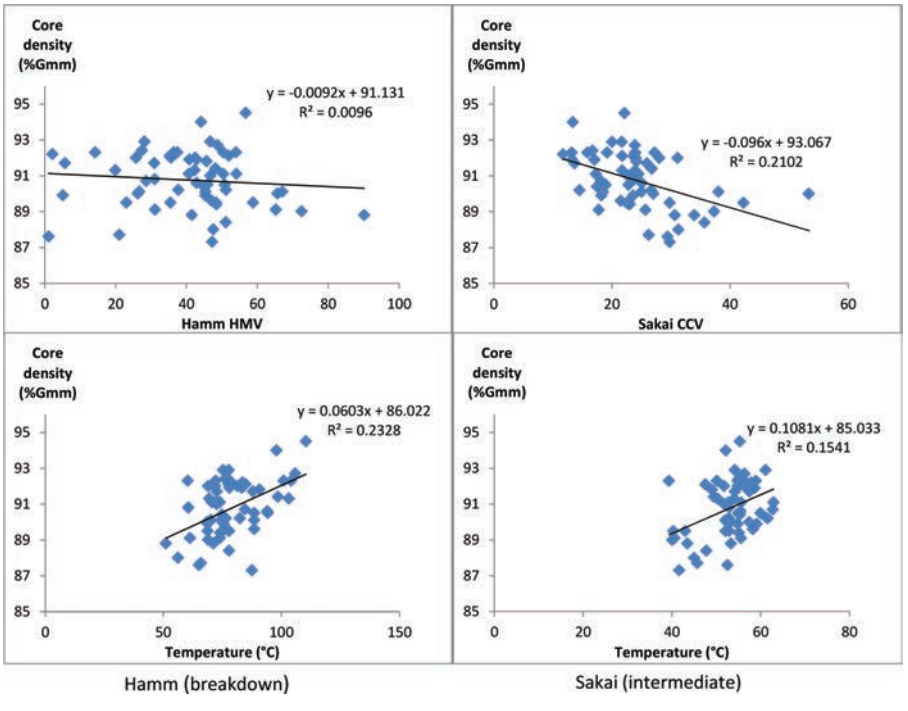

Figure 16. Core density data vs. Hamm HMV and Sakai CCV from breakdown and intermediate compaction in Test Bed 01 (FL site).

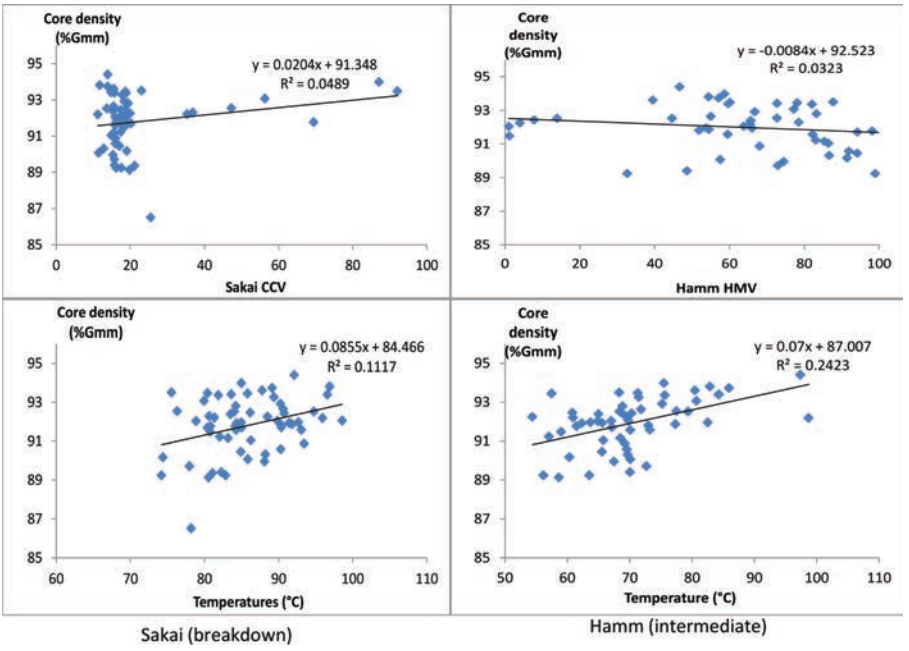

Figure 17. Core density data vs. Sakai CCV and Hamm HMV from breakdown and intermediate compaction in Test Bed 02 (OH site).

Since only three out of nine field sites are completed under the Phase II FHWA IC study, the following discussion serves as a preliminary model trial at this stage. The pass-by-pass IC-NG measurements, when available, were used along with the core-IC data for the IC-density model fitting. Then, the fitted model was used to correlate its density prediction with actual core density data and NG measurements.

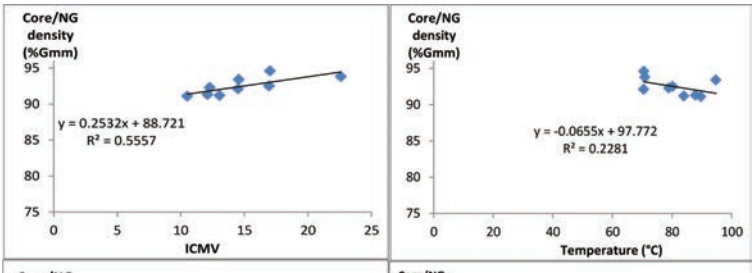
The IC-density model fitting and validation for the Utah site are presented in Figure 18. This process used the Sakai IC final coverage data during breakdown compaction at TB02, but no pass-by-pass Sakai IC data were available. The correlation between a portion of the core/NG density data and ICMV (CCV) is surprisingly good with R^2 of 0.56. On the other hand, the results of IC-density model fitting and validation are relatively poor. This phenomenon is unusual and further investigation is warranted.

The IC-density model fitting and validation for the Florida site are presented in Figure 19. This process used the Sakai final coverage data within intermediate compaction at TB01 and the Sakai pass-by-pass data within breakdown compaction at TB02. The correlation between a portion of the core/NG density data and ICMV (CCV) is poor. On the other hand, the results of the IC-density model fitting and validation are improved with R^2 of 0.52 and 0.46, respectively.

The IC-density model fitting and validation for the Ohio site are presented in Figure 20. This process used the Sakai final coverage data within breakdown compaction at TB02 and the Sakai pass-by-pass data within breakdown compaction at TB01. The correlation between a portion of the core/NG density data and ICMV (CCV) is poor. On the other hand, the IC-density model fitting and validation are improved, but still low, with R^2 of 0.37 and 0.29, respectively.

For the above observations from the three field sites in Utah, Florida, and Ohio, the preliminary conclusion is that the IC-density model produced improved correlation with core/NG density by overcoming the limitation of accelerometer-based ICMV.

There are other considerations for the above observations. The current form of the IC-density model is deterministic to predict density at a given condition (ICMV, frequency, pass



ρ_0	Gmm	α1	α2	α3	α4	β	k1	Tr

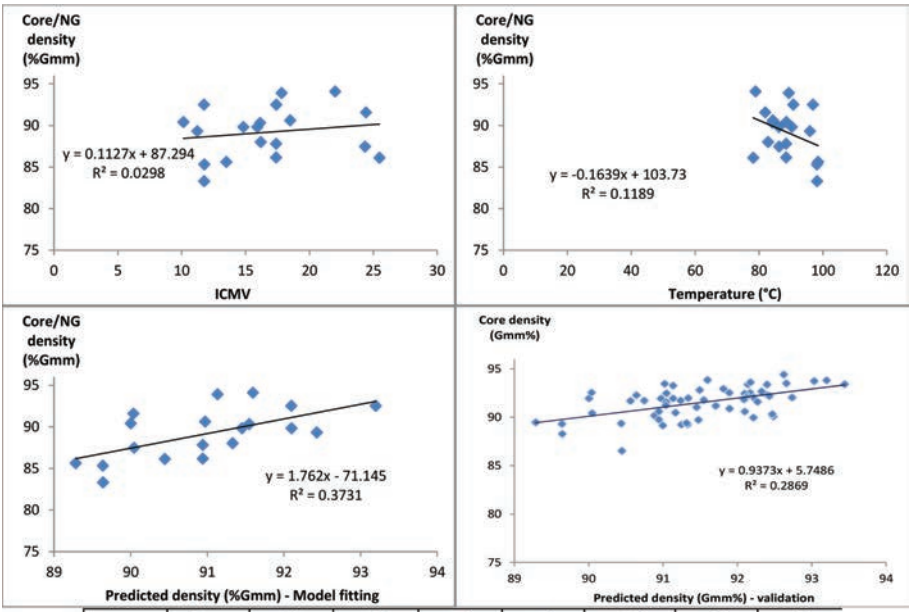
count, roller speed, and temperature). The model fitting with both pass-by-pass and final coverage IC data makes the model equal to a family of compaction characteristic curves in order to capture the entire compaction history, from immediately behind the paver to the finishing rolling. IC data from a single system were for model fitting and validation due to IC systems and ICMV varying from one vendor to another. As observed from the above



ρ_o	Gmm	k1	α1	α2	α3	α4	β	Tr
78	99	26	0.021479	0.001503	0	0.00001	0.501787	80

Figure 20. IC-density model fitting and validation based on the Sakai final coverage data within breakdown compaction at TB02 and the Sakai pass-by-pass data within breakdown compaction at TB01 (OH site).

pass-by-pass IC data analysis, the compaction curves can vary from one location to another even with the same equipment, materials, and paving method. Therefore, a single IC-density model, no matter how well-calibrated, would face the challenge to match a variety of compaction curves. Mathematically, the narrow range of core density values would also pose challenges to the correlation between the IC-density model prediction and core/NG measurements. Therefore, a technique to look beyond the least square (R^2) correlation is warranted.

At this stage, neither ICMV nor the IC-density model can be reliably used for acceptance. Further enhancements of the IC-model are desired in future studies to raise its confidence level for predicting in-place density using ICMV data.

5 SUMMARY AND FUTURE RESEARCH

5.1 *Summary and conclusions*

Under Phase II of the FHWA IC study, specific efforts were focused on evaluating IC technologies for acceptance of asphalt densities. Three (3) of nine (9) planned field validations were conducted in Utah, Florida, and Ohio to collect IC data, nuclear density measurements, and extensive coring with sixty (60) cores taken from each site. A series of model iterations were performed to select the candidate multivariate nonlinear IC-density model for subsequent model validation. The preliminary conclusions from the three field validation sites are as follows:

- The compaction characteristic curves may vary even within the same paving operation. The compaction process is thus more complex than originally thought.
- Pass-by-pass ICMV and NG measurements are reasonably correlated with R^2 from 0.49 to 0.97 during breakdown compaction. The correlation between pass-by-pass ICMV and NG measurements is less satisfactory during intermediate compaction.

- The final coverage ICMV measurements do not represent the eventual in-place density due to the ICMV measurements increasing at cooler condition when binder stiffens while internal aggregate structure stays constant. In addition, the ICMV were averaged within the width of a roller drum (approximately 6 ft. or 1.8 m) where in-place density may vary from one coring location to another (e.g., 4 in. or 100 mm cores), especially when the rolling patterns are erratic.
- The IC-density model improved the correlation between core/NG density and predicted density from no correlation up to R^2 of 0.50 by overcoming the limitation of accelerometer-based ICMV. However, neither ICMV nor IC-density model can be reliably used for acceptance at this stage based on limited field data and model development. Further enhancements of the IC-density model are desired in future studies with extended field data validation to raise its confidence level for predicting in-place asphalt density.

5.2 *Research refinements*

The following are recommended for the remaining six (6) field validations under Phase II of the FHWA IC study:

- More pass-by-pass nuclear density gauge measurements are needed to be conducted within the entire compaction history from zero-pass (immediately behind the paver), breakdown compaction, intermediate compaction, to finishing rolling.
- One IC roller should be limited for each of the breakdown and intermediate compaction to obtain cleaner data for IC-density model validation. A third IC roller can also be running at static mode at the finishing position to collet passes and temperature data.
- Further IC-density model enhancements may consider multiple IC roller data, incremental model form, and robust modeling tools such as the IMSL computing library.
- As the IC-density model matures, simplification of the model form and calibration is recommended in order to apply it to real-world paving operations.

ACKNOWLEDGEMENT

The authors would like to acknowledge the following who made this IC-density study possible: financial support from the US FHWA, technical support and equipment supplies from IC and GPS vendors (Hamm, Sakai, TopCon, and Trimble/Sitech), local DOT and contractors' supports for field validation (Utah DOT, Staker & Parson; Florida DOT, Hubbard; Ohio DOT, Kokosing).

ABSTRACT: In present research, two-dimensional boundary coordinates of 99 irregular aggregates were extracted after digital process of X-ray CT Images of asphalt concrete specimen. The modified Fast Fourier Transformation method (FFT) is used to obtain the fitting functions of those coordinates. With the boundary database from the functions, a method for developing two-dimensional asphalt concrete virtual model with irregular aggregates form is presented. Using the method, virtual models with different aggregate grading are generated. Brazil split tests of asphalt concrete are simulated with the samples by taking into account the actual inhomogeneities and microstructures, especially voids distributions, as the visco-elastic properties of the sand mastic and elastic properties of the aggregates are inputted into the FEM model. The test results show that the presented method can generate 2-D virtual mechanical simulation model of asphalt concrete automatically and the generated micromechanical models are capable of predicting the mixture behavior based on ingredient properties. It is believed that the proposed method can be extended to predict the mixture behavior based on ingredient properties.

Keywords: asphalt; mix; virtual test; CT; inner structure; visco-elastic properties

1 INTRODUCTION

Asphalt mixture is a composite material of graded aggregates combined with asphalt binder and a certain amount of air voids. Current mix design procedures are empirical and are based on trial-and-error methods. It will be time and energy consuming to completely evaluate the asphalt mixture properties with those methods and may sometimes lead to costly pavement failures. Recent research results show that the mechanical behaviors of asphalt mixture are far more complex than what we have recognized. The properties of asphalt mixes are affected not only by the volume fractions of asphalt binder, aggregates and air voids, but also the spacial distributions of these components. Both deformation and strength of asphalt mixture has a strong relationship with aggregate structure, mastic and air voids spacial distributions. By developing techniques to image and to quantify the structure of aggregates in asphalt concrete, and by applying granular mechanics to account for the aggregate structure and rheological methods to explain the dynamic mechanical responses of asphalt binder or mastic,

in such a scientific way as virtual test, it will be possible to quantitatively relate the raw material properties to the performance of pavements. This will develop the foundations to building more durable pavements. Virtual test, an important way to design modern structure and material, is actually a digital simulation process, the best advantage of which is not limited by test facilities and boundary conditions.

In present research, two-dimensional boundary coordinates of 99 irregular aggregates were extracted after digital process of X-ray CT Images of asphalt concrete specimen. The modified Fast Fourier Transformation method (FFT) is used to obtain the fitting functions of those coordinates. With the boundary database from the functions, a method for developing two-dimensional asphalt concrete virtual model with irregular aggregates form is presented. Using the method, virtual models with different aggregate grading are generated. Brazil split tests of asphalt concrete are simulated with the samples by taking into account the actual inhomogeneities and microstructures, especially voids distributions, as the visco-elastic properties of the sand mastic and elastic properties of the aggregates are inputted into the FEM model.

The test results show that the presented method can generate 2-D virtual mechanical simulation model of asphalt concrete automatically and the generated micromechanical models are capable of predicting the mixture behavior based on ingredient properties. It is believed that the proposed method can be extended to predict the mixture behavior based on ingredient properties.

2 CT IMAGE AND DIGITAL IMAGE PROCESS

The hollow cylinder asphalt concrete sample is used in this test. The diameter of the sample is 150 mm and the wall thickness and height of the sample is both 50 mm. This nondestructive technique provides a method to produce gray level images at different depths within a specimen. The material intensity at one point is reflected by the pixel gray intensity. The images acquired by X-ray CT were processed to produce binary images, as it is shown in Figure 1, the black color represents granular particles and white represents asphalt and voids.

2.1 *Theory of Fourier analysis*

There are two possible ways to describe an aggregate particle. One expression can be presented as the following Fourier series:

$$R(\theta) = a_0 + \sum_{m=1}^{M} (a_m \cos m\theta + b_m \sin m\theta) \tag{1}$$

In this function, $R(\theta)$ is the radius at angle θ, $0 < \theta < 2\pi$, a_0 represents the average radius of a particle and M is the total number of the coefficient. a and b, which change when m is

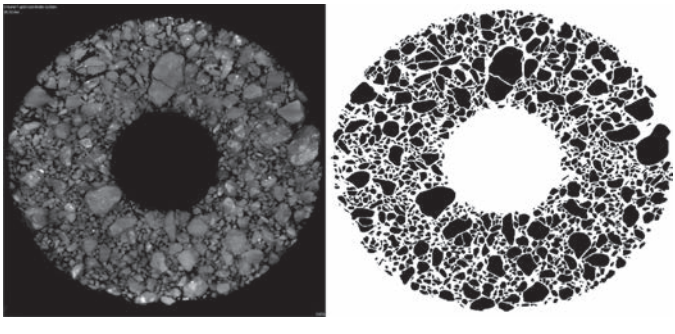

Figure 1. X-ray CT image and binary image.

different, are coefficients giving magnitude and phase for each harmonic. The origin of the coordinate system is usually in the center of the gravity.

Another possible method to quantify the characteristics of aggregates is the Fourier descriptor method. The granular boundaries, defined by the function x(θ) and y(θ), can be analyzed using the following Fourier series:

$$\begin{cases} x(\theta) = \frac{1}{2}A_{01} + \sum_{p=1}^{N}(A_{pi}\cos p\theta + B_{pi}\sin p\theta) \\ y(\theta) = \frac{1}{2}A_{02} + \sum_{p=1}^{N}(A_{pi}\cos p\theta + B_{pi}\sin p\theta) \end{cases} \quad (2)$$

In this expression, x(θ) and y(θ) are coordinates describing the particle, N is the total number of the coefficients, A_{01} and A_{02} reflect the average value of x and y, A_{pi} and B_{pi} reflect the coefficient of the harmonics, pi stands for the pi-th coefficient.

Because the first method could cause some miscalculation which shown as Figure 2, in this research, x and y, which are related to the particle shape, are studied, and the feature of the particle can be described while the problems mentioned before can be avoided.

A_{pi} and B_{pi} can be approximately estimated as following:

θ is a number belong to [0, 2π], the value of θ is

$$\theta_i = \frac{2\pi}{2n+1}(i+0.5) \quad (i= 0, 1, 2, 3..., 2n) \quad (3)$$

u_1 and u_2 are defined in order to compute A_{pi} and $B_{pi.}$

$$\begin{cases} u_{2n+2} = u_{2n+1} = 0 \\ u_j = f_j + 2\cos p\theta\, u_{j+1} - u_{j+2} \quad (j = 2n, 2n-1, 2n-2, \ldots, 2, 1) \end{cases} \quad (4)$$

In Equation (3) $\theta = \frac{2\pi}{2n+1}$. The trigonometric function can be calculated as following

$$\cos p\theta = \cos\theta\cos(p-1)\theta - \sin\theta\sin(p-1)\theta$$
$$\sin p\theta = \sin\theta\cos(p-1)\theta + \cos\theta\sin(p-1)\theta$$

Thus, the value of A_{pi} and B_{pi} can be evaluated using the following formulas:

$$\begin{cases} A_{pi} = \frac{2}{2n+1}(f_0 + u_1\cos p\theta - u_2) \\ B_{pi} = \frac{2}{2n+1}u_1\sin p\theta \end{cases} \quad (5)$$

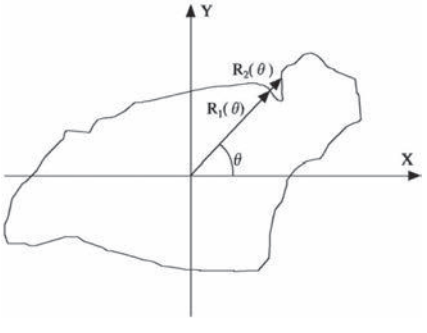

Figure 2. Typical miscalculation.

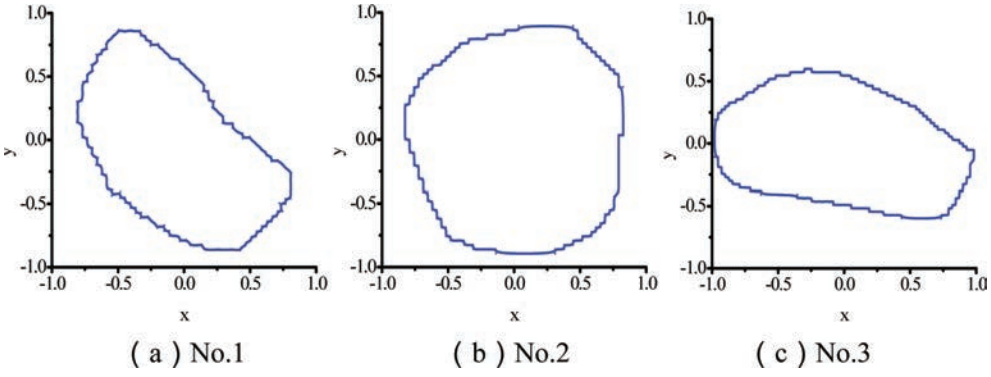

Figure 3. Digital shape of aggregate.

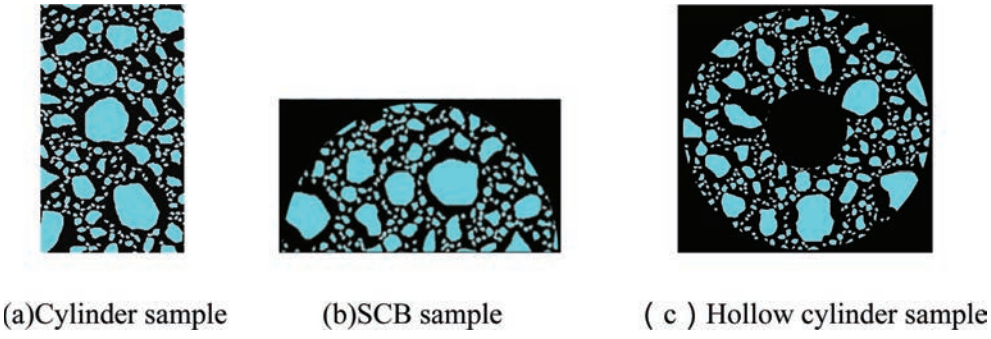

Figure 4. Geometry model of typical specimen particle.

2.2 *Database of 2D aggregate shape*

99 images of different aggregates were selected from the slices of X-Ray CT images of asphalt concrete sample. After digital image process, the coordinates of 2D aggregate skeleton were obtained. The coordinates were analyzed with Fourier analysis method and 99 different formulas were determined with different coefficients.

After normalization of the simulations results, the shape of aggregate can be quantified as Figure 3 with the formula, it is easy to make 2D micromechanical simulation Finite element model of asphalt concrete.

With the established database and PFC2D software, a program for two-dimensional virtual mechanical simulation of asphalt concrete with irregular particles was written. Some typical models are shown as Figure 4.

3 VIRTUAL SIMULATIONS OF SPLIT TEST

3.1 *Mesh generation*

Usually, there are three ways for mesh generation: Octree method; Delaunay method and Advancing front method. The Delaunay mesh generation algorithm is adopted in this paper. The process of its generation is firstly to generate the finite nodes and then to generate the nodes within the region. Due to the very irregular aggregate and complex mastic distribution, both the three-node triangle elements as four-node quadrilateral elements were used in the FE mesh for the complex geometry.

3.2 *Parameters for calculations*

Finite element simulations are conducted to predict the mixture behavior by combing aggregate and mastic properties with consideration of air void distribution.

Coarse aggregates are assumed as elastic material. The used sand mastic consists of asphalt and fine aggregates passing sieve size 1.18 mm and is assumed as visco-elastic material described by Burgers constitutive model. The model parameters are determined by experiments and transformed into Prony series.

Uniaxial creep tests are performed under the controlled-stress 0.2 MPa and viscoelastic parameters of Burgers model is achieved. The relax modulus of Burgers model is fitted with six-term Prony series and can be expressed as follows:

$$G(t) = G_{\infty} + \sum_{i=1}^{n_G} G_i \exp\left(-\frac{t}{\tau_i^G}\right) \tag{6}$$

where

$G(t)$ = relax modulus of Burgers model expressed as Prony series;

G_i = elastic spring constants of Burgers model;

τ_i = viscosity constants of Burgers model

The fitted parameters for six-term Prony series of relax modulus of Burgers model are as follows: $G_{\infty} = 2102868.53135$pa; $G_1 = 285843.50205$ Pa; $\tau_1 = 1807.06941$s; $G_2 = 129943.75591$ Pa; $\tau_2 = 16.77813$s; $G_3 = 291239.25846$ Pa; $\tau_3 = 1974.47877$s; $G_4 = 112455.47173$ Pa; $\tau_4 = 16.77812$s; $G_5 = 295994.1695$ Pa; $\tau_5 = 1682.12124$s; $G_6 = 295270.22585$ Pa; $\tau_6 = 1856.99569$s.

Modulus of 84.4 GPa is used for the aggregate and 84.4 GPa, 8.44 GPa, 2.81 GPa are used for sand mastic separately in the study. Poisson's ratio of 0.3 and 0.25 are input for the aggregate and sand mastic separately.

3.3 *Calculation results*

The tensile stress distributions are present as Figure 5. The numerical results show that the material inhomogeneities can have significant effects on the tensile stress concentration and

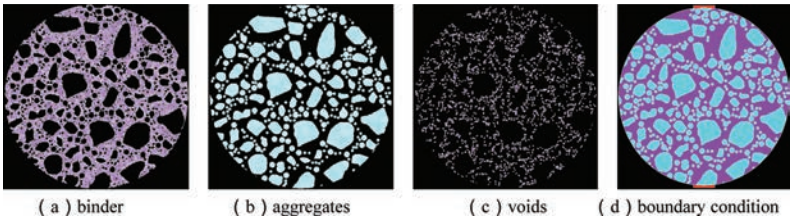

Figure 5. Finite element mesh of AC-16 specimen with 9% voids,150 mm in diameter.

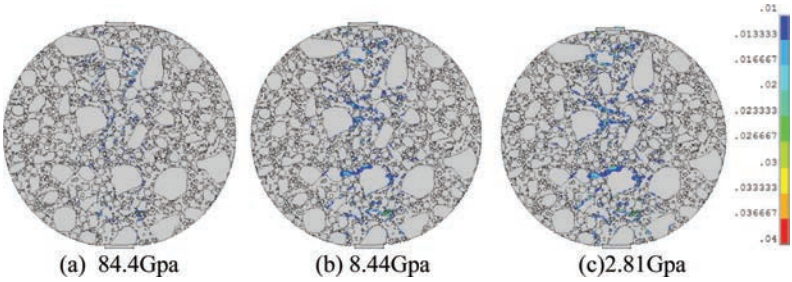

Figure 6. Splitting test results for different binder modulus.

the coarse aggregates skeleton has greater influence on mechanical properties of asphalt concrete. The calculation results also show the tensile stress decrease with the increasing of binder modulus. The presented method can automatically generate digital specimen and the generated digital specimen can satisfy the requirements of micro mechanical properties numerical analysis of asphalt concrete.

4 CONCLUSION

Two-dimensional boundary coordinates of 99 irregular aggregates were extracted after digital processing of asphalt concrete CT images. The modified Fast Fourier Transformation method (FFT) was used to obtain the fitting functions of those coordinates and the irregular particle form database was established. With the established database and PFC2D software, a program for two-dimensional virtual mechanical simulation of asphalt concrete with irregular particles was written. Taking three gradations as an example, under the same void,virtual simulations of Split test were carried out. The test results show that the presented method can automatically generate digital specimen and the generated digital specimen can satisfy the requirements of micro mechanical properties numerical analysis of asphalt concrete. It is believed that the proposed method can be extended to predict the mixture behavior based on ingredient properties.

ABSTRACT: Confocal Laser Scanning Microscopy (CLSM) allows the detailed study of the microstructure of bitumen and is capable of the visualization of fluorescent centers in bitumen. The origin of this fluorescence has been the subject of ongoing debate in the community. However, by the use of chromatographic separation and fluorescence spectroscopy, we were able to obtain new evidence regarding the composition and ageing behavior of asphaltene micelles. In fact, the aromatic mantle, serving as a stabilizing agent around the micelle, is responsible for high intensity fluorescent emissions in the visible range, and not the asphaltenes themselves. These facts serve as the basis for an updated micelle model, capable of describing both the visualized microstructure and the ageing behavior of asphalt concrete in respect to thermal healing of asphalt.

Moreover, based on this micelle structure model a new mechanical model for bitumen ageing was derived, in the framework of continuum micromechanics. Thereby, the bitumen is considered as a viscoelastic four-phase composite, consisting of an asphaltene phase embedded in a maltene phase. A third phase, built up by resins and highly polar aromatic structures, triggers the interaction between asphaltenes, and mechanically describes the age-dependent microstructure of bitumen. This model could be validated by means of shear rheometer tests on differently aged bitumen.

Keywords: Fluorescence spectroscopy, bitumen micro-structure, bitumen ageing, bitumen modeling, Confocal Laser Scanning Microscopy

1 INTRODUCTION

Asphalt concrete is one of the most prominent materials in road engineering. Due to rising crude oil prices and increased manufacturer liability the economic situation for producers, engineering companies, and customer become less and less favorable. Additionally, mineral concrete as a competitive material has become ever more popular over the last decade. This leads to the exploration of new technical processes, like warm mix asphalts and advanced recycling strategies that enable the production recycling asphalt mixes of equal quality levels compared to the original product. However, all these strategies depend on the understanding of bitumen microstructure, which is the defining factor for ageing properties of asphalt.

Bitumen is broadly defined as a *virtually not volatile, adhesive and waterproofing material derived from crude petroleum, or present in natural asphalt, which is completely or nearly completely soluble in toluene, and very viscous or nearly solid at ambient temperatures* [1]. This definition is as exact as possible, given the diversity of bitumina.

Since materials researchers started investigating bitumen several models for the bitumen microstructure and asphalt concrete were developed. This study is based on the micelle theory [2], [3] and the extended 5+1 scales of asphalt observation model [4], which points out the importance of the molecular and bitumen scale analysis for the material properties (Fig. 1).

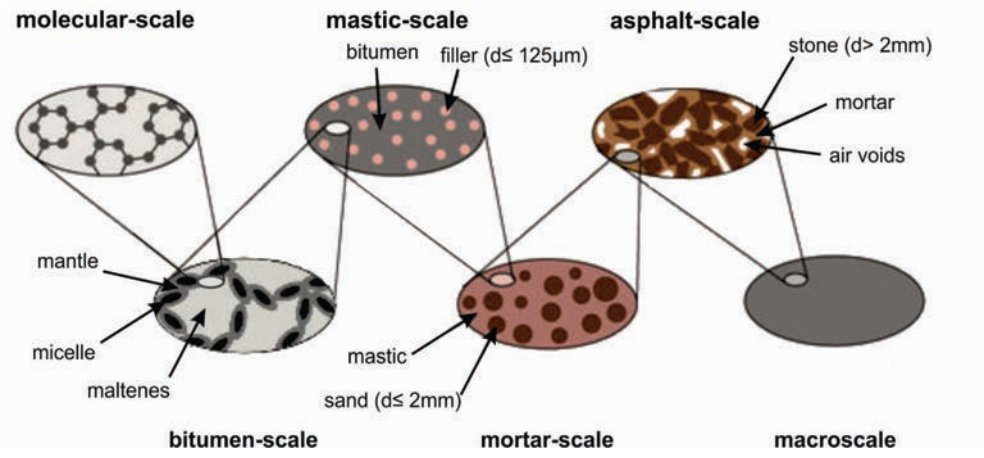

Figure 1. The 5+1 scales of asphalt observation, explaining the relations of material properties to the different scales of study [4].

Basically, this model assumes bitumen to be a colloidal system of asphaltenes micelles dispersed in a maltene matrix.

CLSM is an imaging technique capable of analyzing highly localized fluorescence emission and was used to visualize the bitumen microstructure. Additionally, fluorescence spectroscopy was employed to obtain integrated spectra of bitumen and bitumen fractions. By combining the information, we were able to develop a new model hypothesis for bitumen ageing.

Previous studies employing CLSM on bitumen have mainly been focused on SBS-modified bitumina [3], [5], [6], [7], [8]. The analysis of pure bitumen with this intriguing method was seldom conducted [9], [10], [8]. The discussion of the nature of the fluorescent centers that can be visualized by CLSM is an ongoing debate in bitumen research [11]. Contradictory identifications range from asphaltenes [10], [9] to waxes [12]. Some of these hypotheses can be discarded easily, since certain constituents are not capable of fluorescent emission in the visible range due to their very physical and chemical nature. This study has identified the origin of these fluorescent centers and found conclusive evidence that the aromatics fraction is the source of the strong fluorescent signals in bitumen that can be visualized by CLSM.

2 MATERIALS AND METHODS

2.1 *Bitumen and bituminous specimen*

The materials used in this study were carefully chosen for their material properties and their respective position in the production cycle of bitumen (Table 1). The precursors were studied to examine, if they exhibit a similar structural composition to their respective end products. Bitumen B50/70 was chosen as a typical material used in road construction, while B70/100 bitumina are often used for the production of SBS-modified bitumina.

2.2 *Analytical equipment*

We employed an ECLIPSE TE2000 (Nikon Corporation, Tokyo, Japan) as a confocal laser scanning microscope. The microscope hosts both a transmission and a CLSM (Confocal Laser Scanning Microscope) array. The light source for the transmission array is a T-DH 100 W Illumination Pillar (Koehler Type). An Argon-ion laser is used as source of excitation radiation. Typical for CLSM, laser optics is configured to allow a scanning of the surface and the image is created point by point and line by line. The advantages mentioned above in combination with the highly sensitive detector are key features for the successful application.

Table 1. Samples and description.

Sample	Description
Precursor 1	Vacuum flashed, cracked residuum
Precursor 2	Residuum of vacuum distillation
B50/70	Bitumen for asphalt concrete production
B70/100 1	Bitumen for asphalt concrete production or for production of SBS-modified Bitumina
B70/100 2	Bitumen for asphalt concrete production or for production of SBS-modified Bitumina

However, the capability to scan volumes below the surface, a key advantage of the CLSM technique, cannot be applied here, because of the high absorption cross section in the visible range of all bitumina. For sample preparation, the bitumen was heated to about 150–200°C as necessary for melting the sample. Then a small quantity of bitumen was applied to a glass slide with a piece of wire and a second glass slide was placed onto the sample. After a short period of cooling, the sample was measured. Early experiments showed that this procedure had to be modified. The first step towards a significant improvement in picture quality is the replacement of the standard object carriers by extremely thin glass slides (<0,5 mm). Second, an additional heating period was implemented, allowing the bitumen film to spread and become thinner. These very thin films could then be examined by CLSM.

For fluorescence spectroscopy, an Edinburgh Instruments FSP920 photoluminescence spectroscopy setup was at our disposal. As an illumination source, a XE900 Xenon Arc Lamp is used, which provides high intensity radiation on a broad spectrum. The setup employs double Czerny-Turner monochromators (type TMS300) at both excitation and emission arms, guaranteeing a very narrow spectral bandwidth. The detector is a S900 single-photon photomultiplier (type R928). The spectrometer was used to conduct both excitation and emission measurements. For sample preparation, the bitumina were heated to 150°C and a drop of bitumen was applied to a standard microscopic slide. This slide was stored at the same temperature for 5 minutes to allow the drop to spread and increase its surface. Afterwards the samples were cooled to room temperature and subjected to fluorescence spectroscopy. For bitumen fractions, this treatment was not necessary, because the maltene phase and its components are viscous liquids at room temperature and can be applied directly to the glass slide. The asphaltenes were taken up with toluene and then dripped slowly on the warm glass surface (80°C) to allow the formation of a thin film.

Chromatographic separation was conducted according to ASTM Standard 4124 [13], which is the most prominent and widely used method [11] and based on the Corbett procedure [14]. However, the nomenclature was changed to fit the SARA (Saturates Aromatics Resins Asphaltenes) scheme, deviating from the standards nomenclature (aromatics—naphthene aromatics; resins—polar aromatics). First bitumen was separated into maltene and asphaltene phase by extraction with n-heptane. However, the n-heptane extraction was conducted in a Soxhlet-extractor. The further separation is conducted in a 1000 mm chromatographic column with alumina as the stationary phase with three different solvents/solvent combinations. The eluate was collected in 50 ml beakers, which were sealed, cooled, and then stored at −15°C to slow oxidative degradation. Then each fraction was warmed to room temperature and subjected to distillative separation under vacuum. The sample was then cooled to room temperature before breaking the vacuum. Afterwards, the fraction was weighed. The sample was then again subjected to escalating distillation (max 185°C, 10 mbar, 10 min) and weighing until constant weight was reached to assure gravimetric exact measurements. Then the sample specimens were prepared for fluorescence spectroscopy.

3 RESULTS

3.1 *Microstructure of bitumen, bitumen precursors*

It was possible to obtain new and enhanced pictures of the bitumen microstructure by application of CLSM to pure bitumina. These images proof the existence of a microstructure, which

implicates agglomeration processes and phase separation processes in bitumen, as implicated in the micelle model. The fluorescent centers detected are of roughly ellipsoid shape, vary in size and amount, and their spatial distribution seems to be statistical and unordered. Exemplary, two images are shown in Figure 2. Their exact size distribution and population density varies for each sample and is characteristic for specific bitumina. The micelle model describes bitumen as a colloidal system of dispersed asphaltenes in a continuous maltene phase, which makes the spatial distribution of the fluorescent centers an important issue [3], [11]. Thus, a strong connection to the mechanical and rheological properties can be assumed. Preliminary experiments with picture analysis software have been conducted to assess the particle size distribution for the tested bitumina and whether significant differences between the samples can be found. Although the necessary picture processing is a rather complicated task due to high background fluorescence in bitumen, first results are promising and future experiments and process automation could provide a powerful tool for bitumen analysis.

3.2 *Fluorescence analysis and chromatographic separation*

Initially, fluorescence experiments have been conducted to support the use of CLSM as an imaging technique on bitumen. However, this study found that besides the distribution of fluorescent centers, the fluorescent behavior of bitumen and bitumen fractions can provide additional evidence regarding the actual microstructure of bitumen. Fluorescence spectroscopy yields an integrated spectrum that is not capable of visualizing spatial distributions. Information about the fluorescent centers and their composition in bitumen must be obtained indirectly through inference. A closer look on the basic physicochemical properties of bitumen reveals that bitumen contains only three fractions that could theoretically be the origin of the fluorescent signal. The asphaltenes, the resins, and the aromatics are, based on their general description, capable of fluorescence. Saturates can easily be dismissed as a source of fluorescent emission, due to the well defined chemical nature of fraction. There are two kinds of spectra presented here, excitation scans (variable excitation, fixed detection wavelength) and emission scans (fixed excitation, variable detection wavelength). For the excitation scans, the same detection wavelength as used at the microscope was chosen, 515 nm, and a spectral range of 200–500 nm was observed. For the emission spectra, two wavelengths have been studied carefully. First the excitation wavelength of 488 nm was selected, because this is one of the excitation wavelengths available in the CLSM setup. To check for high energy fluorescence transitions, we employed a wavelength of 280 nm (Fig. 3).

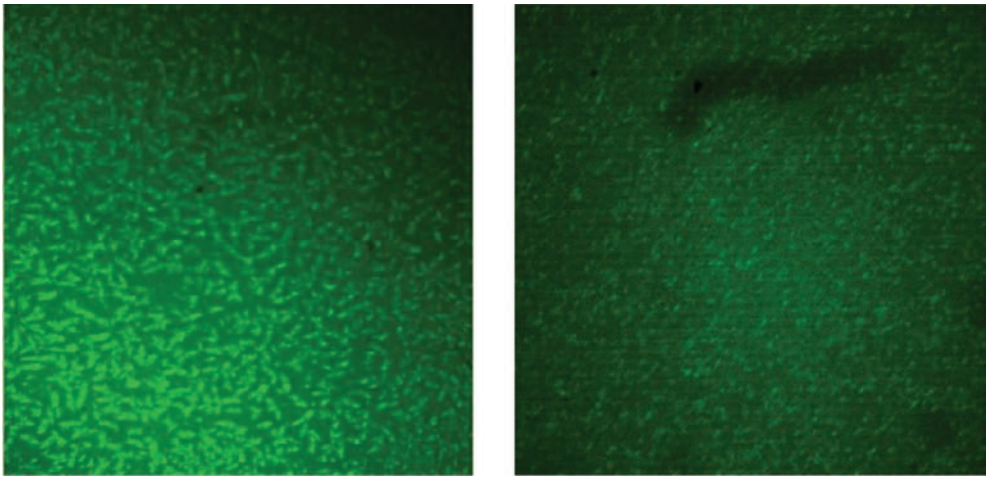

Figure 2. CLSM images of bitumen precursor PE1005 (left) and bitumen B70/100 (right), fluorescent centers characteristic for the respective sample.

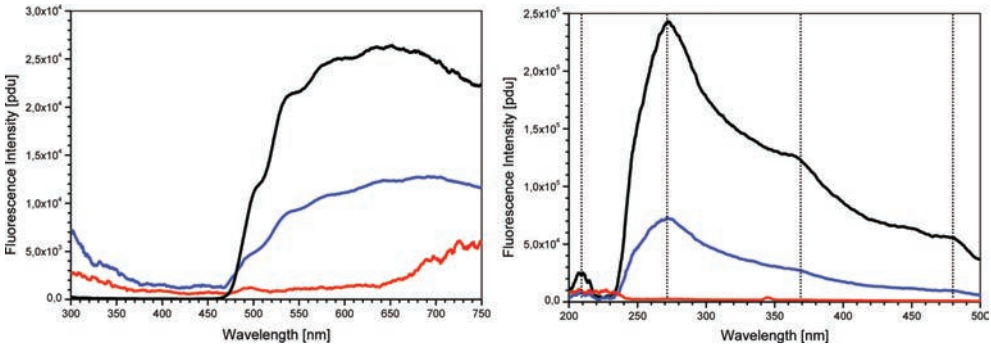

Figure 3. Emission fluorescence spectra of bitumen B50/70 (blue), asphaltenes (red) and maltenes (black) at 280 nm excitation wavelength (left) and excitation spectrum of bitumen B50/70 at 515 nm detection wavelengths.

The excitation fluorescence spectrum of pure bitumen allows the identification of four wavelength of particular interest (Fig. 3, right): 210 nm, 270 nm, 370 nm, 480 nm (dotted lines) for CLSM at a detection wavelength of 515 nm. These are a local and the absolute maximum, as well as the two shoulders visible in the excitation scan of the pure bitumen. The distribution of the fluorescent centers excited at these wavelengths would be of particular interest. Since fluorescence transitions can also be triggered by wavelengths lower than the necessary minimum, it is impossible to visualize the higher energetic transitions exclusively. For the CLSM studies, an excitation wavelength of 488 nm was chosen, because it is very close to the shoulder at 480–490 nm. Also it is one of the spectral lines providing the highest intensity available at the Argon-ion laser and is frequently used for CLSM. The technique was capable of revealing the origin of the fluorescence signals of the different species spatially distributed.

After the completion of the CLSM imaging, soon investigating the source of the fluorescence became a primary goal of further experiments. Usually a detailed interpretation of the fluorescence spectra could be attempted, but for bitumen, this is a rather difficult task. The dependency of fluorescence phenomena on the chemical vicinity of the molecules is very well documented and the effects of the surroundings are hardly assessable for bitumen [15]. Hence, a more empirical approach was chosen. The fractionation by chromatography is a well-known and reliable standard method in bitumen analysis [14], [13], [11]. It is often employed for characterization of bitumina by their relative contents of fractions. The fractions themselves again are complex mixtures of molecules, but exhibit similar chemical/physical behavior. In previous publications, the origin of fluorescence emission was suspected to be the asphaltenes fraction. This theory was explored to full extent. In general asphaltenes are defined as insoluble in n-heptane. While the basic extraction protocol for standardized testing is based on a simple extraction with n-heptane [13], for these experiments, a Soxhlet-extractor was used for the removal of asphaltenes, which guarantees as pure asphaltenes as reasonably possible. The fluorescence spectra of these fractions were surprising. Our experiments strongly indicated that the origin of the fluorescent centers can be found in the maltene phase and not in the asphaltenes phase, as proposed by other researchers [10]. The spectra of the asphaltenes show almost no fluorescent capabilities at either the detection wavelength or the excitation wavelength used by the CLSM (Fig. 3). The maltene phase exhibits strong fluorescence in these areas. The absolute intensity ratings, although being only general tendencies, suggest that the residuum somehow dampens the fluorescence of the pure bitumen 50/70 as it dilutes the extract. Obviously, the fluorescence of the asphaltenes is shifted to wavelengths higher than 750 nm, into the near infrared region, which is not accessible to the fluorescence spectroscope used in this study.

Further fractioning of the maltene phase into saturates, aromatics, and resins, was conducted to obtain their respective spectra. Although the spectra differ within reasonable

bounds, all bitumina show the same behavior: Only the aromatics fraction shows significant fluorescence in the relevant areas. Taking into account the micelle model and that the fluorescent centers are spatially distributed and the fluorescent species seem to agglomerate, they can be interpreted as a stabilizing mantle, composed mainly of aromatics, surrounding the asphaltenes micelles. Figure 4 shows the normalized spectra of the bitumen fractions and show that the aromatics exhibit very strong fluorescence at 480 nm excitation. However, it has to be added that normalization removes the information of fluorescent emission intensity, which is by several orders of magnitude higher for the aromatics than for both resins and saturates.

3.3 *The micelle model and ageing*

Considering this new information about the chemical structure of the micelle we formulated a new thesis regarding bitumen ageing. This model is a refinement of the micelle model and takes the research conducted upon the oxidative properties of bitumen and bitumen fractions [16], [11] into special consideration. The saturated fraction is considered the least reactive, almost inert by comparison, of all fractions. The asphaltenes seem to have a very strong capability for oxidation in liquid state (i.e. melted or in solution), but show low reactivity at ambient conditions due to their highly associated and solid state. Both aromatics and resins show significant susceptibility for oxygen uptake [16]. Due to this research, for mixing and construction, i.e. the first short term ageing step, oxidation can take place across all phases, with the exception of saturates, but for long term ageing, the oxidation of the asphaltenes fraction has to be considered insignificant. Based on the micelle structure model and its structural and chemical constraints, a pathway for oxidative species diffusing through the material can be plotted (Fig. 5, left).

The continuous phase is largely inert, so the first contact between oxidative species and reactive material happens at the surface of the micelle mantle, which is composed of aromatics and resins. There oxidation can occur and the ammount of reactive oxidative species reaching the asphaltenes has to considered reduced strongly by the oxidation happening in the mantle. This is also conclusive with studies on asphalt oxidation which generally show a declining amount of nonpolar aromatics and a buildup of resins and asphaltenes as a result of ageing. This oxidation process has to be considered very slow in nature, due to the low temperature and the stability of most carbohydrates to oxidation at ambient conditions. However, experience in road engineering show that road damages due to asphalt ageing can occur few months after the construction. Furthermore, experiments regarding asphalt heal-

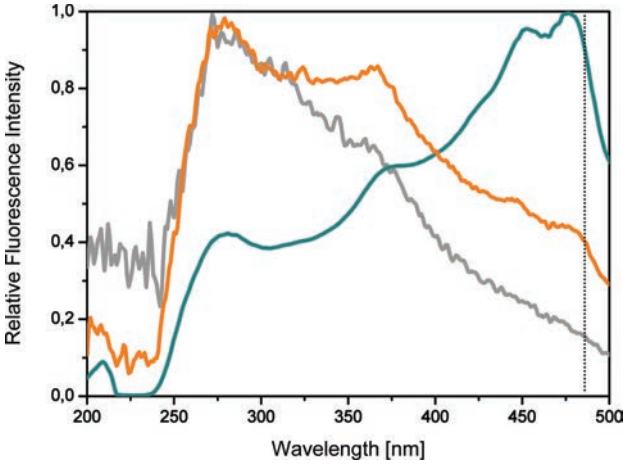

Figure 4. Fluorescence spectra of bitumen fractions: saturates (grey), aromatics (green), resins (yellow), detection wavelength of CLSM: 488 nm.

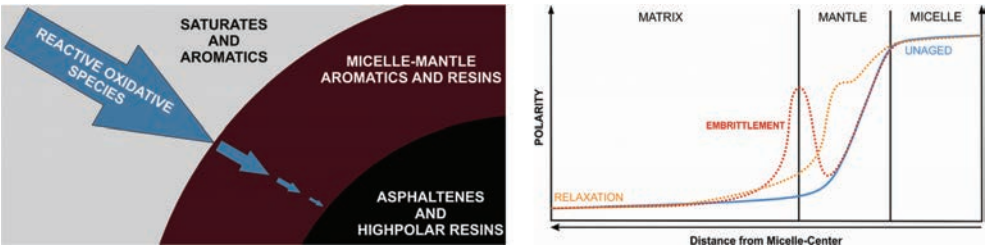

Figure 5. Reactive Oxidative Species (ROS) pathway in bitumen (left). Polarity of bitumen in the micelle structure in fresh (blue), long term aged (red), and relaxed (orange) state (right).

ing in lying asphalt concrete roads show that heating the asphalt can significantly increase road lifetime by enabling self healing [17]. Based on this research we developed a new model hypothesis for asphalt ageing. If the low mobility of molecules at ambient conditions is taken into account, it can be understood that oxidation leads to the formation of a high polar layer on the outside of the micelle mantle. If the polarity reaches a certain limit, then phase separation at this new boundary occurs and the whole, larger micelle plus mantle particle basically forms another immobile center. This reduces transduction of elastic properties and leads to a hardening of the material. If the asphalt is heated, then the diffusion rate significantly increases and the now highly polar resins/aromatics migrate into the center of the micelle and the functionality of the mantle is restored. This also explains why the ageing at road construction is not as destructive as it would have to be considered. At the high temperatures, the high polar oxidation products can simply be transported into the inside of the micelle. However, the increase in micell volume means that the mantle becomes thinner and thus the polarity gradient more extreme and micelle mobility in the matrix decreases. This limits the capability of relaxation by inclusion of high polar molecules in the micelles.

4 MICROMECHANICAL MODELING OF BITUMEN MICROSTRUCTURE

Based on the micelle model introduced before, delivering a basic concept of the bitumen microstructure, and the knowledge gain through the proposed results of chemical analysis, a mechanical model which takes the bitumen microstructure into account could be derived. Therefore, the framework of continuum micromechanis was chosen, allowing for a description of the viscoelastic response of bitumen depending on the volumetric composition and the physical properties of its constituents. Moreover, the interaction between material phases can be taken into account through different so-called homogenization schemes [18], [19], [20], [21], [22], [23]. Thereby, a material is considered as a micro-heterogenous body filling a macro-homogenous Representative Volume Element (RVE). Quasi-homogenous subdomains [20], [21], [22], also known as material phases, with known physical properties describe the microstructure within such an RVE. Correlating the homogeneous deformations acting on the boundary of an RVE with the resulting (average) stress, the mechanical behavior of the overall material can be estimated. Such an approach is refered to as homogenization.

On the basis of the chromatographic separation mentioned before, a reasonable subdivision of bitumen into distinct material phases for the micromechanical modelling were possible (see Fig. 6). Therefore, an RVE of bitumen is built up by a contiguous matrix phase, representing aromatics and resins, in which spherical inclusions are embedded, describing the saturates. While the asphaltenes, acting in the center of micelles, are also modelled by spherical inclusions, the micelle mantles are assumed to form a network-like structure and for this reason are represented by needles with randomly distributed orientations.

Identification of the viscoelastic behavior of the maltene phase (matrix phase and the inclusions representing the saturates) was done by static shear creep tests using a Dynamic Shear Rheometer (DSR). As asphaltenes and their mantle material (highly polar resins and

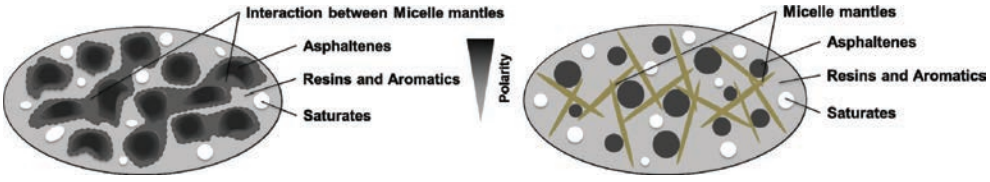

Figure 6. Concept of bitumen microstructure based on micelle model and therefrom derived RVE considered in micromechanical model.

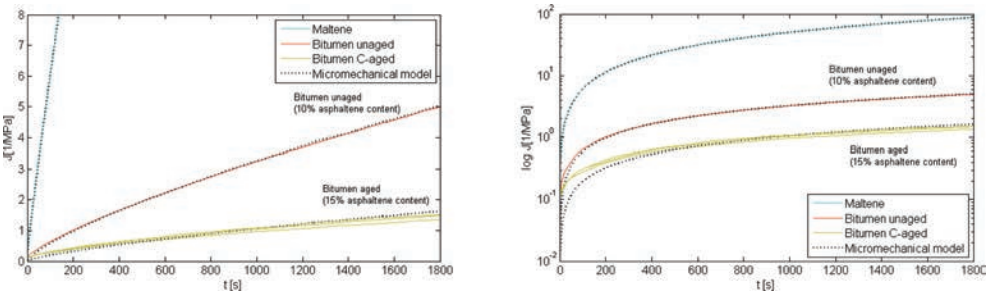

Figure 7. Comparison of experimental results on aged and unaged bitumen (B70/100 at +5°C) from static shear creep tests with predictions from micromechanical modelling.

aromatics) act together in the micelle structure, the same effective viscoelastic behavior is assigned to both phases. To access this effective behavior, static shear creep tests on bituminous mixtures with different (known) asphaltene contents were carried out and by comparison of experimental and model results on a best-fit basis the material behavior could be obtained. In addition, the increase of needles, representing the interaction between micelles, with increasing asphaltene content could be determined, revealing an exponential relationship for asphaltene contents between 0% and 20%. For a detailed validation of these assumptions and the introduced micromechaincal model we refer to further publications.

The influence of longterm ageing was investigated on B70/100 bitumen samples, aged in laboratory using PAV and RTFOT equipment [24]. From static shear creep tests on these samples it was found, that the mechanical behavior of asphaltenes as well as maltenes due to ageing is negligible. However, a significant increase in asphaltene content, and consequently the micelle mantle content, could be observed (detailed information also presented in further publication). This increase, and thus the effect of ageing, can be described satisfactorily by the derived micromechanical model, as can be seen in Figure 7.

5 CONCLUSION

Confocal laser scanning microscopy is an important tool for bitumen analysis, because of its capability to visualize the microstructure of bitumen. It proves the existence of two separate phases in bitumen, as predicted by the micelle theory. Also, it was possible to identify the fluorescent phase in bitumen by chromatography and fluorescence spectroscopy as the aromatics fraction. The aromatic phase contains the molecules that exhibit strong fluorescence capabilities at 488 nm excitation and 515 nm detection and seem to agglomerate. Although other phases also show activity under these conditions, it is by several orders of magnitude lower in intensity, if compared to the aromatics. Thus, an ongoing debate in the scientific community has found its end.

The realization that the fluorescent phase in bitumen is actually the aromatics phase indicates that this is a critical phase regarding ageing and embrittlement. Basically, we developed an enhanced micelle theory for ageing that is capable of explaining the different effects of

short term and long term ageing as well as thermal healing of asphalt concrete. This is an early step on the road to upstream recycling of asphalt concrete and bitumen, because the identification of problematic structural and chemical changes is necessary to overcome their effects.

Based on the introduced micelle model, a mechanical model is derived in the framework of continuum micromechanics considering bitumen as a four-phase composite consisting of asphaltenes, micelle mantles, and saturates embedded in a contiguous matrix of aromatics and resins. The microstructure was implemented in a homogenization scheme to predict the overall viscoelastic response. An increase of asphaltene content, and thus volume content of the micelles, is identified to be responsible for ageing effects, which can be described by the micromechanical model very well.

ABSTRACT: Frost damage is one of the major concerns in pavement design particularly in cold regions. During their service life, asphalt pavements are continuously exposed to various environmental conditions such as oxidation, ultraviolet radiation and moisture. The joint effects of mechanical and environmental loading progressively degrade the mechanical properties of asphalt pavements, resulting thus to frost damage when ice crystals form in the asphalt concrete. In this contribution a 3D energy based micromechanical finite element model is presented for simulation of the volume expansion that occurs during the water-to-ice phase change in the macro pores of the mixture. For the simulations, the internal microstructure of asphalt mixtures was captured with X-Ray Computed Tomography (CT) imaging techniques. The analyses enable the quantification of the contribution of asphalt mixture characteristics such as air voids and pore connectivity in the damage developed in the asphalt binder due to the volume change of water-to-ice in the pores.

Keywords: Frost damage, asphalt mixtures, constitutive modelling, X-ray computed tomography, phase change

1 INTRODUCTION

The detrimental effects of freeze-thaw cycles in Asphalt Concrete (AC) pavements are manifested by stripping of aggregates from the asphalt mixture, which ultimately results to pothole formation and deterioration of the pavement surface. For frost damage to occur, low temperatures and water in the pores have to be concurrently present in an AC pavement.

Depending on the design characteristics, air void content in an asphalt mixture can vary from 3–5% for a dense-graded mixture and up to 20% for an open-graded one. Because of precipitation and other reasons, moisture can accumulate inside the air voids and the microcracks in the top layers of the pavement, Figure 1(b). As the temperature drops below zero, the pavement freezes from the surface downwards and a phase change of water-to-ice takes place, followed by volume expansion, Figure 1(c). The expanding ice crystals impose compressive stresses to the adjacent aggregates, Figure 1(d), which can cause cohesive and/or adhesive damage.

Unlike the majority of substances, water expands upon freezing and its volume increases approximately by 9% under atmospheric pressure. On the basis of thermodynamics, volume expansion of water-to-ice is the result of a phase change from a liquid state to a solid one,

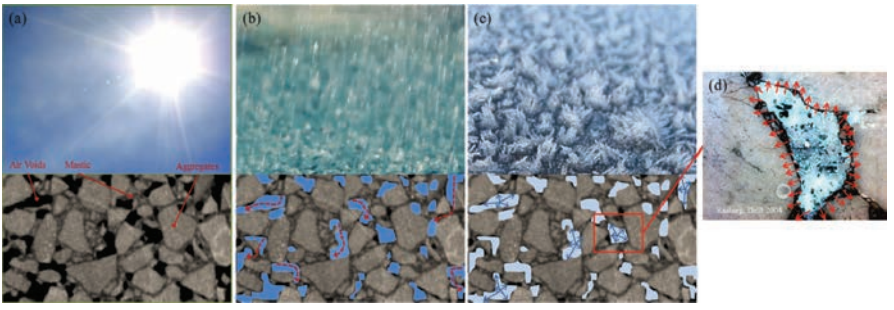

Figure 1. Frost damage: (a) asphalt mixture components, (b) moisture infiltration, (c) ice expansion, (d) developed stresses.

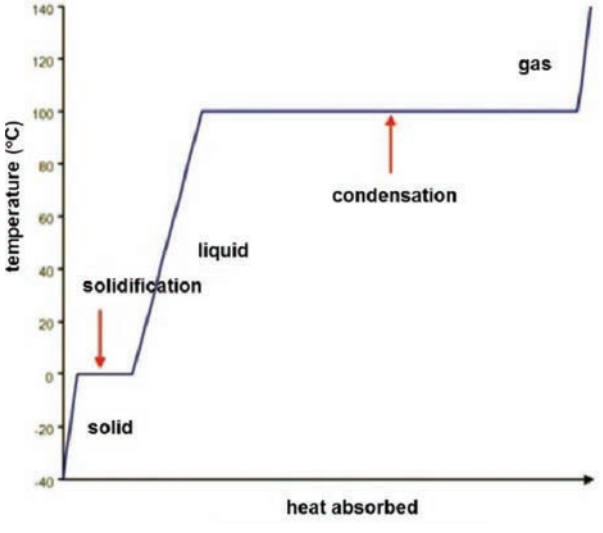

Figure 2. Heating curve for water.

Figure 2. Phase change takes place in a very narrow temperature range around zero degrees and for this reason temperatures below zero have very little influence on volume change.

Several models were proposed for the simulation of freeze-thaw damage mechanisms over the past years for soils [1–3] and cement concrete [4]. However, to the knowledge of the authors, there is no attempt in literature to model binder damage due to frost damage for asphalt mixtures. For asphalt concrete, previous studies focused on the characterization of AC mixtures performance under the influence of freeze-thaw cycles [5–7].

In the present study, a thermal-phase change micromechanical model capable of simulating the phase change driven volume expansion of water is combined with a thermal diffusion algorithm and a binder damage model to investigate the influence of AC mix characteristics on frost damage susceptibility. All Finite Element (FE) simulations were performed by the CAPA-3D FE system developed at Delft University of Technology [8] on 3D micromechanical meshes obtained by X-Ray Computed Tomography (CT) scans of actual asphalt cores.

2 WATER-TO-ICE PHASE CHANGE MODEL

The constitutive model utilized for the simulation of water-to-ice phase change is presented in this section. As shown in Figure 3, the model consists of a hyperelastic component

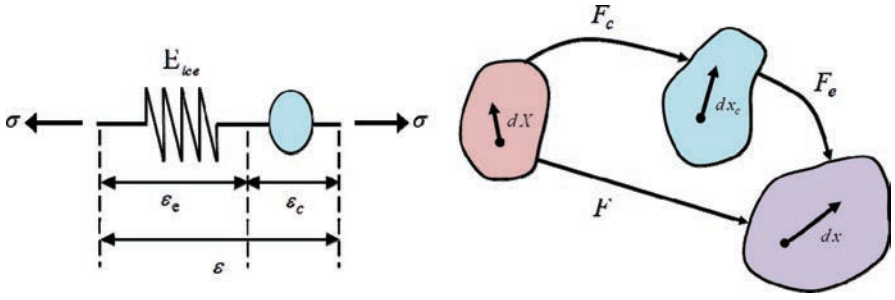

Figure 3. Schematic of the phase change material model.

representing the mechanical stiffness of the ice crystal and a swelling element which, when active, simulates the phase change driven expansion ε_c. For a constrained total deformation case (i.e. $\varepsilon = cnst$), as ε_c in the swelling component increases due to phase change, the hyperelastic spring is compressed and hence it exerts compressive stresses in the surrounding. The evolution equation for the water-to-ice expansion is postulated as

$$\frac{\partial \xi}{\partial t} = \frac{1}{t_c}(1-\xi) \tag{1}$$

where t_c is the characteristic time of the phenomenon. And ξ is the expansion in time. Assuming the initial condition $\xi|_{t=0} = 0$ the ice expansion in time is defined as

$$\xi = 1 - \exp\left(\frac{t}{t_c}\right) \tag{2}$$

A large deformation framework on the basis of multiplicative decomposition is utilized, where the total deformation tensor F is split into an elastic part F_e and an 'ice expansion' component F_c, so that it holds

$$F = F_e F_c \tag{3}$$

Here the ice expansion function as stated in Eq. (3) is incorporated into the 'ice expansion' deformation component as

$$F_c = (1 + k\xi) I \tag{4}$$

where k is the maximum expansion and I the second order identity tensor. By combining Eqs. (3–4) an expression for the elastic deformation tensor results

$$F_e = F F_c^{-1} = \frac{F}{1 + k\xi} \tag{5}$$

With regard to the reference configuration, the right Cauchy-Green strain tensors for the hyperelastic and the swelling component are described by

$$C_c = F_c^T F_c \tag{6}$$

$$C_e = F_e^T F_e \tag{7}$$

For a purely mechanical case, the Clausius-Planck dissipation inequality defines the dissipation of energy D, as

$$D = P : \dot{F} - \dot{\Psi} \geq 0 \tag{8}$$

where P is the first Piola-Kirchhoff stress, Ψ is the time derivative of the Helmholtz strain energy function. For the proposed model the Helmholtz free energy is defined as

$$\Psi = \Psi_c(\xi) + \Psi_e(C_e) \tag{9}$$

in which Ψ_c is the strain energy function of the swelling component, Ψ_e is the strain energy function for the single spring. Substituting Eq. (9) into the dissipation inequality of Eq. (8) results to

$$D = P : \dot{F} - \frac{\partial \Psi_e}{\partial C_e} : \dot{C}_e - \frac{\partial \Psi_c}{\partial \xi} \cdot \dot{\xi} \geq 0 \tag{10}$$

After some mathematical elaboration, the stress tensor and the dissipation inequality are obtained as

$$P = 2F_e \frac{\partial \Psi}{\partial C_e} F_c^{-T} \quad \text{and} \quad 2C_e \frac{\partial \Psi}{\partial C_e} : L_v + q \cdot \dot{\xi} \geq 0 \tag{11}$$

in which L_v is the velocity gradient and Σ is the Mandel tensor. To solve the above inequality, the following minimization problem is defined

$$\text{minimize } -\left(\Sigma : L_v + q \cdot \dot{\xi}\right) \tag{12}$$

$$\text{subject to } g(\Sigma, q) \leq 0 \tag{13}$$

To satisfy the above minimization problem, the following evolution laws can be postulated

$$\Sigma : L_v \geq 0 \tag{14}$$

$$\frac{\partial \Psi}{\partial \xi} \frac{\partial \xi}{\partial t} \geq 0 \tag{15}$$

where the following form for the velocity gradient of the ice component is defined

$$L_v = \dot{F}_c F_c^{-1} = \frac{\kappa \dot{t}_c (1 - \xi)}{1 + \kappa \xi} I = d\, I, \quad d \geq 0 \tag{16}$$

3 THERMAL CONDUCTION MODEL

On the basis of a staggered algorithm, the above phase change model is coupled to a thermal conduction model capable of simulating the conductive flow of heat into the components of the asphalt mixture. Conduction is governed by the following equation

$$q = -k \nabla T \tag{17}$$

where q is the heat flux vector ($W \cdot m^{-2}$), k is the thermal conductivity ($W \cdot m^{-1} \cdot °C^{-1}$) and T is the temperature (°C) at a point within the medium.

By combining Fourier's law for the conduction of heat (Eq. (17)) and the law for conservation of energy, assuming a constant thermal conductivity k, one can obtain the heat conduction equation

$$\frac{\partial T}{\partial t} = \alpha \nabla^2 T \tag{18}$$

where ∇^2 is the Laplace operator in three dimensional rectangular Cartesian coordinates and α is defined as the thermal diffusivity ($m^2 \cdot s^{-1}$) of the material according to Eq. (19)

$$\alpha = \frac{k}{\rho C_s} \tag{19}$$

where ρ is the mass density ($kg \cdot m^{-3}$) and C_s is the specific heat capacity of the conductive medium ($J \cdot kg^{-1} \cdot °C^{-1}$).

4 ENERGY BASED VISCO-ELASTIC DAMAGE MODEL

An energy-based constitutive model for the simulation of mechanical damage is employed for simulation of the damage in the binder. The model falls within the general framework of Continuum Damage Mechanics (CDM) and introduces material damage as an internal state variable representing the irreversible physical processes within the microstructure of the material.

On the basis of energy arguments and multiplicative decomposition of the total deformation gradient, the stress tensor of the damaged material has been derived in Varveri et al. [9] as

$$P = \left(2F_e \frac{\partial \Psi_v}{\partial C_e} F_e^{-T} + 2F_\infty \frac{\partial \Psi_\infty}{\partial C_\infty} F_\infty^{-T} \right) F^{-T} \tag{20}$$

in which F_e and F_∞ are the deformation gradients of the viscous and the hyperelastic components of the model and F is the total deformation gradient.

In the model, damage is a scalar quantity which varies from the undamaged state $(d = 0)$ to the fully damaged one $(d = 1)$. The evolution law for damage is defined as a function of the total dissipated viscous work W

$$d = 1 - e^{-k \cdot W^r} \tag{21}$$

where k and r are calibration parameters.

5 DEVELOPMENT OF 3D MICROMECHANICAL MESHES

The accurate representation of the internal structure of the asphalt specimens is quite significant in micromechanical modelling, since each mixture component has its particular thermal and mechanical properties. For that reason, in this study, three dimensional micromechanical Finite Element (FE) meshes were produced from X-Ray CT scans by means of Simpleware, a specialized 3D-based image processing software [10].

In this study, X-Ray CT scans from a porous (PA) and a dense (SMA) asphalt mixtures were utilized. After cropping the segmented data to the desired dimensions, a robust meshing algorithm was applied to enable the conversion of the 3D images into FE meshes that were used for computational analyses in the CAPA-3D FE system. The FE meshes comprised three phases i.e. aggregates, asphalt binder and (water filled) air voids, as shown in Figure 4. For the spatial discretization of the meshes, 3D linear four-node tetrahedral elements were used. Specifically, the PA and the SMA meshes consist of 412,304 and 1,286,806 elements, respectively.

6 MICROMECHANICAL FINITE ELEMENT SIMULATIONS

The phase change FE model developed was applied to examine the mechanical degradation of AC mixtures due to damage development in the asphalt binder as a result of phase-driven

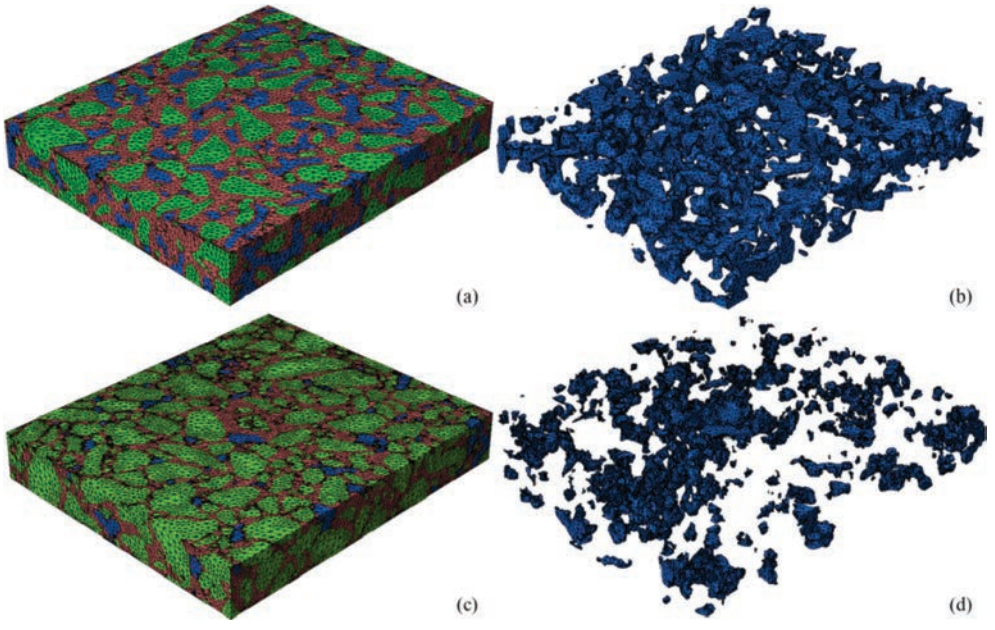

Figure 4. Volume renderings of (a) three-phase material and (b) air void phase in the PA mixture; (c) three-phase material and (d) air void phase in the SMA mixture.

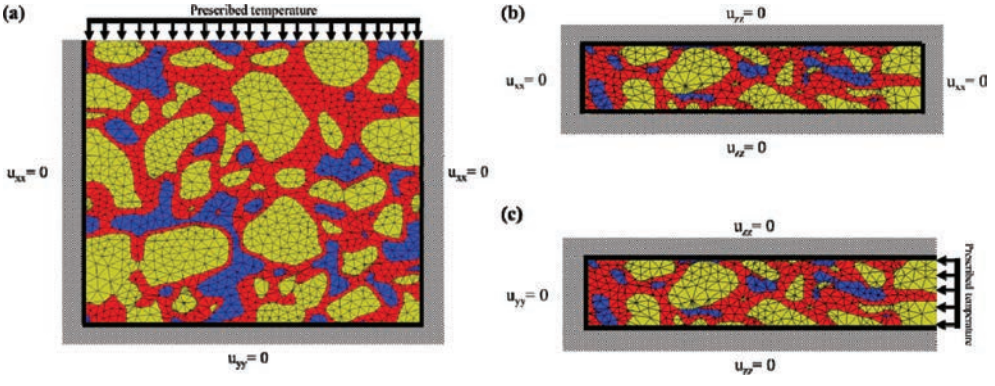

Figure 5. Specified boundary conditions in (a) X-Y, (b) X-Z and (c) Y-Z Plane.

volume expansion of water in the macro pores. Figure 5 shows the boundary conditions imposed during the FE simulations. A constant temperature $T = -2°C$ was applied at the top face to simulate top-down freezing. Adiabatic thermal flow conditions were specified at all other boundaries together with displacement restraints, Figure 5.

The thermal properties governing temperature propagation in AC pavements are volumetric heat capacity ρC_s and thermal conductivity k. In this study, the values of both properties differed for every constituent of the mixture i.e. aggregates (ag), asphalt binder (ab), air voids (av). The thermal conductivity and the volumetric heat capacity for each phase were chosen as $k^{ag} = 0.576$, $k^{ab} = 0.6173$ and $k^{av} = 0.09$ ($J \cdot mm^{-1} \cdot hr^{-1} \cdot °C^{-1}$) and $\rho C_s^{ag} = 2.024 \cdot 10^{-3}$, $\rho C_s^{ag} = 2.275 \cdot 10^{-3}$ and $\rho C_s^{ag} = 1.189 \cdot 10^{-6}$ ($J \cdot mm^{-3} \cdot °C^{-1}$), respectively.

For the viscoelastic asphalt binder, a viscosity of 2200 MPa·s was specified. Furthermore, aggregates were assumed hyperelastic and their mechanical properties were selected based on a study by Artamendi et al. [11]. An elastic modulus of 18.1 GPa and a Poisson's ratio of

0.171 were specified. For the ice material, the elastic modulus and the Poisson's ratio were specified 9.0 GPa and 0.31 (at 0 °C), respectively.

Figures 6(a) and 6(c) show the PA and SMA FE meshes in their undamaged condition, i.e. before freezing; for both meshes, aggregates are in yellow, asphalt binder in red and air voids in blue color. Figures 6(b) and 6(d) illustrate the damage distribution due to the action of the expanding ice crystals for the porous and the dense mixture, respectively.

The results show that damage accumulates in those areas of the binder located around the macro pores of the mixtures. It is observed that damage is more pronounced for the porous mixture than for the dense one. This finding is fairly obvious because the high air void content and interconnectivity of porous mixtures make them more susceptible to frost damage.

Figure 7 shows the expansion of the specimen in the vertical y direction as a result of the ice expansion in the pores. The black horizontal line indicates the height of the specimen in its initial configuration. As shown in Figures 7(a)–(c), damage evolution progresses as the phase-change process takes places and until the volumetric expansion reaches the terminal value of 9% water-to-ice volume expansion.

In Figure 8, the average displacement u_{yy} of the top surface is plotted against the compressive reaction forces developed in the horizontal x boundary direction of the specimen. The

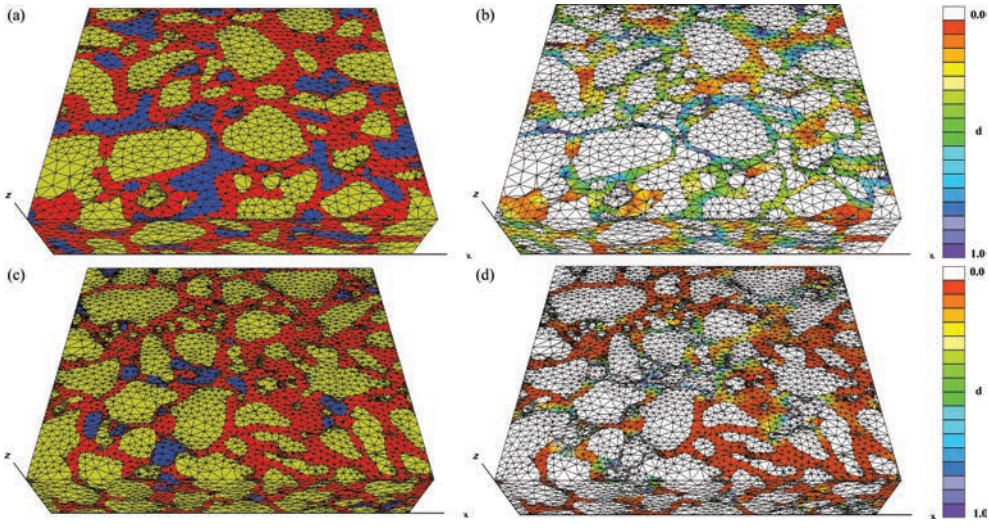

Figure 6. Three-phase finite element mesh and damage distribution due to water expansion in the PA (a–b) and the SMA (c–d) mixture.

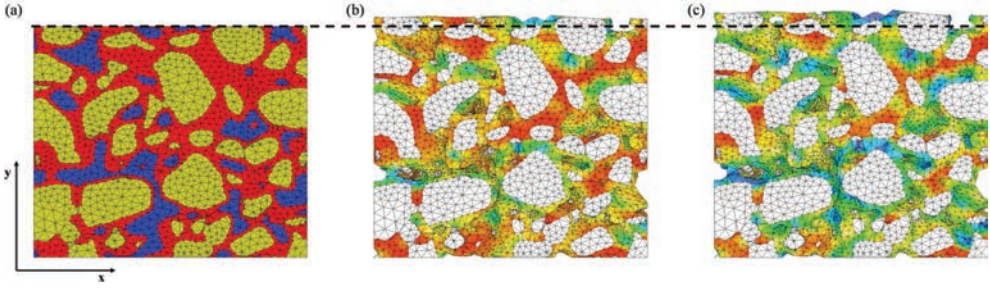

Figure 7. Displacement in vertical direction after (a) 0, (b) 3 and (c) 5 hrs of freezing for the PA mixture.

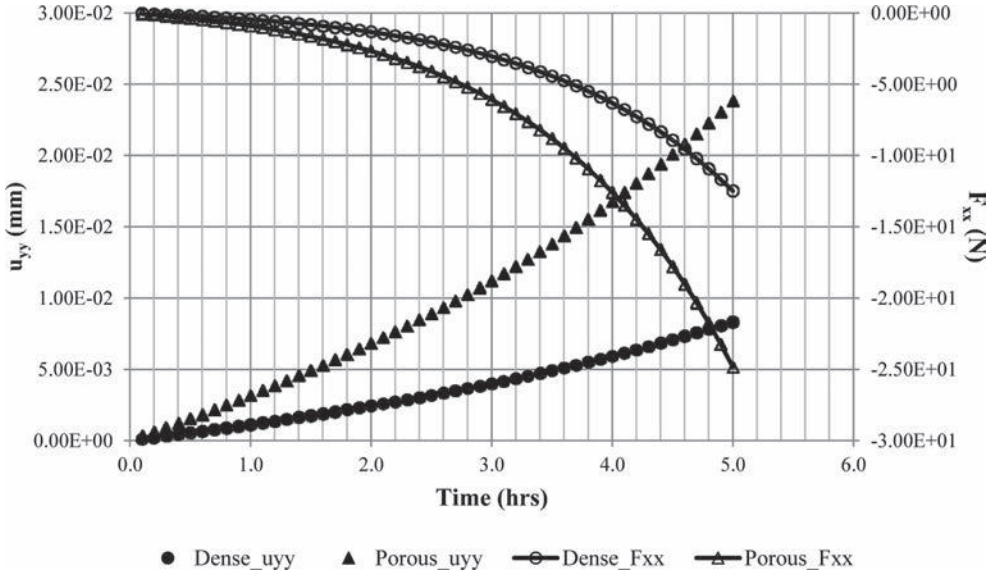

Figure 8. Influence of phase-driven volume expansion on the AC mixtures.

u_{yy} values at any given time correspond to the average shift in the y direction of all nodes for the aggregate and asphalt binder phases.

Calibration of the model is currently performed on the basis of micro-mechanical tests on AC samples similar to those shown in Figure 5 with analogous thermal and restraint boundary conditions [12].

7 CONCLUSIONS

The newly developed water-to-ice phase change model in combination with a thermal conduction algorithm and a viscoelastic damage model for binders are capable of capturing the intrinsic characteristics of frost damage in AC specimens and constitute a useful tool in the quantification of the influence of mix characteristics on the susceptibility of a mix to frost damage.

Sos Agaian
University of Texas at San Antonio, San Antonio, TX, USA

ABSTRACT: This paper presents a comparison between two image segmentation techniques for processing asphalt concrete microstructure X-ray CT images; the Adaptive Enhancement-based Thresholding Algorithm (AETA) and the watershed segmentation embedded into the Volumetric-based Thresholding Algorithm (VTA). Both these methods were used to process the X-ray CT images of nine asphalt concretes. These consisted of three mix types, each prepared with three aggregate types. The mix designs included a Coarse Matrix High Binder Type C (CMHB) mix, a gap-graded Porous Friction Course (PFC) mix, and a fine-graded Superpave Type C (Superpave) mix. The three aggregate types included hard limestone, granite, and soft limestone. All mixtures were prepared with a PG 76-22 modified binder. The comparison of the two methods was carried out both visually and quantitatively. The later was accomplished by comparing the gradation estimated from the images using purpose-designed software to the gradation obtained from mechanical sieving. The results show that the inherent over-segmentation problem with the VTA technique is effectively reduced using the AETA method. Overall, the AETA method outperforms the VTA watershed image segmentation method by producing better separation between connected and overlapping aggregates. Its drawback is that it does not preserve the volumetric properties of the mixtures, as done by the VTA technique.

Keywords: asphalt; microstructure; segmentation; watershed; adaptive threshold

1 INTRODUCTION

High resolution X-ray Computed Tomography (CT) is a non-destructive imaging technique that has become increasingly popular for capturing the microstructure of asphalt concretes. It provides a unique insight into the makeup of mixture constituents and their spatial arrangement allowing detailed analytical modelling of their macroscopic behaviour (e.g., response to various forms of loading). Microstructure images allow the study of a variety of asphalt concrete properties and their distribution, including aggregate structure, air voids, permeability, degree of compaction, and state of damage. A variety of such studies is available in the literature (e.g., Masad et al., 1999; Shashidhar 1999; Tashman et al., 2002; Al-Omari and Masad 2004; Wang et al., 2004; Kutay et al., 2007; Khan and Collop 2010; Partl et al., 2007; Wu et al., 2011; and Zelelew and Papagiannakis 2011a, 2011b).

Processing X-ray CT images involves solving a number technical problems:

- Account for the different absorption rate of X-rays through each of these three phases, caused by their different densities.

- Account for the weakening of X-rays from the outside to the interior of the specimen being scanned.
- Establish grey level thresholds separating the three asphalt concrete phases, (i.e., air binder and aggregate).
- Difficulty in establishing the boundaries between aggregates, especially when they touch or overlap.

Hence, processing images to accurately represent the aggregates morphology, (e.g., size, shape, angularity) and the mixture physical properties (e.g., volumetric properties) remains challenging. This paper presents and compares two alternative X-ray image processing techniques for processing asphalt concrete X-ray images.

2 OBJECTIVE

The objective of this paper is to illustrate the technical highlights of two alternative X-ray imaging techniques for capturing the microstructure of asphalt concrete, highlight their differences and compare their accuracy.

3 THE ASPHALT CONCRETES ANALYZED

3.1 *Mix characteristics*

A total of nine asphalt concretes were included in this study. The mix designs consisted of a coarse-graded Coarse Matrix High Binder Type C (CMHB) mix, a gap-graded Porous Friction Course (PFC) mix, and a fine-graded Superpave Type C (Superpave) mix. Each of these mix designs was prepared with three aggregate types (hard limestone, granite, and soft limestone) and a PG 76-22 modified binder meeting the Texas DOT specifications. The aggregate gradations for each of the mix designs are shown in Figure 1. The design Equivalent Single Axle Loads (ESALs) for the project location was between 3 and 10 million and therefore a design gyrations of 100 (N_{design} = 100) was used. The AASHTO PP60 "Preparation of Cylindrical Performance Test Specimens using the Superpave Gyratory Compactor (SGC)" was followed to fabricate the asphalt concrete test specimens. The CMHB and Superpave

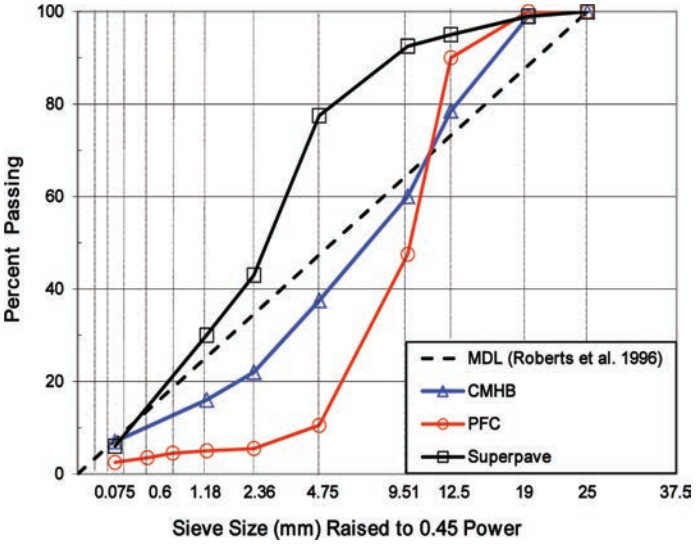

Figure 1. Aggregate gradations from mechanical sieving.

Table 1. Coarse aggregate angularity and texture using AIMS (Zelelew 2008).

Aggregate type	AI	TI	Description
Hard Limestone (HL)	2323	193	Sub-rounded and smooth aggregate
Granite (G)	2791	221	Sub-rounded and smooth aggregate
Soft Limestone (SL)	2195	80	Sub-rounded and polished aggregate

Angularity Index (AI) Range: Rounded (0–2100), Sub-rounded (2100–4000), Sub-angular (4000–5400), and Angular (5400–10,000).
Texture Index (TI) Range: Polished (0–165), Smooth (165–275), Low Roughness (275–350), Moderate Roughness (350–460), and High Roughness (460–1,000).

mixtures were compacted in the gyratory compactor to achieve a target air voids of 7.0% while the PFC mixtures were fabricated using a target air voids of 20%. Detailed mix design data and experimental test plan as well as numerical modeling of creep performance can be found elsewhere (Zelelew 2008).

3.2 *Aggregate characteristics*

The first generation of the Aggregate Image Measurement System (AIMS) (Masad 2005) was used to quantify the gradient angularity and surface texture of the coarse aggregates, retained on sieve size 4.75 mm (i.e., Sieve No. 4), used for the asphalt concretes tested. The gradient Angularity Index (AI) defines the sharpness of the corners of 2D images of aggregate particles. It quantifies changes along a particle boundary with higher gradient values indicating a more angular shape. AI has a relative scale of 0 to 10,000 with a perfect circle having a small but non-zero value. The Texture Index (TI) describes the relative smoothness or roughness of surface features less than roughly 0.5 mm in size. TI has a relative scale of 0 to 1,000 with a smooth polished surface approaching a value of 0. The aggregate shape characteristics can be classified into different sub-categories. Angularity was divided into rounded, sub-rounded, sub-angular, and angular. A higher angularity index indicates a higher aggregate angularity and may yield better aggregate interlocking. Similarly, texture was classified as polished, smooth, low, medium and high roughness. Aggregates with higher surface texture may provide better wheel friction and may improve skid resistance. The AIMS test results are presented in Table 1.

4 VOLUMETRIC-BASED THRESHOLDING ALGORITHM (VTA)

The Volumetric-based Thresholding Algorithm (VTA) utilizes the average volumetric properties of a particular asphalt concrete core to establish threshold levels for the boundary between mastic-aggregate and mastic-air. Prior to carrying out the VTA, the raw X-ray images are processed to enhance contrast and remove noise. Contrast enhancement is performed through histogram equalization using the MATLAB® function *histeq*, (Misiti et al., 2006). Noise removal is done using the median filtering technique and a kernel size of 3×3 pixels.

After this preliminary image treatment, the VTA is carried out in two steps, first for establishing the grey level mastic-air threshold and second for establishing the grey level aggregate-mastic air threshold referred to as T_1 and T_2, respectively. For the mastic-air threshold T_1, a seed (or initial) grey level value is assumed, the volume of the air voids computed for each of the X-ray CT sections and then averaged over the volume of the sample. The mastic-air grey level threshold T_1 corresponds to the grey level that minimizes the error between the laboratory measured air-voids and the X-ray CT image air voids. This process is repeated in establishing the mastic-aggregate grey level threshold T_2. Finding these threshold values involves an iterative process, whereby the grey level of a pixel is compared to the seed threshold values to establish whether it is an 'object' (pixel value equal to 1) or 'background' (pixel

value equal to 0). An example is shown in Figure 2. At the conclusion of this image processing step, the three phases of the asphalt concrete microstructure have been identified, while preserving the average volumetric properties of the mixture.

The images obtained with the VTA are further refined to improve separation between aggregates that are in contact or overlap. This is done through edge detection and segmentation. Edge detection enhances the physical boundaries between the three asphalt concrete phases. It is carried out using the gradient approach. The gradient of an image is the magnitude of the first-derivative of its image function, i.e., gray level $f(i,j)$. A Sobel operator is used to define the gradient:

$$|\nabla f| = \begin{bmatrix} \frac{\partial f}{\partial i} \\ \frac{\partial f}{\partial j} \end{bmatrix} = \sqrt{\left(\frac{\partial f}{\partial i}\right)^2 + \left(\frac{\partial f}{\partial j}\right)^2} \tag{1}$$

The first-order derivatives along the two Cartesian coordinates i and j are given by:

$$\frac{\partial f}{\partial i} = \nabla_i f = \frac{1}{2}[f(i+1,j) - f(i-1,j)] \tag{2a}$$

$$\frac{\partial f}{\partial j} = \nabla_j f = \frac{1}{2}[f(i,j+1) - f(i,j-1)] \tag{2b}$$

The direction of the gradient vector (i.e., the orientation of a unit normal vector perpendicular to the specified edge location), is used to quantify the orientation of the sharpest gray-level intensity change.

The steps involved in the VTA algorithm are summarized as follows:

- Step 1: Analyse the raw X-ray CT asphalt concrete two-dimensional images (i.e., circular slices) one at a time.
- Step 2: Apply the histogram equalization technique to enhance image contrast. This is accomplished through the use of the MATLAB® built-in function called *histeq*.
- Step 3: Apply a median filtering technique with a kernel size of 3 × 3 to remove image noise.
- Step 4: Perform thresholding to establish the threshold grey value T_1 between that separates mastic from air by minimizing the error between the core air voids and the average air voids considering all the two-dimensional images for this core.
- Step 5: Repeat Step 4 for establishing the grey level threshold T_2 that separates mastic and aggregates.

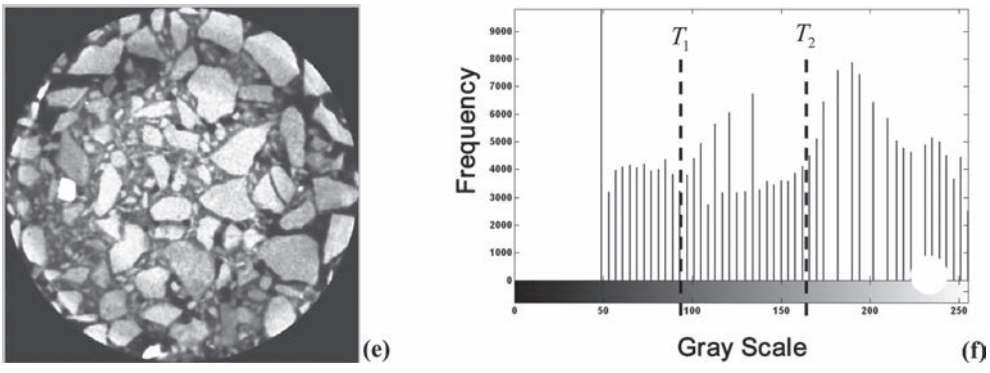

Figure 2. Illustration of VTA thresholding (Zelelew and Papagiannakis, 2011a).

- Step 6: Perform edge detection using the gradient method to separate adjacent and overlapping objects.
- Step 7: Enhance object segmentation using the watershed technique.

These steps were implemented into a MATLAB® code that automates the processing of X-ray CT images of asphalt concrete cores. More details on this technique were given by Zelelew and Papagiannakis (2011a).

5 ADAPTIVE ENHANCEMENT-BASED THRESHOLDING ALGORITHM (AETA)

An alternative to the VTA approach was developed by adapting the Human Visual System (HVS) originally developed for processing medical images (DelMarco and Agaian 2009). This involves an image Enhancement Measure (EME) that allows selecting automatically optimal processing of the best parameters and transforms of the HVS. The method is described next by considering an image $x(n, m)$ being split into $k_1 k_2$ blocks $w_{k,l}(i, j)$ of sizes $l_1 \times l_2$ for a given class of orthogonal transforms. EME is defined as:

$$EME = \frac{1}{k_1 k_2} \sum_{l=1}^{k_2} \sum_{k=1}^{k_1} 20 \log \left| \frac{I^w_{max;k,l}}{I^w_{min;k,l}} \right| \tag{3}$$

where, $I^w_{max;k,l}$ and $I^w_{min;k,l}$ are respectively the minimum and maximum grayscale intensities of the image $x(n, m)$ inside the block $w_{k,l}(i, j)$. This visibility operator was extended in the form of its second derivative (DelMarco and Agaian, 2009 and Zhou et al., 2010) and called the Second-Derivative-like Measure of Enhancement (SDME). It uses an HVS-type image decomposition, which defines SDME as follows:

$$SDME = \frac{1}{k_1 k_2} \sum_{l=1}^{k_1} \sum_{k=1}^{k_2} 20 \ln \left| \frac{I^w_{max;k,l} - 2I^w_{center;k,l} + I^w_{min;k,l}}{I^w_{max;k,l} + 2I^w_{center;k,l} + I^w_{min;k,l}} \right| \tag{4}$$

where, $I^w_{center;k,l}$ is the grayscale intensity of the center pixel in each block; $I^w_{min;k,l}$ and $I^w_{max;k,l}$ are defined earlier. The size of the blocks in Equations 3 and 4 includes odd kernels (e.g., 3×3, 5×5, 7×7, and 9×9).

The SDME measure is used to quantify adaptive grayscale thresholds for the asphalt concrete X-ray CT images. The algorithm seeks to establish an adaptive aggregate threshold (T_{Agt}) to separate aggregates from non-aggregate objects and another threshold to separate mastic from air objects (T_{Air}). The aggregate grayscale threshold T_{Agt} is related linearly to the SDME measure through:

$$T_{Agt} = M - \alpha(SDME) \tag{5}$$

where, M is the maximum grayscale intensity and α is a constant representing the level of details of interest. For establishing the aggregate-mastic boundary, a seed value of $\alpha = 1$ is used based on preliminary results of image processing. Combining Equations 4 and 5, gives:

$$T_{Agt} = M - \alpha \left[\frac{1}{k_1 k_2} \sum_{l=1}^{k_1} \sum_{k=1}^{k_2} 20 \ln \left| \frac{I^w_{max;k,l} - 2I^w_{center;k,l} + I^w_{min;k,l}}{I^w_{max;k,l} + 2I^w_{center;k,l} + I^w_{min;k,l}} \right| \right] \tag{6}$$

In summary, the AETA algorithm for establishing T_{Agt} involves the following steps:

- Step 1: Analyse the raw X-ray CT asphalt concrete two-dimensional images (i.e., circular slices) one at a time.

- Step 2: Apply the histogram equalization technique to enhance image contrast. This is accomplished through the use of the MATLAB® built-in function called *histeq*.
- Step 3: Apply a median filtering technique with a kernel size of 3×3 to remove image noise.
- Step 4: Compute the SDME value.
- Step 5: Define the level of detail of interest by selecting the α value for the aggregates (a value of 1.0 was selected).
- Step 6: Determine T_{Agt}.
- Step 7: Segment connected and overlapping aggregates.
- Step 8: Finally, generate a binary image by labeling white objects (grayscale of 255) for aggregates and black objects (grayscale of 0) for non-aggregates.

Note that the first 3 steps in the AETA method comprise image pre-processing and are identical to those described in the VTA method. The same procedure can be followed for establishing the air voids-mastic threshold (i.e., T_{Air}). More details on the AETA method were given by Zelelew et al., (2013).

6 RESULTS AND DISCUSSION

The two image processing techniques described above, namely the VTA and the AETA were compared in terms of their ability to realistically capture the microstructure of the nine asphalt concrete cores described under Section 3. This comparison involved both visual means, as well as quantitative means. The latter was based on the accuracy of these two methods in yielding the aggregate gradation obtained through mechanical sieving. The aggregate gradation was estimated from the microstructure using established imaging techniques.

6.1 *Visual comparison*

Although qualitative, visual comparisons of images obtained by the two image techniques presented provide valuable information as to their ability to realistically capture the microstructure of asphalt concretes. Figure 3 gives an example of such compassions for the PFC mixtures obtained with Hard Limestone (HL), Granite (G) and Soft Limestone (SL). Similar sets of images were produced for the CMHB and the Superpave mixtures. These images suggest drastic improvements in clarity between the pre-processed images (i.e., end of step 3) and the finished product for both the VTA and AETA methods. Visual inspection yielded no conclusive results as to the relative quality of these two methods, although the AETA-processed images appear to show aggregates with more naturally-shaped edges. On the other hand, the VTA-produced images appear to show a better separation between aggregates.

6.2 *Quantitative comparison*

The quantitative comparison of the two image processing methods, namely the VTA and the AETA, was carried out with reference to the aggregate gradations obtained through mechanical sieving (Fig. 1). The aggregate gradation of the asphalt mixture X-ray CT images was estimated using a purpose-designed MATLAB® program. This involved the *bwboundaries* and *regionprops* built-in functions. They were used to quantify the aggregate morphological and shape properties, such as the area, equivalent diameter, perimeter, major axis length, minor axis length, and orientation. This paper focuses on aggregate size comparisons only. This was defined as the equivalent diameter of an aggregate. These calculations were performed by considering all possible vertical slices by rotating the axis and averaging the equivalent diameter estimates. These in turn were translated to sieve sizes. Past studies also utilized this approach to estimate aggregate gradations in asphalt concrete images (Masad et al., 1999; Brandes and Hirata 2009; Kutay et al., 2010; and Coenen et al., 2012). The aggregate gradation obtained with the 3D statistic is more representative of the entire volume of the mixtures and therefore it was selected for comparisons with the laboratory-measured gradations.

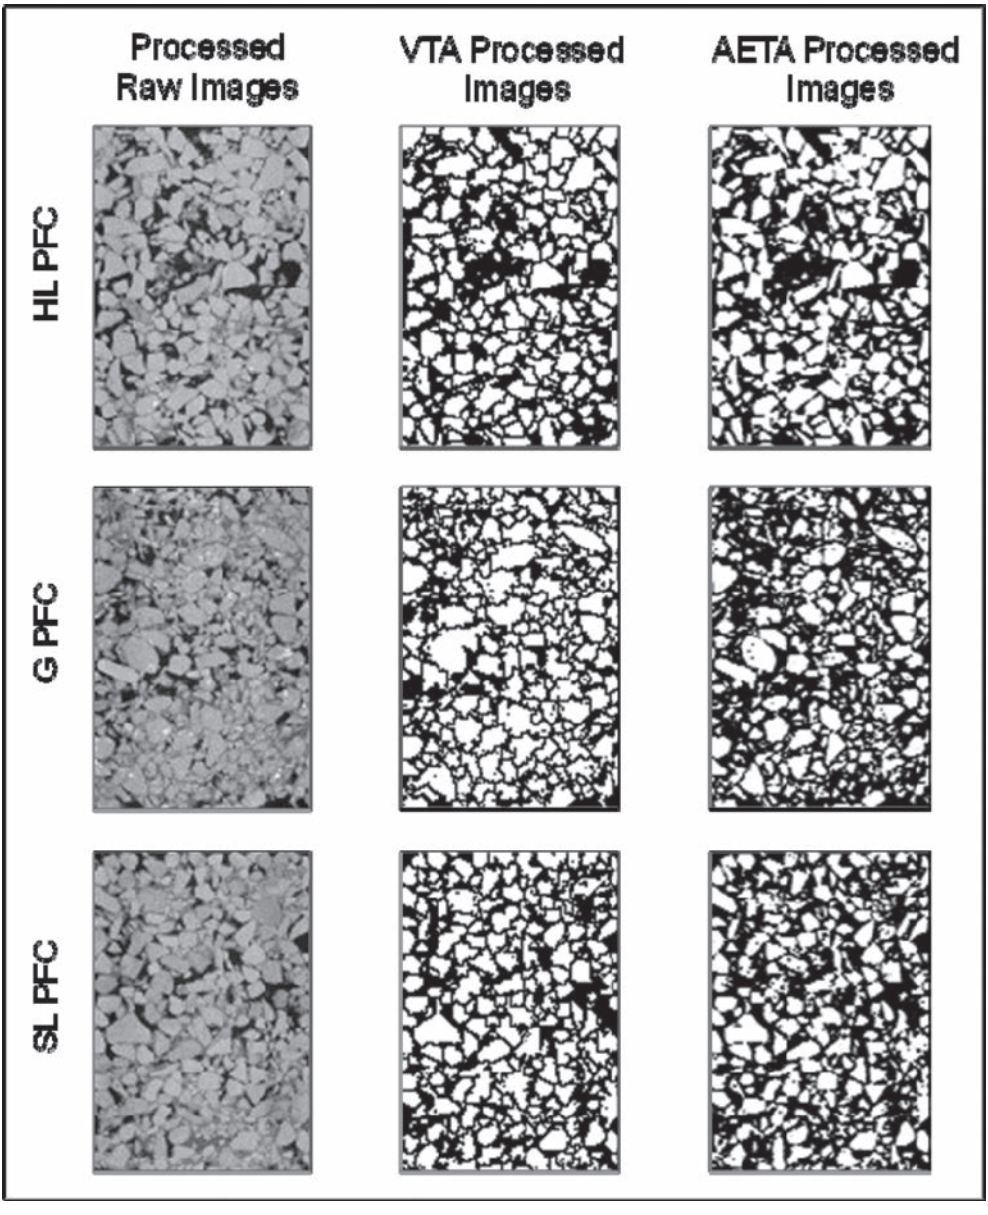

Figure 3. Comparison of VTA and AETA processed images; PFC mix.

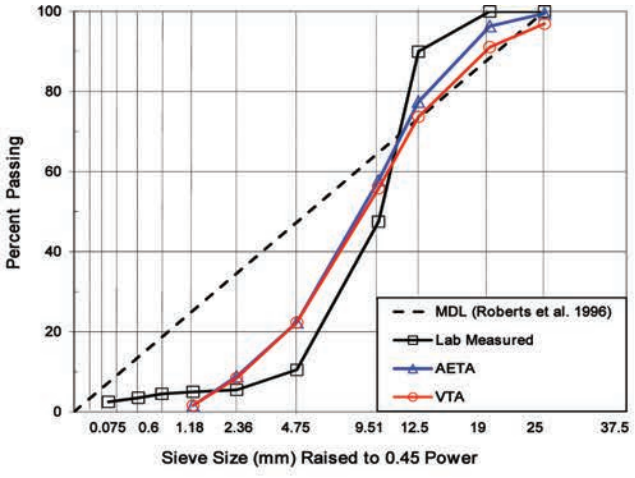
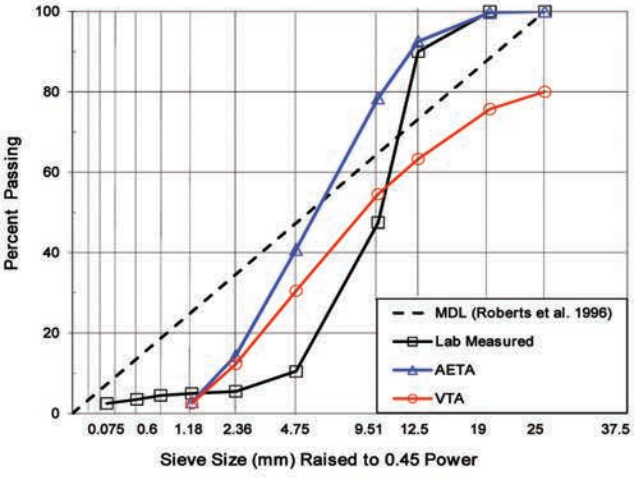
An example comparing the image-based aggregate gradations obtained from the VTA and AETA methods versus the laboratory gradation is presented in Figure 4 for the PFC mix. Similar gradation comparisons were obtained for the CMHB, and Superpave mixtures. It is noted that for both the methods the smallest particle size that can be detected given the image resolution is 1.18 mm (i.e., Sieve No. 16). Hence, particle sizes finer than 1.18 mm could not be considered in this comparison.

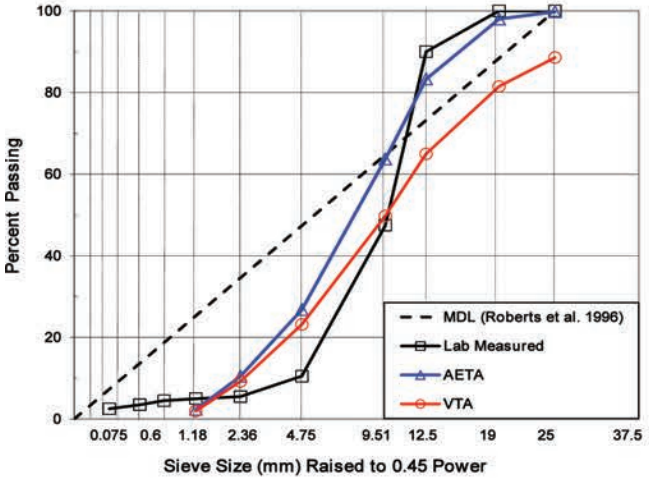
These estimated gradations were compared in terms of absolute percent error with reference the gradations obtained through mechanical sieving. The results of the percent absolute error for individual particle sizes are shown in Figure 5. The general trend observed is that these errors increase as the particle sizes decrease for the CMHB and PFC mixtures while the



(a)



(b)



(c)

Figure 4. Comparison of gradations; (a) HL PFC, (b) G PFC, and (c) SL PFC.

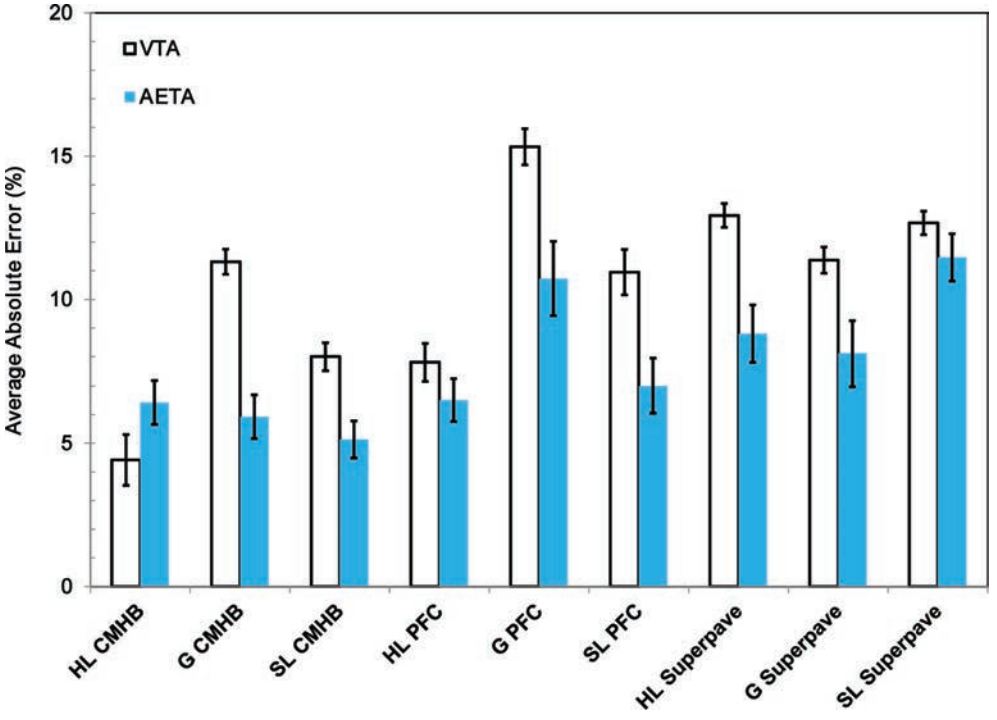


Figure 5. Comparison of gradation average absolute errors.

opposite was observed for the Superpave mixtures. This is likely due to the fine-graded nature of the mixtures. Figure 12 also summarizes the overall average absolute errors for all the samples analysed. The bars shown in this figure reflect the Coefficient of Variation (COV) of these errors. The average absolute error observed for the PFC mixture with granite aggregate type is substantially higher than those observed for the other mixtures. This is likely due to the large errors observed in multiple sieve sizes as well as the gap-graded nature of the mixture. The overall maximum absolute error observed for both methods among the nine mixtures was not higher than 16%. In general, the AETA method resulted in lower absolute errors when compared to the VTA method. For HL CMHB mix, however, the VTA method measured slightly lower absolute error (6.4%) compared to the AETA method (4.4%).

7 CONCLUSIONS

Based on these findings, it is evident that the AETA method outperforms the VTA method by producing more accurate aggregate gradations and more realistic aggregate shapes. Its disadvantage is that it does not preserve the volumetric properties of the samples. Additional objective comparisons are needed in terms of the ability of these two methods to capture other aggregate properties (e.g., orientation, shape, angularity) before deciding which method is best suited in processing asphalt concrete images.

Effect of saturated ageing on fatigue behavior of asphalt pavements

Abhilash Bommerla & K. Sudhakar Reddy
IIT Kharagpur, Kharagpur, West Bengal, India

ABSTRACT: Top-down cracking is a commonly occurring distress in asphalt concrete pavements. Ageing of binder and effect of moisture, besides traffic loading parameters, contribute significantly to the top-down fatigue cracking of asphalt layers. Experimental investigations were conducted in this study to evaluate the effect of these parameters (ageing and moisture) on the fatigue crack initiation and propagation. Saturated Ageing Tensile Stiffness test (SATS), which is a protocol introduced recently in the European standards, has been used for ageing the asphalt mixtures. The ageing of the asphalt mix has been done for different periods: 25, 45 and 65 hours. Ageing indices of the aged mixes were calculated based on the resilient moduli of un-aged and aged mixes. Indirect Tensile Fatigue Test (ITFT) was conducted on aged and un-aged mixes. Fatigue life (load repetitions to crack initiation) of the mix aged under the combined action of temperature and moisture for 25 hours was found to be 30 percent of that of un-aged mix. Ageing the specimens for longer durations did not significantly reduce the fatigue life any further. Laboratory fatigue performance of mixes has been explained in terms of binder rheology and ageing index of mix.

Keywords: Saturated ageing, SATS test, ageing index, crack initiation, crack propagation

1 INTRODUCTION

Fatigue cracking is one of the major distresses in bituminous pavements. Fatigue cracking is not an instantaneous failure but starts as a micro crack at the top of surface layer (Top–down cracking) or at the bottom of asphalt course (Bottom–up cracking) by the action of traffic loads. With continuation of application of wheel loads the micro-crack slowly increases and intensifies to propagate to the entire depth of asphalt layer.

Ageing of binder and effect of moisture, besides traffic loading parameters, contribute significantly to the top-down fatigue cracking of asphalt layers. Ageing reduces binder's ductile property thereby increasing susceptibility of asphalt mixture to crack [1]. On the other hand moisture reduces the adhesion of the asphalt mastic causing easy propagation of crack [2]. So the combined effect of temperature and moisture on the properties of pavement materials has to be understood.

Research has been conducted in the past to understand the effect of ageing and moisture, individually, on the fatigue behaviour of asphalt pavements. But behaviour of the asphalt mixture subjected to different conditions is different from its behaviour under the combined condition. With the growing importance of perpetual or long life pavements, there is need to understand the combined effect of temperature and moisture on the fatigue behaviour of asphalt pavements. Saturated ageing is the term used to denote the combined effect of moisture and temperature.

Saturated Ageing Tensile Stiffness (SATS) Test [3] was used in this research work for observing the combined effect of moisture and temperature on the asphalt mixtures. SATS test is a new ageing method developed in UK. The test conditions represent the properties of asphalt mixture in field conditions (observed in UK) after 8 years of construction [4] [5].

SATS test includes pre-saturation of asphalt samples before placing them into a moist, high temperature and pressure chamber. As per EN 12697-45:2012, the compacted Marshall samples encased in the test specimen holders are placed in pressure and temperature vessel. Sufficient amount of water is added to completely immerse the bottom asphalt sample. The specimens are maintained at a temperature of 85°C and at a pressure of 2.1 MPa for a period of 65 hours before the temperature is reduced to 30°C. The specimens are maintained at 30°C for 24 hours with the pressure being unchanged.

Evaluation of resilient modulus can capture the change in the viscosity of bitumen caused due to ageing [6] and reduction in adhesion/surface energy of bitumen due to diffusion of water into bitumen mastic at high temperatures [7]. Ageing Index, which is the ratio of resilient modulus of asphalt sample before ageing and that after ageing, is used to determine the degree of saturated ageing.

To determine the combined effect of ageing and moisture, asphalt has to be aged in presence of moisture to different levels before evaluating it for fatigue life and crack propagation characteristics.

Experimental investigations were conducted in this study to evaluate the effect of these parameters (ageing and moisture) on the fatigue crack initiation and propagation. Saturated Ageing Tensile Stiffness test has been used for ageing the asphalt mixtures. Ageing of the asphalt mix has been done for different periods—25, 45 and 65 hours. Ageing indices of the aged mixes were calculated based on the resilient moduli of un-aged and aged mixes. Indirect Tensile Fatigue Test (ITFT) was conducted on aged and un-aged mixes. Fatigue life (load repetitions to crack initiation) of the mix aged under the combined action of temperature and moisture for 25 hours was found to be 30 percent of that of un-aged mix. Ageing the specimens for longer durations did not significantly reduce the fatigue life any further. Laboratory fatigue performance of mixes has been explained in terms of binder rheology and ageing index of mix.

2 MATERIALS

Two surface layer gradations, AC11DS and SMA13 have been chosen for carrying out project work, as the saturated ageing will affect mainly the surface layers. The AC11DS is asphalt concrete surface layer (DS—deckschischt) used in Germany. The second mixture is a Stone Matrix Asphalt layer used in India. The gradations selected are shown in Figure 1.

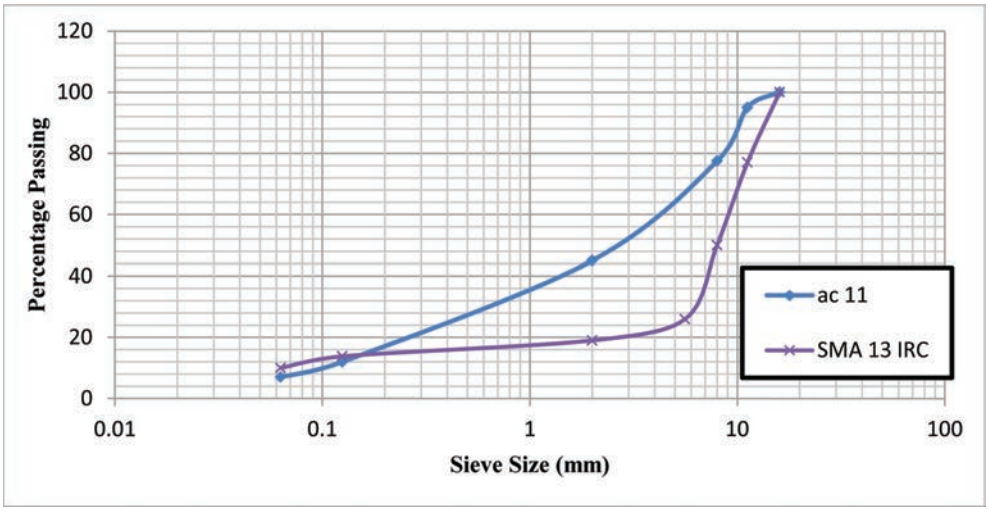

Figure 1. Selected gradations for AC11DS and SMA13.

Table 1. Volumetric properties of AC11DS and SMA13 mixtures.

	AC11DS	SMA13
Bitumen content (%)	5.7	5.7
Bulk density (g/cc)	2.450	2.340
Maximum density (g/cc)	2.526	2.542
Air voids (%)	2.9	8
Voids in mineral aggregate (%)	16.2	19.96
Voids filled with bitumen (%)	81.48	62.42
Bitumen film thickness (μm)	8.26	8.54

Asphalt mixtures are prepared with a bitumen content of 5.7% which is the optimum bitumen content for AC11DS. Table 1 gives the average values of various volumetric parameters. The same bitumen content has been used for both the mixtures. The mixtures developed different VMA and there by different air void content. Average film thickness values, estimated using surface area factors given by Asphalt Institute Manual Series 2, are also given in the table. The film thicknesses obtained for the two mixes are nearly the same.

The effect of saturated ageing on asphalt sample depends on the bitumen content and film thickness, saturated ageing conditions and amount of exposure of bitumen [8] [9]. As same film thickness has been produced by using same bitumen content and similar saturated ageing conditions have been used or both mixes, the degree of saturated ageing in two mixtures shall mainly differ due to the extent of bitumen exposure which depends on the air void content in mixture.

3 EXPERIMENTATION AND RESULTS

3.1 *Indirect tensile strength test*

Indirect Tensile strength test was conducted at 20°C on SMA13 and AC11DS samples before and after saturated ageing. Table 2 shows the values of Ultimate load and deformation, measured during Indirect Tensile Strength (ITS) test. Ageing ratio was also calculated (ageing ratio is the ratio of ultimate load after saturated ageing to that before saturated ageing) as a measure for comparing the change in ITS values with saturated ageing. Ageing ratio values are given in Table 2.

The ultimate tensile load, for both asphalt mixtures (AC11DS and SMA) reduced with ageing period and change is more significant upto 25 hrs of ageing beyond which the ageing ratio did not change appreciably.

3.2 *Resilient modulus test*

Resilient modulus of the asphalt samples has been determined at a temperature of 20°C before and after saturated ageing. Table 3 shows the average resilient modulus values obtained for each ageing period. Values of ageing index, ratio of resilient modulus before and after saturated ageing are given in the table.

3.3 *Indirect tensile fatigue test*

The fatigue testing on asphalt sample was conducted using Indirect Tensile Fatigue Testing (ITFT). The test has been conducted at 20°C with a load frequency of 10 Hz and rest period of 0.1 s. Loads of 3000 N and 1500 N were applied for AC11DS and SMA13 respectively. Micro crack and macro crack initiations were identified by plotting load repetitions against product of load repetitions and stiffness [10]. Table 4 gives the number of load repetitions corresponding to micro and macro crack initiation obtained for various periods of ageing for asphalt concrete and SMA mixes.

Table 2. Indirect tensile strength test results.

	Ultimate load (kN)		Deformation (mm)		Ageing ratio	
Ageing period	AC11	SMA	AC11	SMA	AC11	SMA
0 hrs ageing	16.33	11.13	2.6	2.8	1.000	1.000
25 hrs ageing	11.33	7.00	4.1	4.8	0.694	0.629
45 hrs ageing	10.10	5.70	3.1	5.3	0.618	0.512
65 hrs ageing	9.80	5.60	3.3	4.5	0.600	0.503

Table 3. Resilient modulus and ageing index values for AC11DS and SMA13.

	Resilient modulus (MPa)		Ageing index	
Ageing period	AC11	SMA	AC11	SMA
0 hrs ageing	4584	4975	1.000	1.000
25 hrs ageing	3009	1666	0.596	0.291
45 hrs ageing	2833	1187	0.575	0.253
65 hrs ageing	1782	1120	0.472	0.241

Table 4. Number of load repetitions in ITFT for micro and macro-crack initiation.

	Micro-crack initiation		Macro-crack initiation	
Ageing period	AC11	SMA	AC11	SMA
0 hrs ageing	18024	22126	52767	60493
25 hrs ageing	3541	7736	11341	20552
45 hrs ageing	5698	6468	16060	12968
65 hrs ageing	4463	6916	12958	22817

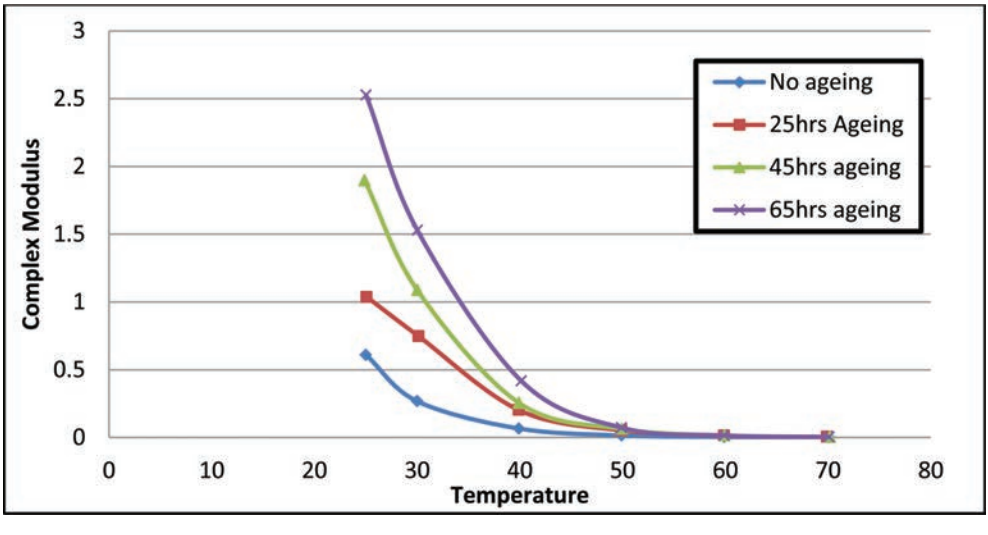

Figure 2. Variation of complex modulus with temperature for AC11DS.

3.4 *Dynamic shear rheometer*

3.4.1 *Stress sweep test*

The stress sweep test was conducted on bitumen sample extracted from asphalt aged for 65, 45 and 25 hours and also on the original binder. The stress sweep test has been conducted to select a single torque value, for all samples, which lie within the linear viscoelastic range of bitumen. A shear stress of 1000 Pa was chosen for the testing for bitumen samples for all degrees of ageing.

3.4.2 *Temperature sweep test*

The temperature sweep test was conducted to understand the behaviour of extracted bitumen sample at various temperatures. The test was conducted on bitumen samples extracted from asphalt mixtures aged to 25 hrs, 45 hrs and 65 hrs. The results were compared with those of original binder. Figures 2 to 4 show the results obtained from temperature sweep tests.

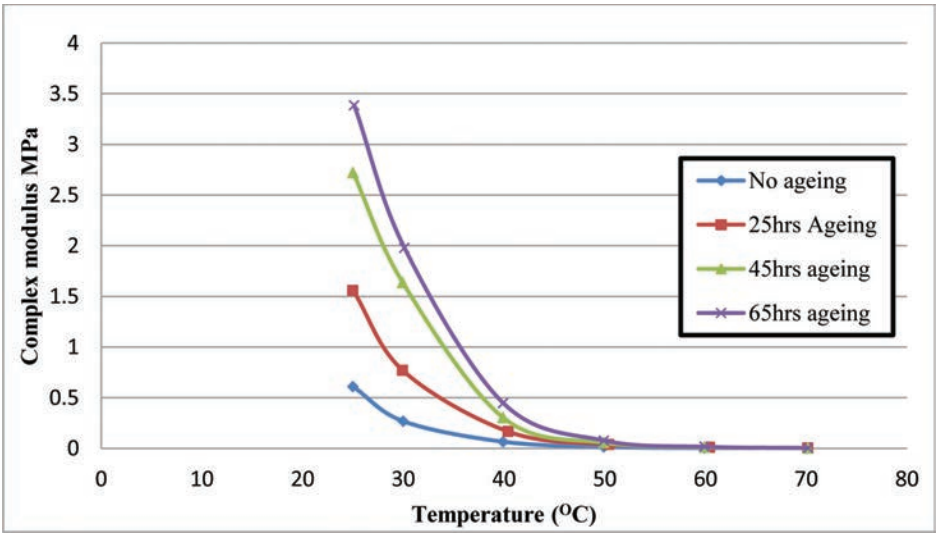

Figure 3. Variation of complex modulus with temperature for SMA13.

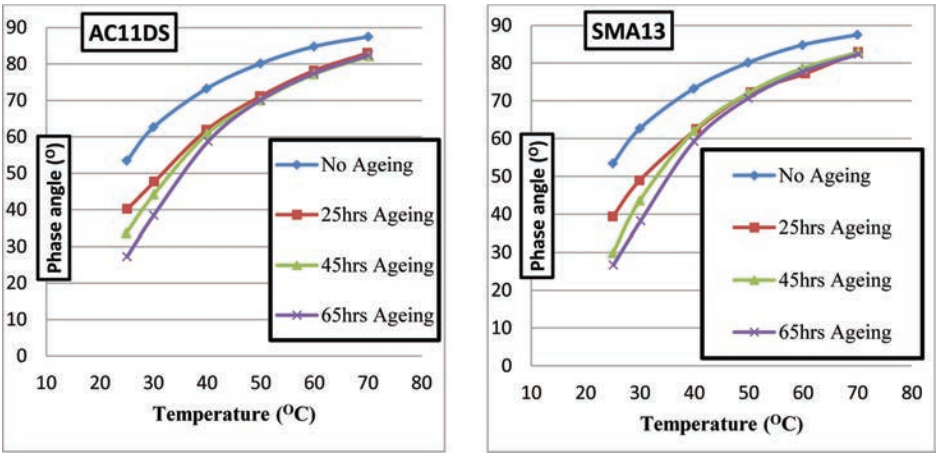

Figure 4. Variation of phase angle with temperature for AC11DS and SMA13 mixes.

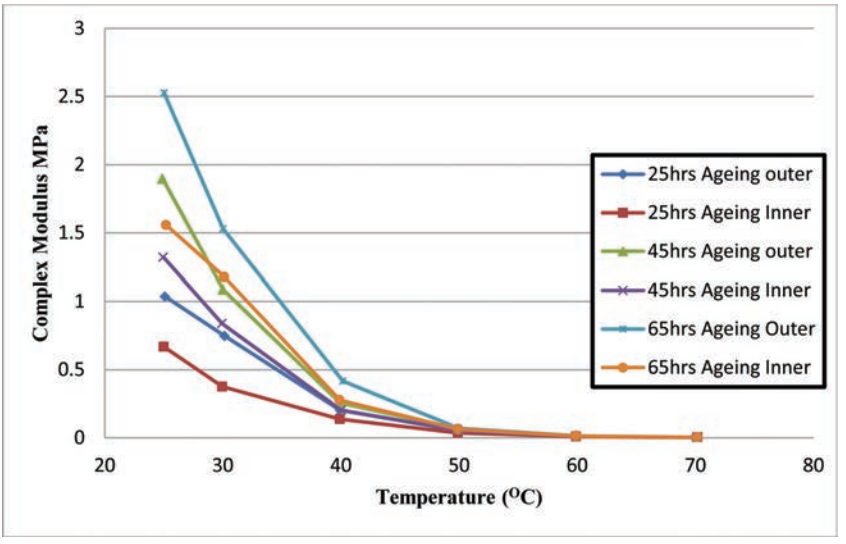

Figure 5. Variation of complex modulus with temperature for inner and outer material.

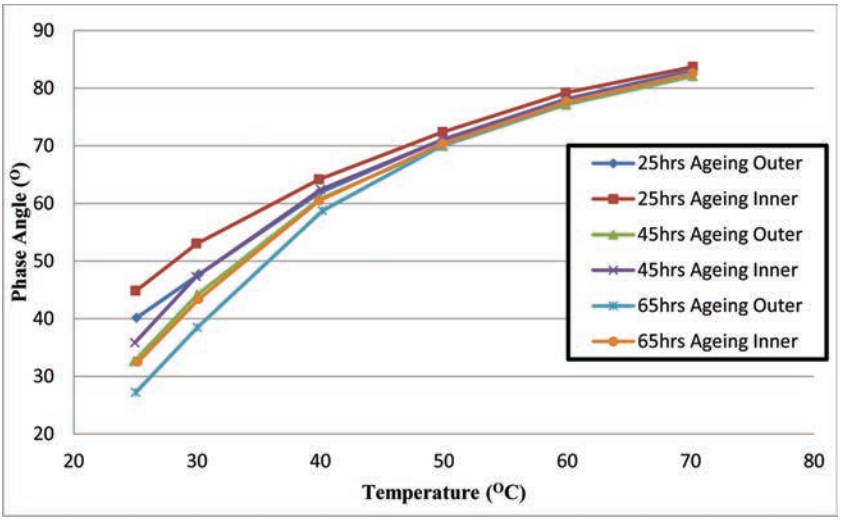

Figure 6. Variation of phase angle with temperature for inner and outer material.

The DSR test has also been conducted on the bitumen samples extracted separately from the outer shell and inner core of asphalt sample. Figures 5 and 6 shows the difference in the degree of ageing of outer and inner samples.

4 DISCUSSION OF RESULTS

4.1 *Indirect tensile strength*

Indirect tensile strength of asphalt mixture or more specifically that of asphalt mastic reduced with increase in the saturated ageing period. The effect of temperature and moisture is more

during the first 25 hrs of ageing after which the effect is reduced. While the binder and as a result of which the mix get stiffer with aging, moisture which leads to loss of adhesion of mastic appears to be more predominant in reducing the ultimate load of asphalt sample, as it reduces the adhesion of asphalt mastic. Katware [11] did not find much variation of tensile strength of asphalt mixtures after dry ageing.

4.2 *Resilient modulus test*

As the exposure of binder to air in SMA mix is more than that expected in AC11DS mix, lower ageing index values were observed for SMA, which indicates greater damage in SMA samples compared to AC11DS mix. It can be understood by the results that air void content has an important role in durability of asphalt mixture. Also after 65 hours of ageing, both the mixtures have very low ageing index values suggesting that the standard test condition of 65 hours of saturated ageing is too severe.

4.3 *Temperature sweep test*

Change in phase angle values represents inter-conversion of viscous and elastic components in the bitumen. The DSR results indicate that with 25-hr ageing most of the viscous component has converted to elastic component. With 45-hr and 65-hr ageing there is not much additional conversion into elastic component. As the phase angle values for AC11DS and SMA13 are similar, it can be concluded that the transition of viscous component to elastic component is influenced by period of ageing rather than exposure of bitumen (air voids).

The complex modulus of the bitumen extracted from SMA13 is more than that obtained for AC11DS extracted binder. This increase in complex modulus is mainly due to the change in exposure. Comparison of the DSR parameters of inner and outer shells of specimens shows that the inner part of the asphalt is ageing at a lower rate than the outer shell.

4.4 *Indirect tensile fatigue test*

The load repetitions for micro as well as macro crack initiation decreased with ageing period. Like other mix parameters, reduction in fatigue life was significant up to 25 hours of ageing. Eq.1 gives the relation between the number of load repetitions to macro-crack initiation and ageing index, G*Cosδ of binder.

$$N = 73636AI + 0.003407\mathrm{G}' + 2.529N_0 - 163091 \tag{1}$$

Table 5. Models for estimation of dL/dN.

Asphalt mixture	Ageing period (hrs)	dL/dN
AC11DS	0	$9.98 \times 10^{-22} * e^{\left(\frac{N}{1973.45}\right)}$
	25	$5.59 \times 10^{-11} * e^{\left(\frac{N}{1613.45}\right)}$
	45	$1.22 \times 10^{-10} * e^{\left(\frac{N}{2800.23}\right)}$
	65	$5.32 \times 10^{-10} * e^{\left(\frac{N}{2537.06}\right)}$
SMA13	0	$2.39 \times 10^{-18} * e^{\left(\frac{N}{3225.97}\right)}$
	25	$1.06 \times 10^{-09} * e^{\left(\frac{N}{5629.08}\right)}$
	45	$1.67 \times 10^{-09} * e^{\left(\frac{N}{2136.48}\right)}$
	65	$1.06 \times 10^{-09} * e^{\left(\frac{N}{10205.22}\right)}$

where, N—number of load repetitions to produce macro-crack after ageing
AI—Ageing Index
G'—G^*Cosδ value of binder after ageing
N_0—Number of load repetitions to produce macro-crack before ageing.

The relationship between compliance (inverse of stiffness) and load repetitions was examined. The rate of change of compliance with number of load repetitions (dL/dN) has been determined and models for estimating dL/dN are given in Table 5.

5 CONCLUSIONS

The effect of saturated ageing on bituminous mixes has been evaluated in this investigation by conducting different tests on two different mixes. The following conclusions are drawn.

- Moisture ageing is found to have similar effect on indirect tensile strength, resilient modulus and fatigue characteristics of the bituminous mixes investigated
- The reduction in strength of the mix with moisture ageing has been found to be significant only up to 25 hours of ageing. This suggests that the 65 hour of ageing period considered in the recently introduced saturated ageing tensile test may be unduly severe
- The reduction in indirect tensile strength of the mix due to 25 hours of moisture ageing is about 31 to 37% while the resilient modulus reduced by 40% and 71% respectively for AC11 and SMA mixes for similar period of aging
- The number of load repetitions required to initiate micro as well as macro cracks reduced by 65% for SMA mix and 80% for AC11 mix
- As in-service mix is subjected to ageing not exactly under dry conditions, moisture ageing represents more realistically the damage that is likely to be caused to the mix in an in-service pavement.

ABSTRACT: The subgrade is a major factor in structural design of flexible asphalt pavements. Although this is well understood, problems continue to occur on military pavements where designers have failed to properly deal with subgrade issues. Invariably, poor pavement performance results. This paper will examine six issues encountered with subgrades for military pavements and provide a brief case study illustrating the problem. The topics will be:

1. Assessment of geologic conditions. A runway and parallel taxiway suffered major structural failures because of misreading geology of the subgrade deposits.
2. Proper sampling and testing. A major military road system failed dramatically because the subgrade was improperly characterized by unrepresentative sampling and engineers failed to properly interpret laboratory tests.
3. Expansive soils. These are among the most difficult subgrade conditions with which we must deal, and an airfield taxiway failed because of incorrect testing, improper QC and QA processes, and construction failure.
4. Mitigation of sulfate attack. Techniques commonly used to deal with sulfate attack on concrete prove unable to prevent similar chemical attack on stabilized soils.
5. Permafrost. Pavement construction on permafrost is difficult and expensive. Attempts to shortcut these expensive requirements have led to unfortunate outcomes.
6. Tropical soils with allophane and halloysite clay minerals. Failure to recognize the unique characteristics of these soils has led to difficulties in the field.

Keywords: Subgrade, geology, expansive soil, soil strength, permafrost, tropical soil

1 INTRODUCTION

In recent years there has been an outburst of renewed interest in long-life or perpetual pavement concepts. However, such promising new concepts will reach fruition only when every aspect of the pavement is properly assessed, including the most basic one: the subgrade.

The strength of the subgrade dominates the thickness design of flexible airfields and particularly of military airfields with their large aircraft wheel loads and high tire pressure [1, 2, 3]. Regardless of the specific methodology used for thickness design, selection of the appropriate design strength is crucial to achieving a satisfactory result. However, many factors are involved in selecting appropriate strength values for design, and factors other than strength may determine success or failure of a pavement under traffic.

This paper will examine six specific areas where both government and civilian designers failed to adequately understand the subgrade soils in the design of flexible military pavements, and the consequences of these misunderstandings led to pavement failure.

2 GEOLOGY: MASIRAH AIR BASE (AB) RUNWAY AND TAXIWAY, OMAN

Past masters of the art of geotechnical engineering such as Terzaghi, Peck, and Casagrande often wrote of the importance of geology in geotechnical engineering, and such views are often quoted in textbooks and other professional literature. Yet in reviewing military pavement design documents, one often sees no mention of geology of a site, or if mentioned, it is simply a verbatim quote from a geologic survey with no interpretation as to what the geology means to the project site and design. Geology provides the framework upon which we hang our other data such as borings, testing results, and field observations to help us grasp the range of soil problems that must be addressed in design. Bad assumptions concerning the site geology tend to come back to haunt the designer.

Masirah Island lies in the Arabian Sea off the coast of Oman; it is remote and arid with an average annual rainfall of 100 mm. The island consists of a core of eroded hills rising to a maximum of 256 m surrounded by broad plains cut by wadis. In 1982–1983, the existing small Masirah AB was expanded to include a new runway and taxiway designed to meet U.S. Air Force (USAF) requirements for a medium load airfield capable of supporting major logistical missions. The design was by a U.S. engineering firm in the Midwest, and construction was by a U.S.-Omani joint venture. By the early 1990s the southern portions of the runway and taxiway had suffered massive rutting and surface distortions and were closed to USAF missions until the runway and taxiway were completely rebuilt in 2002 by a USAF RED HORSE engineering squadron. Normally, a flexible airfield pavement designed for USAF missions will require a resurfacing at approximately 15 to 20 years because of weathering and environmental damage to the asphalt binder, but the structural cross section will normally last 35, 40, or more years before reconstruction is needed. In the case of Masirah AB complete structural failure occurred in only ten years.

The original pavement design called for the in-situ gravelly residual soil to be excavated to the weathered igneous bedrock upon which the runway and taxiway pavement structure would be founded. The designer's borings suggested the existing residual soil varied from a few centimetres to over a meter thick and typically classified as GM or SM silty, gravelly, sandy soils. The design runway and taxiway pavement cross-section consisted of

- 100 mm asphalt concrete—75-blow Marshall mix design for airfields
- 150 mm base course—crushed limestone, California Bearing Ratio (CBR) 100
- 200 mm subbase—processed local GM residual soil, CBR 50
- Select fill subbase—if needed, processed local GM, SM residual soil, CBR 20
- Subgrade—weathered igneous bedrock, CBR 20 (assumed value of CBR).

Construction of the pavement proceeded without major incident except for periodic disputes between the contractor and the government representatives over "excessive" excavation depths to the weathered rock when removing the residual soil.

Unfortunately, the southern portion of the runway and taxiway that failed did not lie on residual soils and weathered rock as assumed by the designer. Instead they were located on a playa or dry desert lake bed. Post-failure borings in this area to a depth of 8 m found lacustrine deposits of silts and clay and a high water table only 100 mm or so below the ground surface. The design CBR for these lacustrine materials for the reconstructed pavement was 5, not the 20 used in the original design calculations.

There were ample warnings available at the time of design and construction:

- Observation of the site shows it is a closed basin warning that playa deposits may exist.
- Local on-base records reveal that periodically since the 1930s the area flooded following rains.
- Twice during construction the site was flooded by rain. The designer was flown to the site, but upon examining the situation, determined that such rare "acts of God" in such an arid environment did not require any adjustment in the design. The southern end of the runway and taxiway would also be closed several times after construction by flooding.

– The original borings used for the design have not been located, and one must wonder how the stratigraphy could be misinterpreted. Perhaps there were no borings taken in this portion of the airfield, but this would be most irregular.
– Finally, observations in the field should have quickly revealed to the contractor, the contractor's quality control inspectors, and the government quality assurance staff that the subgrade below the southern portions of the runway and taxiway were silts and clays with a high water table and not the specified weathered bedrock.

A simple understanding of desert geology and local observations and interpretation of the terrain would have warned of the danger of weak soils in the area, and there were ample opportunities for this fact to become known during design and construction.

3 TESTING: FT. LEONARD WOOD ROAD AND PARKING COMPLEX, MISSOURRI

Ft Leonard Wood was selected to be the Department of Defence (DOD) centralized training site for truck and similar heavy equipment operators as part of a Base Realignment and Closure (BRAC) program. New pavements for the mission required expansion of the motor pool to accommodate 462 additional vehicles ranging from 2-1/2-ton to 14-ton trucks, refuelling vehicles, combat transport vehicles, and tractor trailers, construction of 4 new large vehicle training areas, and an addition to the base road system. The government agency responsible for the project estimated the cost of construction as approximately 20 million dollars, but this was rejected by the BRAC committee in Washington D.C. as excessive. An aggressive redesign of the project was undertaken. A sample of the subgrade soil was obtained, a modified compaction curve and soaked CBR was developed in the laboratory (Fig. 1), a design CBR of 30 was selected from the laboratory data, a sophisticated layered elastic pavement design analysis was conducted, and the final full-depth asphalt concrete

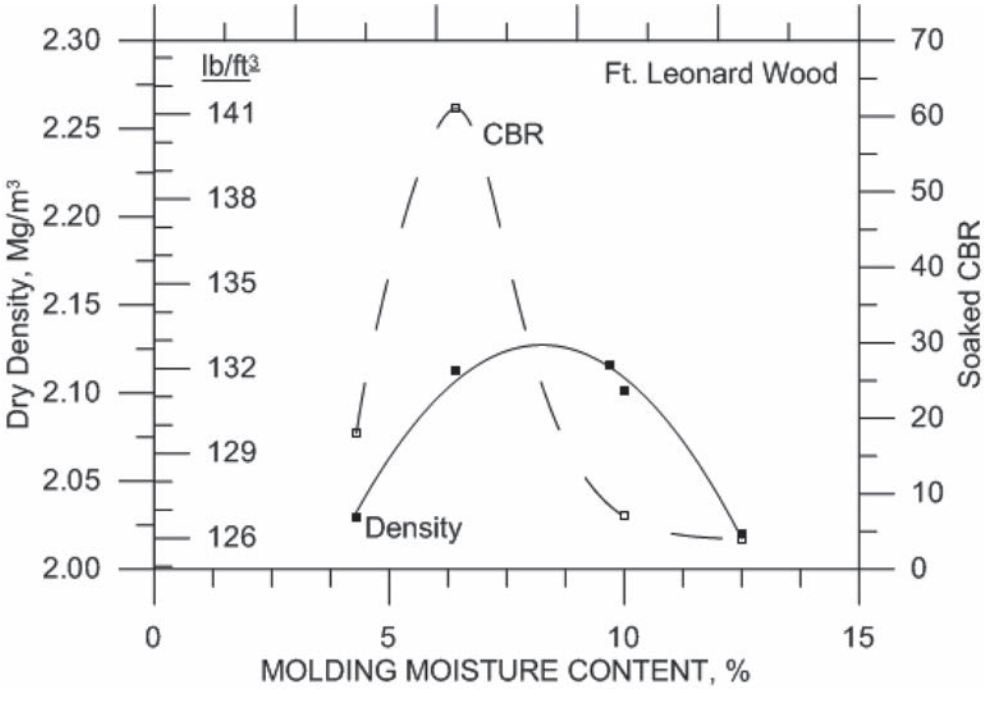

Figure 1. Subgrade compaction and CBR laboratory curves, Ft. Leonard Wood.

pavement for the required facilities cost approximately 14 million dollars. This was viewed by all as a major achievement, and the design was hailed in an industry trade journal as an example of how superior design and use of materials could achieve major cost savings. As soon as the pavements were opened to traffic, they suffered massive shear failures (Fig. 2). Repairs would cost approximately 9 million dollars, and the user's access to the training facilities would be delayed for a year.

Post-failure investigations found the typical subgrade soil CBR was 4 or less, not the 30 that the designer had used. Several elements came together to lead to this design misconception:

- An adequate geologic assessment was not done. The project site subgrade consisted of residual soils developed from weathering of interbedded cherty dolomite and sandstone producing a silty, clayey plastic soil matrix containing chert gravel particles. Such bedrock and weathering conditions do not produce soils with a 30 CBR.
- The U.S. Department of Agriculture (USDA) soil map identifies six soil series in two soil associations occurring as pavement subgrade in different portions of the motor pool, training areas, and road systems for the project area. Five of these six soil series are rated by the USDA as having severe problems when used as foundations for roads because of the clayey nature of the soil.
- A single soil sample is inadequate to assess subgrade conditions for this project, particularly in light of the six different soil series present in the project area.
- The compaction/CBR test series that was run was inadequate for selecting subgrade strength for the one sample that was tested. Military and ASTM guidance requires using three compaction curves of varying compaction energies and details specific methodology to follow to select an appropriate design CBR [1,4,5,6]. These procedures were not followed, and the designer's attempt to estimate an appropriate design CBR from the data was a failure.
- A design CBR of 30 is representative of select subbase material [1, 4, 5]; such a value is almost unheard of for a natural subgrade soil. Laboratory compacted soil specimens with appreciable gravel content give artificially high measurements of CBR because of the confining effects of the compaction mold [1]. For that reason, military pavement design assigns a design CBR to subbase and base course aggregates based on gradation and plasticity characteristics [1, 4, 5]. The tested sample of subgrade soil classified as a GC clayey gravel that failed to meet requirements for a 30 design CBR subbase because of plasticity

Figure 2. Subgrade shear failures, Ft. Leonard Wood.

characteristics and excess fines. Post-failure sampling throughout the project area found that subgrade soils typically classified as gravelly CH clays.

Improper selection of a design subgrade strength in this case was caused by a failure to assess local geologic conditions, inadequate sampling, use of an unrepresentative sample for testing, inadequate laboratory testing, and improper interpretation of test results.

4 EXPANSIVE SOILS: RANDOLPH AIR FORCE BASE (AFB) TAXIWAY, TEXAS

Expansive soils with their volume changes driven by soil moisture changes provide one of the pavement designer's most challenging subgrade soils. The military provides a variety of guidance for the designer [4,5,7,8], but there is no single solution to the problem. The designer must adapt the pavement design to the specific requirements of the site.

A Midwestern A-E firm prepared the design for a new connecting taxiway at Randolph AFB, and a local branch office of the firm had the contract to provide Quality Assurance (QA) services for the Air Force. The subgrade was an expansive, montmorillonite—rich alluvial CH-clay. To deal with the expansive subgrade, the design required the upper 200 mm of subgrade to be lime stabilized and placed and maintained wet of optimum until subsequent layers were placed. This approach has been used successfully for a number of military facilities on expansive clays in Oklahoma and northern Texas. The greatest moisture change under an expanse of airfield pavement occurs in the upper subgrade over the course of 2 to 5 years, and the moisture content then generally stabilizes to an equilibrium that is usually not affected by local environmental variations [1].

The project specifications required the contractor to select and use a stabilization lime content that would reduce the subgrade soil plasticity index to 10 or less. The contractor proposed that the design lime content be selected based on the Eads and Grim pH test [9] in accordance with local practice. The designer concurred, and the Eads and Grim test provided a 4% design lime content. Shortly after construction expansion in the subgrade soil damaged the taxiway pavement and required replacement of the pavement. Several factors contributed to this initial failure:

– The Eads and Grim test identifies the lime content at which the maximum pore fluid pH is achieved optimizing the environment for stabilization. However, the Eads and Grim Test provides no information on actual engineering properties that might be achieved, it underestimates the lime content for some soils, especially for tropical and subtropical weathered soils, and leaching has been a problem for the Eads and Grim predicted lime contents [9, 10, 11, 12]. The plasticity index is often used as an indicator of a soils swelling potential, but it is not always a failsafe indicator. Post-failure testing by several laboratories found the following typical results for this soil:

Lime, %	PI	Expansion, %	
0	45	12.0	
4	15	8.9	(Eads & Grim test result was 4% lime)
7	13	0.1	
13	12	0.4	(specified PI of ≤10 not met)

At the Eads and Grim lime content of 4%, the subgrade remains highly expansive. A soil that swells 3% in laboratory testing is typically considered expansive in the military guidance, and when appropriately lime stabilized, expansions are typically well below 1%. PI is often used as a surrogate to indicate swell potential which is suitable for many but not all soils. In this case, the PI could not be lowered to the specified 10 or less, but lime stabilization could reduce swell to acceptable levels. Military guidance for stabilization to control swelling soils requires the lime content to be based on actual laboratory swell tests [8].

– During construction, two QC tests were run on the lime-stabilized subgrade. The PI of the stabilized material was 30 and 34; these values are within the range of PI considered to be potentially expansive [7]. Neither the contractor's QC nor the designer's QA program identified that the lime stabilization was ineffective and that potentially expansive material was being placed directly under the pavement structure.
– The specification required the stabilized subgrade to be placed and maintained wet of optimum moisture content. However, the lime-stabilized soil was placed dry of optimum and was allowed to dry out after placement. Expansive soils placed dry of optimum have a fabric more prone to swelling than if placed wet of optimum, and the dry conditions allow an increased amount of water to be absorbed by the stabilized material. Both of these conditions increase the soil's swell potential.

In the end, this failure can be ascribed primarily to selection of too low a lime content through improper testing, failure to place and maintain the stabilized material wet of optimum, and failure of the QC and QA programs to recognize high PI test results that showed the lime stabilization was not effective and swelling was likely.

5 SULFATE ATTACK MITIGATION: TEXAS AND NEW MEXICO AIRFIELDS

Calcium-rich stabilized materials, notably those that contain portland cement or lime, can react with sulfates to form the sulfoaluminate mineral *ettringite* which can result in expansion and damage to pavements [13, 14, 15]. The USAF has had two airfield pavements in Texas and New Mexico damaged by this reaction known as sulfate attack (Fig. 3). Conventional concrete technology has well-established methods of coping with sulfate attack.

For conventional concrete, resistance to sulfate attack is commonly provided by using sulfate-resistant cements (Type II or V) which are lower in alumina content than cnvntional portland cement. Without sufficient alumina in the concrete, ettringite cannot form. However, use of sulfate-resistant cement fails in soil stabilization because the alumina needed for ettringite formation is readily provided by clay minerals in the soil, negating the effect of the low-alumina content sulphate-resistant cement.

Addition of fly ash and slag have been effective in combating sulfate attack in conventional portland-cement concrete where it appears that the fly ash and slag react with free calcium hydroxide to form calcium-silicate-hydrate (C-S-H) that is less vulnerable to sulfate

Figure 3. Swelling from sulfate attack on Type V cement-stabilized subgrade, Holloman AFB.

attack [16]. Class F fly ash has been found generally more effective than Class C fly ash for concrete sulfate resistance, and fly ash contents of at least 25–35% of the cementitious mass are needed for concrete sulfate resistance [16,17]. When calcium based stabilizers such as lime or portland cement are used for soil stabilization, addition of fly ash with the stabilizing agent may perform a similar function and tie up calcium ions that would not then be available to form ettringite. On the other hand, stabilized soils have less cementitious material, are far more permeable, and are weaker than portland-cement concrete which all would enhance vulnerability to sulfate attack. Consequently, the benefits of fly ash or slag for protection against sulfate attack may be less pronounced for stabilized soils compared to conventional concrete.

In 2008, the authors conducted a limited scope laboratory trial to examine the effect of fly ash addition with cement stabilization when exposed to soaking in a sulfate solution. Beams were prepared with a Clayey Sand (SC) soil mixed with 10% Type I/II portland cement and with Class F fly ash replacement levels of 0%, 15%, 30%, and 50% by weight of cementitious material. Samples were cured for 7 days and then placed in a saturated sulfate solution. Specimen expansion and cracking were rapid, and all specimens were badly damaged by the sulfate exposure in one to fourteen days of soaking. Specimens with fly ash deteriorated more quickly than samples without fly ash, and deterioration rate increased as fly ash content increased. This limited study suggests fly ash may not be effective for combating sulfate attack of cement-stabilized soils; however, sulfate attack and the role of fly ash is complex and multi-faceted and the topic needs further exploration.

The NCHRP Recommended Practice for stabilization of sulfate-rich soils [15] noted that research on use of fly ash and slag as potential mitigating measures for sulfate attack on stabilized soils was underway. Some success with use of fly ash to combat sulfate attack on lime stabilized soils had been reported earlier when the fly ash addition was combined with other mitigating methods [18]. Use of slag has also been reported as more effective than fly ash for resisting sulfate attack of cement-stabilized soils [19].

Sulfate attack on stabilized materials remains an unresolved issue, and proven methods of dealing with sulfate attack in conventional concrete are not effective in stabilized materials.

6 PERMAFROST: ARCTIC CONSTRUCTION

The need for military airfields in Alaska, northern Canada, and Greenland during World War II and the ensuing Cold War led to a number of airfield facilities being constructed on permafrost. From experience, it was learned the only effective way to deal with permafrost was to keep the permafrost from melting. Thick layers of non-frost susceptible material were required over the permafrost so the active layer of thawing would never reach the permafrost. It was also learned that maintaining the surface organic layer as an insulator was prudent. If ice-rich permafrost melted large settlements invariably resulted.

Thule Airbase was built in Greenland in 1951 and has undergone various expansions at different times. The thaw depth in unimproved areas at Thule with a mean annual air temperature of −11 °C varies from 1.2 to 2.4 m. Pavement designs at Thule AB initially required a minimum of 2 m of non-frost susceptible fill and base course to minimize any melting of the permafrost. During a 1952 expansion of the runway, this was changed to 1 m as an economy move. There was pronounced subsidence in the thinner sections within a year and several of the older 2-m thick sections also suffered settlement. Further studies found that painting the pavement surface white could reduce surface temperatures about 5 °C and reduced thaw penetration about 0.6 m. Recommended pavement design for future Thule AB pavements was a painted white surface and minimum 2.4-m thick pavement section. This design concept has proven effective in avoiding melting of the permafrost with resulting settlement. It has also apparently led to rise in the permafrost under the runway which served as a dam to subsurface flow and contributed to surface flooding of the airfield in 2002. Use of insulating material has been considered for reducing required thicknesses over the permafrost; however, types of materials that can withstand the structural loads applied by aircraft are limited, and

there have been unresolved issues with icing of insulated pavements compared to adjacent uninsulated pavements that do not ice.

Permafrost subgrades have special requirements. Trying to cut corners to save money leads to trouble, and the complexity of the situation makes solutions difficult and expensive.

7 ALLOPHANE AND HALLOYSITE-RICH TROPICAL SOILS: SOUTH PACIFIC

Residual soils developed from igneous rocks, and particularly volcanic ashes, under tropical weathering and constant high humidity are fine-grained and typically classify as MH soils. These soils exist at very high moisture contents and may contain high amounts of allophane and halloysite clay minerals. Allophane is generally considered an amorphous noncrystalline clay material, but this has been the subject of some debate. Halloysite exists as hydrated and unhydrated forms; there are also intermediate levels of hydration. The hydrated form has a distinct elongate tubular structure that may collapse, split, or unroll on drying and drying is irreversible. The irreversible drying characteristics of allophane—and halloysite-rich soils have a dramatic impact on laboratory test results, design, and construction. A sample of such soils that is oven dried, as is routinely done for laboratory testing, and then has moisture added to the sample for testing will be a completely different material from the sample that is air dried to the same test moisture content. Engineering test results from the two samples will be dramatically different so laboratory testing must replicate field conditions to achieve meaningful results.

A major road was to be built on an island in the South Pacific under a military contract. The subgrade was a halloysite-rich residual soil formed on basalt and classified as an MH soil. The continental-U.S.-based design engineer for the project had soil samples shipped back to a laboratory where they were dried, and laboratory compaction curves were run. Modified maximum laboratory dried density averaged around 1,280 kg/m^3, and optimum moisture content averaged around 34 percent. The designer specified the subgrade and embankments made from the subgrade were to be compacted to 85 percent of the modified density at the optimum moisture condition.

Attempts by the contractor to meet this requirement turned into a fiasco. The soil commonly existed at a moisture content of around 60%, and the annual 3.5 m rainfall without any dry season made drying the soil impossible. Occasionally, the 85 percent maximum density could almost be reached, but then a few more passes of the compaction equipment would see the density plummet. Generally, densities were well below the specified level. The oven dried laboratory samples that formed the basis of the designer's requirements were a different soil from the undried in-situ soil, and the specification requirements were meaningless. In contrast, some years before, another engineer familiar with tropical soils had been retained to oversee construction of an airfield on the same soils. This engineer had used test fills and field measurements to develop workable compaction requirements for the soil at the in-situ moisture contents and to select stable slopes for the embankments. He was working with the actual soil as it existed in the field and not an imaginary soil formed artificially by oven drying.

8 CONCLUSIONS

The subgrade soil is ultimately the foundation upon which all pavements must rest, and the design must recognize all of the strength and performance issues that the subgrade may pose. The Masirah AB and Ft. Leonard Wood examples illustrate how failure to appreciate the impact of geology on soil stratigraphy and properties can be catastrophic. Perhaps Karl Terzaghi expressed the role of geology in engineering best [20]:

> *"The geological origin of a deposit determines both its pattern of stratification and the physical properties of its constituents …Therefore, the knowledge of the relation between physical properties and geological history is of outstanding practical importance."*

For any engineering tests to be meaningful, the sample tested must be representative of the actual subgrade soil. The sample tested for the Ft. Leonard Wood example and upon which the entire design was predicated had strengths much higher than the actual subgrade resulting in immediate failure of the system under traffic. For the test results to be useful, the right tests must be run, they must be run correctly, and the results must be interpreted correctly. These were all contributing factors to the Ft. Leonard Wood, Randolph AFB, and tropical soil failure examples.

We can sample only a miniscule portion of the in-situ subgrade soil, and only when construction has revealed the soil to direct observation are we likely to have a good picture of the real situation. This underscores the importance of QC and QA programs to test and verify actual field conditions and also the crucial importance of the designer observing the site during construction to verify design assumptions are actually met in the field. At Masirah AB, Ft. Leonard Wood, and Randolph AFB expensive and embarrassing failures could have been avoided had information revealed during construction been acted upon.

Soils tend to be variable—there is no one real design strength or stiffness. Instead the designer must select a reasonable value recognizing the range of possible values and impact of future changes in moisture content. The analytical design procedure demands a single precise value; Mother Nature provides a variable. Finally, soils are complex and refuse to obey the assumptions we must make to allow tractable analytical solutions. The examples with expansive soils, sulfate attack, permafrost, and tropical soils illustrate that there are other factors besides subgrade strength that can dominate how well or poorly a pavement may perform.

Pavements can perform no better than their subgrade characteristics will allow; an engineer neglects this fact at his or her peril. Only if the subgrade effects are properly accounted for in design and construction will our concepts for long-life and perpetual pavements become possible.

ABSTRACT: This study investigated the influence of moisture on the Resilient Deformation (RD) properties of Unbound Granular Materials (UGMs). A typical UGM used in pavement constructions with three different grain size distributions were tested with a range of moisture contents using Repeated Load Triaxial tests (RLTTs). From the European standard, the procedure for the study of the RD behaviour was used where each stress path is applied for 100 cycles. Additionally, the Multi-Stage (MS) loading procedure for the study of the permanent deformation behaviour were used where each stress path is applied for 10,000 cycles, to compare the results using the two test procedures. Results showed that resilient modulus (M_R) generally decreased with increase in moisture, where the finer grading was more affected. However, for the MS RLTTs, after a large number of load applications, some increase in M_R with increasing moisture was observed. This happened when the moisture content increased up to close to the optimum; above the optimum, M_R always decreased. This may be due to Post-Compaction (PC) aided by moisture in MS RLTTs where a large number of load cycles were applied.

Keywords: Unbound Granular Materials, resilient modulus, moisture, Repeated-Load Triaxial Test

1 INTRODUCTION

In thin flexible pavements, the base and sub-base layers, comprised of Unbound Granular Materials (UGMs), play a vital role in maintaining the structural integrity. The deformation behaviour of UGMs under external loading can be characterized as complex elasto-plastic with a recoverable or Resilient Deformation (RD) part and a small plastic or Permanent Deformation (PD) part [1]. RD of the base layer is associated with fatigue resistance of the asphalt layer while PD is responsible for the development of rutting. Analytical design of flexible pavement structures requires proper understanding and modelling of these deformation properties. Besides stress levels, moisture is considered to be one of the factors that have a substantial impact on the deformation behaviour of UGMs [2–6]. Predictions of variations of these properties with seasonal variation of moisture are therefore essential for a sustainable design approach.

The Repeated-Load Triaxial Test (RLTT) is considered to be the most convenient way of studying the deformation properties of UGMs. The European standard [7] prescribes two different test methods for study of the RD and PD behaviour of UGMs, respectively. The test protocol for study of the RD consists of applying a set of different stress paths for 100 cycles each. On the other hand, the protocol for study of the PD consists of applying a set of different stress paths for 10,000 cycles each. For the both kinds of tests, the standard prescribes two sets of different combinations of stress levels, namely 'High Stress Level' (HSL) and 'Low

Stress Level' (LSL). Since in RD test, only 100 load cycles are applied for each stress path, the accumulated permanent strain and Post-Compaction (PC) in this case are negligible. Thus this test is suitable for the analysis of pure RD behaviour of the material. On the other hand the PD test involves significant amount of PD and PC. The advantage of this latter test is that both RD and PD characteristics can be evaluated from the same test. Further, this test reflects the long term performance of the structure.

The aim of this work was to study the influence of moisture on the RD properties of UGMs. The effect of grain size distribution on the moisture sensitivity and the influence of the number of load cycles (N) and PC were also investigated. For this, RLTTs were performed on a typical UGM used in Swedish pavement construction where the grain size distributions and the moisture contents (w) were altered. Both the RD test and the PD tests were performed and the results were compared to investigate the effect of N and PC.

2 DEFORMATION BEHAVIOUR OF UGMS

In a UGM, the total induced strain due to single load pulse consists of elastic and plastic strains which can be expressed as:

$$\varepsilon_{tot} = \varepsilon_r + \varepsilon_p \tag{1}$$

where, ε_{tot} is the total axial strain, ε_r is the axial elastic strain and ε_p is the axial plastic strain. Usually, the elastic strain consists of the largest part of the total strain with only a small part due to the plastic strain [1]. However, pavements experience a large number of N and plastic strain accumulates ($\hat{\varepsilon}_p$) with N. In a RLTT, the cylindrical specimen is subject to a constant confining pressure, σ_c (constant confining pressure method) and a cyclic deviator stress, σ_d. Thus, the principal stresses acting on the specimen are: $\sigma_1 = \sigma_3 + \sigma_d$ and $\sigma_2 = \sigma_3 = \sigma_c$.

2.1 *Resilient deformation characteristics*

The RD characteristics are quantified using the resilient modulus, M_R which is an estimate of the stiffness modulus of the specimen for rapidly applied loads, calculated as [8]:

$$M_R = \frac{\sigma_d}{\varepsilon_r} \tag{2}$$

where, ε_r is the resilient (recoverable) axial strain, taken after several N, when the deformations have stabilized. M_R is dependent on the state of stress, measured as the sum of the principal stresses, called the bulk stress, $\theta = \sigma_1 + \sigma_2 + \sigma_3$. The variation of M_R with θ can be expressed with the well-known $k - \theta$ model [9–11] in its dimensionless form as:

$$M_R = k_1 p_a \left(\frac{\theta}{p_a} \right)^{k_2} \tag{3}$$

where, k_1 and k_2 are non-dimensional regression parameters and p_a is a reference pressure or atmospheric pressure taken as 100 kPa.

The effect of moisture on M_R can be expressed using the M_R-Moisture model proposed by Andrei [12] which is a slight modification to the current Mechanistic Empirical Pavement Design Guide (MEPDG) model by AASHTO (The American Association of State Highway and Transportation Officials) [13]. This model simplifies the MEPDG model by eliminating density as a variable and using gravimetric moisture content as predictor variable instead of degree of saturation:

$$\log_{10} \frac{M_R}{M_{Ropt}} = \log_{10} a + \frac{\log_{10} b - \log_{10} a}{1 + EXP(\beta + k_w (w - w_{opt}))} \tag{4}$$

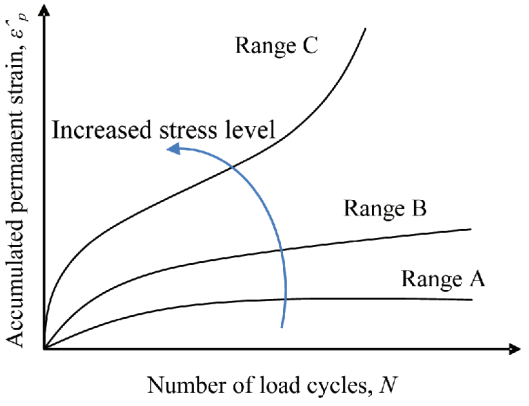

Figure 1. Different types of PD behaviour, depending on stress level [15].

where,

w = gravimetric moisture content expressed as decimal
w_{opt} = gravimetric optimum moisture content expressed as decimal
M_{Ropt} = resilient modulus at optimum moisture content
a = the minimum value of the ratio M_R/M_{Ropt}
b = the maximum value of the ratio M_R/M_{Ropt}
k_w = regression parameter dependent on material properties
and β is expressed as,

$$\beta = \ln_e\left(\frac{-\log_{10}(b)}{\log_{10}(a)}\right) \tag{5}$$

2.2 *Permanent deformation characteristics*

PD in UGMs accumulates with N and its development is very much dependent on the stress level. Werkmeister et al. [14] investigated the development of PD in UGMs using the shakedown concept. For cyclic loading of any constant magnitude, they identified three shakedown ranges for UGMs, shown in Figure 1, depending on the stress level. In shakedown range A (Plastic shakedown), at a relatively low stress level, after a PC period, the material stabilizes and the deformation becomes entirely resilient with no further accumulation of permanent strain. At an increased stress level, range B (Plastic creep) represents an intermediate response where the permanent strain per cycle continuously decreases or becomes constant without complete stabilization. In range C (Incremental collapse), when the stress level is increased even more, the permanent strain rate continues to increase leading to failure. The criteria to calculate the different shakedown ranges from RLTT data can be found in [7, 14].

3 EXPERIMENTAL STUDY

The RLTTs were carried out on cylindrical specimens of 150 mm in diameter and 300 mm in height. The specimens were prepared with target moisture contents and densities applying vibrocompaction. The axial deformations were measured using three Linear Variable Displacement Transducers (LVDTs), 120° apart, anchored to the middle third of the specimen. The loadings used for the tests were haversine pulses with a frequency of 10 Hz with no rest period. The confining pressure was applied through compressed air. Further details of the RLTT setup can be found in Rahman and Erlingsson [4].

The test for resilient modulus at constant confining pressure from the European standard EN-13286-7 [7] with HSL was followed. To minimize experimental scatter and to investigate the influence of moisture on the resilient stiffness, one specimen with a specific grain size distribution and degree of compaction was prepared with the minimum target moisture content. The conditioning from the standard was applied to the specimen. Then the first resilient test was performed. If during the resilient tests, any water drained out through the system, it was measured and the total amount of water required to reach the next target moisture content was added. The drainage was locked and sufficient time was allowed to achieve a uniform moisture distribution. In this way, more resilient tests were performed on the specimen by adding water in steps to achieve the target moisture contents.

For the PD tests, the Multi-Stage (MS) loading method from the European standard with HSL was used. In this case, several specimens identical to that used for the RD tests, with a range of moisture contents were prepared. Then each specimen was tested individually.

The moisture contents were measured after the final RD test with one specimen and after each PD test. The final moisture contents were a little less than the initial due to some losses during the procedure. In this paper, only the target moisture contents have been reported.

4 MATERIAL CHARACTERISTICS

The material used for this study is a crushed rock aggregate, typically used as base course material, obtained from Skärlunda in Sweden. It is characterized as foliated medium-grained granite with quartz, K-feldspars and plagioclase as main constituents [6]. The grain size distributions used were derived using the equation:

$$P = \left(\frac{d}{D_{max}} \right)^{n} \tag{6}$$

where, P is the percentage smaller than sieve size d, D_{max} is the maximum particle size and n is the grading coefficient describing the shape of the curve [16]. For this study, the grain size distributions were altered by varying n, shown in Figure 2. Except for the grading with $n = 0.35$, the other two conforms to the Swedish specifications [17]. The grading with $n = 0.35$ was used to investigate the influence of relatively high amount of fines on the moisture

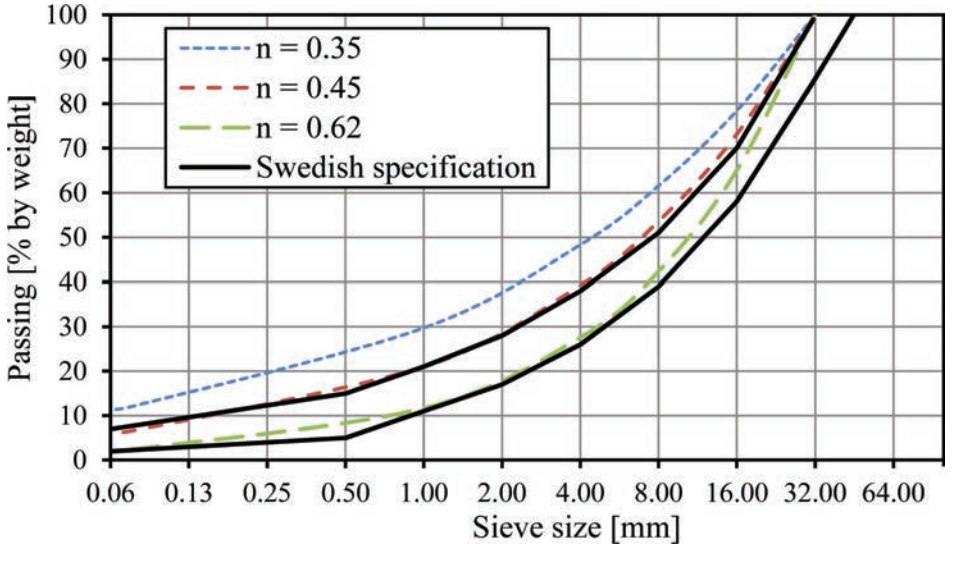

Figure 2. Particle size distributions.

Table 1. Material properties.

Grading coefficient, n	Optimum moisture content (% by weight)	Maximum dry density (g/cm^3)	Fine content (%) (< 0.075 mm)	Specific gravity [–]
0.35	6.5	2.22	12	2.64
0.45	6.0	2.26	6.5	2.64
0.62	5.5	2.11	2	2.64

sensitivity. The maximum particle size used was 31.5 mm. The modified Proctor method according to the European Standard EN 13286-2 [18] was used to determine the optimum moisture contents and the maximum dry densities. The specimens were compacted to 97% of the maximum dry density. Properties of the specimens have been summarized in Table 1.

5 RESULTS

5.1 *Resilient Deformation tests*

The resilient tests were performed with gravimetric moisture contents (w) starting at 1% with an increment of 1% each time up to close to saturation, where it was possible to carry on the tests with sufficient accuracy. For clarity, only a few of the results for $n = 0.35$ are plotted in Figure 3. Results showed that M_R decreased as w increased. The $k - \theta$ model, presented in Equation 3, was fitted to each measurement (with a specific w and n) using the least square curve fitting method. The parameters of the model were optimized employing the Solver add-in in Microsoft Excel. Plots of these parameters as a function of w are shown in Figure 4. It is observed that, the values of the parameter k_1 decreased with increasing w. This decrease was more pronounced for the finer grading indicating greater sensitivity to moisture. On the other hand, the parameter k_2 was less affected by moisture. The values of both the parameters k_1 and k_2 were also influenced by the grading coefficient.

A plot of the resilient moduli (normalized as M_R/M_{Ropt}) as a function of change in w with reference to the optimum is shown in Figure 5. The M_R-moisture model, stated in Equation (4), was calibrated using these data by optimizing the parameters with Solver, in a similar manner as for the $k - \theta$ model. For this, the values of M_R at a typical state of stress $\theta = 550$ kPa were used. These fitted models are also shown in Figure 5. The parameters of the model are presented in Table 2. Visual observation and the coefficient of determination (R^2) values in Table 2 suggest that good quality of fits were obtained with the M_R-moisture model. It is also reflected that the finer grading was more sensitive to moisture variation. From Table 2, it is observed that the values of the parameters a and k_w decreased while b and β increased as the grading went finer (decreasing n).

5.2 *Permanent Deformation tests*

From the PD test data, the M_R values as functions of θ were calculated. It was observed that in the initial stage of the tests, M_R generally decreased when w increased. But in contrast to the RD tests, after a certain N and at higher θ values, M_R started to increase with increase in w for all the cases. This increase was observed for w up to close to w_{opt} and above that, M_R started to decrease again. This behaviour was again more pronounced for the finer gradings. The plots of M_R versus θ for the different moisture contents are shown in Figure 6. For clarity, this is shown only for the grain size distribution with $n = 0.35$. The missing data is due to failure of the specimen having higher w undergoing excessive PD.

The k-θ model was calibrated for these tests and the variations of the parameters k_1 and k_2 with respect to w were plotted in Figure 7. As in the case of RD tests, k_1 was found to decrease with increase in w. On the other hand, in contrast to the RD tests k_2 was not constant. It was found to increase with w up to roughly close to w_{opt} and then it started to decrease. Since

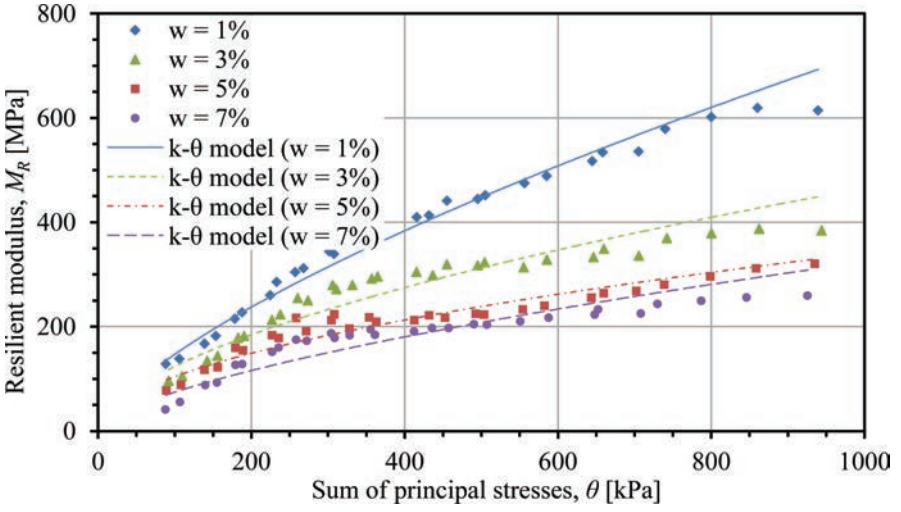

Figure 3. M_R as a function of θ for various moisture contents from RD test ($n = 0.35$).

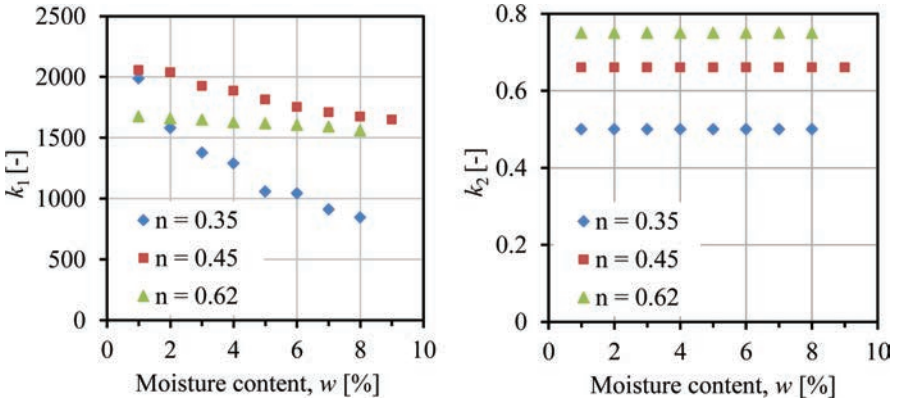

Figure 4. The parameters k_1 and k_2 as a function of moisture content from RD test.

the curves in Figure 6 cross each other, the results from the PD tests did not fit well to the sigmoidal M_R-moisture model, stated in Equation (4) for a reasonable θ value.

This behaviour was further investigated by plotting M_R as a function of N. This was studied for the three different shakedown range conditions, calculated as prescribed by the European standard [7]. An example is shown in Figure 8. The left part of the figure illustrates the accumulation of PD with N and the shakedown ranges for the different stress paths. The right part of the figure illustrates the change in M_R with N for three selected stress paths experiencing the three different shakedown ranges. It was found that when the shakedown range is A or B, M_R remained relatively constant with the number of load applications. But in case of shakedown range C, it increased with N. For the example in Figure 8, this increase was about 11% from 2,000th to 10,000th load cycle. This was the case for all the five C ranges, with different percentages of increase. Similar trend was found by Werkmeister et al. [14]. The explanation may be that M_R increased due to increased degree of compaction arising from PC due to large N. Since the tests were run as long as the materials survived, it may be assumed that any loss in M_R from shear failure did not come into play. Thus all the materials may be considered to be in a stage of PC during the tests. This led to the overall increase of the degree of compaction and M_R of a specimen as the test progressed. With the increase in

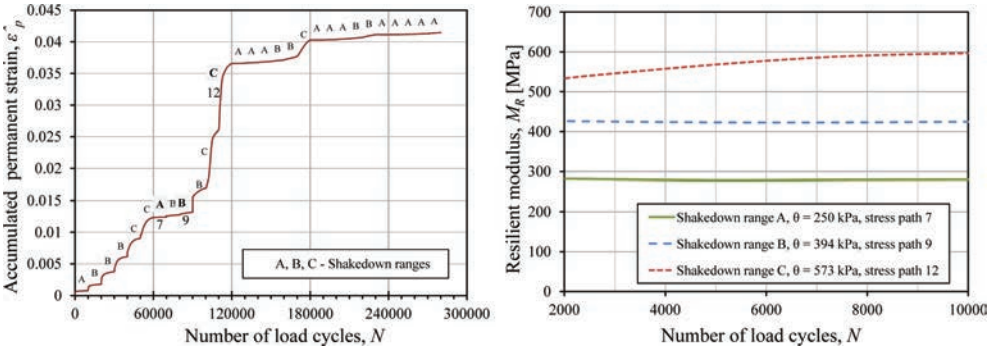

Figure 8. Evolution of M_R with N and PD for different shakedown ranges ($n = 0.35$, $w = 2\%$).

moisture, accumulation of PD increases [19] resulting in increased PC. Since it was easier for the specimen to achieve PC when it had higher w, its M_R increased earlier than the materials with lower w. Close to the optimum, the degree of PC was the maximum and the material reached the maximum dry density. After that this effect started to minimize. This resulted in the increase in M_R with w up to w_{opt} for the PD tests. Regarding the $k - \theta$ model, since it was found that k_2 increased with w for the PD tests, this implies that k_2 is dependent on accumulated PD and PC. Thus k_2 may be considered to be constant when the number of load applications are relatively low and when the accumulated PD and PC are negligible. But for higher N, resulting in considerable PD and PC, k_2 may be increasing up to a certain limit.

6 DISCUSSIONS

It was found from this study that moisture has a negative impact on pure resilient behaviour of UGMs. However, when RD is accompanied by significant amount of accumulation of PD due to PC, this may lead to some increase in M_R with w, depending on the degree of PC. The increase in stiffness was observed for shakedown range C. Since shakedown range C should not be permitted to occur in a well-designed pavement [14], the apparent increase in M_R may not be of practical benefit because the pavement then experiences a large amount of PD.

The PD tests were carried out using HSL from the European standard [7] which gave rise to many stress paths with shakedown range C. This increased the M_R with N. If LSL was

used, there would have been fewer stress paths with shakedown range C. In that case, the results from the RD and PD tests might have been more similar. Again, M_R should decrease if shearing of the specimen occurs. These need further investigation.

The results presented here were based on RLTTs where the variables are better controlled compared to field conditions. In reality there are many factors that may influence the results. For example, the UGMs may lose confinement with time and the grading may change due to crushing of the particles. Results from field studies by Salour and Erlingsson [20] using Falling Weight Deflectometer (FWD) showed that M_R decreased with increase in moisture. Thus this reflected similar results using the RD tests. The reasons may be that the FWD generally applies a limited number of N which is very similar to RD tests where the pure resilient behaviour is analysed. In the study by Salour and Erlingsson, the pavement section was open to traffic which might have led to some amount of PC, but might not have been significant enough to cause any increase in M_R. Generally, the stress levels prescribed by the European standard are relatively high, designed to test the material under a broad range of stress conditions. All of these stress paths may not be experienced by the UGM in reality.

The advantage of the PD test protocol is that it is possible to achieve information on both the PD and RD properties of UGMs from the same test, saving time and effort. This is also closer to reality and an indicator of long term performance of the material. The M_R obtained using this test reflects on its variation with load applications. However, the practical applicability of the value of M_R obtained using the PD test needs to be investigated.

7 CONCLUSIONS

This study was carried out to investigate the influence of moisture on the deformation behaviour of UGMs and the effect of grain size distribution, N and PC on the moisture sensitivity. It was based on RLTTs on a typical Swedish UGM with three different grain size distributions. From this study, the following were observed:

- M_R of the UGMs decreased with increasing w when the deformation was purely resilient with the degree of compaction remaining relatively constant, as in the case of RD tests. M_R increased with increase in w when there was significant amount of PC aided by moisture. This generally happened for the PD tests.
- UGMs with finer grading were more sensitive to variation in w.
- In all the cases, the parameter k_1 of the $k - \theta$ model decreased with increasing moisture. This was more pronounced for finer grading.
- The parameter k_2 was relatively insensitive to moisture for the RD tests with negligible PC. But it increased with moisture in the PD tests. Thus k_2 was found to be dependent on the accumulated PD and PC since these increase with increased moisture.
- The M_R-Moisture model yielded reasonable fit to the data from the RD tests. In that case, the parameters of the model were influenced by the grain size distribution. This model did not fit well to the PD test data.
- In shakedown range A and B, M_R remained constant with N. But in shakedown range C, M_R was found to increase with N.

Since the M_R-moisture model, stated in Equation (4) did not work for the PD tests, it may need to be improved to consider the effect of PC. However, this study was carried out only on one crushed rock aggregate with RLTTs. The conclusions drawn here should be verified with more tests with different materials. It should be further investigated to see which test condition between the RD and PD test protocols better represents reality.

Determination of the preferred intervention point for rehabilitation of dense graded asphalt wearing courses on the sand sub-grades of the Swan Coastal Plain in consideration of the triple bottom line (ecological, economic and social impacts)

Martyn Glover
Curtin University, Perth, Western Australia, Australia
Roads2000 Pty Ltd., Perth, Western Australia, Australia

ABSTRACT: In most cases, decisions made by pavement engineers on the rehabilitation of a road pavement wear course are based on a simple economic model. The model compares the cost of replacing the wear course compared to ongoing maintenance of the existing wear course. There seems to be very little consideration for either the ecological impact (excessive fuel use, tyre wear) or social impacts (personal injury and excessive road noise).

The sand sub-grades of the Swan Coastal Plain provide some of the best road pavement foundations in the world. When combined with Perth's Mediterranean climate without any freeze/thaw it is considered that road pavements on the Swan Coastal Plain have much longer life spans than roads elsewhere in Australia and the world.

The published deterioration models for road pavements and the wear courses from around the world do not take consideration for either the beneficial sub-grade or environment that exists on the Swan Coastal Plain. The paper presents the preliminary findings for a PhD thesis to:

- establish the deterioration model for dense graded asphalt wear courses on the Swan Coastal Plain;
- determine the ecological, economic and social impacts during the deterioration of the dense graded asphalt wear courses;
- propose an appropriate point of intervention for rehabilitation of the dense graded asphalt wear course in consideration of the ecological, economic and social impacts; and
- consider the relative balance between negative environmental inputs during maintenance versus environmental impacts of a delayed response.

Keywords: Intervention point for rehabilitation of dense grade asphalt, sand sub-grades, Swan Coastal Plain, ecological, economic and social impacts, wear course deterioration

1 INTRODUCTION

In Western Australia there has been minimal research on the optimum intervention point for replacing dense graded asphalt wear courses on the Swan Coastal Plain. In the few cases that exist, the modelling has been based on an economic rationale only. Where pavement management systems have been employed by pavement engineers and asset managers, the deterioration models have generally been similar to those in the Eastern states of Australia or elsewhere in the world and these do not take into consideration the unique road building environment of the Swan Coastal Plain. It is anticipated that this research will provide a guide for engineering students, pavement engineers and asset managers who operate on the Swan

Coastal Plain so that the maintenance of dense graded asphalt wear courses is optimised in terms of the ecological, economic and social impacts of the deteriorating pavement.

2 THE SWAN COASTAL PLAIN

The Swan Coastal Plain is a 30 kilometre wide strip on the Indian Ocean coast directly west of the Darling Scarp uplands running from Cape Naturaliste in the south to above the City of Perth. This study will look specifically at the northern section of the Swan Coastal Plain, geologically referred to as the Perth Basin and aligned with most of the Perth metropolitan area.

In the area of the Perth basin, the Swan Coastal Plain is about 34 kilometres wide in the north, 23 kilometres in the south, and is bounded to the east by the Gingin and Darling Fault Scarps, which rise to over 200 metres above sea level. The scarps represent the eastern boundary of Tertiary and Quaternary marine erosion. The Swan Coastal Plain consists of a series of distinct landforms [1], roughly parallel to the coast. The most easterly landform comprises the colluvial slopes which form the foothills of the Darling and Dandaragan Plateaus and which represent dissected remnants of a sand covered, wave-cut platform known as the Ridge Hill Shelf. To the west of the colluvial slopes lies the Pinjarra Plain, a piedmont and valley-flat alluvial plain consisting predominantly of clayey alluvium that has been transported by rivers and streams from the Darling and Dandaragan Plateaus. The plain is generally about 5 kilometres wide west of the colluvial slopes, but along the Serpentine River it is about 15 kilometres wide in an east–west direction. To the west of the Pinjarra Plain, the Bassendean Dune System forms a gently undulating aeolian sand plain about 20 kilometres wide with the dunes to the north of Perth generally having greater topographic relief than those to the south. The dunes probably accumulated as shoreline deposits and coastal dunes during interglacial periods of high sea level and originally consisted of mostly lime (calcareous) sand with quartz sand and minor fine-grained, black, heavy-mineral concentrations. Apart from a small local area to the south of Perth, the carbonate material has been completely leached leaving dunes consisting entirely of quartz sand. West of the Bassendean Dune System are two systems of dunes which fringe the coastline. The most easterly of these is the Spearwood Dune System, which consists of slightly calcareous aeolian sand remnant from leaching of the underlying Pleistocene Tamala limestone. The most westerly dune system, which flanks the ocean, is the Quindalup Dune System (Safety Bay Sand), consisting of wind-blown lime and quartz beach sand forming dunes or ridges that are generally oriented parallel to the present coast, but which may also occupy blowouts within the Spearwood Dune System (see Fig. 1).

These sandy soils have particularly good road sub-grade qualities which along with the Mediterranean climate contribute significantly to the longevity of road pavements constructed upon the soils. These attributes will be discussed in further detail later in the paper.

3 RESEARCH DATA SETS

There are two key data sets that will be utilised for the research. The first is the Roman II dataset which is the Road Management System utilised by 134 of the 140 Western Australian Local Governments. The basic road data recorded in this dataset includes road lengths, widths, construction date and resurfacing dates. The second dataset is the financial information contained in the annual Report on Local Government Road Assets and Expenditure published by the Western Australian Local Government Association (WALGA). This publication provides information on annual Local Government road rehabilitation expenditure which has been consistently reported in the same format for the past 15 years.

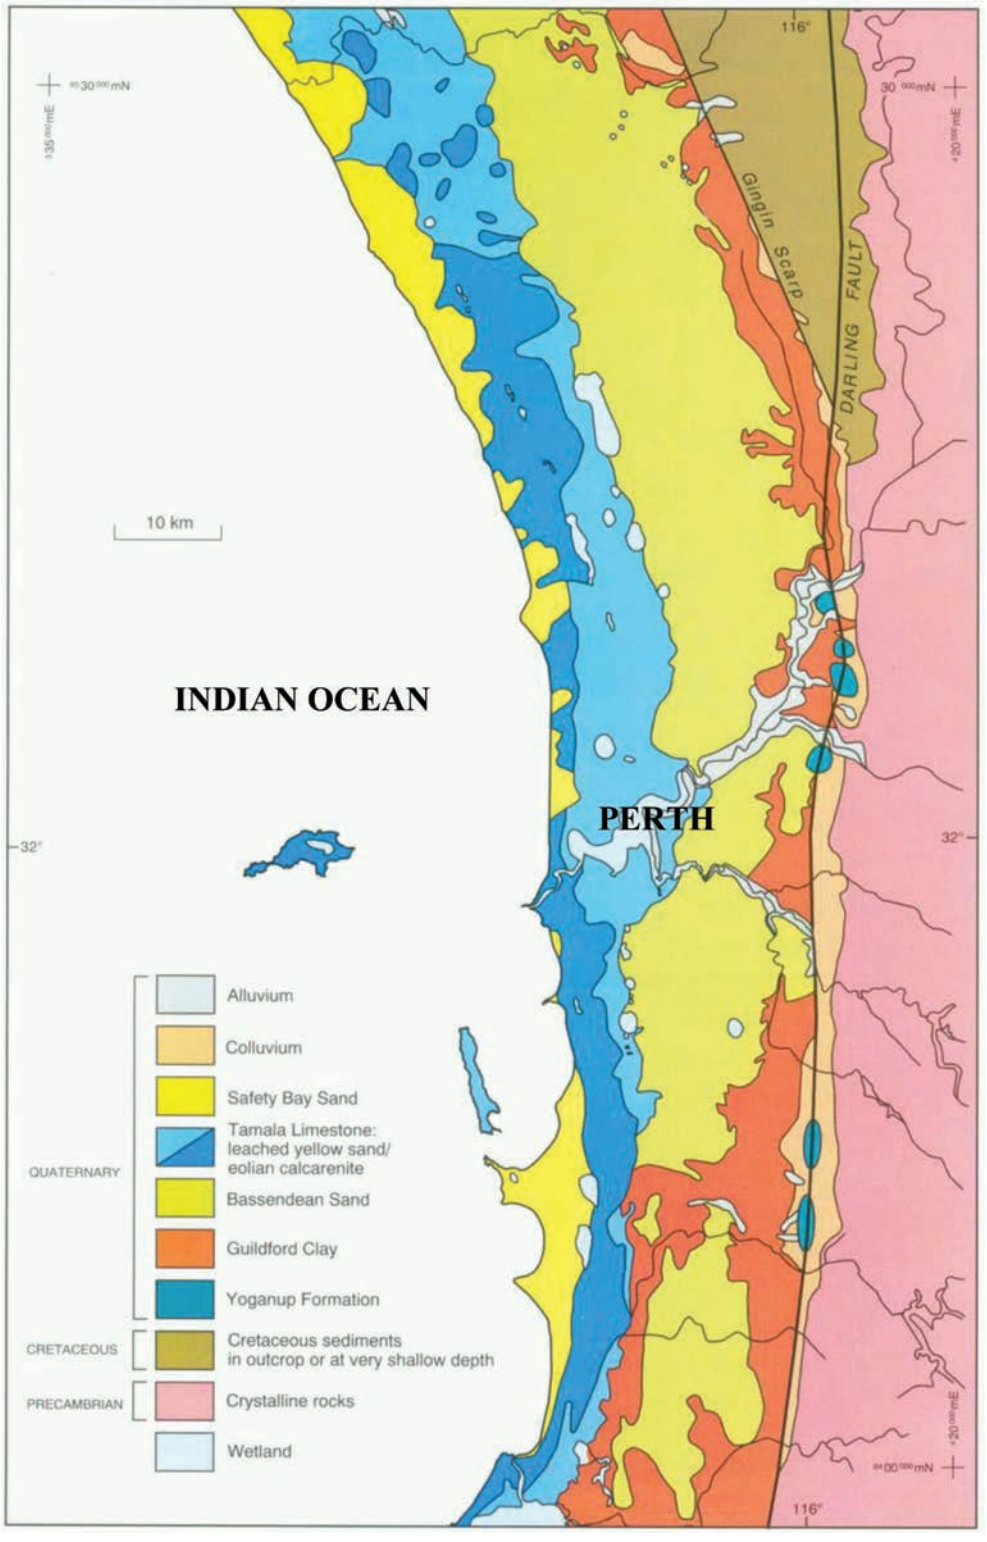

Figure 1. Swan coastal plain geomorphology [2].

4 PARTICIPATING LOCAL GOVERNMENTS

To provide further more detailed data all metropolitan Local Governments were contacted seeking permission to access their data and the following Local Governments provided that permission:

- City of Armadale,
- City of Belmont,
- Town of Cottesloe,
- City of Gosnells,
- City of Joondalup,
- Shire of Kalamunda,
- City of Mandurah,
- City of Melville,
- Shire of Mundaring,
- City of Nedlands,
- City of Rockingham,
- City of South Perth,
- City of Swan, and
- City of Wanneroo.

Because the project is specific to the Swan Coastal Plain it was decided to split the participating Councils into three distinct groups as follows:

- Swan Coastal Plain Group including Belmont, Cottesloe, Joondalup, Melville, Nedlands, South Perth and Wanneroo.
- Darling Range Group (local comparison) including Armadale, Gosnells, Kalamunda, Mundaring and Swan.
- Murray Coastal Group (southern Swan Coastal Plain) comprising of Mandurah and Rockingham.

5 PAVEMENT MANAGEMENT SYSTEM

Most Local Governments in Western Australia utilise the Roman II Pavement Management System. The six Local Governments which don't have Roman II have an alternative system of managing their road asset. All of the participating Local Governments use Roman II. This system and its predecessors have provided asset management tools for Local Government since the 1970's and the oldest data on asphalt was recorded in 1914 (Town of Cottesloe).

6 ROAD PAVEMENTS

Most pavements constructed on the Swan Coastal Plain are extremely thin by international standards and consist of a relatively thin unbound sub-base and basecourse overlaid with an extremely thin asphalt wear course. The Institution of Public Works Engineering Australia (WA Division Inc) Subdivision Guidelines Edition No 2.2, 2012 (the Guidelines) prescribes that pavement thickness is designed in accordance with:

- Pavement Design—A Guide to the Structural Design of Road Pavements (Austroads, 2004);
- A Guide to the Design of New Pavements for Light Traffic (APRG Special Report No. 21, 1998); and
- Main Roads WA Engineering Road Note 9—Procedure for the Design of Flexible Pavements.

The Guidelines [3] also prescribe the design life of pavements as follows:

Unless specified otherwise by the local government, the permanent deformation of the granular pavement must have a minimum design life of 40 years. Unless specified otherwise by the local government asphalt must have the following minimum design life:

- open graded asphalt—10 years;
- dense graded asphalt 50 millimetres total thickness or less—20 years fatigue life; and
- dense graded asphalt greater than 50 millimetres total thickness—40 years fatigue life.

Because the sands of this area of the Perth including the Safety Bay sand, Tamala Limestone and Bassendean Sand formations have California Bearing Ratios (CBRs) in excess of 12.0, the designed pavements are thin. The Guidelines provide three typical pavements ranging from 250 mm to 280 mm thick including an asphalt layer between 25 mm and 65 mm thick overlaying an unbound base of crushed rock and/or crushed limestone between 200 mm and 250 mm thick. Pavements constructed before the 1970's have used limestone spalls and/or lateritic gravels as the unbound portion overlaid by bituminous Macadam of varying thickness. These pavements tend to be even thinner than the more modern pavements with total pavement thicknesses recorded at less than 200 mm however they still perform well today as both residential and distributor pavements.

7 ASPHALTS

In the recent past almost all metropolitan roads were paved with dense grade asphalt. The design was generally a maximum size of 10 mm granite with a class 170 bitumen binder and at 50 blow marshal. The thickness was generally a minimum of 25 mm. Resurfacing activity has predominantly utilised dense grade asphalts although more recently Stone Mastic Asphalt (SMA) has become popular especially where the existing pavement is heavily cracked. Roman II does not differentiate between types of asphalt surface and the use of SMA is a new treatment as well as still at a low proportion of all asphalts, consequently this paper assumes that the great majority of road surfaces requiring resurfacing are dense graded asphalts.

Most of the metropolitan Perth Local Governments in Western Australia now utilise the IPWEA/AAPA Technical Specification, Tender Form and Schedule for Supply and Laying of Hot Asphalt Road Surfacing [4] for their asphalt paving works. The Specification includes mix designs with provision for stiffer bitumen eg class 320, and use of the specification has resulted in a very consistent quality of asphalt surface especially in the metropolitan area.

8 CLIMATE

The climate in the South West of Western Australia plays a substantial part in the longevity of road pavements. The long term average maximum temperature in Perth is 24.7°C (76.5°F) and the average minimum temperature is 12.8°C (55°F). The average rainfall is 731 mm (29 inches) over an average period of 104.9 days [5]. There is no freeze-thaw in Western Australia consequently the climate contributors to the aging of asphalt pavements are limited to the sun and rain. Freeze-thaw or frost weathering is a collective term for several mechanical weathering processes induced by stresses created by the freezing of water into ice. The term serves as an umbrella term for a variety of processes such as frost shattering, frost wedging and cryofracturing [6]. The process may act on a wide range of spatial and temporal scales, from minutes to years and in the case of road pavements from accelerating surface raveling to splitting entire pavements. Frost weathering is mainly driven by the frequency and intensity of freeze-thaw cycles and the properties of the materials subject to weathering. The Local Government Association of South Australia has recently commissioned a comprehensive study by the National Climate Change Adaption Research Facility titled Quantifying the cost of climate change impacts on local government assets. The report

includes predictions on the impact of climate change on Perth road pavements. The prediction is that in the year 2100 the average pavement life will increase as the average rainfall reduces [7].

9 TRIPLE BOTTOM LINE

The triple bottom line (abbreviated as TBL or 3BL, and also known as people, planet, profit or "the three pillars") captures an expanded spectrum of values and criteria for measuring organizational (and societal) success: economic, ecological, and social. With the ratification of the United Nations and International Council for Local Environmental Initiatives (ICLEI) TBL standard for urban and community accounting in early 2007, this became the dominant approach to public sector full cost accounting. Similar United Nations standards apply to natural capital and human capital measurement to assist in measurements required by TBL, e.g. the EcoBudget standard for reporting ecological footprint [8].

In this report, it is recognised that the decision to replace the wear course on a pavement is generally an economic decision based on the deterioration of the existing wear course versus the cost of replacing it and available funding. What is not considered and should be [9] are the ecological impacts of a deteriorating wear course relate to the increased pollution predominantly generated from increased tyre wear and fuel use while the social impacts are increased crashes and road noise. The WesTrack study conducted by the Federal Highway Administration in 2000 indicated that trucks running on smooth surfaces could reduce fuel consumption by 4.5 percent [10], other research has cited increased consumption due to roughness between 10 and 20 percent [11]. Nakamura and Ihara demonstrated that road noise from tyres increases as the asphalt ages [12]. Research in Texas between 2008 and 2009 has realised that poor pavement condition scores and ratings were associated with proportionally more severe crashes [13].

10 ROAD NETWORK

The key road network information for the participating Local Governments is included in Table 1.

Table 1. Local government road network key information [14–23].

			Asphalt road totals		
Group	Local government	Length of sealed road (km)	Area (m^2)	Area reseal (m^2)	Percentage resealed
Swan coastal plain	City of Belmont	229.28	220890	67350	30.49%

The annual Report on Local Government Road Assets and Expenditure published by the WALGA [14–23] provides key performance indicators for pavement performance based on a financial model. The three key financial values are:

- Current Replacement Value—is the current cost of replacing the road assets. It provides a datum from which the consumption of roads can be assessed.
- Written Down Value—is the current value after allowing for depreciation. The difference between replacement value and written down value represents the amount consumed.
- Status Quo Cost—is the estimated cost of maintaining the roads at their current condition. It provides a datum against which actual expenditure performance can be compared.

This paper considers two indicators based on the above financial values. The Road Condition Indicator is the ratio between the Written Down Value and the Current Replacement Value. The Preservation Performance Indicator is the ratio between the actual expenditure on preservation and the Status Quo Cost. These two key performance indicators for the road network since 2000–2001 are included in the Tables 2 and 3.

To provide a measure of the actual cost, Table 4 provides annual expenditure per linear kilometre in built up areas, that is, the roads which have most likely been asphalted.

11 DETERIORATION MODELS

The Roman II data has provided indications of the typical life of thin asphalts on the Swan Coastal Plain. The average resurfacing period for any Local Government has varied from as low as 10.3 years to as high as 27.3 years. The average resurfacing periods are presented in Table 5.

Further research will be required to determine the reasons for the different resurfacing periods including dominance of particular classes of road, Local Government asset policy, traffic volumes etc, however the Group averages are relatively consistent between 17 and 18 years with Swan Coastal Plain Group the longest at 18.2 years.

Table 5. Average resurfacing periods.

Group	Local government	Length of sealed road (km)	Resurfacing Period
Swan coastal plain	City of Belmont	229.28	12.7
	Town of Cottesloe	48.47	27.3
	City of Joondalup	1009.64	23.9
	City of Melville	733.65	16.2
	City of Nedlands	147.00	16.7
	City of South Perth	197.77	10.3

	Average resurfacing period		18.2
Murray coastal group	City of Mandurah	667.16	22.0
	City of Rockingham	961.42	12.7
	Average resurfacing period		17.4
Darling range group	City of Armadale	683.66	18.9
	City of Gosnells	855.05	14.7
	Shire of Kalamunda	645.00	13.9
	Shire of Mundaring	602.75	22.3
	City of Swan	1306.97	19.5
	Average resurfacing period		17.9

12 CONCLUSION

The initial research indicates that road construction conditions in terms of quality subgrades and a Mediterranean climate on the Swan Coastal Plain are conducive to long lasting pavements. The research has provided an actual average resurfacing period which has maintained a favourable road condition. This still needs to be compared with theoretical deterioration models. We have also established that the available data sets are of good quality providing long term data for road pavements in metropolitan Perth. The research is yet to quantify the cost of tyre wear, fuel use, crash risk and road noise to the community and whether this will impact on the optimal intervention point.

ACKNOWLEDGEMENTS

The author wishes to thank the staff of the participating Local Governments, ARRB and WALGA for their contribution to date. The research could not take place without the support of Curtin University and my employer, Roads 2000 Pty Ltd.

Discrete Element Modelling and experimental study on dilation behaviour of asphalt mixtures

Jiantong Zhang, Jun Yang & Keli Wang
School of Transportation, Southeast University, Nanjing, Jiangsu, China

ABSTRACT: This paper investigates the use of Discrete Element Modelling (DEM) to simulate the behavior of a highly heterogeneous nature under triaxial compressive test. The laboratory triaxial compressive test is conducted to capture the dilation of asphalt mixture. Dilative mechanism is analyzed through the microstructure using DEM. Digital specimens are prepared with random generator algorithm that would generate an irregular closed space to incorporate the balls inside of the space for each clump according to the graded mixture. Statistical regression method is developed to capture varying air void distributions along pavement depth. Based on this method, the air void phase of virtual specimen was built, which is close to the real asphalt pavement. Results show that the virtual specimen is similar to the actual triaxial compression test specimen and has the correct volumetric proportions. The dilatancy behavior and shear resistance are simulated by using DEM to investigate the variance of aggregate-binder-aggregate contact under triaxial compressive tests. The results of laboratory triaxial compressive test were in agreement with the result of DEM simulation. Both of these methods show that there was obvious dilation when the specimen was loaded. At the same time, the aggregate-binder-aggregate contact was fractured and formed a shear band.

Keywords: Asphalt mixture, Discrete Element Modelling, dilation, triaxial compression test, Particle Flow Code (PFC), permanent deformation, mechanism

1 INTRODUCTION

Dilatancy behavior plays a key role in asphalt mixture rutting. Dilation is a phenomenon of the volume increase that occurs in the particulate media when loaded beyond the elastic limit [1]. The dilatancy has significant implication; it means that the granular skeleton becomes loose during the shearing [2]. The property of soil dilatancy was first described by Osborne Reynolds [3–4] embodied in the well known "interlocking saw-tooth" analogy of Taylor. Rowe [5–7] developed a basic theory which explains how the geometrical interlocking of the particles influences the strength of the material, and provided a simple relationship between stress ratio and dilatancy factor which basically quantifies the geometrical effect. Within the framework of plasticity theory, Rowe's stress dilatancy relationship represents in fact a flow rule which determines the direction of plastic strains. Nova and Wood [8] later on proposed a stress invariant form of the relationship for addressing general stress and strain conditions. Wan and Guo [9–10] proposed a model which hinges upon concepts of coupled plastic hardening-softening and stress dilatancy in order to address both the void ratio and pressure dependency behaviour of granular soils. However, very little work has been done to address the effect of the dilatancy process on the quality of pavement. The challenges in the modeling of asphalt mixture contain the highly heterogeneous nature including aggregate internal structure and air void distribution, the time, temperature and rate-dependent behavior of the matrix and the limited computation capacity for very precise prediction. Digital specimen and test techniques permit investigation of strength and deformation mechanisms of asphalt

concrete going in a microscopic way that integrates mechanism identification, numerical simulation, and experimental observations. It represents the trend for the future mix design [11]. Virtual test can be utilized to simulate the laboratory test and make microstructure analysis of asphalt concrete under a specific load condition [12–15]. The micro-fabric discrete element method for the microstructure of asphalt mixture in two-dimensional was proposed by Buttlar and You [16]. Then the idealized model in three-dimensional was established to simulate the dilation behavior of asphalt concrete [17].

The aim of this paper is to further study the mechanism of dilation of asphalt mixture, which helps to explain the rutting mechanism of asphalt pavement. Also, the microstructure of asphalt mixture is analyzed using DEM, which can be used to explain the fundamental material properties of asphalt mixture. It is beneficial for designing and testing of asphalt pavements.

2 MECHANICAL MODELS FOR DISCRETE ELEMENT MODELING

There are three kinds of contact interaction effects: (1) interactions within aggregates; (2) interactions within sand mastic; (3) interactions between aggregate and sand mastic. In the DEM model, four contact models are used to represent the rheological characteristics of asphalt: Burger's model, the linear elastic contact model, the slip model, and the contact-bond model. These contact models are available in the PFC3D (Particle Flow Code in three Dimension). Burger's model and the linear elastic contact model are used as the contact-stiffness models for asphalt sand mastic and aggregate particles, respectively. The slip model represents the slip behavior at the two contacting entities and the contact-bond model can specify shear and normal tensile strength. The contact models are distributed according to interaction mechanic characteristics in this paper as shown in Table 1.

3 LABORATORY TESTING

3.1 *Test materials and sample preparation*

The Superpave Gyratory Compactor (SGC) is used to produce compacted specimens for volumetric analysis and determination of mechanical properties. The asphalt mix specimens of 150 mm (diameter) by 165 mm (height) were fabricated using the Superpave Gyration Compactor, and then 100 mm (diameter) by 150 mm (height) specimens were cored from compacted specimens for the test.

The selected aggregates were used in this test and limestone was employed as filler. Three types of asphalt mixture known as AC13, SMA13 and Sup13 which are the most common used mix types used for wearing course construction in China, were studied in details to serve as the baseline case in this study. The properties of SBS modified asphalt can be referred to the research of Zhang et al. [18], but the PG (performance grade) isn't measured. The mix proportions and aggregate gradations for the three mixtures are shown in Table 2.

3.2 *Triaxial compression test*

The three type of mixtures (SMA13, AC13 and Sup13) triaxial compression test results are shown in Table 3.

4 DEM SIMULATION

4.1 *Numerical sample preparation procedure*

Discrete Element Modeling (DEM) for simulating movement and interaction of assemblies of rigid particles was developed by Cundall and Strack [19]. Reference to the study conducted by Lu [20], particles simulated by clumps of balls would be able to introduce the heterogeneity of materials and interlocking among particles from the shape or angularity perspective rather than by only a single ball into the model as shown in Figure 1. At first, a cylinder mold surrounded by walls needs to be created with the size identical to the sample size (height = 150 mm, diameter = 100 mm) for triaxial compression test. A simple model with gradation identical to that of mixtures but consisting of regular shape balls is created. Using the model developed by You et al. [21] and the consideration

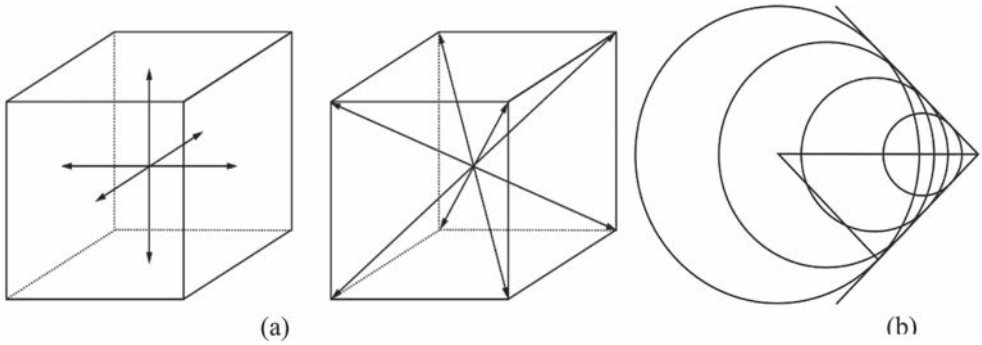

Figure 1. Method of fabricating irregular shaped aggregate. (a) Ball generation along one direction; (b) Directions of ball generation for clumps.

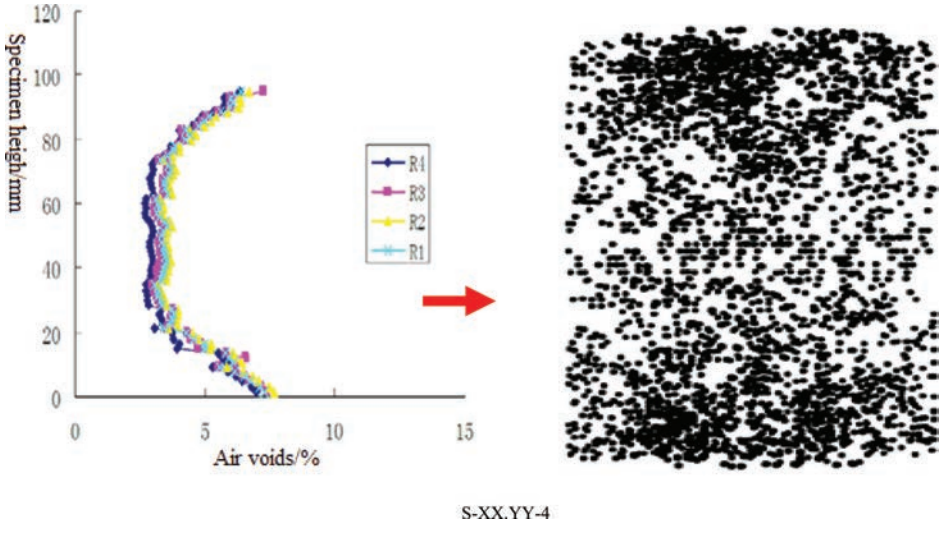

Figure 2. Fabrication process of air void phase of asphalt mixture. The left picture is the distribution of air void along the depth of asphalt mixture under triaxial compression test (The digital specimen's radii are 1 cm, 2 cm, 3 cm, and 4 cm represented by R1, R2, R3, R4, respectively) [22]; The right picture is the distribution of air void (Air voids represented by black spheres) of virtual specimen based on the data of the left picture.

of computing efficiency, the ball's radius (element size) is chosen as one millimeter. The physical information of clumps (balls' locations and radii) is already kept in storage at the former step. Traverse every ball in the new model and the ball with its center located in the same closed space would be added to the same clump. When all clumps had been delineated, the next stage's work is to delete a certain amount of balls to meet the void requirement as shown in Figure 2. It should be noted that the deleted ball should be a "free" one, namely it belonged to no clump. After performing stage two, the rest of the free balls will form the asphalt mastic phase. Finally, it is needed to check the volume ratio between coarse aggregate and asphalt sand mastic. Figure 3 depicts the mechanism for this final DEM model.

Air void distribution inside the specimen is studied using X-ray scanner, according to [23–24]. A statistical model is proposed to establish the air void phase instead of a model with random distribution shown in Figure 2. The air void phase of microstructure for the virtual specimen is established as shown in Figure 3(d).

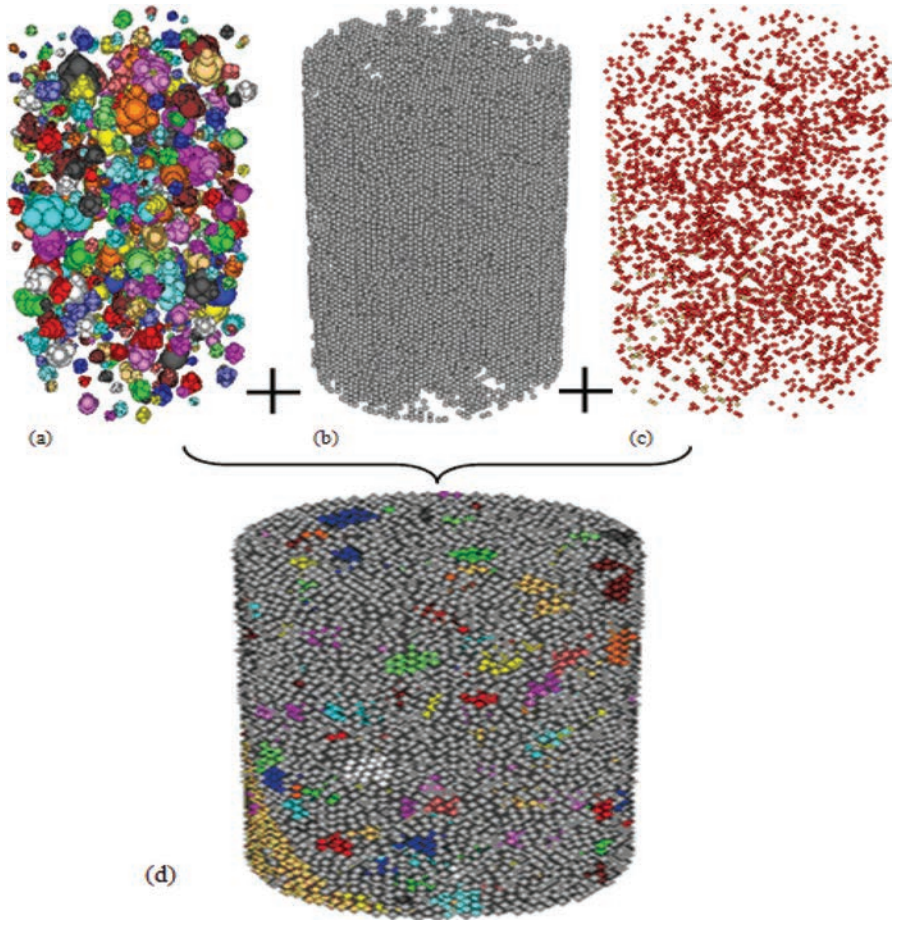

Figure 3. Schematics of mechanism of fabricating virtual specimen. (a) Coarse aggregate phase (>=2.36 mm); (b) Asphalt binder mortar (<2.36 mm); (c) Air void phase (VV = 4%, air voids are represented by red spheres); (d) Testing virtual specimen.

Finally, the information of physical components in the virtual specimen is calibrated by actual gradation of asphalt concrete. So far, the microstructure of asphalt concrete has been established based on DEM. To improve computational efficiency of the three dimensional model, the size of virtual cylindrical specimen is reduced to 60 mm by 40 mm (height by diameter) and the radius of the unit sphere is reduce to 0.5 mm. The coarse aggregate in virtual specimen can be calibrated, for example the coarse aggregate of Sup13 virtual specimen is as show in Figure 4. Also, the volume ratio of aggregate grading in virtual and actual specimen can be calculated (for instance, the Sup13 and AC13 specimen's volume ratio). Results for volume ratio against aggregate grading are plotted in Figure 5. It can be seen that the volume ratios are almost equal. It indicates that both virtual specimen and actual specimen have similar aggregate properties.

4.2 *Parameter determination*

The parameters of burgers model can be calculated by the equation (1) [17].

$$\varepsilon(t) = \frac{\sigma_0}{E_1} + \frac{\sigma_0}{E_2} + \frac{\sigma_0 t}{\eta_1} - \frac{\sigma_0}{E_2} e^{\frac{E_2}{\eta_2} t} \tag{1}$$

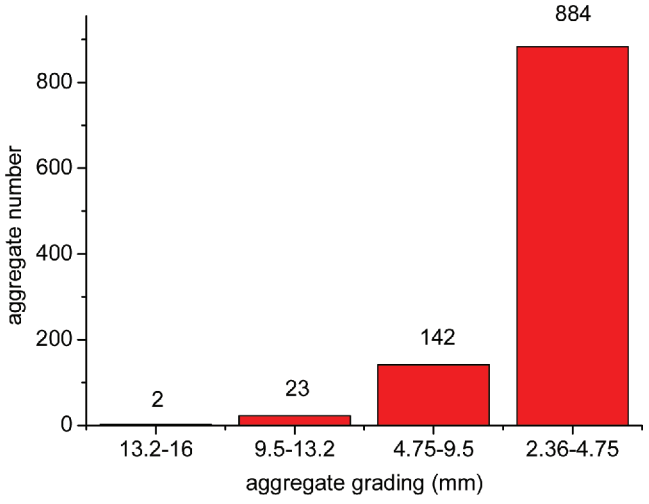

Figure 4. Distribution of coarse aggregates for virtual specimen Sup13.

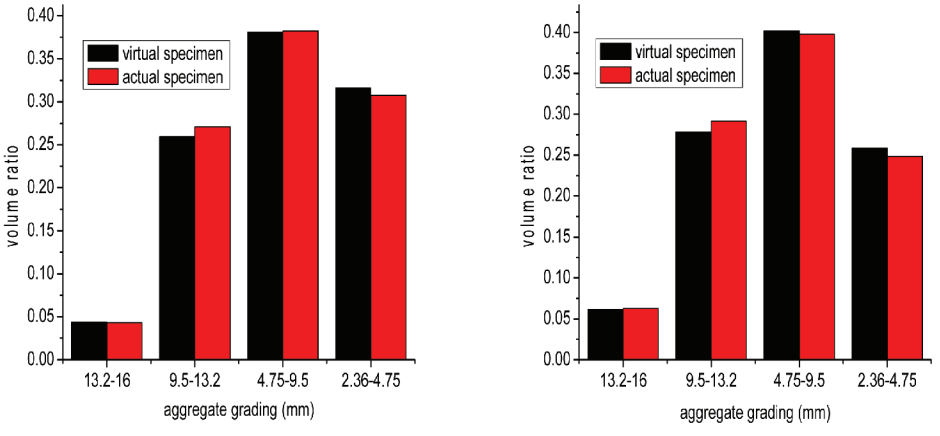

Figure 5. Volume ratio of aggregate grading in virtual and actual specimens. The left picture Is Sup13 specimen and the right picture Is AC-13 specimen.

where σ_0 is the creep loading, 40 KPa, and t is the test time. It can be seen from Figure 6 that the parameters of burgers model can be captured by fitted regression line under triaxial compression test of asphalt mortar of Sup13 and AC13. The parameter of burgers model is shown in Table 4.

4.3 *Virtual triaxial compression test*

The virtual specimen has been build and its parameters have been captured through triaxial compression of asphalt mortar in abovementioned parts. Also, the particle and contact model are ready for DEM model, the next step is to make an assembly of them, namely assign every contact a corresponding contact model and its properties according to the former tables. A FISH program is compiled to finish this task. The Burger's contact model is updated every timestep, and the creation of a new contact would automatically trigger the calling of a FISH function and install Burger's model and its properties dynamically. When a new contact is created, the FISH function would be triggered and all the contact properties within the digital sample would be updated. The bond contact parameters need to take into account.

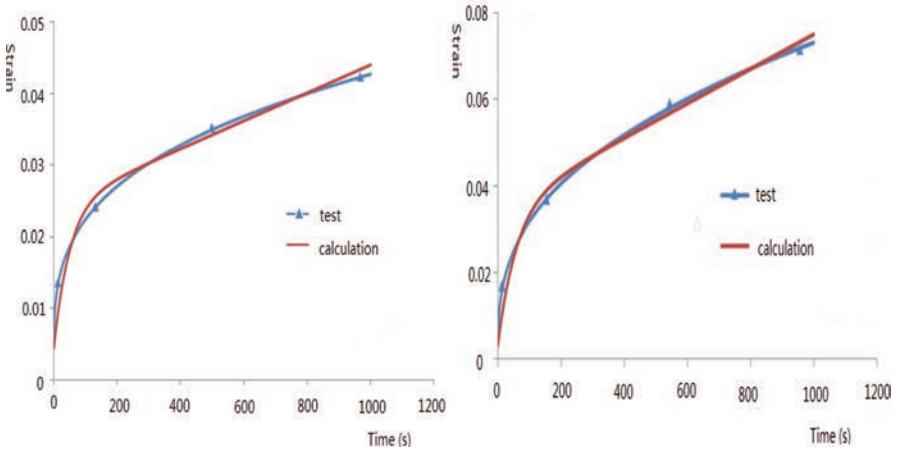

Figure 6. Fitted regression line for triaxial compression test of asphalt mortar of Sup13 (left) and AC13 (right).

Table 4. Parameters of burgers model for AC13 and Sup13 mix.

Mix type	E_1 (Pa)	η_1 (Pa·s)	E_2 (Pa)	η_1 (Pa·s)
Sup13	8.882E+06	2.043E+09	2.012E+06	1.005E+08
AC13	1.248E+07	1.000E+09	1.254E+06	7.416E+07

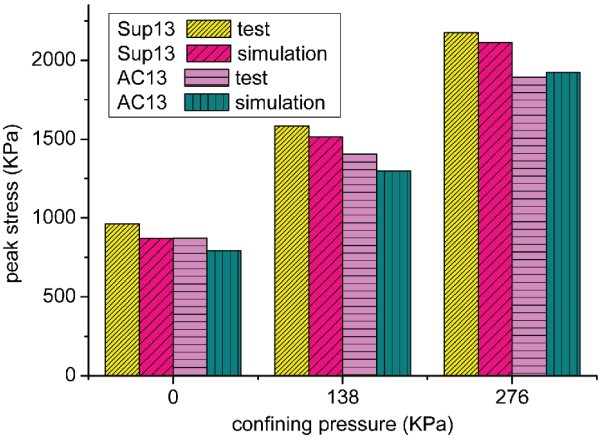

Figure 7. Comparison peak stresses obtained from DEM simulation and the actual test.

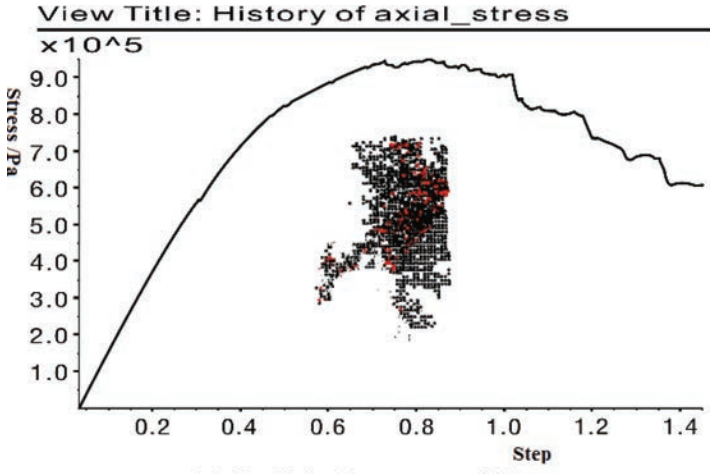
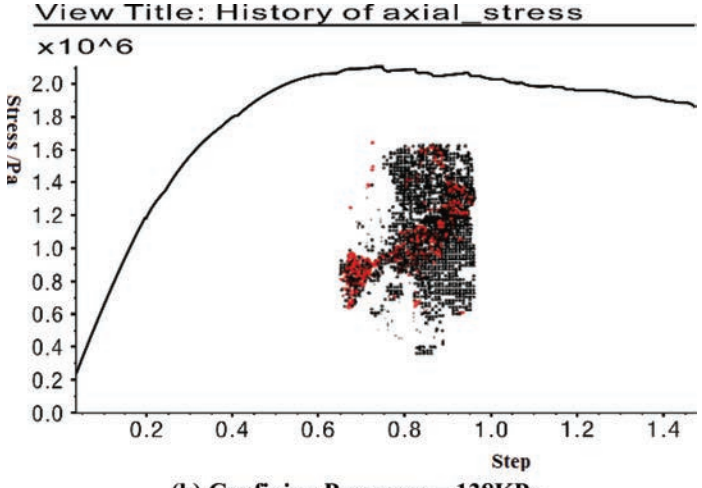
Therefore, it's better to develop concrete laboratory tests to assist obtaining the values as accurate as possible though it never obtains the real values because of many limitations. In this paper, the value of bonds contact parameters is obtained by regressing the DEM simulation and measured laboratory results.

5 DILATION ANALYSIS UNDER TRIAXIAL TEST AND DEM SIMULATION

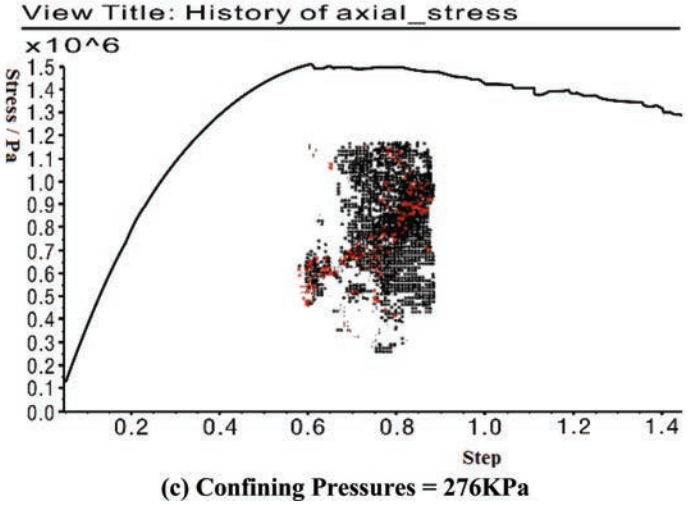
The top plate is loaded at a strain rate of 8.47 mm/mm/min. And some variables are obtained once every 50 time-steps by calling "History" command, including the stress enforced. All



(a) Confining Pressures = 0KPa



(b) Confining Pressures = 138KPa



(c) Confining Pressures = 276KPa

Figure 8. Stress (Pa) versus step (10^7). DEM simulation results of Sup13 mix under triaxial compression test at different confining pressures (That Is 0 KPa, 138 KPa and 276 KPa, from (a) to (c)).

of variables can be predicted with 3D discrete element simulations under cyclic loading conditions. For comparison with laboratory test result, the axial stress is obtained at two confining pressure levels (20 and 40 psi), while the peak stresses were 1.815 MPa and 2.166 MPa. Average values of the laboratory test are shown in Figure 7.

The virtual specimen is subjected to DEM triaxial compression at 0 KPa, 138 KPa and 276 KPa of confining compression. For the sake of brief, here just the results for the Sup13 specimens are presented. Other two types compacted mixes, have the same deformation. Figure 8 shows stress changes in each step. Under the stress-time curves, the change of aggregate-binder-aggregate contacts in virtual specimen is presented. It indicates that the deformation of DEM specimen was calculated under triaxial compression test at different confining pressures. It should be noted that the red dots represent aggregate-binder-aggregate contacts that being destroyed by extend stress, and the black represents aggregate-binder-aggregate contact being destroyed by compression stress. Results from Figures 7 and 8 show that the peak stresses obtained from of DEM simulation are in agreement with the results obtained from laboratory test.

Figure 9 shows the change of specimens before and after loading for DEM simulation and laboratory test. It is obvious that both DEM specimen and laboratory test specimen, in

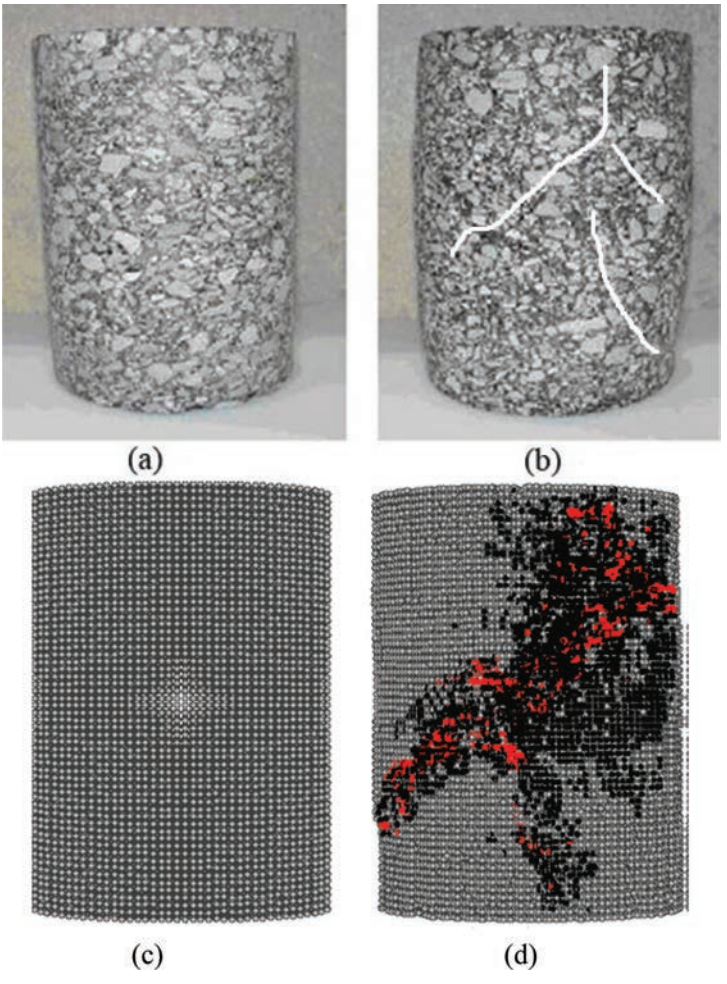


Figure 9. Specimens before and after loading for DEM and laboratory test. The original state of laboratory test specimen is shown in (a) Original state, and (b) The dilatancy state after loading; The original state of DEM specimen is shown in (c) Original state, and (d) Shows the dilatancy state after loading.

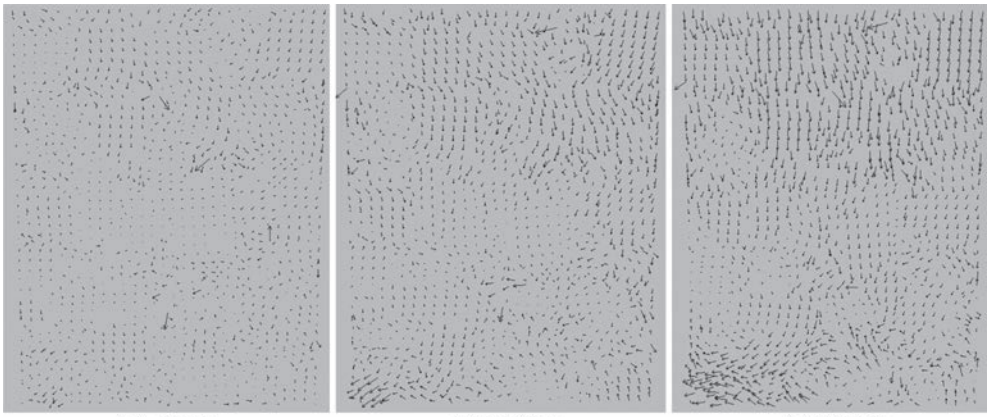

Figure 10. Displacement of digital specimen under 69 KPa, 138 KPa and 276 KPa confining pressures at the middle plane of sample.

original state didn't have the dilative behaviour, on the contrary, there was obvious dilatancy after the specimen was loaded. This result verifies the rationality of modeling processes. The shape change in the specimen also can be observed using simulation. Meanwhile, a shear band can be differed from the contact failure distribution zone. And the red dots represent the tension failure while the black dots represent the compression failure. This result indicates that the change or responses inside the specimen can be easily measured by means of testing the virtual specimen instead of the laboratory testing. A micromechanical analysis will be made by virtue of this advantage of the virtual test.

Figure 10 shows that the displacement plots are seen from the middle plane along the digital specimen height (Fig. 9d) under difference confining pressure. From Figure 10 we can see that the as larger confining pressure is applied to the sample the less dilation occurs. It is obvious that the dilative behaviour can be intuitively simulated by DEM. Therefore, DEM can simulate the dilation of asphalt mixture and it has a very good prospect in the pavement materials field although asphalt mixture has complex heterogeneous nature and mechanic characteristics.

6 CONCLUSIONS

It is important to understand the mechanism of dilation for asphalt pavement design, which helps to explain the rutting mechanism of asphalt pavement. This paper further studies the mechanism of dilation of asphalt mixture through analyzing the microstructure of asphalt mixture using DEM. Several conclusions are reached as following.

A microstructure model of asphalt mixture is established including irregular shape aggregate, asphalt binder mortar phase and air void phase. Digital samples are prepared with random generating algorithm represented by clump, and asphalt mastic is simplified as unit particles. Results show that the virtual specimen behaves similar to the actual specimen in triaxial compression test and has the correct volumetric proportions.

Statistical regression method is developed to capture varying air void distributions along pavement depth. Based on this method, the air void phase of virtual specimen was built, which is close to the real asphalt pavement.

In the mechanical model, Burger's viscoelastic contact model has been used in the DEM viscoelastic simulations. The parameter of Burgers was regressed under triaxial compression test to capture the microstructure parameters.

Based on the sieving mechanism analysis, an algorithm for coarse aggregate structure was developed. This algorithm can create irregular shapes based on a polyhedron unit.

By adjusting the orientations and lengths of the line segments, an aggregate with more variable irregular shapes can be obtained without changing its size.

The result of laboratory triaxial compression test was in good agreement with the result of DEM simulation. Both of these methods show that there was obvious dilation when the specimen was loaded. At the same time, the aggregate-binder-aggregate contact was fractured and formed a shear band.

A bit effective FISH code was developed to capture the microstructure response during loading, such as the aggregate-binder-aggregate contact. Therefore, the dilatancy behavior of asphalt mixture can be calculated by this method and the skeleton of aggregate can be captured.

Fatigue characters of asphalt multilayer surfacing system on steel bridge deck based on the five-point bending tests

Xueyan Liu, George Tzimiris, Tom Scarpas & Jinlong Li
Section of Road and Railway Engineering, Delft University of Technology, Delft, The Netherlands

ABSTRACT: Orthotropic steel deck bridges become popular the last decades due to lightweight and flexibility but then again several problems were reported in relation to asphalt surfacing materials such as rutting, cracking and loss of bond between the surfacing system and the steel deck. In The Netherlands a surfacing structure for orthotropic steel bridge decks mostly consists of five structural layers: top porous asphalt layer, guss asphalt layer, steel deck and two membrane layers.

The five-point bending (5PB) beam test is the standard device in France for characterization of fatigue response of asphalt concrete used on steel orthotropic deck bridges. In this investigation, the 5PB test was employed in order to evaluate the fatigue life of the asphalt multilayer structure on steel deck and also to evaluate the mechanical properties of both top and bottom membrane and the influence they have on the structure. Four membrane products were utilized as the top and bottom membrane layers in the 5PB beams. Furthermore, in the last part of this paper, the dissipated energy has been utilized to explain the incremental damage during the testing.

Keywords: Five-point bending beam test, orthotropic steel deck bridge, membrane, fatigue life, dissipated energy

1 INTRODUCTION

The world-wide reported distress problems between the surfacing layers and the Orthotropic Steel Deck Bridges (OSDB) indicate the need for further research on the interaction between them. The severity of the problem is enhanced by the considerable increase in traffic in terms of number of trucks and heavier wheel loads. Innovative methodologies offer opportunities to mitigate material response degradation and fatigue related problems in this type of structures contributing thus to significant extension of the service life of steel bridges [1].

The fatigue life assessment of OSDB hasn't yet been sufficiently investigated. The inspection results of orthotropic steel decks have shown that their working life can be shorter than other members of steel bridges due to fatigue [1], [2]. This means that particular details of orthotropic decks can be critical regarding the service life of a bridge.

Preliminary investigations have shown that the adhesive strength of the membrane between the surfacing layers and the decks of steel bridges has a strong influence on the structural response of OSDB. The most important requirement for the application of membrane materials on OSDB is that the membrane adhesive layer shall be able to provide sufficient bond to the surrounding materials.

Recently, the Transport Research Centre (DVS) of the Dutch Ministry of Transport, Public Works and Water Management (RWS) has initiated a research project for the evaluation of the performance of modern surfacing systems on steel deck bridges. The research project focuses mainly is on membrane performance and the effects hereof on the structure as a whole.

The Five Point Bending (5PB) beam test is a laboratory scale test that allows studying the fatigue resistance of surfacing layers on orthotropic bridge decks [1]. [3] in 1981 reported the most severe load case for surfacing layers of OSDB is when they are subjected to negative moments. The 5PB beam test has become a French standard test method (NF-P98-286, 2006) [1].

For the purposes of this paper 5PB beam tests were performed at TU Delft in order to understand if this type of test can be directly used to evaluate the performance of the multilayer asphalt surfacing system on OSDB and also to perform a laboratory scale test that would allow studying the fatigue resistance of surfacing layers on OSDB.

In the first part of this paper the experimental device of the 5PB, the test conditions and the instrumentation are described. In the second part, four membrane products ranked by the Membrane Adhesion Test (MAT) [4] were utilized as the top and bottom membrane layers in the 5PB beams. The results of the 5PB beam tests at two temperatures –5°C and +10°C are demonstrated. The results show that the in time deformation measurements are allowable to evaluate the fatigue response of the entire structure. The stiffness and the bonding characteristics of the intermediate membrane sheet as well as the wearing course behaviour seem to have great influence on the mechanical response of multilayer bridge surfacing system. The findings of the 5PB beam tests will assist the verification and the calibration of the finite element predictions and will allow for the further ranking of the best performance of the multilayer surfacing systems for Dutch OSDB.

Furthermore, in the last part of this paper, the fatigue damage in 5PB beam test is related to the amount of dissipated work computed by using the measurement of the actuator load and the loading plate deformation during the loading cycle. The dissipated work, which is equivalent to the lost part of the total potential energy of the beam, has been utilized to explain the incremental damage during the testing.

2 DESCRIPTION OF THE FIVE-POINT BENDING TEST

In order to assess the fatigue resistance of the multilayer asphalt surfacing system on OSDB, the French Five-Point Bending (5PB) beam test has been used. It was developed by the "Laboratoire Central des Ponts et Chausse´es" (LCPC) in the 70s, and its main advantage is the ability to safely represent the conditions on a real steel deck applying negative moments [5]. This occurs at the alignment of the stiffener web when each of the wheels of a double tyre is positioned at each side of the web Figure 1.

In The Netherlands, an asphaltic surfacing structure for OSDB mostly consists of two structural layers, Figure 1. The upper layer consists of Porous Asphalt (PA) for noise hindrance related reasons. For the lower layer, a choice between Mastic Asphalt (MA) and Guss Asphalt (GA), can be made [6]. Therefore, in order to study the fatigue response of the typical Dutch steel deck bridge, 5PB beam sample with the two wearing course bonded by two membrane sheets are investigated.

The 5PB beam sample consists of a 10 mm-thick steel plate, a 2 to 4 mm-thick bottom membrane, a 30 mm Guss asphalt layer, a 4.7~4.8 mm-thick top membrane and a 40 mm thick porous asphalt layer. The test samples is 100 mm wide, see Figure 2.

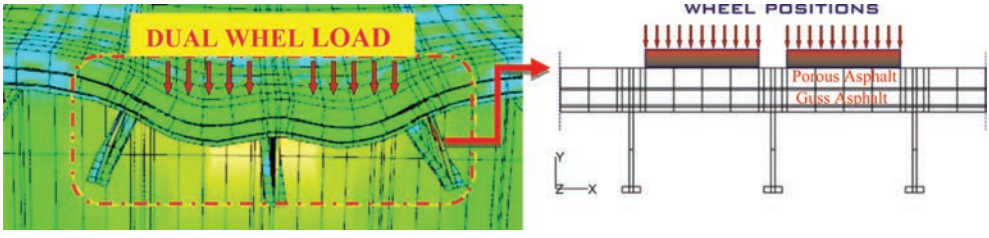

Figure 1. Schematic representation of the area of concern.

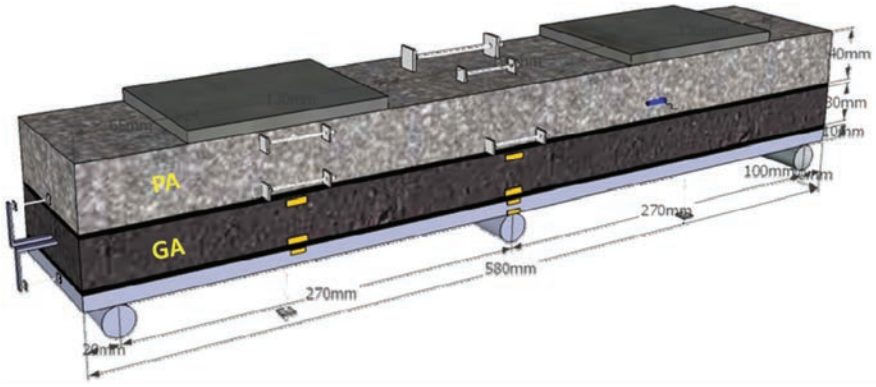

Figure 2. Specimen geometry and composition.

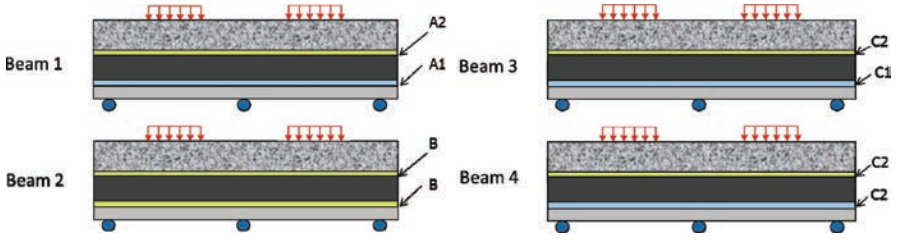

Figure 3. Four different types of specimen.

For the sample preparation a steel plate with 580 mm × 100 mm × 10 mm was used. Four different types of samples have been prepared, named as beam 1 bonded with membrane product A1 and A2 from company A, beam 2 bonded with membrane products B from company B, beam 3 bonded with membrane product C1 and C2 from company C and beam 4 bonded by membrane C2 from company C, see Figure 3.

2.1 *Experimental set up*

Both static and fatigue loading tests were performed under two temperatures ranges (–5°C and +10°C), Figure 4. The static loading tests were performed prior to the fatigue tests by using ramping load. The maximum ramp load is 18.4 kN and the ramp time to maximum load is 40 sec. For the fatigue tests, sinusoidal compression loading P ranging between F_{max} and $0.1 \times F_{max}$ at a frequency of 4 Hz was applied for two million cycles. In order to perform the tests under controlled temperature conditions, the set up was properly insulated and enclosed within a climate chamber.

The test samples are 100 mm wide and therefore each loading shoe print is 130 mm long and 100 mm wide. The pressure load applied on each shoe is 0.707 MPa. This load pressure corresponds to 9.2 kN on each shoe (0.707 MPa × 130 mm × 100 mm), which means a total of 18.4 kN were applied on the sample, see Figure 5. If the same load pressure is applied on a wheel print type B (double tyre 220 mm by 320 mm), it corresponds to 100 kN wheel load which is the typical truck load utilized in The Netherland.

2.2 *Tested membrane materials*

Product A1 and A2 are waterproof membranes manufactured with SBS elastomeric bitumen and internally reinforced with a non-woven polyester textile. These two products are implemented on concrete decks, steel decks, sand asphalt or asphalt concrete. Product A1 is

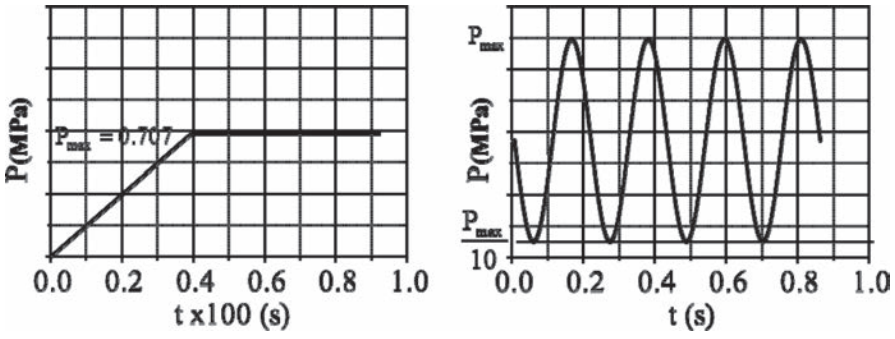

Figure 4. Static and dynamic loading scheme.

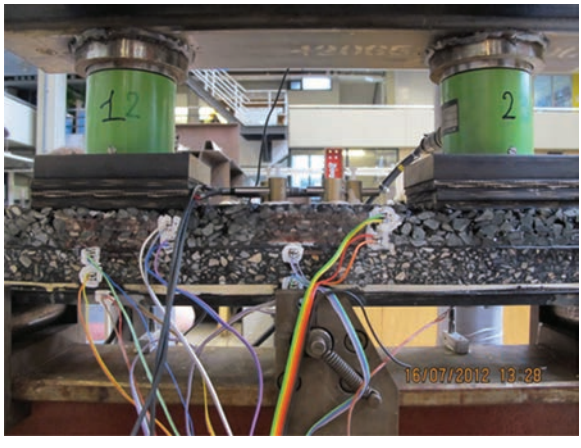

Figure 5. The five-point bending beam test set up.

applied on the steel plate, while product A2 is applied on the Guss aspahlt. Product A1 and A2 can be bonded to the prepared substrate by melting the film on the membrane surface and softening of the bitumen.

Another membrane product is manufactured by company B. This product B can be used as both bottom membrane and top membrane in steel bridge systems. Product B is used as moisture insulation layer on the surfacing system. This membrane is made of a high SBS modified isolation diaphragm which is reinforced with a strong support of polyester.

There are two types of membranes from company C. Product C1 is used only as bottom membrane, whist product C2 can be used both as top and bottom membranes in asphalt surfacing systems on a steel bridge decks. Product C1 is a 2.4 mm single-Ply membrane, with non-woven polyester fleece. This product is used for the single-play sealing under stone mastic asphalt, mastic asphalt or bituminous concrete.

Product C2 is a 4.7 mm single-Ply membrane with 1.5 mm strong fleece. This membrane is provided with a modified bituminous mass of 1.6 mm thickness on both sides. Product C2 is a waterproofing membrane for bridges, and it can provide high resistance to traffic.

3 RESULTS AND DISCUSSIONS

3.1 *Static tests*

The static tests were performed prior the fatigue tests until a maximum total load of 18.1 kN was reached, corresponding to a load pressure 0.707 MPa on each shoe The ramp time to

maximum load is 40 sec. The strains recorded by the strain gauges during the static test can be compared with the strain predictions from the FE simulations but also can give an indication about the integral response of the beam layers.

Figure 6 indicates the two cross sections where the strains have been recorded. Figures 7 and 8 show the transversal strains recorded during the static tests along the thickness of the tested beam. As it can be seen all tested beams produce higher strain values at 10°C rather than at –5°C. The influence of the temperature on the strain of the steel deck plate is not significant. Maximum tensile strain for all tested beams is recorded at the top face of the PA while maximum compressive strain at the bottom of the PA close to the top membrane.

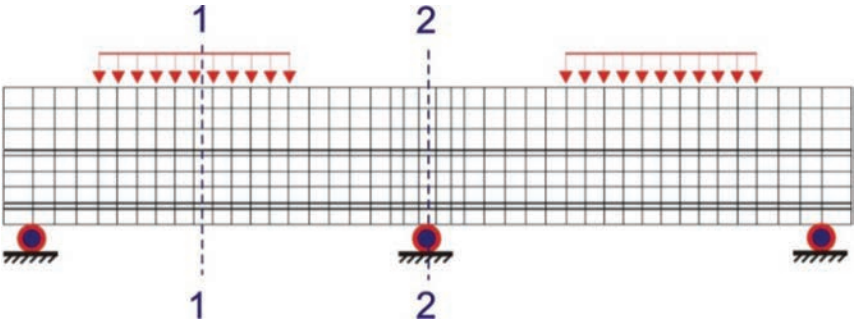

Figure 6. The area of concern.

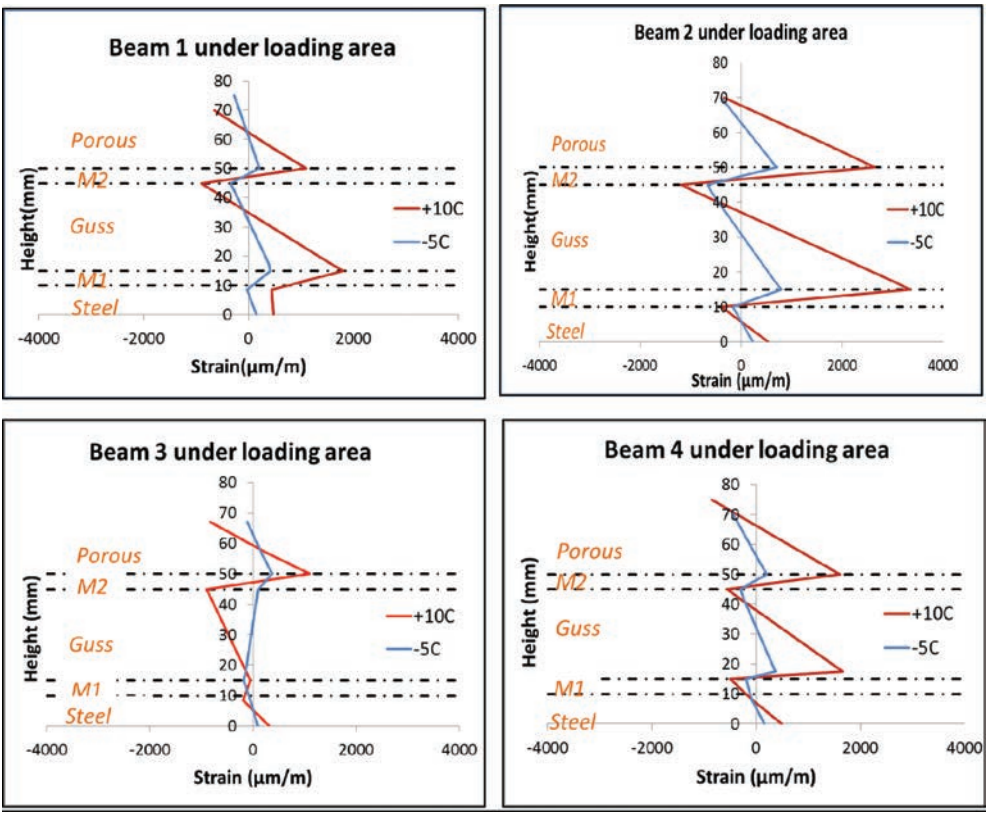

Figure 7. Strain distribution below the loading area, cross section 1-1.

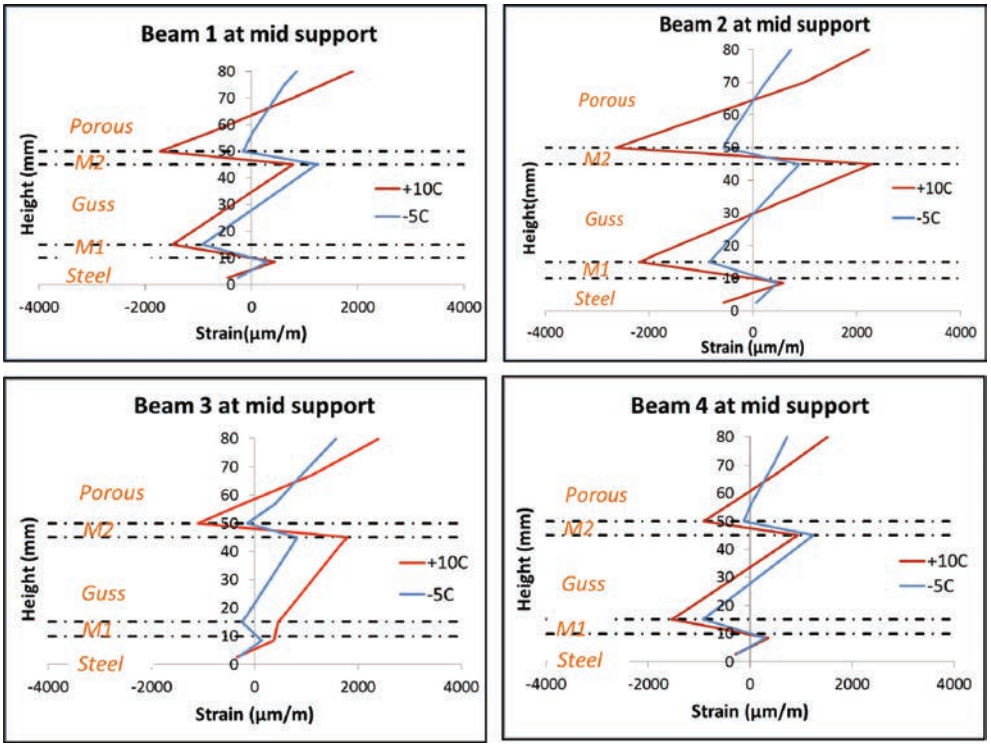

Figure 8. Strain distribution above the middle support, cross section 2-2.

3.1.1 *At cross section 1-1*

Beam 2 was found to be the most vulnerable one with higher strain amplitude compared with the rest of the tested beams at 10°C. High strain concentration was also recorded on beam 4 with high tensile strain at the bottom of GA at 10°C. Beam 3 was found to have the lower strain concentration especially at the area close to steel plate both at 10°C and −5°C. Finally, beam 1 has shown good response with low strain values particularly at −5°C.

3.1.2 *At cross section 2-2*

The same observation can be made at the location above the central support, Figure 7. Beam 2 was found to have higher strain both in compression and tension at 10°C. The influence of temperature is obvious for all cases. Beam 3 and 4 were found to be in the same range in term of the strain distribution. At −5°C, beam 3 was found to have the lowest strain values in GA. Beam 3 demonstrates a higher bonding effect between the GA and the steel plate both at −5°C and 10 °C.

3.2 *Fatigue tests*

Extensive effort was directed towards using dissipated work (energy) in the study of fatigue behaviour of asphalt concrete ([7], [8], [9]). The dissipated work approach has many advantages. For example, it is simple in principle and easy to use, requiring only the dissipated energy in each load cycle.

The dissipated work concept has been widely utilized for Four-Point Bending (4PB) beam test to characterize the fatigue life of asphalt concrete mixture. In most cases, the four-point bending beam consists of only one layer of the same mixture. Assuming that the deflection due to the shear is neglected in 4PB, this produces a uniform bending moment and zero-shear between the loading platen. The horizontal normal stress in the beam between the loading

platen can be directly computed by using the bending moment and the geometry of the beam and this results a simplified analysis.

The 5PB test is essential for the design of the asphalt layers on steel orthotropic decks: essential because the metallic structure is very flexible, and as a consequence, the asphalt concrete is submitted to very high levels of strains under traffic load as compared to asphalt on classic roads. The main advantage of 5PB test is the ability to safely represent the conditions on a real steel deck applying negative moments at the alignment of the stiffener web when each of the wheel of a double tyre is positioned at each side of the web. The disadvantage is that, due to the multi-surfacing layered structure and the presence of the middle support, the shear stress in the centre of the beam cannot be neglected. This makes the analysis become more complicated than the one required for the 4PB beam test. Also the fatigue damage can occur not only at asphalt concrete surfacing layers but also at the interface between the membrane bonding layers and the surfacing layers.

In this investigation, the fatigue damage of the 5PB beams is related to the amount of Dissipated Work (DW) computed by using the measurement of the actuator load and the loading plate deformation during the loading cycle. The dissipated work, which is equivalent to the lost part of the total potential energy of the beam, can be used to explain the incremental damage during the testing. The amount of dissipated work (energy) per loading cycle changes throughout the fatigue test. The average Ratio of Dissipated Work Change (RDWC) is used to relate damage accumulation in 5PB beams. The theoretical background of dissipated work can be found in [8], [10] and [11].

3.2.1 *Experimental results*

Under the controlled load mode of the 5PB tests, with a limited number of load cycles, the development of dissipated work in the four types of 5PB beams show two distinctive stages in Figure 9: (I) The dissipated work increases by decreasing the dissipated work reduction rate, (II) The dissipated work increases gradually with almost a constant slope (constant energy change rate). At higher temperature, under the same loading condition, all the tested beams show higher dissipated work than those at lower temperature. Since the value of the dissipated work can be used to explain the incremental damage during the testing, beam 3 bonded with membrane C1 and C2 shows less damages than the other three beams. The highest damage occurs for beam 2 bonded with membrane B at higher temperature.

In Figure 10, it can be observed that at both test temperatures the RDWC values for the four types of beam at two different temperatures are almost constant after 8000 load cycles. This proves that the second stage is reached (the plateau stage) where the plateau value can be found. This plateau value characterizes a period where a constant percentage of input energy is turned into beam damage. The analysis of the testing data indicates that such a plateau stage starts from approximately the 20% initial structure stiffness reduction until the 50% initial structure stiffness reduction. At higher temperature, the 5PB beams show higher RDWC values than those with lower temperature. Beam 3 with membrane product C1 and C2 at lower temperature shows almost no energy being turned into beam damage.

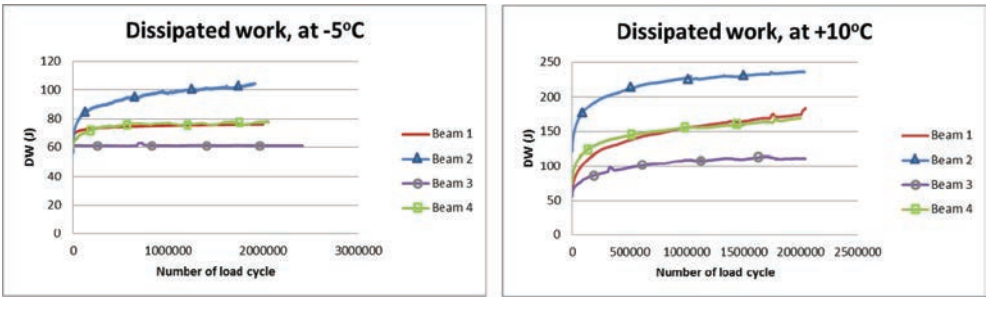

Figure 9. Comparison of dissipated work of 5PB beams.

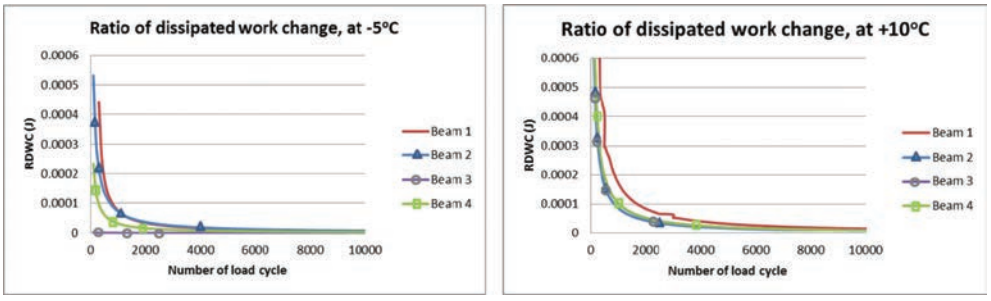

Figure 10. Comparison of ratio of dissipated work change of 5PB beams.

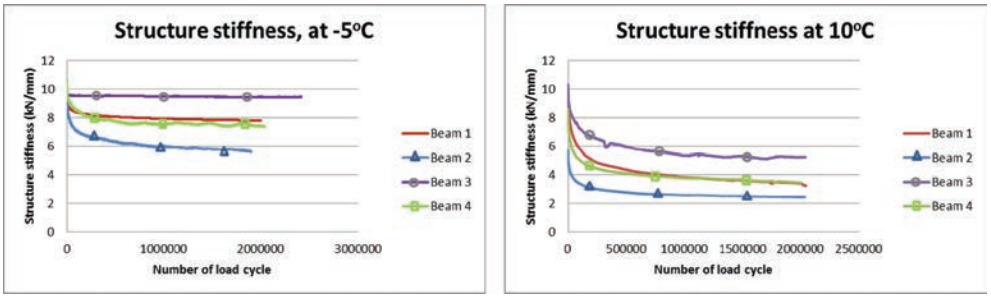

Figure 11. Comparison of structure stiffness in four types of 5PB beams.

Table 1. Comparison of fatigue life of 5PB beams at temperature of 10°C.

Failure criterion	Nf_{50}	DW (J)	RDWC (J)
Beam 1	300000	126.95	5.35e-07
Beam 2	260000	197.91	3.65e-07
Beam 3	2000000	114.52	5.83e-08
Beam 4	350000	137.69	3.25e-07

In this study, similar as the traditional failure definition, the structure stiffness of the 5PB beam is used instead of the material complex modulus. Figure 11 shows the decreasing structure stiffness of the 5PB beam with increasing number of load cycles. The structure stiffness of the 5PB beam is calculated by dividing the total measured actuator load over the load platen deformation during the loading cycle. It can be observed that temperature has important effects on the structure stiffness of the 5PB beams. At higher temperatures, the asphalt concrete layers together with its membrane layers become more flexible. The structure stiffness of the 5PB beam decreases faster at higher temperatures than at lower temperatures.

By a reasonable extrapolation of the testing data, Tables 1 and 2 show the cycles to failure of the 5PB beams with four types of membrane products at 10°C and –5°C respectively. The corresponding values of DW and RDWC at failure are also presented in these tables. It is noticed that using the traditional stiffness approach the predicted fatigue life of the 5PB beam varies from approximately 260,000 to 2 million load repetitions at the temperature of 10°C. Greater load repetitions are predicted for 5PB beam tested at –5°C.

By comparing Figure 9 to 11 along with the data presented in Tables 1 and 2, it can be observed that beam 3 bonded with membrane products C1 and C2 performs better than beams bonded with other membrane types at the two different testing temperatures, proving

Table 2. Comparison of fatigue life of 5PB beams at temperature of −5°C.

Failure criterion	Nf_{50}	DW (J)	RDWC (J)
Beam 1	2.5e+12	97.34	2.47e-14
Beam 2	6.0e+06	112.22	1.34e-08
Beam 3	1.0e+100	65.4	1.2e-102
Beam 4	1.0e+10	103.36	4.03e-12

that this is the best performing mult-surface layer system for the Dutch orthotropic steel deck bridges.

4 CONCLUSIONS

The main findings that can be drawn from the results presented in this paper are summarized as follows:

- The Five-Point Bending (5PB) beam test is a good tool for the study of the composite behavior of multilayer surfacing systems on orthotropic steel deck bridges.
- The response of the 5PB beam with different surfacing systems differs significantly with temperature due to the high temperature sensitivity of the asphaltic materials and the membranes.
- The results of the 5PB beam tests can be utilized for calibration and validation of the finite element tools and allow additional insight into the overall ranking of multilayer surfacing systems.
- 5PB beam 3 with membrane products C1 and C2 has shown the longer fatigue life in comparison to the other three beams with different surfacing systems. Beam 1 and 4 can be recommend as a second option.
- The concept of dissipated energy/work provides a means to quickly estimate the fatigue life of laboratory 5PB fatigue tests. The procedure introduced in this paper presents a simple method of fatigue behaviour analysis at different temperatures based on an energy approach.

ORLEN Asfalt Sp. z o.o., Plock, Poland

ABSTRACT: The key factor in asphalt pavement durability, especially in the presence of water, is adhesion of the bituminous binder to mineral aggregates. There are currently no standard laboratory test procedures that can quickly and accurately measure the strength of the interaction (bond) between the binder and aggregate. In this regard, to evaluate the adhesion force measurements based on the contact angle between the binder and the aggregate by goniometric method were conducted. Contact angles at the mineral-binder-air interface were measured using a high temperature contact angle goniometer by a sessile drop technique. The influence of five adhesion promoters at different temperature (40 to 200°C, 104 to 392°F) for two minerals, granite and limestone, has been investigated. The road binder 35/50 (pen@25°C or @77°F) was used as the bituminous phase. Obtained results show that for granite, for nearly all used promoters, adhesion is better than for pure binder. In case of limestone, the difference of measured contact angles between pure binder and binder with additives is not evident and one can say that activity of some promoters is neutral or adhesion could be even worse. The results of contact angle tests at the full range of temperature can be used also for adhesion assessment for Warm Mix Asphalt (WMA) technologies.

Keywords: binder, aggregate, adhesion, contact angle

1 INTRODUCTION

The key factor in asphalt pavement durability, especially in the presence of water, is adhesion of the bituminous binder to mineral aggregates. However, the important role of adhesion between binder and aggregate has been recognized for almost one hundred years (Nicholson, V. 1932), but still no standard laboratory test procedures, that can quickly and accurately measure or estimate the strength of the interaction (bond) between the binder and aggregate.

In the recent studies it has been well documented that the work of adhesion between binder and aggregate is an important parameter determining the resistance of asphalt mixtures to fatigue cracking and moisture-induced damage. Many methods and techniques were used to determine the adhesive bond strength between aggregate and bituminous binder [2, 3, 9, 10]. Hefer et al. [1, 7] determined the surface free energy of binders and aggregates individually using the contact angle method using the Wilhelmy plate device.

Already in the seventies Ensley and Scholz [4, 5, 6] measured the work of adhesion between the binder and the aggregate using a microcalorimeter.

Also many estimations of surface free energy of aggregates were computed using the acid-base theory [12, 13] or were determined using the vapor adsorption method with a Universal Sorption Device (USD) manufactured by Rubotherm of Germany.

All of these methods are time consuming and require expensive test equipment. Therefore we evaluated the adhesion force by measuring the contact angle between the binder and the aggregate with goniometric method. Contact angles at the mineral-binder-air interface were measured using a high temperature contact angle goniometer by a sessile drop technic [8].

For testing the road binder paving grade 35/50 acc. to European Standard EN 12591 was used. This type of binder is usually used for building lower layers of road pavement structures, i.e. binder courses and asphalt bases. As an aggregate (mineral) material two types of rock were used: limestone and granite, representing different types of rock in respect of silica dioxide (SiO_2) content.

2 EXPERIMENTAL

2.1 *Fine binder spherical particles preparation*

The road binder paving grade 35/50 (range of needle penetration @25°C or @77°F, acc. to EN 1426), detailed properties of which are presented in Table 1, was used as the bituminous phase in the contact angle measurements. The binder samples with mass between 80 to 100 g were heated to 105°C (221°F) and the commercially available adhesive promoters were added and continuously mixed. The concentration of additives was 0.50 ± 0.01% by mass. The chemical composition of additives is presented in Table 2. In the next step the mixtures were heated to 170°C (338°F) and intensively mixed for 5 min with a rotational speed of 500 min^{-1}.

After mixture preparation, spherical binder particles were formed by rolling a small quantity of binder between two stainless steel plates at ambient temperature (about 20°C, 68°F). The range of binder particle size was from 0.5 mm to 1 mm. The spherical shapes of the binder particles were then checked by analyzing photos made with digital camera of particles in the Image Tools software to ensure that shapes are correct.

2.2 *Mineral aggregate samples preparation*

Mineral aggregates (granite and limestone grains 8–11 mm fraction), were crushed to an average particle size of 5–8 mm. Few particles with cubic shapes of the aggregate were dry ground using several abrasive materials with decreasing granulation (180, 220 mesh), then were wet ground with granulation 400, 500, 600, 800, 1000 mesh. The time period of polishing for each granulation was 5 min. Following this the polished aggregate samples were washed in an ultrasonic bath and examined in detail under an optical microscope for surface defects and scratches. Selected aggregate samples were boiled in distilled water for 20 min, and were

washed with acetone and dried at 105°C (221°F). The aim of the polishing of aggregates was to obtain a flat surface of the grain's face and eliminate the influence of mechanical adhesion on the contact angle measurements. The surface should be without any defects which can influence on the binder's wetting power.

2.3 *Contact angle measurement*

The polished and cleaned aggregates sample was glued to the measuring goniometer table and, using the optical system within the goniometer, the level was adjusted until horizontal. The prepared spherical sample of binder was carefully placed on the polished surface of the aggregates and the whole sample was placed in the goniometer heated chamber. The sample was heated at 2°C/min (35.6°F/min). When adjusted temperature was reached the photo of the sample has been taken after the period of time shown in Table 3. Different periods of time needed to reach contact angle equilibrium comes from viscosities of the binder at specified temperatures (earlier evaluated). The schematic diagram of contact angle measurement system is shown on Figure 1, photo of the system on Figure 2.

The contrast and brightness of obtained digital pictures were corrected. Using Image Tools software the binder drops shape were approximated by circle as is shown on Figure 3. Next, the line representing interfacial surface area between aggregate and binder drop was set. The contact angle calculation was performed using following equations:

$$\theta = \arccos(2R/d) \tag{1}$$

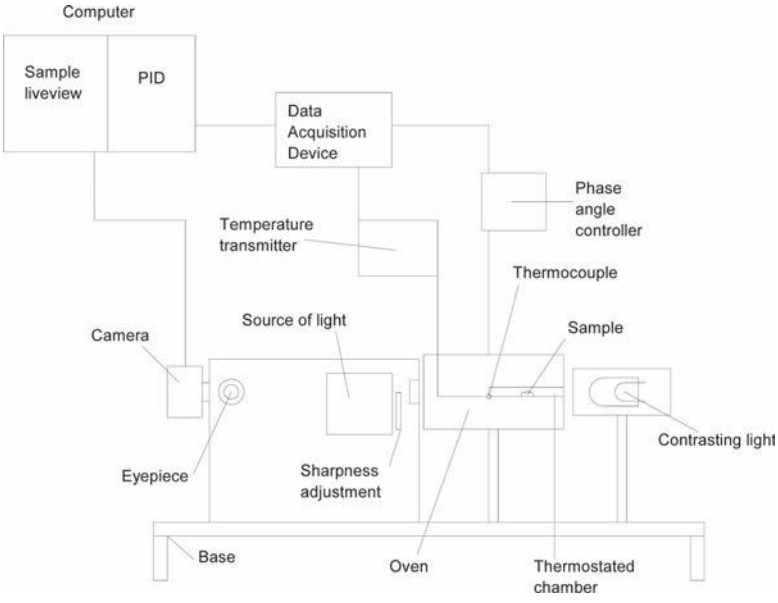

Figure 1. Schematic diagram of contact angle measurement system.

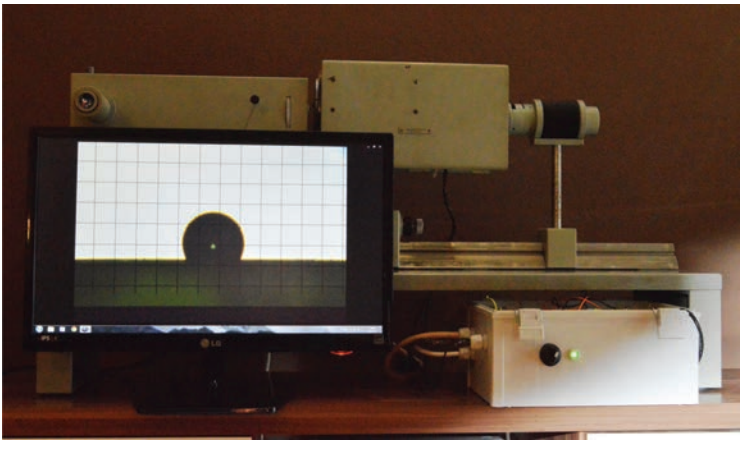

Figure 2. Photo of contact angle measurement system.

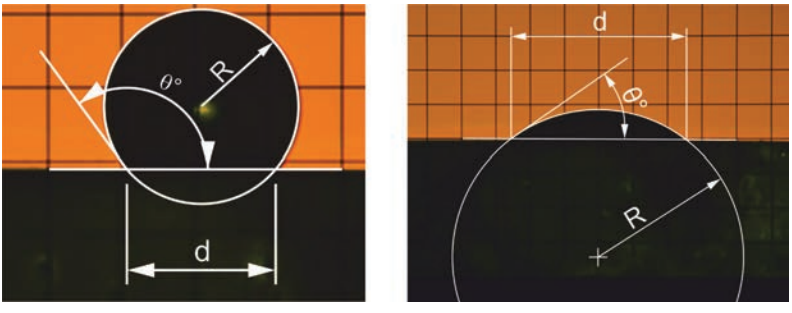

Figure 3. The examples of contact angle measurements methodology.

When the $\theta > 90°$ the contact angle was calculated from Eq. (2).

$$\theta = \arccos(2R/d) + \pi/2 \tag{2}$$

where:

R—radius of circle

d—length of circle diameter of interfacial surface area between aggregate and binder drop.

3 RESULTS

The results of wettability of granite and limestone by unmodified asphalt binder 35/50 are very similar at low temperature ranges (up to 120°C, 248°F). The contact angle was higher than 10 deg in both minerals. In the temperature range 120–200°C (248–392°F) it is clearly evident that the wettability of limestone by bituminous is better than granite (Fig. 4).

The modification of asphalt binder with commercially available additive based on fatty amines (with code A) improved the wettability of the minerals (granite and limestone) especially at higher temperature ranges. The decreasing of the contact angle is much more evident for granite than for limestone which was expected. The repulsive force caused by the hydroxyl group on granite surface is neutralized by the fatty amines, and therefore make the granite surface more hydrophobic (Fig. 5).

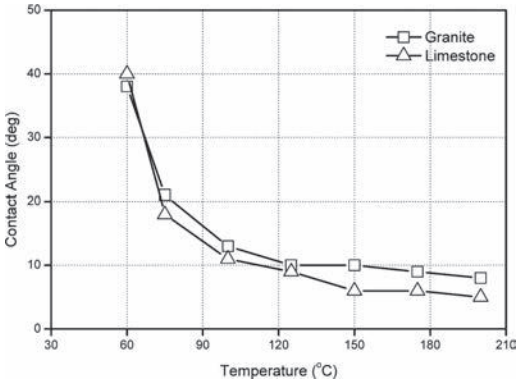

Figure 4. Contact angle of unmodified binder on granite and limestone vs. temperature.

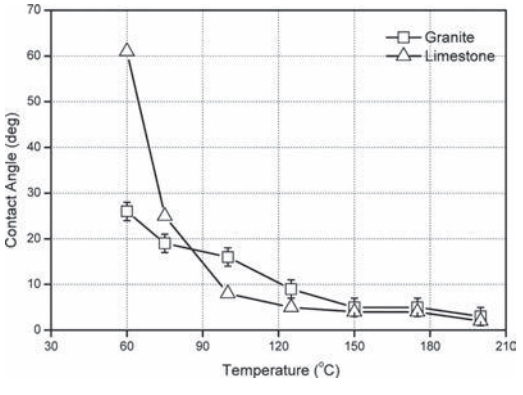

Figure 5. Contact angle of binder modified by A adhesion promoter on granite and limestone vs. temperature.

The opposite effect was observed for asphalt binder modified by additive based on phosphonic acid and its esters mixed with ethoxylated fatty alcohol (code B). Increase of the contact angle was evident for granite samples especially at high temperature ranges and is larger than for unmodified binder.

Alkaline additives containing amidoamine, ethylene amine and glycerol increased the wettability of limestone by asphalt binder significantly (Fig. 7). In the case of granite the contact

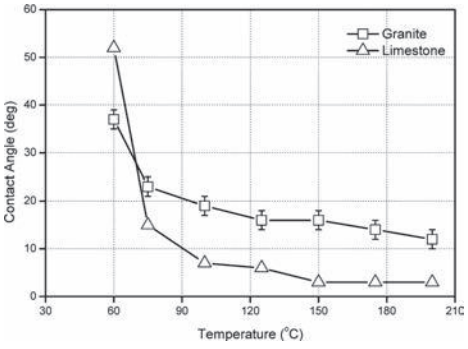

Figure 6. Contact angle of binder modified by B adhesion promoter on granite and limestone vs. temperature.

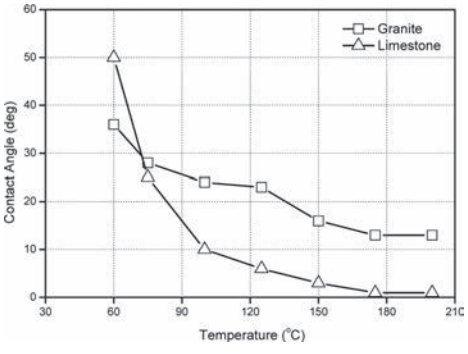

Figure 7. Contact angle of binder modified by C adhesion promoter on granite and limestone vs. temperature.

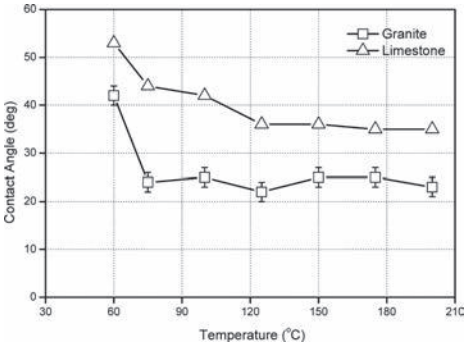

Figure 8. Contact angle of binder modified by E adhesion promoter on granite and limestone vs. temperature.

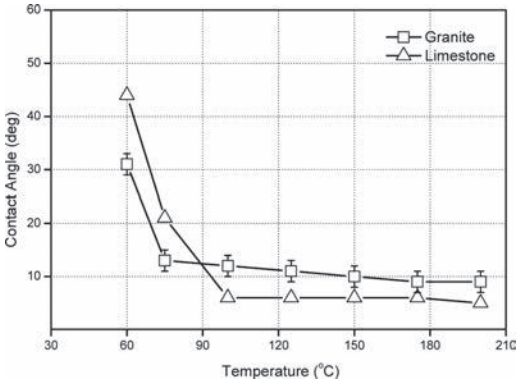

Figure 9. Contact angle of binder modified by D adhesion promoter on granite and limestone vs. temperature.

angle does not change at lower temperature ranges but increased above 120°C (248°F) in comparison to unmodified binder. The same effect was observed for additive D (Fig. 9).

The worst result is observed for pure octylphosphonic acid (Fig. 8), which in both cases (granite and limestone) decreased the wettability by asphalt binder dramatically.

4 CONCLUSIONS

We have developed here a fast low cost technique using the sessile drop. Contact angle measurement by sessile drop can be used to select the most compatible bitumen for a specific aggregate type. The system of contact angle measurements by a sessile drop technique is not so complicated as other techniques and consumes less time and doesn't need high qualified personnel.

Results of granite wettability by modified bitumen show that all based commercial additive except C decreasing contact angle and all acid modifiers increase contact angle, especially one with code E containing octylphosphonic acid.

The smallest contact angle was observed for bitumen modified by amine additives and limestone aggregates especially for A additives.

The worst results of limestone and granite wettability were observed for additives containing octylphosphonic acid. The contact angle decrease was five times higher than for unmodified bitumen. In case of limestone the influence of additives on wettability by asphalt binder much less evident except E modifier.

ABSTRACT: Low temperature cracking of asphalt pavements is a major distress in cold climates. Asphalt mixture strength is a fundamental parameter when designing pavements with increased durability. At low temperatures, asphalt mixtures have quasibrittle behavior with nominal strength strongly dependent on the structure size. In this paper, a simple method to relate the probability distribution function of strength of quasibrittle materials to the mean strength size effect is proposed. This is based on the finite weakest link model, which relates the cumulative distribution function of structural strength to the size dependence of the mean strength curve. A comprehensive experimental set of tests, which includes both mean size effect tests and strength histograms on specimens of asphalt mixture at low temperature, is used to verify the proposed method. The predicted mean strength curve obtained with this method is found to be in very good agreement with the experimental measurements on asphalt mixture specimens of different sizes, providing evidence of the validity of the proposed formulation. In the meanwhile, the effect of the size of the asphalt mixture Representative Volume Element (RVE) on the strength size effect prediction is also evaluated.

Keywords: Strength statistics, histogram testing, scaling, weakest link model

1 INTRODUCTION

Cracking due to low-temperature stresses is a prominent failure mode in asphalt pavements built in cold climates. Therefore, good strength properties are an essential requirement for asphalt mixture used in cold regions. The Indirect Tensile test (IDT) [1] is currently used for measuring strength on cylindrical specimens of asphalt mixtures. In the past different authors [2,3] demonstrated that IDT test presents non-unique strength size effect, which significantly limits the extrapolation of IDT experimental strength results to larger specimen sizes. At low temperatures, asphalt mixture exhibits quasibrittle behavior [4], and for this type of material size effect can be very significant. Therefore, strength size effect needs to be understood, especially when the field performance of asphalt pavement has to be predicted.

Quasibrittle materials, such as concrete, ceramics and asphalt mixture, are brittle heterogeneous materials characterized by inhomogeneities having dimensions not negligible compared to the structure size [5]. For structures made of quasibrittle materials, and without any pre-existing notches (indentations) or stress-free (fatigued) cracks, the associated size effect on structural strength can be described by the, so-called, Type-I size effect. This type of size effect is generally applicable to quasibrittle structures that fail at macro-crack initiation from one Representative Volume Element (RVE), which represents the smallest volume of material containing enough statistical information about the specific material property, in this case strength. Type I size effect is typical of flexural failure, for which the depth of the microcracking layer, where stress redistribution and energy release occur before the formation of a

macrocrack, is comparable to the RVE size. For small structures, this results into an energetic size effect while, for larger structures, the randomness of the materials leads to a statistics size effect [6]. For small and intermediate-size structures, Type-I size effect can be derived from the equivalent linear elastic fracture mechanics, where the distributed damage zone is replaced by a sharp crack [5,6]. The size effect at the large-size limit can be purely described by the classical Weibull statistics.

The size dependence of strength (Type I) for quasibrittle materials can be also obtained with finite Weakest Link Model (WLM) [5,6]. Due to the non-negligible dimension of the RVE, the structure is statistically modeled as a finite chain of RVEs, where the strength distribution of one RVE is obtained through multi-scale transition models and atomistic fracture mechanics [6]. Based on this theoretical framework, the cumulative distribution function (cdf) of the RVE strength is described by a Weibull distribution grafted on the left of a Gaussian cdf [5,6]. Therefore, the failure cdf of the RVE has to be known for obtaining the strength cdf and the mean strength of the entire structure. The RVE cdf can be obtained through strength histogram testing: strength tests are performed on a single-size specimen over a large number of replicates. Results can be analyzed on the Weibull scale [6] to identify the type of failure distribution (brittle, quasibrittle, ductile), and, hence, used to predict the strength size effect with the WLM.

This paper proposes a simple method to determine the mean strength size effect curve of asphalt mixture at low temperature. This approach is based on the WLM and on histogram strength testing of single-size beams in three-point bend configuration. The strength prediction is experimentally validated by further histogram testing on a smaller beam size and by mean strength tests on specimens of different sizes and geometry. The effect of RVE size on the strength cdf and on the prediction of the mean strength curve is also discussed.

2 THEORETICAL BACKGROUND

According to the finite WLM a structure can be modeled as a finite chain of RVEs having failure probability P_1. Assuming the statistical independence of the random RVE strengths and based on the joint probability theorem, the failure probability of the entire structure P_f can be computed as [6]:

$$P_f(\sigma_N) = 1 - \prod_{i=1}^{N} \left[1 - P_1(s_i \sigma_N)\right] \tag{1}$$

where P_1 is the cdf of strength of one RVE having characteristic size l_0, $\sigma_N = cP_{max}/bD$ is the nominal strength of the structure, P_{max} is the maximum load at failure, D is the structure characteristic size (scaling dimension), b is the third dimension of the structure, c is a constant and s_i is the field of the dimensionless maximum principal stress at the center of ith RVE.

It has been recently demonstrated that the failure cdf of one RVE can be approximated by a Gaussian cdf (core) with a Weibull distribution grafted on its left tail within a probability range of 10^{-4}–10^{-2} [5,6]. The grafted cdf of strength of one RVE can be mathematically expressed as:

$$P_1(\sigma) = 1 - \exp[-(\sigma/s_0)^m] \approx \langle \sigma/s_0 \rangle^m \quad (\sigma_N \le \sigma_{gr}) \tag{2}$$

$$P_1(\sigma) = P_{gr} + \frac{r_f}{\delta_G \sqrt{2\pi}} \int_{\sigma_{gr}}^{\sigma_N} \exp\left\{-\left[\frac{(\sigma' - \mu_G)^2}{2\delta_G^2}\right]\right\} d\sigma' \quad (\sigma_N > \sigma_{gr}) \tag{3}$$

where σ is the maximum elastic principal stress at the center of the RVE, s_0 is the scale parameter of the Weibull tail, m is the Weibull modulus (material constant), $\langle x \rangle = \max(x, 0)$, μ_G and δ_G are the mean and the standard deviation of the Gaussian core. $P_{gr} \approx (\sigma_{gr}/s_0)^m$ is the grafting probability between the Gaussian and the Weibull parts of the distribution, σ_{gr} is the grafting

stress and r_f is a scaling factor ensuring that Weibull-Gaussian grafted cdf is normalized: $P_1(\sigma \to \infty) = 1$. The continuity of the probability density function (pdf), $p_1(\sigma) = \mathrm{d}P_1(\sigma)/\mathrm{d}\sigma$, of the grafted distribution requires $p_1(\sigma_{gr}^{+}) = p_1(\sigma_{gr}^{-})$. Based on Eqs. (2,3), six statistical parameters, μ_G, δ_G, m, s_0, r_f and σ_{gr} are used to describe the failure distribution of one material RVE, $P_1(\sigma)$; however, with the normalization and continuity conditions, only four parameters are independent and, thus, fully define the RVE strength cdf.

The weakest link model, Eq.(1), together with Eqs. (2,3) can be used to calculate the strength distribution of the entire structure, which consists of two parts: a Weibull distribution up to the grafting stress followed by a distribution given by a chain of Gaussian elements. As the structure size increases the Weibull cdf extends into the Gaussian part eventually becoming completely dominant. From the strength cdf of one RVE, the mean structural strength for structures of different sizes can be obtained according to equation Eq. (4):

$$\bar{\sigma}_N = \int_0^1 \sigma_N \mathrm{d}P_f = \int_0^\infty [1\text{-}P_f(\sigma_N)]\mathrm{d}\sigma_N \tag{4}$$

However, a closed form does not exist for Eq.(4), and the effect of structure size, D, on the mean strength of geometrically similar specimens has to be determined numerically. Based on asymptotic matching, Bažant and co-workers [6,7] proposed an approximate expression for the size dependence of the mean strength:

$$\bar{\sigma}_N = \left[\frac{C_1}{D} + \left(\frac{C_2}{D}\right)^{rn/m}\right]^{1/r} \tag{5}$$

where C_1, C_2, and r are constant to be calibrated, m is the Weibull modulus, n is the number of dimensions to be scaled (n = 1, 2 and 3). C_1, C_2, and r can be determined using the following asymptotic conditions for small and large-size domains $[\bar{\sigma}_N]_{D\to l_m}$, $[d\bar{\sigma}_N/dD]_{D\to l_m}$ and $[\bar{\sigma}_N/D^{n/m}]_{D\to\infty}$, where l_m is the smallest structure size used in the scaling.

3 MATERIALS AND TESTING

In the experimental investigation, the asphalt mixture was prepared using a PG 64-34 asphalt binder (7.4% by weight) and a blend of taconite aggregates (55% of MIN TAC tailings and 10% of ISPAT tailings) and pit sand (35%). The Nominal Maximum Aggregate (NMAS) Size was 4.75 mm. Recently it was found that, for quasibrittle materials, the RVE size is about 2–3 times the size of the material inhomogeneities [5]. Based on sieve size analysis, the dimension of the asphalt mixture RVE was estimated as double of the size of the material inhomogeneities, which corresponds to the average aggregate size [4]. For the specific asphalt mixture used in this study, an average aggregate size of 1.22 mm and an RVE volume of $V_0 = 14.4$ mm^3 were estimated.

Four parameters are necessary to describe the entire RVE strength distributions: these can be conveniently chosen to be μ_G and δ_G, for the Gaussian cdf core and m and s_0, for the Weibull tail. Histogram strength testing can be performed to obtain these statistical parameters [5] and next used to predict the mean strength curve. Therefore, a comprehensive set of tests, consisting of both histogram strength testing on beam specimens in three-point bend (3PB), and mean strength on both three-point bend beams and Direct Tension (DT) prisms, were performed at low temperature. Table 1 presents a summary of the specimens details, while Figure 1 shows the four types of specimens used.

Specimens were obtained from twenty-six slabs of asphalt mixture (size 380 mm by 200 mm) compacted by mean of a Linear Kneading Compactor (LKC) at target air voids of 7%. Asphalt mixture beams for three-point bend tests were prepared with 1:$\sqrt{3}$:3 size ratio and thickness to span ratio equal to 1:6; since 2D scaling was selected for the beam specimens and to maximize the use the compacted slabs, a constant width b = 40 mm was imposed. DT specimens were also prepared by cutting one-size asphalt mixture prisms (Table 1). The width of the prism and thickness, D, of the beams were set as scaling dimensions of the DT and

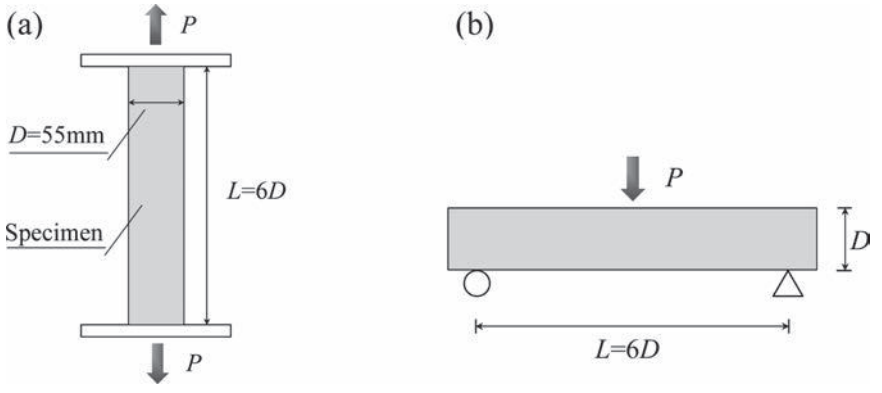

Figure 2. (a) Direct tension strength tests and (b) three-point bend.

three-point bend specimens respectively (Figure 2a and 2b). The overall dimensions of the specimens were chosen based on the dimensions of the compacted slabs and on the limitation imposed by the climatic chamber and loading frame.

Three-point strength histogram tests were first performed on the larger single-size beam specimens (Specimen C in Table 1) to determine the four parameters (m, s_0, μ_G and δ_G) of the RVE cdf. Based on the WLM the obtained RVE parameters were verified with a second strength histogram performed on beams with smaller size (Specimen B in Table 1). Mean strength tests were also run on specimens of different size and geometry (Table 1) to experimentally verify the mean strength curve predicted with the WLM. This is because the size of the three-point bend specimens was limited by the dimensions of the climatic chamber. Therefore, DT tests were selected as alternative test type to achieve a sufficiently large range of sizes to fully verify the ductile-to-brittle transition of material behavior as structure size

increases (Table 1 and Figure 2a). DT tests were performed by gluing the specimens to a set of plates with an epoxy compound, and then attached to loading frame through a set of screws.

Such an approach was used because by varying geometry and test type both failure probability and stress field change; given the same mean strength, it is possible to convert the dimensions of a structure for a specific geometry and stress field into a structure with different geometry and stress field [5]. In this study, the DT specimen was chosen to have the largest possible size that could fit into the climatic chamber to maximize the number of RVEs in the specimen so that the strength cdf of DT specimen would follow the two-parameter Weibull distribution. By doing so, a closed-form expression for calculating the equivalent size of the three-point bend beam can be easily developed. In order to reduce the viscoelastic effect of the binder component, testing temperature was set to $T = -24°C$ (low PG + 10°C) and tests duration was kept sufficiently short in order to avoid significant relaxation effects. The desired testing temperature was achieved through a controlled flow of nitrogen inside the climatic chamber of the servo-hydraulic machine used for testing; a conditioning time of three hours was imposed to all the type of specimens (3PB and DT) before testing.

Both 3PB and DT tests were conducted in load-control mode since only the peak load was of interest for this study. A time to failure of about 5 minutes was set for all the specimens with the aim of achieving a similar loading rate for the Fracture Process Zone (FPZ). Different authors in the past [8,9] used this loading procedure to limit the rate dependence of the FPZ. Therefore, different loading rates were used for different specimen sizes and geometries. Before the actual tests, several preliminary tests were performed to determine the loading rate for each specimen geometry and size.

4 SIZE EFFECT ANALYSIS

The nominal strength of three-point bend and direct tension was calculated as:

$$\sigma_N^B = \frac{3P_{\max}L}{2bD^2} \quad \text{and} \quad \sigma_N^T = \frac{P_{\max}}{bD} \tag{6}$$

where $P_{\max}$ is the peak load, L is the length of the beam, D is the scaling dimension (the thickness of the beam or the width of the DT prism) and b is the width of the beam for three-point bend (40 mm) or the depth of the prism (55 mm) for DT specimens.

In order to evaluate the size dependence of the mean nominal strength, the results obtained from the DT mean strength need to be converted into the corresponding equivalent 3PB beam. The DT prisms has a volume of 756,000 mm^3 (Table 1), which consists of almost 5.25×10^4 RVEs ($V_0 = 14.4$ mm^3). Given such a large number of RVEs, the strength cdf of DT specimens must follow the two-parameter (m, s_0) Weibull distribution [3, 5]. Therefore, the mean strength of DT, $\bar{\sigma}_N^T$, can be written as:

$$\bar{\sigma}_N^T = N_T^{-1/m} s_0 \Gamma\left(1 + \frac{1}{m}\right) \tag{7}$$

where N_T is the number of RVEs in the direct tension specimen. The mean strength of the 3PB beam, $\bar{\sigma}_N^B$, can be written as:

$$\bar{\sigma}_N^B = N_{eq,B}^{-1/m} s_0 \Gamma\left(1 + \frac{1}{m}\right) \tag{8}$$

where $N_{eq,B}$ is the equivalent number of RVEs [5] of the beam, which can be calculated based on the elastic stress distribution:

$$N_{eq,B} = \frac{b}{l_0^3} \int_V [(\sigma(\mathrm{x}) / \sigma_N^B)]^m \, \mathrm{d}V(\mathrm{x}) \tag{9}$$

where V is the volume of the beam. Based on Eqs. (7–9), it is possible to convert the DT specimen to the equivalent three-point bend beam by equating $\bar{\sigma}_N^T$ to $\bar{\sigma}_N^B$, which gives the equivalent depth of the three-point bend beam:

$$D_{eq} = \sqrt{\frac{(m+1)^2 N_T V_0}{3b}} \tag{10}$$

The Weiubll modulus, m, is the only unknown parameter in Eq. (10); together with s_0, μ_G and δ_G, it defines the failure cdf of one RVE. This set of four parameters can be obtained by fitting the WLM and the grafted RVE cdf, Eqs. (1–3), to the experimental strength histogram which, on the Weibull scale, consists of a low straight line (i.e. a Weibull distribution) and an upper curved part. At structure level the Weibull component of the failure distribution becomes more and more significant as the structure size increases. Therefore, in order to reduce the error in the estimation of the Weibull modulus m, and, hence, of the remaining statistical parameters of the RVE cdf, the WLM was fitted to the strength histogram of the larger beam series (beam C in Table 1). The experimental strength failure distribution and histogram plots of beams series B and C were obtained by first ranking the strength values in ascending order, $p = 1 \ldots N_t$, where p is the rank and N_t is the total number of tested specimens. Based on the midpoint position method [10] the strength cdf was calculated as $P_f(\sigma_N^B) = (p - 0.5)/N_t$.

Figure 3 shows the measured strength histograms on the Weibull scale (square and round markers). It is seen that the lower portion of the histograms follows a straight line with similar slope governed by the Weibull modulus, while the upper portion exhibits a clear nonlinearity given by a chain of Gaussian elements. Such a two-segment strength cdf has also been seen in other quasibrittle materials, such as Portland cement mortar, engineering and dental ceramics [11,12]. This also confirms what was found in a different study on asphalt mixture [4], indicating a clear dependence of the failure distribution on the structure size [5,6].

Finally, the histogram of beam size C (Table 1) can be fitted by the WLM, Eq. (1). Based on the 2D scaling used for beams, it was assumed that the macro-crack, causing the structure failure, develops across the entire width of the beam [6]. This implies that one side of the RVE must have the length equal to the beam width [4,5]; therefore, the effective RVE size for 2D beam can be calculated as $l_0 = \sqrt{V_0 / b} = 0.6$ mm. Figure 3 shows the fitted strength histogram for beam size C (solid line).

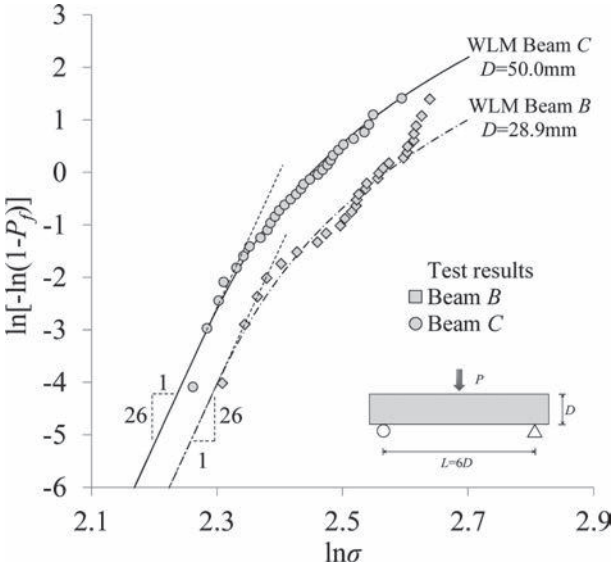

Figure 3. Experimental strength histogram and WLM fitting.

The following values of the four statistical parameters for the cdf of RVE strength were obtained with the WLM: $m = 26$, $s_0 = 12.68$, $\mu_G = 44.49$ and $\delta_G = 14.89$. Based on this set of values, the Coefficient of Variation (CoV) is approximately 33%, which is higher than what is normally observed in the laboratory tests. Nevertheless, it should be noted that the CoV estimated here is for one RVE whereas conventional laboratory test specimens usually consists of more RVEs, which would lead to a smaller CoV. The experimental strength histogram of beam size B was next used to verify the values of the parameters of the RVE cdf. Figure 3 shows that the WLM prediction (dashed line) agrees very well with the measured strength histogram of beam series B, further confirming the validity of the calibration of the strength cdf of one RVE and the finite WLM. Moreover, Figure 3 clearly shows that Weibull modulus is a material constant (Bažant and Pang, 2007) and independent of the structure size.

Given the value, $m = 26$, of the Weibull modulus, Eq. (10) can be finally used to convert the DT mean strength to its equivalent 3PB beam which results in a in a $D_{eq} = 2143$ mm; this is significantly larger than the specimen scaling size of DT prism (55 mm). Table 2 summarizes the mean strength for each specimen type. CoV stands for coefficient of variation.

The type of size effect of asphalt mixture can be finally evaluated by using the mean strength values of Table 2, together with the strength prediction obtained with the WLM and Eq. (5), which provides an approximate expression of the structural strength as function of the scaling size (D) [7]. This type of function does not require computational-demanding solutions, as would be when solving Eq. (4), and can be easily fitted to the experimental data or to the strength values obtained through the WLM for predicting the strength of larger or smaller structures. Figure 4 presents the experimental data, the mean strength predicted by the WLM and the mean size effect curve given by Eq. (5) (where $n = 2$ indicates two-dimensional scaling and $m = 26$ the Weibull modulus).

Figure 4 shows that the WLM predicts very well the mean structural strength of the experimental data. Eq. (5) provides a very good approximation of the size effect curve and, at the

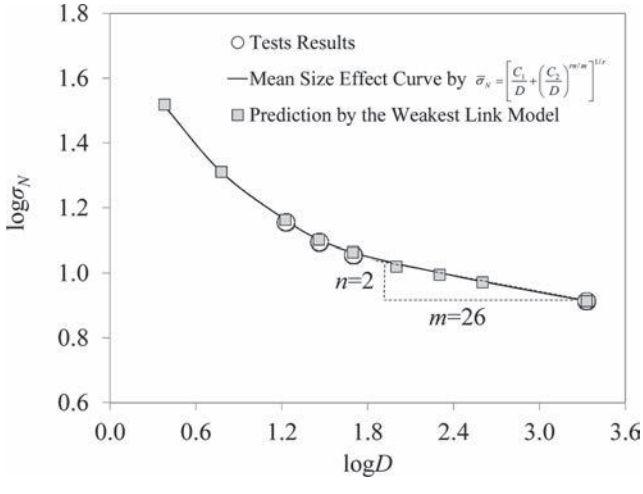

Figure 4. Mean strength curve.

same time, a more convenient formulation of the strength dependence on the structure size. Based on the asymptotic conditions for small and large size limits (see section 2), the following parameters of the mean strength curves, Eq. (5), were obtained: $C_1 = 45.34$, $C_2 = 1.56 \times 10^{15}$ and $r = 1.00$, which is in the typical range of 0.5–2 [7]. Moreover, Figure 4 clearly shows that asphalt mixture behave as a quasibrittle material having Type I mean strength size effect: for small specimen size it presents a ductile failure, while, as structure size increases, it changes toward a brittle failure, characterized by the Weibull distribution.

5 DISCUSSION ON THE RVE SIZE

In section 3, the RVE size of asphalt mixture was selected as double of the size of the material inhomogeneities which corresponds to the average grain size [4]. Nevertheless this differs with what used for other materials such as concrete for which RVE size is estimated to be about 2–3 times the size of the maximum material inhomogeneities [5]. The dissimilarity can be associated to the fact that the previous estimation of the RVE size was based on the size of distributed cracking zone of flexural beam for concrete. This may not be entirely applicable to asphalt mixtures, which may have a different size distribution of aggregates compared to concrete. Furthermore, the distributed cracking zone is defined as the zone experiencing strain-softening in a deterministic model [13], whereas the RVE here is defined as the smallest material volume whose failure causes the failure of the entire structure.

In order to further investigate the effect of RVE size on the materials strength distribution and on the mean strength size effect curve, two larger l_0 values were used for fitting the WLM to the experimental strength histograms. The two values were selected to be $1 \times \text{NMAS} = 4.75$ mm and $2 \times \text{NMAS} = 9.50$ mm which correspond to an RVE volume of $V_{0-1\text{xNMAS}} = 107.2$ mm^3 and $V_{0-2\text{xNMAS}} = 837.4$ mm^3 respectively. By using the same 2D scaling analysis previously selected for beam specimens, the effective RVE sizes was rescaled to $l_{0-1\text{xNMAS}} = \sqrt{V_{0-1\text{xNMAS}}/b} = 1.64$ mm and $l_{0-2\text{xNMAS}} = \sqrt{V_{0-2\text{xNMAS}}/b} = 4.63$ mm. WLM was then fitted to the experimental histograms. Figure 5 presents the WLM fitting for the original RVE size l_0, $l_{0-1\text{xNMAS}}$ and $l_{0-2\text{xNMAS}}$.

The plot of Figure 5 indicates there is a deviation from the optimum fitting as the RVE size increases resulting in a significant under prediction of the mean strength for smaller

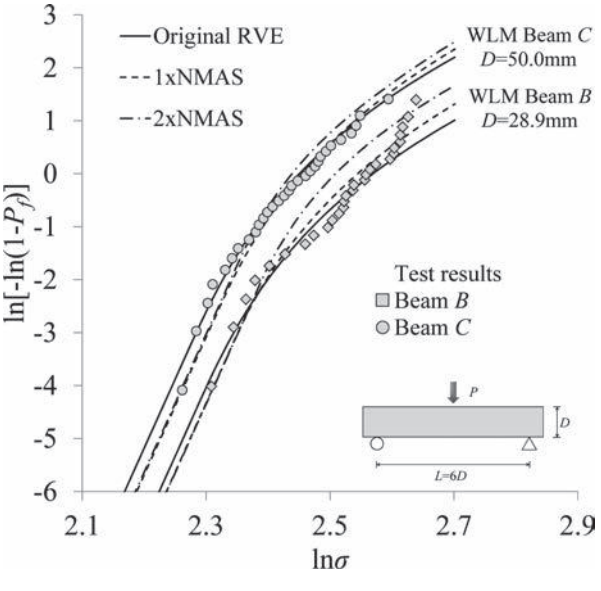

Figure 5. Strength histogram and WLM fitting for different RVE sizes.

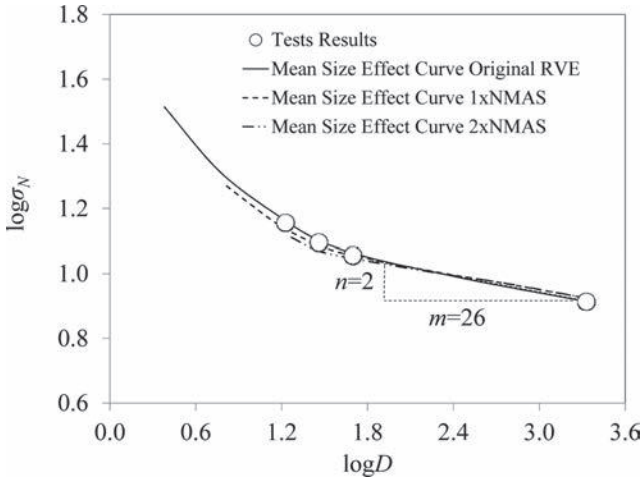

Figure 6. Mean strength curve for different RVE sizes.

structures while it leads to an over prediction for large sizes. This trend is visible in Figure 6, where, for small structures sizes, the mean strength curves become shorter due to the larger RVE size.

The curves obtained from the different fittings confirm that the selected RVE size, l_0, which is based on the average grain size, results in better mean strength predictions and, at the same time, suggest that smaller particles, such as filler, may play an important role in the failure of the material. However, this hypothesis need to be further investigated and verified through additional experimental work and analysis on asphalt mixture having different mix design, including larger NMAS.

6 SUMMARY AND CONCLUSIONS

In this paper a method to obtain the size dependence of mean strength of asphalt mixture at low temperature was presented. This approach is based on finite WLM and on flexural strength histogram testing of beams of a single size. The parameters characterizing the strength cdf of one RVE were first obtained from the experimental results and then used to predict the size dependence of asphalt mixture strength which was finally compared with the experimental values obtained on specimens of different sizes and geometry. The effect of the size of the asphalt mixture RVE on strength distribution and mean strength was addressed at the end. Two main conclusions can be drawn based on the experimental work and theoretical analysis performed:

- Experimental strength histogram confirms that asphalt mixture has quasibrittle failure behavior while mean strength curve follows a typical Type I size effect. Weibull-Gaussian grafted model can be used to statistically describe the RVE cdf of structural strength and together with the WLM can be used to predict strength and cdf of larger structures.
- The choice of the size of the material RVE is critical when applying this method. The fitting results obtained by selecting different RVE size indicate that the use of the average grain size is consistent with the experimental results, while larger RVE results in cdf and strength predictions which significantly deviate from values obtained from testing. The relatively small size of the RVE also suggests that fine particles are crucial for understanding the material failure. Nevertheless, the effect of RVE size on the cdf and mean strength requires additional analysis and experimental research, since, this type of scale effect modeling and investigation was never attempted before for asphalt mixture.

The proposed approach, based on histogram testing, is very promising and offers a tests procedure and an analysis solution to extrapolate small-scale test results to full-scale design without relying on the size effect tests, which is not possible with the current indirect tensile test method. This is attractive for testing asphalt mixtures at low temperatures due to the size limit of climatic chambers. In addition, such a model may become a simple analysis tool for practitioners when a wider range of asphalt mixtures, including different mix design, aggregate size, will be investigated and evaluated to provide a broader validation of the proposed modeling solution.

ABSTRACT: Asphalt mortar is a kind of dispersion system combined asphalt mastic with fine aggregates. Fine aggregates properties have a significant effect on the viscoelastic properties of asphalt mortar. Effect of fine aggregate form, angularity, and texture on the viscoelastic properties of asphalt mortar were studied in this paper. Image analysis procedures consisting of diploid microscope and surface light source were developed to capture fine aggregate properties. Six indices were measured for 10 aggregate samples to describe these properties. The samples were related to the viscoelastic properties of asphalt mortar measured by DSR. The results showed that the form, angularity and texture of fine aggregate exercise a remarkable influence on instantaneous elasticity, viscous component and low temperature performance of asphalt mortar. Resistance to deformation decreased with a flat, elongated shape and a decrease in aggregate angularity and texture. Abundant angularity and texture are beneficial for an increase of viscous component and low temperature performance.

Keywords: fine aggregate, asphalt mortar, morphologic properties, viscoelastic properties, image analysis procedures

1 INTRODUCTION

Asphalt mortar is a matrix of fine aggregate and asphalt binder, including the fillers. Approximately 80 percentage of the total volume of asphalt mortar consists of fine aggregate. It is not surprising that the properties of fine aggregate play an important role in the performance of asphalt mortar, such as shape characteristic. Shape characteristics of fine aggregates are expressed as three independent properties: form, angularity and texture. With the development of Digital Image Processing (DIP) techniques because of its direct and quantitative, it has been a research hotspot to quantify aggregate shape characteristics and their relationship to the behaviour of asphalt mortar or asphalt mixture based on image technique.

Johnson (1998) [1] found that some additional parameters from digital imaging also predicted modulus and rut resistance very well and should be included in future research. Kwan (1999) [2] proposed a method to determine the flakiness and elongation index based on the DIP technique. In Brazil, Oliveira (2004) [3] developed a DIP method to measure the shape of fine aggregate particles based on the concept of volumetric coefficient.

Masad has done a lot of works in this field [4–6]. In 2000 [7], he proposed that images were captured at two resolutions of high resolution and low resolution to describe aggregate texture and angularity, respectively. In his next works (2001) [8], Masad provided procedures used to capture images to analyse form and angularity. A form index FI, an index AI to

represent angularity and a Texture Index (TI) were developed and tests results showed that among the different aggregate shape properties, texture had the strongest correlation with rutting resistance values. In 2006 [9], he evaluated image analysis techniques for quantifying aggregate shape characteristics and recommended some analysis methods.

Thomas (2007) [10] designed and developed a unified computer-automated system, which included the ability to analyse fine and coarse aggregates and to quantify texture, angularity, and the three dimensions of form. Prudencio (2013) [11] carried out experimental tests on mortar samples produced with three different manufactured fine aggregates with distinct shape index. The results showed that mortar flow is strongly influenced by the particle shape.

This study focus on applying image processing techniques to investigate the effects of fine aggregate form, angularity and texture on the viscoelastic properties of asphalt mortar. In order to simplify the imaging approach for measuring fine aggregate shape characteristics, sensitive size of fine aggregate shape characteristics was proposed in this study. Grey relation method was used to determine the sensitive size of fine aggregate shape characteristics based on the results of three standard FAA tests. Image acquisition system was developed to obtain the value of quantitative indices, which described the form, angularity and texture of the sensitive size particles. According to the analysis results of fine aggregate shape characteristics, two indices, E and SP, was proposed to evaluate shape characteristics of fine aggregates. At last, the correlation of E and SP values of different fine aggregates with asphalt mortars were conducted.

2 MATERIALS

2.1 *Fine aggregates*

Thirteen different fine aggregate samples were analysed in this study. Their properties were tested according to *Test Methods of Aggregate for Highway Engineering* (*JTG E42-2005*) and results were given in Table 1.

2.2 *Mineral fillers*

The limestone fillers properties were tested according to *Test Methods of Aggregate for Highway Engineering* (*JTG E42-2005*) and results were shown in Table 2.

2.3 *Asphalt binder*

The properties of asphalt binder were tested according to Standard *Test Methods of Asphalt and Asphalt Mixtures for Highway Engineering* (*JTJ 052-2000*) were given in Table 3.

Table 1. Properties of fine aggregates.

3 TESTS

3.1 *FAA tests*

The underlying fact is that the shape characteristics of fine aggregate are affected by gradation composition. And it is a large work to measure each size particles of fine aggregates based on image analysis method. Therefore, sensitive size of fine aggregate shape characteristics, which mean that shape characteristics of the sensitive size particles can represent shape characteristics of the fine aggregate sample, was proposed in this study to establish a simple way for measuring the shape characteristics of fine aggregates.

In this study, three standard test methods for FAA (Fine Aggregate Angularity) were applied to determine the sensitive size of fine aggregate shape characteristics. They are AFNOR P18-564, the aim of which is to measure the flow time of fine aggregate in seconds through an orifice under specified conditions, AASHTO TP 33 (ASTM C1252) "Uncompacted void content of fine aggregate", in which FAA is defined as the percentage of air voids present in loosely compacted aggregates, and ASTM D3398 "Index of aggregate particle shape and texture", which provides an index value to the relative particle shape and texture characteristics of aggregates. Three fine aggregates samples (2#, 8# and 11#) composed of single size particles (2.36 mm, 1.18 mm, 0.6 mm, 0.3 mm, 0.15 mm and 0.075 mm) and three gradations (shown in Table 4) were measured according to the three standard test methods.

Grey relation analysis [12], which calculates the grey relation degree between target value and effect factors and looks for the primary affecting factors, was applied to determine the sensitive size of fine aggregate shape characteristics.

3.2 *Imaging acquisition and analysis tests*

Image acquisition system was developed to measure fine aggregate shape characteristics, which is shown in Figure 1. This system was consisted of four parts, which were stereo microscope, video camera, and area source, image analyser. Stereo microscope has the advantage of high image resolution and direct observation of objects. The stereo microscope was equipped with the video camera; therefore particle images could be real-time captured on the computer. Area source was used to create accurate definition of the particle boundary. The images were captured and analysed by the image analyser, which contained image captured software and image analysis software.

In this section, 10 kinds of samples were used and the objects of this test were the sensitive size particles. In order to describe different shape characteristics of fine aggregate, images were captured at two resolutions (0.003 mm/pixel high resolution and 0.015 mm/pixel low resolution) according to Masad's work [7]. Shown in Figure 2 are binary images of fine aggregates captured at two different resolutions.

b) 0.015mm/pixel resolution

Figure 2. Fine aggregate particle images in two resolutions.

Six indices were selected for quantifying the different characteristics of fine aggregate shape, the diagrams of which were showed in Figures 3 and 4, and the calculation methods were presented in Table 5.

3.3 *Frequency sweep test by DSR*

Asphalt mortars with four kinds of fine aggregates (2#, 3#, 11#, 13#) were prepared with 11.17% asphalt content and 0% of air voids. The aggregate gradation of asphalt mortar was shown in Table 6. Cylindrical specimens with 100 mm diameter, 100 ± 2 mm height were prepared by Gyratory Compactor. Then the cylindrical specimens were cut into rectangular specimens with 4 mm × 13 mm × 60 mm size, which were used to determine the viscoelastic properties asphalt mortar by DSR.

The frequency sweep test by DSR (Dynamic Shear Rheometer) was applied to determine the viscoelastic properties of asphalt mortar. The procedure consisted of applying

constant shear strain of 0.1% to avoid damaging the specimen over a range of loading frequencies (from 0.1 to 25 Hz). And this was performed at 30, 40, 50 and 60°C. With the resulting data, CAM model (Eq.(1)) was used to relate dynamic shear modulus to reduced frequency.

$$|G^*|(f') = |G^*|_e + \frac{|G^*|_g - |G^*|_e}{[1 + (f_c/f')^k]^{m_e/k}} \tag{1}$$

4 RESULTS AND DISCUSSION

4.1 *Sensitive size of fine aggregates shape characteristics*

The FAA test results of the three fine aggregates samples are shown in Table 7 through 9. And Table 10 presents the grey relation analysis results.

Table 7. Flow time of each size and three gradations (s).

Samples	2.36 mm	1.18 mm	0.6 mm	0.3 mm	0.15 mm	0.075 mm	Gradation a	Gradation b	Gradation c
2#	–	58.7	43.6	34.2	32	59.4	34.6	45.3	38.1
8#	–	55.2	42.5	34.8	32.5	43	33.1	42.1	36.6
11#	–	55.4	43.7	35.4	36.4	–	38.2	43.7	40.5

'–' The FAA value could not be measured and grey relation degree was considered as zero.

11#	14.75	15.27	15.65	16.73	17.62	18.01	15.70	16.06	16.49

Table 10. Grey relation degree of each size.

FAA tests	2.36 mm	1.18 mm	0.6 mm	0.3 mm	0.15 mm	0.075 mm
AFNOR P18-564	0	0.43	**0.76**	0.75	0.72	0.37
AASHTO TP33	**0.79**	0.63	0.50	0.45	0.46	0.43
ASTM D3398	0.56	0.65	**0.77**	0.73	0.54	0.59
Sum of grey relation degree	1.35	1.71	**2.03**	1.93	1.72	1.39

According to Table 9, the grey relation degree of 0.6 mm size is the maximum from the result of AFNOR P18-564 test, which is the same as the ASTM D3398 test result. However, from the results of the AASHTO TP33 test, the grey relation degree of 2.36 mm size is the maximum. In order to determine the most sensitive size of fine aggregate shape characteristics, the grey relation degrees of each size from the three tests were added. The grey relation degree order of each size after adding is 0.6 mm > 0.3 mm > 0.15 mm > 1.18 mm > 0.075 mm > 2.36 mm. It is evident that the grey relational coefficients of 0.6 mm size is the maximum, as a result, 0.6 mm is selected as the sensitive size of fine aggregate shape characteristics.

4.2 *Analysis of fine aggregate shape characteristics based on imaging approach*

The results of shape characteristics indices value using image analysis technique are shown in Table 11.

In order to study the shape characteristics differences between manufactured sand and chips, one-way ANOVA was applied to analyse the differences of the indices value between manufactured sand and chips, and the results are shown in Table 12.

4.2.1 *Form*

On the basis of the results in Table 11, it is evident that the R value of 1# sample (natural sand), which is up to 0.713 and close to $\pi/4$, is greater than other samples. And the fact is that the more R is close to $\pi/4$, the more aggregate particle is nearly round. So compared with manufactured sand and chips, natural sand is more nearly round. However, according to the One-way ANOVA results in Table 12, the F value of R between manufactured sand and chips is 0.15 and smaller than $F_{0.05} = 5.59$ with a 95 percent confidence interval, which indicates that there are no significant differences of R between manufactured sand and chips.

From the point of E, E value of 1# (natural sand) is no marked different from other fine aggregates, especially manufactured sand. On the other hand, the F value of E between manufactured sand and chips is 8.18 and greater than $F_{0.05} = 5.59$ with a 95 percent confidence interval, which indicates that there are significant differences of E between manufactured sand and chips. And the E values of chips are greater than those of manufactured sand. Considering that greater E means more elongated aggregates, chips are more elongated than manufactured sand in terms of form characteristic.

4.2.2 *Angularity*

From the point of A_I,C_R and FF, which values of natural sand are obviously smaller than chips and manufactured sands, we can come to that natural sand is less angular. However, there is no obvious contrast of A_I,C_R and FF between chips and manufactured sands according to the result of Table 12, because all of the F value of A_I,C_R and FF between manufactured sand and chips are smaller than $F_{0.05} = 5.59$.

On the other hand, the SP value of natural sand is obviously smaller than the other fine aggregates, and the One-way ANOVA results in Table 12 show that the F value of SP is 5.98, which is greater than $F_{0.05} = 5.59$. As a result, there are remarkable contrast in terms of SP values among natural sand, chips and manufactured sands, and the SP value of natural sand is the smallest, which followed by chips and manufactured sands are the greatest. In consideration of the fact that the greater SP value is, the more angular fine

Table 11. Quantitative indices value of 10 samples.

	Form		Angularity				Texture			
Samples	*R*	*E*	*SP*	A_I	C_R	*FF*	*SP*	A_I	C_R	*FF*
1#	0.713	1.249	0.559	1.06	1.015	1.162	0.123	1.052	1.012	1.15
2#	0.695	1.365	0.644	1.077	1.023	1.284	0.163	1.097	1.026	1.288
3#	0.685	1.318	0.738	1.099	1.024	1.291	0.257	1.106	1.028	1.318

6#	0.678	1.242	0.827	1.091	1.029	1.266	0.305	1.106	1.028	1.269
7#	0.673	1.27	0.827	1.097	1.03	1.251	0.245	1.113	1.029	1.304
8#	0.677	1.221	0.876	1.063	1.02	1.217	0.196	1.087	1.026	1.253
10#	0.691	1.214	0.947	1.097	1.029	1.271	0.298	1.107	1.027	1.285
11#	0.655	1.264	0.846	1.091	1.023	1.232	0.23	1.085	1.022	1.253
13#	0.665	1.295	0.827	1.073	1.015	1.232	0.156	1.097	1.019	1.263

Table 12. Analytic results of one-way ANOVA.

	Form		Angularity					Texture				
Indices	*R*	*E*	*SP*	A_I	C_R	*FF*	*D*	*SP*	A_I	C_R	*FF*	*D*
F	0.15	**8.18**	**5.98**	0.002	0.57	3.01	2.71	0.21	0.18	0.25	1.02	0.44

aggregate is, natural sands are smooth, chips are subangular and manufactured sands are more angular.

4.2.3 *Texture*

The results of Table 11 shows that the *SP*, A_I, C_R, *FF* value of natural sand (1#) is also smaller than other samples, which indicates that natural sands are smooth compared with chips and manufactured sands. And based on the One-way ANOVA results in Table 12, in which the *F* value of *SP*, A_I, C_R, *FF* value is less than $F_{0.05} = 5.59$, there are no obviously contrast between chips and manufactured sands in terms of texture.

The foregoing analysis shows that the differences of shape characteristics between natural with chips and manufacture sand are in terms of form, angularity and texture. Natural sand is nearly rounded, less angular and texture. And the difference of shape characteristics between chips and manufacture sand is in terms of shape and angularity. Chips are elongated or flaky and less angular than manufacture sand. Form index *E* and angularity index *SP* can describe the differences among different kinds of fine aggregates, so we propose the two indices as the evaluating indices of fine aggregate shape characteristics.

5 CORRELATION OF SHAPE INDICES TO LABORATORY ASPHALT MORTAR VISCOELASTIC PROPERTIES

The master curves of four kinds of asphalt mortars consisted of different fine aggregates are shown in Figure 5. Table 13 shows the fitting results of CAM model parameters.

5.1 *Influence of fine aggregates shape characteristics on* $|G^*|_e$

Equilibrium dynamic modulus $|G^*|_e$ is an index describing asphalt mortar high temperature resistance to deformation. The greater $|G^*|_e$ is, the stronger asphalt mortar ability to resist deformation is. Figure 6 showed the changes of equilibrium dynamic modulus $|G^*|_e$

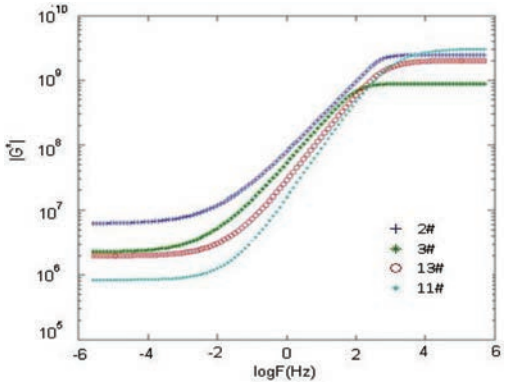

Figure 5. Master curves of four kinds of asphalt mortars.

Table 13. Fitting results of CAM model parameters.

Stockyard	Samples	E	SP	G_e^*/MPa	G_g^*/MPa	f_c/Hz	k	m_e	R	f'_c/Hz
A	2#	1.365	0.644	1.738	3683	544	0.541	0.584	0.324	0.0011
	3#	1.318	0.738	5.927	6380	1284	0.443	0.548	0.372	0.0037
B	13#	1.295	0.827	4.091	1347	171	0.836	0.698	0.251	0.0016
	11#	1.264	0.846	1.796	5045	894	0.442	0.664	0.452	0.0054

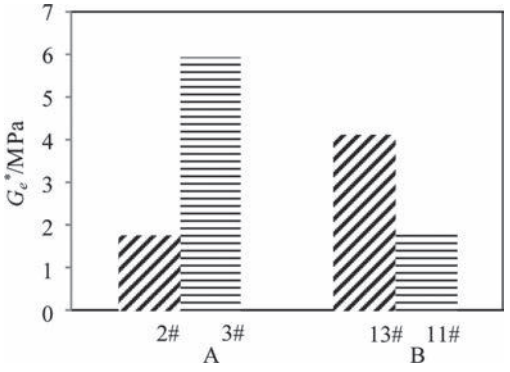

Figure 6. Equilibrium dynamic modulus $|G^*|_e$ of different asphalt mortars.

of asphalt mortar consisted of fine aggregate with different shape characteristics. Figure 6 and Table 13 showed that, for stockyard A, the $|G^*|_e$ of asphalt mortar consisted of fine aggregates with greater E value and smaller SP value is greater, however, for stockyard B, the conclusion is on the contrary. This shows that there is no significant correlation between Equilibrium dynamic modulus $|G^*|_e$ and fine aggregate shape characteristics. The effect of fine aggregate shape characteristics on asphalt mortar at high temperature or low frequency is not notable.

5.2 *Influence of fine aggregates shape characteristics on* $|G^*|_g$

For asphalt mortar, glassy dynamic modulus $|G^*|_g$ describes the ability to resist deformation at low temperature, and greater $|G^*|_g$ means stronger ability to resist deformation. The changes of glassy dynamic modulus $|G^*|_g$ of asphalt mortar consisted of fine aggregate with

different shape characteristics are shown in Figure 7. According to the results of Figure 7 and Table 13, glassy dynamic modulus $|G^*|_g$ of asphalt mortar, which is consisted of fine aggregates with smaller E value and greater SP value, is greater. This result indicates that, fine aggregate particles, which are more elongated and have less angularity, create smaller glassy dynamic modulus $|G^*|_g$. In the other word, fine aggregates with low content of elongated particles and abundant angular can increase asphalt mortar modulus and ability of deformation resistance at low temperature and high frequency.

5.3 *Influence of fine aggregates shape characteristics on shape parameters m_e*

m_e describes the sensitivity of asphalt mortar to temperature and frequency, and smaller m_e means that asphalt mortar is less sensitive to temperature and frequency. The changes of shape parameters m_e with different shape characteristics of fine aggregates are shown in Figure 8. The results of Figure 8 and Table 13 show that fine aggregates with smaller E value and greater SP value create greater m_e. This indicates that asphalt mortar composed of fine aggregates, the form of which is nearly cube and the angularity of which is plentiful, is more sensitive to temperature and frequency.

5.4 *Influence of fine aggregates shape characteristics on f_c*

f_c is the threshold frequency of rheometer zone and elastic zone at low temperature. On the other hand, f_c represents the frequency when storage modulus is equal to loss modulus. Great f_c signifies that asphalt mortar has a high phase angle and show more viscous

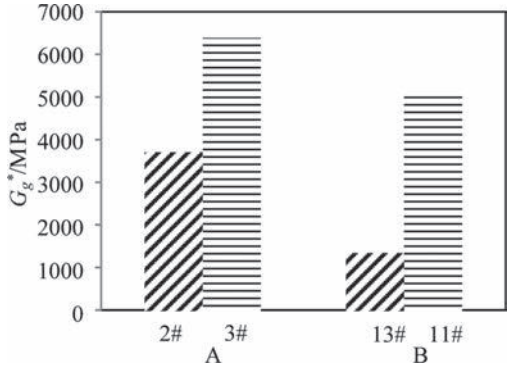

Figure 7. Glassy dynamic modulus $|G^*|_g$ of different asphalt mortars.

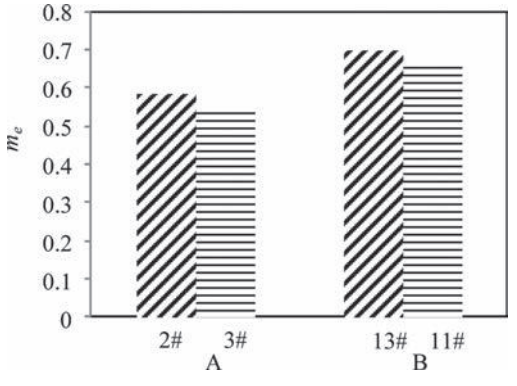

Figure 8. Shape parameters m_e of different asphalt mortars.

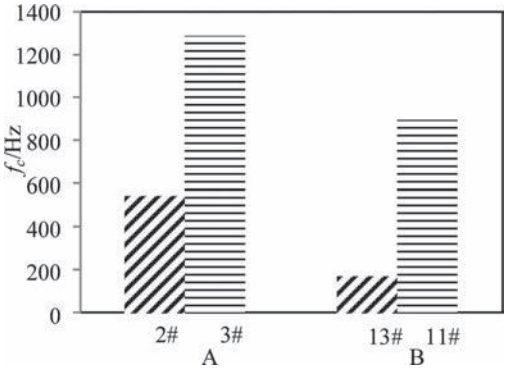

Figure 9. Threshold frequency f_c of different asphalt mortars.

component. As a result, the performance of asphalt mortar at low temperature is good. Figure 9 shows the changes of threshold frequency f_c with different shape characteristics of fine aggregates. In Figure 9, asphalt mortars consisted of fine aggregates with small E value and great SP value have a great threshold frequency f_c, which implies that fine aggregates with less elongated particles and more angular create greater f_c of asphalt mortar. This means that asphalt mortar consisted of fine aggregates, which are closed to cube in form and more abundant in angularity, has more viscous component and better low temperature performance.

In summary, the study about the influence of fine aggregates shape characteristics on the viscoelastic properties of asphalt mortar shows that, fine aggregates with less elongated particles and more angular are helpful to improve the viscous component and low temperature performance for asphalt mortar. However, for the high temperature performance of asphalt mortar, the results of the study don't show a good relationship with fine aggregates shape characteristics.

6 CONCLUSION

This study focused on measuring fine aggregates form, angularity and texture and their correlation with viscoelastic properties of asphalt mortar. The following observations can be made:

1. The grey relation degree of 0.6 mm size is the maximum; as a result, 0.6 mm is selected as the sensitive size of fine aggregate shape characteristics.
2. The image acquisition system, consisted of stereo microscope, video camera, area source and image analyser, can be used to obtain images and indices of fine aggregates shape characteristics.
3. The differences of shape characteristics between natural with chips and manufacture sand is in terms of form, angularity and texture. Natural sand is nearly rounded, less angular and texture. And the difference of shape characteristics between chips and manufacture sand is in terms of shape and angularity. Chips are elongated or flaky and less angular than manufacture sand.
4. Form index E and angularity index SP can describe the differences among different kinds of fine aggregates, and was proposed as the evaluating indices of fine aggregate shape characteristics.
5. Fine aggregates with less elongated particles and more angular are helpful to improve the viscous component and low temperature performance for asphalt mortar. However, for the high temperature performance of asphalt mortar, the results of the study don't show a good relationship with fine aggregates geometric characteristics.

ABSTRACT: The main purpose of this research is to evaluate the fractal features of aggregate surface topography through capturing three-dimensional aggregate images with a three-dimensional optical dense point cloud measurement system and a newly-developed Matlab program calculating fractal dimensions of aggregate surfaces and sizes. Through analysis and comparison on fractal features of both fine and coarse basalt aggregate, it was observed that fractal dimensions of aggregates had an obvious size. Fractal dimension gradually increased along with the measurement size increasing. No fractal feature was shown when measurement size exceeds a certain limit, and the threshold value reflected the complexity of aggregate surface morphology. For basalt aggregates of 13.2 mm, the threshold value was 12.8 mm. Fractal feature was not necessarily shown with measurement size ranged from 0.8 mm to 12.8 mm. Obvious fractal features were shown when measurement size was less than 0.8 mm.

Keywords: basalt, surface topography, fractal feature, optical dense point cloud, newly developed Matlab program

1 INTRODUCTION

In road materials, the proportion of aggregates is the largest. The percentage is 70% to 85% for cement concrete, in hot asphalt mixture, the percentage could reach 90% to 95% [1]. Therefore, one of the most important factors affecting mixture performance is characteristics and quality of aggregates. Studies has been showed that the asphalt mixture's pavement performance is connected with Deformation, fatigue resistance, surface friction of Asphalt, which is affected by size, shape, size distribution and morphology of aggregates [2,3]. Therefore, in order to design a long-life pavement, aggregates must have a reasonable morphology. At present, the most relative experiments on mechanics including aggregates abrasion test, endurance test and polishing value test, chemical experiments including aggregate robustness test and organic content test, physical experiments including aggregate screening test, shape characteristic and surface texture measurement. There is a series of detail test methods in ASTM D3398, which is an indirect measurement method and it can be used for each particles aggregates. In the text, particle shape and macro-texture are used as the test object needing long time and more workload [4–7].

Fractal is a new theory to solve the problem of aggregate surface morphology. This theory was introduced into engineering surface morphology at 1986. Majumdar pointed out that

engineering surface showing different features, such as unstable randomness, disorder, self-similarity and multi-scale [8]. Furthermore, Majumdar infer out self-correlation function based on fractal dimension by Weierstrass-Mandelbrot fractal function. In china, it is not until 1994 that applying fractal theory to engineering surfaces. In connection with Engineering surface sectional profile curve, Ge made research about the changing processes of surface morphology by fractal dimension [9–10]. Cheng pointed out that fractal dimension could also clearly report surface roughness. In particular, it could overcome the lacking of scale in traditional roughness parameters [11].

In recent years, Image Analysis Techniques has been used to analysis material microstructure in different areas of Materials Science and Geotechnical engineering. The Image Analysis Techniques was lead into measure shape characteristics of aggregates in road projects as following. The techniques could measure different sizes of aggregates shape features fast, accurately and objectively. In the Image Analysis Techniques, aggregate shape features can be characterized by three indicators: Form, Angularity and Surface Texture. Therefore, the paper selects fractal dimension as parameter and makes the research of aggregate surface texture by Digital Image Analysis Techniques.

2 THREE-DIMENSIONAL CHARACTERIZATION OF AGGREGATE MORPHOLOGY

XJTUOM measurement system is a three-dimensional optical measurement technology which is based on the latest international technology. Three-dimensional optical measurement technology in this paper is a three-dimensional optical dense point cloud measurement system marking XJTUOM (Fig. 1). The systemic model is XJTUOM-I that includes two 1.3 million to 6.6 million pixel cameras and format size of a single measurement is 150 mm*110 mm to 400 mm*300 mm.

2.1 *3D scanning and three-dimensional coordinates obtaining of aggregates*

In order to acquire three-dimensional coordinates, we should scan aggregates to obtain three-dimensional images and three-dimensional coordinates. Four steps as follows:

1. Selected aggregates. In the study, two different particle size aggregates as the Table 1 shows.
2. Spray painting

As darker of aggregates surface, it is hard to distinguish fine aggregate surface characteristics in the process of scanning and lead data missing easily in the progress. To avoid this situation, during the experiment, aggregates surface was painted (Fig. 2).

3. Three-dimensional optical scanning

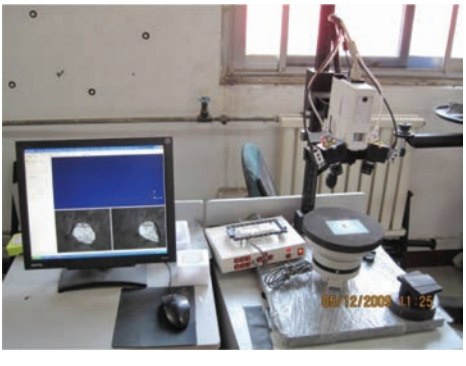

Figure 1. XJTUOM-I.

Table 1. Type and size of aggregates.

Aggregate	Particle size (mm)			
Species	19	16	13.2	9.5
Basalt-1	√	√	√	√
Basalt-2			√	√

Figure 2. Spray painted aggregates.

Aggregates after the spraying is placed on the stage, projection grating projects many fringes for different spatial frequency to the surface of aggregates and then cameras deformed fringe pattern. Phase method used to obtain the phase of the main values of various stripes and then we can obtain the true phase stripes. Cameras and Projection grating on aggregates surface is showed in Figures 3 and 4.

In order to obtain three-dimensional surface characteristics of aggregates more conveniently, aggregates should be tested according to three vertical mutually perpendicular surfaces marked A, B, C for scanning (Fig. 5).

4) Three-dimensional coordinates obtaining

As restricted by scanning image format, we had to scan two times for a aggregate and then automatic splicing would be need for results by Geomagic Studio 8 one of image data processing. Getting the entire three-dimensional aggregates coordinates for next. After stitching processing is completed, there will be an ASC document for 3-dimensional coordinate. This file is converted to TXT format then and each aggregate corresponds to a TXT file.

2.2 *Three-dimensional visualization of aggregates*

After completing three-dimensional optical scanning and obtaining three-dimensional characteristics of aggregates, we need to use appropriate procedures to achieve three-dimensional visualization of aggregates for next, so that we can observe the surface morphology and textures of aggregates more intuitively. It's also providing the basis for data processing and calculating next.

Currently, three-dimensional visualization of aggregates can be achieved by a lot of software. Geomagic Studio and MATLAB are most often used. Geomagic Studio is mainly used to generate three-dimensional model of aggregates and build aggregates complex surfaces. Because of powerful data processing capabilities and superior graph processing capabilities, MATLAB is very suitable for program calculating and feature extraction calculating of aggregate Morphology later. For the reason that, in this paper, Geomagic Studio was chosen as three-dimensional structure software of aggregates and MATLAB was chosen as analysis software of aggregate morphology later.

Geomagic Studio can create three-dimensional models by 3D point cloud data in the scanning before. In our study, Geomagic Studio was used to read TXT point cloud data of 13.2 mm diameter basalt-1 and generating six-sided view of three-dimensional aggregates.

3 AGGREGATE MORPHOLOGY CHARACTERISTICS OF TWO-DIMENSIONAL PRRSING

With diameter of 13.2 mm basalt-1 and 4.5 mm basalt-2 the research object, three randomly particles selected from each of the aggregate particles. Aggregate particles is generated by the software Geomagic Studio 8 sides view, as shown in Figure 6, the three-dimensional figure available aggregate surface three coordinates of point cloud, and in the MATLAB generated three-dimensional topography on the surface of the coarse aggregate, the comparative study of the characteristics of aggregate surface topography.

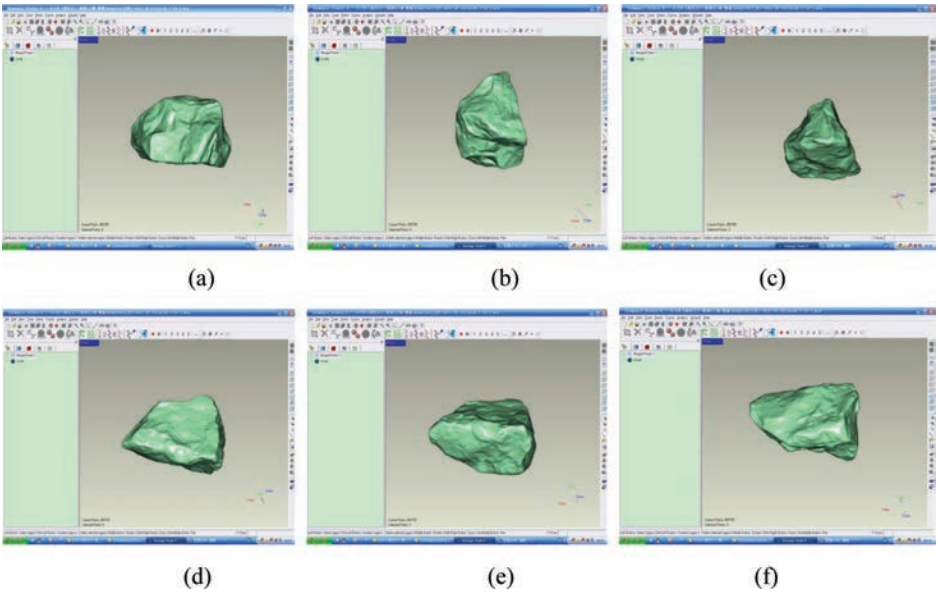

Figure 6. Aggregate particles hexahedral view.

3.1 *Coarse aggregate surface morphology analysis*

In order to understand the characteristics of coarse aggregate surface morphology, the 13.2 mm basalt-1 and basalt-2 of three optical is used to scan data, the calculation process of cube cover method use MATLAB software to write, in the random selection of material surface coverage, the relationship between the establishment and basalt-1–2 calculation data are shown in Tables 2 and 3 reflects the relation of double logarithmic coordinate diagram as shown in Figures 7 and 8.

Combining with the analysis in Table 2 and Figure 7 13.2 mm appearance characteristics of basalt-1 are as follows:

1. Figure 7 (a), for number one, when the delta of the range is 0.1~0.1 mm, coarse aggregate surface fractal dimension is 2.863, when the delta the range is 0.8~3.2 mm, the aggregate surface fractal dimension is 3.68, greater than 3 for unqualified data.
2. Figure 7 (b), for number two, when the delta of the range is 0.1~0.1 mm, coarse aggregate surface fractal dimension is 2.428; When the delta the range is 1.6~1.6 mm, the aggregate surface fractal dimension is 2.669.
3. Figure 7 (c), for number three when the delta of the range is 0.1~0.1 mm, coarse aggregate surface fractal dimension is 2.861; When the delta the range is 3.2~6.4 mm, the aggregate surface fractal dimension is 3.123, the influence of other factors lead to the results of fractal dimension mutation, causing its scope beyond the maximum limits.

Above all, we can draw a conclusion that, for a 13.2 mm basalt-1, when the measurement scale is greater than 12.8 mm, it does not show the aggregate surface fractal, When the measurement scale is between 0.8~12.8 mm, rough surface does not necessarily show the fractal; Only when it is less than 0.8 mm, surface showed the fractal nature.

According to Table 3 and Figure 8, analysis of the 13.2 mm basalt-2 appearance characteristics as follows:

1. Analysis diagram (d), when the delta of the range is 0.1~0.8 mm, coarse aggregate surface fractal dimension is 2.934, when the delta the range is 0.8~0.8 mm aggregate surface fractal dimension is 3.111, it is greater than the scope of the surface fractal dimension for the appearance characteristics of variation points.

Figure 8. Surface fractal dimension results of the 13.2 mm Basalt-2.

fractal dimension is 3.658, when the measurement scale is larger than a certain value, the fractal dimension of the result beyond boundaries.

To sum up, we can draw a conclusion that, for basalt-1, when the measurement scale is greater than 3.2 mm, it doesn't show the aggregate surface fractal; When the measurement scale is between 0.4~3.2 mm, rough surface does not necessarily show the fractal; Only when it is less than 0.4 mm, surface to show the fractal nature.

Contrast of basalt-1 and basalt-2 of fractal features, we can draw the following conclusion:

1. Through comparing the following table (Table 4), it can be concluded that basalt-2 coarse aggregate surface topography is more sophisticated, the range of measurement scale is relatively smaller, aggregate morphology details showed more superior in the asphalt mixture of road performance.
2. By the Figure 8 (a) to Figure 8 (f), the value of fractal dimension is mainly between 2.5~3.0, range interval preference for the upper, the value of fractal dimension D is big. Thus can explain that basalt-1-2 surface morphology intense changing, aggregate on the surface is of high frequency component, morphology is rich in details, the space wavelength of the surface is relatively short. With this kind of coarse aggregate paving asphalt pavement, coarse aggregate can embedded squeeze each other better and forming stable pavement structure relatively. It's good for resistance to rut at high temperature and extending the life of the road.
3. Analysis diagram (a)~(f), measurement scale is smaller, the value of fractal dimension D is smaller; the measurement scale is larger, with larger value of fractal dimension D until it tends to infinity. Coarse aggregate surface morphology of fractal dimension in all scale does not exist a exact value, smaller measuring scale to calculate the fractal dimension is relatively smaller, when the measurement scale δ tends to zero, the fractal dimension of surface topography is more close to the real value.

3.2 *Fine aggregate surface morphology analysis*

In order to avoid affecting the mechanical properties of the interface, because of measured spacing is too small, we come up with a new parameter Scale fractal dimension R_d to analysis surface morphology of fine aggregates that could balance the interaction between measuring distance and fractal dimension.

Calculating scale fractal dimension parameters of fine aggregate, with a particle size of 4.75 mm basalt-1 and basalt-2 for example (Table 5) to analysis surface morphology of fine aggregates. Scale fractal distribution is shown in Figures 9 and 10.

We can conclude from the figure above, in the three basalt-1 aggregates, the change of the frequency of normal distribution curve fitting of scale fractal dimension is mitigatory, and data is continuous and concentrated, there is a relatively small difference among the

Table 4. Fractal features comparison between Basalt-1 and Basalt-2.

	Not exhibit fractal	Exhibit fractal uncertain	Exhibit fractal

fractal dimension values of aggregates; in the scale fractal dimension frequency curve of basalt-2, the difference of scale fractal dimension values of different aggregates is relatively big, the distribution of data is relatively discrete. The scale fractal dimension of basalt-2 and aggregate-3 is shown in box Figure 11.

According to the drawing 11,we can know that in the aggregate-3 the scale fractal dimension of number 4 and 7 random faces are far away to the mean, they are the change points in

Midpoint	12.168	9.212	16.451	19.279	31.995	77.526
Standard deviation	9.715	12.239	12.206	8.103	8.925	15.589
Variance	94.385	149.796	148.985	65.659	79.648	243.003
Minimum value	5.610	1.270	2.350	6.650	26.280	38.860
Maxima	30.400	36.830	39.820	28.060	51.280	97.340

statistic, it indicates that the aggregate's broken is unreasonable, which lead that surface scale fractal dimension have a big change, fine aggregates' morphology inhomogeneity.

Choosing three aggregates of whinstone-1 and whinstone-2, in every aggregate random choose 10 faces, comparing the difference of scale fractal dimension, hunting the morphology feature distribution regulation of fine aggregate, Table 6 shows the whinstone's scale fractal dimension of 4.75 mm.

According to Table 6, we can know that the mean values of scale fractal dimension three whinstone-1 aggregates are 16.901, 13.595 and 18.668. Meanwhile, the mean values of scale fractal dimension three whinstone-2 aggregates are 18.489, 35.654 and 73.007. Comparing the means, we can easily obtain that the scale fractal dimension R_d of whinstone-1 is mostly distributed between 1.27 and 39.82, and it is uniform. At the same time, we can see that scale fractal dimension R_d of whinstone-1 is mostly distributed between 6.65 and 97.34, the data are random and discrete. This indicates that whinstone-2 fine aggregate scale fractal dimension is larger than whinstone-1, also, whinstone-2 surface morphology roughness is fickle, the fine aggregate has a big size effect, which have a big effect to mixture's pavement performance.

But it is conditional that if the scale fractal dimension R_d is reasonable, which depends the rationality of the measuration distance. To fine aggregate the rationality of the measuration distance have a big effect to the scale fractal dimension R_d, if the measuration distance is oversize, the small scale information will be ignored, this is because the small percents in

the fine aggregates would easily cover up by big scale. Meanwhile, because singleness index covers limited information, combined with other index, it is more reasonable to building multi-index.

4 CONCLUSIONS

1. The 3D optical dense point cloud measurement system of XJTUOM type is employed to scan the surface of each aggregate, and the soft geomagic Studio 8 is used to achieve automatic splicing processing and get the 3D free-space diagram of aggregate particles, therefore 3D free-space diagram can obtain the 3D coordinates of point cloud of aggregate surface, in the matlab, 3D appearances of coarse aggregate surface are obtained, using self-similarity fractal dimension and dimension fractal description parameter of fine aggregate as evaluation indexes, we compare and research the feature of aggregate surface.
2. Taking basalt-1 and basalt-2 with the 13.2 mm particle size for example, we can find from the test results, the superficial appearances of coarse aggregate of basalt-2 are more subtle, the measurement scale of every range is relatively small, and appearance details of aggregates are more abundant, they will show up more superior pavement performance in asphalt mixture.
3. Taking basalt-1 and basalt-2 with the 4.75 mm particle size as research objects, statistical analysis software PASW is applied to analyze the appearance of fine aggregate of basalt. We can conclude from the test results, the discreteness of dimension fractal description parameters of basalt-2 is big, the variation of rough details of superficial appearance is big, relative to the basalt-1, the size effect of the fine aggregate is obvious, which will has relatively big influence on the pavement performance of the mixture.

Design of cement stabilized full depth reclaimed mixes using Superpave Gyratory Compactor

Ilker Boz & Mansour Solaimanian
Pennsylvania State University, University Park, PA, USA

ABSTRACT: Full Depth Reclamation (FDR) is a popular technique in rehabilitating distressed pavements. The technique is very effective and economical when the pavement problems extend beyond the surface layers and when base repair is essential in renewing the pavement. Engineering design of the FDR mix is important to ensure strength and durability of the FDR mix. Most of the existing mix design procedures for chemically stabilized FDR are based on laboratory compaction of specimens in a Proctor mold and determination of unconfined compressive strength of the mix. A procedure is proposed here to use the Superpave Gyratory Compactor (SGC) for preparation of compacted specimens and utilizing the indirect tensile strength of the compacted specimens for mix design. As part of this research, correlation between the strength of Proctor prepared specimens and SGC prepared specimens was evaluated. The strength of Proctor specimens was determined using unconfined compressive strength and that of SGC specimens was determined using indirect tensile strength. A total of 18 cement stabilized samples were prepared and tested. Test results indicated that there is a strong correlation between the two procedures.

Keywords: Superpave Gyratory Compactor, cement stabilization, Full Depth Reclamation, unconfined compressive strength, indirect tensile strength

1 INTRODUCTION

As for all structures, pavement structures deteriorate over time due to several factors, mainly by weather and traffic. Thus, there is a need for deteriorated pavements to be rebuilt or reconstructed in order to provide a smooth and safe ride. Economical and environmental reasons in today's world have led recycling or reclaiming of pavements to become convenient and attractive alternatives to rebuilding roads completely. Advantages of recycling or reclaiming can include saving natural resources such as aggregate and asphalt, using less energy, having less pollution, less construction cost, and having landfill spaces not filled by old pavement materials [1].

Full Depth Reclamation (FDR) is one of the most common recycling techniques and a popular one in rehabilitating distressed pavements. The technique is very effective and economical when the pavement problems extend beyond the surface layers and when base repair is essential in renewing the pavement. As it can be readily seen from Figure 1, FDR provides significant benefits in the form of the savings in natural resources and money when compared to a new base. Figure 1 results are based on a 2-lane road that is 1 mile long and 24 foot wide with 6 inches base [1].

FDR process requires pulverization of the existing pavement layers, stabilizing the pulverized material through the use of chemical or emulsion additive, compaction and curing of the mix.

Engineering design of the FDR mix is important to ensure strength and durability of the FDR mix, and compaction in the FDR process is one of the important factors in performance of the reclaimed mix. Poorly compacted mixes can result in pavement failures such as rutting

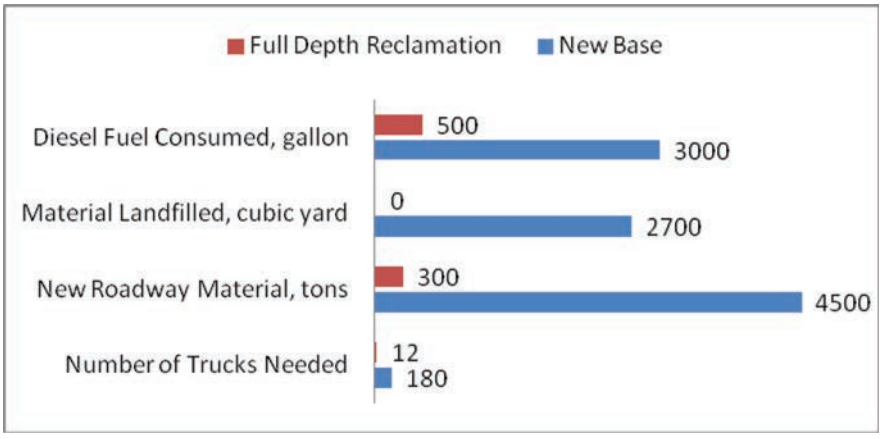

Figure 1. Energy and materials use for FDR and new base [1].

due to more densification under traffic [2]. Most of the existing mix design procedures for chemically stabilized FDR are based on laboratory compaction of specimens in a Proctor mold and determination of Unconfined Compressive Strength (UCS) of the mix. Strength retained after the UCS test can be used to quantify the amount of additive required and to ensure if enough strength is attained for the reclaimed mixes. For example, as indicated in Lewis et al. (2006), minimum strength of 450 psi is necessary for lab-fabricated specimens to have strength of 300 psi or greater achieved in the field [3]. Portland Cement Association recommends the unconfined compressive strength levels to be from 300 to 400 psi after seven days of curing [4].

Superpave Gyratory Compactor (SGC) has been also used in FDR mix design procedures. Mallick et al. (2002) have performed research on the compactive effort of the FDR mixes and suggested 50 gyrations to be used for the FDR mixes [5]. Lee et al. (1999) used the SGC to determine the optimum moisture content and asphalt emulsion content for cold in place recycling mixes [6]. Cross (2003) recommended the use of 30 and 35 gyrations for the reclaimed mixes [7]. Martinez et al. (2007) have studied effect of varying the standard conditions of gyration angle and vertical pressure and recommend a new mix design based on indirect tensile strength test [8].

The purpose of this research was to develop a procedure for cement stabilized FDR mixes to use the SGC for preparation of compacted specimens and utilizing the indirect tensile strength of the compacted specimens for mix design. Thus, correlation between the strength of Proctor prepared specimens and SGC prepared specimens was evaluated.

2 EXPERIMENTAL METHODOLOGY

The research in this study was conducted at Northeast Center of Excellence for Pavement Technology (NECEPT) at Penn State University, and the materials for this research were provided by Pennsylvania Department of Transportation. Specimens were prepared with 40% Reclaimed Asphalt Pavements (RAP), 60% stabilized earth, and determined amount of cement and water. Once specimens were compacted with in a Proctor mold and with a Superpave Gyratory Compactor, Unconfined Compressive Strength (UCS) testing and Indirect Tensile strength Testing (IDT) were performed in order to establish correlation between the strength results from the two compaction procedures.

2.1 *Material procurement*

In this project, Reclaimed Asphalt Pavement (RAP) materials were collected from a low traffic volume road in Dauphin County, PA and stabilized soil base materials were taken from

the road in Butler County, PA. Before collecting the RAP from the road, core samples were taken from arbitrarily determined sections of the road in order to determine the thickness of asphalt layer and the thickness of soil base. Wet coring was used, and during the coring process, a gas powered drill was used with a 6 inch diamond tipped coring bit (Fig. 2). The drill was connected to a water supply to help cool the sample and drill bit during the coring. Drilling was taken to sufficient depth to capture materials of different layers including the subbase. Cores were examined to determine the thickness of various layers (Fig. 2). It was determined that, on the average, the thickness of the asphalt and base layers were 40 mm and 60 mm respectively. This ratio of 2:3 for the asphalt thickness to base thickness layer was key in deciding proportioning materials from different layers in providing laboratory specimens.

In addition to coring, test pits were excavated at the site to verify thickness of layers and to obtain sufficient material for testing and characterization. Figure 3 shows samples from one of the test pits.

2.2 *Specimen preparation*

Following the RAP procurement and transportation to the laboratory, the RAP material was placed in an oven for 30 minutes at 135°C in order to loosen the material to the fullest extent possible. The loosened material was then blended with the base material after cooling. The blend consisted of 40 percent of the RAP (asphalt mix) and 60 percent the base material by the mass of dry weight of total mix. Sieve analysis was performed for the blend.

Figure 2. Coring and a core sample, Dauphin, PA.

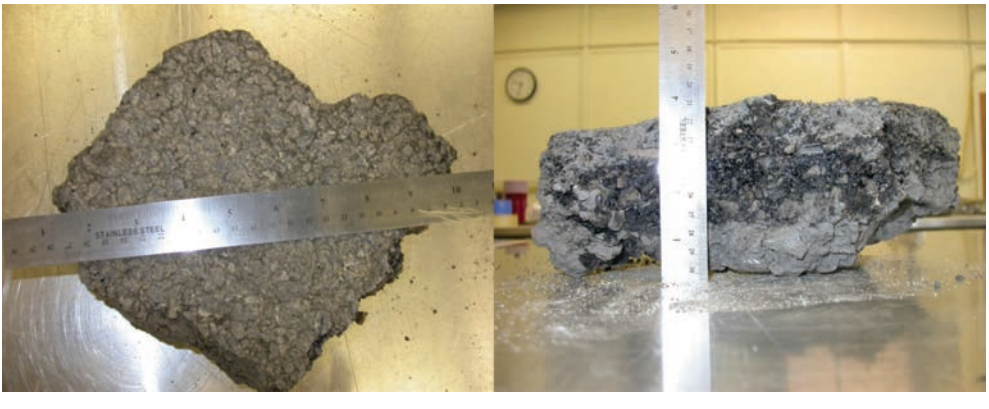

Figure 3. Test pit samples from Dauphin, PA.

The gradation is shown in Figure 4. The blend can be considered a coarse gradation as having a 19-mm nominal maximum size gradation.

2.3 *Mixing*

The optimum cement content was determined to be 7 percent with the corresponding optimum water content of 9.5 percent. Details of establishing optimum water and cement content are provided elsewhere (9). A sample of prepared mixes with cement and water is shown in Figure 5.

Nine specimens, three groups of three, were prepared and compacted in a Proctor for UCS test. Similarly, nine specimens, three groups of three, were also prepared and compacted using the SGC for IDT test. The specimens consisted of X percent cement and Y percent water by dry weight of the mix. Percentages for cement and water are shown in Table 1 for each group.

As it can be seen from Table 1, cement content was lowered and increased by 3 percentage points for the groups. That has resulted in decreasing or increasing water content by 0.75 percentage point for each 3% cement removal from or addition to the mix. The reason for that is to modify corresponding water demand caused by removal or addition of cement.

Figure 6. From left to right; proctor specimen and the steel mold, rammer for the proctor test, one day cured specimen, capped specimen after 7 day curing.

2.4 *Compaction*

A 4 in.-diameter steel mold with a collar attached was used for compaction of the UCS specimens according to AASHTO T 134, Standard Method of Test for Moisture-Density Relations of Soil-Cement Mixtures. The compaction was done in three layers in the mold and a total of 75-blow, 25-blow at each layer, was applied to each specimens. Average height of 6.86, 6.73 and 6.92 in. was achieved for Group 1, 2 and 3, respectively. After compaction, specimens were left in front of a fan overnight, and then were cured for 7 days in a moist room at 100% humidity. The specimens were then capped with a high strength hydro-stone material following the procedure outlined in ASTM C617-10, Standard Practice for Capping Cylindrical Concrete Specimens. After capping, the specimens were subject to curing in an oven at 40 Celsius degree for a day. Figure 6 shows the tools and the steps for Proctor specimens.

The SGC specimens were compacted right after mixing with 600 kPa of vertical pressure and a gyration angle of 1.16°. A 150-mm. diameter steel mold with holes (perforated), shown in Figure 7, was used for group 1 and 2 specimens and compacted to a target height of 52 mm. The recorded number of gyrations and average heights are shown in Table 2.

The SGC molds were perforated to allow water escape from the mold during compaction, and to dissipate pore water pressure. However, the perforated mold was not a successful application for the group 3 specimens, due to high moisture content. There was loss of very fine material through the holes during the gyration process. Thus, a steel mold with no holes was used for the group 3. As the reason for using perforated mold was to prevent water pressure built-up, compaction for the group 3 specimens was conducted in 3 stages. After completion of each stage of compaction, 3 minutes wait time was included to allow dissipation of the induced pressure. Table 3 summarizes gyration data for group 3 specimens.

Following compaction, specimens were left in front of a fan overnight, and then cured for 7 days in a moist room at 100% humidity. Specimens were subject to curing in an oven at 40°C for one full day right after the 7 day curing in the moist room.

3 TEST RESULTS

3.1 *Unconfined compressive strength testing*

Specimens compacted by the proctor underwent unconfined compressive strength testing at a constant loading rate of 1 mm/min as per ASTM D1633, Standard Test Methods for Compressive Strength of Molded Soil-Cement Cylinders. Table 4 summarizes UCS test results. Unconfined compressive strength results presented in Table 4 are based on averaging three replicates for each group.

3.2 *Indirect tensile strength testing*

Specimens compacted by Superpave Gyratory Compactor underwent Indirect Tensile strength Test (IDT). Equation 1 was used to determine the indirect tensile strength. The IDT results are shown in Table 5. Similar to UCS testing, the IDT results presented are average of three replicates per each group.

$$S = \frac{2000P}{\pi * t * D} \tag{1}$$

where:
S = Tensile Strength, kPa
P = Maximum Load, N
t = Specimen thickness, mm
D = Specimen diameter, mm

Table 4. Unconfined compression tests results.

Group	Water content, % (Y)	Cement content, % (X)	Wet density, g/cm³	Bulk specific gravity	Average measured strength, kPa	Coefficient of variation
1	8.75	4	2.0	1.997	1069	9.05

3	10.25	10	2.26	2.259	708	14.2

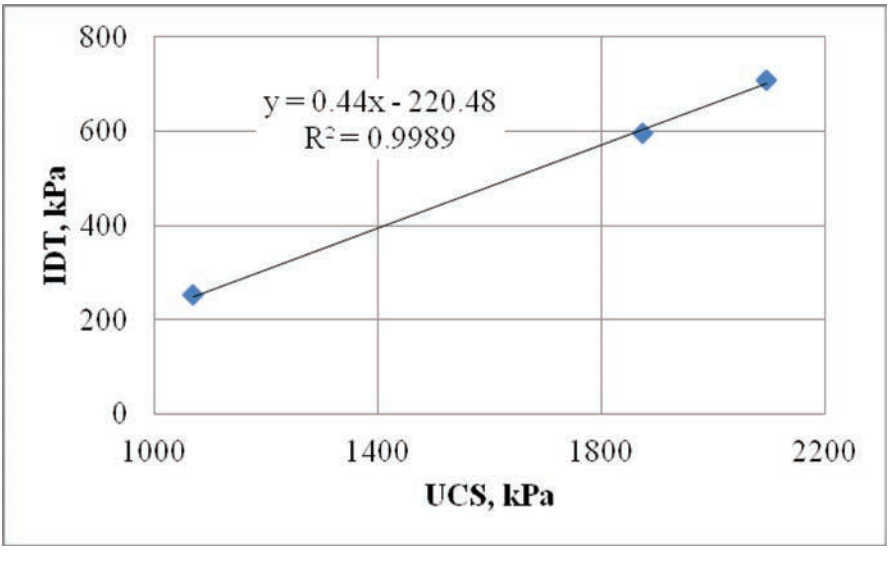

Figure 8. The correlation between IDT and UCS.

3.3 *Analysis*

The correlation between indirect tensile strength and unconfined compressive strength of specimens prepared with cement stabilized full depth reclaimed material is presented in Figure 8. The coefficient of determination, R-Squared, indicates a very strong correlation between the strengths obtained from these two different procedures. This is an indication of the potential for SGC compaction and indirect tensile testing of cement stabilized materials to replace the traditional design using the Proctor procedure. The advantage will be simplicity of compaction, the need for less material (as thinner specimens are prepared for indirect tensile test compared with unconfined compressive test, and a faster testing procedure.

A disadvantage of Proctor specimens prepared with reclaimed material is the surface roughness, especially if the reclaimed material is coarse graded. Uneven or rough surface of the specimen can cause problems during axial compressive loading of the specimens as the loading head may not perfectly sit on the top of the specimen. Sometimes, as was observed in this research, the surface is too rough to be ignored, and smoothening of the surface through capping (for example, with hydro-stone as used in this research) is needed, or the end must be trimmed to provide a smooth parallel surface. These problems are eliminated with the use of SGC and indirect tension.

4 SUMMARY AND CONCLUSION

Environmental and economical reasons have let asphalt recycling or reclaiming gain popularity in the pavement rehabilitation. As one of recycling techniques, Full Depth Reclamation (FDR) is mainly used in pavements for base associated problems. To date, there is no unified standard for design of FDR mixes. Most design procedures take advantage of standard or modified Proctor for compaction of specimens, following ASTM D558 or AASHTO T134.

The main purpose of this research was to find correlation between two different compaction and testing procedures: one using Proctor compaction and unconfined compressive strength testing, and the other using a Superpave gyratory compactor and indirect tensile strength testing. A total of 18 cement stabilized samples were prepared and tested. Test results indicated a very good correlation between the two procedures, and the potential of SGC/IDT process to replace the Proctor/UCS process for designing cement stabilized FDR mixes.

Hot Mix Asphalt for airfield pavements—moving from Marshall mix design to Superpave

Navneet Garg
FAA Airport Pavement R&D Section, Atlantic City International Airport, NJ, USA

Qiang Li, Harkanwal Brar & Injun Song
SRA International Inc., Linwood, NJ, USA

ABSTRACT: Hot Mix Asphalt (HMA) design for commercial airports in the United States (U.S.) is performed in accordance with the Federal Aviation Administration (FAA) Advisory Circular (AC) 150/5370-10F, "Standards for Specifying Construction of Airports," Item P-401—Plant Mix Bituminous Pavements. Currently, P-401 asphalt material is designed using the Marshall mix design procedure and has performed satisfactorily. In 2006, the FAA started a research study to develop an updated P-401 specification based upon Superpave technology. The first phase of the study determined number of gyrations required to produce similar volumetrics as a 75-blow Marshall mix design. The study concluded that mix compacted to 70 gyrations in a gyratory compactor produced a mix with similar volumetric properties to that designed using 75-blow Marshall mix design procedure. The second phase of the study concentrated on laboratory performance tests to be included in the updated P-401 specifications. Performance tests included modified Asphalt Pavement Analyzer (APA) tests, high temperature Indirect tensile Test (IDT), flow number tests, and fatigue tests. This paper will summarize the results from Phase-I and present Phase-II results in detail.

Keywords: Marshall mix design, Superpave, airport pavements, performance tests

1 INTRODUCTION

Approximately 90 percent of the U.S.'s paved runways are paved with Hot Mix Asphalt (HMA) [1]. However, only a small percentage of the total HMA placed in the U.S. is used for airfields. HMA for airfield flexible pavements have been designed using the Marshall mix design method in accordance with FAA AC 150/5370-10 [2].

Marshall mix design procedure has performed satisfactorily. Since the highway industry has converted to superior performing asphalt pavement (Superpave) methodology, it is becoming more difficult to find contractors who are willing to perform mix design according to the Marshall mix design methodology. Hence, it is important that the Superpave method be adopted for HMA design for airfield pavements. Before the Superpave methodology can be adopted by the FAA, the number of gyrations required to provide an adequate compactive effort for airfield pavements must be determined. FAA sponsored three parallel efforts to evaluate the number of gyrations required to provide a density similar to 75 blows with the Marshall hammer. Since the 75-blow Marshall mixes have performed well on airfields in the past, it is believed that providing a density with the gyratory compactor equal to that obtained with Marshall compaction would be a good approach to adopt Superpave and still have confidence of good performance. To date,

three studies have been completed with assistance from FAA funding. The objectives of study were to:

- Determine number of gyrations required to produce an airfield quality HMA;
- Recommend a laboratory performance test to accompany the P401 Superpave specification.

The study is in its final stages and the findings are presented in this paper.

2 PREVIOUS RESEARCH

The FAA had three parallel efforts going on to achieve the above mentioned objective. Work was performed by

- SRA International, Inc. (FAA's support contractor);
- Engineer Research and Development Center (ERDC) at Vicksburg, MS (Interagency Agreement); and
- Parallel project under Airfield Asphalt Pavement Technology Program (AAPTP).

Additional details about these studies can be found elsewhere [3]. Dr. Don Christensen (Advanced Asphalt Technologies), working under FAA contract, summarized the results from three studies [4] and is presented below.

The ERDC research [5] focused on determining the number of gyrations required to achieve the same air void content as produced using 75-blow Marshall compaction. A wide range of mixes were included in this research. The mixes were designed with and without 10% natural sand. Two different binders were used: a Performance Grade (PG) 64-22, and a polymer-modified PG 76-22. The various combinations of aggregate type, size, gradation, natural sand content, and binder resulted in a total of 52 different mix designs. Few mixes that did not meet P401 specifications were included for comparative purposes. This study recommended that 70 gyrations be used to compact specimens in the gyratory compactor when designing HMA for airfield pavements.

In the AAPTP 04-03 project [1], in addition to N-equivalent, the researchers also examined how the mixes selected for the study compacted under traffic, and how much compaction effort was needed to provide adequate rut resistance for the intended application. Eleven primary mixes were used in the study, including seven designed using Marshall compaction and four designed using gyratory compaction. These mixes replicated mixes used in existing airfield pavements from a wide geographic area, and represented a variety of aggregate types, sizes, gradations, and binders. The AAPTP 04-03 researchers based their recommendations on the relationship between the number of gyrations and rutting resistance, as measured using the flow number test, as performed on the asphalt mixture performance tester. Specimens were prepared using two to four gyration levels with varying binder contents, and were then subjected to the flow number test. From these data, the minimum number of gyrations required to prepare specimens passing the flow number test was determined. The final recommendations were given in table form, giving design gyrations as a function of aircraft tire pressure. At tire pressures below 100 lb/in^2, 50 gyrations are to be used; at tire pressures from 100 to 200 lb/in^2, 65 gyrations are to be used; and at tire pressures above 200 lb/in^2, 80 gyrations are to be used in preparing specimens.

FAA/SRA approach was very similar to the ERDC study. However, in the FAA/SRA study, all the mixes used to determine N-equivalent were based on HMA designs used in airfield pavements that have exhibited good performance (mixes used in the ERDC study were not based on ones from actual airfield pavements). The FAA/SRA study also performed laboratory tests to compare the rut resistance and fatigue resistance of mixes designed using both Marshall and gyratory compaction. The average value of N-equivalent was 62; the researchers recommend using 70 gyrations to prepare specimens, since the difference between 62 and 70 gyrations is probably negligible. The rutting resistance of mixes designed using 70 gyrations was found to be slightly better overall than the same mixes designed using 75-blow Marshall compaction. The fatigue resistance of the mixes designed using the two procedures were found to be similar.

3 PERFORMANCE TESTS

Phase II of the study has just been completed. The main objective of the Phase II study is to examine the variability in performance that occurs when designing HMA mixtures using the two different compaction methods and recommend a performance test to accompany the P401 Superpave specification. The objective of the study was not only to evaluate differences in the overall level of performance between the two mix design methods, but more importantly to evaluate differences in the variability in performance between the two methods. The general research approach in Phase II was to prepare specimens from each mix design and perform both rut resistance and durability tests using laboratory procedures. The performance of mixes designed using the 75-blow Marshall mix method was compared to designs prepared using the N_{design} of 70 gyrations. A more effective design method would show a lower degree of variability in performance.

The mix performance was evaluated using the following laboratory tests: Asphalt Pavement Analyzer (APA) (AASHTO TP 63-09) tests, Asphalt Mixture Performance Tester (AMPT) flow number test (AASHTO TP 79-09), and uniaxial fatigue tests. Flow number and APA tests characterize the rut resistance of the mix, and uniaxial fatigue tests characterize the fatigue behavior at low temperatures.

3.1 *Asphalt Pavement Analyzer (APA) tests*

The rutting resistance of asphalt mixture was evaluated using the APA. The loading conditions in the APA are more commonly associated with highway conditions. The APA purchased by the FAA is shown in Figure 1. This APA has been customized to apply 260 psi hose pressure and up to 500 psi with an aluminium wheel with variable rate of loading to simulate different aircraft speeds.

The APA tests were conducted at 0.69 MPa (250 psi) at 64°C (147°F) (high temperature for the binder grade used in mix PG 64-22) to simulate the effects of high tire pressures and high pavement temperatures in airport pavements. Samples were prepared by the U.S.

Figure 1. FAA customized APA.

Army Engineer Research and Development Center (ERDC) at 70 gyrations using three different aggregate types (limestone, granite, and chert gravel), two different aggregate sizes (12.7 and 19.05 mm (0.50 and 0.75 inch)), and two different gradations (fine and coarse). PG 64-22 binder was used in all the mixes. Mixes contained sand content ranging from 0 to 30 percent. Data analysis was performed by direct rut depth measurements.

More details about materials, test procedure, and data analysis can be found elsewhere [6]. Figure 2 shows the results from APA tests for all mixes.

Weak mixes (containing high percentage of natural sand) show rapid accumulation of rutting during the initial load cycles and the samples failed (rut depth > 8 mm) in fewer than 4000 load cycles. Mixes containing chert gravel rutted comparatively quicker than the mixes containing granite and limestone. Based on the results of this study, Rushing et al. recommended a preliminary criterion of less than 10 mm rut depth after 4000 load cycles using 250 psi hose pressure at 64°C (high temperature for the binder grade used in mix PG 64-22) [5]. These were initial findings of the study.

This is an on-going study, and additional tests are being performed by the FAA at their laboratory on eight HMA mixes. These mixes have been used at airport pavements across the U.S. and have performed well under heavy aircraft traffic. These mixes contain different aggregate geologies (granite, dolomite, basalt, limestone, and argillite) and gradations. Both neat and Polymer Modified Asphalt (PMA) binders were used in these mixes. Preliminary tests performed by the FAA showed that Superpave Gyrator Compactor (SGC) mixes showed slightly better rut resistance compared to mixes design using the 75-blow Marshall mix design procedure.

3.2 *Flow number tests*

The AMPT flow number test is used to evaluate the rutting resistance of asphalt mixes. In a flow number test, the sample is subjected to repeated compressive stress of 600 kPa at high temperatures using an AMPT device. The test is performed on specimens that are cored and trimmed (100 mm diameter and 150 mm high) from SGC specimens prepared at the expected in-place air void content. Typical test setup and results are shown in Figure 3. Flow number

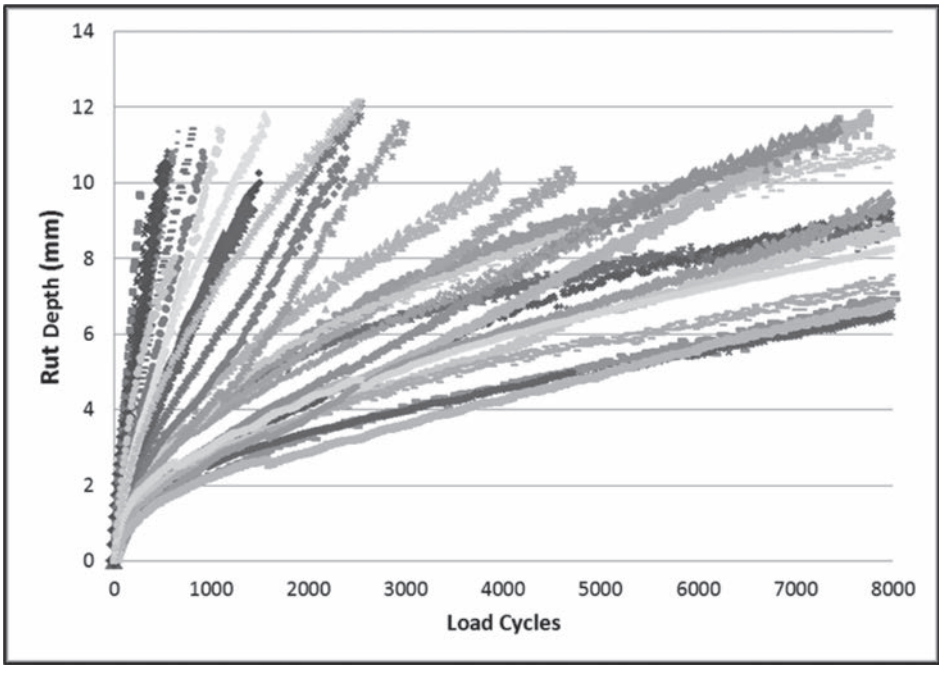

Figure 2. The APA test results on samples prepared by ERDC.

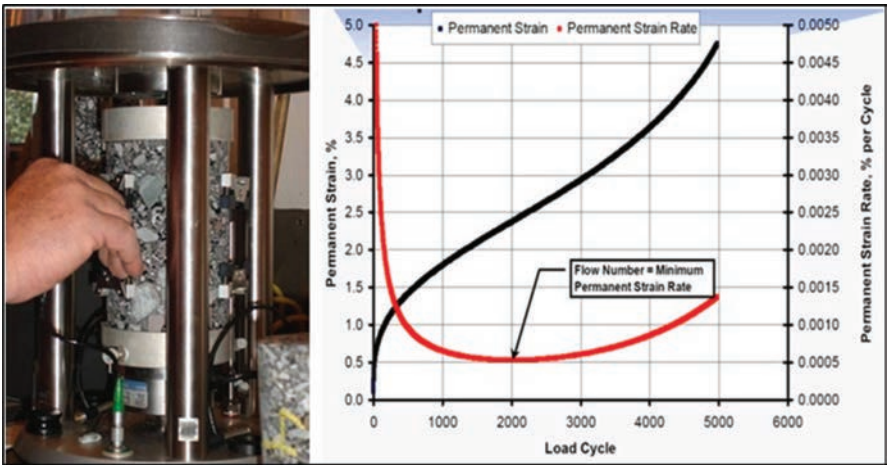

Figure 3. Flow number test.

Table 1. Summary of rut resistance tests (APA and flow number tests).

Mix ID #	FAA aggregate size (mm)	Design compaction method	Design gyrations	Binder grade	Test temperature (deg. C)	Flow number	APA rutting (mm)
1	19	Marshall	40	PG 64-22	50.9	88	4.6
		Gyratory	70	PG 64-22	50.9	120	4.9
2	25	Marshall	70	PG 64-22	51	75	5.6

		Gyratory	70	PG 64-22	55	220	5.5
8	19	Marshall	50	PG 70-22	55.4	130	6.1
		Gyratory	70	PG 70-22	55.4	150	4.9

tests are run at the average 7-day maximum pavement temperature 20 mm below the surface, at 50 percent reliability as determined using LTPPBind version 3.1. The number of cycles corresponding to the minimum permanent strain rate is defined as the flow number. Better asphalt mix designs will have higher flow number.

The flow number tests generally followed the trends shown by APA test results and appear suitable for evaluating the rut resistance of HMA for airfield pavements. The SGC mixes showed slightly better rut resistance, probably because of the slightly lower binder contents that were achieved with SGC designs (to provide same volumetrics as Marshall designs). Table 1 summarizes the results from APA and flow number tests performed in the study.

3.3 *Uniaxial fatigue tests*

Uniaxial fatigue tests were performed at 20°C and 4°C on all Phase II mixes shown in Table 4. In the uniaxial fatigue test, a completely reversed sinusoidal load was applied to the specimen

for an extended period of time. The complex modulus (|E*|) of the specimen was constantly monitored during the test, and the rate at which it declined was considered a measure of fatigue damage. Results were analyzed using continuum damage theory. Based on the test results obtained to date, shown in Figure 4, the HMA mixes designed using both the Marshall mix and SGC tend to have similar levels of fatigue resistance.

3.4 *Indirect tensile strength tests*

Indirect Tensile Strength (IDT) was measured at design air void content in accordance with ASTM D6931 at a temperature of 40°C and deformation rate of 5 mm/minute. Tests were performed on three different well performing HMA mixes used at airports and National Airport Pavement Test Facility. Figure 5 shows the relationship between IDT strength and the temperature difference between the high-temperature performance grade and the test temperature.

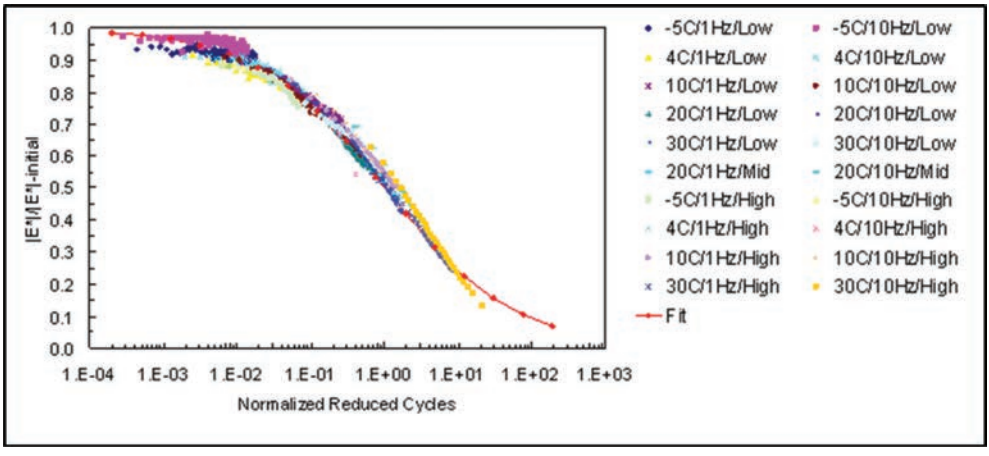

Figure 4. Final master curve for fatigue damage.

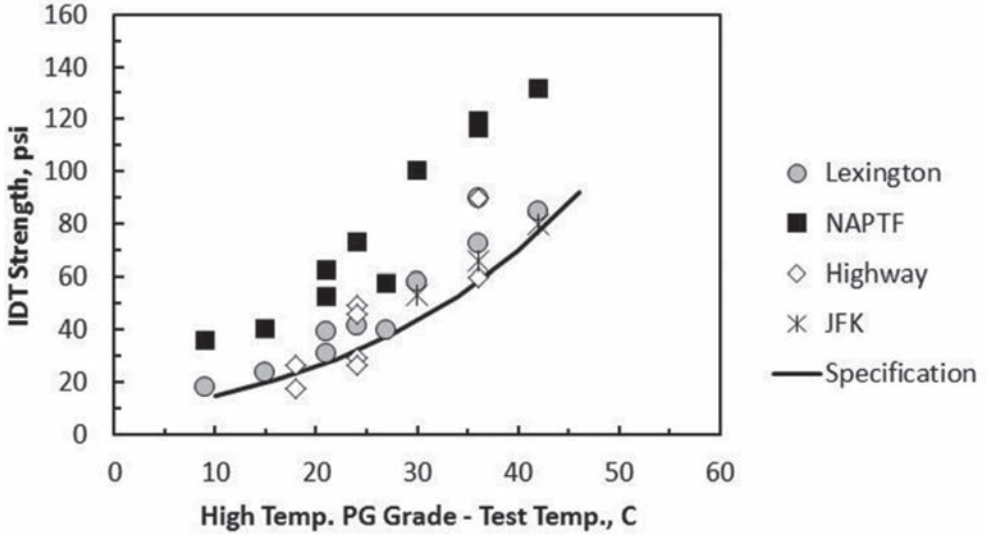

Figure 5. IDT strength as a function of difference between high temperature performance grade and test temperature.

The relationship is fairly reasonable, although the NAPTF mixture exhibits significantly higher IDT strengths than the other mixes. The reason for this difference could be the relatively low air void content of samples of the NAPTF mixes that was tested.

3.5 *Selection of performance test for P401 specification*

There is a need to have an engineering property test for airfield HMA that is simple, quick and inexpensive but still effective. The high temperature Indirect Tensile Test (IDT) meets all these requirements. It is in some ways even simpler than a Marshall stability and flow test, and can be performed using the Marshall press. Based on previous research studies [7–9] it has exhibited excellent correlation to other performance tests in a number of different research projects, including the current research. Other performance tests in the current research (APA, Flow Number Tests, Uniaxial Fatigue Tests) were able to quantify the performance of the mixes but were complicated and time consuming to perform. APA is a simple test, but the availability of equipment capable of loading upto 250-psi is limited and may be considered in the future. In the proposed P401 Superpave Specification, High Temperature IDT test has been recommended as the performance test.

4 SUMMARY

The FAA is in the process of developing an updated P-401 specifications based on the Superpave mix design technology. The Phase-I of the study recommended 70 gyrations for mix designs. The recommendation was based on the fact that HMA volumetrics of mixes designed using 70 gyrations were similar to volumetrics of mixes designed using 75 blow Marshall mix design. High temperature IDT test was recommended as the performance test to accompany the proposed P401 Superpave specification. The main issue with implementing the IDT test for airfield HMA is establishing specification requirements. Because only limited data have been collected on airfield mixtures, lenient IDT design criteria are included in this version of the P-401 Gyratory specification and IDT testing during production is included as a quality control item. This will allow the FAA to use the specification and collect additional data on IDT strengths and production variability to refine the design criteria and ultimately include the IDT test as an acceptance criterion.

ACKNOWLEDGEMENTS

Implementation of a static strength test for evaluating the rutting resistance of asphalt mixtures and its application for quality controls

Silvia Angelone, Marina Cahuape Casaux & Fernando Martinez
Road Laboratory, School of Engineering, University of Rosario, Riobamba and Berutti, Rosario, Argentina

ABSTRACT: There is great concern in Argentina about the rutting resistance of asphalt mixtures mainly related to the high temperatures in summer and the number of overloaded trucks. As a standard, the Marshall mix design procedure is used and improvements have been introduced in order to reduce the risks associated with this kind of damage. Nowadays, the exclusive use of crushed aggregates and harder bitumen are mandatory. Also, the proposed job formula must be tested with the wheel tracking device in order to check the rutting behavior of the mixture. However, during the construction stage, the tests that are carried out for the quality control are not directly related to this issue. Hence, a static strength test named as "the Kim test" has been proposed to be included as a routine using the same equipment and the type of specimens that are currently taken during the works after the asphalt mixture has been placed in the field. This paper presents a brief description of the fundamentals of the test, the correlation between this static strength property and the rutting resistance for different mixtures used in Argentina and the implementation of the Kim test as a rutting quality indicator.

Keywords: asphalt mixtures, rutting resistance, Kim test, wheel tracking test, quality control

1 INTRODUCTION

In Argentina there is a great concern about the rutting resistance of asphalt mixtures mainly related to the high temperatures registered in asphalt pavements during the summer and the increasing number of overloaded trucks. As a standard, the Marshall Mix design procedure is used and, in order to reduce the risk associated with this kind of damage, several improvements have been introduced in the last years. For example, the exclusive use of crushed aggregates and harder bitumen are now mandatory.

However, according to the standards used in Argentina for road construction, the asphalt mixtures are considered with different level of details at the laboratory when the mix is formulated, at the asphalt plant when it is produced and in the field when it has been already placed.

First at the laboratory, the different mixture components are carefully controlled determining mechanical and physical properties for the aggregates and the bitumen. Then, the aggregates are combined in order to have the gradation between the specified limits for the selected kind of mixture and the optimum asphalt content is determined.

Physical (Marshall Density, air voids content, VMA and VFA) and mechanical (Marshall Stability, Flow, Stability/Flow Quotient and moisture susceptibility) properties are determined according to the standard mix requirements and a job formula is finally adopted.

Recently and due to the apprehension about the rutting performance of the mixtures designed according to the Marshall procedure, other complementary tests are carried out like the dynamic modulus test and the Wheel Tracking Test (WTT).

At the asphalt plant, two or three samples of the produced mixture are taken from the trucks every day and the gradation of the recovered aggregates, the bitumen content and other volumetric properties are controlled, verifying if these values are within certain limits of tolerance referred to the values obtained for the job formula. Also, samples are compacted and the Marshall density, stability and flow are determined.

Finally when the mix has been placed, cores are taken and the thickness and density are measured. Finally, if the density of the mixture is greater than a specified value related to the density obtained during the corresponding production day in the asphalt plant, the mixture is considered acceptable.

Briefly, if the results obtained in the asphalt plant are comparable with those obtained in the laboratory for the job formula and, the density of the cores taken from the pavement are also comparable with those obtained in the asphalt plant, it is supposed, by this indirect way, that the placed mixture have the required properties as determined originally during the formulation process. As can be observed, this quality control procedure does not take into account the real rutting behavior of the placed mixture.

Currently, tests of evaluating rut resistance of asphalt mixtures in the laboratory include different types of wheel tracking, repeated loading, dynamic modulus, flow number or flow time tests but these procedures are relatively complex, need sophisticated equipments, well trained technician and in general, are not available in the field laboratories.

The Marshall test is the most used worldwide test and the Marshall stability, the most well known static property of asphalt mixtures. However, several studies have shown that this result or even, the Marshall Quotient Stability/Flow (S/F) have little correlation with rutting characteristics of the mixtures [1].

Hence, this paper presents the use of a static strength test named as the Deformation Strength Test (DST) that could be included as a routine control for evaluating the rutting resistance of asphalt mixtures using the same equipment as for the Marshall Test. The main advantage of this test is that it can be applied for samples compacted at the laboratory or cores currently taken during the works after the asphalt mixture has been placed in the field.

In this study, the ability of the DST for estimating the rutting performance of asphalt mixtures has been evaluated through a correlation analysis with results obtained with the Wheel Tracking Test (WTT) for 20 different asphalt mixtures produced in different construction projects in Argentina. Also, the use of this static strength test for quality controls is proposed as a simple tool for a direct evaluation of the placed asphalt mixture against this kind of damage.

The background of this investigation is the research conducted by Professor K. W. Kim at the Kangwon National University in the Republic of Korea who developed a static test protocol for characterizing the deformation resistance of asphalt concretes and found that the property determined by this test, the deformation strength S_D, has relatively high correlation with the rutting parameters of asphalt mixtures when tested according to the Wheel Tracking and APA Tests.

2 EXPERIMENTAL PROGRAM

2.1 *Materials*

In this study, 20 different asphalt mixtures used in different construction projects in Argentina for base and surface layers were considered. These mixtures were Dense (D) and Semi-dense (S) asphalt concretes with two different maximum nominal aggregate sizes (12 or 20 mm) made with conventional (AC30) and polymer modified bitumen (AM3). Table 1 shows a detail of these mixtures and the main parameters obtained with the conventional Marshall mix design procedure.

Mixtures 9 to 17 were prepared with different percentages of Recycled Polyethylene (RP) from silo bags added by a dry process with two different types of recycled polyethylene, Chopped (C) and in Pellets (P). Details of these mixtures could be found in another paper

Table 1. Asphalt mixtures.

[2]. All the mixtures without recycled polyethylene meet the mechanical requirements used in Argentina. With these mixtures, slabs were compacted to be used in the following tests as described below.

2.2 *Deformation Strength Tests (DST)*

The Deformation Strength Test, developed by Professor K. W. Kim at the Kangwon National University in the Republic of Korea, is a static test for measuring the deformation resistance of asphalt mixtures at a high temperature. In this test, also named as "Kim Test", a static load is applied to a small area at the top centre of a specimen through a round edge loading head (rod) as it is shown in Figures 1 and 2.

During the test, the applied load and the vertical displacement of the loading head are registered as it is shown in Figure 3. The parameter evaluated by this test is considered as the strength against deformation or the deformation strength designated as "S_D" based on the uniaxial peak load P and the vertical deformation Y at the peak load point.

The deformation strength S_D is calculated as:

$$S_D = \frac{4P}{\pi[D - 2(r - \sqrt{2rY - Y^2})]^2} \tag{1}$$

where:
S_D : Deformation strength (MPa)
P : Maximum load at failure (N)
Y : Vertical displacement of the loading head at failure if $Y < r$. Otherwise, $Y = r$ (mm)
r : Radius of edge curvature of the loading head (mm)
D : Diameter of the loading head (mm).

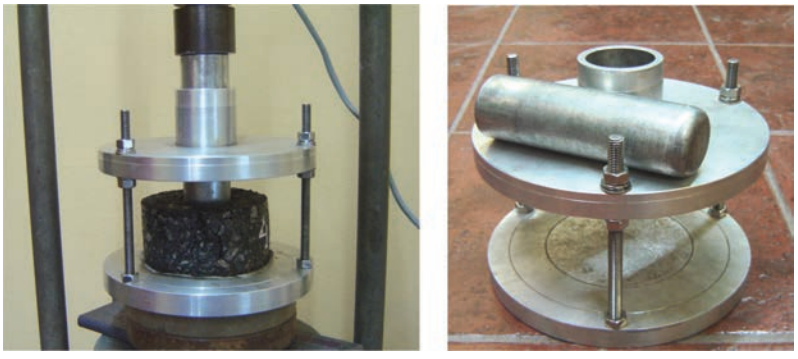

Figure 1. Testing device.

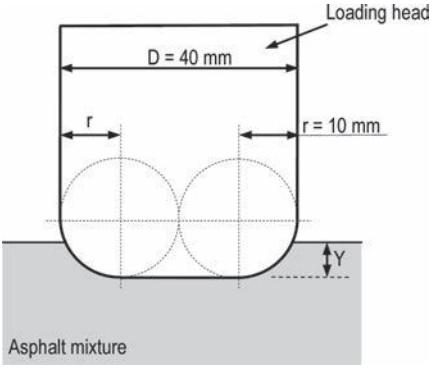

Figure 2. Details of the loading head.

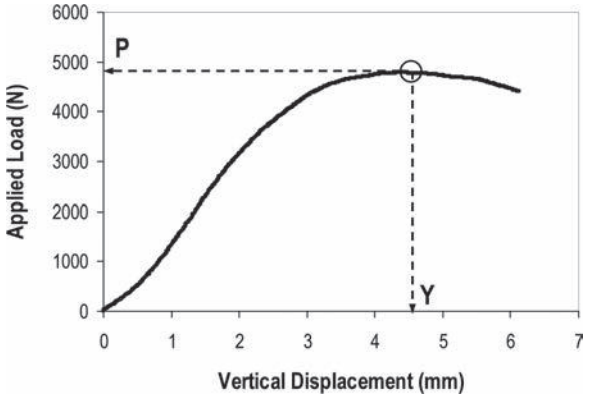

Figure 3. Measured load and vertical displacement.

A detailed description of the test can be found elsewhere [3–5]. After a sensitivity analysis, Dr. Kim has proposed the dimensions of the loading head ($r = 10$ mm; $R = 40$ mm), the testing temperature equal to 60 ºC and a loading rate equal to 30 mm/minute in order to obtain the best correlations between S_D and the rutting resistance of the mixtures. However, a loading rate equal to 50.8 mm/minute was adopted in this study allowing the use of conventional Marshall loading frames.

2.3 *Wheel tracking tests*

Wheel Tracking Tests (WTT) were carried out according to the EN 12607-22:2003 Standard "Bituminous mixtures—Test methods for hot mix asphalt—Part 22: Wheel tracking" for small testing devices, Procedure B. Based on an extensive experience developed in several European countries [6], USA [7] and Argentina [8] showing that the WTT results are good indicators of the observed rutting performance of in-service pavements, this procedure has been adopted as the standard to determine the susceptibility of asphalt mixtures against this kind of damage. In this test, a compacted slab of an asphalt mixture is moved backwards and forwards at a fixed frequency under a loaded wheel and the resulting rut depth at the centre of the slab is measured as a function of the number of loading cycles. Figure 4 shows the typical evolution of the rut depth as a function of the applied number of cycles for this test.

The proportional rut depth at 10000 cycles, PR_{10000}, is calculated as:

$$PR_{10000} = \frac{d_{10000}}{h} \times 100\% \tag{2}$$

with:
d_{10000} : rut depth after 10000 load cycles (mm)
h : specimen thickness (mm).

The wheel tracking slope WTS in millimeters per 10^3 load cycles, is calculated as:

$$WTS = \frac{(d_{10000} - d_{5000})}{5} \tag{3}$$

with:
d_{5000} : rut depth after 5000 load cycles (mm).

The asphalt mixtures used in this study were compacted in slabs with the required dimensions (300 × 300 × 50 mm) using a vibratory hammer. In many cases, the compaction energy was varied in order to obtain, for a given asphalt mixture, slabs with different degrees of compaction. At least, two slabs were prepared for each condition.

If it was verified that the mix was not laterally displaced after the WTT was completed on the centre testing line, a second line was tested on the same slab in order to obtain an additional set of data. A previous paper has shown that comparable results are obtained with this testing methodology [9].

2.4 *Experimental procedures*

The WTT were carried out at 60 ºC in air with a loading frequency of 26 cycles per minute and a wheel load of 700 N. The test ends when 10000 load cycles are applied or a rut depth of 20 mm is reached whichever is the shorter.

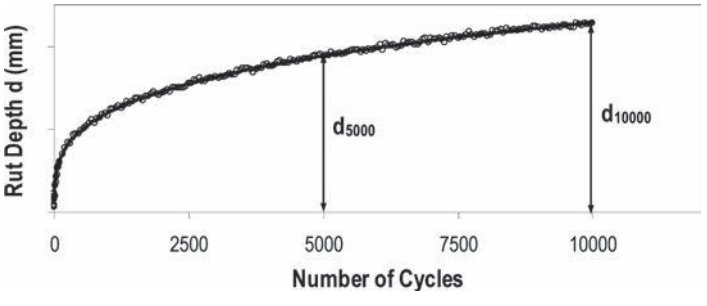

Figure 4. Evolution of the rut depth.

Figure 5. Specimens cored from the slab.

After the WTT was completed on one or two testing lines, two cores with 100 mm diameter were taken from each slab to be tested according to the Deformation Strength Test (DST) as shown in Figure 5. The DST were executed a 60 ºC and a loading rate equal to 50.8 mm/minute.

The averaged values of the PR_{10000}, WTS and S_D were considered for the following analysis.

3 OBTAINED RESULTS

Figures 6(a) and 6(b) show the variation of the deformation strength S_D as a function of the proportional rut depth at 10000 cycles, PR_{10000}, and the wheel tracking slope WTS for all the samples considered in this study.

Regression analysis was performed to evaluate correlation of WTT and DST test results. The best fit curve showing highest R^2 was selected among five regression models: linear, polynomial, exponential, power and logarithm.

As can be observed, a fairly good correlation exists between S_D and the rutting resistance of the mixtures evaluated through the PR_{10000} and WTS values, even for the materials used in this analysis with a wide variety of gradation, maximum nominal aggregate size and bitumen type.

A greater value of S_D implies a better rutting performance with smaller PR_{10000} values and lower WTS slopes.

Figure 7 presents the proportional rut depth PR_{10000} against the wheel tracking slope WTS for the wheel tracking tests carried out in this study.

In this figure, it is seen that a very good correlation exists between the proportional rut depth at 10000 cycles and the wheel tracking slope. Since both values have been considered as good indicators of the rutting resistance of the asphalt mixtures, it is evident that it is enough to consider only one of them because the other result strongly correlated.

In Argentina, several previous studies have shown that for warm climates and heavy traffic, it has been observed a good rutting performance of pavements with asphalt mixtures exhibiting wheel tracking slopes lower than 0.100 mm/10^3 cycleswhen tested in air according to the EN 12607-22:2003 Standard using small size devices [8, 10, 11]. Thus, from Figure 6(b), this acceptable rutting performance could be related with a minimum S_D value in the order of 3.5 to 4.0 MPa as a first approximation for all the asphalt mixtures with similar characteristics than those used in this study.

As a reference, the Ministry of Land, Infrastructures and Transport of the Korean Government has adopted as specification limits for hot-mix asphalt surface course mixtures the following values: $S_D > 3.2$ MPa for secondary road asphalt pavement and $S_D > 4.25$ MPa for first class highways *(Kim K. W., personal communication, 2013)*.

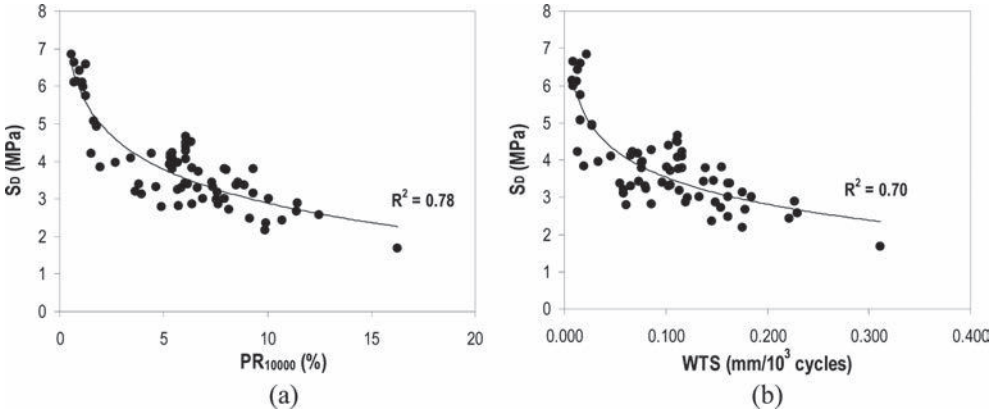

Figure 6. Relationships between WTT and S_D results.

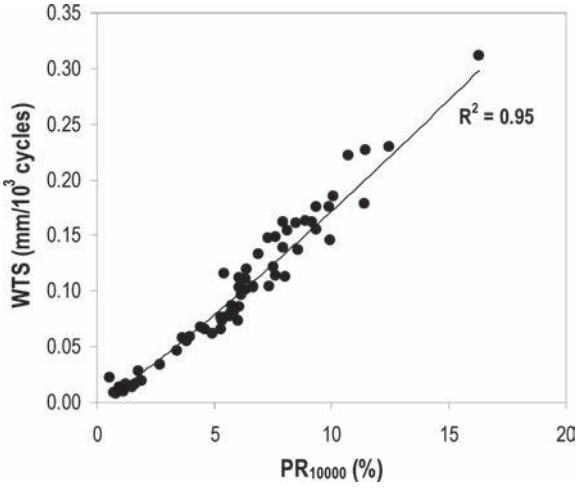

Figure 7. Relationship between PR_{10000} and WTS.

In general, the WTT procedures are relatively complex, need well trained technicians, require special equipments for the compaction and the testing of the slabs and are not widely used in field laboratories. Therefore, this Deformation Strength Test is a good option evaluating the rutting resistance of asphalt mixtures because it requires an inexpensive loading device and conventional testing equipments that can be found in almost all laboratories allowing the use of compacted samples or cores taken from in service pavements.

Based on the obtained correlations, the DST could be used as an indicator of the rutting resistance of asphalt mixtures when the WTT is not available.

4 APPLICATION OF THE DST FOR QUALITY CONTROL

Given that the DST is an inexpensive and simple testing procedure that can provide valuable information about the rutting resistance of asphalt mixtures, its application to the quality control of pavement sections is proposed.

After the optimum asphalt content has been adopted following the conventional mix design procedure, a couple of slabs are compacted in the laboratory and tested in air according to

the EN 12607-22:2003 Standard using a small size device. If the resulting average WTS is lower than 0.100 mm/10^3 cycles, the designed mix is considered as acceptable. Three additional samples are compacted following the Marshall procedure and tested according to the DST. The average of the obtained S_D for each sample is considered as a first reference value designated as S_{DREF1}. Also, two cores with 100 mm in diameter are taken from each slab used for the WTT and subjected to the DST. A second reference value for the Deformation Strength is calculated as S_{DREF2}.

At the construction site during the production of the asphalt mixture, loose mixture is taken from the trucks and Marshall samples are compacted at the field laboratory. Three of them are used for the conventional Marshall test as in the routine quality control but other three additional samples are used for the DST. If the average of the S_D results for these samples, S_{DLAB}, is greater than the S_{DREF1}, the production continues. Otherwise, the production is stopped and the cause for the observed difference is investigated.

When a pavement section is finished, cores are taken from this section in order to verify the density and the thickness of the layer. Then, these cores are subjected to the DST and the average of the S_D of this section, S_{DFIELD}, is compared to the S_{DREF2}. If S_{DFIELD} is greater than S_{DREF2}, the section is approved and the construction process continues.

Otherwise, the rutting susceptibility of the placed mixture must be checked through the WTT.

In this case, the authors have proposed a simple procedure producing susceptible cores to be used in a conventional WTT device. Three cores with 150 mm in diameter are taken along a line and with a special location as is shown in Figure 8. First, the core C is taken and then, two other cores (A and B) are taken on each side in order that the total length L be equal to 300 mm.

If it is necessary, the cores must be trimmed to obtain specimens with the required thickness for the WTT. These "three parts" specimens are constrained in a specially designed support and tested in a conventional WTT device as shown in Figure 9. A detailed description and validation of this procedure can be found in a previous paper [12].

WTS results with no substantial differences have been obtained for the "three parts" and monolithic specimens showing that this coring procedure is able to easily obtain samples for the conventional WTT apparatus. Other option is coring 200 mm specimens from the pavement according to the EN 12607-22:2003 Standard.

If the wheel tracking slope WTS is lower than 0.100 mm/10^3 cycles, the asphalt mixture is considered acceptable. Otherwise, the mixture is considered as not acceptable and corrective measures should be adopted.

Thus, this study proposes the use of the DST as a filter:

- If $S_{DLAB} > S_{DREF1}$ and $S_{DFIELD} > S_{DREF2}$, the asphalt mixture "Pass"
- If $S_{DLAB} < S_{DREF1}$ or $S_{DFIELD} < S_{DREF2}$, the asphalt mixture "No Pass" and other tests are necessary in order to arrive to a final decision.

With this purpose, the Deformation Strength Test is a simple tool that could be used to estimate the rutting resistance of an asphalt mixture when it is produced and placed in the field using conventional testing equipment with important savings in money and time reducing the number of the required Wheel Tracking Tests.

5 CONCLUSIONS

In this paper, the use of a simple static strength test, the Deformation Strength Test DST or "Kim Test", has been evaluated to estimate the rutting potential of asphalt mixtures.

The main advantage of this test is that it uses conventional loading equipments that can be found in the field laboratories and compacted samples or cores taken from in service pavements. The resulting parameter of this test is the Deformation Strength S_D.

Correlation analysis were carried out between the results obtained with this test and the WTT for 20 different asphalt mixtures formulated with a great variety of gradation, maximum nominal aggregate size and bitumen type. It was found that S_D has a fairly good correlation to the Proportional Rut Depth at 10000 cycles, PR_{10000}, and the Wheel Loading Slope, WTS, obtained with the WTT. For the asphalt mixtures considered in this study, a strong correlation was found between the PR_{10000} and WTS values.

In Argentina, several previous studies have shown that for warm climates and heavy traffic, it has been observed a good rutting performance of pavements with asphalt mixtures exhibiting WTS values lower than 0.100 mm/10^3 cycles. Thus, a corresponding minimum value of S_D around 3.5 to 4.0 MPa could be adopted as a first approximation for mixtures with an acceptable rutting resistance.

Finally, the DST is proposed as a complementary test to be included in the quality control plans to estimate the rutting potential of the asphalt mixtures when they are produced and placed in the field. Even though the DST has an empirical basis that do not evaluate the real mechanistic response of the mixture, its simplicity and the use of conventional equipments show that it could allow for a better insight about the rutting performance of the asphalt pavements.

As this investigation is part of an ongoing research project, other asphalt mixtures are being tested in order to improve the obtained correlations. It is also planned that in a upcoming stage, the proposed quality control procedure will be implemented to verify its applicability, produce the necessary refinements and adjust the minimum S_D value through the performance monitoring of several roads that are being constructed in Argentina.

ABSTRACT: Economic, environmental, and engineering benefits led to the rapid implementation of Warm-Mix Asphalt (WMA) during the past decade. While WMA technologies are generally performing well to date, development of standard mix design protocols continues and performance questions remain. This study evaluated laboratory conditioning protocols for WMA to simulate early life when they are more moisture susceptible and proposed 2 hours at 116°C for mix design and reheating to this temperature for quality assurance for all WMA technologies except foaming which requires reheating to 135°C. Next, WMA was shown to be more moisture susceptible as compared to Hot-Mix Asphalt in the early life based on a comprehensive analysis of three standard laboratory tests (wet and dry indirect tensile strengths and resilient modulus and their ratios and Hamburg Wheel Tracking Test stripping parameters) from four field projects that included nine WMA mixtures. Finally, an evaluation of performance evolution showed that WMA can overcome this vulnerability to moisture after a summer of aging and proposed 5 days oven aging at 85°C to capture this effect in the laboratory. Proposed conditioning protocols, aging protocols, and criteria for the tests utilized are provided for WMA mix design and analysis to preclude moisture susceptibility.

1 INTRODUCTION

Past efforts to reduce placement and production temperatures of asphalt mixtures date back to the late 1950s, including binder foaming processes, asphalt emulsification, and incomplete aggregate drying [1–2]. The latest technology adopted to reduce placement and production temperatures is Warm-Mix Asphalt (WMA). This technology offers a number of benefits, including decreased energy consumption, reduced emissions and fumes at the plant, improved working conditions at the construction site, extended haul distances, longer pavement construction season, improved workability and compactability, and reduced aging. Widespread use of this technology and realization of its benefits requires producing WMA with similar performance and durability as Hot-Mix Asphalt (HMA) at substantially reduced production and placement temperatures [3–5].

Despite the attractive economic, environmental, and safety advantages of WMA there are several barriers to its extensive implementation; such as imprecise correlation between laboratory and field performance, incomplete mix design procedures, and a wide variety of WMA technologies that entail a number of changes in the mixture production process as compared to HMA. In addition, several factors related to the lower production temperature of the WMA and the use of certain foaming and additive technologies can increase the moisture susceptibility of WMA, including:

- Introduction of additional moisture with the free water foaming WMA technologies,
- Use of wet/damp aggregates in the production process.

- Reduced binder absorption by the aggregates at lower production temperatures, and
- Reduced binder-aggregate bond strength in the presence of certain WMA additives.

From performance evaluations of various WMA technologies in the laboratory using mainly the Indirect Tensile (IDT) strength test before and after moisture conditioning (Lottman, AASHTO T283) and/or the Hamburg Wheel Tracking Test (HWTT) (AASHTO T324), the conclusion of several laboratory studies is that WMA is more moisture susceptible as compared to HMA [6–11]. However, minimization strategies such as adding anti-stripping agents or recycled materials have been shown to enhance WMA moisture susceptibility [12–21].

Despite the concerns raised by the laboratory test results that indicate that WMA is more susceptible to moisture damage, the documented field performance indicates that moisture susceptibility related distresses are not prevalent in WMA pavements and that the performance between WMA and HMA pavements is equivalent [10,11,22]. This discrepancy between the laboratory and field observations could be due to the relative limited monitoring time of the field sections or other causes that are not adequately represented in the laboratory evaluations.

A number of recent studies have been conducted to evaluate the effect of conditioning and aging protocols on WMA performance. The majority of these studies concluded that an increase in laboratory conditioning temperature and/or time may reduce the gap between WMA and HMA performance [22–25], but an appropriate conditioning protocol for WMA for Laboratory-Mixed Laboratory-Compacted (LMLC) specimens and Plant-Mixed Laboratory Compacted (PMLC) specimens for mix design and Quality Assurance (QA) purposes, respectively, is needed to simulate these mixtures in early life when they are more moisture susceptible. Current recommendations for WMA mix design include conditioning the loose mix two hours at the compaction temperature based on volumetrics and dry IDT strength to simulate Plant-Mixed Field-Compacted (PMFC) cores after construction [26]. Others recommend four hours at 135°C for conditioning prior to performance testing based on HWTT results which revealed WMA becomes equivalent to HMA after longer conditioning time at high temperature [24]. Recent research also indicated that reheating loose mix when compacting off-site PMLC specimens for QA purposes produced stiffer and stronger specimens than those compacted on-site [27]. HWTT results performed on PMFC cores from WMA pavements after one month and one year in-service revealed significant improvement in terms of rutting potential and suggested that the gap between WMA and HMA becomes negligible after a year in service for a specific climate [29]. The stiffening of asphalt mixtures due to field aging can be simulated in the laboratory through a combination of aging time and temperature which can be achieved by subjecting the compacted specimens to Long Term Oven Aging (LTOA) protocols [30–31].

2 RESEARCH APPROACH

The main objective of this research is to provide guidelines for mix design and QA to preclude moisture susceptibility in WMA. Three laboratory experiments were conducted on materials from field sections monitored with time for further correlation of laboratory testing and field performance. The selected field projects, testing protocols, and designs for the WMA laboratory conditioning, WMA moisture susceptibility (including anti-stripping), and WMA performance evolution experiments are described in this section; and detailed results can be found elsewhere [32].

2.1 *Field projects*

Table 1 provides details on location, climate, mixtures including WMA technologies, component materials, field compaction temperatures, coring dates, and corresponding laboratory experiments for the four selected field projects. Three of the four field projects represent the three extreme climates for moisture susceptibility: wet and Freeze/Thaw (F/T) in Iowa, cold and multi-F/T in Montana, and hot and wet in Texas. The fourth field project in New Mexico

Table 1. Summary of field projects.

Location and climate	Mixtures	Aggregates	Asphalt binder	Additives		Field compaction temperature (°C)	Coring dates	Experiment
				RAP	Anti-strip agent			
Iowa (Wet, Freeze)	HMA + RAP	Quartzite, limestone, field sand	PG 58-28	17%	None	146–149	Sep. 2011* Mar. 2012 Sep. 2012	LC MS AS PE
	Evotherm 3G + RAP					116–120		
	Sasobit + RAP					113–116		
Montana (Dry, Freeze)	HMA	Siliceous	Modified PG 70-28	None	1.4% lime	154–157	Oct. 2011* Apr. 2012	MS
	Evotherm 3G					132–138		
	Sasobit					135–138		
	Foaming					132–135		
Texas (Wet, No-Freeze)	HMA	Limestone, field sand	Modified PG 70-22	None	None	135–141	Jan. 2012* Sep. 2012	LC MS AS PE
	Evotherm DAT					110–113		
	Foaming					116–121		
New Mexico (Dry, No-Freeze)	HMA + RAP	Siliceous gravel	Modified PG 64-28	35%	1% versabind	141–143	Oct. 2012*	MS PE
	Evotherm 3G + RAP					124–127		
	Foaming + RAP					129–132		

*Coring right after construction was completed.
LC: Laboratory Conditioning; MS: Moisture Susceptibility; AS: Anti-Stripping; PE: Performance Evolution.

represents a climate that combines aspects of these three extreme climates (dry, cold during the winter, and relatively hot during the summer).

2.2 *Laboratory tests*

Three laboratory tests were utilized to meet the needs of this research. The Indirect Tensile (IDT) Strength Test (AASHTO T283) and the Resilient Modulus (M_R) Test (modified ASTM D-7369) were performed to determine mixture strength and stiffness, respectively. In order to evaluate moisture susceptibility of WMA mixtures as compared to HMA, both tests were also performed after subjecting the mixtures to the Lottman moisture conditioning protocol as described in AASHTO T283 with one freeze-thaw cycle.

In this study, dry M_R was used for comparing mixture stiffness and the wet M_R stiffness and M_R-ratio together with the wet IDT strength and the Tensile Strength Ratio (TSR) values were used as test parameters to compare WMA and HMA in terms of moisture susceptibility for each mixture, specimen type, and aging condition. An Analysis of Variance (ANOVA) followed by Tukey's Honest Significant Differences (HSD) test were performed on the dry M_R, wet M_R, and wet IDT strength values with a 5% significance level to discriminate differences between the mixtures, specimen types, or aging conditions. As only one TSR value is produced from each set of six specimens, the TSR results were compared based on the precision and bias statement for AASHTO T283 that indicates a d2 s acceptable range of two results with more than a 95% confidence level of 9.3% [33]. The same situation applies to M_R-ratio, where only one value is obtained, therefore a d2 s value of 10% was assumed for comparing results.

Additionally, to capture the effect of moisture under extreme conditions, the HWTT was performed and the Stripping Inflection Point (SIP) and stripping slope were calculated. Since

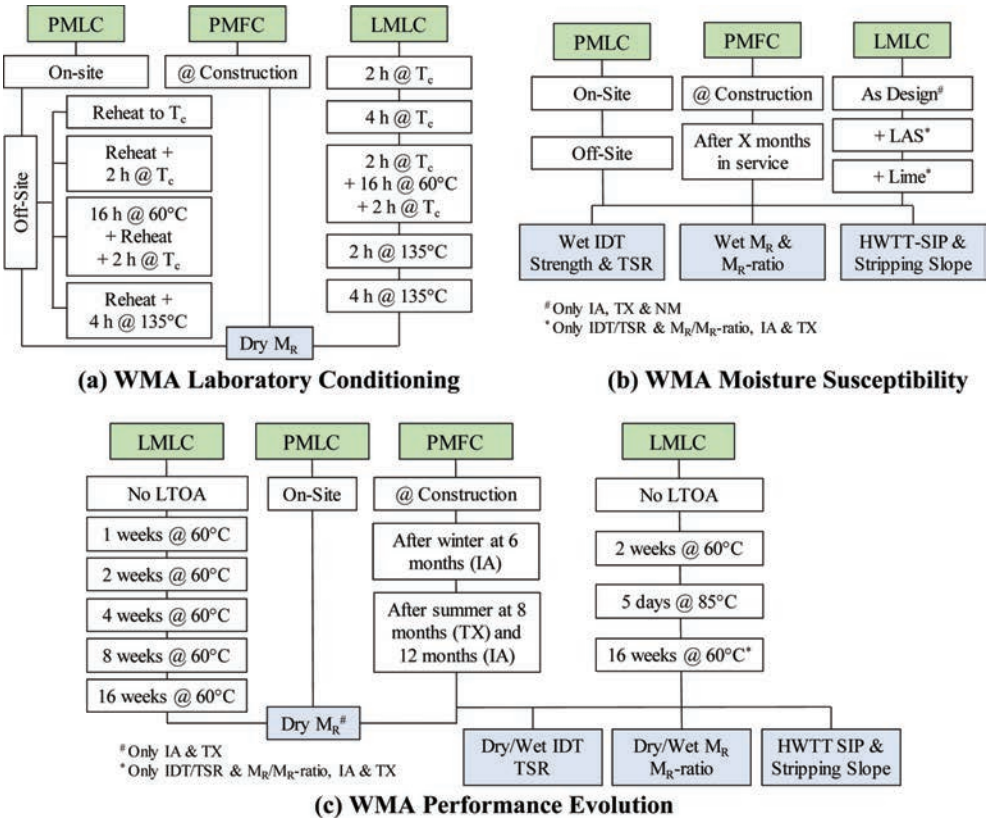

Figure 1. Experiment designs.

a precision and bias statement is not available for the selected HWTT test results, the average differences in SIP and the stripping slope for 20 different mixtures (all corresponding to the Texas field project) that exhibited stripping were calculated and 2,000 load cycles and 0.2 μm/cycle were utilized as d2s values for SIP and stripping slope, respectively.

2.3 *Experiment designs*

To assess the potential for moisture damage in WMA, three laboratory experiments were defined to satisfy the following objectives:

- Reproduce in the laboratory the early life aging condition in which WMA is more prone to moisture susceptibility related distresses in the field by evaluating multiple Short-Term Oven Aging (STOA) protocols as described in Figure 1(a) WMA Laboratory Conditioning
- Compare WMA versus HMA in terms of moisture susceptibility and evaluate the effect of anti-stripping additives as a possible moisture susceptibility minimization strategy as described in Figure 1(b) WMA Moisture Susceptibility.
- Study the effect of field aging in WMA and reproduce this effect in the laboratory by evaluating multiple Long-Term Oven Aging (LTOA) protocols as described in Figure 1(c) WMA Performance Evolution.

3 FINDINGS

This section provides a summary of the findings for each of the three experiments conducted in this study: WMA laboratory conditioning, WMA moisture susceptibility, and WMA performance evolution. In addition, laboratory results are compared to field performance as a precursor to development of guidelines for WMA mix design focused on preventing moisture susceptibility.

3.1 *WMA laboratory conditioning*

Based on the results of the WMA laboratory conditioning experiment that included evaluation of almost 250 LMLC specimens, on-site and off-site PMLC specimens, and PMFC cores from the Iowa, Texas, and Montana field projects; the significant increase of stiffness for LMLC specimens with longer conditioning times and higher temperatures (with the increase in temperature more significant) and the significant effect of reheating plant mix when fabricating off-site PMLC specimens were verified. To meet the main objective of providing guidelines for mix design and QA to preclude moisture susceptibility in WMA, specimens must be fabricated in the laboratory to reproduce the early life aging condition in the field when WMA is most vulnerable. Conclusions from this experiment for conditioning loose mix prior to laboratory compaction of specimens for evaluating moisture susceptibility are as follows:

- For LMLC specimens 2 hours at 135°C and 116°C were proposed as the standard laboratory conditioning protocol for HMA and WMA specimens, respectively.
- For PMLC specimens, compacting on-site after 1 hour at 135°C and 116°C for HMA and WMA, respectively, is proposed to stabilize the temperature.
- When compacting PMLC specimens on-site is not viable, the proposed conditioning protocol for off-site PMLC specimens is to (1) reheat to 135°C for HMA and WMA with foaming process and (2) reheat to 116°C for WMA with additives. Off-site PMLC specimens of WMA with foaming process require a different conditioning protocol as compared to WMA with additives because the foaming effect during production is assumed lost after mixing and cooling of the loose mix.

3.2 *WMA moisture susceptibility*

Based on the results of the WMA moisture susceptibility experiment that included evaluation of more than 850 LMLC specimens, on-site and off-site PMLC specimens, and PMFC

cores from the Iowa, Texas, Montana, and New Mexico field projects; the following conclusions can be made:

- The selected laboratory conditioning protocols simulate the early life of the pavement and produce laboratory compacted mixtures with performance in terms of moisture susceptibility equivalent to that of PMFC cores at construction and/or after winter as indicated by the selected laboratory tests.
- Based on laboratory moisture susceptibility tests, WMA can be more moisture susceptible in the early life (prior to a summer of aging) as compared to HMA, but equivalent performance is shown after a summer of aging for the field projects used in this study.
- When WMA is more moisture susceptible in the early life (prior to a summer of aging) based on laboratory testing, the use of anti-stripping agents may improve WMA performance. Compatibility of the anti-stripping agent with the WMA technology and component materials should be considered for optimizing performance.
- The differences identified between on-site and off-site PMLC specimens in terms of stiffness are also reflected in laboratory measured moisture susceptibility, with off-site PMLC specimens exhibiting improved resistance to moisture.

3.3 *WMA performance evolution*

Based on the results from the evaluation of more than 500 LMLC specimens, on-site PMLC specimens, and PMFC cores from the Iowa, Texas, and New Mexico field projects; the following conclusions can be made:

- For HMA and WMA PMFC cores there was a significant increase in M_R stiffness, IDT strength, and stripping resistance due to field aging after a summer. The difference between PMFC cores acquired after the first winter versus the ones at construction was insignificant for most cases for the field projects used in this study.
- Evaluating the change in dry M_R stiffness with laboratory aging at 60°C, it was observed that somewhere between 4–16 weeks of laboratory aging (different for WMAs and HMA mixtures) was representative of the field aging experienced by PMFC cores after the first summer. Additionally, the laboratory aging protocol of 2 weeks at 60°C was able to represent the time period where the stiffness of WMA was equivalent to the initial dry M_R stiffness of HMA without LTOA (for the Iowa pavement) or where the dry M_R stiffness of WMA and HMA converged (for the Texas pavement).
- As with field aging, the laboratory LTOA protocols used in this study also had a significant effect on performance, not only increasing dry M_R stiffness but also improving moisture susceptibility of the mixtures. In addition, the comparison of mixture performance measured in the laboratory between PMFC cores after several months in-service and LMLC specimens with LTOA indicated that laboratory aging of 16 weeks at 60°C as well as 5 days at 85°C were representative of the field aging that PMFC cores experienced after the first summer in the field.

3.4 *Summary of field performance*

This section focuses on the overall field performance of the HMA and WMA mixtures from the different field projects, comparing limited field performance data to the laboratory results previously discussed. For this purpose *common thresholds* were identified, including minimum 80% for TSR and M_R-ratio, minimum SIP of 10,000 based on the current Iowa specification, and minimum wet IDT strengths of 448 kPa and 552 kPa for unmodified (Iowa) and modified (Montana, New Mexico, and Texas field projects) binders based on averages from the current Nevada, Tennessee, and Texas specifications.

The four field projects exhibited generally good performance through the end of this study in March 2013. The Montana and New Mexico field projects which were characterized as good mixtures based on the laboratory testing and common thresholds did not exhibit any distress related to moisture susceptibility. Common factors for these mixtures include the use

of anti-stripping agents and a relatively elevated high-temperature performance grade binder (Montana) or RAP with a lower high-temperature performance grade binder (New Mexico) (Table 1). The Iowa field project did exhibit some localized raveling in both WMAs (WMA Sasobit® with RAP and WMA Evotherm® 3G with RAP) that was likely exacerbated by paver segregation at the crown and subsequent snow plow damage. The Iowa HMA with RAP did not exhibit raveling. In addition to possible construction issues, the Iowa field project did not include an anti-stripping agent. As for the Montana and New Mexico field projects with good performance for all mixtures in the laboratory and the field, agreement was shown for the Iowa field project between the relatively poor field performance and inadequate laboratory performance for the two WMAs with RAP for all three standard laboratory tests when compared to common thresholds. The Texas field project performed well and did not exhibit distresses related to moisture susceptibility despite construction in January 2012 and heavy truck traffic. This field project did not utilize RAP or an anti-stripping agent but did use a relatively elevated high-temperature performance grade binder, and agreement between the field and laboratory performance as predicted based on common thresholds is not as complete across the different specimen types or across the three standard laboratory tests. Unfortunately, all four field projects were constructed in fall or winter, and thus the overall hypothesis that WMA will exhibit adequate moisture susceptibility after a summer of aging was not fully tested.

4 GUIDELINES TO PRECLUDE MOISTURE DAMAGE IN WMA

Based on laboratory test results, field observations, and considering the common thresholds previously described; the guidelines for mix design and QA of WMA to preclude moisture susceptibility were developed as shown in Figure 2. After mixing WMA LMLC specimens according to the AASHTO R35 Appendix, loose mix STOA for 2 hours at 116°C is proposed prior to compaction. Next, a test to evaluate moisture susceptibility must be selected from the following three choices: wet and dry IDT strengths at 25°C and TSR by AASHTO T283, wet and dry M_R stiffness at 25°C (Modified ASTM D-7369) and M_R-ratio after moisture conditioning by AASHTO T283, or HWTT SIP and stripping slope per AASHTO T324 at 50°C. Two criteria

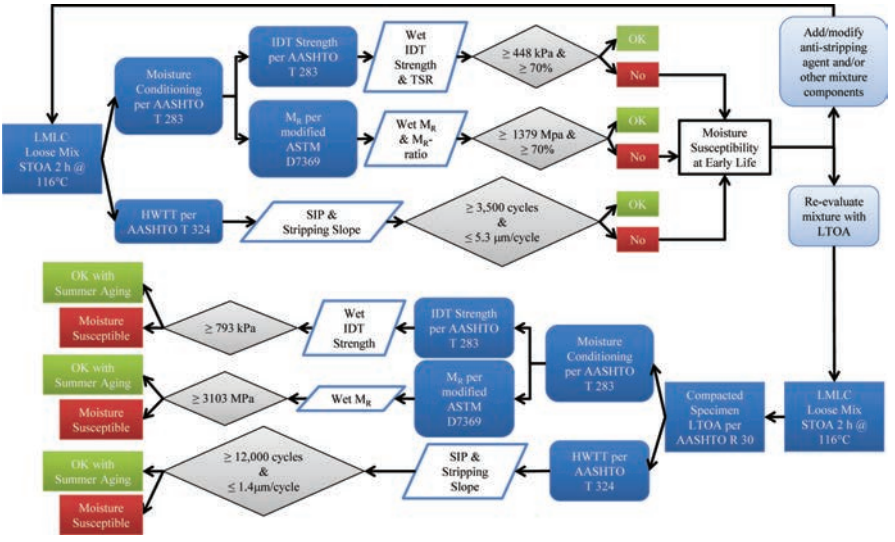

Figure 2. Guidelines for WMA moisture susceptibility evaluation.
Note: [a]LMLC specimens for mix design. For QA purposes use on-site PMLC or off-site PMLC with minimal reheating; [b]select a single test method and use it throughout the mix design verification; [c]If off-site PMLC specimens are used, employ the following thresholds (TSR and M_R-ratio remain unchanged): Wet IDT ≥ 690 kPa, Wet M_R ≥ 2068 MPa, SIP ≥ 6,000 cycles, stripping slope ≤ 2.0 µm/cycle.

for each test for these STOA specimens are shown in Figure 2. If off-site PMLC specimens are utilized to evaluate WMA moisture susceptibility, the thresholds are decreased for stripping slope and increased for wet IDT strength, wet M_R stiffness, and SIP to reflect the reheating effect. If the WMA passes both criteria for the selected test, the mixture is expected to have adequate performance in terms of moisture susceptibility; otherwise, moisture susceptibility in the early life is probable. Mixture modification in terms of adding/modifying anti-stripping agents and/or changing other mixture components (e.g. binder type, RAP, RAS, etc.) is proposed prior to a second evaluation of the modified WMA with these same criteria.

If the original WMA or modified WMA does not pass one or both criteria for the selected test, moisture susceptibility in the early life is probable but the mixture may be capable of overcoming this vulnerable period after a summer of aging prior to exposure to winter conditions. Therefore, a second evaluation is suggested after LTOA of compacted specimens for 5 days at 85°C per AASHTO R30, for which the same selected laboratory test is used with modified criteria that reflect the stiffening effects from aging. As shown in Figure 2, for this second evaluation of aged specimens, only wet properties are specified for IDT strength and M_R stiffness, but two HWTT criteria remain.

These criteria were developed based on separating the results from the relatively good field and laboratory performance of the Texas WMAs and the relatively poor field and laboratory performance of the Iowa WMAs as shown in Table 2 with an example for STOA specimens. Table 2 also shows verification of these criteria through examination of the WMAs from the Montana and New Mexico field projects. For the Montana field project where LMLC specimens were not available, on-site PMLC specimens were utilized. This verification resulted in a prediction of adequate performance in terms of moisture susceptibility for the majority of the standard laboratory tests for the STOA WMAs from both the Montana and New Mexico field projects, which agree with observed field performance.

The alternatives of adding anti-stripping agents and re-evaluating the moisture susceptible mixtures or LTOA to verify if the mixture will possibly overcome this susceptibility with aging were also explored. For the Iowa field project, even with the addition of two different anti-stripping agents, the majority of the Iowa STOA mixtures are likely still moisture susceptible in the early life, except for the WMA Sasobit® with RAP which was improved in terms of wet M_R stiffness and M_R-ratio with the addition of hydrated lime. WMA Foaming from the Texas field project and WMA Evotherm® 3G with RAP from the New Mexico field project (Table 2) marginally did not meet the criteria for M_R-ratio, but after LTOA in the laboratory, these mixtures passed the respective criteria. Adding hydrated lime to WMA Foaming from the Texas field project also produced a mixture that passed the criteria.

Table 2. Example of criteria development and verification for WMA moisture susceptibility evaluation (LMLC STOA 2 h at 116°C).

Test Parameter	Iowa		Texas		Montana[a]			New Mexico	
	Evotherm	Sasobit	Evotherm	Foaming	Evotherm	Sasobit	Foaming	Evotherm	Foaming
Wet IDT (kPa)	345	324	607	531	524	510	531	558	496
TSR (%)	84	77	79	66	59	57	72	73	70
Wet M_R (MPa)	917	1131	1944	1648	1800	2213	1613	2041	2206
M_R-ratio (%)	72	77	80	62	83	86	80	69	76
SIP (cycles)	1,677	2,176	6,256	4,111	>20000	>20000	>20000	>20000	>20000
Stripping Slope (μm/cycle)	10.0	6.6	1.7	2.9	0	0	0	0	0
Key	Does not meet criteria				Meets criteria				

[a]For Montana, no LMLC specimens are available and thus values of on-site PMLC specimens were used.

As shown in these mixtures passed the respective criteria. Adding hydrated lime to WMA Foaming from the Texas field project also produced a mixture that passed the criteria.

Table 2, two of the three STOA WMAs from the Montana field project (WMA Evotherm® 3G and WMA Sasobit®) did not meet the criteria for TSR. Unfortunately, data were not available to assess the effect of modifying the mixture components or aging.

Before being considered for adoption, the proposed guidelines that are suggested based on a limited number of field projects should be utilized on a trial basis. This will provide additional data to further refine the moisture susceptibility criteria and the laboratory conditioning and aging protocols that capture the time period when WMA may be most susceptible to this type of distress. Data from additional field projects will provide increased confidence in the guidelines provided with possible revisions to the framework proposed in this study. In addition, further information should be gathered toward resolving any differences between generally adequate field performance and laboratory assessment that indicates potential for moisture susceptibility for some mixtures. Continued field performance monitoring of the limited number of field projects is also suggested toward further improvement of the guidelines produced.

ACKNOWLEDGEMENTS

The research reported herein was performed under NCHRP Project 09-49 by the Texas A&M Transportation Institute. The research team gratefully acknowledges the cooperation and assistance provided by the agencies and contractors where field samples were collected. In addition, the partnership with the Federal Highway Administration (FHWA) Mobile Asphalt Laboratory and other NCHRP WMA Projects was integral to this work and is greatly appreciated.

Evaluation of Warm Mix Asphalt technology for surface mixtures

Dinesh Ayyala, Haritha Malladi, N. Paul Khosla & Akhtarhusein A. Tayebali
North Carolina State University, Raleigh, NC, USA

ABSTRACT: Warm Mix Asphalt (WMA) has been a major sustainability initiative of the asphalt industry in the recent years. The widespread implementation of WMA has been hindered by concerns over its performance with respect to moisture and rutting susceptibility, and its long term performance. In this study, three WMA technologies—Sasobit, Advera WMA and Foamer device were evaluated in the laboratory and their performance was compared to conventional Hot Mix Asphalt (HMA). The control HMA mix used in this study was a 9.5 mm NMAS surface mixture with PG 64-22 asphalt binder. Mixing and compaction temperatures for WMA mixes used were 136 °C and 120 °C, respectively, representing a 28 °C reduction compared to HMA production temperatures. Moisture susceptibility and rutting evaluations were conducted using various performance tests—AASHTO T283 Tensile Strength Ratio (TSR), Asphalt Pavement Analyzer (APA) and Dynamic Modulus tests. Moisture conditioning of APA and Dynamic Modulus test specimens was also done to study its effect on performance. Although Advera and Foamer mixtures failed the minimum criterion of 85 percent TSR, E* Stiffness Ratio (ESR) test results for all mixtures were greater than 90 percent, indicating that the loss in dynamic modulus is much lower than that indicated by TSR values. APA test results show satisfactory performance for all WMA mixtures with respect to rutting.

Keywords: Warm Mix Asphalt, moisture susceptibility, rutting, ESR, pavement performance

1 INTRODUCTION

Warm Mix Asphalt (WMA) refers to the use of technology and additives to lower the mixing and compaction temperatures during the production of asphalt concrete [1]. Potential benefits of WMA use include energy-cost savings, extended paving season, increased hauling distances and improved compaction in the field [2, 3]. Various technologies currently used to produce warm asphalt mixes are broadly classified into categories based on how they modify the production of the mix [4]. Several other warm mix production methods have been studied to date [4, 5], a few of which are listed below according to type of modification:

- Asphalt foaming technology—Astec Double Barrel Green, Foamer, WAM-Foam
- Asphalt Foaming by Zeolite—Natural zeolites, Synthetic zeolites—Aspha-Min (Aspha-Min GmbH, Germany), Advera (PQ Corporation, USA)
- Bitumen Viscosity Modifiers—Sasobit (Sasol Wax GmbH, Germany), Licomont BS 100 (Clariant, Switzerland)
- Chemical Additives—Evotherm (MeadWestvaco, USA)

Use of WMA in asphalt pavement construction has raised two primary performance issues—moisture damage and low stiffness leading to rutting [5, 6]. Other factors that affect warm mix asphalt use are issues with workability and compactability [4, 6], determination of mixing and compaction temperatures for different binder types, aggregate compatibility with WMA modifier, extent of modification (modifier quantity or water percentage for foamed asphalt), use of anti-stripping additives amongst others [5–13]. The research study presented in this paper sought to evaluate the performance of warm asphalt mixtures prepared using

three types of WMA technology—Sasobit (viscosity modifier), Advera (zeolite) and the Foamer device (asphalt foaming technology).

Sasobit is a crystalline, long-chain aliphatic polymethylene hydrocarbon (paraffin wax) manufactured by Sasol Wax [14]. It modifies the asphalt binder by reducing its viscosity, thereby improving its flow. It has a melting point of 100°C below which it recrystallizes to form a lattice structure in the binder and imparts additional stability to the mixture [7]. Sasobit WMA has been produced in the laboratory at mixing temperatures of 124°C—157°C and compacted at temperatures as low as 88°C [6, 8, 9]. Studies have shown that Sasobit modified WMA exhibited better moisture damage resistance when used with granite aggregate [6] as compared to crushed stone [8] or limestone aggregate [9], and the moisture resistance further improved with the use of liquid anti-strip agent.

Advera is a synthetic zeolite manufactured by PQ Corporation, USA [16]. It is a hydrated aluminosilicate which contains 18 to 21 percent water and is obtained as a fine white powder. This hydro-thermally crystallized water is released upon heating above 100°C. When added to the asphalt concrete mixture, the released water causes micro-foaming making the mixture more workable at lower temperatures. PQ Corporation recommends addition of Advera WMA at a rate of 0.25 percent by weight of the mixture [15]. Due to release of moisture during mixing and lower production temperatures, WMA produced using zeolites results in significant loss of specimen strength after moisture conditioning [6, 8, 10]. These studies [6, 8, 10] have reported an increase in the strength of moisture conditioned mixtures (AASHTO T-283 tensile strength ratio [6] and E* Stiffness Ratio [8]) when hydrated lime was used as an anti-strip additive. Pavement sections constructed in the state of Massachusetts using Advera have showed no signs of moisture damage [8] even though research studies showed that laboratory mixtures failed to satisfy the AASHTO T-283 Tensile Strength Ratio test criteria.

The Foamer is a device manufactured by Pavement Technology, Inc., USA [16]. The device sprays water onto hot asphalt binder in a pressurized reaction chamber to produce foamed asphalt. Reduction in mixing and compaction temperatures are achieved as a result of the increased volume of asphalt foamed at lower temperatures leading to effective coating of aggregate particles. Similar to zeolites, foaming technology also imparts additional moisture to the asphalt concrete mixture increasing its susceptibility to moisture damage and rutting. Performance tests on WMA were conducted on mixtures containing foamed asphalt produced using various foaming devices such as WLB-10 [11], Gencor Green [12] and Astec Double-Barrel Green [13]. Moisture susceptibility tests using the AASHTO T-283 procedure showed variable results depending on the type of aggregate used and inclusion of Recycled Asphalt Pavement (RAP) material in the mixture.

Based on the results from several literature studies, it can be concluded that the performance of WMA mixtures with respect to moisture damage and rutting is a function of several parameters, the most important of which is the WMA technology used.

2 OBJECTIVES

The objectives of this research were to evaluate three warm mix technologies—Sasobit, Advera and the Foamer device and their effect on workability, moisture susceptibility and rutting resistance of asphalt concrete surface mixtures. Sasobit was added at 1.5 percent by weight of asphalt binder [6, 14], Advera was added at 0.25 percent by weight of mixture [8, 15] and the Foamer device was used to produce foamed asphalt by using water at 2 percent by weight of the binder, according to the manufacturer's recommendation.

In this study, the control mixture used was a 9.5 mm nominal maximum aggregate size Superpave mixture and the asphalt binder used was PG 64-22. A liquid anti-strip additive, AdHere LOF-6500 was used in all WMA mixtures as well as control mixture at a rate of 0.75 percent by weight of binder. The mixing and compaction temperatures for the control mix were 163°C and 149°C, respectively as determined from rotational viscometer tests on virgin binder [17]. Mixing and compaction temperatures could not be determined from standard rotational viscometer tests on asphalt binders modified using WMA technologies [5].

Therefore, 136°C for mixing and 120°C for compaction temperatures were selected based on a thorough study of typical values used in several past studies [5–13] and manufacturer recommendations [14–16].

Moisture damage was measured in terms of the Tensile Strength Ratio (TSR) and Dynamic Modulus (E*) Stiffness Ratio (ESR) of WMA mixtures. Rutting was measured using the Asphalt Pavement Analyzer (APA) device for specimens in dry and wet conditions to identify potential damage due to stripping of aggregate.

3 MIXTURE DESIGN

The control mix used in this study was a 9.5 mm nominal maximum size mixture, conforming to Superpave specifications [18] for surface mixtures designed to handle 0.3–3 million Equivalent Single Axle Loads (ESALs).

Superpave mix design was conducted for HMA mixture at the appropriate mixing and compaction temperatures stated previously. A short-term oven aging period of two hours was used for all mixtures according to AASHTO R-35, and mixtures were compacted using Superpave gyratory compactor to a design gyration (N_{des}) level of 65 gyrations. The design asphalt content was determined as 6.0 percent for the control mixture. The same asphalt content was also

Table 1. Mixture volumetrics and superpave specification limits.

Mix properties at N_{des}	Asphalt concrete mix technology				Superpave specifications [18]

% G_{mm} at N_{ini} (7)	83.3	83.7	83.4	88.4	≤89.0%
% G_{mm} at N_{des} (65)	95.6	96.0	95.9	95.8	96%

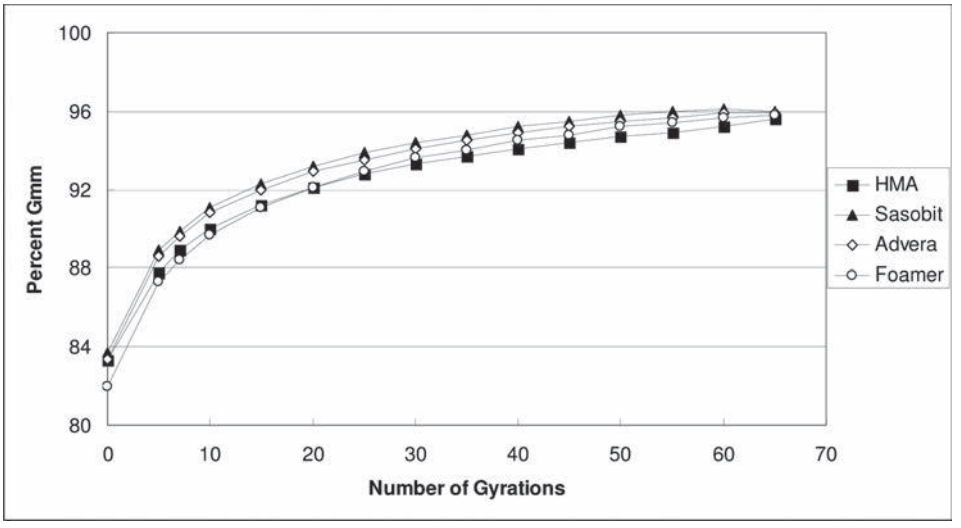

Figure 1. Percent G_{mm} versus number of gyrations.

used for design of WMA mixtures [5, 6]. Table 1 shows the Superpave mix volumetrics for the mixtures used in this study. All mixtures satisfied the volumetric requirements.

Compaction readings for specimen heights at different gyrations were recorded during the compaction of mix design specimens. The trends of decrease in specimen heights with an increase in the number of gyrations did not show any significant difference amongst the four mixtures. This indicates that the compactability of WMA mixtures was comparable to that of HMA. Figure 1 shows the plot of percent G_{mm} values versus number of gyrations for the four mixtures.

4 MOISTURE DAMAGE CHARACTERIZATION

Moisture damage susceptibility of WMA mixtures was analyzed using two test methods—Tensile Strength Ratio using a modified AASHTO T283 test procedure and E* Stiffness Ratio (AASHTO TP79-09). The specimens for the stiffness ratio test were conditioned using the same procedure as the modified AASHTO T283 procedure.

4.1 *Specimen preparation*

Preparation of specimens for TSR testing was done according to the modified AASHTO T283 procedure [18]. Asphalt concrete mixtures were conditioned at room temperature (25°C) for two hours after mixing and then subjected to long-term oven aging at 60°C for 24 hours. The mixtures were then subjected to short-term oven aging at the compaction temperature (149°C for control HMA and 120°C for WMA) before compaction. The specimens were compacted to an air void content of 7 ± 0.5 percent.

Specimens for ESR test were prepared according to the AASHTO R-35 procedure for HMA and WMA mixtures [5, 8]. The short-term oven aging time for the control HMA mixture was 4 hours at 135°C, followed by conditioning the mixture for an additional 45 minutes at 149°C for compaction. WMA mixtures were subjected to short-term oven aging for two hours at compaction temperature (120°C) before compaction. The specimens for ESR test were also compacted to an air void content of 7 ± 0.5 percent in order to directly compare the results with the TSR test. The mixtures did not exhibit any signs of damage or disintegration due to the high air void content in both dry and conditioned states. The original specimens were compacted in a 150 mm diameter mould to a height of 178 mm, and were later cored to a reduced diameter of 100 mm and cut to produce test specimens of height 150 ± 2.5 mm.

4.2 *Conditioning procedure*

Specimen conditioning for both TSR and ESR tests was done according to the modified AASHTO T283 procedure. Two subsets of three specimens each were prepared for the four mixtures. One subset was tested in dry condition and the second set was subjected to moisture conditioning by saturating the specimens to 70–80 percent saturation using vacuum saturation. The specimens after saturation were submerged in a water bath at 60°C for 24 hours. TSR test specimens were conditioned for two hours under water at 25°C after removal from the 60°C water bath, whereas ESR test specimens were air-dried overnight at room temperature (25°C). The reason for air-drying of ESR test specimens was to ensure that specimens were completely surface-dry to allow proper mounting of brass targets for strain measurement using LVDTs.

4.3 *Tensile strength ratio test results*

Table 2 shows the tensile strength ratios for HMA and WMA mixtures. The Tensile Strength Ratio (TSR) was calculated as a ratio of the average indirect tensile strength of specimens in conditioned (wet) state to that of specimens in dry state, as shown in Eq. (1).

$$\text{TSR} = \frac{\text{Average indirect tensile strength of wet specimens}}{\text{Average indirect tensile strength of dry specimens}} \quad (1)$$

Table 2. AASHTO T-283 tensile strength ratio test results.

Mixture type	Anti-strip dosage*	Average indirect tensile strength, kPa		TSR, % (min. 85)
		Dry	Wet	
Control (HMA)	0.75	1036.9	909.1	88
Sasobit	0.75	850.7	826.9	97
Sasobit	1.50	798.0	812.0	102
Advera	0.75	858.2	476.8	56
Advera	1.50	760.5	484.2	64
Foamer	0.75	888.3	700.3	79
Foamer	1.50	886.6	721.3	81

*Liquid anti-strip Ad-Here LOF6500 dosage by weight of binder.

Table 3. E* Stiffness Ratio (ESR) test results.

Mixture type	Temp. °C	Dynamic modulus, MPa						Average ESR, %
		Dry conditioned			Wet conditioned			
Freq., Hz		10	1	0.1	10	1	0.1	
HMA	4	13300	9670	6210	12600	9020	5790	93.7
	20	5560	3040	1460	5260	2810	1330	92.6
	40	1120	438	214	1100	456	240	104.7
Sasobit	4	12100	8400	5170	11700	8160	5120	97.7
	20	4760	2420	1130	4480	2260	1040	93.0
	40	962	395	226	890	364	199	90.9
Advera	4	11600	7910	4700	10800	7240	4170	91.2
	20	4350	2030	819	3790	1910	724	89.9
	40	802	280	132	646	226	105	80.3
Foamer	4	12600	8670	5190	11700	7930	4700	91.6
	20	4680	2250	957	4670	2310	999	102.2
	40	861	335	191	916	359	194	105

The results in Table 2 show that HMA and Sasobit mixtures satisfy the minimum TSR requirement of 85 percent, with Sasobit showing almost no signs of reduction in tensile strength due to moisture damage. This observation is consistent with other studies [6] which observed that Sasobit mixtures show excellent compatibility with chemical anti-stripping agents and granite aggregate, both of which were used in this study. Advera and Foamer mixtures resulted in average TSR values of 58 and 80 percent, both of which fail the minimum criterion of 85 percent. Therefore, the test was repeated with an increased anti-strip dosage of 1.5 percent by weight of binder in an effort to improve the TSR values. The repeated test results showed slight improvement in the TSR values, but this was due to reduced tensile strength of specimens in both dry and wet conditions as opposed to the desired increase in the wet tensile strength.

4.4 *E* Stiffness Ratio Test Results (ESR)*

The E* stiffness ratio or ESR test is based on evaluating the effect of moisture conditioning on the dynamic modulus of an asphalt concrete mixture, and has been reported as an alternative to the TSR test [8, 19]. Unconfined dynamic modulus test was conducted on specimens prepared at 7 ± 0.5 percent air voids according to AASHTO TP79-09, Standard Method of Test for Determining the Dynamic Modulus and Flow Number for Hot Mix Asphalt (HMA) Using the Asphalt Mixture Performance Tester (AMPT). Since the dynamic modulus test is a

non-destructive test, the same specimens were first tested dry and later subjected to moisture conditioning. The test was conducted at three temperatures—4, 20 and 40°C and at three frequencies—0.1, 1 and 10 Hz. ESR was calculated using Eq. (2).

$$\text{ESR} = \frac{\text{Dynamic modulus of wet specimens at test temperature and frequency}}{\text{Dynamic modulus of dry specimens at test temperature and frequency}} \quad (2)$$

Table 3 shows the average dynamic modulus measured in the dry and wet conditions for the four mixtures at the three test temperatures and frequencies, and the average ESR for each mixture at each test temperature.

It was observed that the dynamic modulus of all four mixtures after conditioning was greater than 90 percent of that in the dry condition at all the test temperatures, except for Advera mixture at 40°C. In this test, the difference between mixture stiffness in dry and wet conditions is not as prominent as it was in the TSR test.

5 RUTTING RESISTANCE CHARACTERIZATION

Rutting resistance of mixtures was evaluated using the Asphalt Pavement Analyzer (APA) device. The specimens used for this test were prepared according to AASHTO-R35 with four hours of short-term oven aging for HMA followed by 45 minutes at compaction temperature, and two hours of short-term oven aging for WMA at compaction temperature. The test specimens were prepared at an air void content of 7 ± 0.5 percent with 75 ± 2 mm height. Additional sets of Advera and Foamer specimens were prepared and moisture-conditioned using the modified AASHTO T-283 procedure to evaluate the effect of moisture damage due to stripping. Since HMA and Sasobit mixtures exhibited passing TSR values, they were tested only in the dry condition.

For asphalt concrete mixtures with 9.5 mm nominal maximum aggregate size, the maximum allowable rut depth according to North Carolina specifications is 9.5 mm for the traffic level under consideration. The APA test was conducted at the PG high-temperature of the binder at 64°C and final rut depths at the end of 8000 cycles were measured. Average rut depth of HMA specimens was measured to be 5.1 mm and that of Sasobit specimens was 4.2 mm. Average rut depth for Advera specimens in dry condition was measured as 5.0 mm

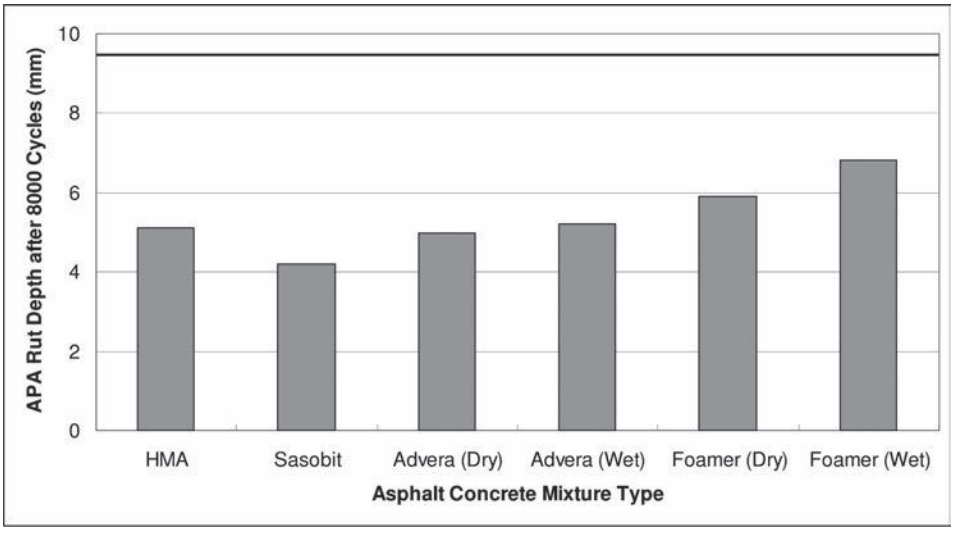

Figure 2. APA rut depth values.

and wet condition as 5.2 mm. For Foamer specimens, rut depth increased from 5.9 mm in dry condition to 6.8 mm in wet condition. Figure 2 shows the APA test results for the mixtures.

The results show that the average rut depth for all mixtures is lower than the allowable value, indicating that the mixtures did not show significant rutting damage. The tests conducted on moisture-conditioned specimens showed an increase in rutting, but the average rut depth was still lower than the allowable limit. Visual inspection of the specimens' broken surfaces did not show signs of aggregate stripping, which signifies that the WMA mixtures exhibited adequate resistance to rutting.

6 SUMMARY AND CONCLUSIONS

This study focused on investigation of performance characteristics of WMA mixtures prepared using three different warm mix technologies—Sasobit, Advera and the Foamer device. Performance characteristics of WMA was compared to a control HMA mixture with respect to moisture damage and rutting. Moisture damage susceptibility was evaluated using the AASHTO T-283 and ESR test methods, and rutting susceptibility of mixtures was evaluated using the Asphalt Pavement Analyzer.

TSR test results showed that WMA mixtures containing Sasobit did not exhibit any moisture damage, whereas Advera and Foamer mixtures failed to satisfy the failure criterion of minimum 85 percent TSR. The test was repeated by increasing the dosage of anti-strip additive to 1.5 percent by weight of binder, which did not affect the TSR values significantly.

Rutting resistance was measured using the Asphalt Pavement Analyzer device for all mixtures in both dry and saturated conditions. Rut depth values at the end of 8000 cycles were less than the specified limit of 9.5 mm for all the mixtures, indicating adequate resistance of the mixtures to rutting. The APA test results for saturated specimens also showed no significant stripping of aggregate from the specimen surfaces, indicating that low TSR values cannot be directly used as a parameter to assess moisture damage, especially for WMA mixtures produced using moisture-inducing technology such as zeolites and foaming devices.

ESR test results showed that all WMA mixtures retained more than 90 percent of their stiffness after moisture conditioning at most test temperatures. This conclusion supports evidence from literature that TSR test is not adequate to characterize the moisture damage resistance of WMA.

ACKNOWLEDGEMENTS

The authors would like to thank the North Carolina Department of Transportation for funding this research project. Special thanks are due to personnel at the NCDOT Materials & Tests Division, especially to Mr. James Budday, PE and Mr. Todd Wittington, PE. Support of PQ Corporation in the supply of materials for the study is also acknowledged.

ABSTRACT: In Japan, recycled asphalt mixtures have accounted for around 75% of the total asphalt production volume in recent years, and the percentage is expected to remain at the same rate. Thus efforts must be made to secure good working environments through measures to reduce asphalt fumes produced during the manufacture of asphalt mixtures and construction, and improve the workability. In reviewing such measures, we focused on a mechanical warm-mix technique (foamed asphalt) carried out in the U.S. and Europe, and introduced it to Japan. When applying foamed asphalt to the recycled asphalt mixtures used in Japan, as the recycled asphalt aggregate content of the mixtures is too high compared to the U.S. and Europe. (50–70%), high effectiveness cannot be obtained if the foamed asphalt is used as it is.

Therefore we reviewed methods for microfoaming foamed asphalt and adding a recycling agent (asphalt softening agent). This succeeded in reducing the temperature and improving the quality of recycled asphalt mixtures.

This paper reports details of the reviews we studied.

Keywords: Microfoaming, foamed asphalt, recycled asphalt mixture, recycling agent, asphalt foam

1 INTRODUCTION

In recent years, soaring prices of asphalt binders and aggregates in Japan have led to the promotion of the recycling of asphalt, and now recycled asphalt mixtures have accounted for around 75% of the total asphalt production volume. For this reason, there is a need to implement measures to reduced CO_2 emissions during manufacturing, improve workability, and reduced asphalt fumes, for recycled asphalt mixtures. One method for implementing these measures is the use of warm-mix asphalts. Considering the needs for mass manufacturing and costs, foamed asphalt which is commonly used in the U.S. and Europe is considered the most suitable. However, in Japan, the percentage (recycling rate) of recycled contained in recycled asphalt mixtures is still as high as 75%, and 46% on average which is a high level. Thus, even if foamed asphalt is used, the amount of foamed asphalt (amount of new asphalt) is small, and the effects of the warm-mix asphalt will also be small. Thus, to apply foamed asphalts to recycled asphalt mixtures with high recycling rate, there is a need to improve the foamed asphalt so that the effects of the warm-mix asphalt also become higher than before. Furthermore, in Japan, there is a regulation requiring the recycled asphalt or recycled asphalt mixture to be returned to the designated properties using recycling agent during manufacture at recycling rates higher than the designated levels. For this reason, a high recycling rate means more recycling agents must be used.

From this background, the authors attempted to enhance the effects of warm-mix asphalt by microfoaming foamed asphalt into even finer foam (microfoam) using a foaming enhancer, and succeeded in applying this technique even to recycled asphalt mixtures with high recycling rate. Furthermore, by applying the technique to recycling agents, the properties of mixtures were also improved.

This paper discusses the performance of recycled asphalt mixtures applying microfoaming foamed asphalt, and reports the results of verifying the effects of foaming recycling agents.

2 FOAMED ASPHALT

Foamed asphalt is made by mixing hot asphalt with water and foaming the mixture. As the asphalt volume increases and the apparent viscosity decreases, miscibility improves during manufacture. The asphalt returns to the original volume during construction work, but the bearing effects of the residual foam improves compaction. If the temperature further decreases after construction, the influence of the foam disappears, ensuring the quality of the mixture. However, increasing the recycling rate of recycled asphalt mixtures decreases the amount of new asphalt, resulting in reduced effects of applying the foamed asphalt. Since foamed asphalt is applied for reducing the manufacturing temperature of recycled asphalt mixtures and improving workability, there is a need to enhance the bearing effects of the foamed asphalt. Figure 1 shows the conceptual drawings of conventional foamed asphalt and improved foamed asphalt by microfoaming. It can be seen that after the conventional foamed asphalt foams and expands, bubbles with relatively large particle size bind together, expand, and then disappear, thus the residual foam amount tends to decrease during construction. Microfoaming is considered an ideal method for increasing the residual amount of this foam and enhancing bearing effects.

3 IMPROVEMENT OF FOAMED ASPHALT

Foamed asphalt was improved using a foaming enhancer. As we have already confirmed the relation between the Foam Index (FI), which uses expansion ratio and half period in a previous study[1)], and diameter of foam, FI was applied in this study to evaluate the performance of the foamed asphalt. Table 1 shows the properties of the straight asphalt used in this study.

Table 2 shows the foaming state of each type of foamed asphalt and state of bubbles under a microscope. With conventional foamed asphalt, as bubbles bind together, expand,

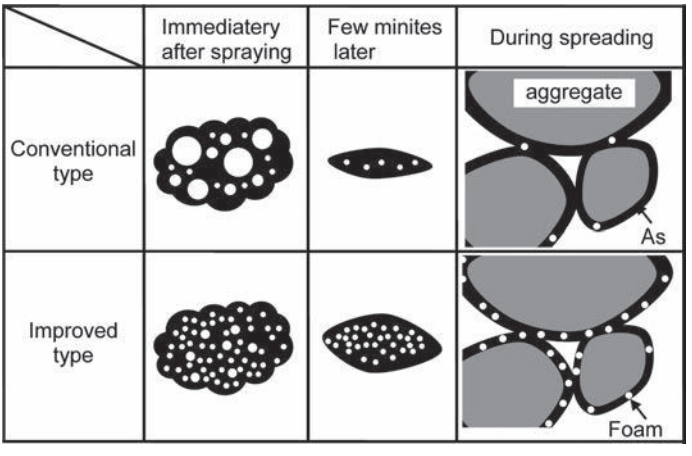

Figure 1. Conceptual drawing of foamed asphalt.

Table 1. Properties of asphalt.

Item	Name	Penetration (25°C) (1/10 mm)	Softening point (°C)	Ductility (15°C) (cm)	Density (15°C) (g/cm^3)
Property	Straight asphalt 60/80	71	47.5	100+	1.039

Table 2. Properties of foamed asphalt.

	Temporal change of expansion ratio	Foaming state	Microscopic image
Conventional foamed asphalt			Improved foamed asphalt			
and then disappear, FI is low and there are very little bubbles remaining. In contrast, with the improved foamed asphalt, the foaming amount is greater. As this prevents the binding and expansion of the bubbles, many micro bubbles are seen to remain. These results indicate that the improved foamed asphalt can improve bearing effects during construction. It was also confirmed that as FI increases, the diameter of the individual bubbles decreases, resulting in the increase in residual bubbles.

4 VERIFICATION OF PROPERTIES OF MIXTURE APPLYING IMPROVED FOAMED ASPHALT

To verify the compaction and workability of mixtures to which the improved foamed asphalt are applied, property tests of various mixtures were conducted at recycling rates of 0, 20, 40, and 60%. Table 3 shows the test items.

The workability evaluation testing device shown in Figure 2 was used to verify workability. The testing device consists of a test container (A) for holding the mixture, rotating paddle for receiving resistance (B), and torque meter (C). The test container can hold 10 liters and is compatible with mixtures of various particle sizes. The test procedure and data test procedure consists of first placing the manufactured mixture inside the test container and then rotating the paddle in the mixture. The resistance is then detected using the torque meter and output to a PC every second. As shown by the waveform in Figure 3, the output torque data stabilizes several ten seconds after the start of measurement. Therefore one measurement completes in about two minutes. The average of the agitation torque values taken 20–40 seconds after the start of the test is used for evaluating workability. Mixtures with good workability have small torques while those with poor workability have large torques.

4.1 *Study mixtures*

In Japan, two methods are used to design the composition of recycled asphalt mixtures: one is by adjusting the penetration and the other is by adjusting the recycled hot mix asphalt to the target split coefficient[2]. When adjusting to the design reference value, either the recycling agent or new asphalt (high penetration asphalt) is used or both are used. The amount of recycling agent added is determined by adjusting to the designed penetration using the recycling agent. Table 4 shows the composition of the mixtures used in this study and Table 5 shows the properties of the recycled aggregates.

4.2 *Compaction characteristics*

Figure 4 shows the relation between the mixture temperature and compaction degree by Marshall compaction at the recycling rate of 60%. The improved foamed asphalt showed

Table 4. Mixture proportion.

Mixture	Recycled asphalt aggregate content (%)	All asphalt (%)	New asphalt (%)	Recycled asphalt aggregate asphalt (%)	Recycling agent (%)
Recycled dense graded asphalt mixture (13)	0	5.7	5.70	–	–

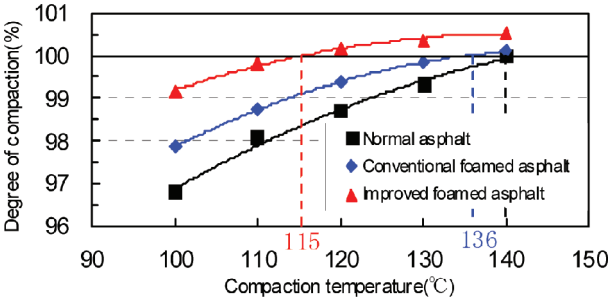

Figure 4. Relation between compaction temperature and compaction degree (recycling rate: 60%).

high compaction degree compared to normal asphalt at the same temperature. The same compaction degree as normal asphalt compacted at 140°C was obtained at 115°C (25°C reduction). The reduction effects of the improved foamed asphalt were 19°C higher than conventional foamed asphalt, and the improved foamed asphalt with many micro bubbles showed remarkable improvement in compaction due to bearing effects.

In consideration of the mechanism of the improvement effects of the compaction of the foamed asphalt, it is expected that the kneading by the roller will show higher compaction degree than the hammering of the Marshall rammer, therefore verifications were carried out using a Marshall rammer and Gyratory Compacter (GC). The number of gyrations of the GC was set the same as the Marshall compaction density of normal asphalt at 140°C. Figure 5 shows the relation between the mixture temperature and compaction degree at the recycling rate of 60% for different compaction methods. These results confirm that compaction tends to be better with GC for both foamed asphalt and improved foamed asphalt and in improved foamed asphalt the tendency is remarkable. Improved foamed asphalt thus promises to be effective for improving compaction even with roller compaction in the construction. The same tendency was seen at the recycling rates of 0, 20, and 40%.

4.3 *Workability*

Figure 6 shows the relation between the mixture temperature and agitation torque at the recycling rate of 60%. The improved foamed asphalt showed lower torque values compared to normal asphalt at the same temperatures, and the same torque as 150°C normal asphalt

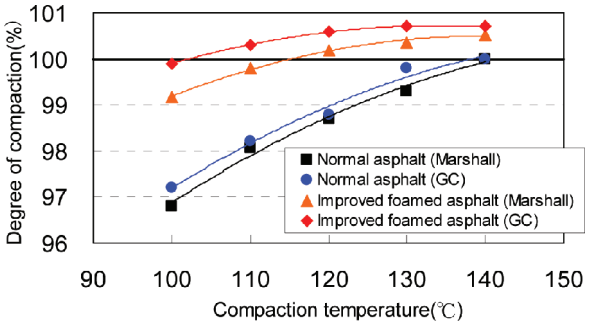

Figure 5. Compaction according to compaction method (recycling rate: 60%).

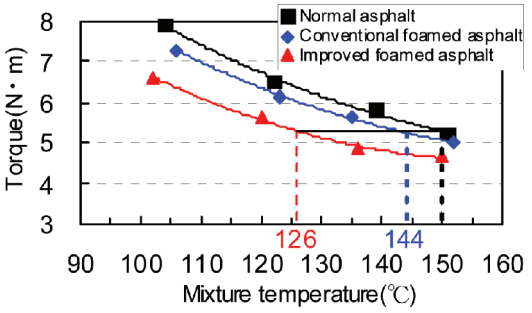

Figure 6. Relationships between mixture temperature and agitation torque (recycling rate: 60%).

was obtained at 126°C (24°C reduction). In the evaluation of workability, the same tendencies were seen at the recycling rates of 0, 20, and 40% as done with compaction.

Table 4 summarizes the improvement effects confirmed in the above study. For improved foamed asphalt, at high recycling rates which means that the amount of new asphalt is less, the improvement effects for compaction and workability decreased. Even at the recycling rate of 60%, improvement effects of about 25°C were seen. In addition, improving the foamed asphalt provided additional improvement effects of about 15°C. These results confirm that improved foamed asphalt can be applied for reducing the manufacturing temperature of recycled asphalt mixtures and improving workability.

4.4 *Continued effects of improved foamed asphalt*

To verify the sustenance of bearing effects using improved foamed asphalt, changes in the compaction degree with time after manufacture of the mixtures were investigated. The curing temperature was set at 150°C, the compaction temperature at 140°C, and the compaction degree at 100% taking 0 hours elapsed time as the reference for each mixture. Figure 7 shows the relation between the elapsed time and compaction degree. It was confirmed that as a result of the microfoaming of the improved foamed asphalt, bearing effects continued for a longer time than conventional foamed asphalt and were the same as normal asphalt.

4.5 *Basic properties of mixtures*

Using the improved foamed asphalt, mixture properties when compaction was carried out at lower mixture temperature were verified. The compaction temperature of the improved foamed asphalt was set at 104°C for the recycling rate of 0% and at 115°C for the recycling rate of 60% based on the results in Table 6. Table 7 shows the test results. No decrease in mixture properties was found as a result of decreasing the compaction temperature from that

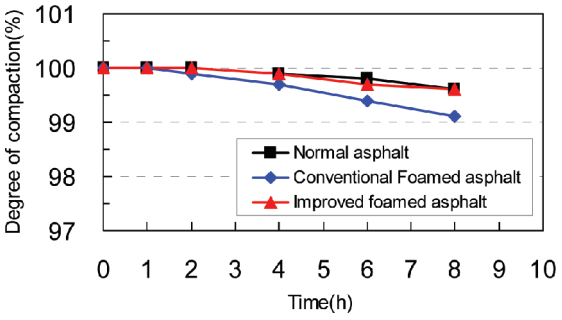

Figure 7. Relation between elapsed time and compaction.

of normal asphalt. In addition, although reduced stripping resistance due to the use of water and foaming enhancer was feared for improved foamed asphalt, no such drop was seen.

5 VERIFICATION OF APPLICABILITY IN MANUFACTURING AND CONSTRUCTION

5.1 *Verification of manufacturing mixture on manufacturing plant machine*

As a result of measuring the FI of improved foamed asphalt using a calibration nozzle installed on manufacturing plant, it was confirmed that the same FI as obtained by a lab foamer can be obtained. Table 8 shows the properties of the recycled dense graded asphalt

Table 8. Mixture properties on laboratory machine and plant (recycling rate: 60%).

*Sampled 3 cores per site.

mixture (13) with a recycling rate of 60% made on the plant. The improved foamed asphalt was made with 25°C lower than normal asphalt, but it demonstrated more or less the same properties as normal asphalt.

5.2 *Verification in construction*

To verify performance in construction, compaction degree was investigated in the construction site using a recycled dense graded asphalt mixture (13) with recycling rate of 50%. Table 9 shows the compaction degree of asphalt shipped at temperatures reduced from normal asphalt by 30°C to decrease manufacturing temperature during summer, and that of asphalt shipped at the same temperature as normal asphalt in the aim to improve workability during winter. As a result, it was confirmed that the same compaction degree as normal asphalt was obtained in the shipment where the manufacturing temperature was decreased in summer, and workability improved and high compaction degree versus normal asphalt was obtained in winter.

6 RECYCLING AGENTS

Reviews to date have confirmed that improving foamed asphalt by microfoaming is effective for enhancing compaction and workability for recycled asphalt mixtures. Given that the

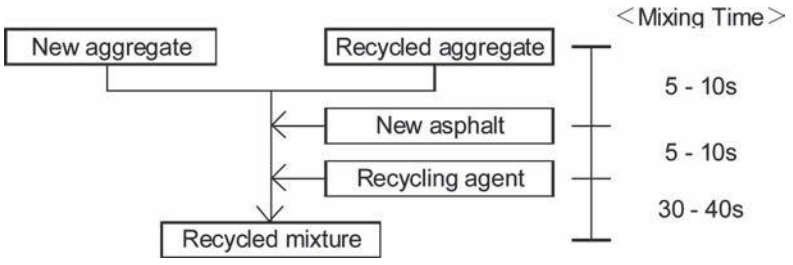

Figure 8. Example of mixing procedure at plant.

amount of new asphalt contained decreases with increasing recycling rate, high recycling rate also means less effectiveness of improving foamed asphalt. Thus it is difficult to achieve the desired effects when improved foamed asphalt is applied to mixtures with high recycling rate and some other methods for applying to high recycling rates are required.

Of the materials used for recycling mixtures, we have been focusing on recycling agents. Figure 8 shows examples of mixing methods used by Japanese manufacturing plants. Investigations were carried out based on the idea that in addition to foaming the asphalt, foaming the recycling agent further enhances bearing effects, allowing foaming techniques to be applied to mixtures with high recycling rate.

7 FOAMED PROPERTIES OF RECYCLING AGENT

Conditions enabling foaming and foamed properties were verified at various conditions. The recycling agents generally used in Japan were employed. Table 10 shows the properties of the recycling agents used. FI was applied for evaluating foamed properties and the foaming device used is similar to one for asphalt.

7.1 *Temperature of recycling agent*

Foamed properties were verified by varying the temperature of the recycling agent. The amount of water added was tentatively set at 3%. It was confirmed that the expansion ratio and half period became maximum at about 130°C, and no changes were found at 130°C or above. It was also clarified that no foaming occurs at around 100°C.

7.2 *Amount of water added*

Foamed properties were verified by varying the amount of water added. Figure 9 shows the maximum expansion ratio and FI. Both expansion ratio and FI were maximum when the amount of water added was about 2%.

Based on this review, the standard recycling agent temperature was set at 130°C and the standard amount of water added was 2.0%.

8 EFFECTS OF FOAMED RECYCLING AGENT ON MIXTURE PROPERTIES

The properties of recycled mixtures with recycling rate of 75% were verified using a foamed recycling agent. Table 11 shows the mixtures studied, namely normal mixture, mixture in which only the asphalt is foamed (As-foamed), mixture where both the asphalt and recycling agent are foamed (W-foamed), and improved foamed asphalt was used.

The split test is a test for evaluating the stiffness of recycled mixtures. The stiffness is known to have a high correlation with the deterioration level of mixtures (penetration of recovered asphalt) and the number of damage (fatigue damage resistance) in flex tests[4]. Recycling

Table 10. Properties of recycling agent.

Density (15°C)	0.905
Flash point (°C)	264

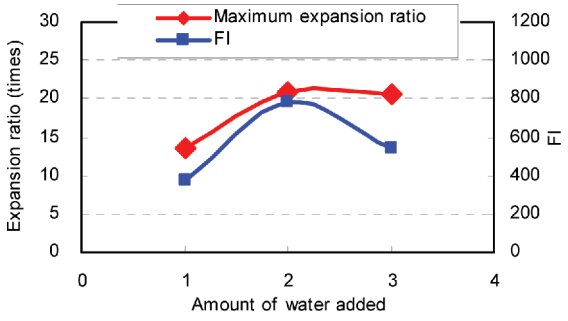

Figure 9. Maximum expansion ratio and FI.

Table 11. Mixture proportion.

Mixture	Recycling rate (%)	All asphalt (%)	New asphalt (%)	Recycled asphalt (%)	Recycling agent added (%)
Recycled dense graded asphalt concrete (13)	75	5.7	2.08	3.29	0.33

agents are added to recover appropriate stiffness values for recycled asphalt mixtures, and it is thought that if the foaming of the recycling agent enhances the effects of recovering stiffness, the mixture will have improved fatigue damage resistance.

8.1 *Compaction*

Compaction was verified in Marshall compaction test. Figure 10 shows the relation between the mixture temperature and compaction degree. Compared with normal asphalt and As-foamed, W-foamed showed a high compaction degree at the same temperatures. When W-foamed showed the same compaction degree as As-foamed, temperature reduction effects were about 5°C higher, resulting in improved compaction by the foaming of the recycling agent.

8.2 *Workability*

Figure 11 shows the results of the workability evaluation test of the mixture. Compared with normal asphalt and As-foamed, W-foamed showed a low torque at the same temperature. When W-foamed showed the same torque as As-foamed, temperature reduction effects were 5°C higher, resulting in improved compaction by the foaming of the recycling agent.

8.3 *Splitting test*

Table 12 shows the results of the split test. Compared with normal asphalt and As-foamed, W-foamed had a lower split coefficient. Foaming the recycling agent was found to increase

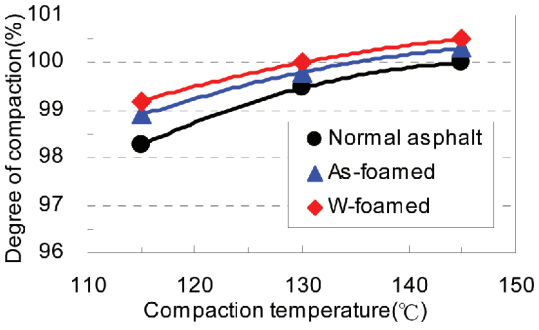

Figure 10. Marshall test results.

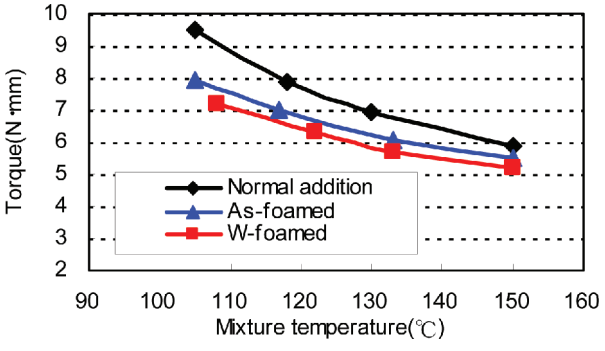

Figure 11. Workability evaluation test.

Table 12. Split test results.

Type of mixture	Normal addition	As-foamed	W-foamed
Split coefficient (MPa/mm)	0.71	0.70	0.64

the effects of lowering the split coefficient and bringing the split stiffness closer to the appropriate value.

From the above results, foaming the recycling agent and applying foaming technique to recycled asphalt mixtures with a recycling rate of 75% were found to enhance both compaction and workability. It was also confirmed to enhance the split stiffness improvement effects of recycled asphalt mixtures and the effects of adding the recycling agent.

9 SUMMARY

The following findings were obtained from the results of the verifications conducted.

1. By realizing foam finer than conventional bubbles using a foaming enhancer, the foaming index could be improved sharply.
2. It was confirmed that improving bearing effects by the microfoaming of foamed asphalt further enhances the compaction and workability of recycled asphalt mixtures with high recycling rates, and bearing effects further increase in roller compaction by kneading in construction.

3. Construction on actual roads demonstrated that the improved foamed asphalt is effective for reducing the paving temperature of recycled asphalt mixtures and improving workability.
4. Foaming the recycling agent was confirmed to improve compaction and workability, and the properties of recycled asphalt mixtures with high recycling rates.

10 CONCLUSION

The results of this study demonstrated the effectiveness of improved foamed asphalt for improving quality by reducing the manufacture temperature of recycled asphalt mixtures with high recycling rate and improving workability. We started full-scale manufacturing and shipment from June 2012. In addition, it was also revealed that the foaming of the recycling agent added may also further decrease manufacturing temperature, improve workability, and enhance mixture properties. Currently, we are verifying the results of manufacturing experiments conducted at our plant. In the future, we plan to verify these effects in construction, and develop a manufacturing system for recycled asphalt mixtures with high recycling rates in the aim to improve the working environment and improving product quality.

Workability and coatability of foamed Warm-Mix Asphalt

Fan Yin, Edith Arambula & David Newcomb

Amit Bhasin
The University of Texas at Austin, Austin, TX, USA

ABSTRACT: Foaming of asphalt binders has become the most popular method for producing Warm-Mix Asphalt (WMA) in the United States. Mixing cold water and hot binder results in an expansion of the binder, a reduction in binder viscosity, and improved workability of the mixture and better coating of the aggregates by the foamed binder. The objectives of this study are to develop laboratory test methods to determine workability and coatability of asphalt mixtures and to validate the improved workability and coatability of foamed WMA as compared to Hot-Mix Asphalt (HMA). In the study, the maximum shear stress obtained during compaction using a Superpave Gyratory Compactor (SGC) is proposed as workability parameter. For mixture coatability evaluation, a testing procedure based on aggregate absorption is used and a coating parameter, coatability index, is proposed. Foamed WMA with different binder sources and grades and various water contents as well as control HMA are produced and evaluated in the study. Test results indicate that there is an optimum foaming water content that produces foamed WMA with the best workability and coatability characteristics when compared not only to other foamed WMA but also to control HMA.

Keywords: warm-mix asphalt, foaming process, workability, coatability

1 INTRODUCTION

Economic, environmental, and engineering benefits have led to the rapid implementation and widespread use of Warm-Mix Asphalt (WMA). Currently, the most popular method for producing WMA is foaming asphalt binder with water. The foamed WMA can be produced by the injection of water, water-bearing mineral additives, or wet aggregates. In the most popular foaming process, small amounts of cold water are injected into a hot asphalt stream ranging from 320°F (160°C) to 360°F (182°C). The mixing of cold water and hot binder results in the formation of steam resulting in an expansion of binder volume, a subsequent reduction in binder viscosity, and therefore, an improved workability of the mixture and better coating of the aggregate by the foamed binder.

Workability of asphalt mixtures is a property that describes the ease with which the mixture can be placed, worked by hand, and compacted. It is a function of temperature, binder properties (e.g., viscosity, grade, polymer modification, etc.), aggregate properties (e.g. size, angularity, etc.), among other factors.

Coatability of asphalt mixtures is defined as the degree of coating of the aggregates by the asphalt binder. This parameter is important to the performance of asphalt mixtures, since well-coated aggregates are likely to have a stronger bond between the particle and the binder, and thus a better resistance to moisture damage and other distresses.

The objectives of this study are to:

- Develop laboratory test methods to measure workability and coatability of asphalt mixtures.

- Evaluate the effect of different binder types and foaming water contents on the workability and coatability of foamed asphalt mixture.
- Compare the workability and coatability of foamed WMA against HMA.

In this study, an analysis method is proposed to evaluate the workability of foamed WMA using Superpave Gyratory Compactor (SGC) compaction data (i.e., shear stress versus number of gyrations). The maximum shear stress is proposed as mixture workability parameter. A modified procedure based on the aggregate absorption method originally developed by Velasquez et al. [1] is used to measure mixture coatability. The coatability index is proposed as the mixture coating parameter.

2 LABORATORY TEST METHODS

2.1 *Workability*

A SGC was used in this study to prepare the asphalt mixtures, which was operated based on a "shear-compaction" principle [2]. During compaction, the loose mix particles reoriented under the vertical and shear pressure for a target number of gyrations (i.e., 300) to ensure that a maximum shear stress was achieved [3].

After sieving, the aggregates were combined into individual batches according to the volumetric mix design and pre-heated in the oven to the mixing temperature. The asphalt binders were heated in the oven for 2 to 3 hours prior to transfer to the laboratory foamer. The laboratory foamer (i.e., Wirtgen WLB 10S) was calibrated according to the manufacturer's recommendation. The pre-heated aggregate batch was introduced into the mixer bucket and the portable mixer was placed under the laboratory foamer, as shown in Figure 1. The specific amount of foamed binder was dispensed into the bucket mixer as it was running. The mixer was stopped after 60 seconds and the loose mix was placed back into the oven for two hours at 275°F (135°C) for HMA and 240°F (116°C) for foamed WMA to achieve the proper short-term aging [4].

The loose mix was divided into individual specimen size batches (4,700 g per batch) after the short-term aging and then compacted. During compaction, the shear stress was continually monitored and plotted for each gyration. As shown in Figure 2, compaction was stopped after a significant reduction in shear stress was observed, which usually occurred between 200 and 300 gyrations.

Figure 2 shows a typical curve of the shear stress versus number of SGC gyrations during compaction. As illustrated, the curve can be divided in three phases. In the first phase, the

Figure 1. WMA foaming process in the laboratory.

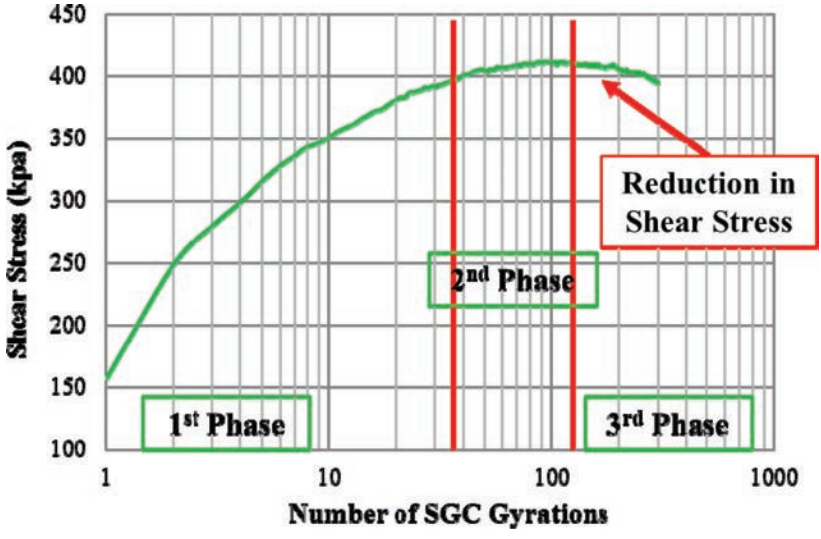

Figure 2. Typical shear stress vs. number of SGC gyrations curve showing the three phases of compaction.

slope of the shear stress curve is steep. The loose mix particles are being reoriented due to the initial compaction, and there is a significant increase in the internal friction within the mix due to the stone-on-stone contact resulting from loose mix particles reorientation. The shear stress starts to level off in the second phase. The density of the mix is expected to be near or at the target value somewhere in this phase. The third phase starts when a decrease in shear stress is observed. The reduction in shear stress is partially attributed to the dominant effect of pore pressure. For practical applications, the third phase in the compaction process should be avoided to prevent aggregate crushing after the maximum density is achieved.

According to Sombre et al., the shear stress versus SGC gyration curve can be used to determine the compaction characteristics of different asphalt mixtures [3]. Specifically, asphalt mixtures which compact more rapidly (steeper slope in loose mix height versus number of gyration curve) in the first few gyrations are expected to have a higher shear stress level afterwards, due to the increased internal friction within the mix. In addition, mixtures with a lower shear stress levels are expected to have better workability than those with a higher shear stress level. Therefore, maximum shear stress in the SGC compaction curve is proposed as the parameter to evaluate mixture workability.

2.2 *Coatability*

The method used in this study for determining the coatability of foamed WMA is primarily based on the aggregate absorption method originally developed by Velasquez et al. [1]. The method is based on the assumption that a completely coated aggregate has no access to water absorption when submerged in water for a short period (i.e., 1 hour), as water cannot penetrate through the asphalt film surrounding the aggregate surface. On the other hand, a partially coated aggregate is expected to have detectable water absorption, as water is able to penetrate and be absorbed by the uncoated particle. The following procedure was used to determine coatability of the asphalt mixtures.

After sieving, coarse aggregate fractions were combined into two individual batches (4,000 g per batch) following mix design, with one batch pre-heated in the oven at the mixing temperature while the other was stored at the room temperature. The amount of binder for the coarse aggregate fraction batch was determined based on the total binder content specified in the mix design and the surface area distribution of the coarse aggregate fraction.

The amount of binder for mixing with the 4,000 g coarse aggregate fraction batch was calculated using Equation 1:

$$W_b = 4{,}000 * \frac{P_b}{1 - P_b} * \frac{SA_{coarse}}{SST} * \frac{1}{P_{s-coarse}} \quad (1)$$

where:
W_b, amount of binder for mixing with a 4,000 g coarse aggregate batch (g)
P_b, optimum binder content from mix design (%)
SA_{coarse}, surface area of the combined coarse aggregates (m^2/kg)
SST, total surface area of mix design combined aggregates (m^2/kg)
$P_{s\text{-}coarse}$, percentage of coarse aggregates retained on 3/8 inch by the combined aggregates (%).

The same mixing and short-term aging procedure as those used in the workability evaluation were used to mix the coarse aggregate fraction batch with foamed binder and to short-term age the loose mix. The loose mix was taken out of the oven after short-term aging and cooled down to room temperature. The loose mix batch and the coarse aggregate fraction were each submerged under water for 1 hour. Afterwards, these two batches were damp-dried with a terry cloth to achieve the saturated Surface Dry (SSD) condition. The SSD weights of the loose mix batch and coarse aggregate fraction batch were recorded as $W_{loose\text{-}SSD}$ and $W_{agg\text{-}SSD}$, respectively. The water absorption for the loose mix batch and the coarse aggregate fraction batch using Equation 2 and Equation 3:

$$Abs\%_{loose} = \frac{W_{loose-SSD} - (4{,}000 + W_b)}{4{,}000 + W_b} * 100\% \quad (2)$$

$$Abs\%_{agg} = \frac{W_{agg-SSD} - 4{,}000}{4{,}000} * 100\% \quad (3)$$

The coatability index for the foamed asphalt mixture was calculated using Equation 4:

$$Coatability\ Index = \frac{Abs\%_{agg} - Abs\%_{loose}}{Abs\%_{agg}} * 100\% \quad (4)$$

Asphalt mixtures with a higher coatability index value are expected to have a better aggregate coating by the asphalt binder than those with a lower coatability index value. Therefore, coatability index is proposed as the parameter to evaluate mixture coatability.

3 EXPERIMENTAL DESIGN

A preliminary laboratory study conducted as part of the National Cooperative Highway Research Program (NCHRP) project 09-53 was performed to validate the workability and coatability test methods described in the previous section and compare the workability and coatability of foamed WMA against those of HMA. The experimental design for the study is shown in Table 1.

The materials used in the study correspond to a field project located on IH-25 in New Mexico. Three fractions of siliceous aggregates were combined following the mix design gradation shown in Figure 3. The optimum binder content by the weight of mix was 5.4%. For the coatability evaluation, the volumetrics for the coarse aggregate fraction were calculated based on the combined aggregate gradation and optimum binder contents from the mix design, as summarized in Table 2.

The Wirtgen WLB 10S laboratory foamer was used in this study to produce foamed WMA and control HMA, using an air-atomized foaming process. The temperature of the asphalt chamber in the foamer was at 320°F (160°C), and the air and water pressure were set to 72 psi

Table 1. Experimental design for workability and coatability evaluation.

	HMA/ 0%	Foamed WMA/1%	Foamed WMA/2%	Foamed WMA/3%
N64-22	X	X	X	X
O64-22	X	X	X	X
Y64-22	X	X	X	X
N70-22		X		
O70-22		X		

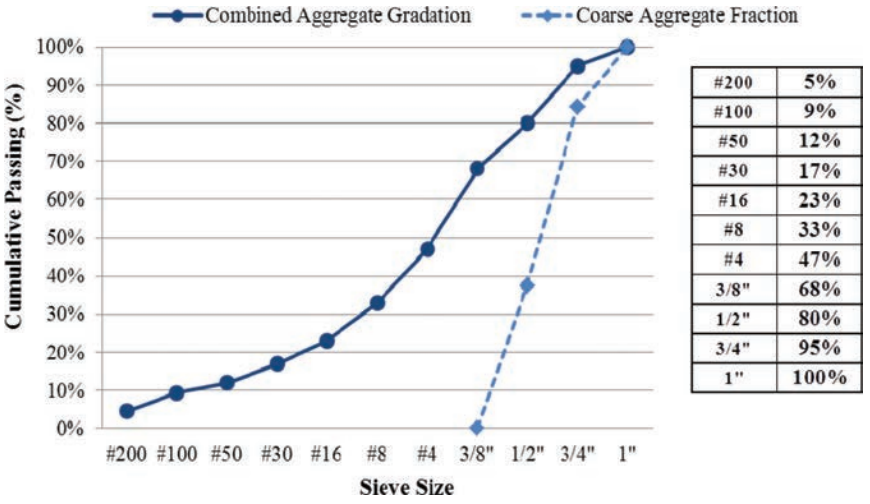

Figure 3. Design aggregate gradation for the New Mexico field project.

Table 2. Volumetrics calculation for New Mexico coarse aggregate fraction.

Volumetrics	Values	Reference
P_b	5.4 (%)	Mix design
SST	5.093 (m^2/kg)	Mix design & [5]
SA_{coarse}	0.410 (m^2/kg)	Mix design & [5]
W_b	57 (g)	Equation 1

per the manufacturer's recommendation. Foamed WMA using three neat binders, N64-22, O64-22, and Y64-22 were produced at three different foaming water contents, 1%, 2%, and 3%. To explore the foaming characteristics of polymer modified binders versus neat binders, foamed WMA with two polymer modified binders (N70-22 and O70-22) were also produced at 1% foaming water content, which was the optimum foaming water content providing foamed WMA with the neat binders with the best workability and coatability, as discussed in the following section. The workability and coatability comparison of those mixtures were used to validate the proposed methods.

In addition, the control HMA using the neat binders was also included in the study. The control mixtures were produced by the same laboratory foamer at 0% foaming water content. The production temperatures for foamed WMA and control HMA are summarized in Table 3.

Table 3. Summary of production temperatures for HMA and foamed WMA.

Foaming water contents	Mixing temperature	Short-term aging protocol	Compaction temperature
0% (HMA)	290°F (143°C)	2 hours at 275°F (135°C)	275°F (135°C)
1% (foamed WMA)	275°F (135°C)	2 hours at 240°F (116°C)	240°F (116°C)
2% (foamed WMA)	275°F (135°C)	2 hours at 240°F (116°C)	240°F (116°C)
3% (foamed WMA)	275°F (135°C)	2 hours at 240°F (116°C)	240°F (116°C)

The mixing temperature for the control HMA was determined based on the binder PG grade and foamed WMA production was at a temperature 25°F (8°C) lower than that for HMA. The comparison of workability and coatability by foamed WMA versus HMA was used to verify whether the foaming process produced WMA mixtures with better workability and coatability characteristics as compared to the control HMA.

4 RESULTS AND DISCUSSION

The workability and coatability results for the control HMA and the foamed WMA mixtures produced using three different neat binders at 1%, 2%, and 3% water contents are shown in Figures 4 and 5. In these figures, the control HMA results are compared against the foamed WMA values within each binder source. Each bar in Figure 4 represents the average value of two replicates and the error bars represent ± one standard deviation from the average value. Based on the span of the error bars, good repeatability for the workability test method was achieved.

A significant difference in workability (Fig. 4) and coatability (Fig. 5) was observed for the various foamed WMA mixtures and as compared to the control HMA for asphalt sources N and O. However, there was relatively little difference for source Y. Therefore, the workability and coatability test methods proposed in this study were validated as valid tools to capture the characteristics of the different mixtures depending upon the asphalt source.

As shown in Figures 4 and 5, foamed WMA mixtures employing N64-22 and O64-22 binders at 1% water content had better workability and coatability characteristics (indicated by a lower maximum shear stress and a higher coatability index) as compared to both the WMA mixtures foamed at higher water contents and the control HMA. This was true despite the fact that the production temperature for the WMA mixtures was approximately 30°F (17°C) lower than the production temperature for HMA. Therefore, a water content of 1% was optimum for these WMA foamed mixtures. Contrary to expectations, however, WMA mixtures foamed at higher water contents (i.e., 2% and 3%) yielded mixtures with equivalent or worse workability and coatability characteristics as compared to the control HMA.

A different workability and coatability trend is shown for mixtures employing the Y64-22 binder. These WMA mixtures had equivalent workability and coatability as compared to the control HMA despite of the amount of water used during foaming. Foaming measurements made outside the scope of this paper showed that this binder did not appreciably foam at any water content (i.e. 1% to 5%). The reduced foaming abilities of the Y64-22 binder are possibly due to the presence of an anti-foaming agent that is sometimes introduced during the crude refining or binder production process [6,7,8]. Further investigation in detecting possible anti-foaming agents in this particular binder using Fourier Transform Infrared Spectroscopy (FTIR) is currently ongoing.

As foamed WMA using N64-22 and O64-22 binders at 1% foaming water content had the best workability and coatability, foamed WMA using the polymer modified binders N70-22 and O70-22 were also produced at this water content. Workability and coatability results for foamed WMA using polymer modified versus neat binders are compared and summarized in Figures 6 and 7, respectively. As illustrated, better workability and coatability are shown for

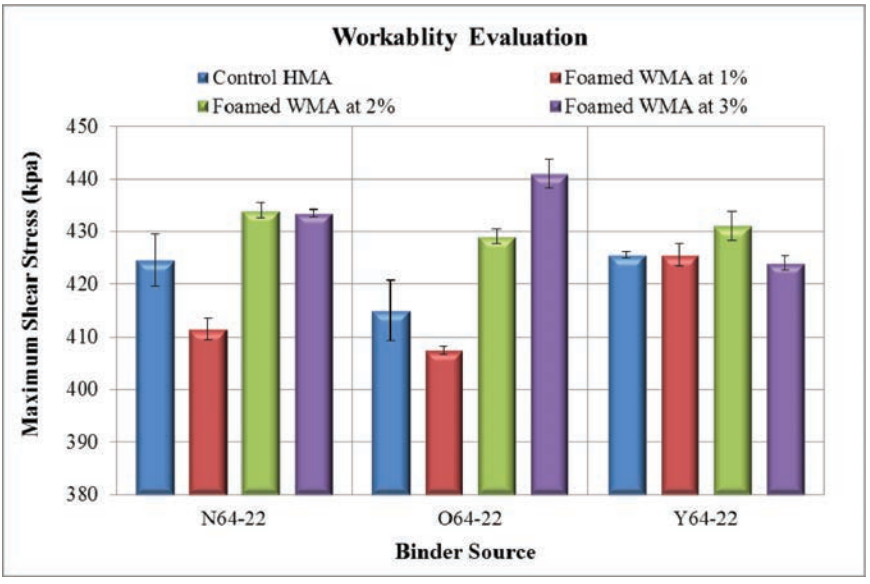

Figure 4. Workability test results for foamed WMA versus HMA.

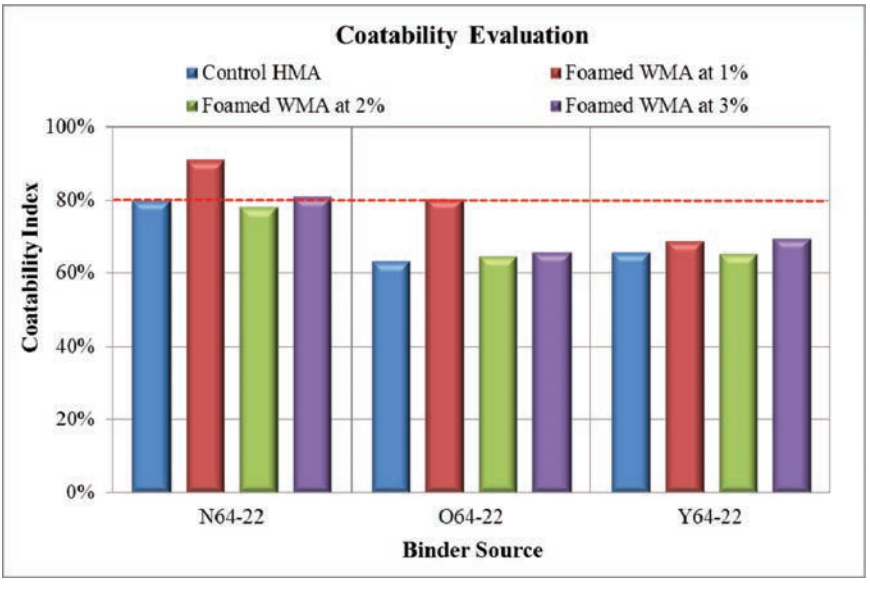

Figure 5. Coatability test results for foamed WMA versus HMA.

foamed WMA using neat binders than those using polymer modified binders. The reduced properties of foamed WMA using polymer modified binders are possibly attributed to the higher viscosity of the binder at the WMA production temperature, which was approximately 40°F (22°C) lower than the production temperature recommended by manufacturers. Thus, it may be advantageous to increase the production temperature for foamed polymer modified binders.

Additionally, the incorporation of polymer modifiers may have an effect on the binder foaming characteristics. Further investigation in workability and coatability of foamed WMA using polymer modified binders produced at higher temperatures is currently ongoing.

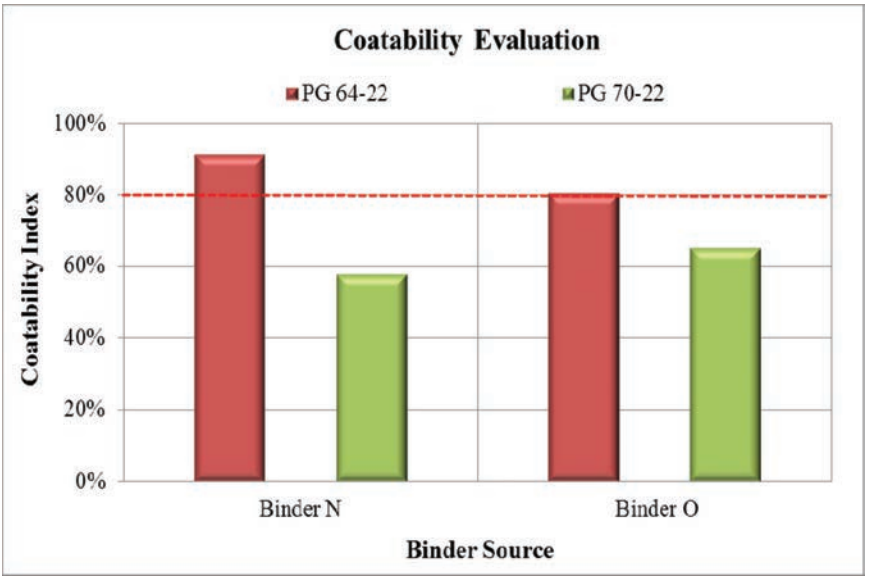

Figure 7. Coatability test results for foamed WMA with neat versus polymer modified binder.

5 CONCLUSIONS AND FUTURE WORK

Economic, environmental, and engineering benefits motivate the reduction of production and placement temperatures for asphalt concrete paving materials. The latest technology adopted for temperature reduction is WMA. The most popular method of producing WMA in the United States is by foaming the asphalt binder. The mixing of cold water and hot binder results in binder volume expansion, a subsequent reduction in binder viscosity, and

therefore, an improved workability of the mixture and better coating of the aggregates by the foamed binder.

In this study, test methods for evaluating mixture workability and coatability were developed using SGC compaction data and a modified aggregate absorption method, respectively. Maximum shear stress and coatability index were proposed as mixture workability and coatability parameters. For the coatability evaluation, only coarse aggregates retained on the 3/8 inch sieve are used. The relative difference in water absorption by the uncoated aggregates versus the loose mix is used to calculate the coatability index.

Foamed WMA using three different binders at three different foaming water contents were produced using a laboratory foamer. In addition, to validate the improved workability and coatability of foamed WMA, a control HMA mixture was also produced using the same laboratory foamer at 0% water content. The workability and coatability of the foamed WMA mixtures were compared against the characteristics of the HMA mixtures. In addition, the effect of binder source, binder grade and foaming water contents on mixture workability and coatability was investigated. The following conclusions were made based on the results of study:

1. Significant differences in the maximum shear stress and coatability index for foamed WMA mixtures versus the control HMA was observed for two of the three asphalts. Thus, the test methods proposed in this study seem promising in evaluating the workability and coatability of asphalt mixtures.
2. Foamed WMA mixtures produced with N64-22 and O64-22 binders had better workability and coatability when 1% foaming water content was used as compared to higher foaming water contents (i.e., 2% and 3%). Thus, for these two binders, 1% was considered the optimum foaming water content. However, equivalent workability and coatability was observed for the WMA mixtures that employed the Y64-22 binder as compared to the control HMA regardless of the foaming water content used. The possible presence of an anti-foaming agent in the Y64-22 binder is currently under investigation.
3. Comparison of foamed WMA versus control HMA mixtures showed that WMA produced at 1% foaming water content had better workability and coatability characteristics, despite the fact that the WMA mixtures were produced at temperatures approximately 30°F (17°C) lower than the control HMA. However, the WMA mixtures foamed at higher foaming water contents (i.e., 2% and 3%) had equivalent or worse characteristics as compared to the control HMA. This finding highlights the importance of identifying the best materials and foaming conditions to maximize the workability and coatability of foamed mixtures.
4. At WMA production temperatures, foamed WMA employing N64-22 and O64-22 had better workability and coatability as compared to those with N70-22 and O70-22. The higher viscosity of polymer modified binders is possibly attributed to the reduced mixture workability and coatability. Further investigation for foamed WMA using polymer modified binders produced at higher production temperature is currently undergoing.

For future work, it is recommended to explore the effect of foaming temperature and the presence of polymer in polymer modified binders on the workability and coatability characteristics of foamed WMA mixtures.

Cleaner Warm-Mix Asphalt (CWMA) at macro level: Case study for the United States

Ali Jamshidi & Meor Othman Hamzah
School of Civil Engineering, Universiti Sains Malaysia—USM, Engineering Campus, Seberang Perai Selatan, Pulau Pinang, Malaysia

ABSTRACT: Although Warm-Mixture Asphalt (WMA) is a great step towards constructing a sustainable pavement, it is still a high energy-intensive technology. More energy-efficient WMA is required to fulfil stricter environmental regulations that might be prescribed by environmental policy makers in future. In this study, the effects of aggregate characteristics on WMA are evaluated in the terms of energy consumption and greenhouse gas (CO_2) emission on a large scale. The paper proposes a method of aggregate source selection to produce a Cleaner WMA (CWMA). The results showed that energy consumption and CO_2 emission of CWMA are lower than those of traditional WMA in the United States as a case study. The results also indicate that the amount of energy savings due to use of CWMA is sufficient to fuel 24,330 to 341,525 American households per annum, depending on aggregate type, source and asphalt type.

Keywords: Energy efficiency, greenhouse gas emission, sustainable infrastructures

1 INTRODUCTION

Asphalt mix production depends on energy resources in two ways: (1) energy required to produce asphalt binders in oil refineries; and (2) carbon-based energy carriers that are used as industrial fuels in asphalt mixing plants [1]. Moreover, energy demand is increasing consistently, and can be expected to do so in the future. For example, The United States Energy Administration (USEA) predicted that by the year 2020, total energy consumption from petroleum, natural gas, coal, electricity and renewable energy will increase by 32%, 33%, 62%, 22%, 45%, and 26% respectively [2]. Meanwhile, asphalt production was the second most energy-intensive manufacturing industry in the United States [3]. Therefore, it is necessary to quench the asphalt mix production's thirst for fossil fuels consumption with development of less energy-intensive construction technologies.

The two prevailing strategies by which the energy sectors in many countries are trying to cope with this problem are the following: searching for inexhaustible and non-polluting new energy sources and generating cleaner production of energy by the development of low-carbon technologies [4]. The challenges of the first strategy are clear: new infrastructure for the production and distribution of new energy sources needs to be constructed, while costs must decrease significantly. Even if new non-polluting energy sources are found, it will be many years before they can be produced on a large industrial scale. The second strategy affords energy producers to achieve results within a shorter period of time. The asphalt industry also needs to abide by environmental restrictions. Warm Mix Asphalt (WMA) technology is one of most important steps taken to reduce energy-intensive characteristics of the asphalt industries. However, it seems that the asphalt industries are thirstier than expected for more environmental-friendly technologies in pavement construction. Hence, new or more improved WMA additives should be developed to reduce the construction temperatures of asphalt mixture more than the current additives without sacrificing structural and functional

asphalt mix performances. Therefore, an extensive research infrastructure, including well-qualified human resource such as highly-educated and experienced researchers and pavement engineers, and well-equipped laboratories, are needed to develop such additives. Moreover, a plenty of raw materials and supporting infrastructures are necessary for mass production. For instance, in 2003 Sasol Wax invested $360 million to pipe natural gas from Mozambique to Sasolburg, South Africa, for the production of Sasobit® [5]. So, a great budget or a reliable line of credit should be provided to support this WMA additive project financially for field investigation and study from the cradle to the grave, such as development of initial version of an additive type, laboratory study of asphalt binder and mixture, long-term field investigation and recycling, as well as environmental impact studies. Under the shadow of this current financial crisis, it would not be free-risk investments for industrial owners and private sectors. Meanwhile, it is impossible to stop doing research on sustainability in asphalt industries. One solution is that the fundamental properties of asphalt mix material, aggregate and asphalt binders being evaluated in terms of energy intensive. For example, WMA technology reduces construction temperatures of asphalt mixes via various mechanisms; hence reduce fuel consumption and greenhouse gas emission. A question rises in the mind that it is possible to produce cleaner warm using current additives without any modification in WMA technology or not. To address this issue, Jamshidi et al. [1] proposed specific heat capacity coefficient of aggregate (C) as indicator of Environmental Polluting Parameter (EPP) in Superpave™ mix design method. In addition to consensus and source properties of aggregate, the Superpave™ will have parameter that enable pavement engineers, researchers and environmental policy makers to study environmental-friendliness of aggregate materials in the paving projects. More details were discussed by Jamshidi [6].

It should be noted that the effects of C of same aggregate type supplied from various sources can be different. It may affect the energy consumption and CO_2 emission in the asphalt mixing plants, specifically on a national scale.

2 MATERIAL AND METHODS

The asphalt binders used for this study were PG 64 and PG 76. Table 1 shows the rheological properties of the control asphalt binder (without WMA additives).

Two aggregate types, granite and limestone, were selected from 2 sources. Table 2 presents the properties of the aggregates in this study. Table 3 shows construction temperatures of hot and warm mixtures.

The amount of required heat energy, fuel requirement, and CO_2 emissions for a 10 km road length were computed using user-friendly computational software developed by Jamshidi [6], called EFEAS (Energy, Fuel and Emission Analyzing Software). Based on the mix design results, the optimum binder content is 5.0% while the corresponding mixture density was 2.38 g/cm^3. Therefore, the mass of mixture required to pave a 10-km dual carriageway with 3 lanes per direction, assuming lane width is 3.65 m and a 5-cm thick wearing course is 27,000 ton.

It is also supposed that the industrial fuel utilized in the asphalt mixing plants is natural gas. The ambient temperature of the environment was assumed to be 25°C. The outputs of

software are the energy and fuel requirements, and greenhouse gases, CO_2, CH_4 and N_2O, emitted to heat materials from ambient temperatures to the mixing points of the asphalt mixtures. Only CO_2 was considered in this study.

3 RESULTS AND DISCUSSION

Tables 4 and 5 show the required heat energy and natural gas to produce HMA and WMA for the assumed paving project. As expected the fuel requirements and CO_2 emissions for WMA production is less than those of HMA, irrespective of aggregate type, source and binder performance grade. For example, the WMA mixed at 130°C and incorporating granite aggregate supplied from source 1 and PG 64 binder requires 23.94% fuel lower than HMA produced using the same material type and source, as shown in Table 4.

Tables 4 and 5 also show the effects of aggregate source in terms of reduction percentages in the fuel requirements. Although the asphalt mixtures were produced using the same type of aggregate, fuel requirements and CO_2 emissions are significantly different. As an instance, WMA produced at 145°C using granite from source 1 requires 110,048 m^3 natural gas, while WMA produced at the same mixing temperature and containing granite from source 2 needs 58,220 m^3, which is 47.09% lower than source 1. It means that granite aggregate supplied from source 2 can be more sustainable as compared to those of source 1 due to lower specific heat capacity indicated in Table 2. Moreover, Tables 4 and 5 show that HMA containing aggregate from source 2, irrespective of aggregate type and binder types, requires less fuel as compared to WMA mixed at 145°C and 165°C for PG 64 and PG 76, respectively and containing aggregate from source 1. As an example, HMA produced using limestone from source 2 and PG 76 requires 93,156 m^3 natural gas as highlighted in grey, while 103,457 m^3 natural gas is needed to produce the WMA at 165°C using limestone from source 1, highlighted in yellow. Therefore, the HMA produced may be more sustainable than some WMA in terms of fuel consumption and CO_2 emissions.

The asphalt mixtures produced using aggregate with high specific heat capacity may meet many problems at various stages of the pavement life, including construction, utility and recycling as follow:

- More fuel is required to raise the temperature of aggregate from the ambient temperature to the mixing point, which translates to more emission and costs. Moreover, more time

[a]:Total required heat energy (Tera Joule) to raise the temperature of asphalt mix materials, including aggregate and asphalt binder, from 25°C to the mixing temperature; [b]:Difference in the fuel requirement between HMA and WMA; [c]:Difference in the fuel requirement between sources 1 and 2.

is required to heat the aggregate in the asphalt mixing plants. Therefore, production time increase and efficiency of the mixing plants decrease.

- More mixing time is required that the asphalt mixture's temperature reaches to the equilibrium temperature (ambient temperature) after compaction. Therefore, it can delay to open the paved surfaces using such mixtures to traffic.
- The extra heat energy due to high specific heat capacity is absorbed by asphalt binder coated the aggregate particles, making asphalt binder more prone to aging. Hence, the

asphalt mixture containing aggregate with high specific heat capacity become brittle and failures, including alligator, and thermal cracklings, during the design life of the pavement. Therefore, the utility expenses of the asphalt pavement increase.

- Since the pavement is supposed as a statically indeterminate structure system and the heat energy distribute in the three dimensions, the extra heat creates internal-residual stresses and deformation in the pavement structure. The each individual deformation due to expansion creates extra stresses and strains that are not predicted during the asphalt mix design and the structural response evaluation in the test of the current asphalt mix. It can lead to accelerate development of cracking and decrease serviceability of the HMA and WMA pavement. It is obvious that the patterns of development and distribution of the cracks depend on many variables, such as asphalt mix materials, traffic loading and environmental factors.
- Meanwhile, a stiff asphalt mix material increases the required energy to the milling during recycling, increasing the fuel consumption, the emissions, and the operational costs, including the precipitation costs.

As a consequence, use of aggregate with high specific heat capacity to produce asphalt mixture can mean spending more money for lower quality, while more energy-efficient as well as high sustainability with a desired performance are required as a perfect pavement. In the other words, specific heat capacity can be considered as an important parameter to evaluate environmental impacts. Therefore, use of aggregate materials posses low specific heat capacity can be suggested as a strategy to select sustainable source of aggregate materials. It would be possible that the selected sustainable sources of the aggregate materials are located far from the asphalt mixing plants and paving projects. The haulage of the sustainable aggregate may increase total costs and emissions of asphalt mix production. The effects of transportation should be included in life cycle analysis of a paving project. Meanwhile, the long-term performance of asphalt mixes produced using low specific heat capacity is needed to study by field investigation. Even though no relationship was found between the specific heat capacity of aggregate and the engineering properties of HMA in terms of the resilient modulus, mix density, Marshall stability and flow [7, 8]. In addition, it is also necessary to study the profile of heat distribution at various depths of the HMA and WMA with compromising thermal diffusity after laying the mixtures as illustrated schematically in Figure 1. It can provide function of cooling rate over the time.

From Tables 4 and 5, it can be seen that mixtures containing granite and limestone from sources 2 require minimum heat energy and fuel. Therefore, an alternative to reduce the requirements of heat energy and fuel as well as CO_2 emission is by substituting the high specific heat capacity aggregate with aggregate possessing lower specific heat capacity. For instance, a fraction of granite aggregate with specific heat capacity of 1188 J/kg°C in mixture is suggested to be replaced by another granite aggregate with lower specific heat capacity, 608 J/kg°C. In other words, the optimum aggregate mixture is a blend of two aggregates from the same aggregate type but with different specific heat capacity values. This suggestion can be industrially feasible but the aggregate with lower specific heat capacity may be unavailable or expensive. Therefore, it may be economically impractical to replace the whole aggregate with those of lower specific heat capacity. Since the minimum specific heat capacity values were attributed to the aggregates extracted from source 2 for both granite and limestone, these sources are considered as the most environmentally friendly sources of substitutes, for

a fraction of aggregates with high specific heat capacities. Table 6 shows different mixtures indicating blends of aggregate with lower specific heat capacity to produce more energy-efficient and Cleaner HMA (CHMA) as well as WMA (CWMA).

Tables 7 and 8 shows that the fuel requirement and CO_2 emissions of the asphalt mixture decreases as percentages of aggregate with low capacity increases, irrespective of aggregate and binder types as well as mixing temperature. As an example, HMA produced using granite aggregate from source 1 and PG 64 binder requires 125, 167 m^3 natural gas (under lined in Table 4), while the HMA produced using suggested the aggregate blend A or the aggregate blend containing 25% low specific heat capacity granite needs 110,424 m^3 natural gas at the same mixing temperature (underlined in Table 7). Another example, WMA produced using limestone supplied from source 1 and mixed at 145˚C requires 82,525 m^3 natural but the same WMA produced using 50% low specific heat capacity limestone requires (the aggregate blend E in Table 6) requires 74,037 m^3 natural gas (as shown in Table 7).

4 CASE STUDY: THE UNITED STATES

In the United States, transportation infrastructure investments account for 7% of the Gross Domestic Product (GDP) according to the National Asphalt Pavement Association [9].

And, asphalt mixture is one of the most common materials used to construct pavements in transportation infrastructures, with almost 96% of hard-surfaced roads constructed using the material [10–12]. Meanwhile, approximately 500 million tons of asphalt mixtures are produced annually in the United States [13]. Therefore, the energy saving due to use of low specific heat capacity aggregate in the asphalt mix production can be significant. In this study, it was assumed that total aggregate and total asphalt binder mass are 475,000,000 tons ($0.95*500*10^6$) and 25,000,000 ton ($0.05*500*10^6$), respectively. Tables 9 and 10 show that heat energy and fuel requirements for HMA and WMA produced using various aggregate type and asphalt binders. It is obvious that PG 64 or PG 76 binder and one type aggregate from a given source are not used to produce the total asphalt mixture in the United States. It is just a simplifying to show the effects of high specific heat capacity of the aggregate on the asphalt industries on a large scale.

Although use of WMA technology reduces the fuel requirements, more sustainable WMA can be produced using low specific heat capacity aggregate on a national scale as presented in the Tables 9 and 10. For example, WMA produced at 145°C using PG 64 reduces the fuel requirement 23.94% as compared to HMA, while use of the granite aggregate with the low specific heat capacity decrease almost 47% for the both WMA and HMA without further technology and any modification in the current asphalt mixing plants. Moreover, use of the low specific heat capacity aggregate on national scale can be supposed as a strategy to reduce the share of the asphalt industries in the CO_2 production, hence the carbon tax of such industries reduce. It is obvious that all the mix production could not be WMA produced using PG 64 or PG 76 and aggregate types shown in Table 2. Moreover, all the asphalt mixing plants do not utilize the natural gas. It is emphasized that this study only tends to shows the effects of thermal properties of aggregate on the fuel requirement and CO_2 emission.

Meanwhile, the considerable reduction in the fuel requirements is even more interesting, in light of the fact that a 1% increase in the growth in the economy requires a 1.5% increase energy supply of a developing country, while crude oil production is declining at the rate of 4.5% per year[14]. A number of households that can be energized are computed based on the Annual Energy Consumption per Household (AECH). The amount of AECH is 107 GJ for the United States [15]. Figure 2 shows number of American households that can be fuelled using the proposed strategies.

Table 9. Heat energy and fuel requirements for production of HMA and WMA using PG 64 in the United States.

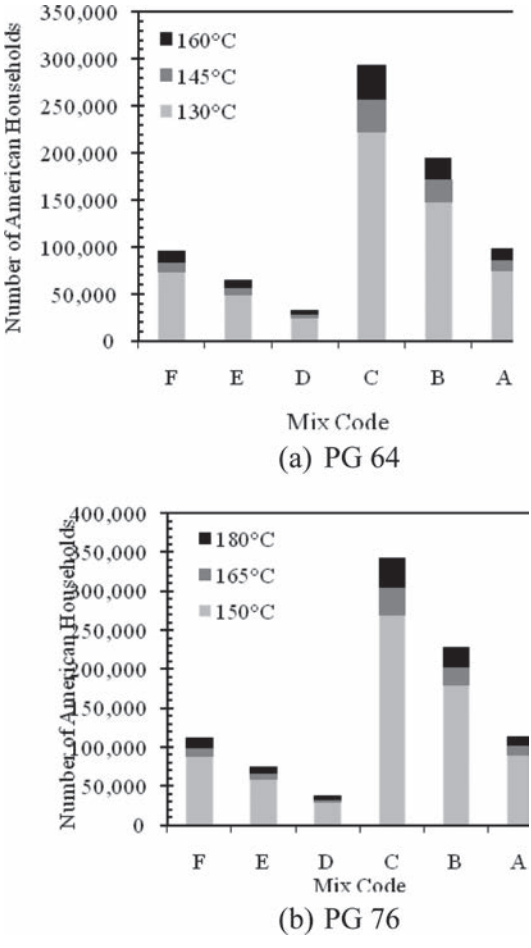

Figure 2. Number of American households that can be fuelled using the proposed strategies.

This can serve a sharp justification for environmental policy makers and energy planning experts to promote the development of WMA using less energy-intensive materials, such as aggregate materials with low-specific heat capacity on a large scale. Analysis of energy saving based on the provision of annual household energy would encourage asphalt industries to save more energy and subsequently reduces the energy cost in asphalt mixing plants, stimulates economic growth and conform to the Kyoto protocol limit on GHG emissions [6]. Therefore, it can be suggested a data bank of the aggregate sources can be developed based on the specific heat capacity to choose the sources of the aggregate materials with low specific heat capacity to produce CWMA and CHMA.

5 CONCLUSION

Although WMA technology reduce the fuel requirements and CO_2 emission via reduction of construction temperatures, selection of less energy-intensive aggregate materials can be led to produce cleaner warm and hot asphalt mixtures without modification of current technology of asphalt mixture construction in a paving projects. The asphalt mixtures produced using aggregate materials with the high specific heat capacity can have many problems for the asphalt mixtures from the cradle to the grave. Moreover, amount of fuel

saving and CO_2 reduction due to use of the low specific heat capacity can be more promising when they were analyzed on national scale in terms of number of American household can be fuelled using the energy saving. The results showed that energy savings due to use of the low specific heat capacity aggregate was enough to fuel 24,330 to 341,525 American households per annum, depending on aggregate type, source and asphalt type, based on the current standard of the life.

However, long-term performance, the costs and environmental impacts of the transportation of the aggregates with the low specific heat capacity to produce CHMA and CWMA should be included in the life cycle analysis of the paving projects to ensure that use of such aggregates is consistent with standards prescribed to construct the sustainable pavements.

Retrofitted fully permeable shoulders as a stormwater management strategy on highways

David Jones, Hui Li & John Harvey
University of California Pavement Research Center, Davis, CA, USA

ABSTRACT: This paper summarizes the results of laboratory testing, computer performance modeling, and life-cycle cost analysis of fully permeable shoulder retrofits as a stormwater management strategy for highways. The use of these types of pavement is being considered as a potential best management practice for managing stormwater in a number of states. The deliverables from this research are a preliminary design procedure and an example set of catalogue-type design tables that can be used to design pilot and experimental fully permeable pavement test sections. The results obtained from the analyses in this study indicate that fully permeable pavements could be a cost-effective stormwater best management practice alternative as a shoulder retrofit on highways, as well as for maintenance yards, parking lots, and other areas with slow moving truck traffic. However, these results need to be validated in controlled experimental test sections and pilot studies before wider-scale implementation is considered. The findings from these full-scale experiments will be used to identify situations where fully permeable pavements are an appropriate best management practice, validate and refine the design method, undertake detailed life-cycle cost and environmental life-cycle assessments, and to prepare guideline documentation for the design and construction of fully permeable pavements.

Keywords: Fully permeable pavements, stormwater management, shoulder retrofit

1 INTRODUCTION

Fully permeable pavements are defined for the purposes of this study as those in which all layers are intended to be permeable and the pavement structure serves as a reservoir to store water during storm periods in order to minimize the adverse effects of stormwater runoff.

Since the late 1970s, a variety of fully permeable pavement projects have been constructed in a number of U.S. states for low traffic areas and light vehicles. Most of the information available in the literature is about successes *[1]*, while few failures have been reported for these applications. Observations of several projects by the authors indicate that failures have occurred in localized areas due to clogging of the permeable surface, and to construction processes that have resulted in severe raveling (loss of particles from the surface) or cracking. Structural design methods have been empirical in nature, with little or no long-term monitoring data to support the empiricism. Purely empirical design methods require good comprehensive empirical data for all of the expected design conditions, which has limited the speed of technology development for fully permeable pavements because of the high cost of learning from inevitable failures. For this reason it is difficult for purely empirical design methods to consider different materials, climates, subgrades, and structural cross sections because of the need for a large factorial set of performance data that considers all of these design variable permutations. A review of design practice across the United States *[2]* shows the very limited scope of current applications for fully permeable pavements, even by the leading design firms specializing in this type of design. The limited scope of current applications is also reflected in the recently produced National Asphalt Pavement Association

(NAPA) *[3]*, American Concrete Pavement Association *[4]*, and Interlocking Concrete Pavement Institute *[5]* manuals for design of porous asphalt, pervious concrete pavements, and permeable interlocking concrete pavements, respectively.

2 PROJECT OBJECTIVES

The study discussed in this paper was part of a larger development program being undertaken by the University of California Pavement Research Center (UCPRC) for the California Department of Transportation (Caltrans), with the objective of developing guidelines and inputs for specification language, for the appropriate use of fully permeable pavements as a potential Best Management Practice (BMP) for controlling stormwater runoff from highways, maintenance yards, rest stops, and other pavements that Caltrans owns and manages. This objective would be met after completion of laboratory testing to characterize the mechanical and hydrological properties of fully permeable pavement materials; structural and hydrological performance modeling to develop initial designs; life-cycle cost analyses and environmental life-cycle assessment studies; and full-scale testing in the field and/or using accelerated load testing (using the Caltrans Heavy Vehicle Simulator [HVS]) to validate the structural and hydrological designs, or if necessary, to calibrate them to match the observed field performance. This paper covers the materials characterization and structural performance modeling components of the first phase of the study completed prior to full-scale testing. The hydrological performance modeling is discussed elsewhere in the literature *[6,7]*.

3 MATERIALS CHARACTERIZATION

3.1 *Subgrade materials*

On most pavements, subgrade materials are usually compacted as densely as possible to provide a platform for the overlying pavement layers and to provide added structural integrity to the pavement. However, on fully permeable pavements, compaction of the subgrade is generally restricted where possible to facilitate infiltration of water. This requires a thicker overlying pavement structure to compensate for the reduced subgrade strength. In this study, testing of subgrade materials focused on the influence of different levels of compaction and different moisture contents on the stiffness of those materials.

Initial studies of the properties of clays in California revealed that there is little difference in the strength and permeability characteristics of these materials. Consequently, only one clay and one silt material were tested. The testing of CH clay was considered unnecessary given the known poor bearing capacity and permeability characteristics of these materials, and the unlikelihood that a fully permeable pavement would be constructed on this type of material. Sand and gravel subgrades were also not included because they are expected to perform well in terms of both structural capacity and permeability, and are not as sensitive to the saturation levels expected in permeable pavements in California. A broad range of moisture contents and compaction levels were assessed. Tests on subgrade materials included standard indicator tests as well as permeability, resilient modulus (AASHTO T-307) and repeated load triaxial tests.

Test results *[8]* indicated that both soil types would add very little support to a pavement structure, and that the stiffness and the associated strength of the materials would decrease significantly as the moisture content increases. Any fully permeable pavement structure on these materials would need to compensate for this poor bearing capacity with thicker base and surfacing layers. Testing was not undertaken in the saturated condition given the already poor performance recorded at compaction moisture contents, and the difficulty in preparing specimens for testing (i.e. specimens "failed" before the test could be started).

3.2 *Permeable concrete subbase materials*

This phase of testing was included to determine whether an "inverted pavement design" approach would be suitable for fully permeable pavements. A stiff subbase would theoretically compensate for the loss of structural stiffness resulting from not compacting the subgrade and provide a stiff platform to confine the base course materials. It might also reduce the overall thickness of the pavement. Testing was limited to compressive strength only (ASTM C-35). Fatigue resistance and flexural strength testing were not undertaken given that cracks in this lower pavement layer would not significantly influence the pavement performance, and would actually improve the flow of water through the structure.

As expected, test results indicated a clear relationship between aggregate grading, cement content, water-to-cement ratio, and strength and permeability *[8]*. All specimens tested exceeded the anticipated permeability requirements, indicating that aggregate gradings and cement contents could be adjusted to increase the strength of the material whilst still retaining adequate water flow through the pavement. The water-to-cement ratio appeared to be critical, as expected, in ensuring good constructability and subsequent performance of the pavement.

3.3 *Base course materials*

The testing of fully permeable base course materials focused on four commercially available aggregates in the state with different geological origins. Performance of these materials was then compared with the results obtained by other researchers elsewhere in the United States. The aggregate gradations of three of the aggregate sources used smaller stone than is currently recommended by the National Asphalt Paving Association's (NAPA) permeable pavement guidelines. Discussions with northern California aggregate producers revealed that the larger stone gradations (approximately 38 mm to 50 mm maximum aggregate size) in the guidelines are generally not widely commercially available in California or are much more expensive to produce than products with a maximum aggregate size of approximately 19 mm to 25 mm. Tests on base course materials included standard indicator, permeability, and resilient modulus tests (AASHTO T-307).

Test results *[8]* on the different commercially available permeable base-course aggregates indicated that these materials would probably provide sufficient support for typical traffic loads in parking lots, basic access streets and driveways, and on highway shoulders, whilst serving as a reservoir layer for the pavement structure. Although three of the four materials tested had smaller maximum aggregate sizes than those typically discussed in the literature, the permeability was still adequate for California rainfall events.

3.4 *Asphalt wearing course materials*

A total of 19 mixes, including a dense-graded control, were assessed. Limited testing was carried out on a European mix, specimens of which were provided to UCPRC from a test track in Spain. These 19 mixes included five different binders and three different aggregates. A range of aggregate sizes, gradations, and air-void contents were covered in the mixes. Tests included standard indicator tests, permeability (ASTM PS129), flexural stiffness and fatigue resistance (AASHTO T-321), rutting resistance (AASHTO T-320), moisture sensitivity (AASHTO T-324) and raveling resistance (ASTM D7064).

Test results *[8]* indicated that the aggregate particle size distribution in the mix and the binder type will be the two most critical factors in designing permeable asphalt concrete wearing courses. Sufficient permeability for anticipated needs in California *[9]* was obtained on a range of mixes tested. Adequate resistance to rutting of the surface material appeared to be mostly a problem for the 9.5 mm mixes with conventional and rubberized binders, based on shear modulus. The 9.5 mm rubberized asphalt and 12.5 mm Georgia-gradation mixes had better rutting resistance in the Hamburg Wheel Tracking Test (which also considered moisture sensitivity), in particular the 12.5 mm mix containing polymers and fibers. Some moisture sensitivity was evident, but this could be overcome by the use of appropriate

anti-strip treatments. Most of the mixes of interest had adequate durability (resistance to raveling) compared to the dense-graded control. Fatigue cracking resistance at a given strain was better for the 9.5 mm rubberized and 12.5 mm polymer-modified mixes compared with the conventional mixes at a given strain. The polymer-modified 12.5 mm mix was stiffest at higher temperatures and under slower traffic (lower frequency of loading), while the conventional 9.5 mm mix had similar stiffness to the 12.5 mm mix at lower temperatures and under faster traffic. The rubberized 9.5 mm mix generally had lower stiffness than the other two mixes.

4 PERFORMANCE MODELING

A mechanistic-empirical design approach was used to evaluate a range of permeable pavements to produce a set of designs for different truck traffic, climate, and soil conditions. A full factorial considering asphalt material types, layer thickness, material properties, climate zone, season, diurnal peak temperature, axle type, axle load, traffic speed, and traffic volume resulted in a total of 15,552 different cases being run *[1,10,11]*. The results of the analyses were used to produce a catalog of designs, similar to the catalog designs prepared by the UCPRC for the Caltrans Rigid Pavement Design Catalog currently used in the Caltrans *Highway Design Manual (HDM)*.

All calculations considered two subbase options, namely no subbase and a 150 mm thick open-graded portland cement concrete subbase to provide support to the granular layer, and help protect the saturated subgrade. Material properties for each of the layers were obtained from the laboratory study. Three types of open-graded asphalt were considered in the calculations. Climate details were obtained from a database of California climatic data, and the temperatures at one-third of the depth of the asphalt layer were calculated from 30 years of data (1961 to 1990) using the *Enhanced Integrated Climate Model (EICM)*. The maximum, minimum, and average of the 30-year temperatures at one-third depth at each hour in each day for January, April and July were calculated. The maximum and minimum of the average day for each of those three months were chosen as the day and night temperatures, respectively for layer elastic theory calculations.

Axle loads were obtained from a database of California Weigh-In-Motion (WIM) stations. The allowable truck traffic (ESAL or Traffic Index) during the design life was calculated using a set of factors, including seasonal factor, day/night factor, axle type factor, ESAL factor (the average ESALs per axle), and load bin factor (percent of total axles in each load range). The value for each factor was determined based on the statistical analysis of statewide traffic information from the UCPRC/Caltrans WIM database. Axle loads less than half the legal load were ignored in order to keep the number of required calculations to an acceptable value, which was considered reasonable since they contribute very little to fatigue damage.

Two truck traffic speeds (7 and 40 km/h) were included in the calculations. The slower speed was selected to represent truck operations during traffic congestion on highways (in this case a detour onto the shoulder) and in maintenance yards or parking areas. The faster speed was selected to represent truck operations on a street or on a shoulder which has had traffic diverted on to it but which is not severely congested.

The stiffness at one-third thickness of the asphalt was calculated from the master curves for each combination of temperature and load frequency corresponding to loading time from flexural beam frequency sweep testing during the laboratory study. The stiffness of each type of asphalt material was averaged for the thickness of each layer to reduce the number of calculation combinations. Consequently, the stiffness of the asphalt used in the calculations was independent of the thickness of the layer.

The distresses analyzed included fatigue cracking of the asphalt layer associated with the tensile strain at the bottom of the asphalt layer, and unbound layer rutting associated with the vertical stresses at the top of the base, subbase (where included) and subgrade. Mechanical responses in terms of the tensile strains from different load configurations were determined using the layer elastic model in the *LEAP* software package *[12]*. Prior to the layer elastic

analysis, the stiffness of the granular base was evaluated using non-linear elastic models in the *GT-Pave* software package *[13]*. A range of values for different structural factors were selected for the structural response values of the granular base stiffness. The Uzan model *[14]* was used to consider the non-linear behavior of the granular base using *GT-Pave.* The procedure proposed by Tutumuller and Thompson *[15]* was used to obtain cross-anisotropic parameters of the granular base for *GT-Pave*. Based on the results of these calculations, three representative values of granular base stiffness, namely 60 MPa, 90 MPa, and 120 MPa, were chosen for the final structural calculations.

These data were then used as input in a Miner's Law equation to calculate the fatigue performance of the asphalt in terms of an allowable traffic index *[1,10]*. The actual repetitions to failure were calculated using this equation to determine the number of ESALs (later converted to Traffic Index) for each combination of asphalt type, thickness, and climate region.

5 PROPOSED STRUCTURAL DESIGN PROCEDURE

A preliminary catalogue-type design procedure based on region (rainfall), storm event design period, design, traffic, design truck speed, surfacing, subbase type, and the shear stress-to-shear strength ratio at the top of the subgrade was developed for preliminary design of fully permeable pavement test sections in California. Example design tables *[1]* were prepared from the computer modeling cases and calculations run as part of the computer modeling task described above. The example hydraulic design table includes 2-year, 50-year, and 100-year storm design events (considering infiltration and draw down for full storm duration and repeat storm events) for three California regions (north coast, Central Valley, and Los Angeles Basin). These three storm design events were selected to test the sensitivity of the design to a wide range of events (e.g., effect of storm intensity, storm duration, geometry, draw down, and degree of clogging on infiltration) and were not necessarily intended to be representative of typical Caltrans storm event design procedures. Example design tables for the asphalt concrete include three different open-graded mix designs (conventional 9.5 mm, 9.5 mm asphalt rubber, and 12.5 mm polymer modified), two truck speeds (7 km/h and 40 km/h), and two subbase options (no subbase and PCC-O subbase). All example tables assume a shoulder width of 3.0 m and cover designs up to a Traffic Index of 18 (~300 million ESALs). The shoulder is considered as a lane for drainage design purposes. The design tables have **not** been validated in full-scale experiments and are currently only intended for the design of experimental test sections. The proposed procedure generally entails the following:

1. **Select the permeability of the subgrade, subbase type, region, storm design event period, and number of lanes drained.** This information is used to determine the thickness of the gravel base/reservoir layer in terms of hydraulic performance. Consideration should be given to whether occasional overflows are permitted (e.g., during a series of heavy storms on consecutive days, prolonged rainfall, etc.) or not, as this will influence the choice of storm design period and dictate the thickness of the base/reservoir layer. Permeability should be measured for each project at a range of depths around the expected depth of the top of the subgrade after excavation of material for the reservoir layer(s). The lowest permeability should be used in the design. It should be noted that clay lenses between silt layers are common in the Central Valley of California, and these will influence permeability.
2. **Select the surface type.** Base thickness, design traffic, and design speed are used to identify the thickness of the HMA layer. Once the HMA layer thickness has been determined, this and base thickness are used to determine whether the shear stress-to-shear strength ratio at the top of the subgrade is adequate to prevent permanent deformation in the subgrade.

The design method assumes that water should only reach the top of the granular base layer for the design storm, and not be stored in the surface layer during the infiltration period, in order to improve the durability of the surface material.

The preliminary tables can be used for designs of test sections for both shoulder retrofit of highways and for parking lots, maintenance yards, and similar facilities. Two typical cross sections for shoulder retrofits were developed (one shown in Fig. 1) and two contractors asked to review them in terms of constructability. Both contractors indicated that construction appeared to be feasible and that they would be comfortable to bid on projects with similar designs. The selection of the most appropriate structure will depend on whether the existing pavement structure can maintain a vertical cut face equal to the height of the fully permeable pavement shoulder structure or not. A drain between the existing travelled way and the new fully permeable shoulder will need to be installed to allow any water in the travelled way to drain away from the road, while not allowing any water from the permeable area to flow into the pavement structure. An impermeable composite liner is included in the diagrams to prevent water flowing sideways from the reservoir layer and causing a slip failure in the embankment. The inclusion of this liner will be project dependent and not always required.

5.1 *Example*

An example design for a rubberized open-graded asphalt shoulder retrofit with no subbase to a three lane highway in Sacramento, CA is discussed below. The project design includes compacted subgrade permeability of 10^{-4} cm/s, a storm design of 50 years, design traffic index of 13 (~22 million ESALs), design truck speed of 7 km/h (due to congestion), and a surface layer of 9.5 mm Nominal Maximum Aggregate Size (NMAS) open-graded Rubberized Hot-Mix Asphalt (RHMA-O).

- **Step 1: Choose the base thickness based on hydraulic performance.**
  Using the appropriate table (Table 1 [Table B.1 in Appendix B in Reference 1]), the minimum thickness of granular base is selected for a subgrade soil permeability of 10^{-4} cm/s and 50-year design storm in the Sacramento region. These variables require a minimum

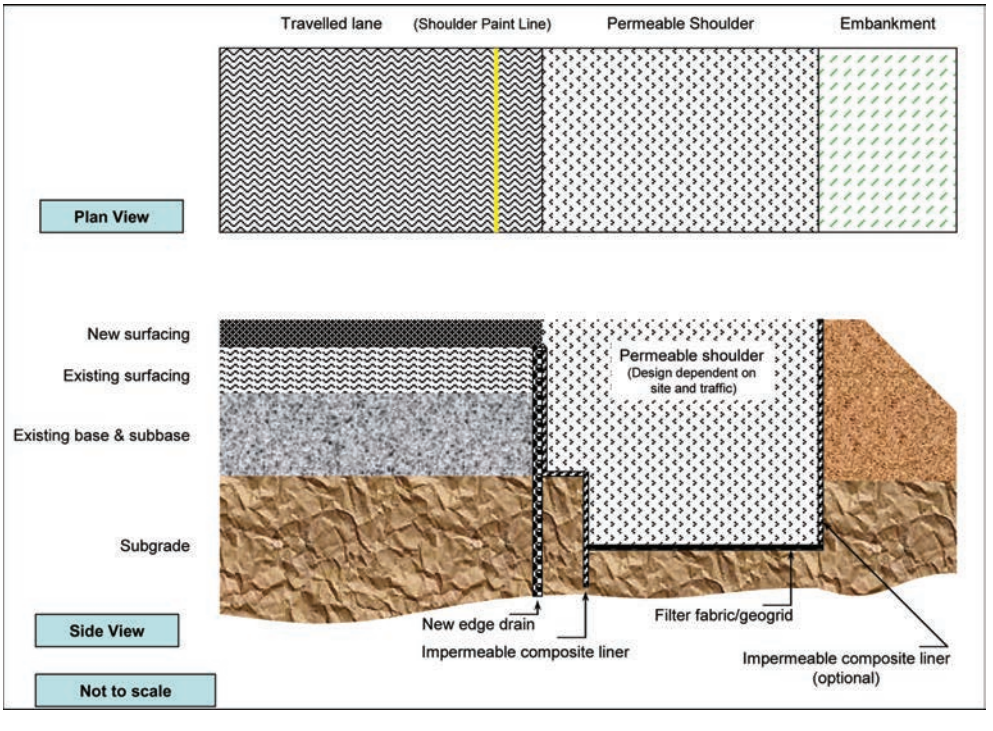

Figure 1. Example fully permeable pavement shoulder retrofit.
(Permeable shoulder placed against pavement layers with fabric separator).

[1] Note that draw down times will vary significantly and are dependent primarily on subgrade soil permeabilities, but also on other factors such as number of lanes drained, storm recurrence interval, etc as well. Draw down times could vary between one hour for subgrades with a permeability of 1.00E-03 to several months for subgrades with a permeability of 1.00E-05 and higher. Refer to Reference 4 for discussion on the calculation of drain down times.

[2] The number of highway lanes must include the shoulder. Shoulder width is 10 ft. (3.0 m).

base/reservoir layer thickness of 680 mm for a shoulder retrofit of a highway draining three lanes plus the shoulder (i.e., 4 lanes are selected in the table).

- **Step 2: Choose RHMA-O layer thickness based on RHMA-O fatigue damage for TI.** Using the appropriate table (Table 2 [Table E.5 in Appendix E in Reference 1]), select the minimum RHMA-O layer thickness for a base thickness of 700 mm (rounded up

from 680 mm from Step 1), and a traffic index of 13. The minimum required thickness of RHMA-O is 395 mm.

- **Step 3: Check the stress/strength ratio at the top of the subgrade.**
  Using the appropriate table (Table 3 [Table E.6 in Appendix E in Reference 1]), check the shear stress-to-shear strength ratio at the top of the subgrade based on the minimum required thickness of granular base of 700 mm and minimum required thickness of RHMA-O of 395 mm. The stress/strength ratio is "G," which implies that the shear stress is less than 0.3 of the shear strength. Consequently, permanent deformation in the subgrade should not be a problem for this pavement design.

Therefore, in this example, the minimum required thickness of granular base is 700 mm and the minimum thickness of RHMA-O is 395 mm for the design requirements and site conditions.

6 LIFE-CYCLE COST ANALYSIS

Example Life-Cycle Cost Analysis (LCCA) comparisons with conventional stormwater Best Management Practices (BMPs) for the Sacramento region *[16]* indicated that fully permeable pavements should cost less than conventional BMPs over a 40-year life-cycle. However, LCCA should be undertaken on a project-by-project basis because alternatives and costs for different types of fully permeable pavement will vary by region and over time.

A framework for environmental Life-Cycle Analysis (LCA) was reviewed; however, it was found that insufficient data were available at this time to complete an example LCA for fully permeable pavements.

7 CONCLUSIONS

Key findings from the computer modeling of structural capacity and development of structural designs phase of the fully permeable pavement study include:

- The use of mechanistic-empirical pavement design equations developed in this project was effective in estimating required structural thicknesses for fully permeable pavements to carry slow moving (between 7 and 40 km/h) truck traffic. Tens of thousands of layer elastic theory calculations to find critical stresses and strains in fully permeable asphalt pavements were performed in order to estimate thicknesses required for structural capacity. Statewide truck axle load spectra from Caltrans Weigh-In-Motion (WIM) measurements (captured in a UCPRC database) were used to select representative axle loads. Representative pavement temperatures were selected from a database of *Enhanced Integrated Climate Model (EICM)* calculations to estimate asphalt stiffnesses.
- The results of strain calculations in asphalt were used to estimate the required thicknesses for preventing fatigue cracking. Nonlinear layer elastic theory calculations were used to estimate the stiffness of the granular base, which were then used to estimate shear stress-to-strength ratios in the subgrade. Together, these results were used to develop structural design tables that can be used with hydraulic design calculations to determine required layer thicknesses. The pavement structures were considered feasible, with all pavement structures less than 1.5 m in total thickness for the heaviest traffic. The use of an open-graded portland cement subbase offers considerably greater protection against the risk of subgrade rutting for asphalt pavements.
- Preliminary design tables for pilot studies were developed considering structural and hydraulic performance based on the following design input variables:
  - Subgrade permeability,
  - Truck traffic level in terms of Traffic Index or ESAL,
  - Two temperature climate regions (Sacramento and Los Angeles),
  - Three design storms (2, 50, and 100 years) for three climate regions,

  - Two traffic speeds (7 km/h and 40 km/h), and
  - Various numbers of adjacent impermeable lanes.
- Design cross sections developed for shoulder retrofit of highways as well as low-speed trafficked areas such as parking lots and maintenance yards were reviewed by construction and maintenance experts and were considered to be feasible to construct and maintain.

Laboratory characterization of North Carolina base course aggregates for permanent deformation model development and calibration

Liang Chern Chow, Debakanta Mishra & Erol Tutumluer
Department of Civil and Environmental Engineering, University of Illinois at Urbana-Champaign, Urbana, IL, USA

ABSTRACT: This paper presents partial findings from an ongoing research study at the University of Illinois aimed at laboratory characterization of North Carolina base course aggregates for permanent deformation model development and calibration. Monotonic triaxial shear strength tests were first conducted on four different aggregate types to establish the Mohr-Coulomb failure envelopes. Repeated load triaxial tests were then conducted on the aggregate materials at shear stress/strength ratios of 0.25, 0.50, and 0.75, to comparatively evaluate the permanent deformation accumulation trends, and subsequently develop improved rutting models for use in mechanistic-empirical pavement design methodologies. Experimental results clearly emphasize the importance of applied stress states, material's shear strength, and number of load repetitions as the most significant factors affecting unbound aggregate permanent deformation behavior. A new model is proposed to adequately capture the effects of applied stresses and shear stress/strength ratios in predicting permanent deformation behavior of base course aggregates. This proposed model can potentially be used to improve the rutting models currently used in AASHTO's mechanistic-empirical flexible pavement design procedure the Pavement ME software.

Keywords: Unbound aggregates, base course, permanent deformation, applied stress states, shear strength

1 INTRODUCTION

Rutting or permanent deformation accumulation is the primary damage/distress mechanism for unbound aggregate base/subbase layers in flexible pavements. Accordingly, rutting resistance is a major performance measure for designing pavements with granular base/subbase layers. Low strength granular materials are generally more susceptible to high permanent deformation accumulation, whereas "good quality" aggregate materials mobilize high shearing resistance to prevent settlement and lateral movement within the layer. Although the influence of stress state on unbound aggregate resilient modulus is relatively well understood, its influence on permanent deformation accumulation is usually not considered while designing flexible pavement structures.

Proper assessment of unbound aggregate layer rutting or permanent deformation behavior is critical to ensure the structural adequacy of flexible pavements. From an extensive review of published literature, Lekarp et al. [1] listed (a) stress levels, (b) principal stress reorientation, (c) number of load applications, (d) moisture content, (e) stress history, (f) density, (g) grading and fines content, and (h) aggregate type as primary factors governing the permanent deformation accumulation in unbound aggregate materials. The relationship between permanent deformation and applied stress was confirmed and different rutting models have been proposed by several researchers. Some of the more commonly used and noteworthy ones were proposed by Lekarp et al. [1], Barksdale [2], Monismith [3], Tseng and Lytton [4], Sweere [5],

Wolff and Visser [6], Paute et al. [7], Bonaquist and Witczak [8], Pappin [9], Huurrman [10], and van Niekerk and Huurman [11]. Moreover, as opposed to resilient modulus (M_R), shear strength properties have shown better correlations with unbound aggregate permanent deformation behavior for predicting field rutting performance [12–14]. Accordingly, characterization of unbound aggregate permanent deformation behavior in conjunction with shear strength properties is one of the primary objectives of an ongoing research effort at the University of Illinois.

This paper presents laboratory test results aimed at characterizing the permanent deformation behavior of four different aggregate materials. Note that the overall scope of the research study involves laboratory characterization of sixteen different aggregate materials used for unbound aggregate base/subbase applications in the state of North Carolina. Accordingly, laboratory tests for only the first four of the sixteen materials are presented in this paper to establish a framework for developing a new unbound aggregate permanent deformation damage model. Each of the presented aggregate materials consisted of different aggregate types such as granitic, basalt and limestone particles. Monotonic triaxial shear strength tests were first conducted on each aggregate material to establish the Mohr-Coulomb failure envelopes. Repeated load triaxial tests were subsequently performed on each material to characterize the permanent deformation behavior under different applied stress states, which were quantified according to certain established ratios of the applied shear stress with the shear strength under same confinement. In addition, multi-stage permanent deformation tests were also performed on each aggregate material to study the effects of stress history on permanent deformation accumulation. As a result, a new permanent deformation model has been proposed to adequately consider the effects of applied stress states and material shear strength while predicting the permanent deformation behavior under repeated loading.

2 AGGREGATE MATERIALS TESTED

The four (4) different crushed aggregate materials discussed in this paper were selected from different quarries, and are commonly used for pavement unbound base/subbase applications in the state of North Carolina. Two of the four aggregate materials comprised granitic particles (labeled as materials G1 and G2); the third aggregate material comprised limestone particles (labeled as material L) whereas the forth aggregate material comprised basalt (labeled as material B) particles. Figure 1 shows the gradation boundaries (black dotted lines) specified

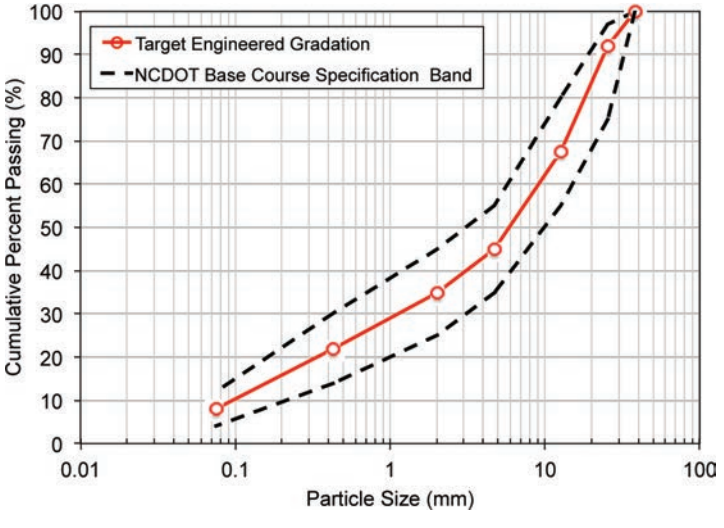

Figure 1. Engineered gradation for tested materials.

Table 1. Aggregate and shear strength properties of tested materials.

Label	Aggregate type	Max. dry density, $\gamma_{d,max}$ kN/m^3	Opt. moisture content, ω_{opt} %	Cohesion c kPa	Friction angle ϕ degree	Compaction water content %
Material G1	Granite	24.1	4.2	85.1	50	$\omega_{opt} \pm 0.1$
Material G2	Granite	21.9	5.5	59.4	45	$\omega_{opt} \pm 0.8$
Material B	Basalt	23.3	5.2	1.1	51	$\omega_{opt} \pm 0.2$
Material L	Limestone	21.1	5.9	2.4	45	$\omega_{opt} \pm 0.1$

by the North Carolina Department of Transportation (NCDOT) for typical unbound base course materials. All laboratory tests in the current study were conducted on specimens blended to achieve the mid-range curve shown in Figure 1.

Aggregate index property tests such as Atterberg's limits for the fines fraction, as well as the moisture-density tests were conducted by the NCDOT Material and Test Unit. Fines from these aggregate materials were found to be nonplastic in nature. The moisture-density characteristics for each aggregate material were established using a modified approach similar to the modified compaction procedure specified in AASHTO T-180. However, aggregate specimens in the NCDOT procedure were compacted in four equal lifts by applying 86 blows per lift (compared to 56 blows per lift specified by the AASHTO T-180 method) with a 4.5-kg (10-lb) hammer dropped from a height of 450-mm (18 in.). Resulting Optimum Moisture Content (OMC) and Maximum Dry Density (MDD) values for the each of the aggregate materials are listed in Table 1. Comparing the MDD values, the four aggregate types can be listed in the following order, from low to high: L, G2, B, and G1.

3 EXPERIMENTAL FRAMEWORK

Monotonic triaxial shear strength tests were first conducted on each aggregate material to establish the Mohr-Coulomb failure envelopes. These Mohr-Coulomb envelopes were then used to compute stress level combinations that would result in applied stress/shear strength ratios of 25%, 50% and 75% being applied on a specimen during repeated load triaxial tests. This was the main approach taken to characterize aggregate permanent deformation accumulation trends under different applied stress/shear strength ratios.

3.1 *Monotonic triaxial shear strength testing*

The primary objective behind this task was to establish the maximum shear stress levels that each material could be subjected to without undergoing shear failure. Cylindrical test specimens, 152-mm (6-in.) in diameter by 305-mm (12-in.) in height, were compacted in six (6) equal lifts targeting the OMC and MDD values listed in Table 1. The specimens were then sheared through the application of 1% strain per minute (0.05-mm/sec for a 305-mm long specimen) at all-around constant confining pressure levels of 35 kPa (5 psi), 69 kPa (10 psi) and 103 kPa (15 psi), respectively. The shear strength properties (cohesion intercept c and friction angle ϕ) for each aggregate material are listed in Table 1. From the table, material B recorded the highest friction angle value of 51 degrees, followed by material G1 ($\phi = 50$ degrees). Both materials G2 and L had a friction angle value of 45 degrees. As previously mentioned, all four materials comprised nonplastic fines; therefore the cohesion (c) values listed in Table 1 are primarily the result of linear interpretation of a nonlinear Mohr-Coulomb failure envelope. Comparing the peak deviator stress values at failure (see Table 2), the four aggregate materials can be listed in the increasing order of shear strengths as: L, B, $G2$, and $G1$.

The Mohr-Coulomb failure envelopes for each material were used to establish the stress state combinations to achieve certain Shear Stress Ratio (SSR or τ_f / τ_{max}) values during

$$\text{Shear Stress Ratio (SSR)} = \frac{\text{Applied Shear Stress}}{\text{Shear Strength}} = \frac{\tau_f}{\tau_{max}}$$

*Deviator stress at failure also corresponds to shear stress ratio of 1.0.

repeated load triaxial testing. The concept of SSR has been diagrammatically illustrated in Table 2, and represents the ratio between the applied shear stress and the material shear strength at a particular applied normal stress level [see Eq. (1)]. At a certain constant confining pressure (σ_3), the shear strength of an aggregate material can be defined when Mohr-Coulomb circle is tangent to the failure envelope. Shear strength (τ_{max}) at this confinement is ϕ degree counter-clockwise rotation from the invariant (center of circle). The normal and shear stresses (represented by σ_f and τ_f, respectively) acting on the failure plane (oriented at an angle of $45° + \phi/2$ with the horizontal), therefore can be computed using Eqs. (2) and (3). The ratio between τ_f and shear strength of the material corresponding to that particular normal stress ($\tau_{max} = c + \sigma_{f*}\tan\varphi$) is defined as the shear stress ratio (SSR = τ_f / τ_{max}).

A list of σ_d and σ_f values corresponding to different confining pressure (σ_3) and SSR combinations are listed in Table 2. Each aggregate material was characterized for permanent deformation behavior by subjecting cylindrical triaxial specimens to SSR values of 0.25, 0.50 and 0.75, representing low, intermediate and high stress/strength ratios, respectively. For instance, an SSR value of 0.50 indicates that the specimen is subjected to stress levels that mobilize only 50% of the aggregate shear strength at that particular confining pressure. For a particular stress state, a limiting value of SSR is believed to control the permanent deformation behavior of unbound aggregate materials [15]. Lower SSR values essentially indicate that the material is subjected to a low stress state, and is less likely to undergo bearing capacity type shear failure. However, high SSR values (typically SSR ≥ 0.7) have been found to result in rapid permanent deformation accumulation, ultimately leading to shear failure [16, 17]. Accordingly, a unity value of SSR (SSR = 1.0) represents shear failure of the material.

$$\text{Shear Stress Ratio (SSR)} = \frac{\text{Applied shear stress}}{\text{Shear strength}} = \frac{\tau_f}{\tau_{\max}} \tag{1}$$

$$\sigma_f = \frac{2\sigma_3 + 2\sigma_3 \tan^2\phi + \sigma_d + \sigma_d \tan^2\phi - \sqrt{\sigma_d^2 \tan^2\phi(1+\tan^2\phi)}}{2(1+\tan^2\phi)} \tag{2}$$

$$\tau_f = \sqrt{(\sigma_d/2)^2 - [\sigma_f - (\sigma_3 + \sigma_d/2)]^2} \tag{3}$$

where

τ_f = Applied shear stress acting on failure plane;
$\tau_{\max}$ = Shear strength determined by $c + \sigma_f \tan\phi$;
σ_f = Normal stress acting on failure plane;
σ_3 = Applied confining pressure;
σ_d = Applied deviator stress, $\sigma_1 - \sigma_3$; and
ϕ = Friction angle determined from shear strength tests.

3.2 *Repeated load triaxial testing*

Permanent deformation accumulation trends of the four aggregate materials were investigated through repeated load triaxial testing at the three different SSR levels listed in Table 2. A confining pressure (σ_3) level of 34.5 kPa (5 psi) was selected, as highlighted in bold in Table 2, for the repeated load permanent deformation tests to ensure that deviator stress levels required for achieving the target SSR values remained within the equipment capabilities.

Cylindrical specimens having equal dimensions of 150-mm height and 150-mm diameter were prepared by following a procedure similar to that previously described, and were subjected to 10,000 load applications at each selected SSR level. Note that the application of only 10,000 load pulses per SSR level may represent a limitation of the test protocol, as it may not capture the transition from plastic creep (Range B) to incremental collapse (Range C) under very high number of load applications as defined by Werkmeister [18]. Nevertheless, the selection of 10,000 load applications per stress level in this study was primarily governed by time constraints associated with conducting tests to a higher number of load applications

(e.g. 100,000 cycles or more per stress level). All specimens tested exhibited "stable" behavior after 10,000 load applications without accumulating rapid and significant permanent strain. Accordingly, multi-stage permanent deformation tests were performed at SSR levels of 0.25, 0.50 and 0.75 by sequentially subjecting each specimen to 10,000 load applications at the different stress level combinations listed in Table 2.

3.2.1 *Characterization of permanent deformation behavior*

Figure 2(a) combines both the laboratory-measured and model-predicted permanent deformation accumulations for the four aggregate materials subjected to different SSR levels. As shown in the figure, higher applied stress levels (higher SSR values) consistently corresponded

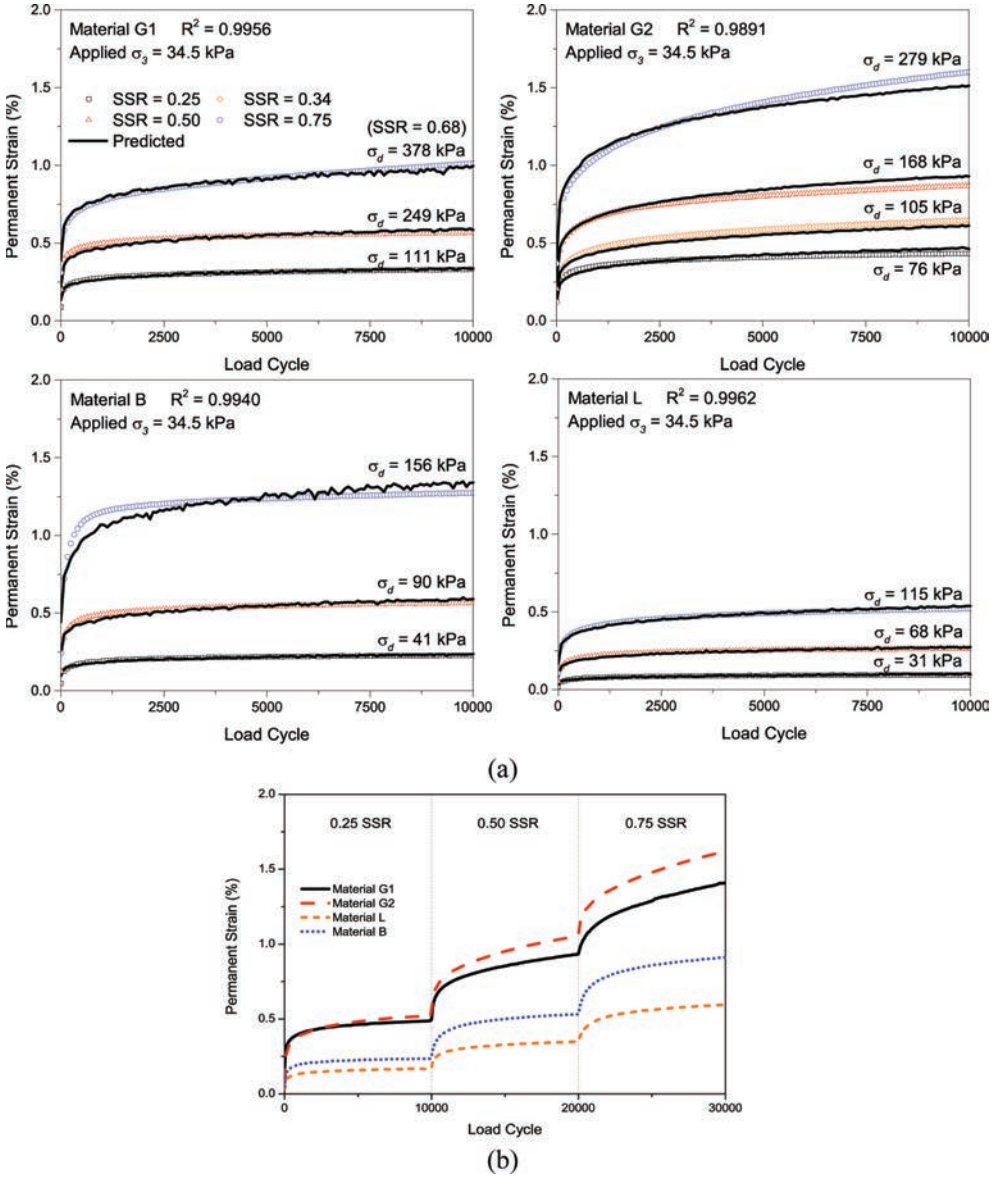

Figure 2. (a) Single-stage measured (symbols) and model predicted (solid lines) permanent strains and (b) multi-stage loading (SSR = 0.25, 0.50, 0.75).

to higher permanent strains accumulations. Note that the highest achieved SSR value for material G1 was limited to 0.68 (instead of 0.75), due to the test equipment loading limits. It is important to note that both the applied stress levels (represented by the deviator stress or σ_d) and SSR values need to be considered while comparatively evaluating the permanent deformation behavior of different aggregate types. For instance, at SSR of 0.50, material G2 records the highest permanent strain accumulation ($\varepsilon_p = 0.89\%$), whereas both materials G1 and B accumulated permanent strain levels of $\varepsilon_p = 0.57\%$, with material L accumulating the lowest permanent strain ($\varepsilon_p = 0.41\%$). However, applied deviator stresses at this level of SSR were 249, 168, 90 and 68 kPa for materials G1, G2, B and L, respectively. Comparing the permanent deformation accumulation trends of different aggregate types solely based on the SSR levels, without considering the applied deviator stress levels, may therefore lead to erroneous conclusions regarding material quality.

One multi-stage permanent deformation test was conducted for each material by sequentially subjecting a compacted specimen to 10,000 load applications each at stress states corresponding to SSR levels of 0.25, 0.50, and 0.75, respectively. Results from the multi-stage permanent deformation tests are shown in Figure 2(b). It is important to note that the permanent deformation accumulation curves shown in Figure 2(b) correspond to different applied deviator stress levels for different aggregate materials even for the same target SSR values. Figure 2(b) clearly highlights the effects of stress history on permanent deformation accumulation. By comparing the single-stage (Fig. 2a) and multi-stage (Fig. 2b) permanent deformation test results, it can be seen that gradually increasing repeated deviator stress levels lead to lower permanent deformation accumulations compared to singe-stage loading tests. Permanent deformation trends for the different aggregate types are unclear at lower applied stress states, and become distinctive as the SSR levels are increased. Similar observations have been reported in the past by Tutumluer et al. [16].

4 DEVELOPMENT OF PERMANENT DEFORMATION MODEL

The primary objective of this research effort is to develop an improved rutting model that can adequately capture the effects of aggregate shear strength and applied stress levels while predicting the permanent deformation behavior of unbound aggregates. Based on the phenomenological model originally proposed by Monismith et al. [3], a new model was developed to incorporate the effects of applied normal stress and SSR [see Eq. (4)]. As shown in Figure 2(a), the developed model was successful in consistently predicting the permanent deformation trends observed in the laboratory, with coefficient of determination (R^2) values of 0.99 or greater.

$$\epsilon_p(N) = AN^B \sigma_d^C \left(\frac{\tau_f}{\tau_{\max}} \right)^D \tag{4}$$

where
$\epsilon_p(N)$ = Permanent strain corresponding to N load applications;
σ_d = Applied deviator stress;
τ_f = Shear stress at failure;
$\tau_{\max}$ = Shear strength at failure; and
A, B, C, D = Regression parameters.

Note that in its current form the proposed model does not incorporate the effects of moisture content on permanent deformation accumulation. This is primarily because all shear strength and permanent deformation tests under the scope of the current study were conducted on specimens compacted at OMC and MDD conditions. Moreover, accuracy of the model has been verified at one confining pressure level only [all repeated load triaxial tests were conducted at a confining pressure level (σ_3) of 34.5 kPa or 5 psi], and further laboratory testing is required to confirm its applicability at different confining pressures. Although

confining pressure (σ_3) is not directly used as a parameter in the model formulation, it should be noted that the effects of confining pressure are indirectly reflected in the calculations for both σ_f as well as τ_f [see Eqs. (2, 3)]. Another mathematical limitation of the proposed model can be realized by assigning a unity (1.0) value to SSR. By definition, an SSR value equal to 1.0 indicates shear failure of the material, and therefore should lead to infinite permanent deformation accumulation. However, the proposed model in its current form fails to capture this phenomenon. The effects of moisture content, particle shape and surface texture, as well as stress history on permanent deformation accumulation will need to be further incorporated into the framework established for developing more comprehensive rutting models based on selected aggregate property databases in the future.

5 CONCLUSIONS

This paper presented partial findings from an ongoing research project at the University of Illinois aimed at laboratory characterization of North Carolina aggregates for permanent deformation model development and calibration. The following conclusions can be drawn from findings reported in this paper:

1. Aggregate shear strength properties and applied stress levels are important factors governing the permanent deformation accumulation in unbound aggregate base/subbase layers.
2. Adequate consideration needs to be given to both the shear Stress-to-Strength Ratio (SSR) and applied deviator stress (σ_d) levels to comparatively evaluate the permanent deformation behavior of different aggregate materials.
3. A "nearly perfect" match between measured and predicted permanent strain values was obtained using a proposed rutting damage model that captures the effects of number of load repetitions, SSR and applied deviator stress.

ACKNOWLEDGEMENTS

This research study has been made possible through insightful discussions with Dr. Judith Corley-Lay and the financial support from the North Carolina Department of Transportation (NCDOT). All laboratory tests were conducted utilizing the resources at the Illinois Center for Transportation, and the University of Illinois Advanced Transportation Research and Engineering Laboratory (ATREL). The help of Chunkun Su and Suriyati B. Supa'at of NCDOT are acknowledged for providing the preliminary laboratory test results. North Carolina aggregate producers are also acknowledged for supplying the materials used in the laboratory test matrix. Finally, sincere thanks to Yu Xie, graduate student at the University of Illinois for his support in conducting the laboratory tests reported in this paper.

ABSTRACT: Long-lasting asphalt surfacing systems still remain desirable for long-spanned stele as the deck pavement on many long-spanned steel bridges have exhibited severe distresses of cracking, rutting, shoving and de-bonding. Based on ten-year research works, this paper presented the state-of-the-practice of deck pavement on long-spanned steel bridges in mainland China. The typical distresses, their characteristics and the propagation have been figured out based on long-term field observation. Potential materials and structure solutions have been proposed according to field survey.

Keywords: long-spanned steel bridge, orthotropic steel decks, asphalt surfacing system, performance

1 INTRODUCTION

Orthotropic steel deck systems with cross-beams and longitudinal ribs have been widely used in modern long-span bridges to reduce the weight and depth of the girders [1]. The orthotropic steel deck plate of highway bridges requires a wearing surface not only to provide a smooth and safe riding surface for the vehicles passing through the bridges, but also for the purpose of loading dispersion layer to reduce the fatigue stresses in deck plate system caused by heavy traffic loading and corrosion protection of steel. The surfacing system on steel orthotropic decks act compositely with the steel deck plate and must be regarded as an integral part of the structural deck system [1–3]. It should be watertight, develop no cracks, be well bonded to steel deck plate, and long-lasting [3–8].

The application of orthotropic steel deck plate in highway bridges in China can be dated back to 1970s. However, it is only in recently fifteen years that experienced a rapid development of long-spanned steel bridges with orthotropic deck plates. Bituminous materials, such as gussasphalt, SMA and epoxy asphalt are commonly candidate surfacing materials. Their performances vary from excellent to poor, even a successful system in one bridges applied to another bridges with the similar weather conditions and traffics [9]. Many of pavements on the orthotropic steel decks of long-spanned steel bridges have exhibited cracking, rutting, shoving and de-bonding. The surfacing system on many long-spanned steel bridges can last no more than five years, some are reported to fail even within two or three years and visible fatigue cracks have been observed in the steel superstructure of deck plate system. It is thus

of paramount importance to summarize the state-of-the-practice not only for a contribution towards a long-lasting surfacing system, but also for pro-longing fatigue life of superstructure of long-spanned steel bridges.

2 LONG-SPANNED STEEL BRIDGES IN CHINA

Within recently twenty years, more than twenty long-spanned steel bridges with orthotropic deck plates have been constructed to meet the requirements of rapid economy developments and travel demands. The deck system of long-spanned steel bridges in China normally consists of a deck plate, 12–14 mm thick and longitudinal trapezoidal or rounded closed ribs, supported with cross beams spaced from 3.2 to 4.5 m apart, as listed in Table 1. The steel decks are sand-blasted and then coated with zinc primer and waterproof membrane/bonding coat prior to the construction of 50–80 mm thick asphalt surfacing layers.

Typical structures of deck pavement used in China are shown as in Figure 1. Gussasphalt or Mastic Asphalt (MA), Epoxy Asphalt Concrete (EAC) and Stone Matric Asphalt (SMA) are the commonly candidate surfacing materials for those steel bridges. These materials are different in composition as illustrated in Figure 2. Their properties are also different according to the research results of Southeast University, as illustrated in Table 2.

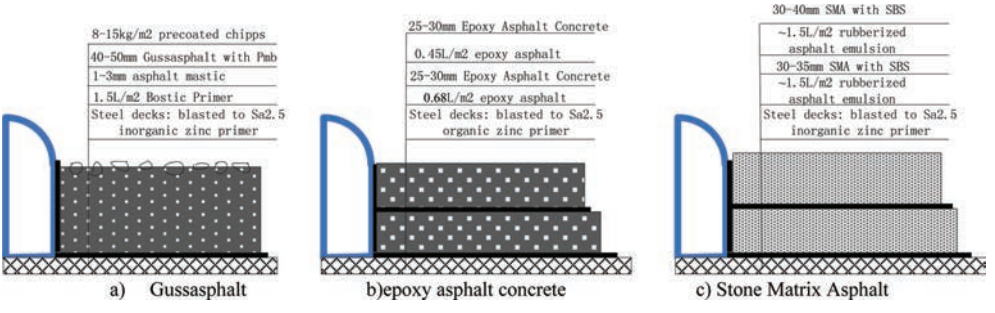

Figure 1. Basic pavement structures for long-spanned steel bridge decks in China.

3 THE TYPICAL DISTRESSES AND THEIR PROPAGATIONS

The performances of asphalt surfacing on steel bridge decks in China vary from excellent to poor depending largely on local climate, deck plate flexibility, volume of heavy truck traffic, and the type and structure of the surfacing. The main distresses are fatigue cracking, slippage and de-bonding, rutting and shoving, and pothole. The performance of EAC systems is generally better other types of asphalt surfacing and its mean service life is longer than other systems.

3.1 *Fatigue cracking*

Fatigue cracking has been recorded in all type of pavement on orthotropic steel bridges decks. These cracks are located on the surface of the pavements near the conjunction ribs of the longitudinal and transverse stiffeners. The cracks were observed to propagate in depth and in length firstly, several weeks later, a second parallel longitudinal cracks could be initiated if the original one be not been sealed or repaired on time. And alligators or block cracking will be inevitable within several months, as summarized in Figure 3.

3.2 *Slippage and de-bonding*

Slippage of deck pavements were mainly observed in the surfacing system of SMA and MA at hot summer. The U-shaped cracks occur with the corrugation and shoving of the pavement. The cracks generally have a width of 2 cm to 10 cm covering at least lane, as shown in Figure 4.

Localized de-bonding has also been observed in the surfacing system of GA and SMA as shown in Figure 5. According to the repairing practice, asphalt layer adjacent the alligators or potholes will lose bonding as water can penetrate down to steel deck plate surface. Experiences also indicate that large area of the pavements will soon fail once the deck pavements system loses bond strength at the interface.

3.3 *Rutting, shoving and corrugations*

Rutting, shoving, and corrugations are typical distresses of the surfacing systems with thermal-plastic binder such as MA and dense graded asphalt concrete with polymer modified asphalt. Severe rutting has also occurred in the surfacing system of SMA. These problems could become even worse as the occurrence of fatigue cracking, the rapid increase of heavy duty traffic and the absence of efficient fighting against overloading, despite of higher performance grade polymer modified asphalt was adopted or natural hard asphalt was blended.

3.4 *Bubbles and hair cracks*

Bubbles and irregular micro-cracks were mostly found in the surfacing system of EAC. The bubble can be easily recognized with two or three radial micro-cracks. A ring crack of 15 cm to 30 cm in diameter will then develop within several weeks if the bubble crack be not properly repaired and sealed, and consequently, a pothole will form from bubbles as shown in Figure 6.

4 CANDITATE MATERIALS AND STRUCTURES FOR DECK PAVEMENTS

4.1 *Gussasphalt*

Gussasphalt for road surfacing was developed principally by German engineers in the 1950s. It is estimated that some 45% of all existing autobahn surfaces in Germany are surfaced in gussasphalt and that many of them are 30 years old or more [11]. The application of GA on long-spanned steel bridge in the mainland of China begins from Jiangyin Bridge in 1999, with the paving technology introduced from England. The bridges opened to traffic 28th, September, 1999. Cracking was soon been founded in the first winter and visible rutting can been seen in the next summer. The whole system failed in the spring of 2002.

A schematic survey by Southeast University [12] has been launched soon after the first cracking and rutting have been observed in the deck pavement of Jiangyin bridge. According to the report, GA as a single layer cannot meet the requirements under the local traffic conditions and environments, although the use of pre-coated chips on the top can contribute to some content of rutting resistance. New binders with high viscosity at service temperature while low viscosity at construction temperature is desirable for a better rutting resistance against heavy duty traffic [13]. And the construction temperature should be lowered to decrease the reverse effect on primer coat, bonding and waterproofing layers below, as well as to shorten the aging effects of the binder itself. A new method for proportioning the gussasphalt is proposed based on workability, rutting resistance and low temperature flexibility [14]. The gradation is re-designed with a little bit higher content coarse aggregates and mineral filler used. The binder is a blend of 70% specially designed SBS-modified bitumen and 30% Trinidad lake asphalt. A polyolefin wax of Sasobit is added to the cooker to ensure that the gussasphalt is constructed at 180~200°C [15], which is relative low compared to conventional construction temperature up to 240°C. The new gussasphalt is proved to be successful in the test bridge of Runyang Bridges (2002), and in the test section of Jiangyin Bridge (2004), both are act as binder courses with a wearing courses of epoxy asphalt concrete. As the test section in Jiangyin Bridge lasted over than six year and developed only few longitudinal cracks and the test bridge of Runyang Bridges is still in very good condition up to now. Considering the flexibility and mechanization construction requirement of Taizhou Bridge [16], a blend of 70% straight bitumen with a penetration grade of 30–50 dmm and 30% TLA is adopted, and the content of limestone filler content decreases to 23%. A special blending system was designed to pre-blend before pumped into batch plant. Manufacture is in a batch plant with an output of 600 tonnes/day suitable for bridge deck work. The gussasphalt is held in the cookers for at best one hour with the mixing temperature (200°C) raising to 220°C for application by means of a small non-vibrating screed working on a 5 m width. An amount of 8 kg/m^2 of basaltic chips with the particle size of 13.2~19 mm was sprayed immediately the machine-laid surface of gussasphalt and compacted into the surface with a 2 tonnes steel roller, to increase the rutting resistance and interfacial shear strength.

4.2 *Epoxy asphalt concrete*

Epoxy asphalt concrete is a thermal-setting polymer concrete that is composed of a slow curing, Epoxy Asphalt binder mixed together with specially manufactured basaltic aggregates in the pug mill of an asphalt plant. The binder of Epoxy Asphalt is a two-phase chemical system in which the continuous phase is a thermoset epoxy resin and the discontinuous phase is a mixture of specialized asphalts. Epoxy Asphalt was first developed by Shell Oil Company in the late 1950's as a jet fuel and jet blast resistant specialty pavement for airfield applications.

In 1998, epoxy asphalt imported from United State (Type-C) has been introduced into China and firstly been used in 2nd Nanjing Yangtze River Bridge in 2000. In 2006, first commercial product of epoxy asphalt was manufactured with the patent developed by the deck pavement group of Southeast University (Type-N). The local epoxy asphalt has been applied successfully on Tianxinzhou Bridge in Wuhan, Minpu Bridge, Shanghai Yangtze

River Bridge and many other steel bridges in China. The viscosity of those two kind of epoxy asphalt and their hauling time are compared as shown in Figure 7 and Figure 8 [17].

Epoxy asphalt is a thermoset polymer-it will not melt after cured-rather than a thermoplastic material like SBS modified bitumen. It does not soften as much as bituminous materials and has shown no signs of rutting and shoving on previous projects in China that experience very high temperature up to 68°C in hot summer. Epoxy asphalt concrete is proved to be the super durable surfacing material for heavy duty traffic and extreme high temperature. It is widely used as surfacing materials not only for newly constructed long-spanned steel bridges, but also for resurfacing materials used in many rehabilitation applications in China. Epoxy Asphalt concrete is applied and compacted with conventional asphalt concrete paving equipment. The most difference of construction is that the mixture should been compacted before gel point. As mixing temperature and blending ration can both affect the time for the reactive system reaching the gel point, it is critical to ensure that the whole construction process are well organized and controlled. In order to avoid the hauling trucks running directly on the sticky surface of epoxy asphalt bonding coat, feeding machine has been adopted in Sutong Bridge. Full width paving technique, is employed in Taizhou Bridge to improve the construction efficiency and avoid potential cracking on longitudinal cracking that observed in the construction joints. Due to the specially designed bonding materials of two-stage reactive epoxy resin, hauling trucks can running on the surface of the bonding coat with no membrane removed by wheel, as shown in Figure 9. The cure reaction of epoxy resin will be activated during the paving process of the hot mixed epoxy asphalt concrete, which will contribute to a strong bonding at the interface of the two layers.

5 CONCLUSION

This paper presented state-of-the practice of asphalt surfacing on long-spanned orthotropic steel bridge decks in China. Fatigue cracking, de-bonding and rutting are main premature distresses on the deck pavements of long-spanned steel bridges. To overcoming the problems, we recommend that double layered epoxy asphalt for cable-stayed steel bridge with heavy duty traffic. SMA with high viscosity binder could also be used in the upper layer for cable-stayed steel bridge with light traffic loading. For the pavement on long-spanned suspension bridge with heavy duty traffic, the structure of epoxy asphalt constructed upon gussasphalt is recommended. The upper layer could be changed into SMA of dense grade asphalt concrete with high viscosity binder for suspension bridges with light traffic loading. It is also critical to improve the interfacial properties of deck pavement for both type of long-spanned steel bridges.

ABSTRACT: This study investigates the mechanical impact of the constitutive material behavior of asphalt layer (both nonlinear viscoelastic and fracture) for the prediction of pavement performance. In this study, a cohesive zone model was utilized to consider the fracture behavior of an asphalt mixture. The Semi-Circular Bend (SCB) fracture test was conducted to characterize the fracture properties of the asphalt mixture. Fracture properties were then used to simulate mechanical responses of pavement structures. In addition, Schapery's nonlinear viscoelastic constitutive model was implemented into the commercial finite element software ABAQUS via a user defined subroutine (user material, or UMAT) to analyze asphalt pavements subjected to heavy truck loads. A series of creep-recovery tests were conducted at various stress levels to obtain the stress-dependent viscoelastic material properties of the asphalt mixture. Utilizing the derived viscoelastic and fracture properties and the UMAT code, a typical pavement structure was modeled to investigate the effect of nonlinear viscoelasticity and fracture damage due to repeated heavy truck loads. Mechanical responses from two-dimensional finite element simulations of the pavement structure are presented and discussed.

Keywords: Asphalt pavement, nonlinear viscoelasticity, cohesive zone fracture, rutting, cracking

1 INTRODUCTION

Distresses in asphalt pavements, such as rutting and fatigue cracking, are critical safety issues affecting roadway users. Rutting, or, permanent deformation, is surface depression resulting from the accumulation of vertical displacements in asphalt pavement layers. The presence of this distress is even more dangerous for roadway users when the surface depression is filled with water. Accumulation of water in surface depressions increases the risk of vehicle hydroplaning, and, as a result of freezing and thawing cycles in cold regions, weakens pavement layers. Large damage areas, such as potholes, result from severe fatigue cracking in the pavement, combined with thermal stress. Pavement design methods should account for the combination of multiple factors that cause these distresses (i.e., traffic loads, environmental effects, and composite material constituent's combinations and interactions), in order to improve the reliability of the structures.

Recently, several studies including [1,2] have conducted viscoelastic analyses that consider the asphalt layer as linear viscoelastic and the other layers as elastic, using the finite element method in two-dimensional (2-D) or three-dimensional (3-D) models for predicting the time-dependent

response of flexible pavement. However, nonlinear response was not taken into consideration for their models in spite of abundant experimental observations [3,4] that present nonlinear response of asphalt binders and mixtures at certain levels of stress and strain.

The recent mechanistic-empirical (M-E) design guide predicts fatigue cracking resistance of asphalt pavements by considering various factors mentioned above. However, the M-E design guide is known to be limited in its ability to accurately predict mechanical responses in asphaltic pavements due to the use of empirically developed prediction models. Recently, the fracture behavior of asphalt mixtures has been studied by several researchers through fracture tests and numerical analysis by means of a cohesive zone model [5–8]. However, most studies were conducted at low temperature conditions, since fracture behavior at intermediate service temperatures is sensitive to loading rates. This study considered the fracture behavior of asphalt mixtures at an intermediate temperature condition (30˚C) using the cohesive zone model.

The primary objective of this study is to investigate more realistic pavement responses considering nonlinear-inelastic damage behavior of pavement structures. To this end, the SCB fracture test and creep and recovery test were performed to characterize the fracture properties and viscoelastic properties (linear and nonlinear) of an asphalt mixture. Then, the resulting test data were incorporated into relevant theories (such as Schapery's nonlinear viscoelastic model and the cohesive zone model) and numerical techniques (i.e., ABAUQS) to model a two-dimensional pavement structure subjected to heavy truck loads.

2 THEORY

2.1 *Schapery's nonlinear viscoelasticity*

Schapery's nonlinear viscoelastic single-integral constitutive model [9] for one-dimensional problems can be expressed in terms of an applied stress (σ) as follows:

$$\varepsilon(t) = g_0 D_0 \sigma + g_1 \int_0^t \Delta D\left[\psi(t) - \psi(\xi)\right] \frac{d\left(g_2\sigma\right)}{d\xi} d\xi \tag{1}$$

where,

ψ is the reduced time given by:

$$\psi(t) = \int_0^t \frac{d\zeta}{a_\sigma} \tag{2}$$

where,

g_0, g_1, g_2 and a_σ are the nonlinear viscoelastic parameters associated with stress level, t is the time of interest, and ξ is the integration variable. These parameters are always positive and equal to 1 for the Boltzmann integral in linear viscoelasticity. It is noted that Eq. (2) can include not only stress effect, but also effects such as temperature, moisture, and physical aging with each shift factor. D_0 and ΔD are uniaxial instantaneous and transient creep compliance at linear viscoelasticity respectively. The Schapery's nonlinear viscoelastic constitutive model was numerically implemented into the well-known commercial finite element software ABAQUS [10] via a user-defined subroutine called UMAT using recursive integration scheme developed by Haj-Ali and Muliana [11]. The UMAT subroutine code has been verified in the authors' previous study [12].

2.2 *Cohesive zone model*

Cohesive zone models regard fracture as a gradual phenomenon in which separation takes place across an extended crack tip (or cohesive zone) and where fracture is resisted by cohesive tractions, as illustrated in Figure 1. The cohesive zone effectively describes the material

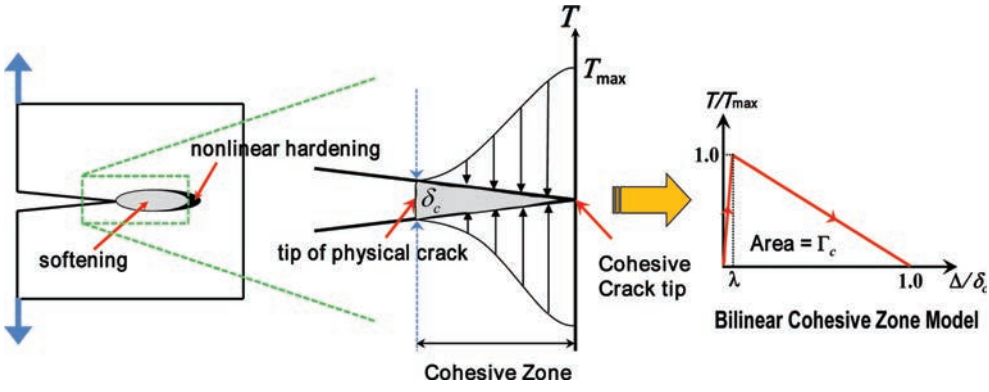

Figure 1. Illustration of cohesive zone model.

resistance when material elements are being displaced. Equations relating normal and tangential displacement jumps across the cohesive surfaces with the proper tractions define a cohesive zone model. Among numerous cohesive zone models developed for various specific purposes, this study used an intrinsic bilinear cohesive zone model [13–15]. The cohesive zone fracture energy (Γ_c), which is the locally estimated fracture toughness, can then be calculated by computing the area below the bilinear traction-separation curve with peak traction (T_{max}) and critical displacement (δ_c) as follows:

$$\Gamma_c = \frac{1}{2}\delta_c T_{max} \tag{3}$$

3 MIXTURE AND SPECIMEN FABRICATION

Table 1 summarizes mixture information, including Superpave PG asphalt binder grade, aggregate gradation of the mixture, and resulting binder content to satisfy mixture volumetric requirements. Binder content of 6.00% was determined as an appropriate value that satisfied all key volumetric characteristics of the asphalt mixture including the 4% ± 1% air voids.

To conduct the uniaxial static creep-recovery tests, a Superpave gyratory compactor was used to generate the cylindrical samples with a diameter of 150 mm and an approximate height of 170 mm. The compacted samples were then cored and sawn to produce testing specimens targeting an air void of 4% ± 0.5% with a diameter of 100 mm and a height of 150 mm after the compaction and coring-sawing process. To measure the axial displacement of the specimen under the static compressive force, epoxy glue was used to fix mounting studs to the surface of the specimen so that the three Linear Variable Differential Transformers (LVDTs) could be attached to the surface of the specimen at 120° radial intervals with a 100 mm gauge length. Next, the specimen was mounted in the UTM-25kN testing station for creep-recovery testing. Figure 2 illustrates overall laboratory processes to obtain a specimen for the uniaxial static creep and recovery test.

Figure 3 demonstrates the specimen production process for the SCB fracture test using the Superpave gyratory compactor and saw machines. The Superpave gyratory compactor was used to produce tall compacted samples: 150 mm in diameter and 175 mm in height. Five slices (each with a diameter of 150 mm and a height of 25 mm) were obtained by removing the top and bottom parts of the tall sample. Finally, the slice was cut into two identical halves, and the saw machine was used to make a vertical notch 25 mm long and 2.5 mm wide.

Table 1. Mixture information.

Mixture ID	Binder PG	Aggregate gradation (% passing on each sieve)									% Binder	% Voids

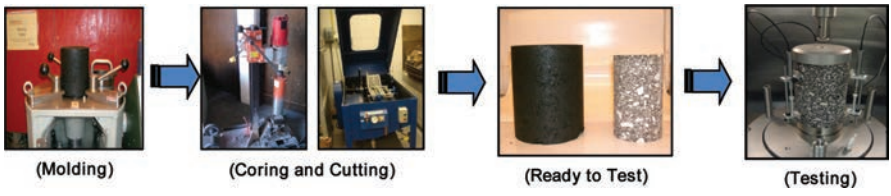

Figure 2. A specimen production process.

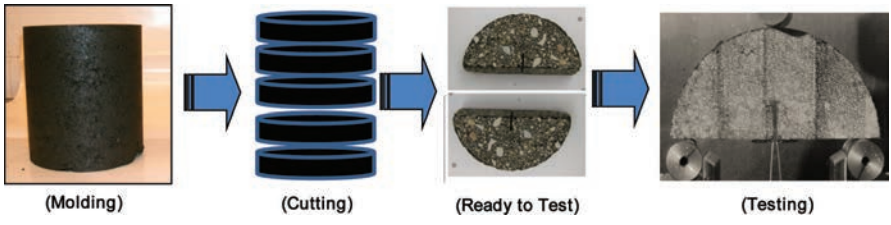

Figure 3. SCB specimen fabrication and fracture testing configuration.

4 LABORATORY TESTS AND MATERIAL PROPERTIES

4.1 *Creep-recovery test and viscoelastic material properties*

The static creep-recovery test was conducted on replicate specimens of the asphalt mixture at 30°C. Based on several preliminary tests conducted to find an appropriate creep loading time and recovery time, a creep stress for 30 seconds followed by recovery time of 500 seconds was applied to the specimens. A large range of stress levels was applied to identify the level of (stress-independent) linear viscoelastic range and to characterize stress-dependent nonlinear behavior of the mixture. Repeated preliminary tests indicated that the asphalt mixture was linear viscoelastic up to 700 kPa uniaxial creep stress. In other words, nonlinear viscoelasticity starts when the stress level is greater than 700 kPa. Therefore, a creep-recovery curve at the threshold stress level within the linear viscoelastic range was used to find linear viscoelastic properties, and other creep-recovery curves obtained from higher stress levels than the threshold stress were used to characterize the stress-dependent nonlinear viscoelastic properties. Figure 4 presents repeated creep-recovery test results. As shown in the figure, the higher stress level generated larger creep strain and provided less recovery at the testing temperature (30°C).

Using creep-recovery test results, the linear viscoelastic properties at the threshold stress level were identified, as were the nonlinear viscoelastic properties at higher stress levels. The procedure to obtain viscoelastic material properties of the asphalt mixture is well described in the authors' previous study [12]. Table 2 summarizes the viscoelastic parameters of the asphalt mixture: linear viscoelastic Prony series coefficients and nonlinear viscoelastic parameters.

4.2 *SCB fracture test and fracture properties*

In this study, the SCB fracture test was adopted. Even if the SCB geometry has some limitations such as complex stress state [6], it is practically attractive in that it is very repeatable,

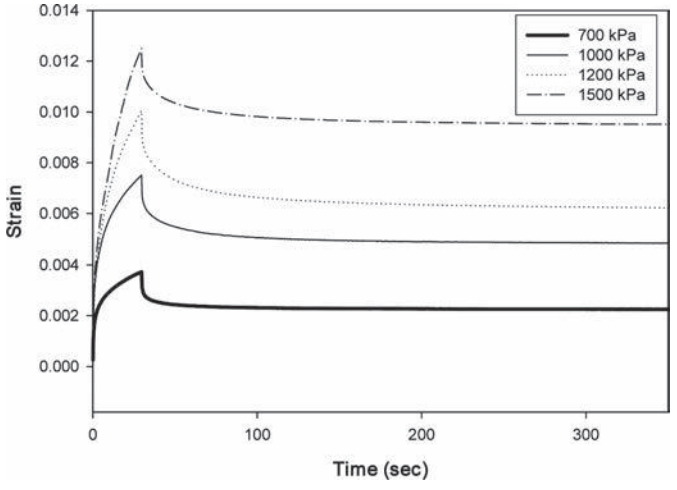

Figure 4. Creep-recovery test results at various stress levels.

Table 2. Viscoelastic properties determined through the characterization process.

Linear viscoelastic properties (Prony series coefficients)			Nonlinear viscoelastic parameters			
				Polynomial constants, *i*		
N	λ_n (s^{-1})	D_n (MPa^{-1})	Parameters	1	2	3
1	10^2	6.70×10^{-4}	g_0 (α_i)	0.05	0.77	–0.54
2	10	8.91×10^{-5}	g_1 (β_i)	0	0.01	–0.01
3	1	5.17×10^{-4}	g_2 (γ_i)	0.36	0.83	–0.71
4	10^{-1}	6.45×10^{-4}	a_σ (δ_i)	–0.14	0.84	–0.83
5	10^{-2}	9.47×10^{-4}				
6	10^{-3}	2.60×10^{-4}				
7	10^{-4}	2.73×10^{-4}				
8	10^{-5}	7.54×10^{-4}				

simple to perform, and that multiple testing specimens can be easily prepared through a routine process of mixing and Superpave gyratory compacting of asphalt mixtures. Furthermore, the SCB geometry is even more attractive considering the fracture characteristics of field cores, which are usually circular. Based on these practical benefits, the SCB testing configuration has become a popular geometry for evaluating the fracture behavior of bituminous mixtures.

Multiple SCB specimens of the asphalt mixture were prepared and tested with four different monotonic displacement rates (i.e., 1, 5, 10, and 50 mm/min.) at a testing temperature of 30˚C. As shown in Figure 3, metallic rollers separated by a distance of 122 mm (14 mm from the edges of the specimen) were used to support the specimen. Reaction force at the loading point was monitored by the data acquisition system installed in the mechanical testing machine. In addition, this study utilized the Digital Image Correlation (DIC) system incorporated with the SCB fracture test to more accurately capture the displacements at the mouth (denoted as Notch Mouth Opening Displacements [NMOD]) and at the tip (denoted as Notch Tip Opening Displacements, [NTOD]) of the initial notch. The accuracy of the DIC test results was well verified in the authors' previous study [16].

Fracture properties of the asphalt mixture were then determined by numerical simulations of the SCB fracture tests. This was implemented to identify fracture characteristics along the

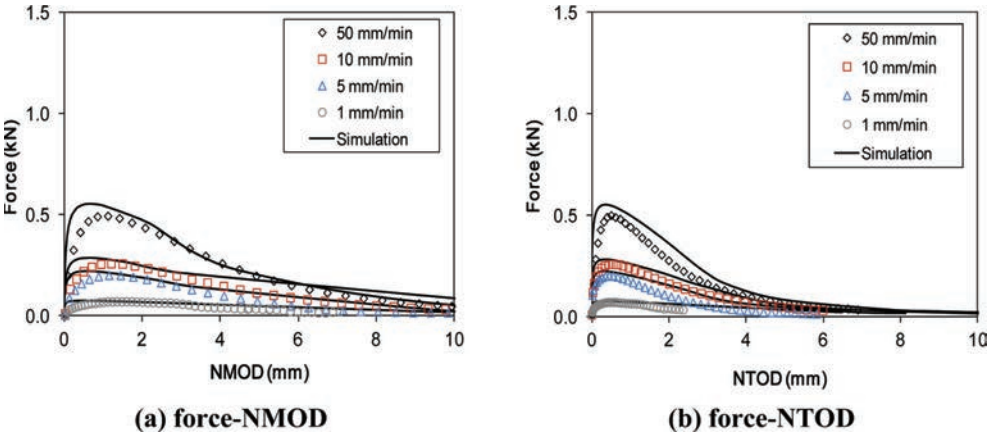

Figure 5. SCB test results vs. cohesive zone model simulation results.

Table 3. Cohesive zone fracture parameters determined.

Temperature (°C)	Loading rate (mm/min.)	Cohesive zone fracture parameters	
		T_{max} (kPa)	Γ_c (J/m^2)
30	1	8.0E+01	220
	5	2.5E+02	400
	10	3.2E+02	550
	50	6.5E+02	900

Fracture Process Zone (FPZ), which is locally associated with initiation and propagation of cracks through the SCB specimens. The cohesive zone fracture properties (two independent values of the three: T_{max}, δ_c, and Γ_c) in the bilinear model were determined for each case through the calibration process until a good match between test results and numerical simulations was observed. Figure 5 presents good agreements between the test results (average of the three SCB specimens per case) and finite element simulations. Resulting fracture properties (T_{max} and Γ_c) at each loading rate are presented in Table 3.

5 FINITE ELEMENT ANALYSIS OF PAVEMENT

A standard asphalt pavement was modeled through the 2-D finite element method in order to investigate the mechanical performance behavior of the pavement when subjected to heavy truck loading. The 2-D finite element modeling was conducted using a commercial package, ABAQUS Version 6.8 [10], which was incorporated with the cohesive zone fracture and the developed nonlinear viscoelastic UMAT.

Figure 6 illustrates a four-layered asphalt pavement structure (101.6 mm thick asphalt layer, 254 mm Portland Cement Concrete (PCC) layer with PCC joints, 101.6 mm Bituminous Foundation Course (BFC) and 152.4 mm subgrade). Both sides of the vertical edge of the finite element pavement model were fixed in the horizontal direction, and the bottom of the model was fixed in the vertical direction to represent a rock foundation. The red line in the figure indicates the region where cohesive zone elements were inserted in the mesh to allow cracking (reflective and/or top-down). The underlying layers (i.e., PCC, BFC, and subgrade) were modeled as isotropic linear elastic, while viscoelastic response was considered to

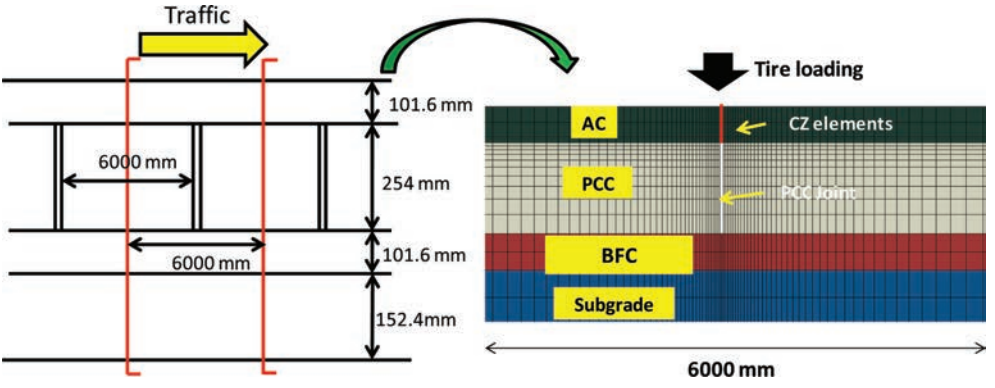

Figure 6. A pavement geometry and boundary conditions for fe modeling.

describe the behavior of the asphalt concrete surface layer: Prony series coefficients and nonlinear viscoelastic parameters presented in Table 2. Also, cohesive zone fracture parameters, Γ_c = 400 J/m^2 and T_{max} = 250 kPa presented in Table 3, were used for the fracture behavior of the asphalt concrete surface layer. Correspondingly, the surface layer can dissipate energy due to its viscoelastic nature and cohesive zone, which results in permanent deformation (rutting) and fracture of the layer.

A tire pressure of 720 kPa and axial load of 35.5 kN were applied to the pavement based on a study by Yoo [17]. The loading configuration of the Class 9 truck was used in this study. A 15.4 m Class 9 truck trailer traveling at 80 km/h takes 0.692 seconds to pass over a fixed point on the pavement. Therefore, the first truck passes the fixed point for 0.692 seconds and after 30 seconds a second truck passes through the same point. The passage of a total of 50 trucks was simulated in this study. The details of the truck loading conditions and properties of the underlying layers can be found elsewhere [18].

6 SIMULATION RESULTS

Among many mechanical responses, the vertical displacement from the pavement surface and the crack opening (horizontal) displacement through the depth of the asphalt concrete layer were examined since they are strongly related to the two primary distresses of asphaltic pavement: rutting and cracking.

Figure 7 compares permanent deformation (rut depth) accumulated from each truck loading up to the 50 cycles obtained from the four modeling approaches: linear viscoelastic with or without the cohesive zone fracture and nonlinear viscoelastic with or without the cohesive zone fracture. It clearly shows the increasing difference in the rut depth from the all four cases as the number of loading cycles increases. At the end of the 50 cycle simulation, the total rut depth predicted from the nonlinear viscoelastic with the cohesive zone fracture was the greatest, while the rut depth simulated from the linear viscoelastic without cohesive zone was the smallest. Figure 8 shows crack opening displacements from the top surface to the bottom of the asphalt layer at the end of 50th loading cycle from the two modeling approaches: linear and nonlinear viscoelastic with the cohesive zone fracture. As shown in the figure, the two modeling cases presented significant differences in the fracturing of the asphalt at the bottom of the layer. This is because the nonlinear viscoelastic case with cohesive zone fracture experienced tensile stresses approximately four times greater than those from the linear viscoelastic case at the bottom of the asphalt layer. The figures clearly demonstrate the effects of material characteristics on the overall pavement performance.

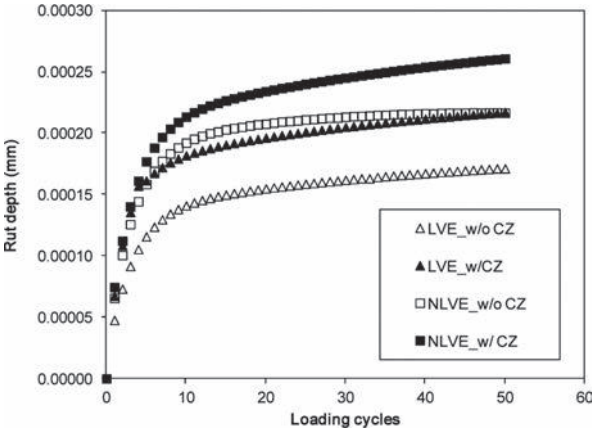

Figure 7. Comparison of permanent deformation up to 50 loading cycles.

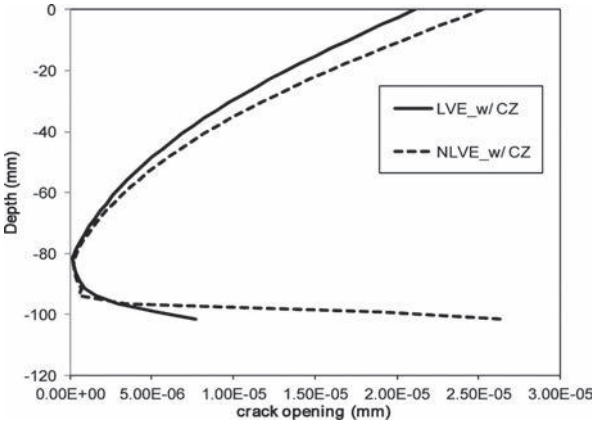

Figure 8. Depth-crack opening: LVE vs. NLVE.

7 SUMMARY AND CONCLUSION

More realistic pavement responses were attempted by considering the nonlinear-inelastic damage behavior of an asphaltic pavement structure subjected to repeated heavy truck loads in this study. The following bullet points summarize the conclusions that can be drawn:

- Schapery's nonlinear viscoelastic model was implemented into the ABAQUS via a user material subroutine UMAT.
- Creep-recovery tests at varying stress levels were conducted to identify viscoelastic mixture characteristics. As expected, test results clearly demonstrated stress-dependent mixture characteristics.
- At intermediate service temperatures such as 30°C, cohesive zone fracture properties of asphalt mixtures varied as the loading rate changed.
- Two-dimensional finite element simulations of a pavement structure showed significant differences among the cases (linear viscoelastic vs. nonlinear viscoelastic with and without fracture damage) in the prediction of pavement performance (both rutting and cracking).

- Although test results and numerical simulations presented in this study are limited to make any definite conclusions, performance differences observed between individual cases are considered significant and should be addressed in the process of performance-based pavement design. This further implies the importance of proper and more realistic characterization of paving materials.

ABSTRACT: The concept of strain limit design as applied to heavy industrial pavements is discussed. The strain limit approach has been applied following the mechanistic design methodology provided in the Asphalt Institute's MS 23 document. This design approach has been found to be beneficial in some cases when used in the design of flexible pavement sections for heavy duty industrial asphalt pavements with high load repetitions.

Several multilayer pavement systems are considered when subjected to various heavy wheel load configurations, to assess the potential benefit to pavement cost and performance. The paper assesses how the design input conditions of subgrade support, applied wheel load stress, and load repetitions influence the effectiveness of the strain limit design approach. Under some combinations of design conditions the strain limit design approach shows promise for use in the design of these heavily loaded pavements.

Keywords: heavy industrial pavements, multi-layer mechanistic analysis, strain limit design of flexible pavements, applied wheel load stress

1 BACKGROUND

The concept of improving the design life by incorporating a fatigue resistant asphalt base has been recognized for around 20 years. Numerous studies indicate that fatigue life is increased with higher asphalt binder content in the rich-bottom mix [1–7]. Coupled with the long life pavement concept, the fatigue resistant asphalt base has enabled pavement designers to significantly improve the cost effectiveness of asphalt pavement sections for many highways. The concept is to produce a layer at the bottom of the asphalt layer which is more flexible and less susceptible to the initiation of fatigue cracking at the bottom of the asphalt layer system that consequently is effective in increasing the fatigue life of the pavement section. The practice has been to increase the asphalt content of an asphalt base layer by about 0.5% from the target mix design value. This has the effect of decreasing the effective air voids in the mix, and improving mix compactability. This approach, sometimes called a rich asphalt base, can also be achieved by reducing the design air voids of the asphalt base material, resulting in an increase in effective asphalt content.

This design approach has also been shown to be effective in improving the cost effectiveness of industrial asphalt pavement sections designed for heavy wheel loads. While the use of a fatigue resistant base typically does not result in a long life pavement at conventional thicknesses in these cases, it can result in the effective design of a thinner, less costly pavement section due to the ability to better resist the higher stresses produced from heavy wheel loads.

Our experience over the past dozen years with heavy wheel load design projects has been that in some cases this approach to a reduced pavement thickness works in some cases, but not in others. So the objective of this paper is to present additional assessment of these designs to better identify when the fatigue resistant base concept is effective, and when it is not.

2 SENSITIVITY ANALYSIS

Several input factors are of great importance in pavement design. These include, in addition to the wheel load factors, the subgrade stiffness, number of load repetitions, and layer thickness. Multiple analyses were conducted evaluating the effect of these input parameters on the effectiveness of a fatigue resistant asphalt base. Analyses were performed using an elastic layer tool, following the design methodology of the asphalt institute, and specifically MS 23. The analysis of each input factor follows.

The flexible pavement design principle is based upon multilayered elastic design concepts developed by the Asphalt Institute (AI). This procedure assumes that the application of a load to the pavement produces two critical elastic strains, horizontal tensile strain at the bottom of the asphalt concrete layer, and the vertical compressive strain at the top of the subgrade layer. Design criteria, in terms of maximum allowable values for both critical strains, are used as the basis for designing pavement thickness.

A storage area failure model has been used for the pavement damage analysis. This military storage model is considered to be suitable as it was developed specifically for heavy, slow moving vehicles with large tires.

AI equations for fatigue and rutting are expressed as follows:

$$N_f = f_1(\varepsilon_t)^{-f_2}(E_1)^{-f_3} \tag{1}$$

$$N_d = f_4(\varepsilon_c)^{-f_5} \tag{2}$$

where ε_t is the tensile strain at the bottom of the AC layer, and ε_c is the compressive strain on the top of the subgrade. The constants f_1, f_2, f_3, f_4 and f_5 are coefficients, whose valuese for the milirary storage model are presented below:

$$f_1 = 479; f_2 = 5; f_3 = 2.665; f_4 = 1.0E-17; f_5 = 7.10227 \tag{3}$$

2.1 *Subgrade modulus*

The importance of subgrade stiffness is even greater for heavy wheel load design than for conventional roadway design. An assessment of the effect of subgrade modulus illustrates this importance. In this analysis, the subgrade modulus value is varied from 12,500 to 22,500 psi. When the subgrade modulus is 22.5 ksi, pavement failure is controlled by fatigue. Decreasing the elastic modulus of the bottom AC layer will result in an increase in pavement life. When the subgrade modulus is 15.0 ksi, the pavement failure is controlled by rutting. Increasing the elastic modulus of the bottom AC layer will result in an increase in pavement life. When the subgrade modulus is 18 ksi, pavement failure is first controlled by rutting, and then switches to fatigue, which as pavement life is first increased with the increase in the modulus of the lower asphalt layer and then decreased once the pavement failure is controlled by fatigue. Results of this assessment are illustrated in Figure 1.

2.2 *Base modulus*

As shown in Figure 2, when the base modulus is 65 ksi, pavement failure is controlled by rutting. Increasing the elastic modulus of the bottom AC layer will result in an increase in pavement life. When the base modulus value is set at 50 ksi and 40 ksi respectively, pavement

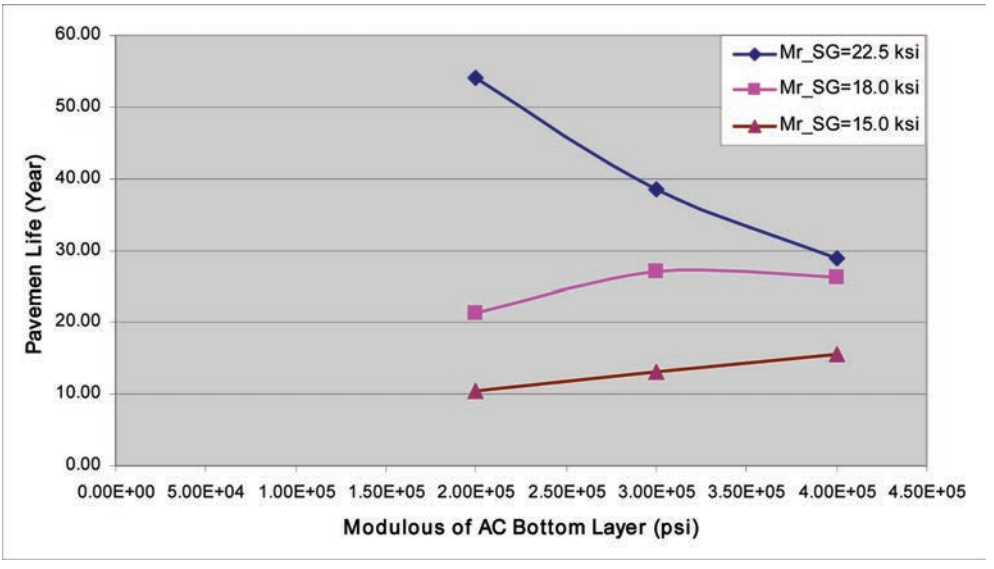

Figure 1. Effect of rich bottom AC layer on pavement life due to subgrade moduli.

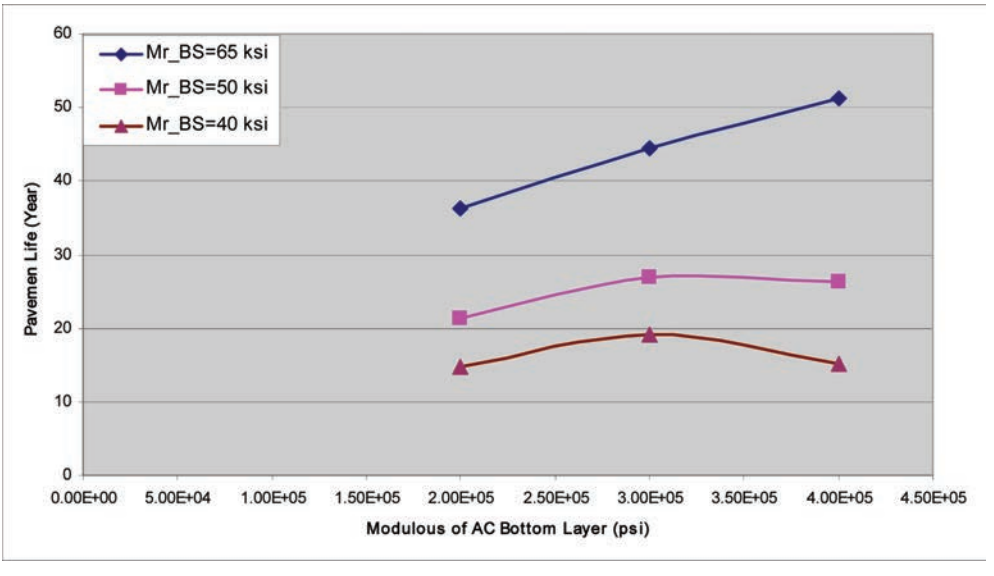

Figure 2. Effect of rich bottom AC layer on pavement life due to base moduli.

failure is first controlled by rutting, and then switches to fatigue, as the pavement life is first increased with the increase in the elastic modulus of the bottom AC layer and then decreased once the pavement failure is controlled by fatigue.

2.3 *Asphalt base thickness*

As shown in Figure 3, when the base thickness is 15″, the pavement failure is controlled by rutting. Increasing elastic modulus of the bottom AC layer will result in an increase in pavement life. When the base thickness is increased to 18″, the pavement failure is first controlled

by rutting as pavement life is first increased as the elastic modulus of bottom AC layer is increased, and then decreased as the failure mode switches to fatigue.

2.4 *Wheel load*

As shown in Figure 4, when the wheel load is light (for both 35,000 lbs and 25,000 lbs cases), pavement failure is controlled by fatigue. Increasing the elastic modulus of the bottom asphalt layer will result in a decrease in pavement life. When the wheel load is increased to 45,000 lbs, pavement failure is first controlled by rutting with a low AC modulus, and then switches to

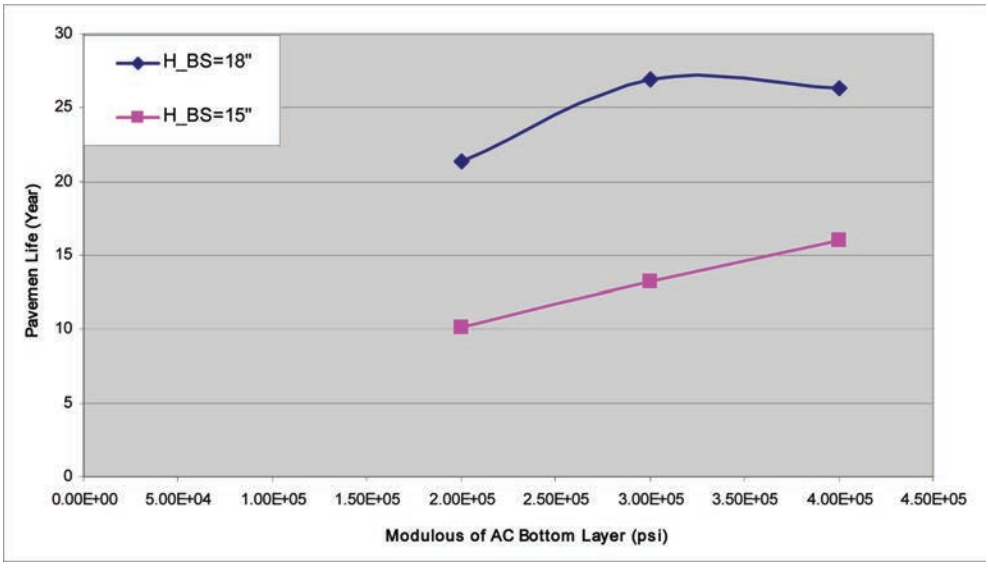

Figure 3. Effect of rich bottom AC layer on pavement life due to base thickness.

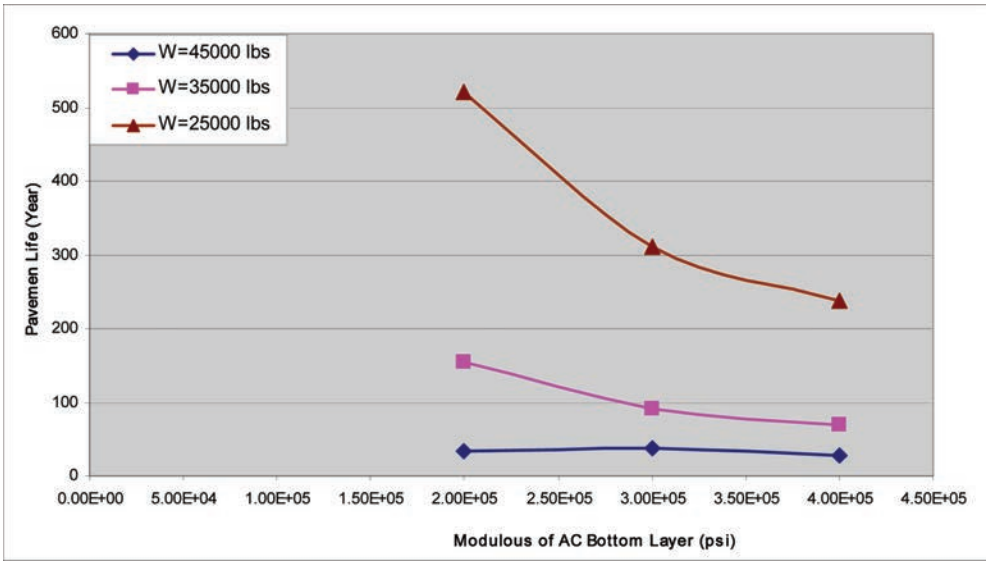

Figure 4. Effect of rich bottom AC layer on pavement life due to wheel load.

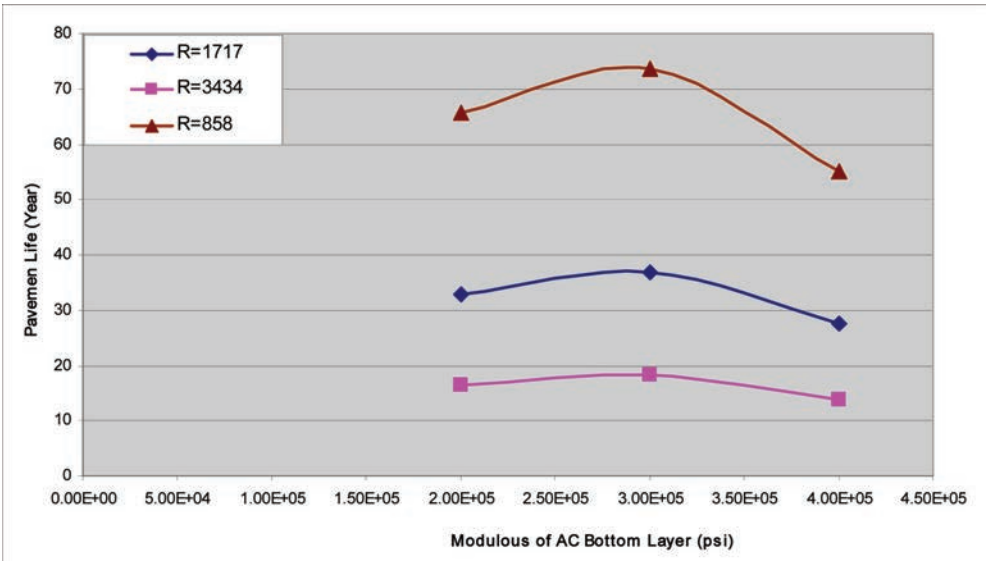

Figure 5. Effect of rich bottom AC layer on pavement life due to load repetitions.

fatigue as the AC modulus increases. This results in the pavement life first increasing with an increase in the elastic modulus of the bottom AC layer, and then decreasing once the pavement failure is controlled by fatigue.

2.5 *Load repetitions*

As shown in Figure 5, changes of load repetitions have no effect on the change in failure model. In general, increasing load repetitions will result in reduced pavement life.

By examining the above analysis of individual parameters, it can be observed that the contribution of a rich bottom asphalt layer to increased pavement life is only effective when failure is controlled by the fatigue design criteria. In this case, decreasing the elastic modulus of the asphalt rich bottom will have the effect of increasing pavement life. If pavement failure is controlled by the rutting criteria, a rich bottom will result in a decrease in pavement life.

3 DYNAMIC RESPONSE

In order to check the dynamic response on the tensile stress at the bottom of the asphalt layer, and vertical compressive stress on the top of the subgrade, a dynamic analysis was conducted using the 3D-Move software to compare the different stress responses between a conventional bottom asphalt mix and rich asphalt bottom mix. Five percent (5.0%) asphalt content by weight is assumed for the conventional bottom asphalt mix, and 5.5% asphalt content is assumed for the rich bottom asphalt mix. The loading configuration used in the analysis is shown in Figure 6, where x is the vehicle travel direction. The dynamic responses of the tensile stress at the asphalt bottom are presented in Figures 7 through 12 at three critical locations; A, B, and C. The results indicate the rich bottom asphalt mixture will result in less tensile stress than the conventional asphalt base mixture. Considering the vertical compressive stress on the top of the subgrade, the rich asphalt bottom mix has very little impact, as shown in Figure 13. This may be attributed to the thick thickness of the asphalt pavement. Table 1 summarizes the results of the dynamic response. As shown, the maximum tensile stress was reduced by around 3% when rich-bottom asphalt mix is used.

Table 1. Summary of dynamic analysis.

	Asphalt content					
	5.00%		5.50%		Difference	
Location	Stress-xx (psi)	Stress-yy (psi)	Stress-xx (psi)	Stress-yy (psi)	Stress-xx	Stress-yy
A	–122.27	–73.45	–119.05	–71.47	2.63%	2.69%
B	–114.35	–6.56	–111.26	–6.26	2.70%	4.53%
C	–108.21	–5.79	–105.26	–5.57	2.73%	3.89%

4 CONCLUSIONS

The results of the analysis indicate that the inclusion of a fatigue resistant asphalt base in the design will improve pavement life for heavily loaded pavements only when the design is

controlled by the fatigue criteria. This finding is consistent with a rational understanding of the design methodology when typical design life of 20 years is the objective.

To further quantify the effect of the use of a fatigue resistant asphalt base, results of the dynamic analysis indicate that the inclusion of an asphalt rich base layer can increase pavement life by 3% for the parameters investigated. The increase in life could be greater if it is determined that a larger increase in asphalt content is practical. This effect in increasing pavement life is evident in the design of pavements for heavy wheel loads, as the balance between rutting and fatigue control is achieved.

ABSTRACT: Bituminous pavements are known to exhibit a thermo-viscoelastic behavior which is strongly dependent on temperature and load velocity. However, for many applications (pavement design, FWG analysis …) it is more convenient to deal with elastic calculations which facilitate parametric studies. But to be accurate such an approximation requires rules defining the right choice of elastic data sets. In this context, this paper presents a method to derive an equivalent elastic system to a multilayer viscoelastic pavement under given conditions of temperature and subject to loads moving at constant speed. Thus, the tool proposed hereafter should ease the elaboration of such rules. This paper explains the proposed method and illustrates its use on the case of a thick flexible pavement. By the way, we reexamine the "10 Hz rule" of the French pavement design method within this framework. We recall that this rule assumes that the equivalent modulus of a bituminous layer is approximately equal to the norm of its complex modulus computed at 10 Hz and at the temperature of the layer.

Keywords: thick flexible pavement, viscoelasticity, equivalent elastic system

1 INTRODUCTION

It is well known that the resilient behavior of asphalt concrete under traffic load is viscoelastic and highly sensitive to temperature, these features being inherited from those of bitumen binders. To take account of these features numerical programs such as ViscoRoute© 2.0 were developed more or less recently [1–5]. The high accuracy potential of these tools was demonstrated by way of comparison with experimental measurements stemming from instrumented pavements under simulated traffic, when varying amplitude and velocity of the loads, the pavement geometry or the profiles of temperature. Nevertheless for many applications such as pavement design or survey and back analysis, the use of elastic-based programs still remains at first step a very easy, fast and useful mean of modeling, which is also capable of providing an accurate quantitative description of pavement behavior. However the main condition for this is to make the right choice of the "equivalent elastic moduli" to be affected to the viscoelastic layers of the structure. In this context, the present paper aims at developing a methodology based on viscoelastic simulations and back calculation for determining these moduli. In addition, the results obtained from the method developed are eventually compared to the choice of modulus recommended by the French design method [6].

2 CALCULATION METHOD

The calculation method relies on the use of software ViscoRoute© 2.0 dedicated to the computation of the dynamic response (3D) under moving loads of pavements incorporating viscoelastic material layers. The software program is based on a semi-analytical solution technique described in other references to which the reader is referred for a comprehensive description [3–5]. The viscoelatic model is considered as the reference to simulate the pavement response at a given temperature and loading speed. The same tool is then used to calculate the response of the associated elastic structure of same geometry and subject to similar loading. The Young moduli of the different layers will be determined in order to obtain, in "some sense", comparable responses for the two structures. For this purpose, we define a mathematical function $\phi(\boldsymbol{E})$ to minimize which expresses the "distance" between the two models:

$$\phi(\boldsymbol{E}) = \sqrt{\sum_{i=1}^{n}\left(\frac{c_{i,\max}^{ve}(V,\theta,z_i) - c_{i,\max}^{e}(\boldsymbol{E},z_i)}{c_{i,\max}^{ve}(V,\theta,z_i)}\right)^2} \tag{1}$$

$c_{\max}^{ve}$ and $c_{\max}^{e}$ denote the selected quantities (e.g. deflection, strain, etc.) that we wish to be close in the viscoelastic and the elastic cases, respectively. The "equivalence criterion" ϕ is defined using n quantities which may be calculated at different depths z in the structure. $c_{\max}^{ve}$ represents the reference computed using ViscoRoute© 2.0 in which asphalt layers are modeled through the Huet-Sayegh model [7–9] (Fig. 1). $c_{\max}^{ve}$ is thus a function of speed V and temperature θ so the minimization technique is run for given values of these parameters. $c_{\max}^{e}$ depends on $\boldsymbol{E}$ which is an array of size *nve* (number of viscoelastic layers) composed of the unknown elastic moduli.

The minimization is performed according to a gradient method with respect to $\boldsymbol{E}$ for which an increment of modulus, $d\boldsymbol{E}$, is computed at each iteration as follows:

$$d\boldsymbol{E} = -\lambda\frac{\partial\phi(\boldsymbol{E})}{\partial\boldsymbol{E}} \quad \text{with} \quad \lambda = \frac{\alpha\phi(\boldsymbol{E})}{\left|\partial\phi(\boldsymbol{E})/\partial\boldsymbol{E}\right|^2} \tag{2}$$

The minimization process is stopped when $\left|\nabla\phi(\boldsymbol{E})\right| \le \varepsilon$. α and ε are small positive quantities.

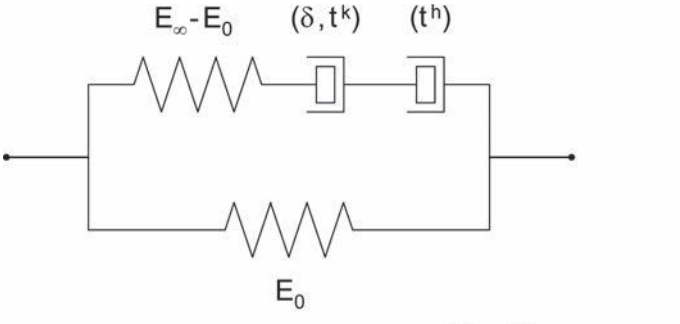

Figure 1. Schematic of the Huet-Sayegh rheological model and its complex modulus as a function of pulsation and temperature ($h > k > 0$; $j^2 = -1$).

For pavement design applications, the important issue is to obtain comparable true and equivalent critical strains or stresses governing the material damage criteria. Thus here we define ϕ as a function of the maximal strain and stress at the bottom of the asphalt layers, considered as the most relevant quantities for asphalt fatigue prediction. Note that this function can be extended to other quantities. For instance, if the application is focused on deflections or curvature then the whole deflection bowl could be used in the ϕ function.

3 STUDY OF A THICK FLEXIBLE PAVEMENT

The calculation method is applied to the study of a typical thick flexible pavement modeled with either two or three viscoelastic layers. In the first case, only two unknown moduli must be determined. This case will be used to illustrate the shape of the ϕ function and evaluate the calculation method. On the other hand, the case with three viscoelastic layers aims at illustrating a complicated situation involving thermal gradient in the structure. For both cases, we also examine the validity of the "10 Hz rule" used in the French pavement design method [6] to assess the elastic stiffness of bituminous layers (see further).

A schematic representation of the pavement structure is shown in Figure 2. It is composed of viscoelastic layers supported by a semi-infinite elastic foundation. For the analysis of the two-viscoelastic-layer case we consider that the two GB3 layers are melded. Table 1 gives the values of the Huet-Sayegh parameters of the different viscoelastic layers.
