Two loading configurations are considered further. The imprints of these configurations are represented in Figure 3. These are composed of two or three identical circular loads.

3.1 *Case of a two-viscoelastic-layer structure*

In this section, the pavement is subjected to the French standard dual-wheel moving at constant speed V = 72 km/h = 20 m/s. The weight of each wheel (32,5 kN) is assumed to be uniformly distributed at the surface of the pavement over a disk of radius 0.125 m (Fig. 3).

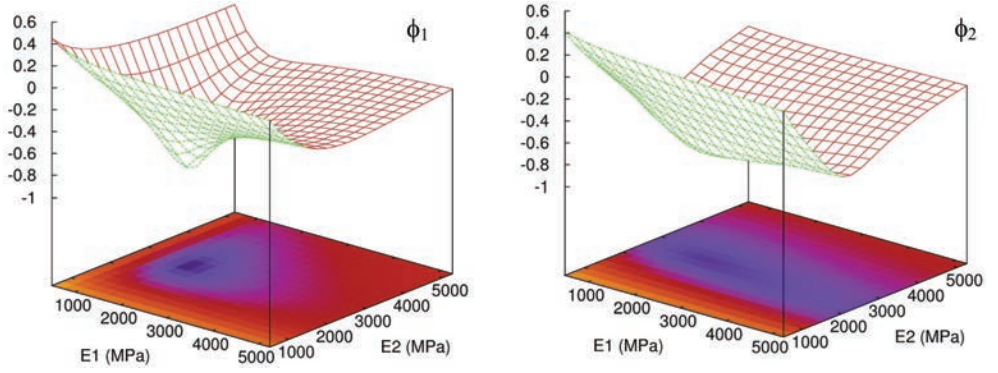

Figure 4. Plot of function $\phi_1(E_1,E_2)$ and $\phi_2(E_1,E_2)$ for the two-viscoelastic-layer pavement.

3.1.1 *Choice of ϕ and validation of the calculation method*

In the present case, function ϕ depends on two elastic moduli and its minimum can be graphically determined in a simple way. To validate the calculation method these moduli can be compared to those obtained by minimization. To evaluate the impact of the selected function ϕ on the back-calculated moduli, two functions composed of three quantities ($n = 3$) are used below.

The first function ϕ_1 includes ε_T and σ_T computed at the bottom ($z = 0.33$ m) of the pavement as well as ε_T computed at the top ($z = 0.04$ m) (see Fig. 2). ε_T denotes the maximum between the absolute values of the longitudinal strains ε_{xx} and ε_{yy}; σ_T is the equivalent for stress. In the second function denoted ϕ_2, ε_T in $z = 0.04$ m is replaced by ε_{zz} calculated at the top of the soil foundation ($z = 0.35$ m). Figure 4 shows a plot of the logarithm ($\log_{10}$) of these two functions. In this figure, E_1 and E_2 are respectively the values of the Young modulus of layer 1 and 2 attributed for elastic structure. Besides the viscoelastic computation is performed for $V = 20$ m/s and $\theta = 30$°C (temperature is uniform in both layers).

These two functions exhibit a single minimum which is more apparent for ϕ_1 in contrast with ϕ_2. Consequently, function ϕ_1 is probably more conducive to determining numerically the equivalent moduli by means of gradient descent. Note that depending on its definition, function ϕ may have several local minima and the choice of the quantities included in ϕ should be made with caution. For instance, ϕ_2 has not a well defined minimum probably because the value of ε_{zz} in $z = 0.35$ m is more sensitive to the mechanical properties of the soil foundation than to E_1 and E_2. In the rest of the paper, we use function ϕ_1 (ϕ=ϕ_1). Under the present conditions, this function leads to values of the equivalent moduli obtained by minimization of 1625 and 2712 MPa for E_1 and E_2, respectively. These values match those of the minimum shown in Figure 4 thus validating the calculation method.

3.1.2 *Detailed comparison between the viscoelastic and elastic equivalent solutions ($\theta = 30°C$)*
The viscoelastic response of the pavement is compared to that obtained in the elastic case using the equivalent moduli computed before (i.e. for $V = 20$ m/s and $\theta = 30°C$). For that purpose, Figure 5 shows horizontal profiles in the x- or y-direction (at a given depth z) of the mechanical fields used to define the equivalence criterion, i.e. to calculate function ϕ. We observe that these profiles provide as expected a good estimate of the maximal values ε_T and σ_T. Nonetheless, the shapes of the profiles are somehow different since creep/relaxation inherent to viscoelasticity leads to non-symmetric profiles in the moving direction and to a shifting of the maximum positions.

Besides, Figure 6 shows profiles of other signals which were not incorporated in the function ϕ. For these fields, in addition to some differences in shape between the elastic and the viscoelastic response non negligible differences are also observed at peak values. This could be expected since no constraint is imposed to match these components of the viscoelastic response. Nevertheless, the maximum of these fields remain lower than ε_T and σ_T and in the present example this difference would not impact design based on maximum strain or stress. Globally, the elastic calculation leads to quite acceptable results.

3.1.3 *Equivalent moduli as a function of temperature ($V = 20$ m/s)—the "10 Hz rule"*
The variation of the equivalent moduli with respect to temperature is now studied. The minimization is run for different temperatures which are assumed to be homogeneous with the same value in both viscoelastic layers. The temperature is varied successively from 0 to 40°C. Figure 7 shows the results obtained for the BB and the GB3 layers. As expected the equivalent moduli decrease with temperature ($V = 20$ m/s), i.e. as the viscoelastic materials soften. At $\theta = 30°C$ the equivalent moduli are those already computed in the previous section

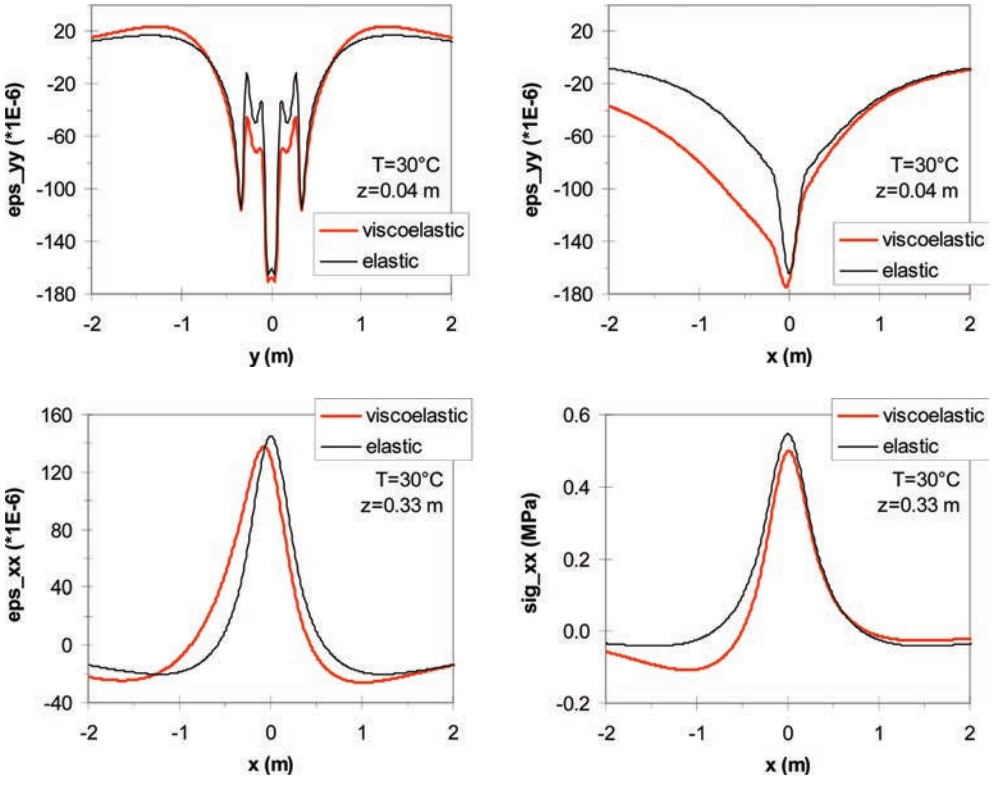

Figure 5. Profiles in the x- or y-direction of the fields used in the minimization process: comparison between elastic and viscoelastic computations.

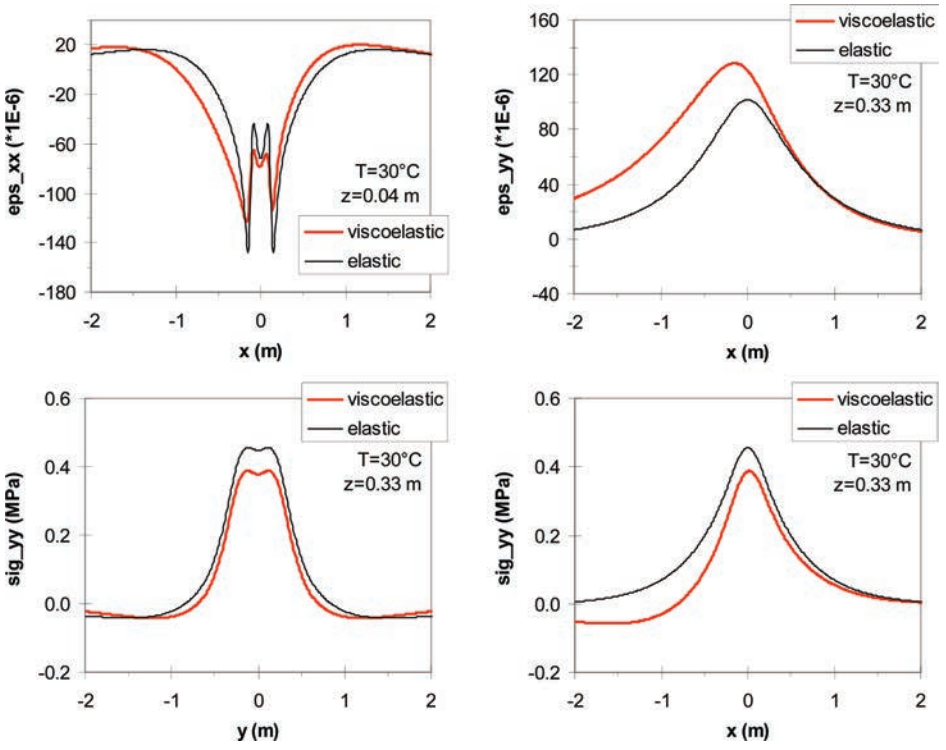

Figure 6. Profiles of fields not incorporated in function ϕ: comparison between elastic and viscoelastic computations.

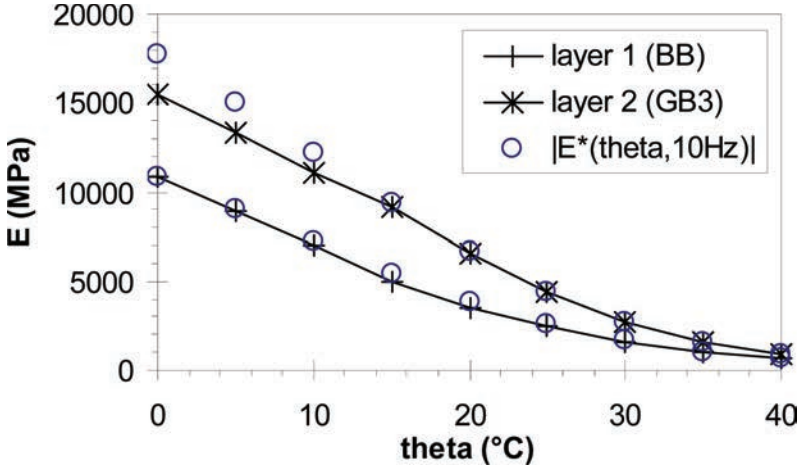

Figure 7. Variation of the equivalent moduli with respect to temperature and comparison with the norm of the complex modulus computed for θ and 10 Hz.

(E_1 = 1625 MPa and E_2 = 2712 MPa). For the different temperatures, the equivalent moduli are also compared to the magnitude of the complex modulus of the corresponding layer computed at temperature θ and frequency $f = \omega/2\pi = 10$ Hz, which is the rule applied in the design of pavements in France to account for variations of temperature. The values of the complex modulus for each layer are plotted using circle markers in Figure 7. These values are

in good agreement with the equivalent back-calculated moduli indicating that the rule under consideration performs well in the present case.

3.2 *Case of a three-viscoelastic-layer structure*

We consider in this section a three-viscoelastic-layer structure subjected to a tridem loading configuration. A thermal gradient is imposed in the asphalt concrete part of the structure. The temperature in the viscoelastic materials is assumed uniform per layer and equal to 35, 25 and 15°C for layer 1 (BB), 2 (GB3) and 3 (GB3), respectively. The same function ϕ as previously is used in the minimization. Figure 8 shows profiles of the selected fields used to compute function ϕ. The comparison between the viscoelastic and the elastic equivalent responses leads to similar conclusions as evoked for the two-viscoelastic-layer structure, i.e. a good match of the maximum values with some differences in the shape of the profiles. However, the back calculated moduli obtained and summarized in Table 2 are much lower

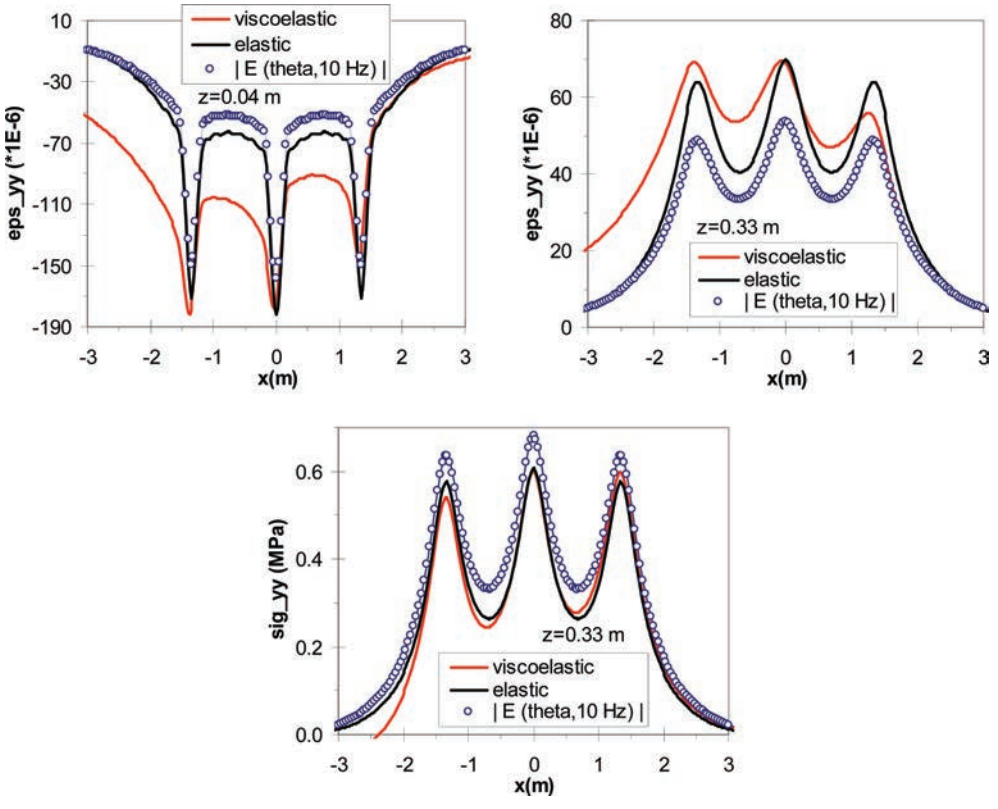

Figure 8. Profiles versus x of the fields used in the minimization process of the three-viscoelastic-layer structure: comparison between viscoelastic, elastic equivalent, and "10 Hz rule" computations.

Table 2. Back calculated moduli for the different layers and design moduli from the "10 Hz rule".

	Layer 1—BB (35°C)	Layer 2—GB3 (25°C)	Layer 3—GB3 (15°C)
Eeq (Mpa)	929	2695	6379
|E(theta,10 Hz)| (MPa)	1029	4461	9375

than the current design moduli stemming from the "10 Hz rule". In terms of mechanical response shown in Figure 8, this yields underestimation of ε_T in $z = 0.04$ m and 0.33 m, and overestimation of σ_T in $z = 0.33$ m when considering the design rule. The application of this rule is thus not well adapted to the present case whereas the elastic calculation still performs well provided that the equivalent elastic moduli are correctly chosen.

The differences observed could be attributed to a change of the appropriate loading frequency (load pulse duration) to be selected at different depth [10] for the thick asphalt pavements. As a remark, the loading frequencies corresponding to the back calculated moduli (inversion of the Huet-Sayegh law) are 7.6, 2.0 and 1.5 Hz for the layers 1, 2 and 3, respectively.

4 CONCLUSION

The aim of this paper was to present a method intended to help the setup of rules for defining equivalence between viscoelastic and elastic calculations of pavements, depending on the context of use and of a desired accuracy. In this framework, the proposed method was used to compute the equivalent moduli to be affected to bituminous layers of a thick flexible pavement subject to moving loads. This method has proven to provide accurate estimate of the equivalent moduli for various conditions of loading and temperature. The back calculated moduli obtained using the developed tool have also been compared to those recommended by the French pavement design method. Depending on the situation under consideration, the difference between these moduli was found more or less important. Nevertheless, to conclude on this aspect it would be necessary to define an acceptable difference after integrating weighting of the results to account for traffic, weather conditions, etc. which are elements considered in the design method. Finally, the type of approach presented here could be used to extrapolate the pavement design method to other contexts as done already for airfield pavements in France for which the equivalent moduli are determined as a function of temperature, load speed and thickness of the layers.

Best sensing location in pavement to compare loading conditions

Wenjing Xue & Linbing Wang
Department of Civil and Environmental Engineering, Virginia Tech, Blacksburg, VA, USA

Eric J. Weaver
Turner-Fairbank Highway Research Center, Federal Highway Administration, McLean, VA, USA

ABSTRACT: In the past decades, both the number of tire models and tire inflation pressure are increasing to transport oversized and overweight loads on highways. In-situ monitoring is an effective and reliable way to evaluate the influence of various complicated loading condition to the pavement. Since pavement instrumentation, experiment and following data analysis are expensive. Therefore, a study was made to find suitable locations of sensors in the pavement to evaluate the influence of various loading conditions. Based on the data analysis of the measured strain responses, the best sensing location is in the longitudinal plane at the bottom of pavements, because the responses were more stable and convergent, and the responses match with viscoelastic analysis the best.

Keywords: pavement instrumentation, sensing location, loading condition, pavement monitoring, 3D-move simulation

1 INTRODUCTION

The pavement is one of the very important assets of the society, and designed to carry the predicted traffic without exhibiting failure during its design life. So it is important for pavement engineers to understand the pavement responses induced by the traffic loads, then the material and structure of the pavement can be determined to stand the traffic loads. In the conventional calculation method, traffic loads are simplified to be uniform, circular and static, and so the distribution of pavement responses can be calculated using traditional plate theories. However, the results from this simplification are far from the actual responses, especially with the complicated traffic loading conditions on today's highways.

With the development of truck industry, more and more tire models have been supplied in the market to meet various tire requirements for different vehicles. Different tire models might induce different impacts to the pavement. Since the early 1990s, the conventional wide-base tires (385/65R22.5 and 425/65/R22.5) were proved to induce higher strain/stress to pavement structures and more cracking and rutting damage compared with dual tire assemblies [1–3].

At the same time, the last several years have seen an increase in the tire inflation pressure to transport oversized and overweight loads on highway. Based on the research conducted in the last several decades, TIP was proven to influence the tire-pavement contact stresses and pavement responses. As early as 1971, Seitz and Hubmann indicated that Tire Inflation Pressure (TIP) is an important factor which influences the distribution of the contact stresses [4]. In 1999, the experiment of Sime and Ashmore [5] indicated that TIP may affect the distributions of the contact pressure between tire and pavement obviously. In 2006, Fernando and his colleagues [6] evaluated the effect of tire size and inflation pressure on tire contact stresses and pavement responses.

As described above, the loading conditions on highways are far from the conventional simplification with numerous kinds of tires and different tire inflation pressures. In this case, in-situ monitoring is a good way to tell the influence of different loading conditions

on pavement responses under various circumstances. In the recent decades, many scholars in transportation field embedded sensors in pavements to study the influence of various loading conditions on pavement responses. In 2002, Al-Qadi and his colleagues measured pavement responses to different tire configurations with climatic parameters monitored at Virginia Smart Road [7]. In 2013, Xue and Weaver developed a methodology to compare the pavement responses induced by different tire configurations [8]. This methodology was also used to evaluate the influence of tire inflation pressure on pavement responses and distress predictions [9].

Based on the previous research, it is effective and reliable to instrument pavement sections and use the collected responses to evaluate the influence of various loading conditions. However, pavement instrumentation, experiment and following data analysis are very expensive. Therefore, a study, as presented in this paper, was made to find suitable locations of sensors in the top layer of pavement to evaluate the influence of loading conditions.

2 EXPERIMENT

The controlled load test was performed on the 100-mm and 200-mm thick Asphalt Concrete (AC) sections of the SPS-8 replacement sections: sections 39A803 and 39A804. These AC sections were constructed over a dense graded aggregate base at the Specific Performance Sections Experiment Number Eight (SPS-8) Ohio Strategic Highway Research Program (SHRP) Test Road. During the construction, Dynatest and Canadian strain gauges [10, 11] were placed; and after the construction, strain gauge Rosettes were retrofitted into 100-mm square holes cut through the AC surface layer as shown in Figure 1(a). After affixing the rossettes to the existing pavement, the removed part was back-filled and affixed to the pavement. X represents the direction of traffic, and Y represents the direction transverse to the traffic. One set of rosettes was placed 25 mm below the surface (referred as "top") and another 25 mm above the bottom of the AC layer (referred as "bottom"), each set in both the direction of, and transverse to, the direction of traffic, as shown in Figure 1 (b). For the purposes of this paper, the rosettes strains were used in the following data analysis because of their high survival rate, consistent signal quality, great conformability with the pavement structure and minimal effects from discontinuities. Based on Dynamic Cone Penetration Tests, the modulus of the base layer is 513 MPa; the modulus of the subgrade is 769 MPa.

A single-unit two-axle truck was used to conduct the load tests, as shown in Figure 2. The total weight of the loaded truck was 85.63 kN for the test series; the wheel base was 6.477 m. Four tire types and two configurations were used in the experiment: two wide-base and two duals. Tires were changed on-site as necessary. Table 1 lists the configuration parameters of the four involved tires.

The test runs of the experiment used three speeds (8, 40 and 89 km/hour), three tire inflation pressures (483, 689 and 827 kPa) on two pavement structures (100-mm and 200-mm thick). As a result, there were 18 test series (3 speeds $\times$ 3 tire inflation pressures $\times$ 2 thicknesses) for each kind of test tire listed in Table 1. Each test series was repeated at least three times or until three different tire prints around the gauges were achieved.

3 NUMERICAL SIMULATION

A new pavement analysis software 3D-Move, which is released by the University Nevada Reno, was used to calculate the strain responses in pavement. 3D-Move uses the continuum-based finite-layer approach to compute pavement responses. The software can take moving loads, three dimensional localized contact stress distribution of any shape, and viscoelastic material characterization for the pavement layers into consideration. The interface of 3D-Move is shown in Figure 3.

Due to the many advantages, 3D-Move was used to simulate the whole loading process numerically. In 1999, Sime and Ashmore [5] measured the localized stress distribution

under several tire models with different tire inflation pressure, including the two GoodYear tires in this experiment (Table 1), and the measured stress distributions were incorporated in the database of 3D-Move. The pavement structures, shown in the previous section, was modeled in 3D-Move, and the tire-vehicle interface pressure distribution, measured by Sime and Ashmore [5] in similar loading conditions (load and TIP), was applied on the viscoe-

lastic pavement model with the corresponding temperature and speed. The calculated strain responses are compared with the measured ones in Figure 4.

As shown in Figure 4, the calculated horizontal strain was smaller than the measured data, but calculated vertical strain was bigger than the measured one. In general, the distribution of strain responses calculated by 3D-Move match well with the measurement in shape, with obvious differences in magnitude. The main reason might include the inaccuracy of the modulus of the base material, the anisotropy of asphalt concrete and various uncontrollable conditions during the experiment.

The research group in UIUC leaded by Professor Al-Qadi [12] has been conducting lots of Finite Element simulations in the past decades and matched very well with experimental results in both shape and magnitude. Their computations and measurements are not presented and compared in this paper because the loading and environmental conditions in their experiment were totally different. Two reasons are proposed to explain that the 3D-Move simulation in this paper doesn't match with experimental measurements as well as the numerical simulation they conducted. The experiment described in this paper was conducted with manually driven individual truck instead of the accelerated loading equipment used in the UIUC's experiment [12], and so many loading conditions (wheel load, speed, wandering position, and so on) couldn't be controlled as well as in the UIUC's experiment. As a result, it is understandable that the comparison in Figure 4 is not as good as the one conducted in [12]. At the same time, it is also possible that Finite Element model developed by Al-Qadi is more accurate than the Finite Layer model used in 3D-Move in simulating pavement responses, but more research is necessary to compare 3D-Move with Finite Element method on computation accuracy and efficiency.

4 DATA ANALYSIS

Since the experiment was conducted in a hot weather (averaged 32 ºC), and shear deformation is the dominant cause of rutting in asphalt concrete when temperature is high [12], shear strain was chosen to reveal the difference between different locations in pavements. Comparisons about shear strain responses at different locations in the pavements are made in Figure 5.

As shown in Figure 5 (a-b), the shear strain in the transverse plane was much smaller and sharper than the longitudinal one, which meant that a little error in the original measured strain would be enlarged a lot when it was adjusted to the maximum value in the whole loading area. So according to the distribution of longitudinal and transverse shear strain, the conclusion was that the shear strain in the longitudinal plane is better to tell the difference of loading, in other words, the effect of various tires to the pavement.

Comparing the strain distributions at different depth in Figure 5, the distribution curves of shear strain at the bottom of the pavements were much milder than the ones at the top. The drastic fluctuations at the top might induce unreasonable error during the process of the offset distance adjustment. So theoretically, the adjustments with the distribution curve at the bottom of the pavement might have higher accuracy.

According to theoretical calculation, the shear strain in 4 inch pavement is larger than that in 8 inch pavement both at the top and the bottom, as shown in Figure 5, because of the stress transfer over the depth of the pavement.

To verify the conclusion above, all the available shear strains (two longitudinal and 2 transverse) under various tires loading were adjusted with 3D-Move simulation, and the statistics of the results are concluded as in Table 2. A few unbelievable results, which were far beyond reasonable range, were caused by the small error enlargement and deleted as outliners. The less was the average standard deviation; the better was the adjustment, since it means the adjustments for temperature, offset distance and speed, match well between different runs.

As shown in Table 2, the average standard deviation of adjusted shear strain in longitudinal plane was much lower than that in transverse plane for all the monitoring points throughout 4 inch and 8 inch pavements. At the same time, the standard deviations of the

Table 2. Standard deviation of adjusted shear strain with 3D-Move (10^{-6}).

	100-mm section				200-mm section			
	Longitudinal		Transverse		Longitudinal		Transverse	
	Top	Bottom	Top	Bottom	Top	Bottom	Top	Bottom
GoodYear widebase	216.3	133.5	288.1	454.7	164.6	152.9	650.8	515.3
GoodYear duals	163.7	115.5	314.3	256.6	279.1	78.0	836.6	363.9
Michelin widebase	263.8	106.4	729.2	256.5	308.9	76.3	674.5	144.1
Michelin duals	105.2	114.8	216.8	584.1	114.0	86.6	529.7	336.0

adjusted shear strain at the bottom of the pavement were much less than those at the top. The standard deviation of adjusted measurements validated the assumptions above: the strain distribution in the longitudinal plane at the bottom of pavements is the most stable and wild with the least drastic fluctuations, and most suitable to tell the differences between loading conditions.

5 CONCLUSIONS

This paper presents a study to find the best sensing location in pavement to evaluate loading conditions. Based on the data analysis of the measured strain responses, the best sensing location is in the longitudinal plane at the bottom of pavements, because the responses were more stable and convergent, and the responses match with viscoelastic analysis the best.

Structural and functional deterioration of porous asphalt pavement under moving wheel load in laboratory

Nobuyuki Yoshida & Syunpei Tani
Kobe University, Nada, Kobe, Japan

ABSTRACT: In Japan, the structural design method of porous asphalt pavement is presently empirical, and in order to apply porous asphalt pavement to heavy traffic roads in urban areas, the progress of both structural and functional damage to porous asphalt pavement due to traffic loads needs to be grasped. This paper describes an attempt that was made to understand the damage progress of porous asphalt pavement by carrying out a moving wheel load test on an instrumented small-scale porous asphalt pavement. The pavement consisted of a porous asphalt surface/binder layer, an asphalt-treated porous base-course, a crusher-run subbase-course and a sandy subgrade. The test was conducted in series with four conditions of (a) room temperature, (b) pavement surface temperature of 60°C, (c) room temperature after watering and (d) pavement surface temperature of 60°C after watering. It is shown that the load transmission function deteriorates with the number of wheel passing, especially under the higher temperature, that permeability in the rutted track is smaller than that in the other locations, and so on. This permeability deterioration is attributed to accumulated plastic deformation in the pavement but it is not easy to identify which layer controls this.

Keywords: Porous asphalt pavement, small-scale experiment, moving wheel load, earth pressure, permeability

1 INTRODUCTION

In Japan, porous asphalt pavement is used roughly in two ways: one is so-called "drainage" asphalt pavement and the other is "permeable" asphalt pavement as schematically shown in Figure 1. The former allows rainwater to enter from the road surface into the pavement but

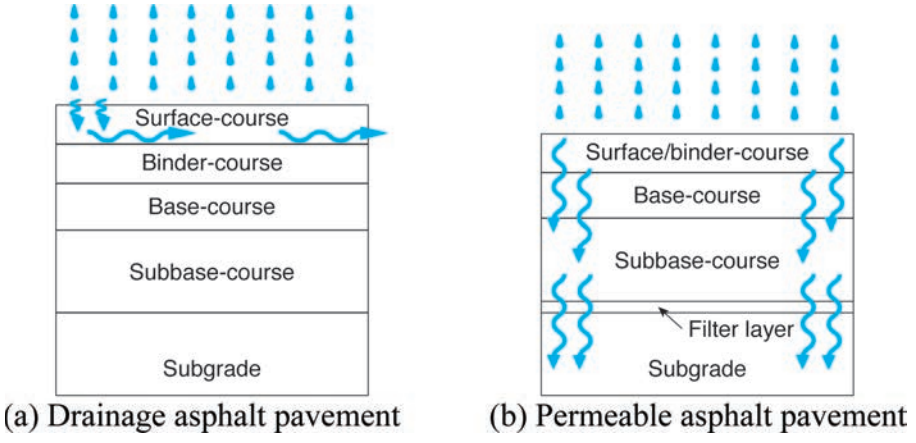

Figure 1. Typical porous asphalt pavements in Japan.

drains it laterally on the top or bottom faces of binder-course and the latter permits rainwater to flow further down to subbase-course, subgrade or further down. Drainage asphalt pavement was first adopted at an arterial road in Tokyo in 1987 and since then its construction is steadily increasing: for instance, about 25% of the area of national roads directly controlled by the government was replaced by the drainage asphalt pavement as of 2005 [1].

Regarding the permeable asphalt pavement on which this paper specifically focuses, its application to sidewalks was first explored around 1972 in Tokyo for improving soil conditions for roadside trees and walking difficulty in rainy days in urban areas and also for serving as flood control measures. From about 1984, then, the application of permeable asphalt pavement to sidewalks started in earnest. Presently, permeable asphalt pavements on sidewalks and parking areas are growing across the country. Meantime, some trial applications of permeable asphalt pavement to heavy traffic roads have been made in Japan mainly for flood countermeasure and groundwater recharge. In 2004, a law called Act on Countermeasures against Flood Damage of Specified Rivers Running Across Cities was put in force; by this, urban areas susceptible to flood damage had to take any measures. One of the measures is to replace existing usual asphalt pavements by permeable asphalt pavements. Since then, trial constructions of permeable asphalt pavement have gradually increased in national roads and some prefectural roads with limited follow-up investigations [2].

Permeable asphalt pavement is also used in other countries, but to the authors' knowledge, it is not too much to say that, unlike drainage asphalt pavement, most of them are as flood measures and a way of runoff management [3–6]. It has been favorably applied to sidewalks, car parks, pedestrian access, container yards, etc. but its application to heavy traffic roads seems scarce probably because there is no necessity of such.

The structural design method of porous asphalt pavement is empirical regardless of drainage or permeable one in Japan [7]. Considering the situation stated above, as long as permeable asphalt pavements concerned, it is urgent that a mechanistic design method be established. For this, it is needed to grasp the progress of structural damage and also functional deterioration such as permeability. This drove the authors to initiate a research program. In the research program, which has just started lately, a moving wheel load test on an instrumented small-scale permeable asphalt pavement has been carried out. In the followings, a brief outline of the moving wheel load test is presented first. Then, some of the results are described focusing on the vertical earth pressure, rut depth and permeability since the first two items reflect the structural damage and the third item the functional deterioration.

2 MOVING WHEEL LOAD TEST ON SMALL-SCALE PAVEMENT

2.1 *Test apparatus*

The test apparatus consists of three main components: a moving wheel load unit, a small-scale pavement unit and a control and data acquisition unit. Figure 2 is a bird's eye view of the moving wheel load unit together with the small-scale pavement. Regarding the moving wheel load unit, along the two guide rails of aluminum beams fixed on the high-strength steel frame, which are anchored to the concrete floor of the laboratory, a loaded wheel is moved back and forth on the small-scale pavement surface by a ball screw connected to an AC servomotor. The wheel is composed of a 100 mm-thick aluminum disk with a radius of 85 mm, of which outer periphery a 15 mm-thick hard rubber is bonded to. The wheel load is 1.37 kN. The wheel travel distance is 780 mm: a 110 mm from the both ends of the 1000 mm long small-scale pavement is marginal. The wheel speed is 19.22 m/min, which corresponds to twice the speed of the standard wheel tracking test in Japan [8]. Here, one travel counts the number of load applications as one.

The small-scale pavement tested here is a four-layered permeable asphalt pavement. Its structure is shown in Figure 3 together with installed sensors. The small-scale pavement is 800 mm wide and 1000 mm long but its height can vary depending on the thickness design. Here, the four-layered permeable asphalt pavement consists of a surface/binder-course and base-course of porous asphalt, a crusher-run subbase-course underlain by a sandy subgrade.

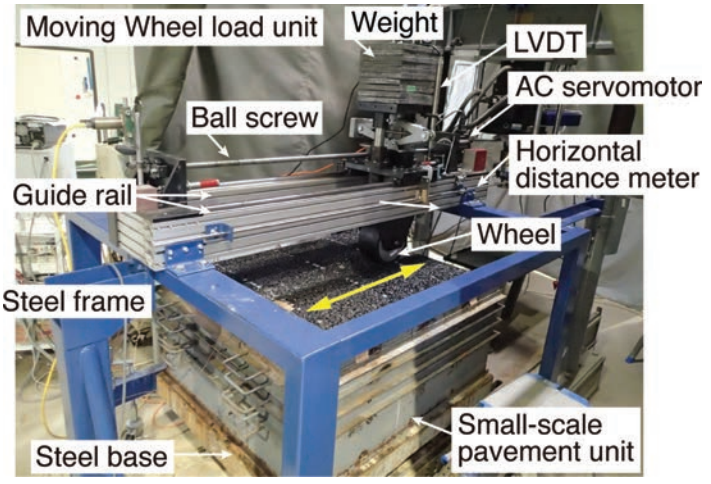

Figure 2. Moving wheel load test apparatus.

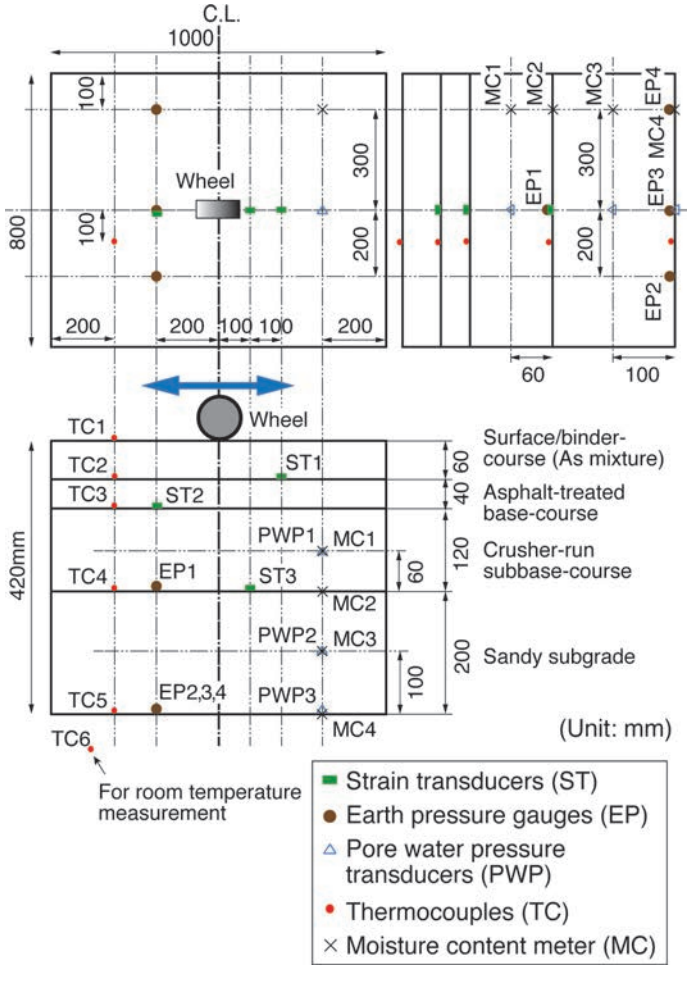

Figure 3. Small-scale asphalt pavement.

An actual empirical structural design of permeable asphalt pavement was first carried out with the conditions that: the design CBR is 12%, the design period is 10 years, the traffic volume class is N_7 (more than 3000 heavy vehicles per direction per day; the heaviest class) and the amount of seepage water per 15 seconds is greater than 1000 ml. Then, each thickness of the constituent layers was scaled down by being multiplied by 0.4, considering the size limit of the moving wheel load unit.

The surface/binder-course is 60 mm thick and made of a Type-H polymer-modified porous asphalt mixture (max. aggregate size of 13 mm) and the base-course is a 60 mm thick Type-II polymer-modified porous asphalt mixture (max. aggregate size of 20 mm). The grain size distributions and the Marshal stability test results of these two asphalt mixtures are given in Table 1. The subbase-course is 120 mm thick and made of a crusher-run (max. aggregate size of 30 mm) and the subgrade is 200 mm thick Toyoura sand. For the crusher-run, the maximum dry density and optimum water content are 2.267 g/cm^3 and 5.2%, respectively. The Toyoura sand has a maximum dry density of 1.584 g/m^3 and an optimum water content of 14.2%.

2.2 *Constuction of small-scale pavement*

The four-layered small-scale pavement was constructed as follows. First, a steel rectangular frame for the subgrade layer was fixed onto the steel base (Fig. 2); and at the same time, three earth pressure transducers, a pore water pressure transducer, a moisture content meter and a thermocouple were installed at the prescribed locations on the steel base shown in Figure 3. Then, Toyoura sand with its optimum water content was placed in the frame and compacted using a hand tamper and a 1 kN vibratory roller compactor till the amount required to achieve its maximum dry density was poured in. Meantime, at the specific locations on the face of 100 mm from the bottom, a pore water pressure transducer and a moisture content meter were carefully installed (Fig. 3). The surface roughness of the subgrade was then confirmed by using a straight edge ruler.

Next, the subbase-course was constructed in the similar way to the subgrade. A steel rectangular frame for subbase-course was stacked on the one for subgrade. After placing an earth pressure transducer, a strain transducer, a moisture content meter and a thermocouple

Table 1. Properties of porous asphalt layers.

Locations	Surface/binder-course	Base-course
Percentage finer by mass (%)		
31.5 mm		
26.5		100.0
19	100.0	98.1
13.2	97.3	55.3
4.75	18.6	27.6
2.36	14.1	14.8
0.6	10.6	10.0
0.3	8.0	7.0
0.15	5.5	4.6
0.075	4.5	3.5
Types of asphalt binders	Polymer modified asphalt (Type-H)	Polymer modified asphalt (Type-II)
Asphalt content (%)	5.0	3.5
Density (g/cm^3)	2.003	2.084
Theo. max density (g/cm^3)	2.511	2.571
Air void (%)	20.2	18.9
Marshal stability (kN)	5.21	5.31
Marshal flow (1/100 cm)	30	28
Dynamic stability (times/mm)	$\geqq 6000$	–
Permeability (m/sec)	11.57×10^{-4}	$\geqq 1.0 \times 10^{-4}$

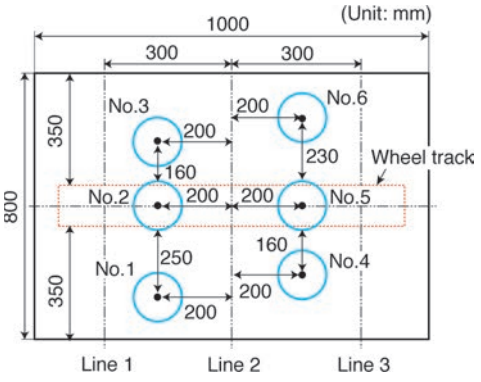

Figure 4. Locations of on-site permeability tests.

at the specific locations of subgrade surface, a prescribed amount of crusher-run with its optimum water content was poured in and compacted in the same way as for the subgrade; at the same time, a pore water pressure transducer and a moisture content meter were installed at a face of 60 mm from the subgrade surface.

Then, after stacking a steel rectangular frame for base-course on the one for subbase-course, a strain transducer and a thermocouple were installed at the prescribed locations of the subbase-course. The porous asphalt mixture for the base-course was carefully placed in and compacted using the hand tamper and 1 kN vibratory roller compactor so as not to cause a detrimental influence on the installed sensors.

Finally, the surface/binder-course was constructed in the same manner as the base-course after placing a strain transducer and a thermocouple at the prescribed locations on the base-course.

All the steel rectangular frames used in the preparation of small-scale pavement have an inner width of 800 mm, an inner length of 1000 mm and a variable height ranging from 20 to 50 mm depending on the thickness of the corresponding layer and the number of stacks.

2.3 *Test conditions*

The moving wheel load test was carried out sequentially under four environmental conditions: (a) room temperature, (b) 60°C pavement surface, (c) room temperature after watering the pavement surface and (d) 60°C pavement surface after watering the pavement surface. The test proceeded from the conditions (a) to (d): moving wheel load test continued till the number of load applications reached 10000 in each condition. Increasing the pavement surface temperature up to 60°C and maintaining it were done by turning on and off 6 pieces of 500-watt reflect lamps. Regarding the conditions (c) and (d), the pavement surface was watered evenly using a hose till the water seeped out at the bottom of subgrade without paying an attention to the flow rate and amount.

During all the tests, the room and pavement temperatures were monitored and at prescribed numbers of load applications, vertical earth pressure, horizontal strain, pore water pressure and surface roughness were measured. Moreover, after the completion of moving wheel load test at each condition, an on-site permeability test was carried out at six locations on the pavement surface shown in Figure 4, following the test method designated in the Manual of Pavement Investigation and Testing Method [9].

3 TEST RESULTS AND DISCUSSIONS

3.1 *Pavement temperature*

Figure 5 shows variations in the pavement temperature during the moving wheel load tests. Since all the tests were carried out in the mid December of 2012, the room temperature

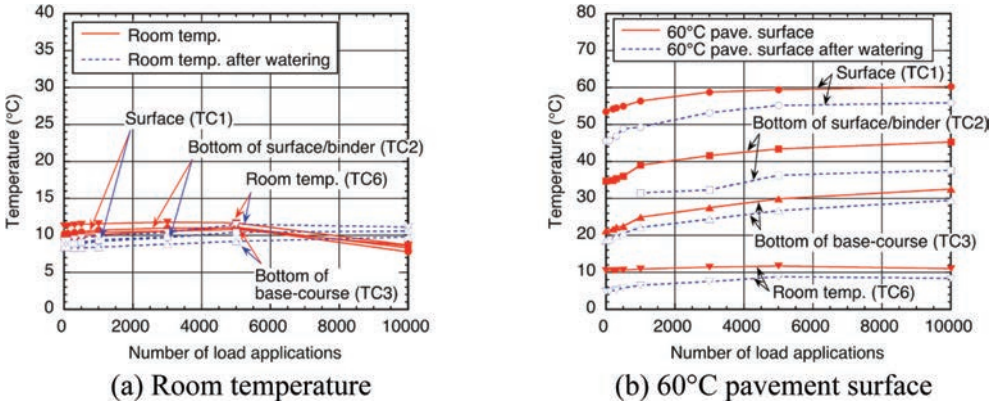

Figure 5. Pavement temperature variations during test.

was as low as about 10°C and showed little change for all the cases as can be seen in the figure.

In the case of the room temperature with or without watering, it is seen from Figure 5(a) that the pavement temperature shows only a little variation from the bottom of base-course to the pavement surface and is kept at about 10°C during the test. On the other hand, in the case of 60°C pavement surface without watering, the temperature control takes some time due to inexperienced handling of the six reflect lamps; that is, the surface temperature is about 54°C at the beginning but after the number of load applications of 3000, it is maintained at about 60°C as expected. It is also understood that there is a significant gradient in the vertical distribution of pavement temperature. At 10000 load applications, the temperature is 60°C at the pavement surface, 45°C at the bottom of surface/binder-course, 33°C at the bottom of base-course; the temperatures at the mid-depth of surface/binder-course and of base-course are about 53°C and 39°C, respectively.

In the case of 60°C pavement surface after watering, heating-up of the pavement surface using reflect lamps was conducted in the same way as for the 60°C pavement surface without watering; nonetheless, as seen in Figure 5(b), the pavement surface temperature does not reach 60°C even at the number of load applications of 10000 and is low by about 4°C. This is probably attributed to that the heating energy was consumed in evaporating water retained in the pavement. Thus, it is indicative that a surface temperature reduction effect can be expected in the permeable asphalt pavement.

3.2 *Vertical earth pressure*

Every time the test wheel passes over the embedded earth pressure gauges, vertical earth pressure is recorded in a waveform, from which the peak value is read out. Figure 6 shows changes in vertical earth pressure measured at the top and bottom of subgrade with the number of load applications for the four test conditions. At first glance, the cases of 60°C pavement surface with or without watering develop a larger vertical earth pressure than the cases of room temperature. This seems reasonable because the stiffness of both surface/binder and base-course becomes smaller due to a higher temperature, resulting in deterioration of their load transfer capability. At the top of subgrade, the vertical earth pressure increases rapidly in the early stage, then gradually; the ratios of vertical earth pressure at 1000-load applications to the initial value are 1.76 for the case of 60°C pavement surface and 1.80 for the 60°C pavement surface after watering.

In the case of room temperature without watering, it is seen in Figure 6(a) that the vertical earth pressures at the top and bottom of subgrade are about 6 kPa and 5 kPa, respectively and little change during the test. On the other hand, in the case of room temperature after watering, the vertical earth pressure gradually increases with the number of load applications

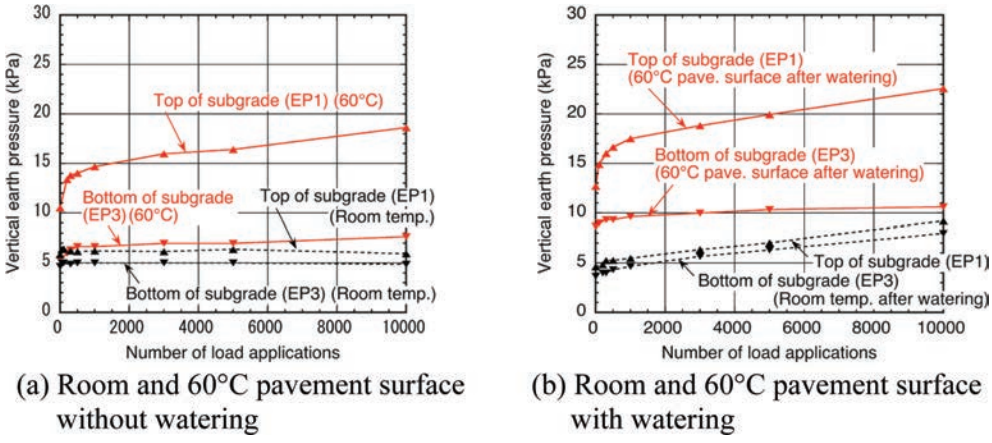

Figure 6. Changes in vertical earth pressure with number of load applications.

as seen in Figure 6(b). Taking into account the facts that the pavement temperature little changes (Fig. 5(a)) and that rut depth little increases during the test (see the next subsection and Fig. 8), this increase of vertical earth pressure can be attributed to the gradual deterioration of load transfer capability with an accumulation of wheel passes.

The horizontal distributions of vertical earth pressure measured at the bottom of subgrade are given in Figure 7 for the test conditions without watering. It is seen that, in the room temperature case, the magnitude of vertical earth pressure just below the wheel center is about 5 kPa and a vertical earth pressure of almost the same magnitude develops at a horizontal distance of 200 mm from the wheel center but at a distance of 300 mm, the vertical earth pressure drops down to about 2.5 kPa. The ratio of the vertical earth pressure just below the wheel center to that at a distance of 200 mm is about 1.0 initially and it little changes during the test. Similarly, the ratio of the vertical earth pressure just below the wheel center to that at a distance of 300 mm is about 0.5 and it remains almost unchanged. It can be said that, in the case of room temperature, the asphalt mixture layers (surface/binder-course and base-course) provide an excellent load transfer capability and it is sustained during 10000 load applications.

In the case of 60°C pavement surface, on the other hand, the vertical earth pressure is the largest just below the wheel center and decreases with distance from the wheel center, regardless of the number of load applications. Moreover, the vertical earth pressure at all three locations tends to increase with the number of load applications: for instance, from 5.3 kPa to 7.7 kPa just below the wheel center and from 3.5 kPa to 4.5 kPa at a distance of 200 mm. The ratio of the vertical earth pressure just below the wheel center to that at a distance of 200 mm is about 0.66 initially and it decreases asymptotically to 0.59 at the end. The ratio of the vertical earth pressure just below the wheel center to that at a distance of 300 mm is about 0.30 and it varies a little around 0.30 without any trend. Since the stiffness of asphalt mixture layers (surface/binder-course and base-course) decreases due to the elevated temperature and its load transfer capability deteriorates, the influence of wheel load on the pavement appears localized beneath the wheel. Furthermore, as the number of load application increases, the load transfer capability lowers with an accumulation of wheel passes.

Although not shown here, in the two cases with watering, the vertical earth pressure measured just below the wheel center and at a distance of 200 mm was larger than those without watering, especially just below the wheel center.

3.3 *Rut depth*

Changes of rut depth measured at three measurement lines (Fig. 4) on the centreline of wheel track during each test are plotted in Figure 8 in a consecutive manner. Note that for the cases

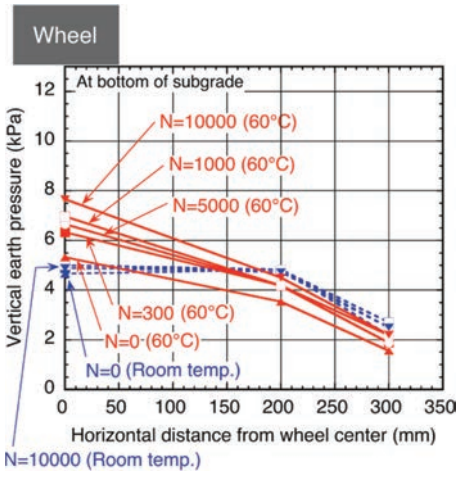

Figure 7. Horizontal distribution of vertical earth pressure in cases without watering.

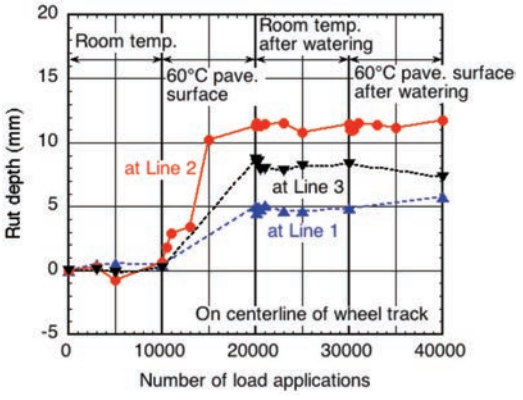

Figure 8. Changes of rut depth during test.

of 60°C pavement surface with and without watering, measurements of rut depth at Lines 1 and 3 were taken only at the beginning and end of each test because of avoiding a cumbersome operation of removing and attaching the reflect lamps. As seen in the figure, there is only a little rut developed in the room temperature condition but in the 60°C pavement surface condition, relatively large rut occurs: from 0.43 mm initially to 5.0 mm at the end at Line 1, from 0.65 mm to 11.3 mm at Line 2 and from 0.22 mm to 8.7 mm at Line 3. Figure 9 is a photo of pavement surface taken during the test, giving an image of rutting around Lines 2 and 3. After the 60°C pavement surface condition, rut depth seems not to increase as a whole, though only a little increase in rut depth may be noticed during the condition of the 60°C pavement surface after watering.

Rutting (vertical permanent displacement of pavement surface) is considered as an outcome of the accumulation of plastic deformation of each pavement constituent layer and it is speculated that beneath the rutted portion, void could be somewhat reduced.

3.4 *Permeability*

An on-site permeability test was carried out at the six locations shown in Figure 4 for the cases of room temperature and 60°C pavement surface. The two locations, 2 and 5, are in the

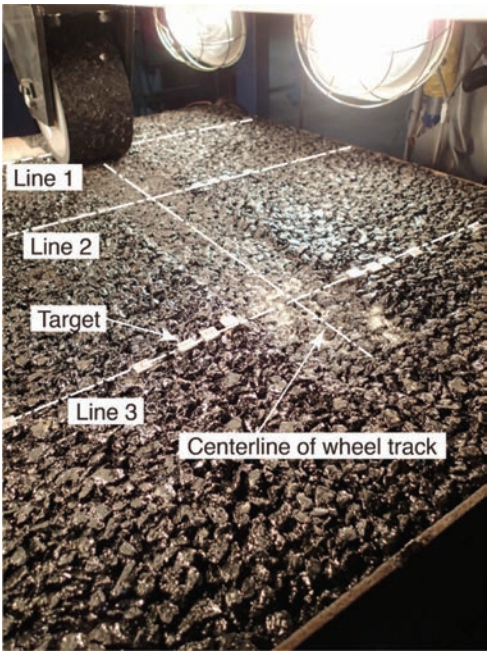

Figure 9. Rut along wheel track (60°C pavement surface condition).

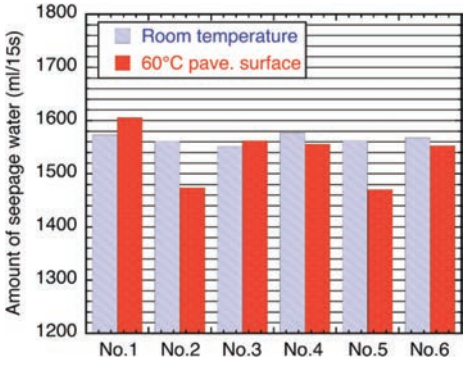

Figure 10. On-site permeability test results.

rutted portion. The test is a kind of falling head permeability test and measured is the time required for 400 ml of water to seep into pavement from its surface under an initial water head of 600 mm. Using the measured time and the amount of water, the amount of seepage water in ml/15 s is computed. Here, the test was carried out three times at each location and their average value was obtained.

Figure 10 summarizes the average amount of seepage water obtained at each location for the two cases. In the case of room temperature, it is seen that there is not much difference among the locations and the average value is 1566 ml/15 s which is almost the same as the value obtained immediately after the pavement was constructed. This is expected since there is little rut developed during the test. On the other hand, in the case of 60°C pavement surface, there is little difference in the amount of seepage water among the locations, 1, 3, 4 and 6, which are outside of the rutted portion: the average amount of seepage water is 1569 ml/15 s which is comparable to the value in the case of room temperature. The amount of seepage water at the location 2 is the same as that at the location 5, their average value

being 1472 ml/15 s; this is noticeably smaller than the other locations' values. Since these two locations are in the rutted portion as stated above, this reduced amount of seepage water seems to reflect a possible reduction of void at least in the surface/binder-course.

4 CONCLUSIONS

This paper describes a moving wheel load test on an instrumented small-scale permeable asphalt pavement conducted under four test conditions, the room temperature and 60°C pavement surface with or without watering, and some of the results are presented. The followings can be pointed out based on the study.

As expected, the influence of wheel load on the pavement is greater in the case of 60°C pavement surface than in the room temperature. At the elevated temperature, the stiffness of porous asphalt mixture layers decreases, leading to deterioration of load transfer function. It is further worsened by accumulation of wheel passes. As demonstrated in the test results, by these effects, the vertical earth pressure exerted on subgrade increased and rutting progressed. The permeability measured at the rutted portion of pavement surface was noticeably smaller than that at the other locations. This permeability deterioration seems to be attributed to accumulated plastic deformation in the pavement but it was not easy to identify which layer controls this. The permeability outside of the rutted portion of pavement surface was pretty much unchanged from the initial state. In reality, however, dust, tire rubber shavings, etc. would clog the near surface voids of permeable asphalt pavement, resulting in a long-lasting deterioration of permeability; it was outside the scope of this experimental study.

ABSTRACT: Flexible test road structures have been built and tested in Accelerated Pavement Tests (APT) using a Heavy Vehicle Simulator (HVS) at VTI in Sweden for 15 years. The objectives have been to investigate pavement responses and pavement performance behaviour which can be used to validate mechanistic performance schemes. The pavement structures have been instrumented to measure their responses and performance and the surface profile was estimated. Here the accuracy of the measurements was estimated and a performance prediction was carried out. The registrations of the measurements were rather smooth with good repeatability and acceptable accuracy. The response, performance and accumulation of permanent deformation were modelled and generally good agreement was established between the measurements and calculations. From the analysis a performance prediction can be carried out as a function of time to evaluate the performance of new road concepts and maintenance strategies. The performance prediction provides the option of performing a life cycle cost analysis which can decrease both costs and environmental impacts.

Keywords: Accelerated Pavement Testing, Heavy Vehicle Simulator, instrumentation, response modelling, performance prediction

1 INTRODUCTION

For the development of mechanistic designing methods to proceed, the behaviour and properties of the pavement materials have to be properly understood under various traffic loadings and environmental conditions. The Accelerated Pavement Test (APT) is a test performed on full scale instrumented test roads, where the magnitude and location of the applied loads, the number of load repetitions and the environmental conditions are controlled. At regular intervals condition surveys and pavement response measurement are performed giving valuable validation data for the mechanistic designing methods. The development of APT with instrumented pavement structures has increased the understanding of pavement behaviour and built a foundation for new, more sophisticated design methods [1].

At the Swedish National Road and Transport Research Institute (VTI) flexible road structures have been built and tested in an APT using a Heavy Vehicle Simulator (HVS) for the last 15 years. The HVS machine operated at VTI (HVS Mark IV) is a mobile linear full-scale accelerated road-testing machine with a heating/cooling chamber system to keep a constant pavement temperature during testing. The objectives have been to investigate pavement responses and degradation development to understand pavement behaviour. This information can be used to validate mechanistic performance schemes. The pavement structures have been instrumented to measure their responses and performance and the surface profile was

also measured. From the data the response, performance and accumulation of permanent deformation can be calculated and a performance prediction done as a function of time for different materials, structures, climate conditions and traffic. The HVS machine can be used to evaluate new road concepts and maintenance strategies by assessing the total cost of constructing, maintaining and operating different road constructions under various conditions. A life cycle cost assessment comparison between investment alternatives of feasible designs can then be performed to decrease costs and environmental impact of road structures [2–6].

2 THE PAVEMENT STRUCTURE AND TESTING PROCEDURE

2.1 *The pavement structure*

Several pavements have been tested at VTI during the 15 years of operation. The main focus has been on flexible pavement structures with high quality base and subbase material. Tested pavements, both in the field and at VTI's test facility are constructed by normal road construction machinery. The VTI indoor full scale test facility has three test pits that are 3 m deep, 5 m wide and 15 m long, but the length of the monitored structure is normally 6 m. One of the tested structures referred to as SE10 is described here; it represents a typical flexible pavement structure according to the Swedish Road Administration [7–10]. The structure was equipped with the present instrumentation used at VTI: εMU coils, Soil Pressure Cells (SPC), Linear Variable Differential Transducers (LVDT's), and Asphalt Strain Gauges (ASG) to measure their response and performance, as well as moisture content sensors (Fig. 1). A laser beam on a straight edge was also used to measure the surface profile [2–6].

The structure (Fig. 1) consisted of a Hot Mix Asphalt (HMA) divided into a surface course (AC pen 70/100; d_{max} = 16 mm) and a bituminous road base (AC pen 160/220; d_{max} = 32 mm). Under the asphalt were two layers of unbound crushed rock (granite), a base layer (0–32 mm) and a subbase layer (0–90 mm). The subgrade consisted of silty sand. The structure was instrumented to measure stress, strain and deflection responses as a function of load repetitions as well as permanent deformation manifested on the surface as rutting (Fig. 1) [2].

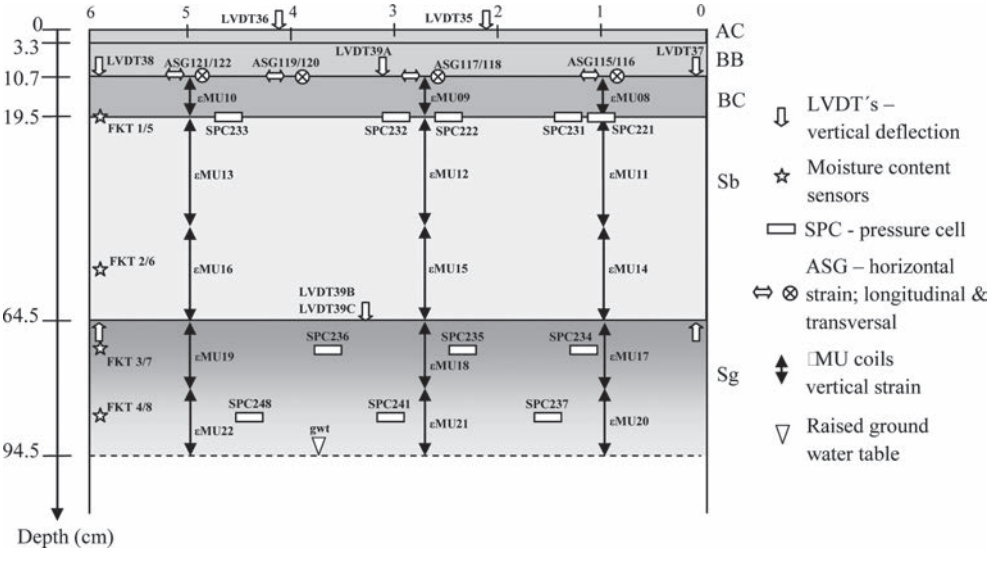

Figure 1. Cross section of the pavement structure SE10 (AC—asphalt concrete, BB—bituminous base, BC—granular base course, Sb—granular subbase and Sg—subgrade), along with its instrumentation. SPC221 and SPC222 are from the University of Nottingham, other pressure cells were from Geokon. Profile measurements are taken for 5 sections at one meter intervals (1 to 5).

2.2 *The testing procedure*

The test procedure was typical for the HVS testing performed at VTI. The test was divided into three phases with bidirectional loading applied in all the phases [2]:

- Pre-loading phase: for post-compaction, 20,000 load repetitions applying light loading (30 kN single wheel load and 700 kPa tyre pressure).
- Response phase: where responses are estimated from single and dual wheel configuration using various tyre pressures and axle loads.
- Main accelerating loading test: with more than one million load cycles applied, dual wheel configuration, 120 kN axle load (60 kN dual wheel load) and 800 kPa tyre pressure.

The dual wheel configuration had a centre to centre spacing of 34 cm. The lateral distribution of the loading followed a normal distribution where the wander was divided into eleven segments in steps of 5 cm, from plus to minus 25 cm. Half-way through the test water was added to the level of approximately 30 cm below the top of the subgrade, which is supposedly the worst case in Sweden (Fig. 1). No other alternations are usually made [2–5].

3 ACCURACY OF THE MEASUREMENTS

In the following figures a dual tyre loading was used; the registration taken under the centre of one of the wheels at a 120 kN axle load, 800 kPa tyre pressure, the speed of a rolling wheel of 12 km/h, and a constant temperature of 10°C. The responses are shown for both "moist", before the groundwater table was raised, and "wet" state, after the groundwater table was raised. The registrations of the measurements were rather smooth with some exceptions in the εMU coils, where the signal showed some noise. To assure reliability, in most cases multiple sensors were used at each depth, but it is recommended to have at least three sensors at each measured depth due to difficulties in measuring the response of unbound materials. This is due to the inhomogeneous nature of the materials and other variants influencing the results such as compaction and quality of the contact between the material and the meters.

3.1 *Moisture content sensors*

Water content reflectometer, CS616, from Campbell Scientific [11] was used to measure the volumetric water content in the pavement structure. In Figure 2 the water content of the structure (SE10) over the testing time is shown as well as the average moisture content with depth. In the figure MM1 and MM2 represent the measurements from meters 1 and 2. The measurements were stable and good correlation was observed between sensors, with the least correlation in the coarse subbase layer.

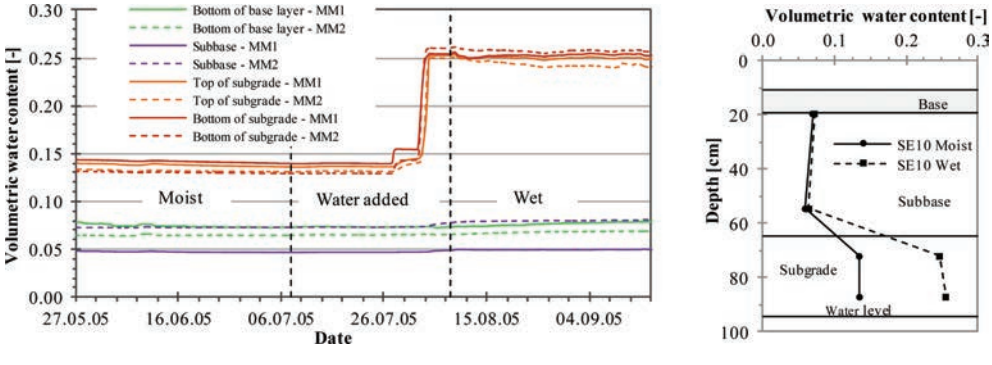

Figure 2. Change in the volumetric water content with time and as a function of depth.

3.2 *εMU coils*

Strain measuring unit or εMU coils (inductive coils) were used to measure the vertical strain, both elastic and permanent [12]. In Figure 3 the strain development is shown. The measurements were fairly constant over the "moist" and "wet" phases but all the sensors showed higher readings once the groundwater table was raised, indicating a softer structure. Typical values of the induced vertical strain registration of the εMU sensors are shown in Figure 4, with the measurements taken approximately in the middle of the "moist" and "wet" phases.

Individual sensors showed reasonable performance with most of them having less than 10% variation and only two around 20%, which is less variation than observed in previous tests. There was a slightly higher difference between sensors at the same depth in SE10 compared to previous tests. The difference varied from 8.8% up to 42.7%, but two sensors out of three were often close to one another, indicating the importance of having at least three sensors at each depth.

3.3 *Soil Pressure Cells (SPC)*

Soil Pressure Cells (SPC) or earth pressure cells are used to obtain the vertical stresses in the unbound pavement layers and subgrade soil. In SE10 earth pressure cells from Geokon

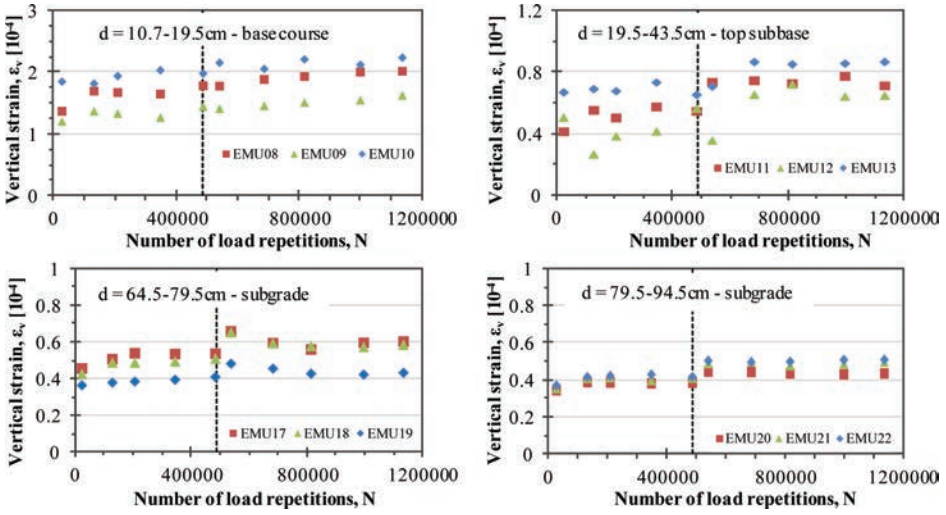

Figure 3. Induced vertical strain as a function of load repetitions for SE10 at depths from 10.7–19.5 cm, 19.5–43.5 cm, etc. (see Fig. 1). The vertical dotted lines indicate when the groundwater table was raised.

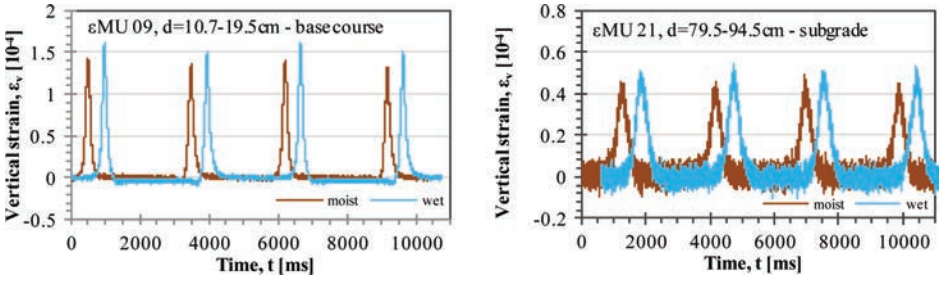

Figure 4. Induced vertical strain registration of εMU sensors at depths from 10.7–19.5 cm and 79.5–94.5 cm for SE10 in "moist" and "wet" states.

(Geokon 3500 pressure cells) were mainly used, but some older ones from the University of Nottingham were also included (Fig. 1) [13, 14]. In Figure 5 the vertical stress as a function of load repetitions is shown; the stress was reasonably constant during the first part of the main testing phase with a gradual increase as the test continued, indicating some post-compaction. The stress values decreased as the water was added, indicating a softer structure. Individual sensors in SE10 showed better performance than observed in previous tests. All the sensors in SE10 were under 8% variation in the "moist" state but the difference was higher in the "wet" state with a maximum of 28%. When examining the difference between sensors at the same depth the importance of having at least three SPC sensors at each depth is clearly visible.

3.4 *Linear Variable Differential Transducers (LVDT's)*

Linear Variable Differential Transducers (LVDTs) were used to measure the vertical deflection within a pavement structure in relation to the bottom of the test pit and over the base and subbase layers (Fig. 1). The development of resilient deformation measured with LVDTs is presented in Figure 6. The deformation was reasonably constant in the "moist" and "wet" phases, but it increased when the groundwater table was raised. A maximum of two LVDTs were placed at each depth and in some cases only one meter was in place due to practical limitations, but LVDTs are known for its accuracy.

3.5 *Asphalt Strain Gauges (ASG)*

Asphalt concrete Strain Gauges (ASG) (H-bar) of type PAST II AC produced by Dynatest were used to obtain the in-situ tensile strain at the bottom of the asphalt bound layers. In Figure 7 the tensile strain as a function of load repetitions is shown. The registered values were reasonably constant for individual sensors in the "moist" and "wet" states but the difference between sensors was great. The shape of the signal was as expected but the tensile

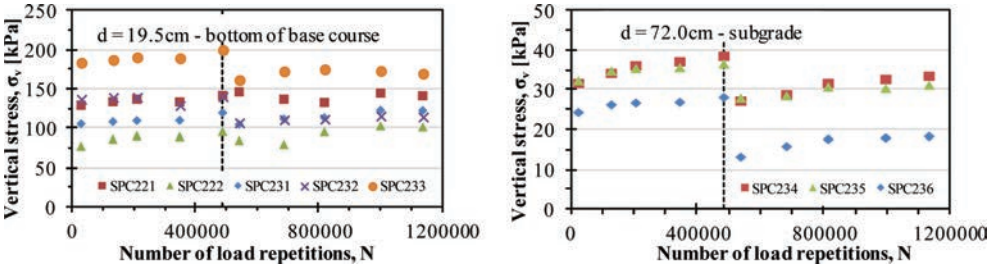

Figure 5. Vertical stress as a function of load repetitions for SE10, at depths 19.5 and 72.0 cm (see Fig. 1). The vertical dotted lines indicate when the groundwater table was raised.

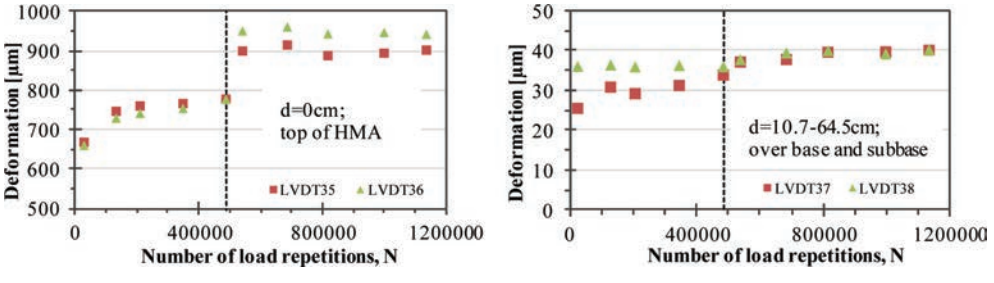

Figure 6. Induced deformation measure with LVDTs for SE10; from the bottom of the testing pit to the top of the HMA layers and over the base and subbase layers (see Fig. 1). The vertical dotted lines indicate when the groundwater table was raised.

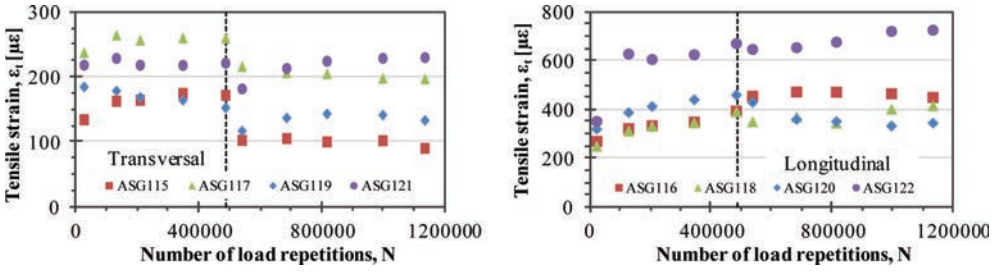

Figure 7. Induced tensile strain registration of ASG gauges at the bottom of the bituminous base for SE10 (see Fig. 1). The vertical dotted lines indicate when the groundwater table was raised.

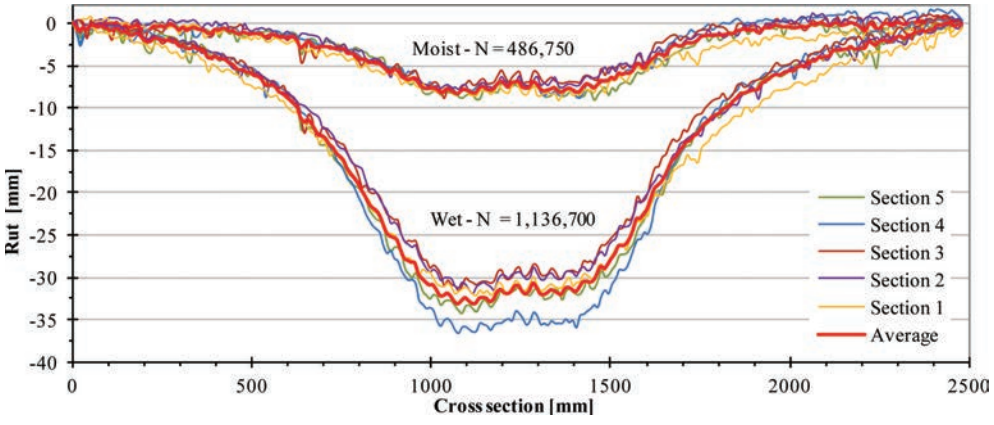

Figure 8. Cross section of the rutting profile after 486,750 load repetitions in the "moist" state and in the "wet" state after 1,136,700 load repetitions. Measurements were taken at 5 different sections, indicated by profiles 1–5 (Fig. 1).

strain was higher in the longitudinal direction than the transversal. For a single wheel the transversal tensile strain is normally higher but the situation is more complex with a dual wheel configuration. There are many factors that affect the tensile strain such as the wheel configuration, the tyre type and pressure, the material properties, the speed of the loading wheel and the applied load [15–17]. Generally the tensile strain increases with increased moisture content but here a decrease was observed in most cases. This should not have happened and indicates some error in the installation of the devices or, for example, a change in the properties of surrounding materials, some post-compaction or insufficient binding [6].

3.6 *Laser to measure the profile*

A custom-made laser beam on a straight edge has been used to measure the pavement profile. The laser measures the transverse profile of the pavement and then the data are converted to calculate the rut depth development under the straight-edge. The use of a laser has been proven to be reasonably accurate to estimate the amount of rutting at the surface. In Figure 8 the rutting profile at all measured sections for SE10 is shown at the end of the "moist" phase after 487,500 load repetitions and at the end of the "wet" phase after 1,136,700 load repetitions. The registered values were reasonably constant in the "moist" and "wet" states and a reasonable correlation between profiles was observed. The big impact water had on the structure can clearly be seen in the figure, with a great increase in rutting once the water was introduced.

4 RESPONSE MODELLING AND ANALYSIS

The response, performance and accumulation of permanent deformation are modelled to demonstrate a typical data process. From the analysis a performance prediction can be carried out as a function of time to evaluate the performance of new road concepts and maintenance strategies [18].

The pavement structure was modelled in an axisymmetric analysis where the responses were calculated using a Multi-Layer Elastic Theory (MLET) with the computer program ERAPAVE (EP) [19, 20]. The analysis was carried out with the asphalt bound layers and the subgrade treated as linear elastic materials. The stiffness modulus for granular materials (base and subbase) was treated as stress dependent [21, 22]:

$$M_r = k_1 p_a \left(\frac{3p}{p_a} \right)^{k_2} \tag{1}$$

where k_1 and k_2 are experimentally determined constants, p is the mean normal stress level of the loading, i.e. $p = \frac{1}{3}(\sigma_1 + \sigma_2 + \sigma_3)$ where σ_1, σ_2 and σ_3 are principal stresses, and p_a is a reference pressure, $p_a = 100$ kPa. This relationship has been shown to be able to capture the main behaviour characteristics of unbound granular materials under various rolling wheel loading situations [8, 9, 23].

The material parameters used in the numerical analyses of the responses are given in Table 1. When estimating the material parameters results from Plate Load (PL) tests, Falling Weight Deflectometer (FWD) tests, Indirect Tension Tests (ITT) of the bituminous layers and Repeated Load Triaxial (RLT) tests of the unbound layers were considered [2, 9, 18, 24]. The material parameters for the HVS testing were optimized for dual wheel configuration, under the centre of one of the tyres, with an applied axle load of 120 kN and 800 kPa tyre pressure. In all layers Poisson's ratio (ν) was set to 0.35. The parameters used in the permanent deformation predictions were estimated based on the materials being used as well as compaction, degree of saturation and stress state, where appropriate. The cohesion, c, was reduced by 10% from "moist" to "wet" state in the base and subbase layers and by 50% in the subgrade [18, 25–27].

Table 1. Material parameters of different layers used in the response analyses and of the unbound layers to predict the permanent deformation with the KT model.

		Response analysis				Permanent deformation			
SE10		E/M_r [MPa]	k_1 [–]	k_2 [–]	γ[kN/m^3]	c [kPa]	ϕ [°]	C [10^{-4}]	b [–]
Asphalt concrete	Moist	3500	–	–	24	–	–	–	–
	Wet					–	–	–	–
Bituminous base	Moist	3500	–	–	24	–	–	–	–
	Wet					–	–	–	–
Unbound base	Moist	–	500	0.6	20	40	43	1.1	0.35
	Wet		400			36		75	0.05
Unbound subbase									
Upper half	Moist	–	1450	0.6	19	40	43	0.6	0.33
	Wet		1150			36		440	0.05
Lower half	Moist	–	2850	0.6	19	40		0.5	0.31
	Wet		1550			36		330	0.05
Subgrade	Moist	50	–	–	16	14	35	0.05	0.55
	Wet	45				7		1.3	0.3

In table, E—Young modulus of bound materials; M_r—Resilient stiffness of unbound materials; γ—Unit weight.

The accumulation of the vertical strain in the unbound pavement materials was modelled according to a procedure developed by Korkiala-Tanttu (KT) [28, 29]. The KT model is a simple work hardening material model for unbound material:

$$\hat{\varepsilon}_p(N) = C \cdot N^b \cdot \frac{R}{A - R} \tag{2}$$

where $\hat{\varepsilon}_p$ is the accumulated vertical permanent strain, C is a material parameter depending on the compaction and saturation degree, N stands for the number of load repetitions, b is a shear ratio parameter depending on the material and stress state, R is the deviatoric stress ratio defined as, $R = q/q_f = \sigma_1 - \sigma_3/q_0 + Mp$, where $M = 6 \cdot \sin\phi/3 - \sin\phi$ and $q_0 = c \cdot 6 \cdot \cos\phi/3 - \sin\phi$, defined by the static Mohr Coulomb failure envelope, and A is the maximum value of R (here taken as 1.05).

The permanent deformation of the granular layers is gained by multiplying the permanent strain with the thickness of the layer (sublayer). Each layer has been divided into sublayers and the total deformation occurring in each layer is determined by summing up the permanent deformation over the sublayers. The lateral wander of the traffic is further accounted for by using the time-hardening summation approach, taking the calculated principal stresses representing the field conditions in the middle point of each layer over the area the wheels travel over [18, 20, 30, 31]. The calculations in Figures 9 and 10 were performed by using the KT model and the responses from MLET (ERAPAVE). The measured deformation of the asphalt bound layers was less than 1 mm, as the test was performed at a constant temperature of 10°C, and therefore not taken into account. In Figure 9 the rutting profile is displayed after 5 different load repetitions; two profiles are in the "moist" state and three in the "wet" state. The rutting profile in the "moist" state is overestimated, as well as the predicted rutting first after the water was added, but a fairly good correlation is reached in the end with a slight underestimation of the amount of rutting.

The Measurement (MM) of accumulated permanent deformation as a function of load repetition and the predicted deformation are displayed in Figure 10. In the figure the permanent deformation is shown for the base course, the subbase, and the top 30 cm of the subgrade, as well as the total deformation of the structure. In all layers the raised groundwater table accelerated the development of the permanent deformation, with the base layer showing the smallest increase whilst the subgrade showed the largest and greatest extent of increase in permanent deformation.

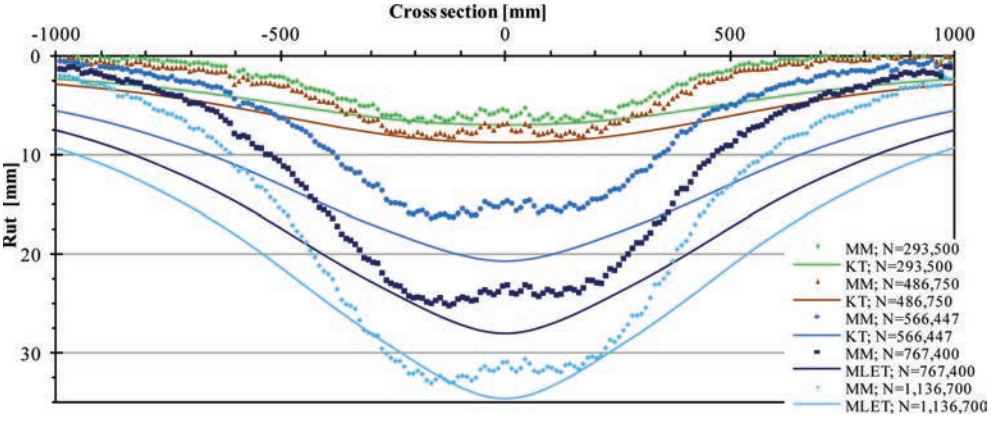

Figure 9. Cross section of the rutting profile after different numbers of load repetitions, two in the "moist" state (N = 293,500 and N = 486,750) and three in the "wet" state (N = 566,447, N = 767,400 and N = 1,136,700).

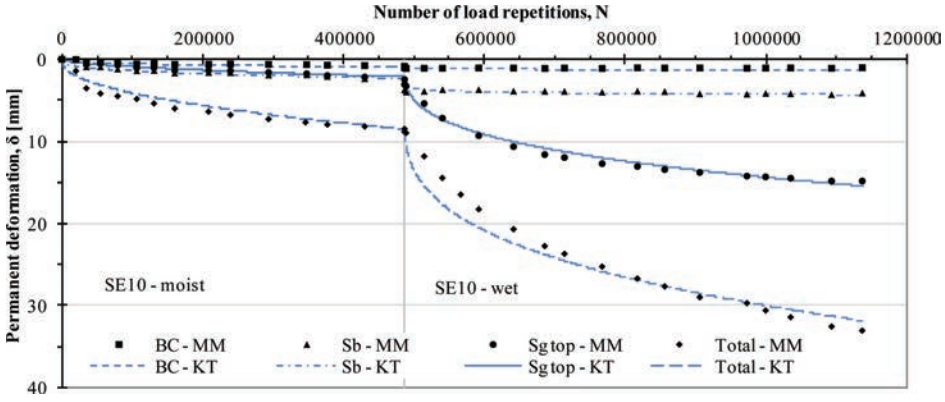

Figure 10. Permanent deformation in the unbound layers.

5 CONCLUSIONS

After 15 years of operating the HVS machine the test procedure and instrumentation have become quite robust. Test road structures have been built and tested to investigate their performance behaviour. The performance behaviour can thereafter be used for validation in a mechanistic performance scheme. A good correlation is observed between the measurements and calculations giving trustworthy results. These results can improve our understanding of pavement materials under a moving wheel loading.

It is believed that the accuracy of the pavements instrumentation is acceptable. In general the agreements were better for vertical strains than for stresses, but often it is more difficult to measure the vertical stresses in granular materials because of the complex inherent intergranular interactions between the aggregate particles and the sensors. The variation of the measurements for all sensors decreased as their location depth increased, most likely due to the fact that the influence of the dynamic loading diminishes with depth as well as having finer and more homogenous material in the subgrade. The ASG sensors performed fairly well but this was the only meter where a better performance was gained in previous tests compared to SE10, described here. As two sensors out of three at the same depth often gave good correlation it is recommended that at least three sensors be used at each depth. Due to the inhomogeneous nature of unbound materials it can be hard to measure their responses, with many factors influencing the results such as compaction and the quality of the contact between the meter and the material being measured.

ABSTRACT: Oxidative aging of asphalt binder is a well-known phenomenon that has been studied by numerous researchers. Significant breakthroughs have been made in the fundamental understanding of this phenomenon at the asphalt binder level, and practicing engineers now have the tools needed to quantitatively assess the oxidative aging potential of these materials. Conversely, pavement engineers do not have a reliable method to assess the oxidative aging potential of an asphalt mixture because it is unclear exactly how aging in the asphalt binder affects the behaviour of asphalt mixture. Analysis that supports the use of existing models for this purpose is shown in this paper. The study begins with an examination of the effects of oxidative aging on binder and mixture moduli. Then, four existing predictive models that relate these moduli are examined. It is found that all four models do an adequate job of predicting the effect of asphalt binder oxidation on asphalt mixture modulus, but that two of the models, the Witczak models, match the trends observed in mixture experiments the best.

Keywords: oxidative aging, asphalt binder, asphalt mixture, dynamic modulus

1 INTRODUCTION

Aging has long been recognized as a major distress mechanism for asphalt concrete and by extension asphalt pavements, but the term aging can have multiple meanings. For some it is applied to mean the overall deterioration of an asphalt pavement from exposure to both climatological and load factors. In other cases, aging is meant to describe only the effects of climate, which includes oxidative aging, ultraviolet radiation, and moisture related damage [1]. The more common usage of the term aging, and the meaning of the term as used in this paper, is as a descriptor for the process of asphalt binder oxidation. This process causes the material to stiffen and embrittle, which leads to a higher potential for cracking.

The issue of oxidative aging in asphalt binder has been recognized and studied for almost a century. Hubbard and Reeve [2] published the results of a study examining the effect of a year of outdoor weathering on the physical and chemical properties of paving grade asphalt cements. Subsequent historical studies confirmed the basic findings that oxidation, and not volatilization alone, was responsible for the changes in asphalt properties which occurred due to exposure [3–5]. Significant literature has also been produced on the chemical aspects of the aging process and excellent reviews of these studies are given in the literature [1, 6, 7]. In some of the cited studies, researchers have used sophisticated experimental studies to propose conceptual, empirical and/or analytical models for the aging phenomenon in asphalt binder [8–11].

Probably the most well-known binder based aging model is the Global Aging System (GAS) model [12]. This empirical model includes relationships to predict the change in viscosity within an asphalt mixture both with time and with depth in an asphalt pavement structure. While certain aspects of this model have been criticized, the model predicts two trends that most agree to be fact; 1) aging occurs most quickly after initial construction and 2) aging effects are greatest near the pavement surface. An alternative to the GAS model is the transport model, developed through several independent research efforts under the direction of Dr. Charles Glover [8, 9, 11]. In comparison to the GAS model, the transport model treats the asphalt binder aging phenomenon with more scientific rigor and is thus believed to produce a more reliable aging to depth relationship.

A review of the pertinent literature shows that while significant research has been devoted to better understanding and modelling the aging phenomenon of asphalt binder, relatively little has been devoted to aging in asphalt mixtures [13–16]. The lack of significant research in this area, particularly in the years since the Strategic Highway Research Program (SHRP) concluded, is a reflection of the complexity involved in asphalt binder aging alone. When additional factors, like physico-chemical interactions between asphalt binder and aggregates occur and when the material becomes structured and contains air voids, the aging process becomes more complex. However, to date, there exists no comprehensive study that links the known behaviour of an asphalt binder to those of the asphalt mixtures. The lack of such a study makes it almost impossible to rigorously judge the impact of certain conditions on asphalt mixture behaviour simply by measuring the impacts of those changes on the properties of asphalt binder. Without such a study, and given the current state of understanding of this relationship, it is argued that the only way to determine the impact of aging on mixture properties is direct experimentation of the mixtures [17–19]. The complexity of the problem is quite staggering when one considers that in mixtures; 1) the aging kinetics are highly binder specific and dependent upon temperature; 2) physico-chemical interactions may be significant, 3) thermal exposure during the mixing and placement operations can be highly variable and in some cases not very well controlled; and 4) void content can vary. With these issues in mind, the objectives of this paper are to report on and demonstrate the following;

1. The effect of oxidative aging on the apparent viscosity of asphalt binder and how this effect compares with changes in the asphalt binder LVE properties after oxidative aging,
2. The effect of oxidative aging on the LVE response of asphalt mixture over the range of typical in-service temperatures, and
3. The ability of existing analytical models that relate asphalt binder and asphalt mixture LVE behaviours to capture the effect of asphalt binder aging on asphalt mixture modulus, and

This work is not intended to develop a new model, but rather to provide quantified evidence that existing tools can be used to provide insight into the effects of asphalt binder oxidation on asphalt mixture modulus. While this may be expected, the authors have been unable to identify any existing literature that attempts to confirm the hypothesis. Additionally, it should be understood that oxidation impacts behaviours beyond the LVE range (cracking, permanent deformation, etc.), but it is believed that before such impacts can be fully understood that the relationships within the LVE range must be first studied.

2 MATERIALS

The materials used in this study have been compiled from numerous studies and separated into two databases; one for asphalt mixtures (Table 1) and one for asphalt binders (Table 2). Both databases represent a broad range in material characteristics and together afford a unique opportunity to compare and contrast viscosity and rheological based aging characteristics over the range of conditions typically experienced in-service.

Viscosity data are available for all of the asphalt binders in the form of the viscosity temperature susceptibility relationship (A and VTS) coefficients. The dynamic shear modulus,

$|G^*|$, has been measured using the Dynamic Shear Rheometer (DSR) and is available for the combination of temperatures between 15°C and 115°C and frequencies between 0.1 and 100 radians per second. Some of the asphalt binders have beam stiffness measured with the Bending Beam Rheometer (BBR) for temperatures between approximately –30° and –10°C and for times between 8 and 240 seconds. Available binder conditions include; Original (unaged), RTFO aged, PAV aged at the standard temperature, PAV aged at 110°C (PAV110), and recovered from an asphalt mixture (REC). Mixture data is available for the unaged, STOA, LTOA, plant mixed, and field aged conditions. Since the binder RTFO and mixture STOA are meant to represent the materials after placement, they serve as the datum for comparison between and among materials.

3 AGING AND ASPHALT BINDER PROPERTIES

It is well known that asphalt binder becomes stiffer as oxidative aging occurs. Historically, this effect is quantified with aging indices defined as shown in Equation (1).

$$AR = \frac{A_{age}}{A_{ref}} \tag{1}$$

where, A_{ref} is the binder property, viscosity or $|G^*|$, at some reference condition and A_{age} is the same binder property determined at a different aging condition but the same temperature-rate/frequency combination. The advantage of AR is its simplicity and that it works well to quickly show the aging sensitivity of a given material. Its disadvantage is that when defined at a single temperature, it does not provide a full picture of the effects of oxidative aging over the range of conditions that would be experienced under service [20]. In this analysis, ARs will be calculated based on both viscosity and $|G^*|$, using the basic form in Equation (1), but at various temperatures and frequencies of loading. In both cases the RTFO aged binder will serve as the reference condition.

3.1 *Aging effects on viscosity*

Viscosity values are determined for all of the asphalt binders in the database using the A and VTS function, Equation (2). This equation has been characterized for each material by using viscosity measures such as kinematic viscosity, absolute viscosity, penetration, etc. It is assumed, based on the work of others [12], that a maximum viscosity of 2.7×10^{12} cP exists for all materials.

$$\log\left(\log(\eta)\right) = A + VTS\log\left(T_R\right) \tag{2}$$

where, η is the viscosity in cP, A is the intercept of the temperature susceptibility relationship, VTS is the slope of the temperature susceptibility relationship, and T_R is the temperature in Rankine.

The results of viscosity based aging analysis are shown in Table 3 for 5° and 54°C. Although 5° and 54°C are shown, the *AR* values have been computed for −10°, 5°, 20°, 40° and 54°C, which together represent the range of in-service conditions. Through the analysis, it is found that the *AR* can be strongly dependent on temperature, see for example the MnRoad binders at the PAV aging condition. The aging characteristics are also found to depend on the specific binder and aging condition examined, but no clear correlation exists for predicting how the *AR* will manifest itself for the PAV condition given the behaviour of the Original binder. In some cases asphalt binders that show significant effect from the RTFO aging, show little effect from the PAV aging, see the Maryland PMB. In other cases, such as the MnRoad Pen 120/150 asphalt binder, significant Original to RTFO aging is observed and a large RTFO to PAV change is also observed. Note that several asphalt binders are found to have *AR* of 1 at −10°C (not shown), due to the assumption that the maximum viscosity of the asphalt binder is 2.7×10^{12} cP.

3.2 *Aging effects on linear viscoelastic properties*

Superpave binder specifications have caused $|G^*|$ to replace viscosity as the primary asphalt binder property. The *AR* calculated from $|G^*|$, unlike that calculated from viscosity, is a function of both frequency and temperature. Since the low end of the temperature range of interest (−10°C) cannot be accurately measured using the DSR, an analytical technique, presented elsewhere, that combines the results from the BBR and DSR tests is utilized in this study [21]. The *AR* results are shown for different aging levels and for all of the asphalt binders in Figure 1. Note that asphalt binders with BBR data available are plotted for −10°, 5°, 20°, 40° and 54°C whereas the other asphalt binders are shown for only 20°, 40°, and 54°C. The recovered asphalt binder samples do not have BBR data and thus their results are plotted at only 20°, 40° and 54°C.

To properly interpret Figure 1, it must be recognized that $|G^*|$ decreases as either the temperature increases or the frequency decreases. Thus, the $|G^*|$ based ratios show a larger effect from aging at higher temperatures and/or slower frequencies. For the highest frequencies

Table 3. Viscosity based aging ratios for study binders at selected temperatures.

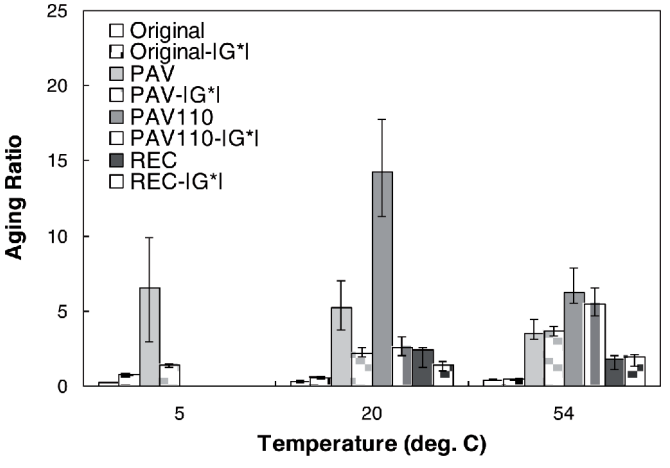

Figure 2. Comparison of viscosity based and $|G^*|$ based aging ratios at selected temperatures.

at −10°C some of the asphalt binders have the largest modulus for the Original aging condition. This is a result of extrapolation in the fitting procedure. Although BBR data is measured at temperatures as low as −30°C, the times at which measurements are taken are sufficiently long so that the equivalent frequency is slower than 10 Hz at −10°C. This issue could be avoided by strictly defining the glassy modulus of each binder and aging level at a constant value, some have suggested a value of 1 GPa [19]. Such an approach was not followed because the difference in AR from the chosen procedure was generally small and only affected a few frequencies at −10°C. Further, a better representation of the modulus at other temperatures was obtained by not assuming a constant glassy modulus.

A comparison of the $|G^*|$ and viscosity based aging ratios at some selected temperatures is shown in Figure 2. In this figure, the average AR, both $|G^*|$ and viscosity based, for all study materials is plotted. For the $|G^*|$ based quantity the value is computed by averaging the results at frequencies between 1 and 100 radians per second for a given temperature. Error bars are shown to represent the 75th and 25th percentiles. The agreement between the $|G^*|$ and viscosity based ratios is mostly favourable for the case of the Original and Recovered asphalt, but not for the PAV and PAV110 conditions. In these latter two aging conditions, the viscosity AR may be as large as 10 to 18, but the $|G^*|$ ratio never exceeds 7. This difference

may be attributed to the fact that some of the viscosity measurements used to generate the A and VTS relationships are non-fundamental quantities. At high temperatures, when kinematic or rotational viscosities are measured, the material is mostly Newtonian and a viscosity measurement may be a fundamental characteristic. However, at lower temperatures, where penetration is measured, the material is shear rate dependent and thus viscosity is an engineering quantity rather than a fundamental one. It is hypothesized that these shear rate effects will become more significant as the material becomes stiffer and thus overemphasize the true effects of oxidative aging. Examining only the data at 54°C, where non-Newtonian effects are reduced (although not eliminated), the agreement between the $|G^*|$ and viscosity based quantities improves.

4 AGING AND ASPHALT MIXTURE PROPERTIES

The standard LTOA aging procedure affects the LVE properties of asphalt concrete in the following ways [22]:

1. Aging universally increases mixture stiffness at high and intermediate temperatures and shows little effect at the lowest temperatures;
2. Increased aging has little effect on the t-T shift factors except for at higher temperatures;
3. The maximum phase angle is delayed to a slower reduced frequency upon further aging, which causes the elasticity to be greater at intermediate temperatures, but less at high temperatures;
4. The overall impact of aging is most noticeable in the intermediate temperature range.

Observations 1 and 2 are consistent with what is observed in the asphalt binder while observations 3 and 4 are not, which is an indicator of the complicated mechanisms that dictate how asphalt binder influences behaviours of asphalt mixtures. These mechanics have not yet been fully described with analytical or computational methods. Nevertheless, in the subsequent sections of this paper existing simplified tools will be shown to sufficiently capture some of these fundamental differences.

The impact of laboratory and in-service aging of asphalt concrete mixtures is summarized for the study materials in Figure 3. This figure conveys the same type of oxidative aging effect information shown for the asphalt binder in Figure 1. In Figure 3 the reference modulus (STOA or plant mixed) is plotted on the x-axis and the moduli at different aging levels (noted in the legend) are plotted on the y-axis. For convenience, lines at aging ratios of 2, 1.5, 0.67, and 0.5 are also shown. From this figure it is first observed that the field sections have a significant amount of variability. This variability is attributed to three primary factors; 1) the specimen-to-specimen variability were higher than usual for these materials, 2) the field sections were exposed to aging for only a very short period of time, less than five years, and 3) the well-known, but hard to quantify effects of lab-to-field compaction differences are

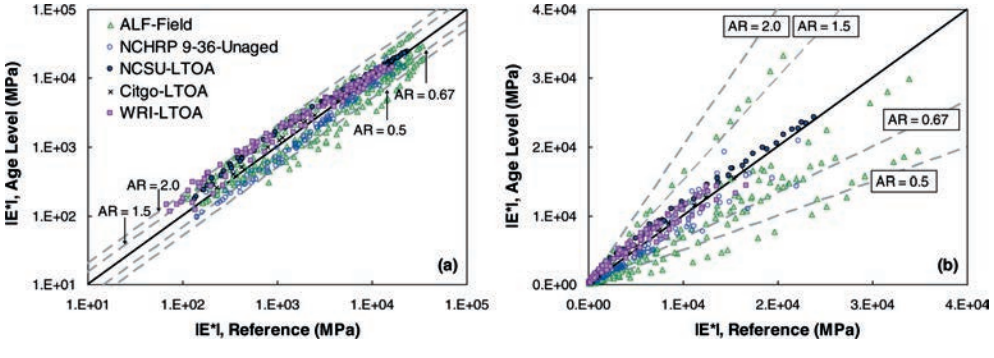

Figure 3. Effect of aging on measured $|E^*|$ in; (a) logarithmic space and (b) arithmetic space.

present. Comparisons of the different laboratory aged materials show that the unaged samples are almost consistently softer and the LTOA aged samples are almost consistently stiffer than the reference. Cases that do not follow this trend are likely the result of experimental variability since the differences are small. Some mixtures also show a trend towards a reduced aging effect at the extremely low modulus values.

Comparing Figures 1 and 3 it is seen that the mixture aging ratios are smaller in magnitude than those found for the asphalt binder. This effect could be related to the mismatch in aging conditions between binder and mixture because *unaged* asphalt mixture may not necessarily be the same as Original binder, STOA may not equate to RTFO, and LTOA may not equate to PAV. However, numerous research studies have concluded and engineering practice suggests an approximate and *on the average* agreement in material states at these aging conditions [16, 17, 23]. As noted in the introduction, the exact aging time correspondence is dependent upon many confounding factors, but in taking the general guidelines as truth or near truth, then it can be concluded that oxidative aging has a less noticeable effect on the mixture modulus than it does on the binder modulus.

5 COMPARISON OF OBSERVED MIXTURE LVE AND PREDICTED LVE FROM MODELS

The relationship between the mechanical properties of an asphalt mixture and its asphalt binder is highly complex and dependent upon many diverse factors such as aggregate gradation, void content, thermal history, etc. Some existing analysis methods exist for predicting this relationship and they have been applied to assess their ability to match the quantitative observations in the preceding sections of this paper. In total, four different analytical methods are used; 1) the Original Witczak model, 2) the Modified Witczak model, 3) the Hirsch model, and 4) the NCSU ANN model. Each of these models is explained in substantial detail in the literature and interested readers are referred to the review in [21] for more information and the equations.

The measured Original, RTFO, PAV, PAV110, and REC asphalt binder properties are used as input in these models to predict the effect of aging on mixture modulus. Plots similar to that shown in Figure 3 (a) are created to qualitatively and quantitatively examine the given model's ability to match the trends observed in mixture testing. These plots are shown in Figure 4 for each of the models. In Figure 4 (c) shaded areas are shown to represent conditions where the Hirsch model has not been fully calibrated [21]. These extrapolation areas are included since users would likely apply the model irrespective of extrapolative errors. Long term aged mixture moduli are predicted using only the Original Witczak model because it is the only model that utilizes viscosity (the output from the GAS model) as an input variable.

The predictions in Figure 4 shows that while each model predicts different values for the mixture modulus, each captures the fact that a given amount of stiffening in the asphalt binder does not directly translate to an equivalent amount of stiffening in asphalt mixture. The relationship between asphalt binder and mixture stiffness is not linear, and as such a major change in the properties of the asphalt binder does not necessarily mean a big change in the mixture modulus. In application, any of these models can be used irrespective of the magnitude of their prediction by using the model as a normalized formulation, i.e., use the model to predict AR instead of the modulus directly. Comparisons between Figure 3 (a) and Figure 4 (a)–(d) show that each predictive model matches the magnitude of the aging effect observed in the experiments. Recall that the influence of aging on the asphalt binder alone was shown in Table 3 and Figure 1 to regularly result in AR greater than 12 and less than 0.2. These observations are independent of the exact agreement between mixture and binder aging conditions and reflect a larger difference in behaviour of the two materials.

All models except the Original Witczak predict that aging is the most significant at intermediate conditions and becomes less significant at the extremes. This behaviour gives a characteristic elliptical shape to the plots in Figure 4 (b)–(d), but is most pronounced for the Hirsch and NCSU ANN models. Both of these models utilize only the $|G^*|$ and mixture

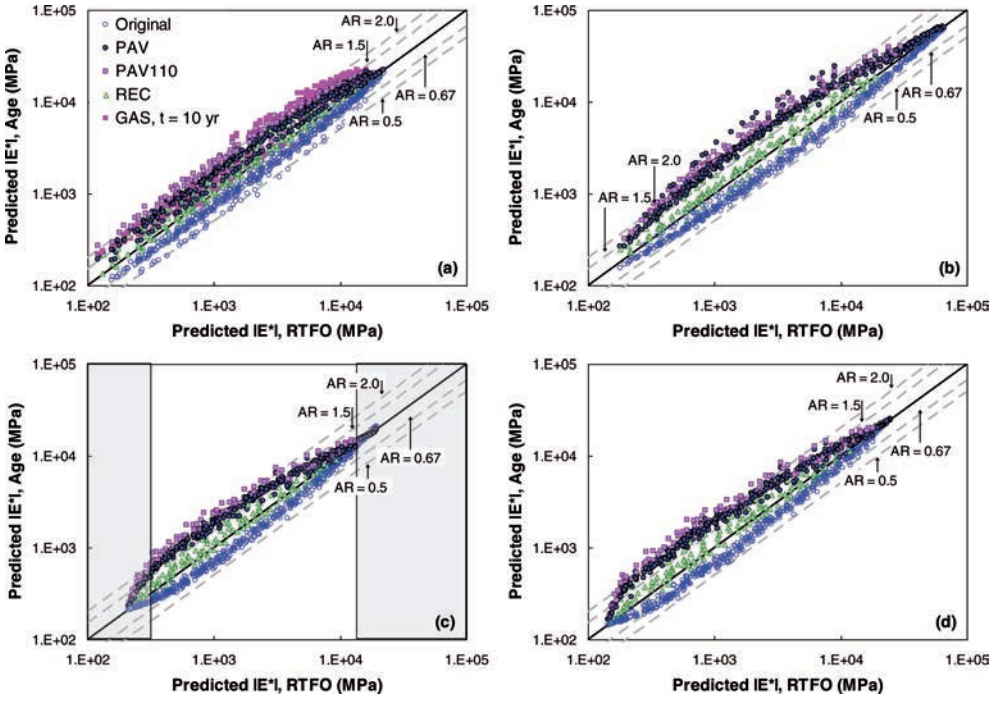

Figure 4. Predicted aging susceptibility with existing $|E^*|$ prediction models; (a) Original Witczak model, (b) Modified Witczak model, (c) Hirsch model, and (d) NCSU ANN model.

volumetrics as input parameters, but have no parameters to account for aggregate gradation. The Original Witczak model suggests that the effect of aging increases as the material softens, but it does not show the characteristic elliptical shape and instead this model predicts that the influence of aging is very similar at the intermediate and low modulus conditions, e.g. a parabolic shape. The characteristic shape from Figure 3 (a) varied from slightly elliptical (NCSU-LTOA and Citgo-LTOA series) to parabolic (WRI-LTOA and NCHRP 9-36). The better match from the two Witczak models may be related to the fact that they include parameters to directly account for the aggregate gradation, which may indirectly capture some of the influence of aggregate surface characteristics on the aging phenomenon.

6 CONCLUSIONS AND SUMMARY

The influence of oxidative aging on the viscosity and modulus of asphalt binder and on the modulus of asphalt mixtures has been studied. It was found that very little experimental data has been gathered on the influence of oxidative aging in asphalt mixtures. Surprisingly, no studies were found wherein researchers have attempted to study the effects of aging in asphalt binder and asphalt mixture at a consistent aging level and over the entire range of in-service conditions. Since data for direct comparison is not available, an indirect method was adopted wherein materials with vastly different properties were examined at many different aging levels. Using qualitative and quantitative methods it was shown that oxidative aging may influence the viscosity and linear viscoelastic modulus of asphalt binder by a factor of 10 or more. However, it was also observed that this influence does not directly translate to increases in the modulus of asphalt concrete mixtures. Such a direct translation does not occur due to the complex interactions that can occur within an asphalt concrete mixture including the mitigating effects of aggregate particles and the fact that asphalt binder typically represents only about 10–15% of the total volume of an asphalt concrete mixture. A rational method

that utilizes existing analytical models was shown to predict the influence of asphalt binder aging on mixture modulus with a reasonable degree of accuracy. With this method, engineers can better assess the influence of asphalt binder aging on the modulus of asphalt concrete mixtures.

ACKNOWLEDGEMENTS

Evaluation of cracking resistance of Superpave mixtures in Kansas

Syeda Rubaiyat Aziz & Mustaque Hossain
Department of Civil Engineering, Kansas State University, Manhattan, KS, USA

Greg Schieber
Bureau of Construction and Materials, Kansas Department of Transportation, Topeka, KS, USA

ABSTRACT: Reclaimed Asphalt Pavement (RAP) is a useful alternative to virgin aggregates in Hot-Mix Asphalt (HMA) as it reduces cost, conserves energy and enables reuse of existing asphalt pavement. However, use of higher percentage of RAP sometimes leads to drier mixes that are often susceptible to early cracking. In this study, cracking resistance of Superpave mixtures with varying asphalt and RAP contents were investigated. HMA specimens were prepared based on Superpave mix design criteria for 12.5-mm (1/2-inch) nominal maximum aggregate size. Specimens were compacted using the Superpave gyratory compactor. Repeated load Semi-Circular Bending (SCB) tests and Texas Overlay Tests (OT) (TEX-248-F) were performed to evaluate cracking resistance of Superpave mixtures containing three asphalt contents (5.2%, 4.9%, and 4.6%) and three RAP percentages (20%, 30%, and 40%) from two distinct sources. Results from both crack tests showed that, with the decrease in asphalt content, cracking propensity increases. Thus conclusions regarding proper RAP percentage use were drawn depending upon the binder content and grade of the RAP source.

Keywords: Semi-Circular Bending test, Texas Overlay Test, cracking resistance, Reclaimed Asphalt Pavement (RAP), Superpave mixtures

1 INTRODUCTION

Recent rise in crude oil price, emphasis on sustainability, and limited virgin aggregate availability have increased RAP material usage. Nationwide, approximately 100 million tons of RAP are produced each year. Approximately 80 million tons are reused in various aspects of pavement construction [1]. RAP contains long-term aged binder, thus asphalt mixes containing RAP could be a matter of concern, especially from the aspects of durability and long-term pavement performance. Asphalt binder present in RAP is stiffer than the virgin binder. Stiffer mix has benefits, such as being less susceptible to permanent deformation or rutting. However, it decreases fatigue life and thermal cracking resistance. There is a limitation to the maximum amount of RAP that could be used in surface layers, certain mixture types, and, in some instances, large or critical projects. Traditionally, the amount of RAP used has been limited to 15% or lower so no binder-grade changes are necessary. Current national guidelines indicate that a softer binder will be required if more than 15% RAP is used in the HMA mix [2]. Softer binders are expensive. Henceforth, it is necessary to come up with a certain percentage of RAP which would be cost effective as well as provide sufficient cracking resistance. In this study, Semi-Circular Bending (SCB) and Texas Overlay (OT) tests were selected to evaluate the cracking resistance of Superpave mixtures.

1.1 *Problem statement*

Some HMA mixtures are produced in Kansas, with asphalt content lower than the design asphalt content. As a result, relatively "drier" mixture is obtained, often leading to early cracking. This type of phenomena is severe for mixtures with Recycled Asphalt Pavement (RAP). Recently, the Kansas Department of Transportation (KDOT) took some initiatives to ensure sufficient amount of asphalt in their mixtures. The contractors, however, instead of adding extra binder, introduced dust into the mixtures with lower number of design gyrations. The rutting and moisture susceptibility of mixtures with lower binder content have already been investigated, but cracking resistance is yet to be evaluated.

1.2 *Objectives*

The main objective of this research was to evaluate the effect of increasing percentage of RAP and varying asphalt content on the cracking resistance of Superpave mixtures. The secondary objective was to establish the minimum asphalt content and maximum RAP content while ensuring acceptable cracking resistance.

2 MATERIALS AND MIX DESIGN

To achieve the objectives of this study, 12.5-mm Nominal Maximum Aggregate Size (NMAS) Superpave mixtures were evaluated. The design binder content of the base SM-12.5A (no RAP) mixture is 5.2%. SM-12.5A mixtures with 4.9% and 4.6% asphalt content were also included, to study the effect of varying asphalt content. In order to control the effect of the RAP source on HMA performance, all tests of SR-12.5A (Superpave mixture with RAP) have been conducted on two different sources of RAP. Both RAP sources were locally owned asphalt contractors and are mentioned here after as Shilling and Konza. The asphalt contents of Shilling and Konza RAP are 5.8% and 4.2%, respectively. The PG binder grade of Shilling RAP is 84-16, whereas the Konza RAP asphalt grade is PG 90-10. From each RAP source, mixtures with three RAP contents, 20%, 30%, and 40%, were evaluated. In order to compare the effect of RAP source on HMA performance, same virgin aggregates were used for all Superpave mixtures. The combined blend had five different virgin aggregates including coarse-crushed limestone (CS-1), fine-crushed limestone (CS-1A), manufactured sand (MSD-1), crushed gravel (CG-5), and natural/river sand (SSG). Table 1 shows the percentages of aggregates used in each blend. Figures 1(a) and 1(b) show the 0.45-power chart for SM-12.5A and SR-12.5A mixture with both sources of RAP materials, respectively. Table 2 tabulates the gradation of both sources of RAP.

Table 1. Percentage of aggregates and asphalt in superpave mixtures.

		Total asphalt content (%)				Virgin aggregates (%)					
		Shilling RAP		Konza RAP							
Mixture	RAP content (%)	Total asphalt	Virgin asphalt	Total asphalt	Virgin asphalt	CS-1	CS-1A	MSD-1	CG-5	SSG	Lime stone dust
SM-12.5A	0		5.2			25	15	15	20	25	0
	0		4.9			24	15	15	20	25	1
	0		4.6			24	15	15	20	25	1

Konza RAP	100	96	92	78	64	48	35	21	15	12

3 PERFORMANCE TESTING

3.1 *Repeated load Semi-Circular Bending (R-SCB) test*

The Semi-Circular Bending (SCB) test was used in this study to evaluate the cracking resistance of HMA mixtures. The test is conducted on a half disc-shaped HMA specimen subjected to a three-point loading in compression. The specimen is typically 150 mm in diameter and 50 mm thick with a 6-mm notch at the bottom to initiate cracking there.

Repeated load SCB (R-SCB) test is a two-step process which involves establishing the input compressive load via monotonic or static SCB testing and then using a fraction of the maximum SCB failure load as the R-SCB input load. Repeated load of 10 Hz frequency with no rest period is applied to the specimen at 25 °C. Three replicates were tested for each RAP and asphalt content.

The cracking resistance potential of a mix under this test setup is characterized by the number of SCB load repetitions to cracking failure, where failure is tentatively considered as full crack propagation through the HMA specimen [3]. The R-SCB test setup in UTM-25 environment is shown in Figure 2(a).

Four fractional peak load (static SCB) levels obtained at 30%, 40%, 50%, and 60% of the maximum load were arbitrarily tried as the R-SCB input loads. The test continued until a crack propagated through the entire specimen. The final parameter for comparison was the number of load cycles to failure. The more the specimen could withstand cycles prior to fracture failure, the better cracking resistant it would possess. According to previous studies [4–5], approximately 50% of static SCB peak load should be considered as the R-SCB input load.

3.2 *Texas Overlay (OT) test*

Texas Overlay Tester (OT) test has been used for mix screening and for evaluating cracking (reflective) resistance of HMA overlays. Past research has shown that there is a strong correlation between OT test results and field performance [6]. OT test continues until the initial load decreases by 93%. The number of cycles to this load reduction represents the number of cycles to failure and is an indicator of HMA mixture cracking resistance. The test was conducted at 25 °C, consistent with the Tex-248-F test procedure. Test specimen is 150 mm long, 75 mm wide and 37 mm thick. The Asphalt Mixture Performance Tester (AMPT) machine was used to perform the test. Loading configuration of this test consists of a cyclic triangular displacement-controlled waveform at a standard maximum opening displacement of 0.635 mm and 10 seconds load cycle (5 seconds of loading and 5 seconds of unloading). Three replicates were tested for each varying RAP and asphalt content. Figure 2(b) shows the typical test setup. During testing, only one plate was pulled at the specified displacement rate and pushed to return to its original position. This load simulates the movement of the overlay and directly produces tensile stress in the specimen.

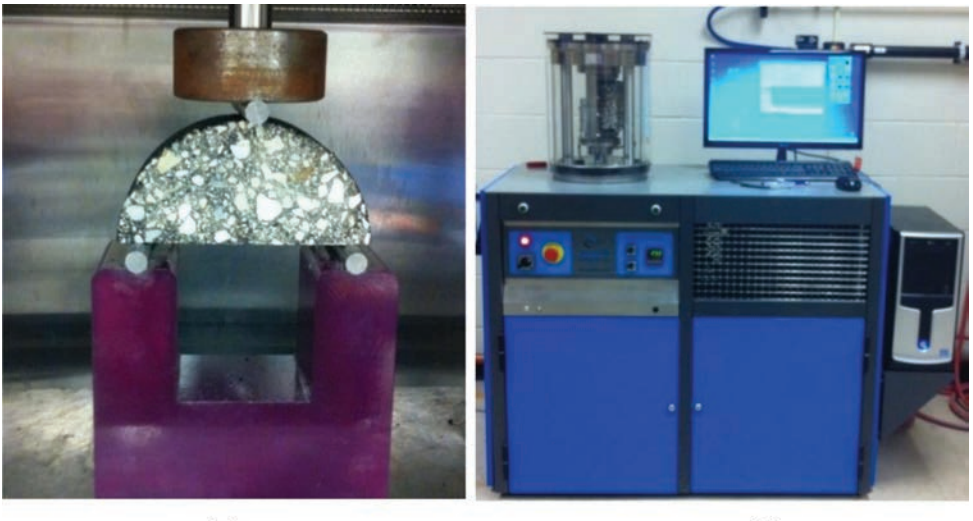

Figure 2. (a) R-SCB test setup in UTM-25; (b) OT test setup in AMPT.

4 TEST RESULTS AND ANALYSIS

4.1 *Repetitive load SCB test results*

The results of R-SCB test are shown in Figures 3, 4 and 5. Figure 3 shows that SM-12.5A mixture with 5.2% asphalt content provides the best cracking resistance because it can resist high R-SCB load repetitions before fracture failure when compared to two other mixtures. Performance deteriorated with decreasing amounts of asphalt content.

Figure 4 shows that SR-12.5A mixture with 20% RAP content has the best cracking resistance when Shilling RAP is used. This mixture demonstrated the highest number of load repetitions before fracture failure compared to the other two mixtures. Performance of these mixtures deteriorated with increasing RAP content and had trends similar to results of static SCB test of the SR-12.5A mixture. On the other hand, Figure 5 shows that SR-12.5A mixture with 40% RAP content has the best cracking resistance, when Konza RAP is used. This mixture endured the highest number of load repetitions before fracture failure compared to the other two mixtures. Konza RAP was relatively aged and drier as mentioned earlier, which could be the reason behind such behaviour.

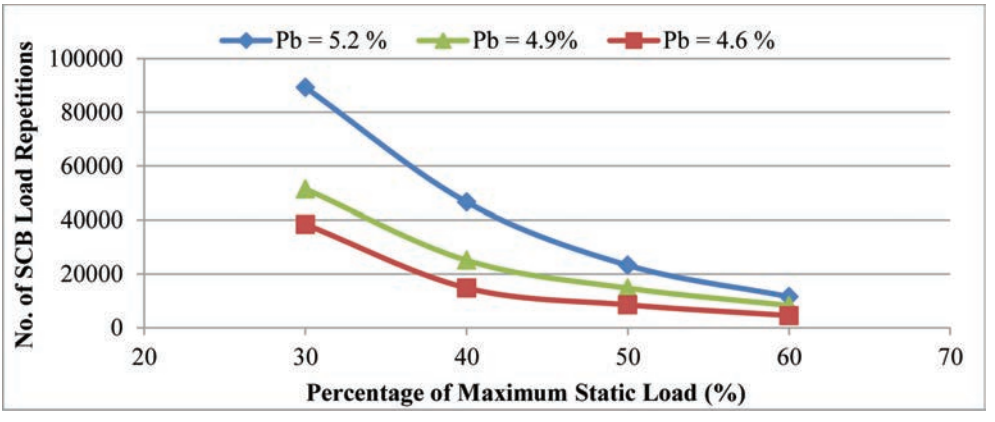

Figure 3. R-SCB percent load relationship vurves for SM-12.5A.

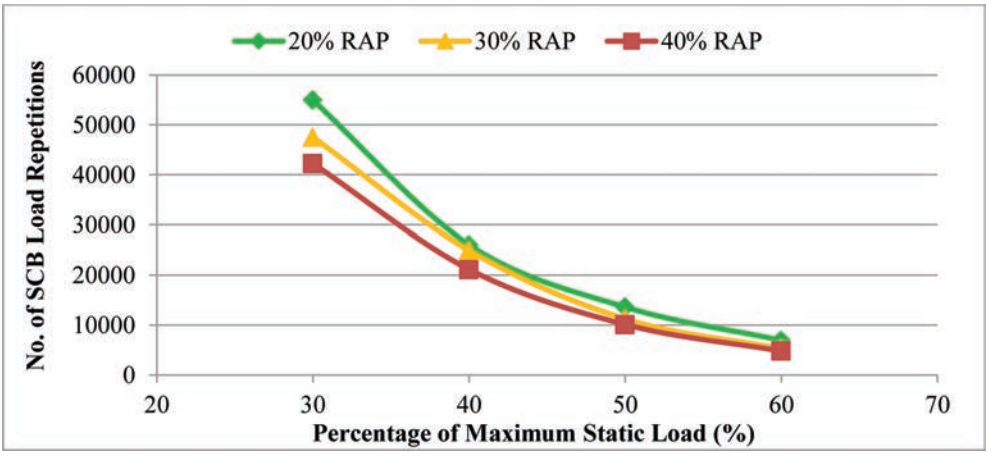

Figure 4. R-SCB percent load relationship curves for SR-12.5A with Shilling RAP.

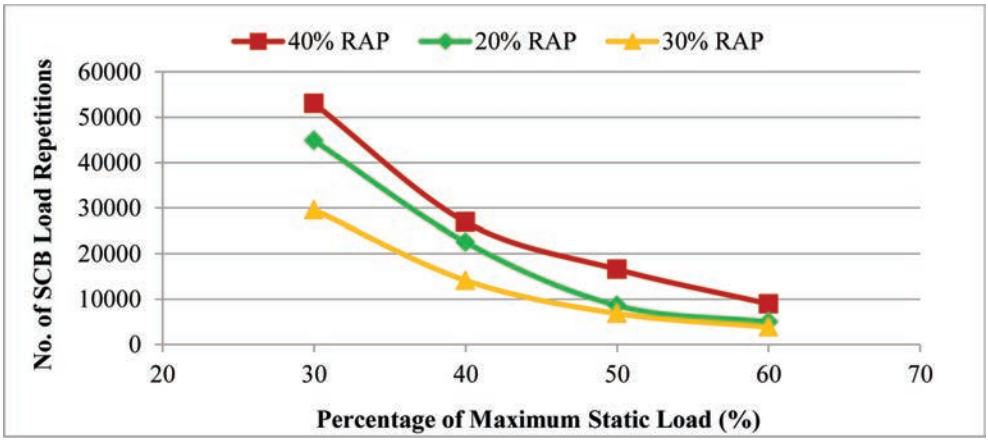

Figure 5. R-SCB percent load relationship curves for SR-12.5A with konza RAP.

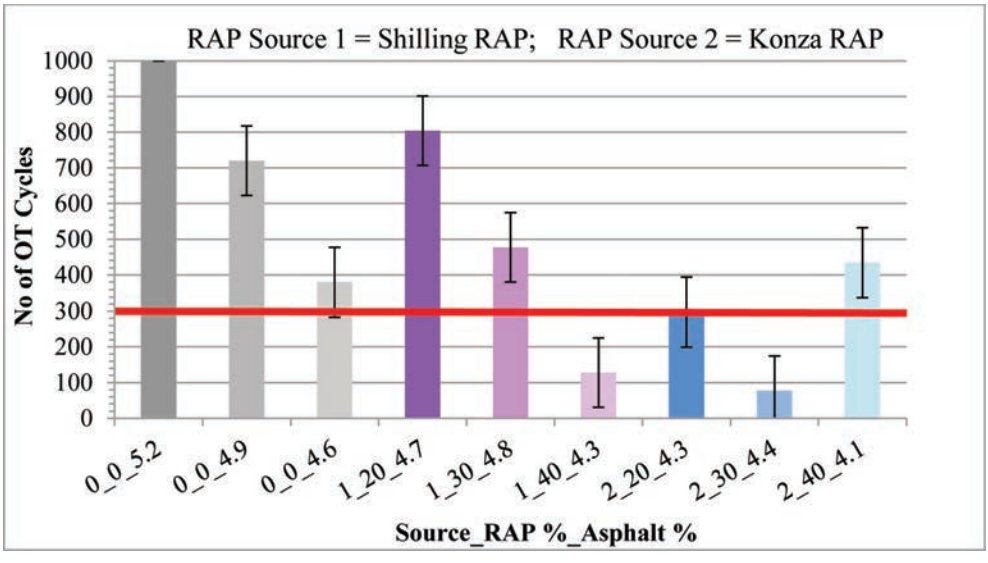

Figure 6. Summary of OT test results.

4.2 *Texas Overlay (OT) test results*

OT test was the other laboratory test performed for characterizing the cracking resistance of the Superpave mixtures. As a mix screening criteria, mixtures that last over 300 cycles are considered satisfactory with respect to the laboratory fatigue resistance [7]. With this criterion, in Figure 6 the best cracking resistance is shown by the mixture with 5.2% asphalt content. All replicates of this mixture passed 1,000 cycles (maximum threshold) before reaching 93% load reduction. The mixture with 4.9% asphalt had a fairly good performance. SM mixture containing 4.6% binder had a satisfactory performance, but it still was the worst among three.

For the SR-12.5A mixture with Shilling RAP, the mixture with 20% RAP content had the best cracking resistance among the three mixtures. The mixture containing 30% RAP had a somewhat satisfactory performance; however, SR mixture with 40% RAP was below 300 cycles. Thus, this mixture can be considered to have unsatisfactory fracture resistance.

For the SR-12.5A mixture with Konza RAP, the mixture with 40% RAP content had the best cracking resistance among the three mixtures. The mixture containing 20% RAP portrayed an average number of 296 OT cycles, which was marginal when compared to the threshold value (300 cycles). SR mixture prepared with 30% RAP from the second source also performed poorly.

4.3 *Statistical analysis*

Mean results obtained from both R-SCB (50% of $F_{static\ SCB}$ as input) and OT tests were compared to check if differences were significant. In addition, comparisons were done to find a combination of minimum asphalt content and maximum RAP content based on the test results, which would be able to ensure a satisfactory cracking resistance. Initially, using Tukey's adjustment method, means from both cracking resistance tests were compared as a whole. The adjusted *p*-value from the test output was compared with the level of significance (0.05). If *p*-value was less than or equal to 0.05, then it was considered that there were statistically significant difference between the means. In this study, the statistical analysis was performed using a software package, Statistical Analysis System (SAS)®. Tables 3 and 4

*Mix types not connected by same letter are significantly different.

demonstrate the multiple comparisons performed using the mean test results obtained from all mixtures in this study. Source 1 and 2 denote Shilling RAP and Konza RAP, respectively. Though Tukey's multiple comparisons of means for the R-SCB test results (Table 3) showed groupings, several overlaps did not allow formation of distinctive group. Mixtures with no RAP and 5.2% asphalt content had statistically significant different means than all other mixture types.

Table 4 shows the summary of the Tukey's multiple comparisons for the OT test results. Mixtures enclosed by the same colour border denote that they did not have any statistically significant difference among them. Results from the OT test showed almost clear groups.

Cracking test results of the SR-12.5A mixtures portrayed completely opposite patterns, which could be due to the intrinsic properties of various sources of RAP materials used in the mixtures. Therefore, without considering at least another source of RAP, it would not be possible to make a general conclusion about such asphalt content and RAP content combination by overall multiple comparison between the treatments.

Because of such limitations, the Bonferroni method of mean comparison was later used for simultaneously planned comparisons within different sources. This method controls family-wise type-I error [8]. Tables 5(a) and 5(b) show summaries of pairwise comparisons from the Bonferroni method for the R-SCB and OT tests, respectively. SM and SR mixtures are shown in ascending order of number of cycles. *p*-value obtained from the SAS® outputs were compared to the Bonferroni adjusted level of significance which was the ratio of level of significance to the number of comparisons from each test (n = 9 for SCB test and n = 7 for OT test). If the obtained *p*-value was less than or equal to the Bonferroni adjusted level of significance, then the means were considered to have statistically significant difference.

Pairwise mean comparisons (R-SCB test results) within the Shilling RAP indicate that there was no statistically significant difference among the mean number of cycles obtained for mixtures with 20%, 30%, and 40% RAP. Though the mixture with 20% RAP and 4.7% asphalt showed the best performance, it does not provide the maximum RAP and minimum asphalt combination. Henceforth, the mixture with 40% RAP and 4.3% asphalt can be considered to provide good cracking resistance performance under such conditions. For mixtures with Konza RAP, results were even clearer. The combination of 40% RAP content and 4.1% asphalt content had significantly different mean compared to the other two mixtures. Therefore, this mixture can provide good performance, especially when Konza RAP is used. When analysing the OT test results, a minimum threshold level of 300 OT cycles was taken into consideration. For mixtures with Shilling RAP, all result means were significantly different. However, the combination of maximum RAP and minimum asphalt portrayed the poorest performance and was below the threshold level. Thus, from OT test results of SR-12.5A

Table 5. Summary of Bonferroni method of comparisons.

(a) R-SCB test				(b) OT test			
SM-12.5A				*SM-12.5A*

*Mix types not connected by same letter are significantly different.

Table 6. Virgin asphalt as a percentage of total asphalt content for both RAP source.

Shilling RAP			Konza RAP		
Total asphalt (%)	Virgin asphalt (%)	Virgin asphalt as a percentage of total asphalt (%)	Total asphalt (%)	Virgin asphalt (%)	Virgin asphalt as a percentage of total asphalt (%)
4.7	3.6	77	4.3	3.5	81
4.8	3.1	65	4.4	3.2	73
4.3	2.1	49	4.1	2.5	61

mixture with the Shilling RAP, it can be concluded that 30% RAP and 4.8% asphalt can provide satisfactory cracking resistance at the 95% confidence interval since the mean estimate of passing cycles is clearly above 300 (minimum threshold).

For mixtures with Konza RAP, test means did not show any statistically significant difference. Also, the mixture with 40% RAP and 4.1% asphalt was able to exceed the threshold level of 300 OT cycles. Therefore, this mixture has the potential to ensure good cracking resistance when material similar to Konza RAP is used.

Thus, with the results obtained from this study, conclusions can be made based on what type of RAP is used. If the RAP considered for the mixture is more binder rich, then results from the Shilling RAP should be considered. On the other hand, for a drier RAP, results from the Konza RAP should be taken into account. Statistical analysis suggests SR-12.5A mixture with Shilling RAP have two best cracking resistant mixtures: 40% RAP with 4.3% total asphalt content (from the R-SCB test results), and 30% RAP with 4.8% asphalt content (from the OT test results). For the Konza RAP, mixtures with 40% RAP and 4.1% asphalt content performed best in both cracking tests. Table 6 shows that proportion of virgin asphalt content in the best cracking resistant mixtures from the Shilling RAP are 49% and 65% of total asphalt content, while the best mixture from Konza RAP contains 60% virgin binder. Henceforth, it can be concluded that, based on statistical analysis, Superpave mixtures containing 30%–40% RAP and virgin asphalt content between 50%–65% of total asphalt should be able to provide good cracking resistance. A range for Asphalt and RAP content was concluded instead since the opposing results from both RAP sources indicate that study requires results from few more RAP source.

5 CONCLUSION

The objectives of this study were to evaluate the effect of increasing the percentage of RAP and asphalt content on the performance of Superpave mixtures in terms of cracking resistance; to compare the performance of Superpave mixtures when only the source of RAP is changed; and to establish the minimum asphalt and maximum RAP content while ensuring acceptable cracking resistance. Based on the test results obtained from this study, following conclusions can be made:

(a) Results from both static load SCB test and repeated load SCB test indicate that SM-12.5A mixture with design asphalt content (5.2%), SR-12.5A mixture with 20% Shilling RAP, and 40% Konza RAP demonstrate the best cracking resistance among the SM and SR mixtures, respectively.
(b) Performance deteriorated with decreasing asphalt content and increasing RAP content (for the Shilling RAP). However, the Konza RAP, which contained less asphalt, performed in the opposite manner.
(c) Results of the OT tests showed that the SM-12.5A mixture with 5.2% asphalt passed 1,000 cycles (maximum threshold) but still did not reach 93% load reduction. SR-12.5A mixture with 20% Shilling RAP and 40% Konza RAP, respectively, passed the minimum level of 300 OT cycles. Thus, these mixtures are expected to show less crack propensity.

(d) Using Tukey's method of multiple comparisons, test means were compared. Though the overlay test results formed almost distinct groups, R-SCB test results showed similarity within groups. Because of such overlaps and completely opposite behaved RAP sources, a general conclusion regarding minimum asphalt and maximum RAP content could not be done.
(e) Bonferroni's method was finally considered to draw conclusions within each source of RAP. For the Konza RAP, both R-SCB and OT test suggested a combination of 4.1% asphalt content and 40% RAP content which can provide satisfactory cracking resistance while using the least possible asphalt and maximum allowable RAP content. On the other hand, for the Shilling RAP, conclusions were split between 4.8% asphalt with 30% RAP content and 4.3% asphalt with 40% RAP content.
(f) Superpave mixtures containing 30% to 40% RAP and virgin asphalt content between 50% to 65% of total asphalt content should be able to provide good cracking resistance.

An experimental study on viscoelastic behaviour of bituminous mastics

Marco Pasetto, Stefano Damiano Barbati & Giovanni Giacomello
Department of Civil, Environmental and Architectural Engineering, University of Padua, Padua, Italy

ABSTRACT: The viscoelastic properties of asphalt mastics are influenced by the type of aggregate that is mixed with the bitumen. The objective of the investigation reported in this paper is to explore the use of an inorganic municipal waste filler (WBA) in bituminous mixtures. These materials are available in large quantities and provided at shipping cost, because of landfill problems. However, their use is still limited due to the intrinsic variability of the electrochemical relationship that occurs between aggregates and bitumen.

A comparative study on the viscoelastic performance of bituminous mastics is presented. The bitumen were free of polymer modification. All adhesive mastics were prepared using a single type of filler. The filler-bitumen mass ratio was varied in order to analyse its influence on material response. The filler is homogeneous; particles larger than 0.063 mm were excluded.

The programme of laboratory tests evaluated both the rheological and empirical properties, according to the European Standard. The results obtained demonstrate that the slag filler can be used as a replacement for the standard filler. The composition of the structure of the aggregates in bituminous mixtures was noticeably altered. However, the variation of the filler-bitumen mass ratio can determine some advantages on mechanical response, strength and yield level of the mastic.

Keywords: Bituminous mastics, inorganic fillers, viscoelastic properties, complex modulus, dynamic shear rheometer

1 INTRODUCTION

Two commercial strategies dominate the maintenance and construction of road pavements: the recycling of previously used raw materials; the use of marginal materials, collected from the wastes of other industrial processes. The interest in these sectors is due to environmental reasons, as it reduces the demand for raw materials of natural origin. On the other hand, their success is determined by the reduction of the unitary fixed costs and depends on the maintenance of an acceptable performance level for a sufficient length of time. Different studies have tackled this question in the last sixty years and recently, with the proliferation of refuse incinerators in Europe, research has begun into the use of slag from the combustion of Solid Municipal Wastes (SMW) [1–15]. In general these materials can be classified according to the dominant component: combustible, metallic, hazardous and mixed waste. However, not all parts of the slags may be used in road construction. This is because serious problems arise if there are phenomena of release, for example of heavy metals or fine and very fine particles, which can affect the working performances of bituminous mixtures or even leach and pollute the groundwater. Materials can be incompatible with the bitumen, in consequence of electrochemical profile (glass), or they can have the role of solvent. In most cases combusted SMW slags are partially utilizable, therefore an operation of selection of the acceptable fractions is necessary [16]; although partitioning is possible, the result may vary over time. Vitrification processes, even if costly, do not provide an acceptable improvement [16]. For this reason

alternative solutions are searched in order to use the product as it is or, at least, without expensive treatments.

One option is represented by bituminous mastics. They are the result of the physical and chemical pairing of bitumen and filler ($\varnothing < 0.075$ mm) and therefore offer an intermediate mechanical response between the bitumen and a concrete [17]. It has been demonstrated that the presence of fines can lead to important increases in the mixture performance: mechanical resistance, plasticity, voids content and water resistance. However, there are intrinsic critical qualities: the variability of the product of origin, potential toxicity of the fumes and polluting residues. Some cases documented in the literature report a reduction in the performance (sensitivity to temperature variations, functional and structural stability, fatigue and rutting resistance) and service life of the mix containing marginal materials compared to an analogous conventional one [17–26].

There are different variables of the composition that regulate the behaviour of these mastics: bitumen, i.e. the asphaltene content, fractional voids, particle size, chemical composition etc. [17]. Although the rheological characterization of mixtures can be complex, there are various studies in the literature that demonstrate the potentials of the use of incinerator slag, particularly when compared with conventional filler and cement. A rheological characterization of the bitumen is not sufficient to guarantee a result for the same tests done on the mastics and on the derived mixtures [27,28]. When the structure of the material allows it, the viscoelastic response of these mixtures can be represented by means of a Dynamic Mechanical Analysis (DMA) in an oscillatory regime, often of a sinusoidal type, with a Dynamic Shear Rheometer (DSR). Under the hypothesis of the principle of time-temperature equivalence, a dynamic analysis allows the problems of the viscoelastic characterization of the original bitumens and mastics to be dealt with, determining the main rheological properties (complex modulus, phase angle, viscosity) in a wide range of temperatures and loading times (or frequencies) [17–26].

The sensitivity of the analysis to the variation of the dominant factors is such that there is still no technical standard with indications on mastics (performance-based or prescriptive). An empirical characterization is also speedy and economical, enough to obviate any other determination, however advanced and robust. In the economics of the product and its application, the content and the cost of the bitumen are also important; for this reason the binder must be selected with care, choosing the best compromise between performances and unit cost. This paper describes the result of an experimental analysis on the use of the slags in the production of bituminous mastics, identifying the effects of filler content on the mechanical behaviour, and on the consistency of rheometric and empirical tests. The analyses were supported by laboratory activities aimed at gathering the data from the tests and limiting the storage times of the original materials. The analyses of the results are aggregated in order to present the mechanical response of the mastic in the preliminary phases of preparation of the mixtures and in the initial periods of use on the road, excluding the accelerated thermal treatments that substitute the different levels of aging.

2 EXPERIMENTAL PROGRAMME AND RESEARCH SET UP

The research studied the viscoelastic behaviour of mastics in the initial preparation and operating phases of mixtures of filler and bitumen. This paper presents the results obtained with the pairing of an inorganic non-conventional aggregate, composed of slags from the combustion of municipal waste, with a bituminous binder for road uses (EN 12597, EN 12591). The experimental proposal was in two phases. In the first, an empirical characterization was made of the binders to verify the penetration class and select them for the project, and of the bituminous mastics, to define the general and operational characteristics of specimen preparation. In the second phase the test protocol of the viscoelastic properties of the bitumen and its mixtures was developed, varying the dose of filler.

2.1 *Materials*

The trial followed a market survey of the main producers and suppliers of bitumen in Italy. Different traditional bitumens (unaged, unmodified and without additives) were offered for the study, with a variety of origins and performances. For this reason, an experimental phase was necessary to select the binders. Following the empirical analysis a single producer was identified: the bitumen was supplied in at least three penetration classes: 35/50, 50/70 and 70/100 0.1 mm (UNI/TR 11361), coming from the same plant and same production line. Products with different (or undeclared) origins and binders with intermediate behaviour between two adjacent penetration classes were excluded from the study.

The bitumens were sampled, placed in containers of approximately 75 g (±5 g) and stored at a constant temperature of 20 °C (±2 °C) for the entire period of the trial (EN 58). The aggregate was collected from the plant, placed in 10 kg containers, and transported to the laboratory. It was then heated to 105 °C until it reached a constant weight. The material was sieved and reduced to the fraction passing through a sieve with a nominal diameter of ∅ = 0.075 mm (mechanical sieving with an average yield of 4.38% in dry weight of slag). Table 1 gives details of the chemical analyses conducted on a representative sample of filler.

The filler, bitumen and mixing tools were placed in an oven at a temperature of 130 °C (±5 °C). The mastics were prepared using different doses of filler: 25%–50%–75%–100% of the weight of mastic. These values are in line with the typical prescriptions for bituminous mixtures for road use, and are consistent with traditional products and other research done in this field [27]. The binders were heated twice to a temperature above that of storage: when they were taken to the laboratory, on the reduction into small-sized samples, and during the mixing for specimen preparation. The additional thermal treatments are those necessary for the execution of the tests and included in the standard protocols (EN 1426; EN 1427; EN 12593; EN 13702; EN 12607/1; EN 14770). All the preparation and mixing phases were monitored using an infrared thermal camera (T-IR). This study is based on the characterization of the mastic in the phases immediately after preparation (condition: unaged); it was therefore decided not to give any thermal treatment to the bitumens and mastics.

2.2 *Empirical analysis*

The rheological characterization and preparation of the mastics was preceded by an analysis of the consistency of the binder and mastics. The selection was done on the basis of the tests in the Italian technical standard (Table 2) and the viscosity, to guarantee a workable product in the mixing phase.

2.3 *Dynamic and rheological analysis*

The mechanical properties of the materials prepared for this study were determined in the region of the prevalent mechanical behaviour of a viscoelastic type. A test protocol was used that allows both the temperature and frequency to be varied, in an oscillatory regime of the sinusoidal type. The tests were conducted with an AntonPaar MCR 302 Dynamic Shear Rheometer (DSR, Fig. 1), taking into account the necessity to also test the mastics and in expectation of a possible problem of "spindle compliance".

The geometric characteristics of the tests of the two testing plate geometries are presented in Table 3. To verify the "spindle compliance", produced with two different geometries (spindles), it was decided to check the curves in a frequency sweep at temperatures of 30 and 35 °C.

The test in the oscillatory regime was conducted according to the prescriptions in the technical standard (EN 14770), pouring the bitumen onto the lower plate at a temperature of 130 °C (±10 °C). The gap is established, but the descent of the upper plate stops 20 μm above the value of the gap required by the test (Table 3). During the descent of the upper plate the normal force N_f must be no more than 0.5 N to avoid pre-stressing the bitumen due to

excess material. The control of the perpendicular force also continues during the "trimming" phase and, immediately after, when the upper plate is lowered by 20 μm, to be placed in the position required by the test. During each test the plate-bitumen contact is maintained with the control of the perpendicular force at $N_f = 0$ N.

The first series of tests involved the characterization of the region of Linear Viscoelastic (LVE) mechanical behaviour in an oscillatory regime (amplitude sweep, controlled strain), in the point in which the value of the complex modulus |G*| is equal to 95% of its initial value $|G_0|$ [21, 22, 27]. The limit value of the strain was determined on the average of five samples of bitumen, taken from different points of the original container to represent the entire supply. The second series of tests regarded the construction of the isothermal curves of the complex modulus (Fig. 2, left) and phase angle (Fig. 3, left) in an oscillatory sinusoidal regime and frequency sweep, with gradual 5 °C (ΔT) temperature increments between one cycle and the next.

For the construction of the "Master Curves" of the "standard complex modulus" |G*| (Fig. 2, right) and the phase angle δ (Fig. 3, right), an arbitrary reference temperature of 25 °C was chosen (Fig. 2 and 3, black curve). The individual isothermal curves represent the response of the material to a loading cycle in frequency sweep (see Figs. 2 and 3: PP08-void grey dot; PP20-bulk grey dot). These were shifted utilizing a form of shift factor (Williams, Landel and Ferry Method—WLF) present in the literature for bitumens [31] and mastics [27].

In this relationship the principle of overlapping Time-Temperature (TTS) is accepted as valid and the materials are "thermo-rheologically simple": an increase in temperature reduces the resting times of the structural processes associated to the strain and flow. If this reduction

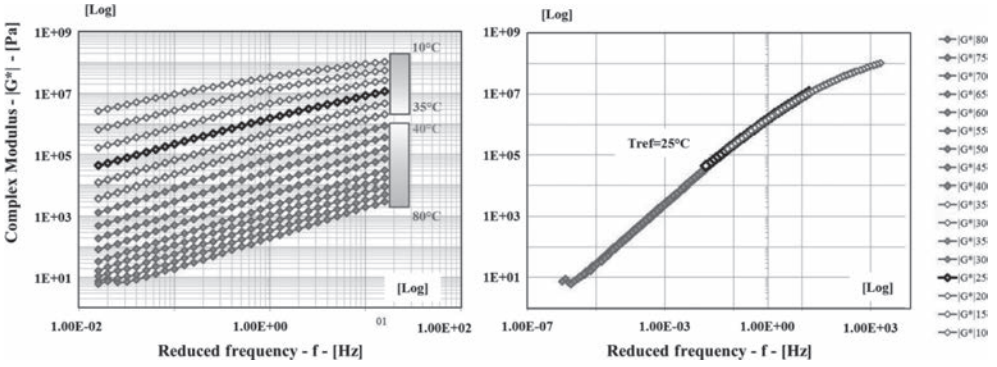

Figure 2. Isothermal plot of complex modulus for two spindle geometries. Bit. 50/70.

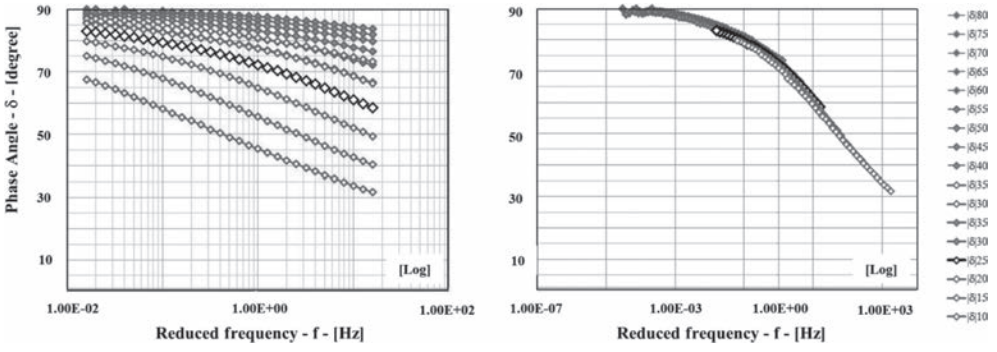

Figure 3. Isothermal plot of phase angle δ for two spindle geometries. Bit. 50/70.

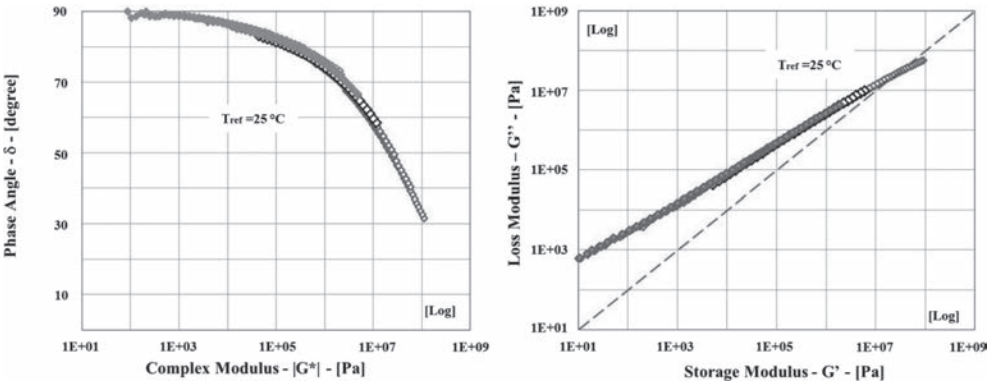

Figure 4. Extended plot: black (left) and Huet-modified (right) diagrams. Bit. 50/70.

is equal for all the times of the resting spectrum, an increase in temperature determines a horizontal shift of the response G(f) in the diagram log(|G*|) – log(f) towards shorter times and without substantial vertical shifts [29]. The values of the complex modulus |G*| and phase angle δ were introduced in the diagrams of Black (Fig. 4, left, phase angle versus complex modulus) and Huet-modified (Fig. 4, right, loss modulus versus storage modulus). This representation points out some typical characteristics of the mechanical behaviour, any problems deriving from the use of the DSR and the two testing plate geometries; influences less visible on the diagrams of the "Master Curves" [28].

3 RESULTS AND DISCUSSION

3.1 *Empirical test results*

The empirical analyses played a dominant role for the preliminary selection phase of the bitumen. They were also used to delineate the consistency of the bitumen and mastics produced with different doses of filler. Tables 4 and 5 show the results obtained in the checks of the softening point temperature (T_{Sp}) and penetration (P_{25}).

The values obtained are in line with those supplied by the producer (Table 2). A general increment was observed in the consistency of the mixture with the increase in the dose of filler: the increase in softening point temperature is not linear with respect to the increase in dose and is more marked for the 35/50 bitumen; penetration reduces with the dose of filler and is less marked for the harder bitumens; in the case of the 35/50 bitumen the effects of the addition of filler are shown for doses of 50% and above. Statistical analysis of the results, also taking into account the low number of specimens, did not provide a trend of the dispersion, expressed in terms of filler dose or consistency.

3.2 *DSR test results, master curves and viscoelastic behavior*

The limits of the region of the mechanical linear viscoelastic behaviour of the binders (35/50, 50/70 and 70/100), at various temperatures and frequencies, were determined with the objective of defining a common working condition for all the materials (Table 6). It should be pointed out that all the bitumens examined have demonstrated quasi-fluid characteristics of the pseudo-plastic polymer, also in the case of the mastics with a high dose of filler. The LVE limit, while depending on the consistency of the bitumen, does not appear to be noticeably linked to the dose of filler. The presence of filler clearly leads to an increase of the initial modulus $|G_0|$ in the "amplitude sweep" tests and, in the best observations, this value is about 10 times higher than the original bitumen. This effect is dominated by the reduction of the distance between the particles of filler, with the consequent increase in the number of points

of contact efficacious for the distribution of internal stresses. Further research on the values of the mass ratio between filler and bitumen are planned for the future.

Due to problems linked to the timetable of the research project, it was not possible in this phase to completely define the two Newtonian plateaux (for $d\gamma/dt \rightarrow 0$ and $d\gamma/dt \rightarrow \infty$) and the dynamic viscosity curves in the oscillatory regime and plate-cone configuration (EN 13702). The results of the shift of the isotherms (frequency sweep) with the "WLF law" are summarized in Table 7 (see the mean value of the C_1 and C_2 coefficients). The values were calculated with the data of six tests: three specimens per geometry (PP08 and PP20). The WLF coefficients increase with the penetration grade; for some doses the mastic with 35/50 bitumen is analogous to 50/70. The general increase in the C_2 values suggests less sensitivity of the mastics to the temperature variations, in a more obvious way for the curves relating to the softer bitumen (70/100 mm/10).

Figure 5 reports the results of the viscoelastic analysis of the 35/50 bitumen and relative mastics, with the varying of the dose of filler.

The filler-bitumen pairing has improved the general performances of the mastic, reducing the dominant effect of the viscose component: the filler determines a general increase of both the stiffness (complex modulus $|G^*|$) and elasticity (phase angle δ) in the entire field

of frequencies. The result is included in the Black diagram, which also shows the problems of coherence caused by the filler and phenomena of non-linearity. These data partially complete the information obtained from the WLF: with the increase in the dose of filler, the mastic results as being more sensitive to the thermal variations at high working temperatures and lengthy loading times.

Figure 6 reports the results for the 50/70 bitumen and different mastics. In this case, the stiffening effect is less marked than in the 35/50 bitumen and is greater at the low frequencies. This indicates that the variation of the stiffness is dominated by the structure assumed by the solid skeleton in the bitumen matrix. The elasticity also apears to be less influenced compared to the 35/50 bitumen, and the thermal effect at high temperatures and low frequencies is absent. The action of partial modification of the bitumen, shown by the mastic with most filler in the case of the 35/50 bitumen, is attenuated in both the Black and Huet-modified diagrams. However, on the whole, the results obtained with the first two binders are comparable.

Figure 7 summarizes the results relating to the 70/100 bitumen (most widespread class in Italy), modified most by the contribution of the inorganic filler. The effect on the stiffness and elasticity is amplified by the structure of the filler: both improve with the reducing of the loading frequency and increase of the test temperature. Nonetheless, it should be observed

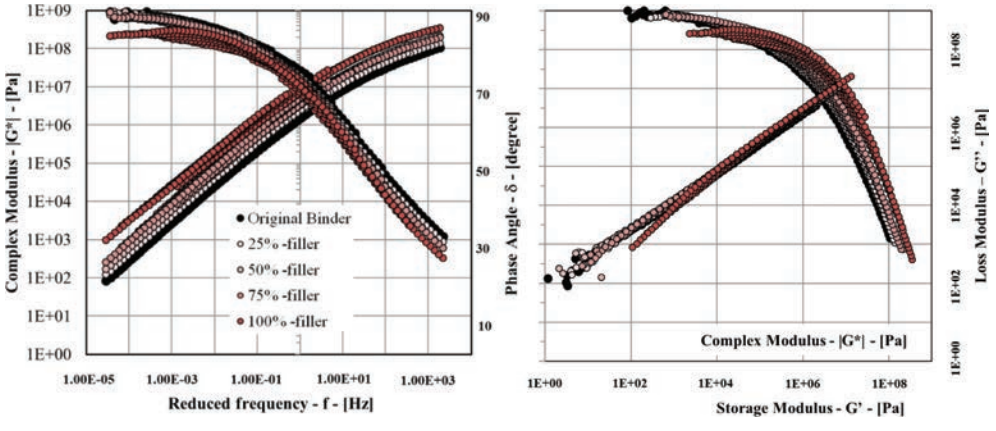

Figure 5. Extended plot: master curve |G*| and δ, black diagram and Huet-modified diagrams (right). Bit. 35/50.

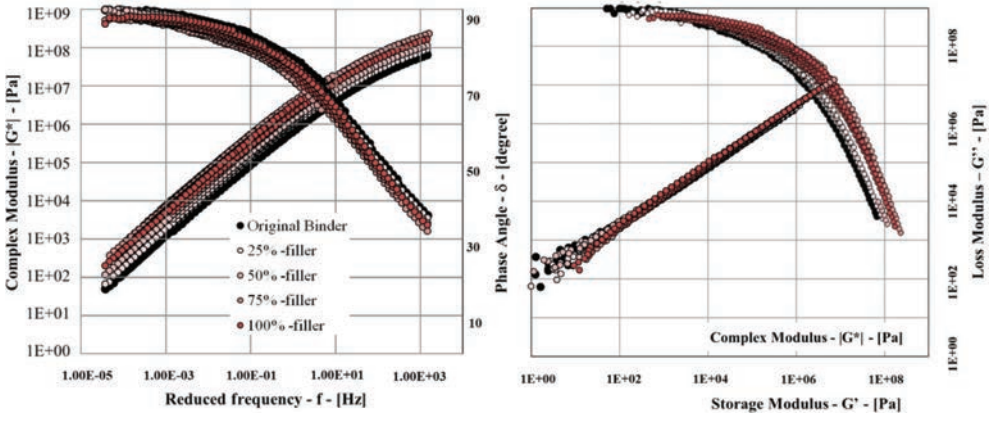

Figure 6. Extended plot: master curve |G*| and δ (left), black diagram and Huet-modified diagrams (right). Bit. 50/70.

that the problems of inconsistency of the rheological data are located in this same region of the mechanical response, linked to the relation between instrument and studied material, to phenomena of non-linearity and partial modification of the bitumen.

The phenomenon of "spindle compliance" is instead attenuated and the overlapping of the isotherm of the two geometries, at 30 and 35 °C, is positive. It is worth remembering that the evaluations produced on the Black and Huet-modified diagrams are totally independent of the operations of shifting of the isothermal curves, therefore of the law chosen for the shift factors and the model identified to build the master curves, as they eliminate the relation with the frequency and temperature. The disjointed shape of the curves of the mastic with the maximum dose demonstrates, at the same time, the increasing importance of the non-linear phenomena linked to the presence of large quantities of slag.

4 CONCLUSION

The mixtures, produced varying the unconventional filler-bitumen mass ratio, offer performances in line with the traditional products and a low sensitivity to temperature. The filler determines an increment in stiffness (G*) and elasticity (δ), increasingly evident with its dosage. The increment in stiffness is highest with the maximum dose (100%) of filler and is about 10 times the initial modulus, for the three bitumens considered. However, this mixture presents the biggest problems of "spindle compliance" and non-linearity, with a significant separation of the response to the stresses induced by the testing geometries.

With the increment in the dose of filler the contribution of the viscose component of the mechanical response is attenuated and the sensitivity of the instrument becomes a significant factor. In the conditions of maximum dose, the effect of the filler tends to depend also on the frequency of loading, as the lithic skeleton forms a more efficient and interconnected structure. The monotone, continuous and uniform shape of the curves (Black and Huet) demonstrates an acceptable equivalence between frequency and temperature.

Lastly, if the results offered by the 8 mm spindle are satisfactory, the 20 mm spindle shows problems at low frequencies/high temperatures (above 60 °C), where the sensitivity of the instrument is dominant.

Viscoplastic strain modeling of asphalt binder based on repeated creep recovery test

Chao Wang & Jinxi Zhang
Transportation Research Center, Beijing University of Technology, Chaoyang District, Beijing, P.R. China

ABSTRACT: The viscoelastic and viscoplastic properties of asphalt binder are valuable to the performance research on the asphalt mixture and pavements. Especially at high-temperature condition, the viscoplastic characteristics of binder play an important role in rutting-resistant performance. This paper presents a viscoplastic modeling method, which originates from the strain-hardening model, to study the unrecoverable strain response for binder in a repeated shear creep recovery test using a Dynamic Shear Rheometer (DSR). Two types of asphalt binders were evaluated in this study, namely the neat binder PG58-28 and the SBS polymer-modified binder PG70-28. In order to fit the model coefficients, a series of 10 cycles repeated creep recovery test were designed to conduct under multiple stress levels 25 Pa, 50 Pa, 100 Pa, doubled to 6400 Pa and three different time durations which included 0.1 s creep + 0.9 s recovery and 1 s + 9 s as well as 10 s + 90 s. Test results and modeling work indicate that, compared with the measured viscoplastic strain, the strain-hardening viscoplastic model can work well on the binder unrecoverable strain response prediction in repeated creep recovery test under lower stress levels and shorter creep duration and it is necessary to take the damage factor into consideration in the future work.

Keywords: Asphalt binder, high-temperature characteristic, repeated creep recovery, viscoplastic strain modeling

1 INTRODUCTION

Asphalt mixture performance prediction is crucial for pavement structure design based on the laboratory test and mechanical analysis. The common prediction approach used today is to develop the constitutive equations which can describe the material behaviour accurately under different temperature and loading conditions. The asphalt mixture modeling has been under research for many years to capture and characterize the rutting and cracking distresses. For rutting evaluation, the NCHRP Project 9–19 proposed the Flow Number (FN) test, in which method repeated creep loading and recovery test is conducted on a Universal Testing Machine (UTM) or Asphalt Mixture Performance Tester (AMPT), to assess the HMA mixture permanent deformation resistance under traffic load. In the FN test analysis proceeding, the permanent strain curve can be divided into three zones: primary, secondary, and tertiary. The cycle number where tertiary flow starts is regarded as the key parameter associated with the mixture rutting potential. Based on FN test data, several statistics modeling work were carried out to investigate the influences of dynamic modulus, gradation and short-term aging as well as long-term aging on the rutting performance of asphalt mixture [1, 2]. But it is still a challenging task to model the mixture strain responses in a three phases creep recovery test like the FN procedure. In order to complete this objective, a viscoelastic-viscoplastic constitutive model with damage is required for characterizing asphalt mixture behaviour.

It is has been widely accepted that the asphalt materials response to load is composed of four components, the elastic and plastic components which are time-independent and

Viscoelastic (VE) and Viscoplastic (VP) components which are time-dependent. Generally, the elastic portion is included in the viscoelastic one and the plastic portion is either very small or hardly distinguished from the viscoplastic response. So the model can be simplified to viscoelasticity and viscoplasticity. A nonlinear VE model with damage was developed by Schapery in 1990 [3]. Later, a combination of this VE model and an undamaged strain-hardening VP model was applied to describe asphalt mixture behaviour under uniaxial loading either in tension or compression [3–8]. Recently, Uzan supplemented the strain-hardening VP model with damage function consideration on viscoplastic components [9, 10]. Therefore, the completed VE-VP model with different types of damage evolution laws for different deformation components are formulated to enable the advanced constitutive model more powerful to characterize the asphalt mixture behaviour.

At the same time, the correlations between asphalt binder properties and mixture testing performance are also under investigation. Although it is still hard to accurately quantify the asphalt binder contributions to the core performance of asphalt mixture and pavement, it is also a fact that the VE-VP properties of asphalt mixtures are exactly derived from the asphalt binder components. So a better understanding of viscoelastoplastic fluid behaviour like asphalt binder will be of great help for the research on viscoelastoplastic solid like asphalt concrete. Recently, some studies revealed an interesting but key test finding that tertiary flow may also occur during a static creep test for asphalt binder on a DSR. And tertiary flow has been proved to be an intrinsic property of asphalt binders, which is similar to that in mixture, and should be considered in modeling the permanent deformation characteristics of asphalt binders [11–14]. Although the loading conditions in binder test and mixture test are different, shear loading and pull-push loading respectively, the common phenomenon of tertiary flow still seems to be a promising link between binder and mixture. Besides, it is the truth that most of the rutting failures are caused by a lack of sufficient shear-resistance in asphalt mixture.

This paper attempts to check the possibility of applying the strain-hardening VP constitutive equation on modeling binder unrecoverable shear strain responses under a series of Repeated Creep Recovery (RCR) tests. This effort is part of a larger research work devoted to development of a VE-VP model with growing damage for simulating the tertiary flow of asphalt binder.

2 THEORETICAL BACKGROUND

Based on the fundamental formulation proposed by Uzan (1985) and Schapery (1999), the theoretical strain-hardening VP model is employed to characterize the unrecoverable strain responses behaviour [15, 5]. The VP constitutive function form is as follows:

$$\dot{\varepsilon}_{vp} = \frac{g(\sigma)}{\eta_{vp}} \tag{1}$$

where $\dot{\varepsilon}_{vp}$ is the VP strain rate, $g(\sigma)$ is the constant-stress loading function, and η_{vp} is the material's coefficient of viscosity. When η_{vp} is assumed a power law of the measured VP strain (6), the following equation is obtained:

$$\dot{\varepsilon}_{vp} = \frac{g(\sigma)}{A\varepsilon_{vp}^{p}} \tag{2}$$

In which A and p are material model parameters. Then Equation (2) can be integrated and rearranged to:

$$\varepsilon_{vp} = \left(\frac{p+1}{A}\right)^{\frac{1}{p+1}} \left(\int_0^t g(\sigma)dt\right)^{\frac{1}{p+1}} \tag{3}$$

For the constant-stress loading condition, $g(\sigma)$ is independent of time so the Equation (3) turns to be:

$$\varepsilon_{vp} = \left(\frac{p+1}{A}\right)^{\frac{1}{p+1}} g(\sigma)^{\frac{1}{p+1}} t^{\frac{1}{p+1}} \tag{4}$$

Assuming a power law of the form $g(\sigma) = B\sigma^q$ where B and q are material coefficients, then Equation (4) becomes:

$$\varepsilon_{vp} = \left(\frac{p+1}{A}\right)^{\frac{1}{p+1}} (B\sigma^q)^{\frac{1}{p+1}} t^{\frac{1}{p+1}} \tag{5}$$

Coupling coefficients A and B into one coefficient C, the Equation (5) can simply reduce to:

$$\varepsilon_{vp} = \left(\frac{p+1}{C}\right)^{\frac{1}{p+1}} \sigma^{\frac{q}{p+1}} t^{\frac{1}{p+1}} \tag{6}$$

So there are totally three material parameters p, q, and C existed in the ultimate VP model formulation.

3 EXPERIMENTAL PROGRAM

Two types of asphalt binders were used in this study, one is neat binder PG58-28 and the other one is SBS modified binder PG70-28. Ignoring the aging effect on binder properties, only original binder samples were tested using a DSR under a constant temperature at 60 °C. In order to determine the coefficients in Equation (6), a series of 10 cycles Repeated Creep Recovery (RCR) tests with different stress levels and loading-unloading time durations were designed to conduct respectively. The details of the materials and test plan were summarized and provided in Table 1.

The 10 cycles RCR tests were conducted on each binder using nine stress levels and three time durations to measure the unrecoverable strain responses for the next binder VP modeling work. A typical RCR data for SBS binder PG70-28 from DSR is given in Figure 1.

4 VISCOPLASTIC MODELING

When applying the VP constitutive function shown in Equation (6) on the shear strain modeling of asphalt binder. It should firstly convert the mechanical symbol from compression or tension mode to shear mode. So the equation can be expressed as follows:

$$\gamma_{vp} = \left(\frac{p+1}{C}\right)^{\frac{1}{p+1}} \tau^{\frac{q}{p+1}} t^{\frac{1}{p+1}} \tag{7}$$

Table 1. Repeated creep recovery test plan.

	Neat binder PG58-28
Binder types	SBS binder PG70-28
Stress levels (Pa)	25, 50, 100, 200, 400, 800, 1600, 3200, 6400
Creep + recovery time durations (s)	0.1 + 0.9
	1 + 9
	10 + 90
Test cycles	10 cycles
Temperature	60 °C

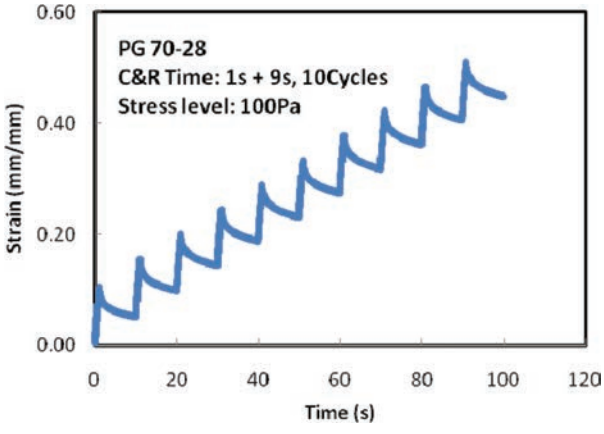

Figure 1. Typical RCR test data on DSR.

In order to fit the material coefficients p, q and C, it is need to respectively separate the stress variable and time variable, and the RCR test program given in Table 1 can be regarded as two series: (i) constant stress RCR tests at fixed stress level but varying the loading-unloading time duration. This series is to determine the parameter p with the Equation (7) reduced to:

$$\gamma_{vp} = C_1 t^{\frac{1}{p+1}} \tag{8}$$

Performing a logarithmic transformation, the Equation (8) becomes the common form of a linear equation $y = b + a \cdot x$, where a is the slope and b is intercept, as shown in Equation (9). Hence, $1/p+1$ is the slope of a line formed as Log γ_{vp} versus Log t and Log C_1 is the intercept of this line. Solving for the slope and the intercept of the plot is easily accomplished by model fitting using the test data.

$$Log\,\gamma_{vp} = Log\,C_1 + \frac{1}{p+1} Log\,t \tag{9}$$

Another test series is: (ii) Constant time RCR tests at fixed loading-unloading time duration but varying the stress levels, which aims to calculate the material parameter q and C. Similar to the transformation used above, Equation (10) and (11) are easily available to fit the test data and determine the q and C with the solved p value.

$$\gamma_{vp} = C_2 \tau^{\frac{q}{p+1}} \tag{10}$$

$$Log\,\gamma_{vp} = Log\,C_2 + \frac{q}{p+1} Log\,\tau \tag{11}$$

Next sections specifically present the model fitting and parameters calculating proceeding as well as the verification work for the two used asphalt binders.

4.1 *Determination of parameter p*

Based on the RCR tests at fixed stress level but varying the loading-unloading time duration, the plot of Log γ_{vp} versus Log t for the two binders are provided in Figures 2 and 3, respectively. In fact, plotting the line at any one fixed stress condition from the totally nine stress levels, for example the line of 800 Pa, is enough to fit the line slope because the slope value should be theoretically independent on the stress level according to the Equation (9). This point could

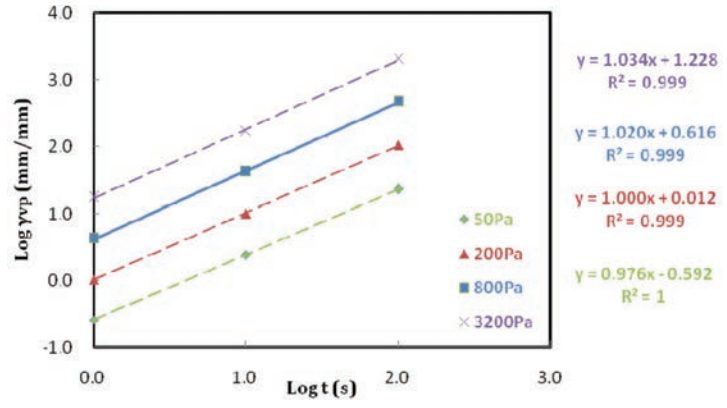

Figure 2. Neat binder linear fitting of Log γ_{vp} versus Log t.

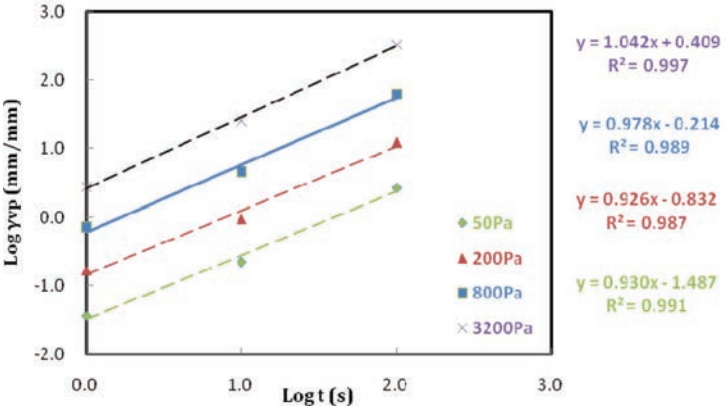

Figure 3. SBS binder linear fitting of Log γ_{vp} versus Log t.

also be proven by the extra three lines of 50 Pa, 200 Pa and 3200 Pa shown in the two figures and it was observed that the four lines at different stress levels exhibited the similar slope.

Using the fitting line of 800 Pa in this paper, the values of parameter p were respectively calculated as –0.0196 and 0.02249 for the two binders.

It should be noted that parameters q and C can also be determined since additional results at other stress levels are available. But using this method the q value is sensitive to parameter p during the calculating process. The slop shown in Figures 2 and 3 is similar but not exactly the same, which is more obvious for SBS binder. So it is still recommended to using the Equation (11) to determine the more accurate value of parameter q.

4.2 *Determination of parameters q and C*

For the RCR tests conducted at fixed loading-unloading time duration but varying the stress levels from 50 Pa to 3200 Pa, Log γ_{vp} versus Log t were plotted respectively in Figures 4 and 5 for the two binders. Similarly, the line of one time duration can work sufficiently but the extra two lines are also given to demonstrate the independence of the line slope on the time factor in accordance with the Equation (11).

Based on the line fitting of 1 s + 9 s loading-unloading time duration and the solved p values, the parameters q and C can be determined and then the ultimate calculated results of the model coefficients are summarized in Table 2.

Model coefficients		
p	–0.0196	0.02249
q	1.00588	1.16359
C	210.25	4939.57

4.3 *Model verification*

Figure 6 presents the comparison of measured and predicted unrecoverable strain using the VP strain-hardening model for the SBS binder PG70-28 in an arithmetic scale. The figure shows that the VP model is able to provide a reasonable prediction across all time duration. Meanwhile, increasing the stress level was found to negatively impact the prediction accuracy, which might be caused by the damage effect on binder under larger creep stress. Hence, on the basis of the

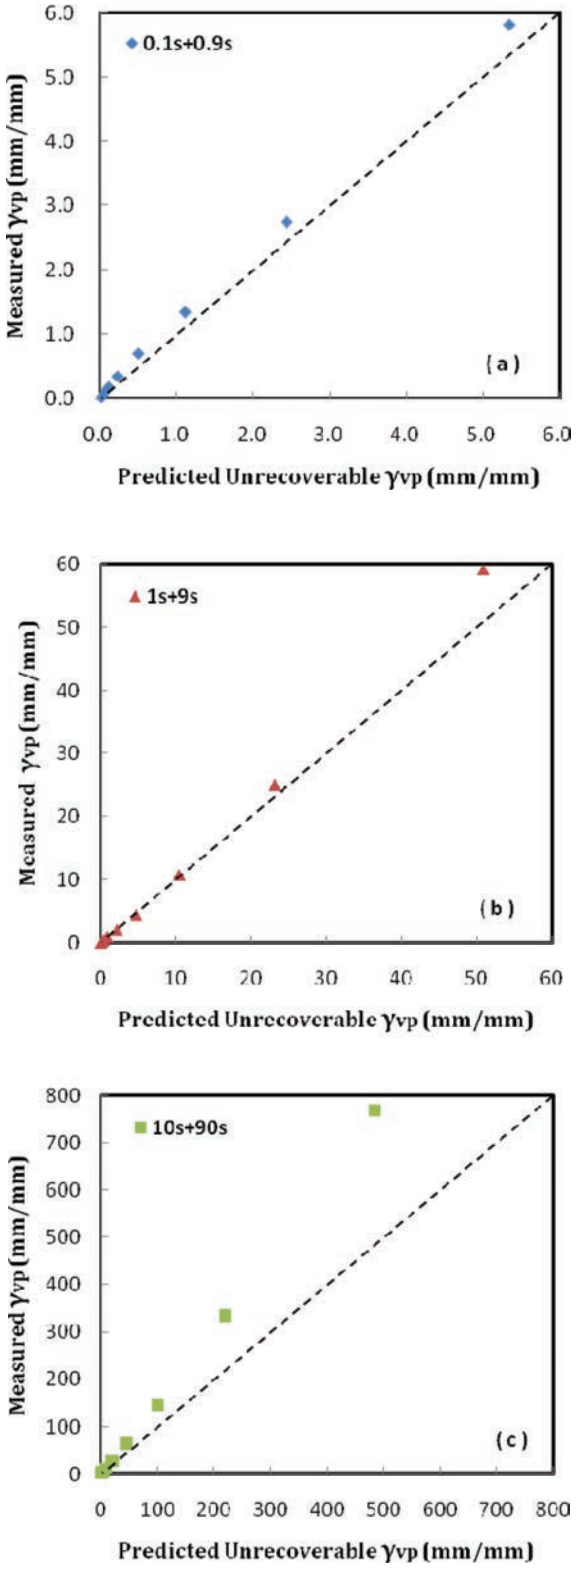

Figure 6. Predicted vs. measured unrecoverable VP strain in arithmetic scale.

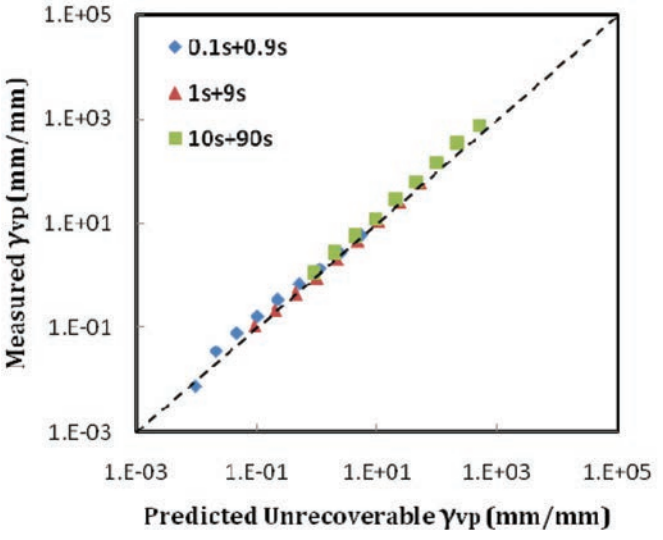

Figure 7. Predicted vs. measured VP strain for all cycles data in logarithmic scale.

undamaged VP model used in this paper, further study need to cover the damage influence on the VP modeling of asphalt binder under high stress levels and longer loading duration.

The comparison data of SBS binder plotted in a log scale is given in Figure 7. Besides, the neat binder P58-28 also exhibited the similar prediction results so they are not included.

5 SUMMARY

This study focused on applying the viscoplastic stain-hardening model on the characterization of asphalt binder. This model has been successfully employed to predict the asphalt mixture behaviour in compression and tension. Findings in this paper indicate that the VP model can also be used to describe the asphalt binder unrecoverable strain responses in a shear loading test on a DSR under lower stress levels and shorter loading duration.

In order to predict the binder behaviour more accurately, it may be possible take the damage impact into consideration and supplement the undamaged VP constitutive function with damage modification. This effort will contribute to develop a VE-VP model with growing damage to modeling the tertiary flow of asphalt binder, which is a promising approach linking the binder property to mixture permanent deformation performance.

Fatigue performance and stiffness properties of Stone Mastic Asphalts with steel slag and coal ash

Marco Pasetto

ABSTRACT: This paper describes the results of an experimental investigation and a theoretical study on the fatigue behaviour of Stone Mastic Asphalt (SMA) mixes, determined by the four-point bending test, according to the EN 12697-24 Annex D standard. The testing was performed on SMA mixes with Electric Arc Furnace (EAF) steel slag and Coal Bottom Ash, used at different proportions, in partial substitution for natural limestone and filler. The mix design method was based on the volumetric properties, as well as on the moisture resistance of the asphalt concretes. Both the Bailey's method and a conventional approach were used in order to identify the design grading curves of the mixes. Fatigue life was evaluated by means of the empirical approach, related to a 50% reduction in the initial stiffness modulus, as well as using more rational concepts, related to the macro-structural damage condition of the mixtures, in terms of dissipated energy and damage accumulation. With respect to the control SMA with limestone aggregates, the asphalt concretes with EAF slag and Coal Ash presented improved fatigue properties and delayed macro-crack initiation.

Keywords: Stone Mastic Asphalt, steel slag, coal ash, volumetric mix design, fatigue life

1 INTRODUCTION

Fatigue in asphalts, which is the type of damage caused by the repeated transit of vehicles at medium-low temperatures, leads to the development of crackings that may degenerate into the complete fracture of the road pavement. It is, therefore, a primary failure mode of flexible pavements, that has to be properly investigated in relation to the design of bituminous mixtures for road superstructures. The paper discusses the results of a laboratory testing concerning the fatigue and stiffness properties of Stone Mastic Asphalts designed by means of a conventional trial and error procedure, as well as a volumetric procedure, namely the Bailey method. The SMA mixes investigated were partially made with Electric Arc Furnace (EAF) steel slag and coal ash (up to 20% and 10% by weight of the aggregate, respectively), in order to valorize the environmental sustainability of the designed mixes.

The purpose was to evaluate the stiffness properties and the fatigue behavior of the SMA mixtures, by means of the four-point bending test, according to EN 12697-26 Standard, Annex B and EN 12697-24 Standard, Annex D, respectively.

2 MATERIALS

Three granular materials were used in the study: EAF slag, coal ash and natural aggregate (crushed limestone). The grading curves of the aggregates are presented in Figure 1, whereas Table 1 reports their physical-mechanical properties, as well as the specific road test protocols adopted.

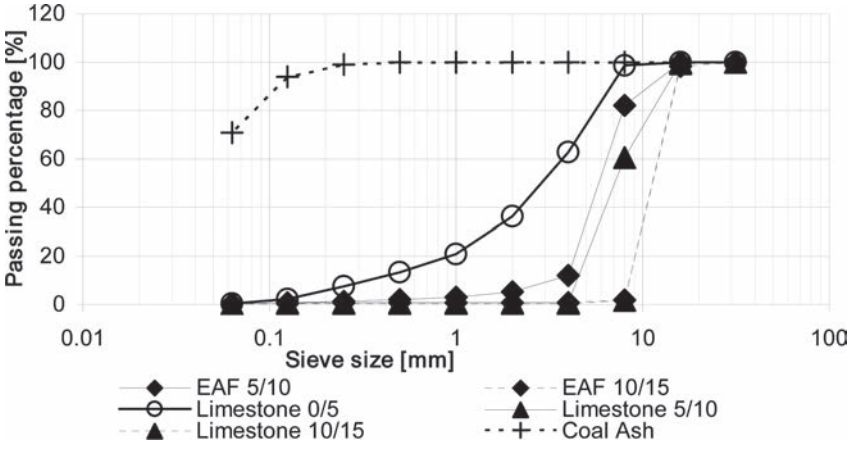

Figure 1. Grading curves of the aggregates.

Table 1. Physical and mechanical characteristics of the aggregates.

Physical ÷ mechanical properties	Crushed limestone 0/5	Crushed limestone 5/10	Crushed limestone 10/15	EAF 5/10	EAF 10/15	Coal ash
Los Angeles coefficient [%] EN 1097-2	–	–	30	–	8	–
Equivalent in sand [%] EN 933-8	69	–	–	–	–	–
Shape Index [%] EN 933-4	7	5	5	11	1	–
Flakiness Index [%] EN 933-3	6	8	6	9	5	–
Loose unit weight [g/cm^3] AASHTO T-19	1.47	1.25	1.26	1.72	1.67	0.85
Rodded unit weight [g/cm^3] AASHTO T-19	1.57	1.38	1.40	1.87	1.88	–

The binder used was a SBS polymer modified bitumen for all the mixtures investigated. It was characterized by a 46 dmm penetration (EN 1426), a Ring & Ball softening point of 75°C (EN 1427) and a Fraass breaking point of –13°C (EN 12593). The elastic recovery value, certified by the bitumen manufacturer, is higher than 50% at 25°C (EN13398).

3 MIXTURES

Four different SMA mixes were studied: two with both recycled and natural aggregates (S/RA, B/RA) and two, used as a control, with limestone only (S/LS, B/LS). For the control LS mix (all natural) various amounts of marginal materials are substituted by limestone with an equivalent grading fraction; instead of the coal ash, a conventional Portland Cement (PC) has been used as filler.

3.1 *Grading and composition of the mixes*

The particle size distribution of the mixes S/RA and S/LS was optimized by means of a conventional trial and error procedure, with reference to the design grading envelope of SITEB [1], in order to identify a curve as close as possible to its centre, but compatible with

the availability of the different aggregates in the sizes necessary to construct this "ideal" grading.

The aggregate skeleton of the mixes B/RA and B/LS has been developed following the Bailey method [2], in order to ensure aggregate interlock and suitable aggregate packing. The present study have been focused on 12.5 mm Nominal Maximum Particle Size (NMPS). Therefore, according to the Bailey criteria, Half Sieve, Primary Control Sieve (PCS), Secondary Control Sieve (SCS) and Tertiary Control Sieve (TCS) resulted equal to the 6.25 mm, the 2.36 mm, the 0.60 mm and the 0.150 mm sieve, respectively [2].

To achieve the level of coarse aggregate interlock desired in the SMA mix, the rodded unit weight, which is determined for each specific coarse aggregate, is used as the reference for the chosen unit weight of the coarse aggregate. With regards to different coarse aggregates, the Bailey Method combines them by volume mathematically, using the corresponding chosen unit weights. The chosen unit weight for the coarse aggregates (namely EAF 10/15 and Limestone 10/15) has been fixed to 125% of their corresponding rodded unit weight.

The Bailey procedure, have been implemented in an electronic spreadsheet, on the basis of the equations reported in the Transportation Research Circular No. E-C044 [3]. Table 2 reports the composition of the mixtures with (RA) and without (LS) marginal aggregates; the corresponding grading curves are presented in Figure 2.

Table 2. Aggregate type and particle size distribution of the mixtures.

Aggregate type	S/RA content [%]	S/LS content [%]	B/RA content [%]	B/LS content [%]
EAF slags 5/10	20	0	10.92	0
EAF slags 10/15	0	0	8.54	0
Coal ash	10	0	10.37	0
Limestone 0/5	25	25	20.79	22.56
Limestone 5/10	45	65	49.38	60.22
Limestone 10/15	0	0	0	6.89
Synthetic filler PC	0	10	0	10.33

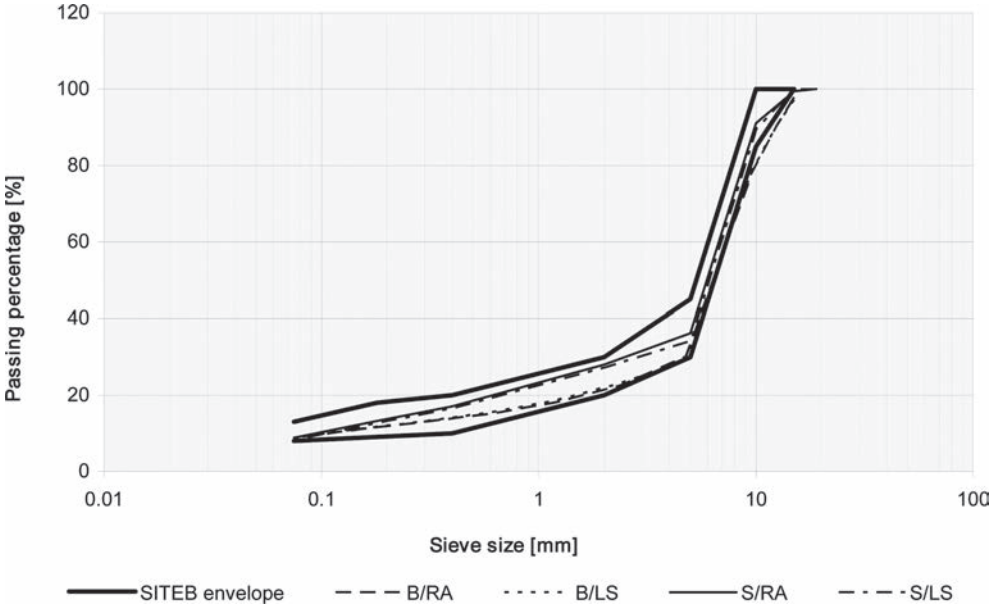

Figure 2. Design grading curves of the mixes.

The aggregate ratios, computed according to Eqs (1, 2, 3), have been reported in Table 3. The recommended ranges for the aggregate Ratios in SMA mixtures [2] are also evidenced.

The aggregate ratios requisites, recommended in the Transportation Research Circular No. E-C044 [3], for SMA mixes with a 12.5 mm NMPS, were completely satisfied for the B/RA as well as for the B/LS.

$$\text{CA Ratio} = \frac{\%\text{Passing Half Sieve} - \%\text{Passing PCS}}{100\% - \%\text{Passing Half Sieve}} \tag{1}$$

$$\text{FA}_c = \frac{\%\text{Passing SCS}}{\%\text{Passing PCS}} \tag{2}$$

$$\text{FA}_f = \frac{\%\text{Passing TCS}}{\%\text{Passing SCS}} \tag{3}$$

However, a partial noncompliance of the Bailey design grading curves with respect to the SITEB reference envelope, is worth mentioning. The discrepancies are related to the passing percentages at the largest sieves (greater than 4.75 mm), so denoting a coarser gradation for the design curves obtained by the Bailey method.

3.2 *Optimization of the mixture*

According to CIRS-Italian Ministry of Infrastructure Specifications [4], a mix design method based on the gyratory compaction and the Indirect Tensile Strength (ITS) test at 25°C, on both dry and wet cylindrical specimens, was adopted in order to optimize the bitumen content, for all the SMA mixes. Regarding the main gyratory test parameters, a speed of 30 revs/minute, a pressure of 600 kPa, an angle of rotation of 1.25° and a diameter of the mould of 150 mm, were adopted.

For each SMA mix, the Optimum Bitumen Content (OBC) was identified with respect to specific volumetric requisites: a residual air voids content (Va) at 10, 100 and 180 revs, of 8–12%, 2–4% and over 2%, respectively [4]. Then, for the optimal mixes, the dry indirect tensile strength at 25°C and the Tensile Strength Ratio (TSR) were determined and compared with the CIRS acceptance requisites. The TSR was calculated as the ratio between the indirect tensile strength of the samples conditioned by means of 15 days of immersion in a thermostatic bath at 25 °C (ITS_{wet}) and unconditioned (ITS_{dry}), respectively. The ITS_{dry} and the TSR values of the optimal SMA mixtures should result higher than 0.6 MPa and 75%, respectively. The results of the mix design procedure are presented in Table 4, which

Table 3. Aggregate Ratios for the design mixes.

Aggregate Ratio	B/RA	B/LS	Recommended range
CA Ratio	0.389	0.390	0.250–0.400
FAc Ratio	0.675	0.672	0.600–0.850
FAf Ratio	0.734	0.725	0.600–0.850

Table 4. Mix design results.

Mixtures	VMA [%]	VFB [%]	Va @ 10 res [%]	Va @ 100 res [%]	Va @ 180 res [%]	Bulk density [g/cm^3]	ITS_{dry} [MPa]	ITS_{wet} [MPa]	TSR [%]
S/RA	17.75	78.66	9.13	3.79	3.67	2.59	1.24	1.08	87
S/LS	17.00	78.00	9.08	3.74	3.55	2.46	1.13	0.85	75
B/RA	17.76	79.23	8.79	3.69	3.36	2.61	1.31	1.16	89
B/LS	17.02	78.56	8.22	3.65	3.13	2.48	1.25	0.98	78

details for each SMA mixture: Air Voids (Va) at 10, 100 and 180 revs, ITS for dry and wet conditions, Voids in the Mineral Aggregate (VMA), Voids Filled with Bitumen (VFB) and bulk density at 100 revs.

The Air Voids requisites prescribed by CIRS mix design procedure, at 10, 100 and 180 revs, were completely fulfilled, for all the SMA mixes, in correspondence of a bitumen content equal to 5.5% of the weight of the aggregate. For SMA mixtures a percentage of Voids in the Mineral Aggregate (VMA) higher than 17% and a percentage of Voids Filled with Bitumen (VFB) between 75% and 85% [5] are needed. According to data in Table 4, all the additional volumetric requisites are verified for the designed mixes. The mechanical requisites, in terms of ITS_{dry} and TSR were also satisfied, for all the designed SMA mixes (Table 4).

The SMA mixes designed by the Bailey method (B/RA and B/LS) showed improved ITS values, with respect to the reference asphalt concretes (S/RA and S/LS), varying from 5% to 18%, depending on the dry/wet condition.

Focusing the attention on the comparison between mixes with and without marginal aggregates, it is possible to observe higher ITS values for the SMA concretes made with EAF steel slag and coal ash. The highest TSR values recorded for the mixes with marginal aggregates, with respect to the corresponding natural SMA concretes, confirm the strong affinity between EAF steel slag and the modified binder, already observed in other investigations [5–8].

Given the high specific weight of the EAF slags, the bulk density of the mixes with Recycled Aggregates (RA) resulted higher than the limestone-only mixtures (LS), for both the aggregate skeleton design method.

4 PERFORMANCE TEST PROGRAMME

Four-point bending tests were conducted using the protocol described in Annex B of the European EN 12697-26 Standard for stiffness evaluation, as well as that reported in Annex D of the European EN 12697-24 Standard for fatigue analysis. The latter have been performed in a regime of stress control, with a wave of sinusoidal loading without rest periods. As reported by Artamendi and Khalid [9], the stress control procedure has to be preferred to the controlled strain testing, in the fatigue evaluation, for high stiffness materials, as the SMA. The fatigue tests were all conducted at a temperature of 20 °C, frequency of 10 Hz, and at three stress levels: 0.9, 1.4 and 1.9 MPa. For each test, in addition to the stress and strain values, the angle phase and energy dissipated at each loading cycle were also monitored, in order to be able to analyze the experimental data with an energy approach. The beam specimens submitted to the bending tests, with dimensions of 400 mm × 50 mm × 60 mm, were cut from 300 mm × 400 mm × 50 mm slabs, prepared using a laboratory compacting roller in accordance with the EN 12697-33 Standard.

4.1 *Stiffness test results*

Table 5 reports the results of the Stiffness Modulus evaluation, at different temperatures (0 °C, 10 °C, 20 °C, 30 °C), in correspondence of a frequency of 10 Hz.

Table 5. Stiffness modulus data [MPa].

Mixture	0 °C	10 °C	20 °C	30 °C
S/RA	12,863	10,647	6,916	3,376
S/LS	13,287	11,087	7,224	3,611
B/RA	10,917	8,465	6,030	3,205
B/LS	12,583	9,929	6,458	3,359

As it was expected, given the visco-elastic nature of the mixes investigated, the higher the temperature, the lower the Stiffness Modulus. The Bailey mixtures presented lower stiffness than SITEB concretes; the asphalt concretes made with marginal materials recorded lower Modulus in comparison with the correspondent natural mixes.

4.2 *Fatigue test results*

The classical fatigue curves, elaborated according to the initial value of strain ε_0 and number of cycles N_f, at which a 50% reduction of the initial stiffness is registered, are presented in Figure 3. The initial strain was evaluated at the 100th cycle (EN 12697-24, Annex D), since as generally recognized in the literature, this is the stage of the test when the material shows a stress-strain response that reliably represents the initial conditions, without yet being significantly affected by damage phenomena. The regression analysis of the fatigue data was performed using a power law model of the type:

$$\varepsilon_0 = \mathrm{a} N_f^{\mathrm{b}} \tag{4}$$

where a and b are regression coefficients depending on the type of material. Figure 3 presents, for the different mixtures, the experimental data and the Fatigue Curves (FC), while Table 6 report the regression coefficients and coefficient of determination R^2.

With reference to a fatigue resistance of 1,000,000 loading cycles (as indicated in Standard EN 12697-24, Annex D), and using Eq. (4), it was possible to calculate the corresponding tensile strain $\varepsilon(10^6)$, which was higher for the asphalts designed by means the Bailey method; in particular the highest value, 44 μm/m, was obtained for B/LS (Table 6).

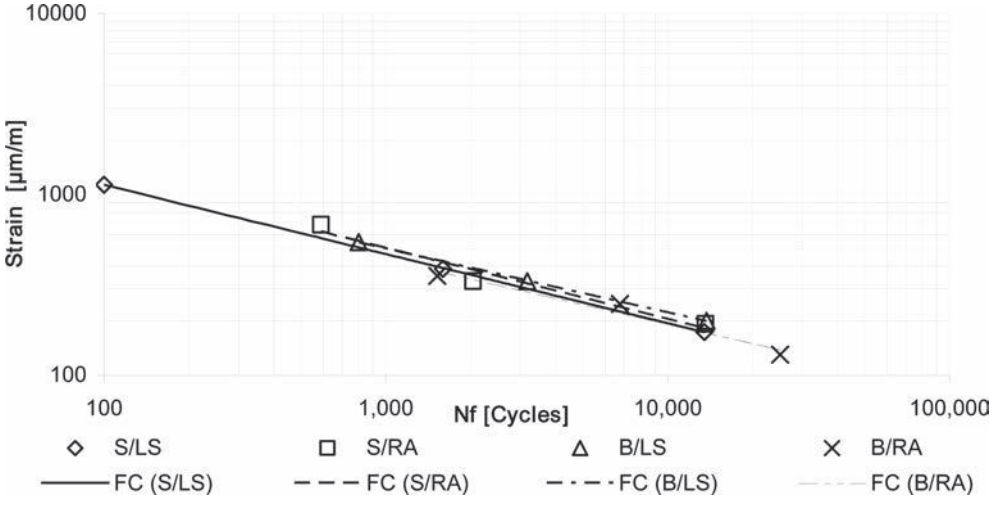

Figure 3. Fatigue life N_f versus initial strain.

Table 6. Fatigue curves—regression coefficients.

Mixture	a [μm/m]	b [–]	$\varepsilon(10^6)$ [μm/m]	R^2 [–]
S/RA	7601.9	–0.392	34	0.9594
S/LS	6571.5	–0.383	33	0.9999
B/RA	5088.0	–0.356	37	0.9581
B/LS	5712.0	–0.352	44	0.9997

4.3 *Dissipated energy analysis*

The data gathered in the fatigue tests were also analyzed with Carpenter's energy approach [10, 11], recently also utilized by other Authors [12, 13, 14]: the Plateau Value (PV) of the Ratio of Dissipated Energy Change (RDEC) is assumed as a fundamental damage parameter. This approach defines the RDEC as the ratio of the change in dissipated energy between two cycles and the dissipated energy of the first cycle, according to the formula:

$$\mathrm{RDEC} = \frac{\mathrm{DE}_{n+1} - \mathrm{DE}_n}{\mathrm{DE}_n} \tag{5}$$

where DE_n and DE_{n+1} represent the dissipated energy produced in load cycle n and n+1, respectively.

The RDEC is considered as a reliable indicator of the damage being done to the asphalt concrete from one cycle to another, as a function of how much dissipated energy was involved in the previous cycle [10, 11]. It results to be independent from other types of dissipated energy, due to mechanical work or heat generation and therefore it represents a true indicator of the internal damage developed into the material, during a fatigue test.

As discussed by Carpenter et al. [10, 11], the damage curve represented by the evolution of RDEC with the varying of the load cycles, can be divided into three different zones. RDEC decreases with the number of cycles in zone 1, then it is almost constant in zone 2, representing a stage during which there is a constant percent of input energy turned into internal damage. The third zone is characterized by a consistent and rapid increase of the RDEC with the load cycles; it describes the onset of true failure of the mixture. The stage of relevant interest in the Carpenter's approach is zone 2. The approximately constant RDEC value in zone 2 is named Plateau Value (PV) of RDEC and it is assumed as a fundamental damage parameter; a lower PV value corresponds to a longer fatigue life of the mixture [10, 11]. Figure 4 reports an example of the determination of PV value for the mix S/LS at 0.9 MPa.

Shu et al [12] have already used the PV value in order to compare different bituminous mixtures, but with regards to four point bending tests in a regime of strain control and using a single strain level for each asphalt concrete.

In this study, the damage curves (PV curves—PVC) have been elaborated, in order to compute the PV value for a 1,000,000 loading cycles (PV_6). Figure 5 shows the damage curves, determined as a function of N_f (load cycles that correspond to a 50% stiffness reduction) and the PV value.

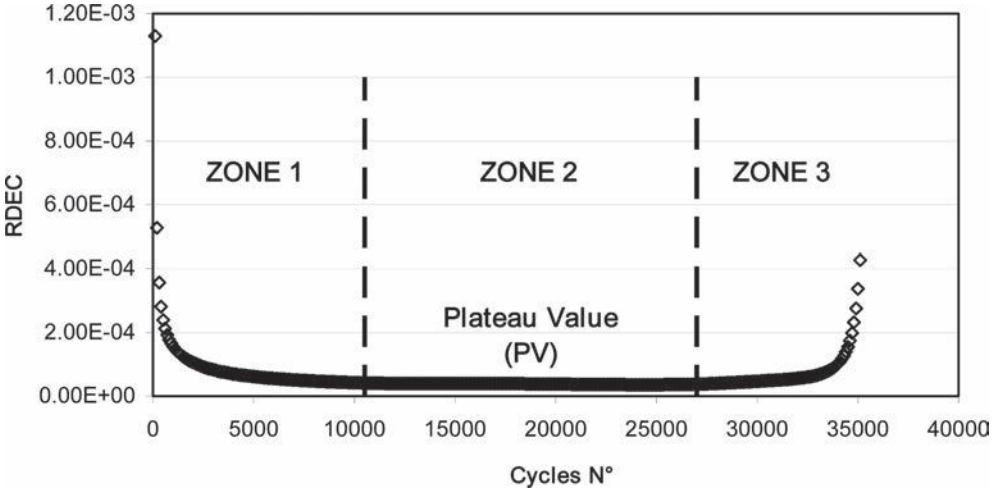

Figure 4. Determination of PV value for mix S/LS at 0.9 MPa.

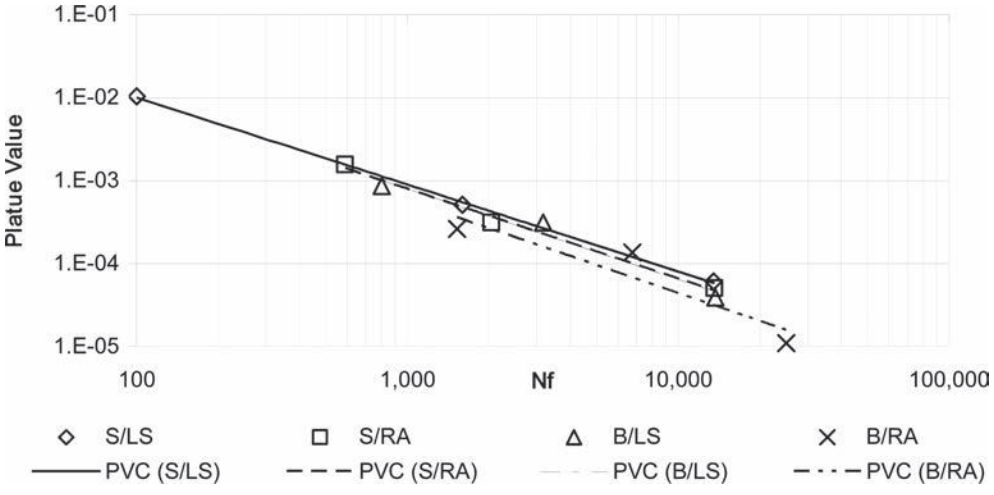

Figure 5. Plateau Value (PV) versus cycles to failure (N_f).

Table 7. Damage curves—regression coefficients.

Mixture	a [MPa]	b [–]	R^2 [–]	PV_6 [–]	ΔPV_6 [%]
S/RA	1.3715	–1.079	0.9925	4.60464E-07	76
S/LS	1.2458	–1.048	0.9994	6.41872E-07	50
B/RA	1.2798	–1.115	0.8741	2.61302E-07	–
B/LS	1.4808	–1.090	0.9688	4.27067E-07	–

For the analytical interpolation of the damage curves, a power law model was used:

$$PV = aN_f^b \tag{6}$$

where a and b are regression coefficients depending on the type of material. Table 7 reports the coefficients of regression and determination, as well as the PV value computed using Eq. (6) with reference to a 1,000,000 loading cycles. The percentage variations of the PV_6 of the SITEB mixtures, compared to the corresponding Bailey concretes (named ΔPV_6) have been also reported.

The analysis of the PV_6 values, determined with the energy based approach, allows the different types of mixtures to be compared. The Bailey's mixtures presented lower PV values and therefore lower damage, with respect to correspondent mixes studied with the conventional skeleton design approach. SITEB mixes developed consistent damage increments, expressed in terms of ΔPV_6, up to 76% for the S/RA mix. Comparing the two Bailey mixtures, it can be observed the higher damage developed for the mix with limestone (B/LS), 64% more than the B/RA asphalt. Therefore, according to the experimental results (Table 7), it has been verified the beneficial effect of the Bailey method in order to improve the fatigue behaviour of the bituminous mixtures investigated.

However, a relevant difference in the ranking of the mixtures, using the two methodologies, is worth mentioning. The energy based analysis led to rank the B/LS mix as less resistant to fatigue, whereas the conventional approach identified the B/RA mix as that characterized by the lower fatigue life. Such a discrepancy was already observed in a previous study regarding crumb rubber asphalt concretes and SBS polymer modified mixes [8]. As observed by several researchers [9–14], in the standard approach the failure of the sample is empirically based on the 50% stiffness reduction, whereas the energy based analysis can be considered more

reliable and effective, since the key parameter considered, the Plateau Value of the Ratio of Dissipated Energy Change, is rationally related to the internal state of damage achieved into the material during the fatigue test.

5 CONCLUSIONS

The four point bending fatigue tests, conducted on bituminous concretes of SMA type, have demonstrated the superior performance of the Bailey mixtures when compared with those designed with a conventional approach.

The better performance of the Bailey mixes is also fully confirmed by means of the Carpenter's energy based approach.

The effectiveness of the Bailey method in the increase of fatigue life was also clear for the mixtures made with EAF steel slag and coal ash up to 20% and 10% on the weight of the aggregates, respectively.

In this study a discrepancy emerged between the empirical fatigue evaluation and the energy based analysis, therefore it is recommended to approach very carefully the fatigue characterization based on the 50% stiffness reduction criterion.

It is has been verified a complete congruence between the different performance tests used in the investigation, in fact, the lower the stiffness at 20°C and 10 Hz, the higher the fatigue life of the mix at the same testing conditions.

Comparison between SBS and crumb rubber modified asphalt—laboratory and field study

Erik Nielsen
Danish Road Directorate, Hedehusene, Denmark

ABSTRACT: A modification concept called ROAD+, which combines crumb rubber granulate and an additive, Vestenamer®, has been studied in a huge laboratory and trial section study in Denmark. The objective has been to bridge gaps in existing documentation for the product and to gain experience with its application among Danish asphalt concrete producers.

A comparison study has been performed in 2011–2012 with trial and reference sections on a Danish highway with Stone Mastic Asphalt with nominal aggregate size 11 mm and a recipe not optimized for noise reduction. Three variations of Stone Mastic Asphalts differed only by the bituminous binder: SBS modified bitumen 40/100-75 according to European binder specification EN 14023 and a standard paving grade 70/100 modified with either 15% or 8% of ROAD+ by the "dry" mixing process.

Numerous samples have been taken from asphalt plant production and cores and slabs from the different sections for in depth study in the laboratory. Field tests for noise reducing effects have been performed by SPB and CPX measurements approx. 0, 2 and 12 months after paving. Various properties have been analysed in several laboratories: resilient modulus, creep, fatigue, cold temperature properties (TSRST) and rutting resistance (both laboratory and full scale).

Keywords: crumb rubber; SBS modified bitumen; Stone Mastic Asphalt; durability; noise reduction; laboratory and field trials

1 INTRODUCTION

The application of Ground Tyre Rubber (GTR) from old scrap tyres in bituminous materials for road applications has been introduced in Denmark more than 30 years ago. The first tests were performed in the late 1970s and early 1980s. In the early attempts GTR was utilized as both powder and granulates in order to produce an ice repellent road surface. The Board of Technology sponsored a literature study at the asphalt contractors' association [1] to examine the potential for reuse of rubber in asphalt pavements. The conclusion was that introduction of GTR would on short term mean substantial extra expenditure for road maintenance and on long term "more research was needed". The available quality of GTR in that period gave some problems with respect to technical issues and occupational health. Some test sections had been performed on national highways in 1986 showed premature failures in 1992 and were replaced [2]. The parallel development of alternative additives (polymers like Styrene-Butadiene-Styrene (SBS) and Ethylene-Vinyl-Acetate (EVA) did not show the same problems, and the interest in GTR declined.

In the last 15 years the re-use of GTR (0/2 mm and 0/4 mm fractions) have popped up from time to time related to the development of noise reducing pavement. But again the trials resulted in poor durability, technical problems associated with the production and the distance from "success" to "failure" was smaller compared to other alternative pavements.

The introduction of different technologies for reducing the mix temperature in asphalt production ("Warm Mix Asphalt") has accelerated in the last decade. Some of the technologies use additives that facilitate the incorporation of GTR in hot asphalt materials at "normal" mixing temperatures. Such a modification concept is called ROAD+. The product is a polymer bitumen and asphalt modifier produced by a process patented by Degussa. It has been used for many paving jobs in USA since 1998, and was later introduced in Europe.

2 ROAD+ —PRODUCT DESCRIPTION

The introduction of ROAD+ to the Danish road professionals coincided more or less with the Eurasphalt & Eurobitume Conference in Copenhagen in 2008, where the product description [3] was on display at the exhibition. ROAD+ combines crumb rubber particles having a size below 1.4 mm with 4.5% of an additive, Vestenamer®, described by the producer Degussa as a semicrystalline polyoctanamer.

The product description mentioned that both wet and dry process can be used with equal result. Wet process means that ROAD+ is added to the bituminous binder in a percentage between 8 and 15 and "digested" to create a modified binder that later can be used in asphalt production. The dry process means the ROAD+ is added at the asphalt plant together with aggregates, filler and bituminous binder in similar percentages as for the wet process; during hot storage and hauling the asphalt matures to create the modified asphalt.

The product description for ROAD+ stated—as a rule of thumb—that a standard bitumen modified with 10% ROAD+ as a minimum performs on level with a similar bitumen modified with 4% SBS (polymer; Styrene-Butadiene-Styrene). Among other characteristics it was mentioned that ROAD+ reduces traffic noise.

3 PREAMBLE AND OBJECTIVES OF THE DANISH COMPARATIVE TRIALS

It was decided by the national road administration, the Danish Road Directorate (DRD), in 2010 to perform an internal review on the documentation of ROAD+ supplied by the Danish crumb rubber producer GENAN A/S. This documentation consisted mainly of reports from Germany where several activities (research and trials) had been on-going recently. Supplementary information from other sources either on ROAD+ or crumb rubber modified asphalt was added to the review. One of the major contributions of additional information came from the Swedish Transport Administration which in a seminar [4] reported the findings of a huge three year study of crumb rubber modified asphalt after the wet process.

The review resulted in defining the objectives and focus points of Danish comparative trials with ROAD+ modified asphalt in order to provide confirmation or verification:

1. Gain practical experience with application of ROAD+ in Denmark
2. Verify the rule of thumb—"2.5% ROAD+ equals 1% SBS"
3. Obtain comparative characteristic properties of SBS and ROAD+ modified bitumen/asphalt to assess durability and other important properties for a road administration responsible for a heavily loaded road network.
4. Verify the statement that "ROAD+ reduces traffic noise."

The first three bullets are perhaps obvious points but the fourth requires some explanation. Noise reducing pavement has been a high prioritised subject for the Danish road administration for several years. The documentation on noise reduction for provided by GENAN included various test reports on a huge project [5] in Cologne, Germany (site: Konrad Adenauer Ufer) where ROAD+ modified binder was used in a noise reducing asphalt, LOA 5 D [6], developed by Ruhr University, Bochum, Germany [7]. Martin Radenberg states in [7] that "the open surface texture of the pavement is responsible for the noise reduction, and that modified binder is needed to obtain a durable surface texture". He gives no preference to the

type of modified binder. Wolfgang Fuchs [8] states in an article on the trials in Cologne that "the noise reducing potential of rubber modified asphalt is approx. 1–2 dB(A) compared to polymer modified asphalt". He offers no reference to document that claim.

4 ORGANISATION OF THE TRIALS AND SELECTIONS OF SITES

A project group was set up to follow the study and participate in its evaluation. The group consisted of representatives of

- the different levels of road administrations in Denmark (national and local including the city of Copenhagen),
- the Technical Committee of the Danish asphalt contractors' association (Asfaltindustrien),
- GENAN A/S, the Danish crumb rubber producer representing ROAD+
- Colas Danmark A/S, the asphalt contractor to perform the trials.
- The Research and Development department of the Danish Road Directorate.

The intended test protocols—especially for the noise measurement (acoustic environment and composition of traffic) and the full scale rutting experiment—meant that study had to accommodate a pre-trial before the actual trial sections where produced on a rural highway. The reference section was also not just intended to be used for this project but be part of a reference group for future pavement studies in noise and texture.

A suitable site (4 km) on Highway 411 was found in the North of Jutland between the cities Viborg and Aalborg for the main trials, and lorry parking lot on a recreational area on the motorway leading towards Aalborg was selected for the pre-trials. The contractor Colas Danmark A/S had the maintenance contract for the Danish Road Directorate in that area. The company had the main research laboratory nearby and was very experienced in handling SBS modified bitumen and asphalts. The Highway 411 had a new binder layer paved prior to the trial sections in order to ensure the best conditions for the comparison between the different surfaces and avoid that bearing capacity variations could interfere with the interpretation.

5 MATERIAL SELECTION

5.1 *Stone Mastic Asphalt (SMA)*

The optimal choice of asphalt type that would fulfil the objectives and conditions on the two trial sites was a Stone Mastic Asphalt (SMA) with a Nominal Maximum Aggregate Size (NMAS) of 11 mm. The aggregate gradation was chosen to be a standard gradation (meaning not optimised for noise reduction).

5.2 *Selected bituminous binders*

In the comparative study the three variants were intended to have the same surface texture and only differ by the applied bituminous binder. The compared binders have in this paper the following description (the subparagraph headings will be used to identify the various binders respectively asphalts in this comparative study):

5.2.1 *40/100-75*

The reference bitumen is SBS polymer modified bitumen in accordance with the European Modified binder specification EN 14023. The grade designation 40/100-75 means that the penetration is 40 – 100 × 0.1 mm and the softening point ring and ball is above 75 °C.

5.2.2 *ROAD+ 15%*

This modified binder consists of paving grade bitumen 70/100 mm with addition of 15% ROAD+. Under the assumption stated in [3] ("2.5% ROAD+ = 1% SBS") this binder shall be

directly comparable to the reference bitumen and represents a high level of binder modification for road application in Denmark.

5.2.3 *ROAD+ 8%*

This modified binder consists of paving grade bitumen 70/100 mm with addition of 8% ROAD+. Under the same assumption this binder represents the typical medium-low level of binder modification used in Denmark.

6 CONDITIONS THAT INFLUENCED THE EXPERIMENTAL PROGRAM

The initial experimental program had presumed that the wet process should have been used, since that would have provided the largest amount of information in testing the binder "before and after" paving. Facilities to produce the crumb rubber modified binder was available, but the practical configuration of Danish asphalt plants seemed to give problems with respect to handling the modified binder. During the preparation stage GENAN A/S offered information and technical expertise from the German experience and two obstacles were identified.

1. Virtually all Danish asphalt plants are equipped with horizontally placed binder storage tanks with internal heating pipes, and agitation is achieved by pumping to circulate the binder. The lack of internal propellers and the presence of heating pipes would lead to precipitation of crumb rubber particles on the pipes. This would create heat transfer problems and lack of control of binder properties (composition and ageing).
2. The viscosity of ROAD+ (crumb rubber) modified binder demands pipes with approx. 100 mm internal diameter in order to be pumped. Many of the Danish asphalt plants capable of handling highly SBS polymer modified bitumen have internal diameter not larger than approx. 75 mm.

For these reasons we were forced to use the dry process, since major investments in plant equipment had not been anticipated. This means that the study will compare crumb rubber modified asphalt with asphalt produced with a SBS polymer modified bitumen.

7 EXPERIMENTAL PLAN

7.1 *Division of experimental plan*

Instead of an experimental plan on the materials used for the trial sections we had to add an initial model study on the binder part in order to gain some experience for comparison of the properties of binders assumed to be present in the trial mixes. But the main focus was on the properties of the asphalt materials. Some properties were tested at the asphalt contractor (Colas) and some at the road administration (DRD). A few properties were even tested both places in order to gain experience on the variability in testing. This could prove to be useful information in future quality control efforts at contractors' and third parties level as larger standard deviation was anticipated than for ordinary paving grades.

7.2 *Model experiment for bituminous binders*

The model binders of ROAD+ were produced in the laboratory according to procedure found in ROAD+ documentation [9]. The paving grade 70/100 was heated to 180 °C and appropriate amount of ROAD+ was added during steering by a propeller. When ROAD+ after a short period was blended in the bitumen the temperature was reduced to 170 °C and steering continued for 2 hours before the sample was divided into subsamples. These were later treated in accordance with EN 12594 "Sample preparation" before each binder test which is stated in Table 3 together with the results (to avoid repetitions).

7.3 *Experimental plan for the asphalt materials*

The experimental plan for the asphalt material was based on full scale asphalt plant production, and not on laboratory mixed samples. The specification from the contractor on the individual mixes can be found in Table 1.

Samples of loose mix were taken directly from the plant. These samples were used for mix control and mechanical tests that required special laboratory compaction procedures (Marshall compaction, gyratory compaction, wheel tracking test, Temperature Stress Restrained Specimen Test and trapezoidal fatigue test). Numerous cores and plates were either drilled or cut from the pre-trial sections in order to test resilient modulus, dynamic creep, indirect tensile fatigue and full scale permanent deformation.

The total plan for testing of the asphalt materials can be found in Table 2, divided with the laboratory to perform the test. The full report can be found in [10], but indirect tensile fatigue will be reported in this paper as a measure of durability.

7.4 *Experimental plan for road inventory of the trial sections*

Apart from normal quality control for a pavement (e.g. coring for determination of compaction degree and voids) the trial sections on Highway 411 were intended to be as undisturbed as possible. The purpose was to facilitate road inventory measurements for years to come (friction, evenness and bearing capacity) but especially to provide the conditions for acoustic measurements of noise reductions and texture profiles.

The comparative noise reduction between the trial sections was assumed to be small. For this reason two methods were chosen; a spot measurement ISO 11819-1:2001 Statistical Pass By (SPB) and a continuous measurement of the entire length of the pavement with trailer ISO/CD 11819-2 Close Proximity (CPX) at 50 and 80 km/h. The measurements would be repeated frequently from paving the trial sections to the normal period for reference measurements for the Danish Noise classification of surface layers. This is after approx. 80 days for SPB and approx. 50 days for CPX. These periods are intended to obtain a representative surface texture after the traffic has removed the surplus bituminous mortar on top of the newly paved sections. The time difference needed for the two methods lies in the fact that the CPX trailer is running in the worn wheel tracks as opposed to the SPB measurement that is more dependent of the surface area in the vicinity of the location of the measurement point.

Table 1. Specification for gradation (percentage passing), binder content and some volumetric characteristics for Stone Mastic Asphalt 11 paved at Highway 411.

SMA 11	ROAD+ 8%	ROAD+ 15%	40/100-75 (Reference)
11.2 mm	100%	100%	100%
8 mm	52%	52%	52%
5.6 mm	35%	35%	35%
4 mm	30%	30%	30%
2 mm	22%	22%	22%
1 mm	18%	15%	18%
0.5 mm	15%	12%	15%
0.250 mm	13%	9%	13%
0.125 mm	9%	8%	10%
0.063 mm	6.5%	6.0%	7.5%
Binder content	5.6% 70/100 + 0.448% ROAD+	5.6% 70/100 + 0.84% ROAD+	5.6% 40/100-75
Asphalt density	2.630 Mg/m^3	2.630 Mg/m^3	2.640 Mg/m^3
Void volume	2.9%	2.3%	3.3%
Voids filled with bitumen	84.0%	88.0%	81.7%
Voids in mineral aggregate	18.4%	18.8%	17.8%

Table 2. Experimental plan for asphalt materials with reference to property, test methods and performing laboratory [10].

Property	Test method	Road directorate (DRD)	Contractor (Colas)	Third party laboratory
Compactability	Marshall Compaction (EN 12697-30) at 145 °C	+	+	
	Gyratory compaction (EN 12697-31) at 145 °C 150 mm Ø	+		
Stiffness	Resilient modulus (EN 12697-26 Annex F) at 2 °C, 10 °C and 20 °C	+	+	
	Stiff modulus (EN 12697-26 Annex A) at 15 °C			+
Fatigue	Resistance to fatigue (EN 12697-24 Annex E) at 15 °C	+	+	
	Resistance to fatigue (EN 12697-24 Annex A) at 15 °C			+
Permanent deformation	Dynamic creep (EN 12697-25 Test Method A) at 40 °C	+		
	Wheel Tracking Test (EN 12697-22 Model B in water) at 60 °C		+	
	Full scale wheel tracking (DART [11]), 5 kN load, 900 kPa, Super single tyre, temperature gradient 40 °C–20 °C, 110,000 passages	+		
Low temperature	Temperature Stress Restrained Specimen Test (AASHTO TP-10)			+

The surface texture can also be determined like Mean Profile Depth (MPD) or texture spectrum as the CPX trailer is equipped with a laser measuring device recording the profile of the wheel track simultaneously. The acoustical measurements are repeated approx. one year after paving.

For this paper the acoustical measurements (CPX and SPB) will be reported, but the full study can be found in [10].

8 EXTRACT OF RESULTS FROM THE COMPARATIVE STUDY

8.1 *Results of model experiments for bituminous binders*

The obtained results from the model experiment in the laboratory are stated in Table 3.

The model study leads to the following conclusions:

- Addition of ROAD+ and reaction with the bituminous binder will in asphalt lead to a modified concept.
- The effect is dependent of the added amount (and presumably of the base bitumen).
- Modification of paving grade 70/100 with 15% ROAD+ gives much higher viscosity than the SBS polymer modified reference bitumen even though the softening point R&B is much lower.
- The examined combination of 70/100 an 8% addition of ROAD+ shows an elastic recovery above 50%, but the test could not be performed according to the standard for addition of 15% ROAD+ due to premature failure.
- Ductility at 25 °C shows that ductile properties of ROAD+ modified binders are not good. This is presumably due to the presence of crumb rubber particle that act as crack initiators.

Table 3. Properties of the bituminous binders in the model study of properties.

Test	Reference	Unit	70/ 100	40/ 100-75	ROAD+ 8%	ROAD+ 15%
Penetration @ 25 °C	EN 1426	× 0.1 mm	77	64	47	42
Softening point R&B (water)	EN 1427	°C	46.4	–	55.4	63.0
Softening point R&B (glycerol)	EN 1427	°C	–	83.5	–	–
Penetration index, I_P	EN 12591		–1.1	5.5	–0.1	1.2
Dynamic viscosity @ 135 °C	EN 13302	mPa s	431	1,920	1,028	3,860
Dynamic viscosity @ 160 °C	EN 13302	mPa s	146	620	283	1,097
Elastic recovery @ 10 °C	EN 13398			84%	69%	Failure at 88 mm
Ductility @ 25 °C	ASTM D-113	cm		73	17	16
Rolling Thin Film Oven Test (RTFOT) EN 12607-1						
Change of mass	EN 12607-1	%		0.041	0.053	–0.013[a]
Penetration @ 25 °C	EN 1426	× 0.1 mm		47	37	35[a]
Softening point R&B (water)	EN 1427	°C		–	63.0	75.6[a]
Softening point R&B (glycerol)	EN 1427	°C		82.5	–	–
Penetration index, I_P	EN 12591			4.5	0.9	2.8[a]

[a]The values are only indicative. The binder ROAD+ 15% was too "structured" at 163 °C at RTFOT (EN 12607-1 Rolling Thin Film Oven Test) to spread out in a uniform film during conditioning. In this comparative study it was not relevant to raise the temperature for this binder to 180 °C as prescribed in the standard as an option.

8.2 *Results from asphalt materials*

The fatigue test was performed by Danish Road Directorate with Nottingham Asphalt Tester in accordance with EN 12697-24 Annex E. The results indicate that the fatigue performance of ROAD+ 15% is poorer than the comparable SBS polymer modified bitumen 40/100–75, while ROAD+ 8% gave results on the same level. Similar findings were obtained at the contractors' laboratory, but the trapezoidal two point bending fatigue showed that both ROAD+ combinations gave poorer fatigue life than the reference [10]. These results and the ductile properties (ductility and elastic recovery) of ROAD+ in Table 3—especially in high contents—can indicate that some of the remaining crumb rubber particles may act as crack initiators.

8.3 *Results of noise reduction from the trial sections on Highway 411*

The trial sections on Highway 411 are placed in a rural area, where the speed limit is 80 km/h. In order to compare the CPX (Close Proximity) measurements with other test sections in city streets, the CPX trailer measurements have been performed at both 50 and 80 km/h. The results of the noise level the three types of binder for both speeds can be seen in Figure 2a and b as a function of the number of days after paving.

The reference level for the Danish noise declaration of noise reducing pavement is also given in the two figures. The two figures indicate that the used SMA mix—as intended—is not a noise reducing asphalt for urban application, but for 80 km/h roads the three variations could pass when new as a noise reducing type. There is a significant increase in noise levels within the first two weeks after paving, but with a CPX measurement accuracy of approx. 0.5 dB there is no significant difference between the three binders. The minute decline in noise level from the 1st to the 2nd year which is most dominant in Figure 2b at 80 km/h can partly be explained by renewal of the test tyre and the fact that the rubber in the new tyre is softer than the old, and thereby a decrease in noise.

The results for the SPB measurements (Statistical Pass By) are shown in Figure 3a and b for passenger cars at 80 km/h and multi axle trucks at 70 km/h respectively.

The SPB measurements for passenger cars at 80 km/h show in Figure 3a the same type of increase in noise level the first weeks after paving as the CPX measurements in Figure 2a and b.

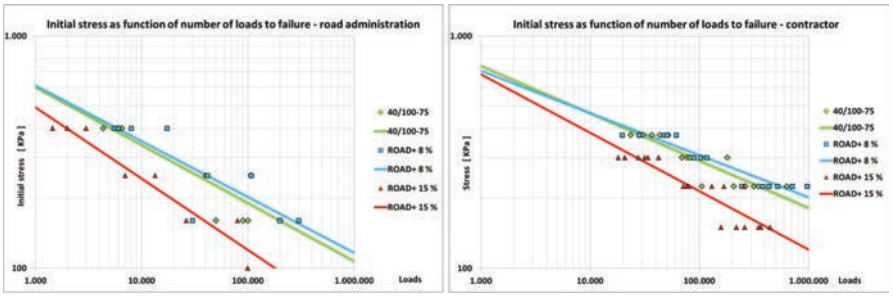

Figure 1a and 1b. Indirect tensile fatigue performed at 15 °C on cores (diameter 100 mm; thickness 23–40 mm) from pre-trial sections of SMA with three different bituminous binders.

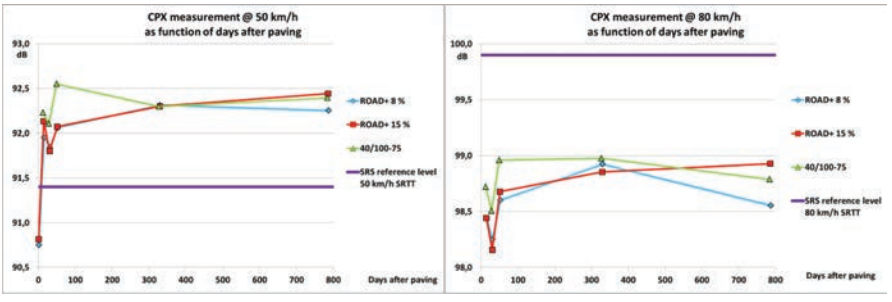

Figure 2a and 2b. CPX measurements on Highway 411 on the trial sections of SMA mixes with the three different bituminous binders as function of number of days after paving. The relevant noise reference level of the Danish noise declaration of noise reducing pavement are given as information.

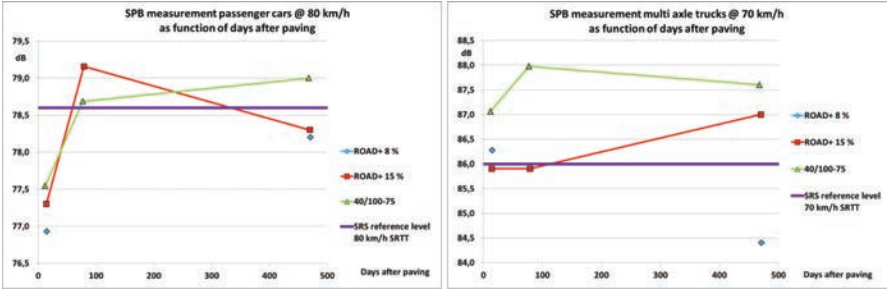

Figure 3a and 3b. SPB measurements on Highway 411 on the trial sections of SMA mixes with the three different bituminous binders as function of number of days after paving for passengers cars and multi axle trucks respectively. The relevant noise reference level of the Danish noise declaration of noise reducing pavement are given as information.

The results for multi axle trucks at 70 km/h in Figure 3b must only be taken as indicative since the extract of this category of vehicles on the highway trials is below the number recommended in the standard.

The noise measurements (CPX and SPB) lead to the following conclusions:

- Stone Mastic Asphalt with 11 mm as nominal maximum aggregate size and a aggregate gradation which has not optimised for noise reduction has been used in a study where ROAD+ in 8% and 15% have been compared to SBS polymer modified bitumen. Within the accuracy to the test methods the noise reduction of the three binder variations cannot significantly be distinguished.

- Wolfgang Fuchs' [8] stated potential improvement of "approx. 1–2 dB(A)" on noise reduction by using ROAD+ as opposed to SBS polymer modified bitumen cannot be verified.

9 ANSWER TO THE OBJECTIVES OF THE DANISH COMPARATIVE TRIALS

This paper presents parts of the documentation of the Danish comparative trials which has been organised to gain experience with ROAD+ modified asphalt including its characteristics and application in Denmark. In paragraph 3 the objectives and focus points of the study were defined and the overall conclusions from the whole study [10] can be summed up in the following statements:

1. ROAD+ (Ground tyre rubber and Vestenamer®) can be utilised by the "dry" process for the production of modified asphalt with the present level of technology at the Danish asphalt contractors.
2. The rule of thumb—"2.5% ROAD+ equals 1% SBS"—could not be verified.
3. ROAD+ with 15% addition do not give quite the same level as SBS modified bitumen 40/100–75 with respect to durability (fatigue) and other characteristics; among others ductile properties.
4. The use of ROAD+ modified binder as opposed to SBS polymer modified bitumen do not significantly by itself reduce traffic noise.

ACKNOWLEDGEMENT

This project was sponsored by the Maintenance Department of the Danish Road Directorate. The author will like also to thank Lars Ladehoff, Colas Danmark A/S, and Michael Hvam, Genan A/S, for their contributions to the project.

Mechanical influence of mineral fillers on asphalt mixture cracking behaviour

Elena Romeo, Riccardo Roncella, Silvia Rastelli & Antonio Montepara
Parco Area delle Scienze, University of Parma, Parma, Italy

ABSTRACT: The role of asphalt modifiers and/or modified fillers on the cracking behaviour of asphalt mixtures is extremely complex and has not been fully explained. To characterize the mechanical influence of fillers on asphalt mixture cracking behaviour it is essential to assess the viscoelastic properties of the mastic. Accurate description of strain evolution and distribution in mastics is essential for revealing significant information on mixtures macroscopic behaviour.

In this study, 16 different mastics composed by the combination of four different fillers and four asphalt binders, were evaluated on the basis of test results and their mechanical analyses. The Dynamic Shear Rheometer (DSR) and the Bending Beam Rheometer (BBR) were used to characterize the rheological properties of the different mastics. Their cracking behaviour was investigated using a Modified Direct Tension Test (MDTT). Strain localization and damage distribution were observed using a completely redesigned in-house developed Digital Image Correlation System (DIC) capable of accurately capturing localized or non-uniform stress distributions in asphalt materials. The role of fillers in cracking resistance was quantified, and induced mechanisms due to filler addition were investigated. The effect of hydrated lime was further discussed by comparing test results from hydrated lime filler and test results from limestone and clay fillers.

Keywords: HMA mixtures; mineral filler; mastic; direct tension test; digital image correlation

1 INTRODUCTION

Cracking in flexible pavements is widely recognized as a mastic-related distress meaning that fracture in asphalt mixture is governed by the properties of the asphalt binder and the filler [1–2]. The stiffness of the mastic affects the ability of the mixture to resist permanent deformation at higher temperatures, influences stress development and fatigue resistance at intermediate temperatures, and influences stress development and fracture resistance at low temperatures [3].

As discussed by many authors [4–7], the effect of the filler is based on a volumetric effect and/or a physico-chemical interaction between the filler and the asphalt binder. Polymer modifiers in the binder and/or hydrated lime in the filler are commonly introduced in attempt to enhance the mechanical performance of asphalt mixtures. However, previous studies [8–10] have shown that the addition of the same modifier to different asphalt binders may lead to contrasting results in terms of fatigue resistance and low-temperature cracking. Similarly, it was shown that hydrated lime reacts quite differently as a filler with different asphalts (SHRP AAD-1 and SHRP AAM-1), leading to great discrepancies in terms of cracking resistance and fatigue life [11–13]. In summary, the role of asphalt modifiers and/or modified fillers on the cracking behaviour of asphalt mixtures is extremely complex and has not been fully explained.

Accurate description of strain evolution and distribution in mastics is essential for revealing significant information on the influence of microstructure properties on asphalt

mixture macroscopic behaviour. The analysis of strain development requires appropriate experimental techniques. Very few studies in the past have been focused on the evaluation of the strain magnitudes within the mixture microstructure [14]. Masad et al. [15–17] used both digital imaging and X-ray computed tomography techniques to evaluate the microstructure of asphalt mixture in terms of aggregate orientation and air voids concentration, as well as strain distribution, finding that the percent of air voids is the main factor that controls strain distribution. However, the influence of strain evolution in the mastic on mixture crack initiation and propagation has not been addressed previously. Therefore, it is of considerable interest to investigate how filler particles and their interaction with asphalt binder affect mixture's cracking behaviour.

The present study evaluates the influence of mineral fillers on asphalt mixture macroscopic cracking response by analysing the localized strain distribution within the mastic microstructure. Four different fillers where associated to four asphalt binders (two unmodified and two polymer modified) to obtain 16 asphalt mastics. The rheological properties of the mastics were evaluated conducting Superpave testing procedures, including the DSR and BBR over a wide range of temperatures. The cracking behaviour of the mastics was investigated using a Modified Direct Tension Test (MDTT). Strain localization and damage distribution were observed using a completely redesigned in-house developed DIC software code called DICe, which was initially designed to facilitate the quantification of strains in the mastic in between the aggregates in a typical asphalt mixture [18]. The DIC-based system was employed to obtain 2D full-field strain maps of mastic specimens during tensile loading.

2 MATERIALS

Sixteen asphalt mastics were used in this study. The mastics were composed by four different asphalt binders, labeled as NV, N2, MR and ML. NV and N2 are two unmodified binders, graded as PG64-28 and PG58-22 respectively. MR and ML, graded as PG64-22 and PG70-22, are two polymer modified binders obtained blending the N2 unmodified one with a 3.5% of SBS cross-linked and SBS linear polymers, respectively. The SBS was blended with the base asphalt by the manufacturer using high shear milling.

Four fillers were associated to the four binders: a limestone filler, a clay filler, and two combinations of limestone + hydrated lime (20% weight) and clay filler + hydrated lime (20% weight). The selected filler concentration was 60% by weight for all mastic formulations. Following are the properties of the three materials:

- Limestone filler is composed of $CaCo_3$ with a density of 2.65 g/cm^3, a specific surface area of 0.28 m^2/g and a 9 pH.
- Clay filler is composed of SiO_2 (66.06%), Al_2O_3 (16.57%), Fe_2O_3 (7.1%), K_2O (2.69%), CaO (2.46%) and MgO (1.99%) with a density of 2.8 g/cm^3, a specific surface area of 0.32 m^2/g and a 7 pH.
- Hydrated lime is composed of $Ca(OH)_2$ with density of 2.34 g/cm^3, a surface area of 13.5 m^2/g and a 12.5 pH.

3 RHEOLOGICAL PROPERTIES

The Dynamic Shear Rheometer (DSR) and the Bending Beam Rheometer (BBR) were used in this study to determine the rheological properties of asphalt mastics. The DSR was used to measure the complex dynamic shear modulus (G*) at 25°C and 60°C. The appropriate applied stress amplitude for each test temperature was determined by conducting a stress sweep at a constant frequency of 10 radians/s. With known stress and measured shear strain values, the linear range of the materials behavior was determined. The testing was conducted with an 8-mm plate with a 2-mm gap and a 25-mm plate with a 1-mm gap at 25°C and 60°C, respectively.

The BBR was used to determine the stiffness of the binder and mastics at –25°C, –12°C and –5°C. A constant load of 980 mN was applied for 240 s, and the creep stiffness at 60 s was determined.

Figure 1 shows the results obtained from DSR at 60°C and 25°C. The mastic properties at high temperature are more affected by the asphalt binder rather than the filler composition. The combination of clay filler and hydrated lime makes the mastic very stiff decreasing significantly its workability. Similar results were obtained at intermediate temperatures. The most important role is played by the base asphalt binder. N2 performs better than the NV one and the addition of SBS modifier does not increase the performance of the mastic.

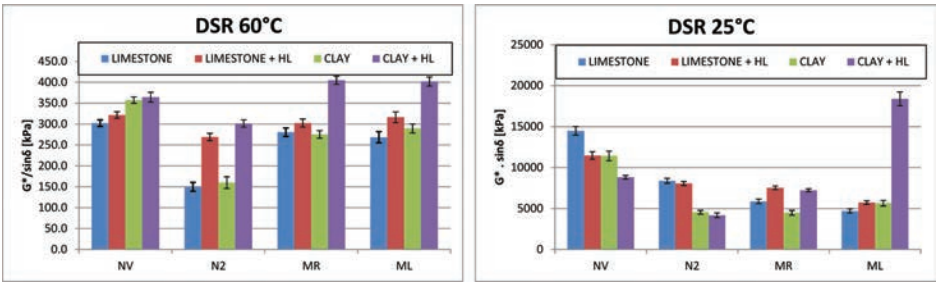

Figure 1. DSR results at 60°C and 25°C.

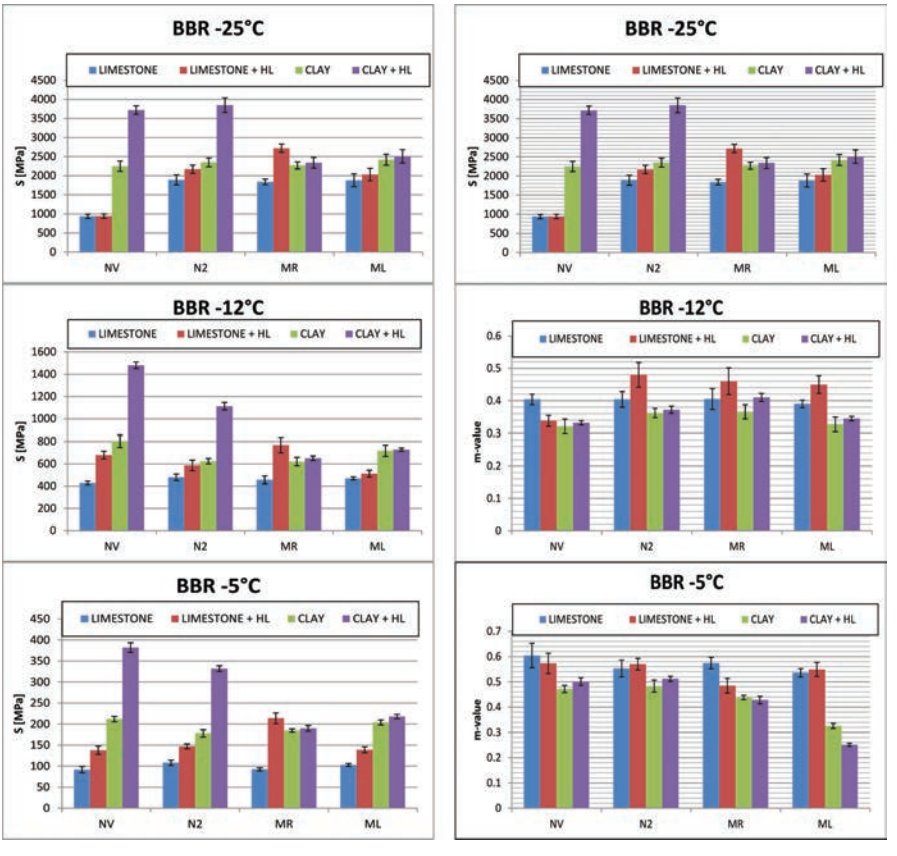

Figure 2. BBR results at –25°C, –12°C and –5°C.

Conversely, the results obtained from BBR, shown in Figure 2, highlight that the stiffness at low temperatures is more affected by the type of filler. The trend is similar at different temperatures.

Clearly, the clay filler and the addition of hydrated lime provide the most overall stiffness to the mastic. The surface activity of hydrated lime and hence physiochemical stiffening potential seems to be quite high.

4 CRACKING BEHAVIOR

4.1 *Modified Direct Tension Test (MDTT)*

The cracking behaviour of the mastics was investigated using a Modified Direct Tension Test (MDTT) performed in a servo-hydraulic load frame to allow the material to stretch up to rupture.

The specimen geometry was optimized to meet the following criteria: uniform stress distribution within the specimen web, adequate gauge length for accurate strain measurements, ease of specimen preparation. A Finite Element (FE) analysis was conducted to determine adequate specimen dimensions (specimen total length, web length, flange length and width) in order to obtain uniform stress distribution within the specimen web. The material property was assumed as viscoelastic; fixed boundaries were assumed at one end of the specimen, while a pulling load was applied at the other end. The final specimen dimension was determined to be 106 mm long, 20 mm wide and 10 mm thick, with an effective gauge length of 46 mm.

A further critical point was identifying the correct testing speed to assure correct data analyses. Different constant strokes were tested: from 0.084 mm/sec to 3.36 mm/sec. It was observed that, at lower speeds, the mastic exhibits extreme strain before rupturing as well as a significant reduction in the cross-sectional area, leading to not reliable calculation of stresses. Conversely, higher loading rates have shown to fracture the asphalt mastic before it reaches the minimum extension not allowing for a representative differentiation among the different mastic compositions. The optimum speed was identified as 1.68 mm/sec.

4.2 *Mastic specimen preparation*

The mastic specimens were prepared following the improved SuperPave™ binder testing specimen preparation procedure suggested by Ho and Zanzotto [19]. For each specimen, 28 g of asphalt binder and 42 g of filler were prepared and heated at mixing temperature (150°C for unmodified binders and 175°C for modified ones) in separate tins for 30 minutes. Then, the filler was slowly added to the asphalt in the oven. A mechanical mixer, with a maximum nominal angular speed of 8,000 rpm, was used to blend the materials at mixing temperatures. The mixing process was carefully followed so that the filler was homogeneously dispersed in the binder.

The mastic was continuously stirred as it cooled to prevent settling and then was poured to the preheated dog-bone shaped aluminum mold. The specimen is allowed to cool to room temperature for one hour and de-molded. It is then placed in the environmental control chamber for one hour at testing temperature before the test is performed.

4.3 *Strain analysis*

The influence of mineral fillers on mastic strain localization and damage distribution is simplified by field measurements of deformation over an area of finite extent through a Digital Image Correlation (DIC)-based method. The method is based on the application of a photogrammetry-based technique together with a properly designed laboratory test configuration. MDTT strains were evaluated using a completely redesigned in-house developed DIC software code called DICe, which was initially designed to facilitate the quantification of strains in the mastic in between the aggregates in a typical asphalt mixture. In this study, the method

was for the first time employed to measure and observe strain evolution and crack initiation in mastics.

The new DICe software code implements, for the image correlation step, a fairly innovative Least Squares Matching approach [20] that uses higher order polynomial shape functions to model the displacement field between the reference and the measured image of the DIC sequence: proposed also by other authors in different application fields [21][22]. The technique is, for the first time, applied to this kind of DIC scenario. The most important issue addressed by the new code is that, with high strain phenomena, especially just before crack initiation, is rare that the strain distribution in the area evaluated by the punctual Least Squares Matching measure can be considered strictly constant, even if that area is small. Hence, with lower order shape function (e.g. with (linear) affine transformation models) higher residuals can be expected in the estimation process, statistical error rejection techniques (i.e. observation data snooping) are harder to be applied, and lower levels of accuracy can be expected.

The previous DIC system has shown to achieve satisfactory accuracy compared to strain gauges, resulting in 0.04% accuracy in compressive/tensile strains and 0.03% accuracy in shear strains (further details on the method are discussed elsewhere [18]). In this case, due to the peculiar, localized, behavior of the mastic, it's hard to perform the same comparison with the new technique. Nonetheless, assuming that the nonlinearity of the displacement field can be considered similar to the ones obtained in the schematic (and general) tests performed in [22], smaller errors (up to a factor of 4) can be expected. Further investigation and a rigorous evaluation of the accuracy performance of the new algorithm should be performed in the future.

A digital camera Basler piA1600-35 gm (resolution 1608 × 1308, focal length 8 mm, pixel size 7.4 micrometers, 35 fps@max resolution), directly connected to the testing control system, is located on a support inside the climatic chamber where tests are performed. The chamber is provided with a proper LED lighting system which assure good illumination without heating up the specimen. Since the crack phenomenon is very fast and short-lasting (1÷2 seconds), the camera was properly set up to acquire the images in a smaller area of the sensor (1600 × 500 pixel) reducing the bandwidth required for transmitting each frame and, consequently, allowing a higher frame rate (ca. 80 fps). Thanks to the elongated shape of the specimen, once provided an optimal imaging geometry, the reduced size of the images still allowed the complete acquisition of the whole specimen surface. The images are automatically processed by the software, providing accurate displacement/strain fields. To achieve high accuracies in the strain field measurements, the specimen surface must present a well-contrasted grey scale speckle pattern, easily obtainable by a water paint-based treatment [14][18].

4.4 *Test procedure*

MDTT tests were performed on three replicates at 10°C using an MTS closed-loop servo-hydraulic loading system adopting a 2.5 kN load cell. The specimen was fixed at one end and pulled from the other end applying a constant stroke of 1.68 mm/sec until rupture occurs.

The engineering stress was computed according to the SuperPave™ binder specification:

$$\sigma_f = \frac{P_f}{A_0} \tag{1}$$

where: s_f = failure stress; P_f = measured load at failure; A_0 = original cross-sectional area

Failure is defined as the point on the stress-strain curve where the load reaches its maximum. The rapid loading rate and the interpretation of the test only up to fracture allow for a continuum representation. Strains were obtained from DIC system, interpolating all the strain values of the grid points located at the 46 × 20 mm specimen central cross-sectional area. The test configuration is shown in Figure 3.

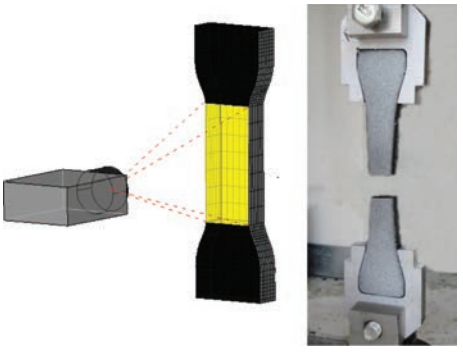

Figure 3. Mastic modified direct tension test configuration.

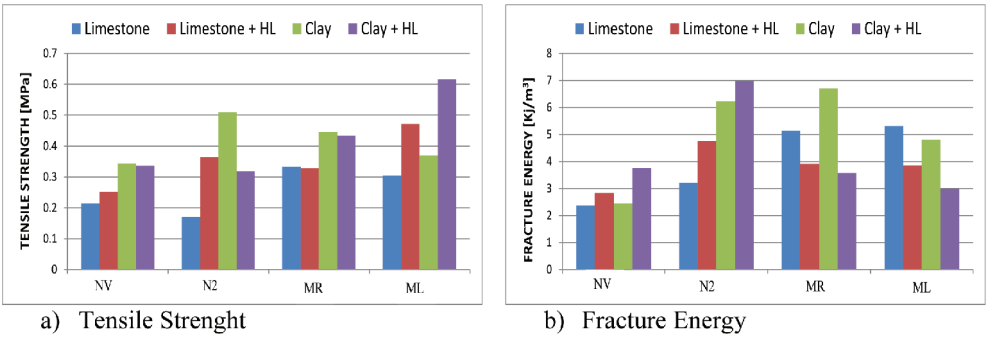

Figure 4. Effect of filler on mastics tensile limits.

4.5 *Results*

Tensile strengths and Fracture Energy (FE) densities computed as the area under the stress-strain curve at fracture initiation [23] were compared. Tensile strengths of the mastics are shown in Figure 4a. The results clearly show that the nature of filler influences the resistance of the mastics, since all the clay-composed materials result in a higher tensile strength. Conversely, the influence of hydrated lime on ultimate strength is not clear: it seems capable of either enhancing/decreasing (+50% for MLA; –38% for N2LA) the mastic resistance not making any difference (for NV and MR).

More significant are the fracture energy results shown in Figure 4b. The filler nature plays an important role in defining this failure parameter: clay-filler mastics exhibit higher fracture energies. Moreover, the presence of hydrated lime in unmodified mastics significantly enhances the fracture limit, while in polymer modified ones gives a negative contribution.

Figures 5–8 show full-field tensile strain maps at crack initiation for the 16 mastics, obtained from NV, N2, MR and ML asphalt binders, respectively. It can be observed that the unmodified mastics containing limestone fillers (with and without hydrated lime) exhibit distributed damage in the all area, showing different points of microcrack coalescence. Conversely, the unmodified mastics containing clay fillers, show high strains localized solely along the fracture path. The opposite behaviour was observed in modified mixtures. In detail, the modified mastic containing only limestone filler results in a more localized damage concentration, while the mastic containing clay filler and hydrated lime exhibits different areas of excessive damage.

The most likely reason for the observed trends is attributable to the physico-chemical interactions between binders and fillers and thereby to the particular network established within the mastic. Indeed, while the result of the reaction between unmodified binders and clay

fillers is a toughened matrix capable of redistributing part of the stress, modified binders combined with the same clay fillers result in a weaker matrix which allows for the development of highly distributed microcrack.

5 SUMMARY AND CONCLUSIONS

Rehological properties and cracking behaviour of 16 asphalt mastics composed by the combination of four asphalt binders (two unmodified and two SBS polymer modified) and four different fillers, were examined. A Modified Direct Tension Test (MDTT) was employed to estimate the failure limits of mastics. A completely redesigned in-house developed Digital Image Correlation (DIC) system was used to observe strain development and damage distribution in mastics. From rheological and MDTT results, it was observed that the filler nature influences the stiffness and the resistance of the mastics, since all the clay-composed materials results stiffer and exhibit higher tensile strengths. Conversely, the mastic rheological properties at high and intermediate temperatures are more affected by the base asphalt binder rather than the filler composition and/or the addition of SBS polymer modification. DIC analyses revealed that the nature of filler has a great influence on mastic cracking patterns. In detail, clay fillers seem to improve unmodified mastics cracking behavior leading to strain localization, while decreasing the performance of polymer modified mastics, resulting in the development of different areas of excessive damage.

Conversely, when limestone filler is employed, the damage distribution depends uniquely on the properties of asphalt binders: unmodified mastics show highly distributed damage in the critical area, while modified mastics exhibit high strain concentrations around the point of fracture.

ABSTRACT: Based on the failure mechanism under the limit load of the pavement and long-term aging mechanism of the asphalt mixture, taking the residual value as the constraint condition for termination, the decay law of road performances of Cement-Emulsified-Asphalt-Cold-Recycled Mixture (CEACRM) in the recycling process by comprehensive tests of mechanical properties, water stability, high and low temperature performance, modulus performance, and fatigue performance were studied. Results showed: 1) The decay of road performance of cold recycled mixture caused by circulatory recycling is nonlinear; 2) New-aged asphalt membranes generated in the multiple recycling sharply lower the cohesion of the binder, which leads to a negative effect on mechanical properties and the modulus performance of the mixture; 3) The adding of the cement reduces the sensitivity of the recycled mixture to water and temperature. Though the water stability and high temperature performance is obviously attenuated, it can still meet application requirements. 4) With the increase of the cement and the aging of the asphalt, the attenuation of the low temperature crack resistance of the mixture is obvious. 5) As asphalt membranes and cement slurries generated in the multiple recycling are stress concentration positions for fatigue failure, the decay of the fatigue life is the most remarkable in road performances. The research defined a relation between the cycle period of recycled mixture and the performance decay, which laid foundation for sustainable reusing of the recycled mixture in the future.

Keywords: Cement-Emulsified-Asphalt-Cold-Recycled Mixture (CEACRM); cold recycle; decay law; residual value; road performance

1 INTRODUCTION

With the proposition of the sustainable development strategy and the low-carbon concept, the cold recycling technique of asphalt pavement, as a green maintenance technique, which is energy-efficient and environmentally friendly, is gradually being focused on, and has been widely used in overhaul engineering of every highway. Since 1980s, it has been started on research and applications of the cold recycling technique of asphalt pavement in China, and till now, thousands of kilometers of cold recycled pavements have been built. However, under the effect of the load and natural factors, these completed and opened cold recycled

pavements start to be close to or have reached their service life, and whether they can be cold-recycled twice even many times, has become a difficulty that the development of the cold recycling technique of asphalt pavement must encounter and need to be addressed urgently.

Through the analysis of the current situation of the application of the cold recycled asphalt pavement and the properties of the recycled material it can be known that, the residual value of the recycled material is still huge, which makes the reusing of cold recycled pavements possible when they reach their service life. Two main existing process forms of cold recycling of asphalt pavement are the cold recycling with cement-foamed-asphalt and the cold recycling with cement-emulsified-asphalt, of which the cold recycling essences are both to make up for losses of performances of original pavements, and this kind of making up is merely an approximation instead of a recovery of the original level. Accordingly, along with the increase of recycling times of the cold recycled mixture, its residual value will undoubtedly decrease gradually until it can not reach the request of the road performance. In order to maximize recycling times and to achieve the goal of circulatory cold recycling, the developmental state of the decay law of the cold recycled mixture must be grasped; thereby the foundation could be laid for research of later improvement measures.

2 DECAY LAW OF THE PERFORMANCE OF THE OLD MATERIAL ON THE ASPHALT PAVEMENT

According to effects on the long-term aging of the old material on the asphalt pavement from external conditions such as the coupling of the light, the heat and the water, the traffic load and so on, the simulating test method of the multiple cold recycling in door of the old material on the asphalt pavement was developed, and then experimental studies were done about the gradation and the performance of the old material in the multiple cold recycling, of which the results are as follows:

From Table 1 it is seen that, in the multiple cold recycling, the old material on the pavement is presented to be the trend that the coarse aggregate decreases while the fine aggregate increases. Through observation, the fine aggregate can be gradually filled into structural poles of the coarse aggregate, which proves that the residual value of the old material after experiencing the multiple recycling is still very huge.

From Table 2 it is seen that, along with the increase of recycling times, the anti-pressure ability and the wear resistance ability of the old material decrease gradually. Researches

0.60	6.18	5.40	5.17
0.30	0.94	2.40	3.11
0.15	0.76	1.30	2.09
0.075	0.35	0.80	1.39

Table 2. The changing rule of the performance of the aggregate in the old material in the multiple cold recycling.

Technical index	Crushing value (%)	Los Angeles abrasion value (%)	Apparent density (10 g/cm^3)	Water absorption ratio (%)	Adhesion level with the asphalt
Primary recycling	19.3	21.1	2.52	1.76	5
Secondary recycling	21.6	23.2	2.53	1.88	5
Tertiary recycling	27.8	29.0	2.55	1.92	4
Four times recycling	34.3	38.8	2.59	2.25	3
Code requirement	≤28	≤30	≥2.5	≤2	≥4

show that, the continuity presented by the gradation of the multiple recycling old material, is mainly caused by discrete asphalt micelles, which contribute less to mechanical properties of the old material and is the main factor leading to the pavement cracking. Hence, the residual value of the old material after the multiple cold recycling, meanwhile, is limited.

3 DECAY LAW OF THE CEACRM (CEMENT-EMULSIFIED-ASPHALT-COLD-RECYCLED MIXTURE)

Through research on the decay law of the old material on the asphalt pavement it can be found that, the residual value of the old material on the pavement is limited, so during the process of the multiple cold recycling, how to make full use of its residual value, depends on research on the decay law of the road performance of the cold recycled mixture.

3.1 *Proportion design of the circulatory cold recycled mixture*

In order to avoid effects on the decay law of the mixture during the process of circulatory cold recycling from factors like the proportion of the material, in this test, the same design proportion was adopted in every cold recycling proportion design:

- The proportion of the old material is 100% (Full utilized);
- The gradation of the old material is selected to be the "A" gradation of the fine-grained type of the emulsified-asphalt-cold-recycled mixture in *Technical Specifications for Highway Asphalt Pavement Recycling*;
- The optimum asphalt content is 3%, which means the asphalt content in the emulsified asphalt is 3% of the total mass of the cold recycled mixture;
- The solid content of the asphalt in the emulsified asphalt is 62%;
- The proportion of the cement is 1%.

3.2 *Decay law of the mechanical performance*

The mechanical performance of the cold recycled mixture is the evaluation index that indicates the bearing capacity of the structural layer of the cold recycled pavement, and it is the most fundamental request of the road performance of the cold recycled mixture that it can meet the requirement of the bearing capacity of the pavement after being treated by the cold recycling technique. Based on the technical regulation for the emulsified-asphalt-cold-recycled mixture in *Technical Specifications for Highway Asphalt Pavement Recycling* (JTG F41-2008), in this test, 15° Csplitting strength and 40°C Marshall stability were adopted as evaluation indexes.

From Figure 1 it is seen that, in the multiple cold recycling, along with the increase of recycling times, the air void of the cold recycled mixture is gradually enlarging. This variation of the skeletal structure, when reflected on the mechanical performance of the mixture, is that the Marshall stability and the splitting strength decay simultaneously, and along with the

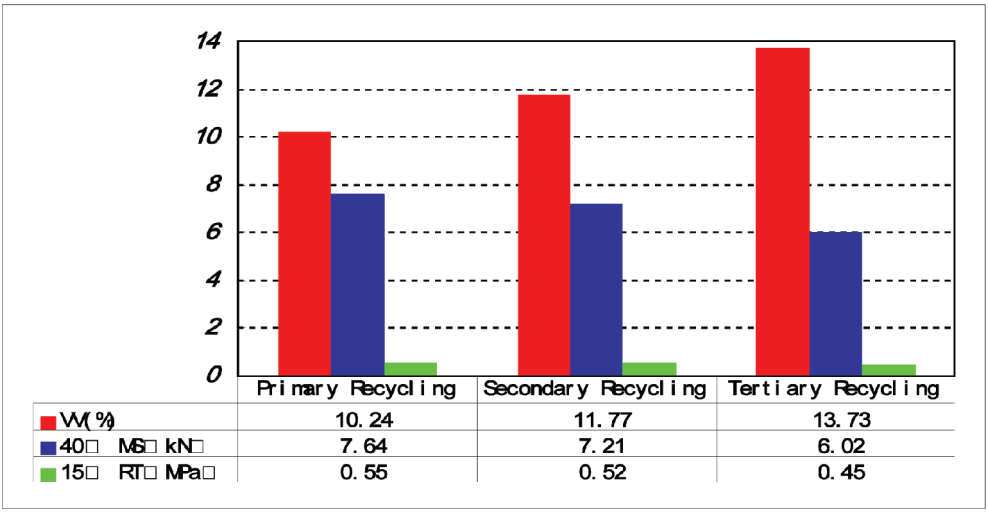

Figure 1. The variation trend of the mechanical performance of the mixture after the multiple cold recycling.

increase of circulatory recycling times, the range of the decay is also enlarging; in addition, when it is circulated to the third time, its Marshall stability has already decayed to the lower limit requested by the specification, while the splitting strength has not reached the operating requirement of the asphalt surface.

In order to preferably indicate the decay law of the mechanical performance of the CEACRM in the multiple cold recycling, here introduces the concept of the decay ratio of the mechanical performance. Taking the mechanical performance index after the primary recycling as the reference value, of which the difference with the later mechanical performance of the recycled mixture divided by the reference value is the decay ratio of the mechanical strength, which can also be worked out by the following equation.

$$R_{decay} = \frac{R_1 - R_i}{R_1} \times 100\% \tag{1}$$

where

R_{decay}= the strength decay ratio of the mechanical performance;

R_1= the strength value after primary circulatory cold recycling (Marshall stability: kN; splitting strength: Mpa);

R_i= the strength value after i times circulatory cold recycling (Marshall stability: kN; splitting strength: Mpa).

After data processing of test results according to the equation above, the decay ratio of the mechanical strength of the CEACRM in every cold recycling cycle was worked out, and this is shown in Table 3 in detail.

From Table 3 it is seen that, with the increase of recycling times, the decay ratio of its strength performance is presented to be the downward trend. Researches show that, the asphalt added during the process of the multiple cold recycling may form repeatedly wrapped new-aged asphalt membranes on the surface of the old material, which may become a weak surface in the bonding system of the recycled mixture, making the cohesion of the binder decline sharply. Meanwhile, the wrapping effect of added emulsified asphalt on the aggregate comes into play, under which the fine aggregate bonds together to form the aggregate micelle with a certain grain size. The increase of recycling times causes the soaring of the amount of the aggregate micelle, and then leads to the change of the skeletal structure of the whole mixture. The formation of the aggregate micelle also causes the lack of enough fine aggregate

Table 3. The decay ratio of the mechanical strength of the multiple cold recycled mixture.

Test content	Primary recycling	Secondary recycling	Tertiary recycling
Decay ratio of 40° C Marshall stability (%)	–	5.62	21.20
Decay ratio of 15° C splitting strength (%)	–	5.45	18.18

to fill into the skeletal structure, which causes that the air void of the cold recycled mixture starts to enlarge. However, because the bond force on the surface of the new-aged asphalt membrane is limited, the aggregate micelle, meanwhile, is unstable, which may be easily separated under the effect of the traffic load. Therefore, it may cause the instability of the skeleton, and then leads to the decline of the mechanical performance.

3.3 *Decay law of the water stability*

Because the cold recycled mixture is compacted and formed under normal temperature environment, the problem of its large air void is unavoidable. Because of this material characteristic, the cold recycled pavement may be easily eroded by the water and then generate damages such as the stripping of the asphalt membrane, the raveling, the pothole and so on. Accordingly, for the CEACRM surface, the water stability is similarly a significant factor that influences the road performance. The water stability of the asphalt mixture is finally indicated by the declining degree of the physical and mechanical performance of the asphalt mixture under the water-immersion condition. In this test, the decay law of the water stability is shown in the following figure.

From Figure 2 it is seen that, in the multiple cold recycling, along with the increase of recycling times, three evaluation indexes that reflect the water-resisting performance of the mixture, which are the emersion retained Marshall stability, the tensile strength ratio after the freeze-thaw cycle and the tensile strength ratio after the wetting-drying cycle, decline simultaneously, and with the increase of circulatory times, the degree of this decay is also increasing gradually, and when it is circulated to the third time, its performance index has already decayed to approach to the lower limit requested by the specification. It indicates that, with the increase of circulatory times, especially in the later period of the multiple cold recycling, the water damage of the mixture may easily occur when the mixture is in the service period.

In order to preferably indicate the decay law of the water stability of the CEACRM in the multiple cold recycling, here introduces the concept of the decay ratio of the water stability. Taking the water stability index after the primary recycling as the reference value, of which the difference with the later water stability of the recycled mixture divided by the reference value is the decay ratio of the water stability, which can also be worked out by the following equation.

$$S_{wd} = \frac{S_1 - S_i}{S_1} \times 100\% \tag{2}$$

where

S_{wd}= the strength decay ratio of the water stability;

S_1= the strength value after primary circulatory cold recycling (Marshall stability: kN; splitting strength: Mpa);

S_i= the strength value after i times circulatory cold recycling (Marshall stability: kN; splitting strength: Mpa).

After data processing of test results according to the equation above, the decay ratio of the water stability of the CEACRM in every cold recycling cycle was worked out, and this is shown in Table 4 in detail.

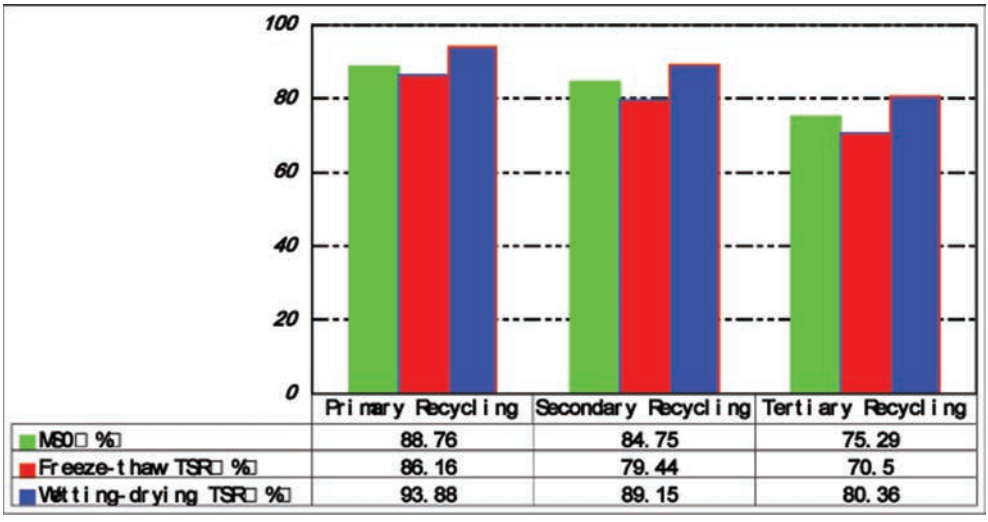

Figure 2. The varying trend of the water stability of the mixture after the multiple cold recycling.

Table 4. The decay ratio of the water stability of the multiple cold recycled mixture.

Test content	Primary recycling	Secondary recycling	Tertiary recycling
Decay ratio of the emersion retained Marshall stability (%)	–	9.02	20.81
Decay ratio of the tensile strength ratio after the freeze-thaw cycle (%)	–	7.80	18.18
Decay ratio of the tensile strength ratio after the wetting-drying cycle (%)	–	5.04	14.40

From Table 4 it is seen that, with the increase of recycling times, the decay ratio of its strength performance is also presented to be the upward trend; however, it can still meet the using requirement of the specification. The reason is that, the adding of the cement causes the decline of the sensibility of the emulsified asphalt cold recycled mixture to the water; Through the hydration reaction, to a certain degree, the cement can absorb a part of the water, while the humid environment formed by the residual water is also beneficial for the formation of the cement strength, which is somewhat helpful to the water-resisting performance of the emulsified asphalt cold recycled mixture. However, during the circulatory process from the secondary cold recycling to the tertiary cold recycling, the decay ratio of the water stability increases sharply. After the tertiary cold recycling, the water stability of the material has already been close to the critical point that can meet fundamental using requirement. The reason is that, during the process of the circulatory cold recycling, the air void of the molded specimen is enlarging gradually, which leaves enough space for the water to enter into, and the increasing water greatly influences the aggregate and the asphalt binder. Besides, the aggregate micelle in a free state is also a main factor that influences the water stability of the cold recycled mixture.

3.4 *Decay law of the durability*

For the service life of the CEACRM surface in the process of the multiple cold recycling, this study adopted four-point bending fatigue test to do the evaluation. By the fatigue test, its

Table 5. The testing result of the fatigue performance of the multiple cold recycled mixture.

Test content	Strain level (10^{-6})	Fatigue life (times)	Original stiffness modulus (Mpa)	Phase angle (deg)	Cumulative dissipated energy (kJ/m)
Primary cold recycling	100	458646	4628	23.7	34.2
	200	418562	4470	22.6	32.4
Secondary cold recycling	100	305867	3964	21.8	25.8
	200	276545	3703	20.5	21.1
Tertiary cold recycling	100	135682	3002	13.6	13.8
	200	106332	2985	10.2	9.8

Table 6. The decay ratio of the fatigue life of the multiple cold recycled mixture.

Test content	Primary recycling	Secondary recycling	Tertiary recycling
Decay ratio of the fatigue life under the strain level of 100 (%)	–	33.31	70.42
Decay ratio of the fatigue life under the strain level of 200 (%)	–	33.93	74.60

loading times at the fatigue life were worked out, which was considered to be the quantitative index to evaluate the service life of the mixture during its circulatory cold recycling period.

From the result of the fatigue performance test of the CEACRM in the multiple cold recycling in Table 5, it is seen that, along with the increase of recycling times, its fatigue performance is presented to be remarkable downward trend, and with the increase of the strain, the downward trend becomes more remarkable.

In order to preferably indicate the decay law of the fatigue performance of the CEACRM in the multiple cold recycling period, here introduces the concept of the decay ratio of the fatigue life. Taking the fatigue life after the primary recycling as the reference value, of which the difference with the later fatigue life of the cold recycled mixture divided by the reference value is the decay ratio of the fatigue life, which can also be worked out by the following equation.

$$F_{decay} = \frac{F_1 - F_i}{F_1} \times 100\% \tag{3}$$

where

F_{decay} = the decay ratio of the fatigue life;

F_1= the fatigue life after primary circulatory cold recycling;

F_i= the fatigue life after i times circulatory cold recycling.

After data processing of test results according to the equation above, the decay ratio of the fatigue of the CEACRM in every cold recycling cycle was worked out, and this is shown in Table 6 in detail.

Researches show that, the new-aged asphalt membrane and the new-aged cement paste are the stress concentration point where the fatigue failure occurs, which directly causes remarkable influences on the fatigue performance of the circulatory cold recycled mixture as a result of the increase of recycling times.

4 CONCLUSIONS

1. Through the research on the decay law of the old material on the asphalt surface it is found that, the residual value of the old material of the cold recycled asphalt pavement that has achieved the service life is still very huge.

2. The proposed decay ratio index can quantitatively indicate the decay trend of the cement emulsified asphalt in the process of the circulatory cold recycling.
3. Through the experimental research on multiple cold recycling of the cement emulsified asphalt mixture it is found that, with the increase of recycling times, its mechanical performance and its water stability decline gradually. In the later period of the multiple cold recycling, a number of performance indexes such as the mechanical performance of the mixture can not meet application requirements in the specification; the addition of the cement has declined the water sensibility of the circulatory recycled mixture, and even though its water stability can meet the application requirement in the specification, it has already been close to the lower limit in the specification, which is on the critical point where the failure occurs.
4. Through the fatigue test on the CEACRM it is found that, totally speaking, the four-point blending fatigue performance of the CEACRM is poor, and the increase of the strain level and recycling times has a great influence on the fatigue performance of the cold recycled mixture. At the same strain level, with the increase of cold recycling times, the fatigue performance is presented to be a downward trend, and in a high strain level, this trend is more obvious.
5. The results has quantitatively evaluated decay trends presented by every road performance of the CEACRM during different circulatory recycling periods, which have great guiding significance on promoting measures specifically proposed in the late period.

ABSTRACT: This paper investigates merits of introducing bio-binder and liquid Warm Mix Asphalt (WMA) additives to asphalt rubber to enhance its rheological properties. It is hypothesized that amine-based liquid additives can facilitate rubber devulcanization and speed up the release of rubber polymer into the asphalt matrix. This in turn can enhance asphalt rubber rheological properties including high temperature properties. This paper specifically focuses on high temperature properties and temperature susceptibility of the asphalt rubber modified by amine-based additives. High temperature properties were investigated by quantifying the effect of warm mix asphalt additives (Rediset and Evotherm) and bio-binder on the shear susceptibility and temperature susceptibility of asphalt rubber. Ambient crumb rubber with 10% and 15% concentrations by the weight of asphalt binder was used in this study. The rotational viscometer was used to evaluate the effect of additives on the asphalt rubber high temperature properties and pumpability. FT-IR analysis was studied to determine presence of devulcanized rubber polymer inside the asphalt matrix. It was found that all three additives reduced the viscosity and improved the pumpability significantly. In addition, the effect of additives found to be more significant when higher percentages of rubber were used. Additives with higher perecentages of amine compunds found to be more effective in devulcanizing rubber.

Keywords: crumb rubber; devulcanization; asphalt binder; bio-binder; warm mix additive

1 INTRODUCTION

Asphalt binder resistance to deformation at intermediate temperature and hot summers significantly affects overall pavement resistance to rutting deformation under heavy traffic at high temperature. Such deformation is more pronounced during the summer season when the asphalt reaches temperatures closer to its softening point. Recent studies indicate that when the air temperature is 30°C, the surface temperature of asphalt can reach up to 50°C thus reaching or exceeding the softening point of asphalt [1]. Also, the softening point of asphalt can be correlated with its viscosity: asphalt with a higher softening point tends to have higher viscosity and higher resistance to deformation [1]. To enhance asphalt resistance to deformation, researchers have used various modifiers and additives such as Styrene Butadiene Styrene (SBS) block copolymer, Ethylene Vinyl Acetate (EVA), Polyvinyl Acetate (PVA), Styrene Butadiene Rubber (SBR) and natural rubber latex [2, 3]. The last two of these additives have been identified as constituents of crumb rubber, a recycled rubber produced from scrap tires [4]. Crumb Rubber (CR) is produced by removing steel and fluff and using

a granulator and/or cracker mill (aided by cryogenic or mechanical means) to reduce the size of the tire particles [5]. The rubber particles are then sized by passing them through a set of sieves. It has been found that the application of rubber in asphalt can enhance high temperature properties and rutting resistance of asphalt pavement while improving asphalt pavement skid resistance, noise and construction cost [6].

Crumb Rubber Modified asphalt (CRM) has two diffrent effects on the asphalt matrix: one can be characterized as filler effect and is the impact of of rubber particles or physical filler effect and the second one is due to the release of rubber polymer into the asphalt matrix [7]. The physical effect of rubber is the main player in increasing rubber visosity and in some case reduce CRM pumbability and the resulting mixture's workability which makes its application problematic. Such problems include the reduction in asphalt workability and the difficulty of pumping asphalt containing high percentages of crumb rubber [8]. It has been documented that interaction environment could significantly affect devulcanization of CRM and consequencly releasing backbone polymer of rubber. This phenomenon reduces the viscosity of asphalt and enhances its physical properties [9]. It has been well documented that the interaction of amine-based compounds with rubber particles at high temperature could significantly speed up devulcanization [9]. In addition, existence of alkali metal such as sodium or potassium within the medium can facilitate the breakage of the cross-linkages in the rubber particles releasing the rubber polymer. However, it has been reported that this process is highly sensitive to temperature and heating rate; as such, thermal cracking of rubber polymer could occur due to excessive heating [9, 10].

Ever since the sixties when Charles McDonald employed the dry processes to produce a rubberized asphalt mixture named Overflex TM, a number of researchers have studied the benefits of applying Crumb Rubber Modified (CRM) binders into asphalt pavements [11]. It has been well documented that rubber asphalt shows better resistance to rutting. Rutting is one of the common pavement distresses which can occurs due to traffic loading, especially under hot climatic conditions [12]. It has been reported that the rutting resistance parameters of CRM binders improves as the CRM percentages increases. Introducing some additives to CRM has been studied. Golzin and his collaborator used Poly Phosphoric Acid (PPA) to evaluate the effect of CR on the performance of unmodified asphalt binder at different temperature; they showed that by increasing the PPA content, the values of softening point was increased while the penetration grade was decreased. Furthermore, it has been reported that increasing the PPA content from 1.5% to 2% could improve the binder performance at high temperature [13]. Their test results showed that adding crumb rubber, reduced penetration, temperature susceptibility, ductility and increased the softening point, elastic recovery and adhesion [13].

Wang et al. measured viscosity of several asphalt rubber at different temperatures using a rotational viscometer; these researchers found that the addition of crumb rubber can greatly increase the binder viscosity, and that in order to meet the Superpave maximum viscosity threshold of 3.00 Pa.s, CR asphalt needs to be heated to higher temperature. In addition, it was found that to maintain same viscosity, one has to continuously increase the mixing temperature as the percentages of rubber increase. As such, when 15%, 20% and 25% crumb rubber were introduced to the base asphalt (viscosity > 3.0 Pa.s at 135°C), the temperature had to be increased from the original 135°C to 147°C, 162°C and 174°C, respectively, in order to maintain viscosity below the 3.0 Pa.s threshold [14]. Therefore, the mixing temperatures and compaction temperatures of rubberized asphalt binders were much higher than those of non-modified asphalt mixtures. This in turn, can cause further challenges in the construction schedule as well as increase the fuel consumption used for heating purposes [14]. More importantly, it can damage the rubber structure and cause disintegration of rubber particles [15].

In this paper, certain amine-based liquid additives are used to facilitate rubber asphalt interaction so that the dramatic increase in viscosity due to introduction of rubber is prevented. Amine compounds facilitate release of rubber polymer into asphalt, thus softening the overall asphalt-rubber matrix. As a result, the viscosity threshold could be met at relatively lower temperatures. This not only prevents disintegration of rubber particles due to reduction in

the mixing temperature but also facilitates pumping and hence allows for application of higher percentages of rubber into the asphalt.

In this paper bio-binder is used as an amine based additives. Bio-binder is produced under the thremechemichal conversion of swine manure. The efficiency of this process is 70% meaning a swine farm with 10,000 hogs per year could produce 5,000 barrels of crude oil per year [16]. The estimated cost for bio-binder production using this method is only estimated to be $0.54/gallon while the cost of petroleum-based asphalt is reported to be $2.5/gallon [17]. Chemichal analysis of bio-binder showed that it has high amine content [18]. Rheological properies of asphalt binder improved by introdicing 5–20% of bio-binder [19]. By comparision of the price of petroleum based binder with bio-binder, considering the fact that bio-binder has higher amine content and improvment in rheologichal properties of asphat binder, bio-binder has been selected as one of the amine based additives.

In this paper merits of application of bio-binder and liquid warm mix amine based additives to enhance asphalt rubber workability by reducing its shear viscosity at high temperatures is investiagted [18–20]. It is expected that introduction of such additives can produce rubberized asphalt mixtures with desirable properties at lower mixing temperature. Therefore, this paper evaluates the effects of these three specific amine based additives on high temperature properties of CRM asphalt by conducting selected Superpave binder tests.

2 MATERIALS AND METHODS

2.1 *Asphalt binders*

The base binder for this study was PG64-22 which is commonly used as an asphalt binder in the state of North Carolina.

2.2 *Crumb Rubber (CR)*

Crumb rubber is produced by mechanical shredding at the ambient temperature. The crumb rubber was provided by re-Rubber LLC of Ontario, Canada. Table 1 shows the grading of the rubber particles and has 200-80 mesh size.

The rubber characteristics are given in Table 1. The asphalt rubber was produced in the laboratory incorporating an ambient CRM source at two percentages of 10% and 15%, (by the weight of asphalt binder) into commonly-used PG64-22. The blending of the CRM with the base asphalt (PG64-22) was done mechanically using a 1600 rpm drill equipped with a mixing blade. The CRM (200-80 mesh) was gradually poured into the PG64-22, as the shear was conducted at 250°C by the usage of a hot plate for 30 minutes, following California Department of Transportation specification. The drill speed was maintained at 800 rpm, and the blade on the mixer was completely submerged into the sample to prevent the whipping of air into it and subsequent bubbling. The same procedure was used for both rubber concentrations.

Table 1. Crumb rubber gradation.

Sieve no.	mm	Weight retained	Individual % retained	Cumulative % passing
80	0.177	42	41.50%	58.50%
100	0.149	13.7	13.60%	44.90%
120	0.125	16.5	16.30%	28.60%
140	0.105	13.9	13.70%	14.80%
170	0.088	7.2	7.10%	7.70%
200	0.074	7.8	7.70%	0.00%
Pan		3.1	0.00%	
Total		104.2	100.00%	

2.3 *Amine based additives*

Three amine-based liquid additives were investigated in this study. These include Bio-binder, Evotherm and Rediset. Bio-binder was produced in NC A&T University's Sustainable Infrastructure laboratory and Evotherm and Rediset were provided by MeadWestvaco (MWV) and Akzonobel, respectively. These additives were added to the rubber asphalt at the dosages recommended by manufacturers. Bio-binder was added at 5% and 10% dosages by weight of asphalt binder to create the bio-modified binder. Accordingly, Evotherm and Rediset were added at dosages of 0.5% and 1.5% to the rubberized asphalt binders, respectivly [21].

The bio-binder was derived from swine manure manufactured at the NC A&T farm. It was produced from the thermochemical conversion of swine manure to bio-oil followed by distillation and filtration [20]. In this method, the animal waste is charged in the reactor. Nitrogen gas is used as a processing gas to purge the residual air in the reactor three times and the reactor is heated up to the setting temperature which is maintained at a constant level for a specific time. After the reaction is complete, the reactor is rapidly cooled down to room temperature using a recycled ice-water cooling coil. The gas is then released from the autoclave reducing the pressure in the autoclave to atmospheric pressure. The sticky residue is then separated from the aqueous solutions by filtration followed by polymerization and vacuum distillation to produce bio-binder.

2.4 *Viscosity measurement*

To study effects of rubber and various amine based additive on rheological properties of asphlat binder as well as pumpability, each rubberized binder sample (un-aged) was tested using Brookfield viscometer following ASTMD4402 specification to evaluate its viscosity, and high temperature properties. Viscosity was measured at four different temperatures (105°C, 120°C, 135°C, 150°C), and six different speeds (rpm) (5, 10, 20, 25, 50 and 100). A smooth spindle SC4-27 was used for measurements. The testing specimen was prepared by pouring 10.5 g of each material into an aluminum chamber. At each temperature, the reading was recorded after the specimen was preheated for 30 minutes.

2.5 *Temperature susceptibility*

Temperature susceptibility is a measure of variation of asphalt binder viscosity with temperature change [22]. Follwing Eq. (1) has been commonly used to calculate the Viscosity-Temperature Susceptibility (VTS) [23].

$$VTS = \frac{[\log(\eta T_2)] - \log[\log(\log(\eta T_1)]}{\log(T_2) - \log(T_1)} \tag{1}$$

T_1 and T_2 are the temperatures of the binder at known points; ηT_1 and ηT_2 are the viscosities of the binder at the same known points (cP). The dimension of the VTS is directly proportional to the temperature susceptibility of the binder.

2.6 *Shear susceptibility*

The rate of change in viscosity with the shear rate is called Shear Susceptibility [24].

The shear susceptibility or also known as the shear index is determined by calculating the slope of the line formed by a log of rotational speed versus the log viscosity graph using Eq. (2)

$$SS = \frac{\log(Viscosity)}{\log(speed)} \tag{2}$$

2.7 *Attenuated Total Reflectance Fourier Transform Infrared Spectroscopy (ATR-FTIR)*

A FTIR spectrometer, Shimadzu, 1.30(2005) single reflection zinc selenide prism was used in transmission mode to acquire the spectra of asphalt samples in wave-numbers ranging from 4000 cm^{-1} to 500 cm^{-1}. The prism was cleaned with methylene chloride and back ground spectrum was taken. To consider the effect of dissoltion part of rubber, before each measurment, the asphalt samples were dissoved in methylene chloride, fitrated to separate the rubber particles and then dried to make sure removal of solvent.

3 RESULTS AND DISCUSSIONS

The influence of the amine-based additives (Rediset, Evotherm and Bio-binder) as well as rubber concentration, temperature and shear rate on viscosity of modified and non-modified rubber asphalt was investigated. Figures 1a and 1b show the amount of viscosity change with the increase in temperature for the rubber asphalts at the two different rubber concentrations. As it can be seen, the viscosity of all specimens decreases with the increase in temperature. However, the change in viscosity is more significant in rubber asphalt compared to that for control asphalt. It was also shown introduction of 10% Bio-binder could compensate the stiffening effect of the rubber. As such the blends with both 10% and 15% rubber with 10% bio-binder showed significant improvemnet in pumpability.

In addition, the effects of the three additives on rubber asphalt are shown in Figure 2. It can be observed that the effect of additive on viscosity change is more pronounced in 15% rubber dosage compared to 10% rubber cases. Furthermore, 10% bio-binder was found to be most effective in reducing viscosity.

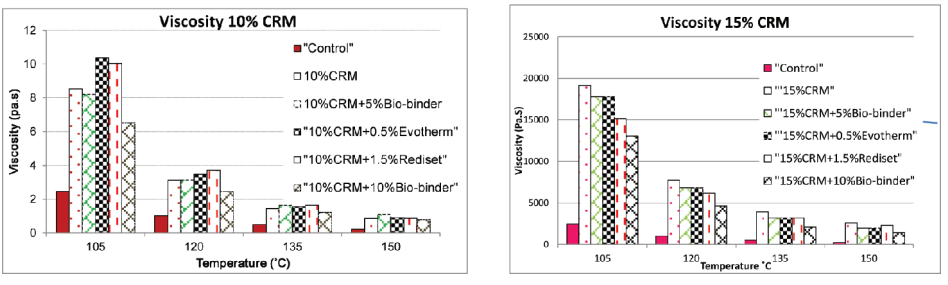

Figure 1. a) (10% CRM) and b) (15% CRM). Viscosity vs. temperature for control, 10% and 15% CRM, with WMA at 10 rpm.

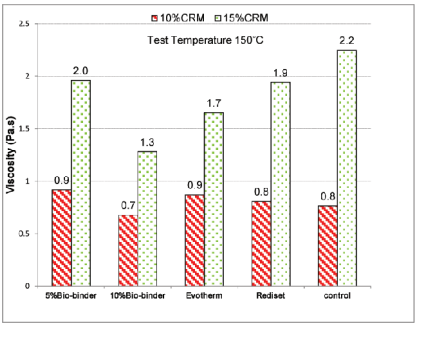

Figure 2. Viscosity comparisons of the CRM at the two concentration levels with the different WMA, and 150°C test temperature.

It was also found that the viscosity at 150°C was increased between 100% and 214.28% by increasing the rubber content from 10 to 15%. The test temperature was found to be the most dominant factor affecting asphalt rubber viscosity. However, it should be noted at all temperatures (105°C to 150°C) the viscosity was below the Superpave specification threshold (maximum asphalt binder viscosity no greater than 3 Pa.s at 135°C) designated to ensure mixture workability.

3.1 *Viscosity temperature susceptibility*

Figures 4a and 4b; are a graphical plot of Log (temperatures) versus Log (Log (viscosity)) for the control binder, 10, 15% CRM binder, with and without additive. It can be observed that the control binder has higher slope than all the CRM binder at different rubber concentration level with or without additive, as the results showed the temperature susceptibility of control binder was reduced by incorporating the additives. Also Figure 3a shows that the 10% CRM binder with Evotherm and Bio-binder has the same slope as the 10% CRM binder without any additive while the slope found to be lower than 10% CRM binder with Rediset. The same trend holds true for the 15% CRM binder. Consequently, it can be stated that with the incorporation of amine-based additives and Bio-binder into CRM binder, one can achieve higher rubber concentration in rubberized asphalt while reducing the modified asphalt temperature susceptibility.

3.2 *Shear susceptibility*

The shear susceptibility is illustrated in Figure 4a for 10% CRM and Figure 4b for 15% CRM which show plots of log (shear rate) versus Log (viscosity) at 150°C temperature. From the

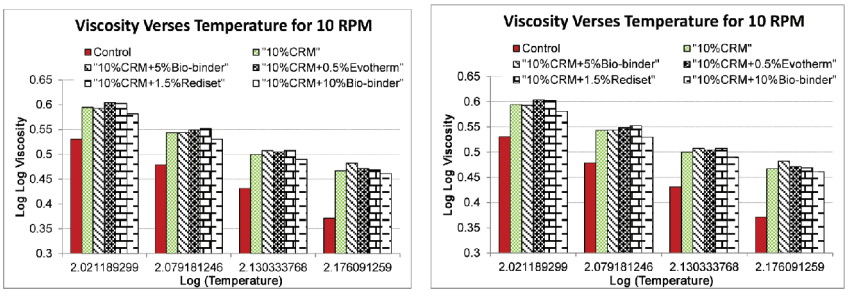

Figure 3. a) (10% CRM) and b) (15% CRM). Viscosity Temperature Susceptibility (VTS) for CRM with additives and bio-binder at 150°C.

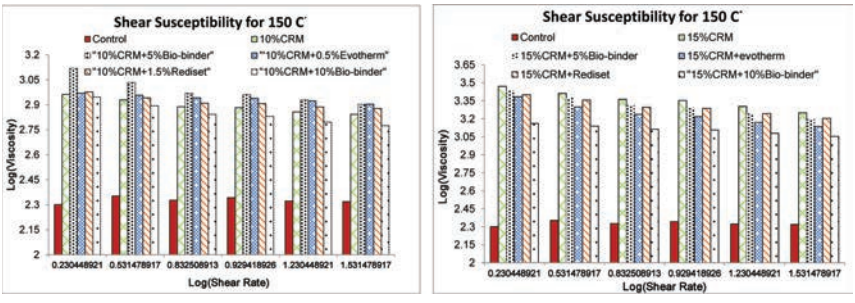

Figure 4. a) (10% CRM) and b) (15% CRM) Shear Susceptibility (SS) for CRM with additives and bio-binder at 150°C.

analysis of Figure 4, it can be seen that the shear susceptibility of the control binder is considerably reduced by modifying it with bio-binder and rubber. Furthermore, it is seen that the higher is the rubber concentration; the lower is the shear susceptibility. This can be due to the chemical interaction of additive, Bio-binder, and the rubber particles with the control binder.

3.3 *FT-IR analysis*

To analyze effect of additives and presence of polymer in asphalt matrix, characterization of molecular structure was done using Fourier Transform Infrared Attenuated Total Reflectance Spectroscopy (FTIR-ATR). This technique operates the Mid-Infrared (MlR) range, where all organic compounds interact with infrared radiation (4000 cm^{-1} to 400 cm^{-1}) providing direct information about the specific elements in the sample, as well as their molecular structure and chemical composition. In this method, total internal reflectance of infrared light in a non-absorbing prism is used. Contact of absorbing substances with the prism surface will attenuate the internally reflected light and provides an infrared absorption spectra, corresponding to a spectra recorded if the light passed through the surface layer of the material [25]. To remove the filler effect of rubber from devulcanization effet, all the samples dissolved in methylene chloride and rubber particles separated by filteration. To conduct the test, after removing the solvent, thin layers of each specimen were applied on top of a Zinc Selenide (ZnSe) ATR prism. It was shown that FTIR analysis can be used to monitor appearance of new molecules from devulcanized rubber inside the asphalt which is known as "capture presence of rubber" on the IR spectra.

For investigation of the effect of amine compounds on devulcanization of the rubber particles, neat asphalt and CRM samples with three different types of addtive were tested. Figures 5a, 5b and, 5c compare the spectra for 15% rubber without additive (control), 15% CRM with three amine additives (1.5% rediset, 0.5% Evotherm and 10% bio-binder). Figure 6 is the spectra for neat asphlat and crumb rubber asphalt without additive.

The main polymer components of crumb rubber are Nature rubber, Butadiene styrene rubber and Cis-butadiene Rubber [4]. Each of these polymers has special related peaks, these

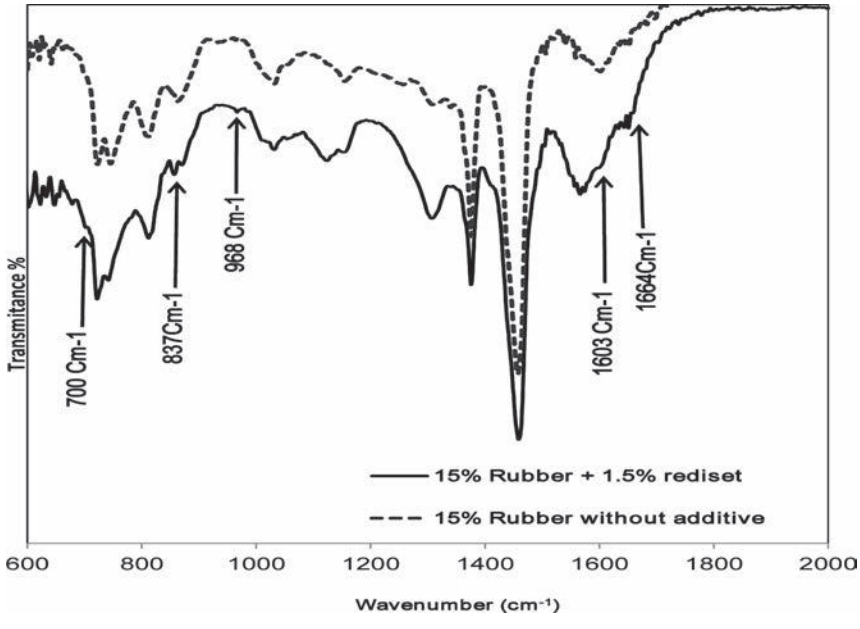

Figure 5a. FT-IR spectra of 15% rubber + 1.5% rediset.

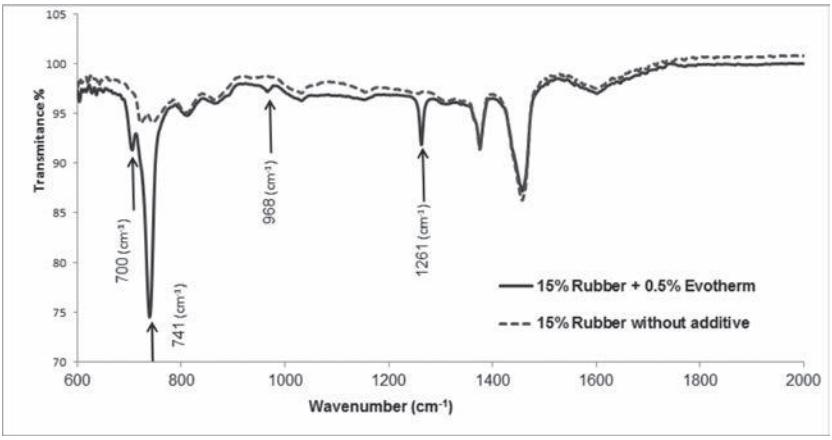

Figure 5b. FT-IR spectra of 15% rubber + 0.5% evotherm.

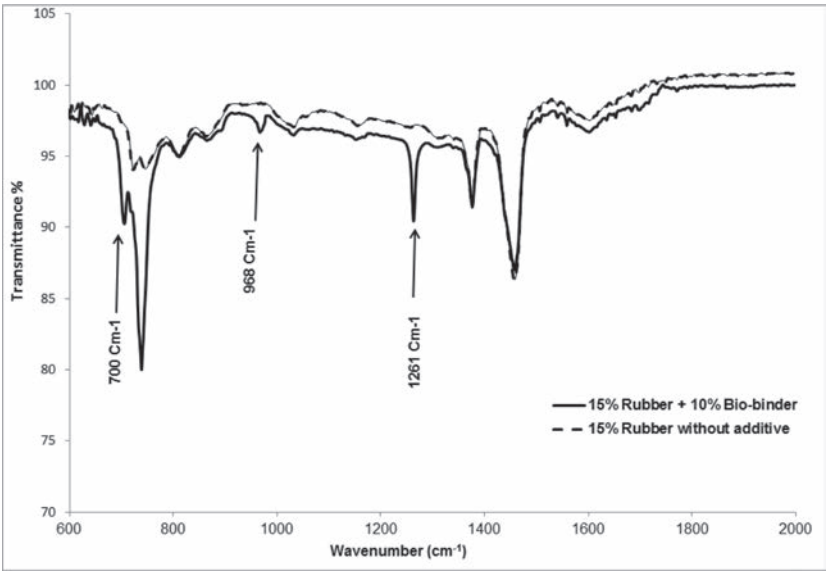

Figure 5c. FT-IR spectra of 15% rubber + 10% bio-binder.

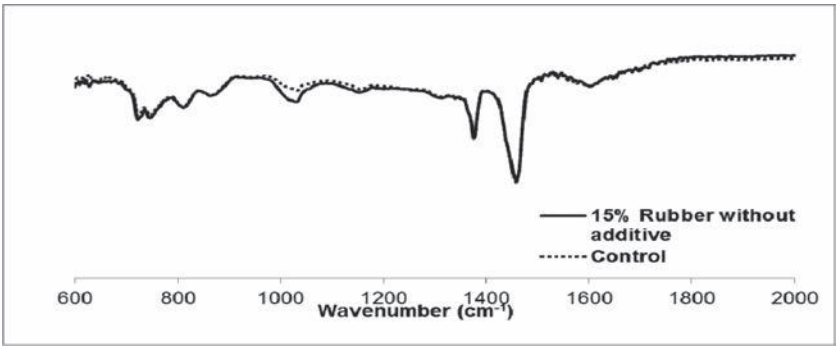

Figure 6. FT-IR spectra of 15% rubber without additive.

spectra helps to better understand devulcanization of rubber and releasing the polymer to the asphalt matrix. The presence of the peak around 968 cm^{-1} is attributed to the trans and vinyl double bond out-of-plane C-H bending of poly butadien, this peak was observed in all three addtives [26].

One of the dominant infrared peaks is due to the out-of-plane aromatic C-H deformation at 700 cm^{-1} which indicates the prsence of poly styrene butadiene rubber. This peak was appeared in the three additive [27]. Other significant peak is related to the aromatic ring breathing mode at 1,603 cm^{-1}, this peak was appeared in samples containing Rediset and it is an indication of releasing Styrene butadiene polymer.

Appearance of a peak in1664 cm^{-1} for the C=C stretch and 837 cm^{-1} is related to =C-H out-of-plane wag for poly isoprene (natural rubber backbone) which was observed in the sample prepared with rediset [26, 27].

Figure 6 represent the spectra for crumb rubber modified asphalt without any additives. It was clear that there is not any siginificant differences with neat asphalt spectra and rubber modified one. This spectra is the witness for devulcanization of rubber to realse polymer in the asphlat matrix by application of amine based compounds.

4 SUMMARY

This paper investigates effect of amine-based additives on the viscosity of asphalt rubber. It was shown that the viscosity increases with the increase of the percentage of rubber in asphalt binder. However, when amine-based additives were introduced, the viscosity was reduced significantly. It can be observed that the asphalt rubber with Rediset has the lowest viscosity at 10% rubber concentration, followed by Evotherm and bio-binder. At 15% rubber concentration level, asphalt rubber with 10% bio-binder showed the lowest viscosity followed by Evotherm and Rediset. Considering that reduced viscosity is one of the main factors affecting the pumpaing and workability, the additives used in this study could be promising candidates for enhancing the workability of asphalt rubber. This is important because reductions in viscosity can allow for reduction of mixing and compaction temperature of asphalt rubber. It has been reported that, high temperature exposure of asphalt rubber leads to rubber degradation [28]. In addition, utilizing such additives can facilitate the application of higher percentage of rubber in asphalt without exceeding viscosity threshold. This paper demonstrates that introducing the aforementioned additives to rubber asphalt mixes can significantly improve the Viscosity Temperature Susceptibility (VTS) and shear susceptibility of binders, thereby enhancing the high temperature performance of asphalt binders.

FT-IR studies revealed devolcanization of rubber inside the asphlat matrix by releasing polymer component. From this studies, the trace of poly styren butadien was seen when either of the additives were intoduced. But trace of natural rubber was captured just by rediset. The study results showed significant imporvment in viscosity of 15% CRM asphalt when bio-binder and evotherm were introduced. This in turn promotes application of bio-based additives with high amine content to faciliate devulcanization while improving CRM pumbpability.

By considering the effect of bio-binder on devulcanization of rubber, our future work would be based on replcement of bio-binder with regular asphalt binder and mixing with crumb rubber to improve binder performance. This approach will have benefit to pavement industry including reduction in cost of asphalt production while increasing the perfomance of bio-binder on road construction.

Micro-scale investigation of oxygen diffusion on bitumen surfaces

Prabir Kumar Das, Niki Kringos & Björn Birgisson
Division of Highway and Railway Engineering, KTH Royal Institute of Technology, Stockholm, Sweden

ABSTRACT: This study investigates the evolution of microstructures due to oxygen diffusion on bitumen surface and its effect on bulk properties utilizing Atomic Force Microscopy (AFM) and Differential Scanning Calorimetry (DSC). The bitumen specimens were conditioned in four different modes: both light and air, only air but no light, only light but no air and neither light nor air, for 15 and 30 days. From the AFM investigation after 15 and 30 days of conditioning period, it was found that the percentages of microstructure on the surface reduced with ageing. The DSC heating scan showed that the amount of wax remains constant even after the systematic conditioning. Interestingly, during the cooling cycle, crystallization of wax molecules started earlier for the oxidized specimens than the non-oxidized one. The analysis of the obtained results indicated that the oxidation created a thin film upon the exposed surface, which acts as a barrier and creates difficulty for the wax induced microstructures to float up at the surface. From the DSC analysis, it can be concluded that the oxidation product induced impurities in the bitumen matrix, which acts as a promoter in the crystallization process.

Keywords: Wax induced microstructure, diffusion, bitumen, Atomic Force Microscopy

1 INTRODUCTION

The viscoelastic behaviour of bitumen plays a prominent role in asphalt mixture durability, such as cracking (thermal or traffic induced) and raveling. Being an organic substance, with time its viscoelastic property can deteriorate due to exposure to the environment, which is known as age hardening. Oxidative ageing, which takes place within the top layer of exposed bitumen surface, can be noted as a dominant part in the ageing process of bitumen in asphalt mixtures [1]. Ageing involves chemical and/or physical property changes that usually make the bitumen harder and more brittle, consequently increasing risks of premature pavement failure.

The existing accelerated ageing tests [2], make use of the time-temperature superposition principle in which artificially severe conditions are created to replicate the ageing process. Aging of bitumen by using high temperature and pressure is, however, a fundamentally different process from long-term aging at (normal) lower temperatures and (ambient) pressures. So, an investigation on accelerated test residue bitumen might not give the true information of what happens due to ageing in the field [3]. To understand the actual changes of bitumen properties due to the slow oxidation process, it is important to investigate the bitumen through a controlled test environment. For this reason, and given recent advanced, the Atomic Force Microscopy (AFM) has been employed in this study.

AFM is an imaging tool that can deliver the surface topography, stiffness and tackiness information of materials [4]. AFM has gaining in popularity over the past years for examining bitumen samples [5–13] because of relatively simple sample preparation and operates under ambient conditions. While operated in the simplest mode, the tapping mode, imaging of the surface topology and phase signal information can be obtained. Topography image can provide insight on the phase separation information and any presence of topography

features, whereas phase signal can indicate areas that differ in stiffness and tackiness. One specific focus point of several studies has been the appearance of structures, named 'bees' given their black and yellow stripes under the AFM. The earliest studies mainly explained the appearance of these structures on the 'asphaltene' phase in bitumen (i.e. the phase that is not soluble in n-heptane and is often referred to as the more heavy and polar molecules in the mixture) [6,7]. Recent studies have, however, conclusively shown that the bee structures are directly linked to the presence of crystalline fractions in the material, often referred to as the waxes [9–13]. The presence of such microstructures will dictate, if not heavily influence, the macro scale properties of bitumen, such as stiffness, viscoelasticity, plasticity, adhesion, fracture and healing characteristics. Having a better understanding of how these microstructures are evolved with ageing and related to the resulting mechanical response thus opens a large potential for tailoring and enhancing the long term properties of asphalts.

Any chemical changes due to the surface oxidation process may have some effect on the crystalline fractions present in bitumen. To investigate such effects, Differential Scanning Calorimetry (DSC) can be a useful tool. DSC is the thermo-analytic method that can determine any physical changes in bitumen associated with heat exchange. If there are any crystalline molecules present in the bitumen then during the heating scan these molecules needs more heat to melt and thus once the bitumen absorb extra heat and be cooler than the furnace, causes the flow curve point down which is known as endothermic event. The reverse logic applies to exothermic events where energy is released. Since AFM is only applicable for the surface investigation, to study the surface ageing effect on bulk crystalline fractions, DSC has also been employed.

In this paper, the oxygen diffusion on bitumen surface has been investigated utilizing the AFM and the DSC, where the evolutions of microstructures on the bitumen surface due to the oxidation were studied.

2 EXPERIMENTAL

An unaged and unmodified straight run bitumen was used in this study provided by Nynas AB, Sweden. The physical-chemical properties of this bitumen are presented in Table 1. The penetration, softening point, dynamic viscosity, kinetic viscosity and Fraass breaking point were measured in accordance with the European standards EN 1426, EN 1427, EN 12596, EN 12595 and EN 12593, respectively. The chemical characterization (SARA analysis) of bitumen was done by using the thin-layer chromatography with flame ionization detection (TLC-FID) technique.

Specimen preparation: Using material from the top of a can is not recommended for a representative sample as more aging occurs at the surface. Therefore, the bitumen was first stirring

properly at 120°C to avoid such bias. For AFM scanning, approximately 30 mg of hot liquid bitumen was carefully placed on a rectangular aluminum plate (10 mm × 10 mm × 1 mm) and kept for 5 minutes on a hot plate at the same temperature to allow the bitumen to spread out and create a smooth surface. In the preparation process, the specimens were left horizontally and covered to prevent dust pick-up. During the preparation, the specimen surfaces were exposed to the air. Since all specimens went through same preparation process, this minor oxidation during specimen preparation can be ignored.

Right after the specimen preparation, specimens were exposed to the following four different levels of conditioning: both light and air, only air but no light, only light but no air and neither light nor air, for 15 and 30 days. One specimen was kept unconditioned to give a reference measure.

The light source used in this study was normal commercial fluorescent lamp, which does not emit ultraviolet radiations. Since argon is one of the noble gas and heavier than the ambient air, it was used to create an oxygen free (no air) environment. To create oxygen free environments, specimens were placed in glass containers in which argon gas was introduced via an inlet. In this process, argon gas was allowed to spread in the container until the air was pushed out completely leaving for an airtight environment. For the dark (no light) conditioning, specimens were placed inside containers, carefully wrapped in multiple layers of aluminum foil and kept in a dark place.

After 24 hours, the unconditioned bitumen specimen was scanned with the AFM to investigate the topography features. The 15 and 30 days conditioned specimens were investigated by using AFM and the percentage of observed microstructures at the surface compared to investigate the ageing propensity. Thereafter, the 30 days conditioned specimens were investigated furthermore utilizing DSC and compared to study any change of the crystalline fractions due to the systematic conditioning. More details on AFM and DSC will be given in the following sections.

2.1 *Atomic Force Microscopy (AFM)*

In this study, AFM (using a VECO Dimension 3100 device) was used for the microstructural characterization of the conditioned specimens. The scanning of size 50 × 50 μm was carried out in tapping mode at room temperature (25°C) and scan rate was 1 Hz. In this process, cantilevers with spring constant of 40 N/m were used at the resonance frequency of 300 kHz, with a minimum of damping of the amplitude signal.

Depending on the type, source, time-temperature history of bitumen, microstructures may be observed (Fig. 1a) on the bitumen surface from the AFM scans [5–13]. To quantify these microstructures, the open source Gwyddion 2.3 software was utilized. For this, at first the AFM topography image was analyzed using a Laplacian of Gaussian edge detection technique [14] as shown in Figure 1b. Once the microstructures were marked then the marked grains were extracted (Fig. 1c) and thereafter, used for pixel area quantification to calculate

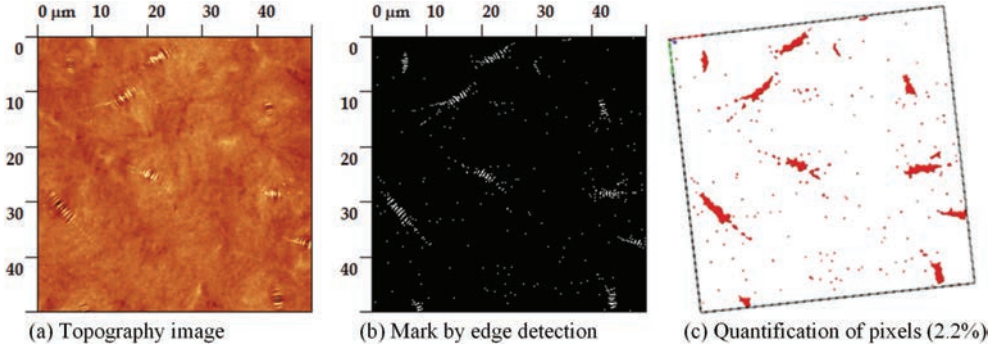

Figure 1. Quantification of microstructures.

the percentage of microstructure present in the frame. For each specimen, AFM scans were conducted at three different locations and the average percentage from these was used as representative average of the percentage of microstructure present at that specimen's surface.

2.2 *Differential Scanning Calorimetry (DSC)*

To investigate any change in the crystalline fractions of specimens due to the previously described conditioning procedures, the DSC analysis was conducted on the 30 days conditioned specimens. The tests were performed using a METTLER instrument (model METTLER TOLEDO DSC 1) equipped with a refrigerated cooling system.

Approximately 15 mg of bitumen was scraped from the each AFM specimens into the DSC sample pans, which were sealed with lids with a small hole to prevent pressure build up and possible deformation of the cups during the tests. The sample pan was then placed horizontally on a hot plate at 80°C for 10 minutes to let the bitumen touch the pan bottom and also level out the surface. Afterwards, the sample pan was placed in DSC furnace and cooled from 25°C to −70°C and kept at this temperature for 5 minutes. Data was recorded during heating from −70°C to +110°C and cooling from +110°C to −70°C, where the heating and cooling rate was 10°C/min. Bitumen were melted completely during the heating, which means the oxidized surface layer also been homogenized in the bulk. If there are any changes in the crystallization process due to the conditioning of the specimens, thus, can be observed in the cooling cycle.

3 RESULTS AND DISCUSSIONS

Figure 2 shows the typical topography image with the computed percentages of microstructure of the unconditioned bitumen specimen. Typical bee structures can be seen since this bitumen contains 6.2% natural wax (Table 1). This topography information of the unconditioned specimens can be used as a benchmark, to detect any change due to the systematic conditioning.

The AFM topography images of the bitumen under four different levels of exposures are shown in Figure 3. In this figure, top row images were aged over 15 days and images in the bottom row over 30 days. To investigate the microstructure evolution due to increased exposure intensity, all the exposed specimens were compared with the reference specimens (unexposed one). After 15 and 30 days, the combined effect (Air + light) caused a reduction of 100%. The oxidation caused a reduction of microstructures by 38% and 58%, and the light caused a reduction of 19% and 14%, respectively. Comparing the specimen exposed to air during 15 and 30 days of exposure (i.e., (b) vs. (f)), it can be observe that the percentage

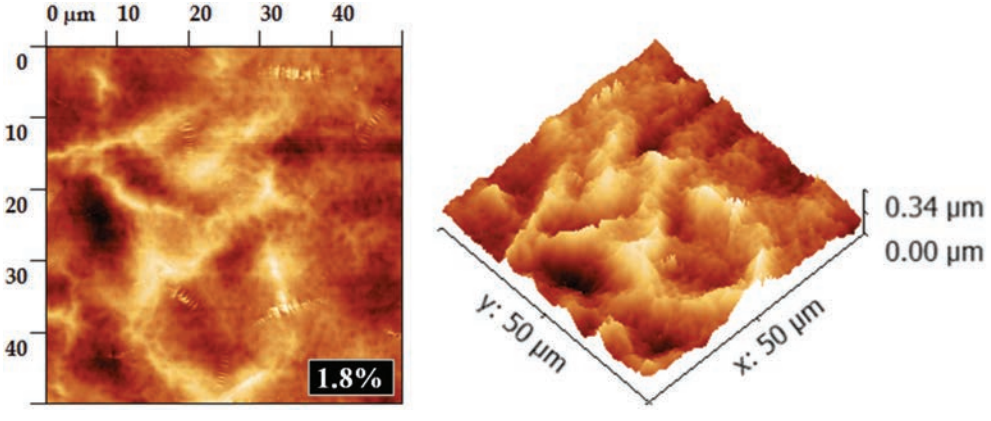

Figure 2. Topographic 2D (left) and 3D (right) AFM image.

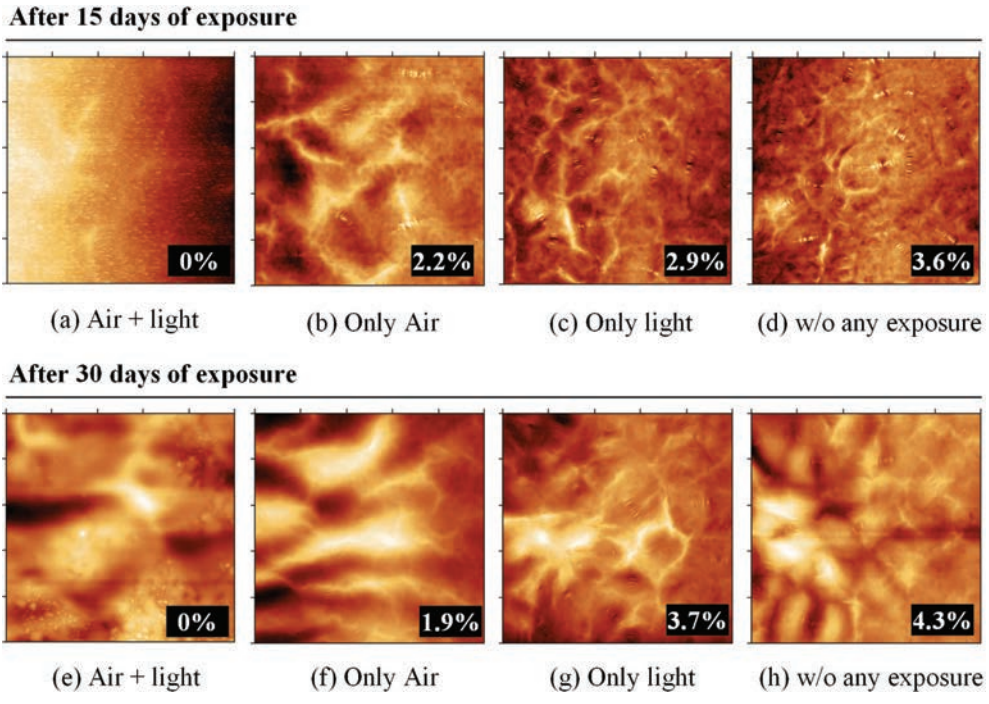

Figure 3. Topography images of conditioned specimens after 15 and 30 days.

of microstructure decreases. In case of non-oxidized specimens, however, the percentage of microstructure increases with time.

From this analysis, it was observed that the visible microstructures at the surface decrease with an increasing degree of oxidation and time. In the case of only light exposed and unexposed specimens, with the time the percentage of microstructure at the surface increases. This confirms that the thin film at the specimen surface caused due ageing may create a barrier, which restricts the microstructures to float towards the surface, and if there is no such barrier at the surface, the percentage of microstructure increases with time.

From the aforementioned AFM topography analysis, it has been observed that there are certainly changes on the bitumen surface caused by the different ageing history. To investigate any change in crystalline molecules due to this thin film surface ageing, DSC analysis has been conducted. Since DSC can determine any physical changes in bitumen associated with heat exchange, it can determine any changes in melting and crystallization phenomena due the systematic conditioning.

The heat flow characteristics of all the specimens with 30 days of exposures have been investigated. Since this is a 'waxy' bitumen (Table 1), both endothermic and exothermic effect was observed as shown in Figure 4a-b. The correspondent zones to the endothermic and exothermic event of the specimens are zoomed in as shown in the figure (right). In the figure, the areas under the wide endothermic peaks represent the enthalpy absorbed due to melting of wax. One may observe that all the four curves in Figure 4a have almost same starting-ending points, and can be superimposed into one curve. This indicates that there is no change in enthalpy due to the different exposures which means the percentage of wax in the bitumen remains constant after 30 days of exposures. Since the percentage of wax remains constant, then the total area under the exothermic peaks in Figure 4b should also have a constant value. It can be observed that during the cooling the shape and the starting-ending point of the exothermic peak somehow differ from each other. The starting point of exothermic event represents the starting of crystallization process. The crystallization starts earlier for oxidized specimens than the unaged one. In this crystallization process, any presence of impurities

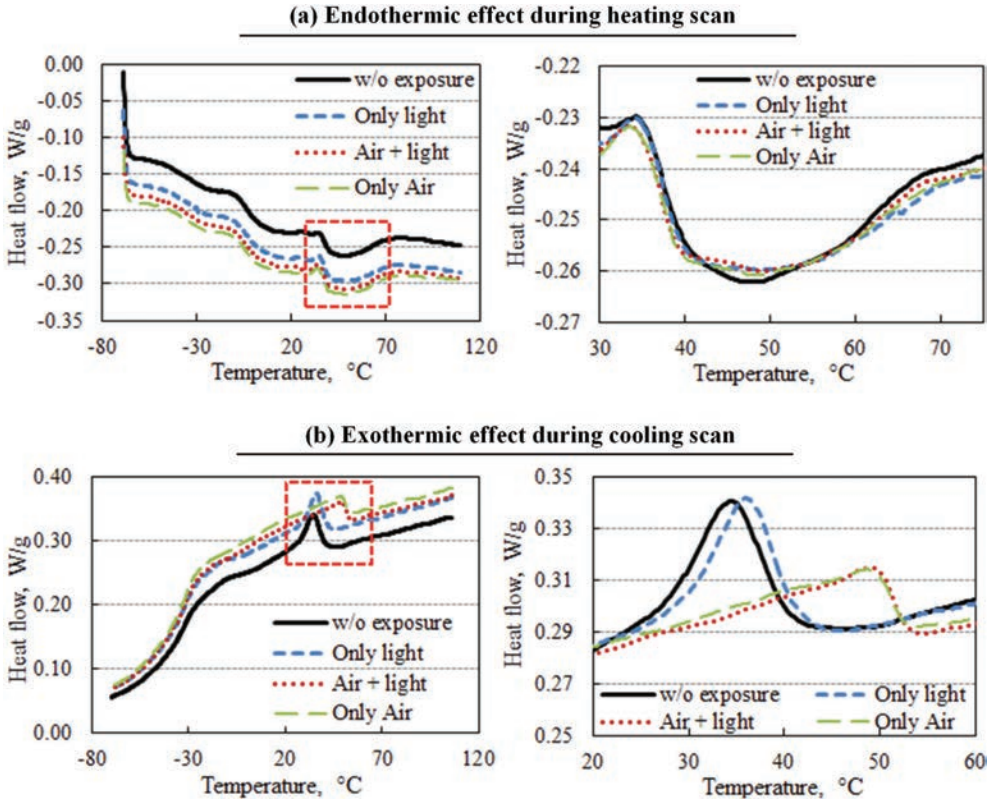

Figure 4. Heat flow analyses of different levels of exposure.

may act as a promoter that may accelerate the process. The product due to the oxidation process may introduced such impurities in the bitumen matrix and thus the crystallization process starts earlier than the without oxidized one.

4 SUMMARY OF FINDINGS

Since bitumen was exposed to air, the oxidation created a thin film upon the exposed surface. This thin film acted as a semipermeable barrier that created difficulty for the wax induced microstructures to float up at the surface. As film becomes thicker or denser with time and increasing degree of exposure, thus the percentage of microstructure seen at the surface was decreased as depicted in Figure 5. For without exposed specimen, with time the percentage of microstructure was increased at the surface, since there was no such thin film caused due to oxidation.

5 LABORATOTY VS. FIELD AGEING

One may notice from aforementioned results and discussions that with oxidation the percentage of bee-shaped microstructures reduces on the surface and the amount of wax remains constant. However, the previous AFM studies [15–17] on PAV aged bitumen had reported the increase of bee-shaped microstructure compared with unaged bitumen.

The hydrocarbons in bitumen react with atmospheric oxygen, where the reaction type and rate depends on the surrounding temperature and pressure. Thus, the type of chemical reac-

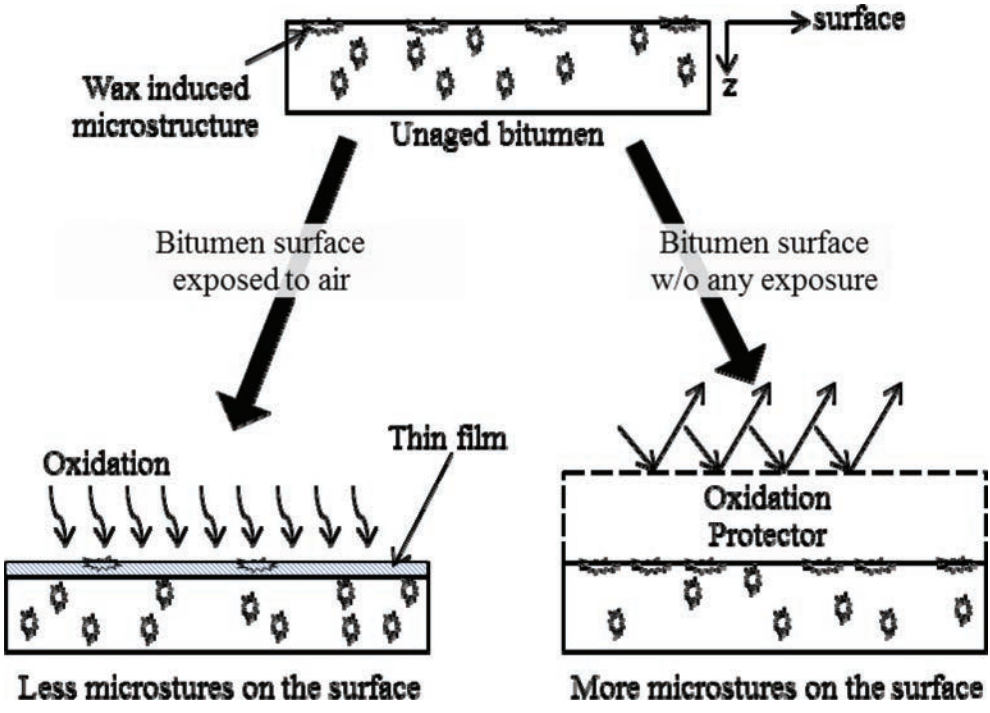

Figure 5. Microstructures evolution due to thin film surface ageing.

tions may vary with the change of pressure and temperature. In the accelerated ageing simulations, especially the PAV test, bitumen gets exposed to extremely high pressure and elevated temperatures for a short time. There is the possibility that the product after the accelerated aging test may differ from the slow but long ageing process with different temperature and pressure history (field ageing). This would then lead to the conclusion that 'ageing' from a PAV tests is indeed a completely different process from ageing in the field [3].

Moreover, AFM is only capable to provide surface information not the bulk. The PAV residue bitumen undergoes heating and cooling for several times during sample collection and specimen preparation for AFM. Due to this thermal history, the aged surface layer (which acts as a barrier) melts down homogeneously in the matrix. In this way, the surface changes entirely and shows completely different surface information than that observed in this study. Thus, the surface information one gets from the disturbed PAV residue bitumen is not even representing the bitumen surface right after the PAV ageing.

6 CONCLUSIONS

The evolution of microstructure due to oxygen diffusion on bitumen surface and its effect on bulk properties has been investigated utilizing Atomic Force Microscopy (AFM) and Differential Scanning Calorimetry (DSC), respectively. The bitumen specimens were subjected to four different environmental conditions: both light and air, only air but no light, only light but no air and neither light nor air, for 15 and 30 days.

From the analyses it was found that the percentage of microstructure on the surface reduced with ageing. For the specimens exposed in oxygen environments, the quantity was lowest and with the time it became even lower. Since it was previously concluded that the microstructures are linked directly to the wax content, one would expect the wax content to also become less. From the DSC results, however, it was proven that this is not the case, as the wax content stayed in fact the same. From this, it can be concluded that a thin film forms

at the specimen surface caused due ageing thus creating a barrier, which restricts the microstructures to float towards the surface.

Though the thermo-analytical investigation showed that the crystalline fractions in the bitumen remain constant even after been exposed to air, crystallization of wax molecules did start earlier for the exposed specimens than the without exposed one. This implies that the chemical reaction product due to the exposures creates impurities in material and causes the acceleration of the crystallization process.

ACKNOWLEDGEMENTS

This research was sponsored by Swedish Road Administration and KTH Royal Institute of Technology, Sweden. The authors acknowledge Måns Collin and Per Redelius for many valuable discussions around the table. Nynas AB is thanked for providing the bitumen.

ABSTRACT: This study presents a multiscale computational model with its verification and validation efforts for predicting damage-dependent mechanical behavior of asphaltic media that are subject to fracture damage. Two length scales (global and local) are two-way coupled in the model framework by linking a homogenized global scale to a heterogeneous local scale representative volume element. Based on the two-way coupled concurrent multiscaling and the use of the finite element technique incorporated with material viscoelasticity and cohesive zone fracture, the model approach can successfully account for the effect of mixture heterogeneity, material viscoelasticity, and damage accumulation due to cracks in the small scale on the overall performance of larger scale mixtures or structures. Along with the theoretical model formulation, two example problems are shown: one to verify the model and its benefits through comparisons with analytical solutions and single-scale simulation results, and another to validate the model for various cases where material viscoelasticity, mixture heterogeneity, and cohesive zone fracture are involved.

Keywords: multiscale model, asphalt, heterogeneity, viscoelasticity, cohesive zone fracture, finite element method

1 INTRODUCTION

Asphalt materials are classical examples of multi-phase composites consisting of aggregate particles surrounded by a cementitious phase. The understanding of the mechanical behavior of asphalt materials has been a challenge to the civil engineering community due to multiple complexities related: mixture heterogeneity, anisotropy, nonlinear inelasticity, and damage growth in multiple forms.

Microstructure-based computational modeling has been actively pursued by many researchers as a means of overcoming the aforementioned challenges, since the microstructure-based computational modeling can readily account for the geometric complexities and inelastic constitutive relations of mixture components. Even though various computational techniques based on the mixture microstructure and its component characteristics have demonstrated sufficient modeling feasibility in addressing the challenges, solutions for the mixture problems are sometimes limited because they usually require a tremendous amount of computational time and effort, which is rarely feasible with currently available computing power. Asphalt mixtures and pavement structures typically contain thousands of irregularly-shaped,

randomly-oriented aggregate particles along with thousands of potential cracking sites which would require a highly refined microstructure with enormous degrees of freedom. These clear limitations have led researchers to seek alternative approximate approaches that can account for the hierarchical structure of heterogeneous materials without having to model every microstructural detail, but still considering the most important ones.

One approach, which has been receiving increasing attention from many different engineering-science disciplines, is that of multiscale modeling as demonstrated in many studies [1–11]. In this approach, different length scales within the macroscopic body are separately analyzed and then linked together. When statistical homogeneity on the smaller scale Representative Volume Element (RVE) is satisfied, constitutive equations for the larger scale can be produced using a homogenization principle [12–15]. Therefore, the global constitutive behavior of heterogeneous objects can be determined by the solution of a smaller scale RVE boundary value problem.

In this paper, we present the modeling framework developed so far and its verification and validation with model calibrated. At this stage of model development, only two length scales (called herein global and local scales) with material elasticity, viscoelasticity, and damage due to cohesive zone fracture are considered.

2 TWO-WAY COUPLED MULTISCALE MODEL

The multiscale model developed has been implemented into a finite element code. At this stage of the model development, two length scales (i.e., global and local) are considered together with material viscoelasticity and cohesive zone fracture.

As presented in Figure 1, a global scale solid object (length scale l^G) with evolving microcracks (length scale l_c^L) on the local scale (length scale, l^L) RVE is modeled. The object is statistically homogeneous at the global scale where the continuum is represented by a heterogeneous local scale RVE. The RVE is the smallest object size that is sufficiently large so that the estimation of the effective properties is independent of the object size. As illustrated in the figure, in the local scale RVE, various sources of heterogeneity such as particles, voids, and cracks can be considered.

The primary variables in the model are the displacement vector, the strain tensor, and the stress tensor. It should be noted that in order to produce reasonably accurate predictions through the multiscale process, the global length scale needs to be much larger than the local length scale, and the local length scale should be much larger than the length scale of microcracks. Theoretical details on the multiscale model presented in this paper can be found elsewhere [15–17].

The multiscale model herein is termed two-way linked because the applied displacements on the boundary of the local scale are computed from the global scale strain tensor

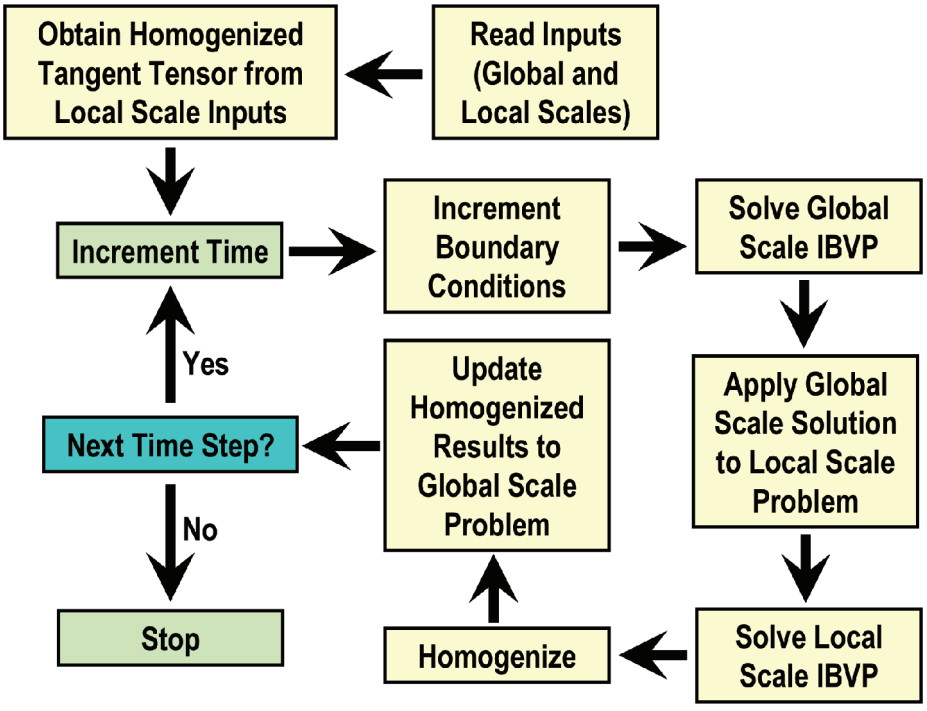

Figure 2. Two-way linked multiscale modeling process.

(global-to-local linking), and the homogenized constitutive quantities are obtained from the solution of the local scale problem (local-to-global linking). A simple description of the two-way coupled multiscale modeling algorithm is given in Figure 2. Basically, the model is operated in seven primary steps: 1) read inputs for global and local scales; 2) obtain initial homogenized tangent tensor for global Initial Boundary Value Problem (IBVP); 3) solve the global IBVP at a given time step; 4) apply global scale solution to local scale IBVP; 5) solve the local scale IBVP at the time step; 6) homogenize local scale results; and 7) update homogenized local scale results to the global scale object at each integration point for the next time step. The two-way linking is essentially necessary when the problem is subjected to material viscoelasticity and evolved microstructure such as microcracks, since the problem with material viscoelasticity and cracking is typically time-, history-, and spatial-dependent. In the multiscale modeling process, the global scale can be discretized with a homogeneous finite element mesh, which dramatically reduces the time required for mesh refinement and computation, while the local scale considers mixture heterogeneity. A local scale RVE is attached to each global scale integration point of selected global scale finite elements.

As illustrated in Figure 2, global scale response can be obtained by performing a local scale analysis, and using homogenization principles, relationships connecting both length scales can be established. In other words, the constitutive relationship at the global length scale is based on the constitution of the local scale RVE.This indicates that there is no need to determine the global scale constitutive functional *a priori*, since it is determined concurrently as the analysis of local scale is performed.

3 MULTISCALE MODEL VERIFICATION

In order to verify the multiscale computational model developed, a heterogeneous tapered bar as presented in Figure 3 is introduced. The tapered bar is a general composite consisting

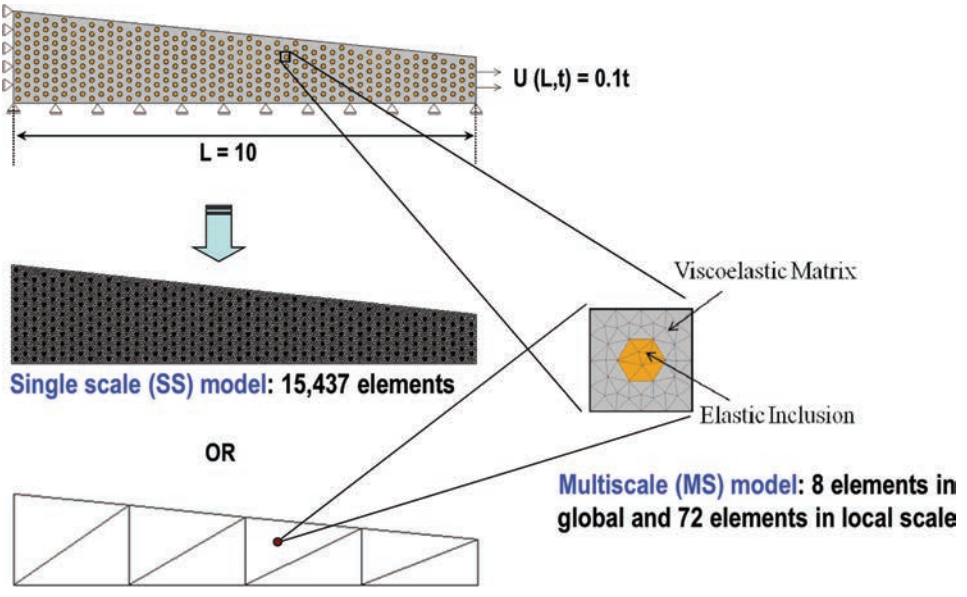

Figure 3. Elastic-viscoelastic tapered bar problem for model verification.

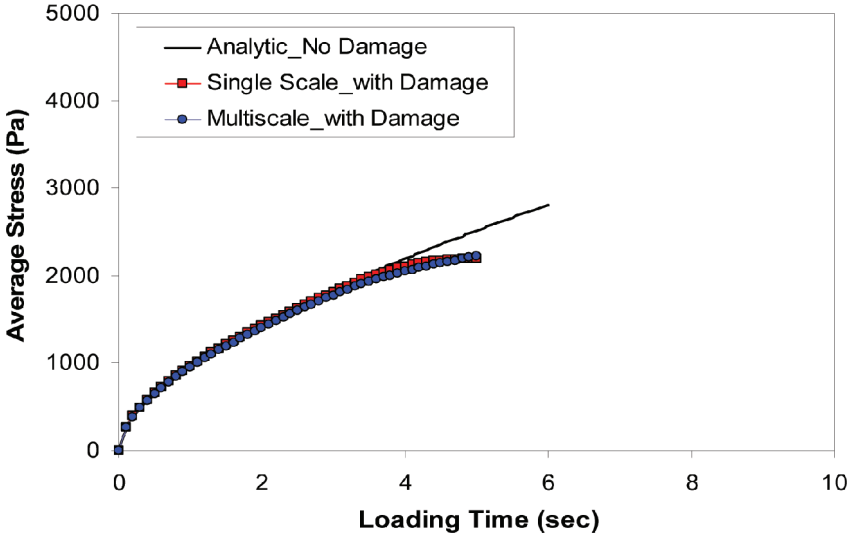

Figure 4. Model verification results.

of viscoelastic matrix and elastic particles. Due to the axis of symmetry, only half of the bar is modeled, and monotonically increasing displacements are applied at the right end of the bar, as shown in the figure.

For the multiscale analysis, a local scale microstructure describing the important geometric heterogeneities is needed. In the present verification problem, a unit cell is selected which possesses the same volume fraction and equal level of mesh refinement obtained from the single scale reference mesh. Model verification was performed by comparing multiscale simulation results to single scale results and analytical solutions available.

Figure 4 plots the average stresses of the tapered bar as loading time increases. Due to the formation of cohesive zones followed by cracks, it can be noticed that the average stress

deviates from the non-damage (linear viscoelastic) case (presented by analytical solution). The multiscale solution was considered satisfactory when compared to the single scale simulation results. The accuracy of the multiscale model with only 8 elements for the global scale and 72 elements for each local scale RVE suffice, as opposed to 15,437 elements needed by the single scale reference simulation. In terms of computational time required to run this problem, the multiscale solution was obtained approximately 250 times faster than the single scale case. With only one processor (2.50 GHz CPU with 4 GB RAM) 26,700 seconds were necessary to complete the single scale case, whereas only 105 seconds were used to run the multiscale problem. Furthermore, the multiscale model can also run in parallel computing environments, which highlights the benefit of multiscale modeling approach. The parallel computing can vastly reduce simulation time, since individual local scale problem can be solved in parallel by multiple processors. Clearly, this example demonstrates the accuracy and efficiency of the multiscale model. This benefit will further be noticeable when one models typical multiphase composites and structures that present very complicated geometry and material inelasticity.

4 MULTISCALE MODEL VALIDATION-CALIBRATION

To validate the two-way linked multiscale model for predicting the mechanical behavior of asphalt mixtures, three-point bending beam tests of asphalt mixture specimens were performed at 21 °C, and test results were compared to model simulation results. As presented in Figure 5(a), the rectangular beam specimens were placed inside a three-point bend fixture and loaded by a UTM-25 kN machine at a constant displacement rate (0.83 mm/s) until the specimens failed completely. Three replicates were tested. Figure 5(a) shows the experimental setup.

Figure 5(b) presents the two-way linked multiscale simulation accomplished by linking the heterogeneous local scale RVE (10.0 mm by 10.0 mm square) to a homogeneous global scale beam specimen (150 mm by 40 mm rectangle). The global scale bending performance was modeled as a damage-induced, non-linear viscoelastic continuum by a two-way linking strategy. For the modeling, the loading configuration was simulated in the same manner as the test setup. It is important to mention that at this point the numerical model simulations were performed allowing microcraks and their coalescence to macrocracks only at the local scale. The damage in the global scale was then accounted indirectly by the loss of stiffness of the homogenized constitutive tensor, due to the cracking at the local scale.

The selected local scale RVE was discretized into a finite element mesh with triangular elements with 0.5 mm size as presented in Figure 5(c). The aggregate particles were modeled as isotropic and linear-elastic, and the surrounding mastic was modeled as isotropic, viscoelastic with cohesive zone fracture. To determine the global mesh refinement which is a primary factor that affects total computing efforts, a mesh convergence study was also performed. Different global meshes were linked to the local scale RVE until the finite element numerical solution converged to an analytical solution. A set of homogeneous global scale meshes in a different level of mesh refinement (10-mm element size to 2.5-mm element size) was evaluated. Considering a balance between the level of accuracy desired and the computational time spent, in this study, the global mesh with 5-mm triangular elements (Fig. 5(d)) was finally selected since it required a reasonable computing time by providing a relatively fair level of accuracy.

The model validation-calibration was accomplished by comparing the model simulation results with analytical and experimental results. To that end, three scenarios were attempted: i) multiscale w/o cracks, where no damage was considered in the analysis, ii) multiscale w/cracks (validation), where the damage parameters used in the simulation were directly obtained from the semicircular bend fracture tests [18,19], and iii) multiscale w/cracks (calibration), where one of the damage parameters (m-value) used in the simulation was calibrated for a better agreement with experimental results. Figure 6 shows the results.

Model simulation results showed a fairly good agreement with the analytical solution when damage was not involved (i.e., multiscale w/o cracks). This verifies the accuracy of the model

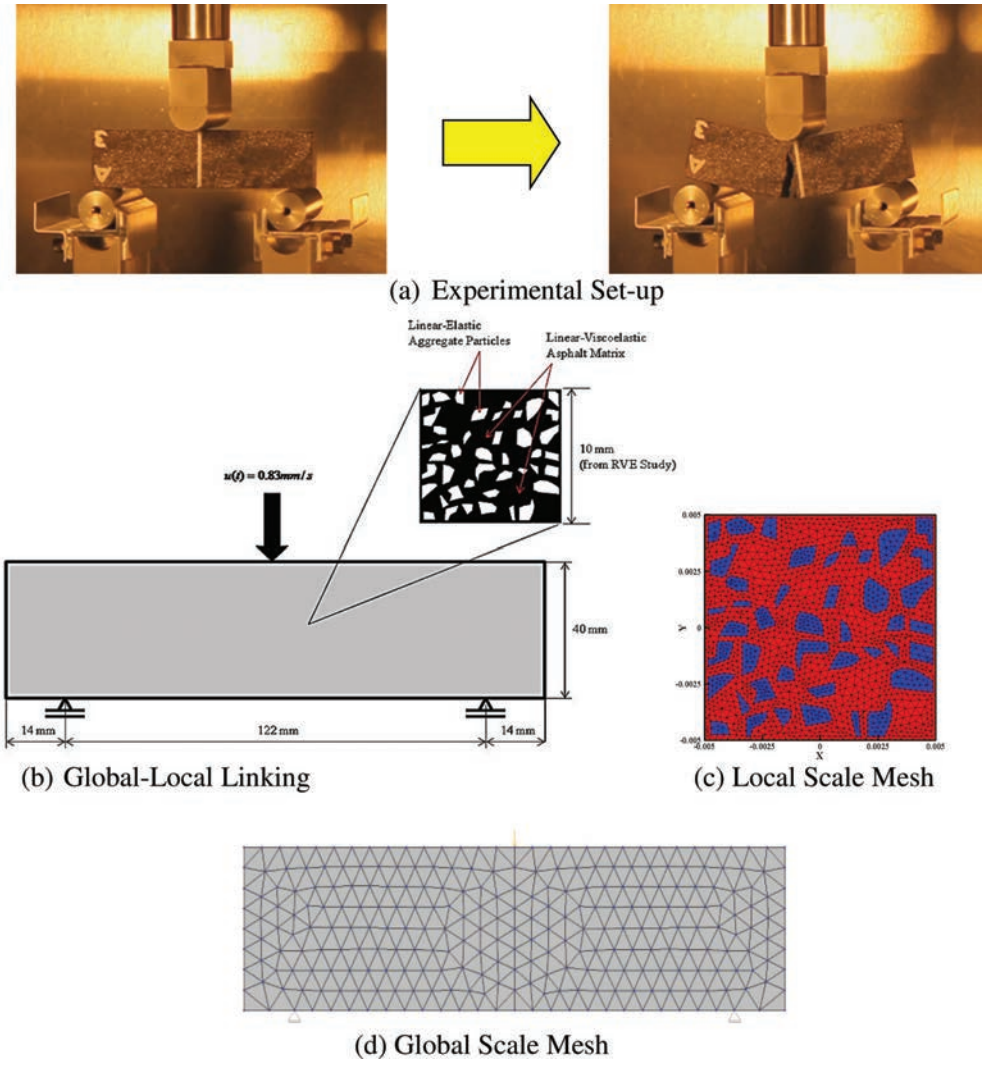

Figure 5. Multiscale model validation-calibration.

when damage is not associated. In addition, the model simulation results without damage seemed to follow the experimental test results nicely up to 1.2 seconds (stage 1) by representing some energy being dissipated due to the material viscoelasticity. The initial slope from model simulations matched very well with the experimental results, which demonstrates that, along with the appropriate constitutive model and the properly defined properties of mixture components, the multiscale model can satisfactorily capture the mixture response when damage is not induced. After passing the stage 1, due to the formation of cohesive zones followed by microcracks, it can be noticed that the average stress deviates from the non-damage (linear viscoelastic) curve. After 1.5 seconds of loading, the three-point bend test results started to deviate from simulation results with cracks. The rate of damage propagation seemed to be underestimated in the numerical simulations (case of multiscale w/cracks_validation_m = 2.5) using the damage parameters determined from the semicircular bend fracture test incorporated with the viscoelastic cohesive zone model. The mismatch between the simulation results and test results can be from multiple sources including the approximated finite element meshes, limited model capabilities at the current stage, and the assumed constitutive

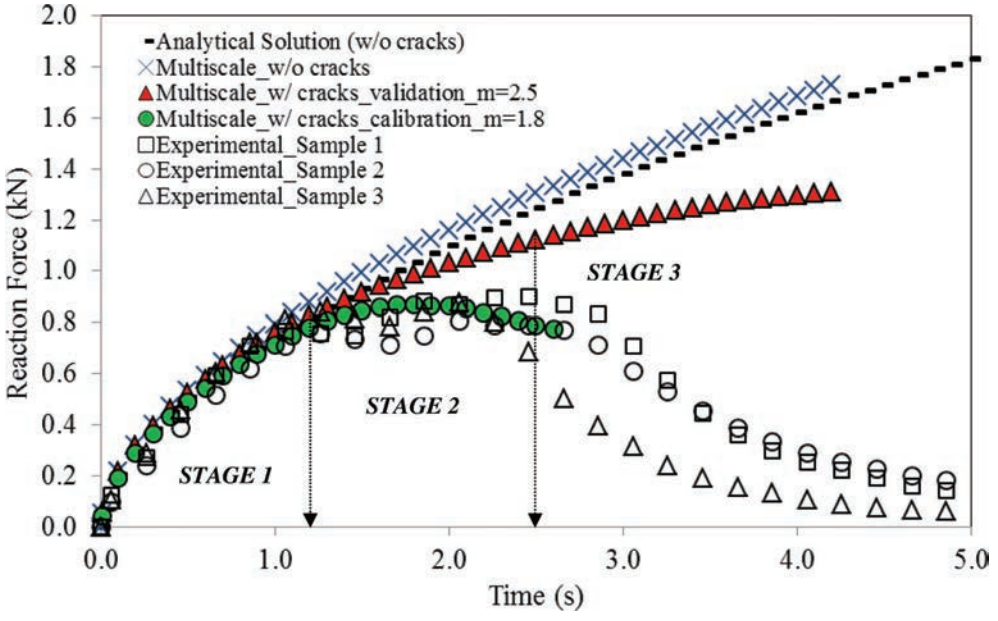

Figure 6. Multiscale simulations vs. experimental tests and analytical results.

relations (i.e., linear elastic behavior of aggregates and viscoelastic behavior of asphalt mastic with cracking) for the mixture, etc.

Since it is not feasible to identify the sources of mismatch at the current stage, model calibration was attempted in a simple way by merely varying one of the cohesive zone damage parameter, *m*-value. In this way, it can be investigated how the model represents the effects of damage characteristics of component properties on entire mixture/structure performance. In the damage evolution law, the damage parameter *m* significantly changes the damage evolution rate. By varying the *m*-value from 2.5 to 1.8, which induces a faster degradation of the mixture, model calibration was achieved. All other material characteristics were kept the same as the ones used in the validation case. The simulations results with the calibrated *m*-value (multiscale w/cracks_ calibration_m = 1.8) showed a good agreement with experimental results, as demonstrated in Figure 6.

Aside from the efficiency of the multiscale model, another clear benefit is the capability of the model to visualize the small-scale phenomena. To do this, three local scale RVEs (21, 156, and 451) were selected. Each local scale RVE was named accordingly with the global element it was linked. The deformed mesh and elemental stresses at both global and local scale structures at 2.5 seconds (stage 3) were selected and presented in Figure 7 for the validation case ($m = 2.5$) and the calibration case ($m = 1.8$), respectively. Clearly, at the same loading stage, the case with $m = 1.8$ presented severe damage evolution from the local RVEs and correspondingly, greater stiffness reduction in its global scale. It can also be noted that the mixture behavior with damage phenomenon can be captured by the model, as seen by the different stress responses in the selected RVE microstructures. The microstructure linked to the global element 21 (RVE 21) showed the highest tensile stress compared to the other elements. This result was expected as the highest tensile strains developed at the bottom of the three-point bending beam test. Similarly, highest compressive stresses were observed from the local RVE linked to the global element 451.

The level of damage in the microstructure linked to the global elements from the region of higher stresses was noticeably pronounced, and microcracks began to connect to each other, forming macrocracks. The insertion of cohesive zone elements, which was eventually converted to a crack, reduced the stresses on the sample compared to the case with no damage. With the unique model capability to visualize the smaller length scales, damage

evolution could be analyzed in a more detailed manner than traditional approaches that did not account for microstructural details.

5 SUMMARY AND CONCLUSIONS

A computational multiscale model for predicting mechanical behavior of heterogeneous, inelastic asphaltic media was presented. The model can account for mixture heterogeneities by taking into account individual mixture constituents through the unique scale-linking technique: a local scale in a form of the heterogeneous RVE and a global scale which has been homogenized from the local scale responses. The model was implemented using the finite

element formulation, so that geometric complexities and material inelasticity with physical cracks can be properly handled without any significant loss of accuracy.

Verification of the model was conducted by simulating a simple tapered bar where two distinct phases (i.e., elastic particles and viscoelastic matrix) exist. By comparing multiscale simulation results to single scale results and analytical solutions available, model verification was confirmed. Moreover, a significant reduction in computational effort by using the multiscale approach compared to the single scale simulation was observed.

The multiscale model was also validated and calibrated by comparing laboratory test results with model simulation results of the three-point bending beam specimens, where elastic fine aggregate particles are surrounded by viscoelastic mastic that was subjected to fracture. Clearly, the model can simulate the laboratory tests by capturing the formation of microcracking and the propagation in the heterogeneous local scale RVE and update the local scale fracture process to the global scale damage-dependent performance.

The clear understanding of the small scale phenomena can then be guidelines to select mixture constituents in a more appropriate way and to improve current asphalt mixture design methodology so that better-performing and longer-lasting roadway mixtures can be produced. In addition, since only small scale material properties are required in the model, this modeling approach can reduce the amount of laboratory testing required, thereby providing substantial additional cost savings. Although many challenges still exist, and further improvements are necessary remain for the future studies, this study demonstrates the potential power and efficacy of this modeling approach as a purely mechanistic method for the analysis and design of various asphaltic media.

Structuralization as characteristic to link the mechanical behaviours of asphalt concrete at different length scales

B. Shane Underwood
Arizona State University, Tempe, AZ, USA

Y. Richard Kim
North Carolina State University, Raleigh, NC, USA

ABSTRACT: Multiscale characterization and modelling is an increasingly popular technique for the investigation of asphalt concrete due to limitations with the level of insight possible from macroscale mechanistic models with respect to certain key performance characteristics. Four key questions arise in the multiscale experimental/mechanical evaluation of asphalt concrete; 1) what are the different characteristic length scales within asphalt concrete, 2) how should these materials be constructed in the laboratory for experimentation 3) what are the characteristic behaviours of these different scales, and 4) how are these behaviours linked across the scales. In this paper the authors present research findings concerning the fourth question. A characteristic index, the structuralization index, is identified as a scale independent characteristic that explains the stiffening characteristics of asphalt concrete across length scales. The definition and basis for the development of this structuralization index is presented. Next, the application of this structuralization index to two different materials is shown. It is the authors' belief that this structuralization index can serve as a means to link the characteristic behaviours of asphalt concrete for analytical upscaling of the modulus, and perhaps other properties as well.

Keywords: asphalt, multiscale, mastic, structuralization

1 INTRODUCTION

In previous papers the issues of defining the characteristic length scale in asphalt concrete and how these should be constructed in the laboratory as well as evaluated the characteristic behaviours of these materials has been evaluated [1–3]. In this document the multiscale modelling issue of linking the behaviours across scale is examined. The ultimate vision and goal for this line of research is in articulating an alternative framework with which to investigate the mechanical behaviours of asphalt concrete and to develop new insights that may lead to improvements in the engineering of this material. Existing methods have proven useful in the field of asphalt technology, but fundamental limitations with respect to their ability to more fundamentally understand cause and effect relationships is becoming apparent. The concept of internal structuralization within asphaltic composites was introduced by Rigden [4], when he applied the fractional compaction, *FC*, quantity to asphalt mastics. This value evolved from empirical packing studies and from analytical studies on the stiffening of dilute solutions. Although the term itself was, apparently, first coined by Rigden, it has been used by others without specific reference to Rigden's work or the term fractional compaction. The mathematical definition of *FC* is given in Equation (1). Its value generally varies from 0 to approximately 3 with 0 indicating infinite space between particles and the upper value corresponding to a void less condition.

$$FC = \frac{100 - \%Voids}{100 - \%Void_{ref}} \quad (1)$$

where $\%Voids$ is the void volume in a given material expressed as a percentage of total volume and $\%Voids_{ref}$ is the void volume in a given material expressed as a percentage of total volume and determined from a separate experiment. Keep in mind that $\%Void_{ref}$ is determined from dry compacted filler whereas $\%Voids$ is from the filler plus asphalt. The addition of asphalt facilitates compaction and hence the ability of mastic to have $\%Voids$ lower than $\%Voids_{ref}$.

The concept of *FC* is used to normalize materials with respect to their basic packing characteristics under some standardized compactive effort. It follows from the hypothesis that materials of different composition behave similarly when the internal structure is under a similar state of inter-particulate interaction. The reference void content can be chosen at any condition, but it is typically taken as the dry compacted density of the material. Since the concept has been historically applied to fillers in mastics, this compacted void content is usually that determined by the Rigden apparatus and is referred to as the Rigden voids. For real materials this void content may range from 20% to 40% or more depending on the characteristics of the material.

The concept also suggests that it is important and necessary to understand the way that particles pack and assemble within a body at a particular volumetric concentration. Experimental evidence shows that for most materials a rapid change in mechanical properties begins to occur at a *FC* of approximately 0.6, e.g., at particle volume concentrations of 40% to 60%. At this point the modulus begins to qualitatively change from a liquid-like response to a solid-like response and to rapidly increase in magnitude [1, 5–8]. It is hypothesized that the transition from liquid-like (e.g., binder-like) to solid-like (e.g., mixture-like) behaviours within only the mastic scale as particle concentration increases suggests a universal linkage between scales through the internal structuralization within the composite. This index, termed the structuralization index, would quantify the effects of internal structure and inherently supposes that the internal structure is responsible for much of the stiffening observed in the high concentration mastics, Fine Aggregate Matrix (FAM), and the mixture. It is further supposed that this index, like the *FC*, should be based upon the packing characteristics of the raw aggregates since these properties give an *indication* of the surface texture, particle shape, frictional characteristics, etc. of the aggregates as they exist within the material. Each of these properties is expected to contribute to either how the structure forms within a given scale, or how the structural skeleton reacts to loading. In this paper, this hypothesis is evaluated.

2 STRUCTURALIZATION INDEX

The definition of the structuralization index, *SI*, is given in Equation (2), which is very similar to the definition of *FC* except the reference void content is now the void content when the *internal structure* just forms. Thus, Equation (2) represents a more functional definition of the concept of *FC*. It is supposed that this void content is between the loose and compacted void ratios ($\%Voids_{loose}$ and $\%Voids_{comp}$ respectively) measured via the standard laboratory methods.

$$SI = \frac{100 - \%Voids}{100 - \%Voids_{str}} \quad (2)$$

In Equation (2), $\%Voids$ is the void volume in a given material expressed as a percentage of total volume. It is not simply the air void content, but rather it is the volume content of all space that exists between aggregate particles. It is very similar to the VMA value that is typically computed for an asphalt concrete mixture. In fact, for the mastics, the $\%Voids$ is the VMA. However, in the case of mix and FAM the $\%Voids$ is slightly different than VMA because it does not include the volume of space occupied by the filler. To calculate the $\%Voids$

for Equation (2) requires one to carry out volumetric calculations using known aggregate size distribution, bulk specific gravity and effective specific gravity for each aggregate size or range of sizes, asphalt content, and air void content. The $\%Voids_{str}$ is the structuralized void ratio and is computed by Equation (3), where B is a theoretical parameter ranging from 0 to 1 that indexes the void ratio where structuralization onset occurs with respect to the compacted and loose void ratios.

$$\%Voids_{str} = B\left(\%Voids_{loose} - \%Voids_{comp}\right) + \%Voids_{comp} \tag{3}$$

Structural onset is an abstract term, but it is functionally considered to be the point at which interparticulate contacts are sufficient enough in number and/or in strength to support the structure and resist substantial deformation under load. One might consider this characteristic as the cumulative contact strength and it is a function of both the number of contacts and the individual strength of each contact. The compaction level needed to create a stable structure should be aggregate specific and it likely depends on the physical properties of the aggregate (texture, angularity, shape, etc.), the mineralogical composition (physico-chemical properties), and the gradation. The relative importance of these factors is not known, but each is believed to contribute at least somewhat to the observed structuralization potential. The following are hypothesized based on literature review and the authors' experience;

- The physical properties are the most important factors affecting the achievement of a stable skeleton structure and these factors are similar at all scales for a given source.
- The void structure in a loose and compacted voids test, i.e., the void structure at any fixed compactive effort, is influenced to a significant enough amount by each of these factors that none can be ignored.
- The amount of compaction effort needed to reach a stable configuration is constant for a given aggregate source, but the actual void structure at this stable configuration will depend on scale specific factors (gradation, physico-chemical influences, etc.). Thus B is a material constant but since $\%Voids_{comp}$ and $\%Voids_{loose}$ change, $\%Voids_{str}$ is scale dependent.
- The loose and compacted void contents serve as consistent markers for these additional influences and provide reliable measures by which one can find this stable structure.

The hypotheses regarding bounding of the structuralized void ratio by the coarse and fine void contents is accounted for by the B parameter in Equation (2). If the B parameter is 0.5 then the structuralized void ratio is the average of the loose and compacted void ratios. When B is zero then the SI is equivalent to the FC. Based on the hypotheses above, more angular and rough surface textured stone should lead to a B that is closer to 1 than it is for rounded and smooth aggregate. Since the critical cumulative contact strength is the physical parameter that dictates whether a given microstructure is structuralized ($SI = 1$), under structuralized ($SI < 1$), or over structuralized ($SI > 1$), it is believed that the more angular and rough sources will reach the structuralized configuration with less compaction effort. In this work, the goal is to identify the existence of a structuralization index and quantify its value for two different materials. If this concept is verified then an experiment to measure its value may be developed in later work.

3 MATERIAL

Two highly granular and generally cubical, granite-based AC mixtures with no deleterious materials are utilized. The primary AC mixture is well-graded with a Nominal Maximum Size of Aggregate (NMSA) of 9.5 mm. The secondary mixture consists of a blend of aggregates with a NMSA of 19.0 mm. These mixtures are respectively referred to as the 9.5 mm and 19.0 mm mixtures throughout this paper. Aggregate Imaging Measurement System (AIMS) parameters have been measured for these aggregates. It is found that they have statistically similar angularity (sub-rounded), Form 2D (Semi-Elongated), and Sphericity (low) and significantly different texture (primary mixture shows high-moderate roughness and the

secondary mixture shows low-low roughness properties) [9]. More details on these materials are given elsewhere [2].

From these two study mixtures various materials have been created to support this study. These materials include: mastic at different volumetric concentrations; FAM with different maximum aggregate size, gradation, asphalt content, and air void content; and full scale asphalt concrete mixture. These materials are summarized in Table 1 (Primary mixture) and Table 2 (secondary mixture). These tables also include the structuralization index values for each material, the $\%Voids_{str}$ used to compute this quantity is described later.

4 TEST METHODS

Temperature and frequency sweep tests were conducted on the materials at different length scales; binder, mastic, FAM, and mixture. The strain levels for the tests shown in this paper

were confirmed to be low enough so as not to induce any permanent damage or significant nonlinear viscoelastic behaviours [10]. The experiments were performed using either a parallel plate shear geometry (binder and mastic at particle concentrations below 50%), a torsional cylinder geometry (mastic at particle concentrations of 50% and above and FAM), or an axial tension-compression geometry (mixture). Tests were performed to confirm that the geometrical inconsistencies between the parallel plate and torsional cylinder did not contribute to the differences in mechanical behaviours observed across the length scales. The axial and radial strains were measured in the axial tension-compression geometry tests and used to compute the shear properties. Experiments were performed over the range of 10° to 54°C. Details of the analysis procedures can be found elsewhere [1].

Void content tests were performed to identify both the loose and compacted voids at different length scales and combinations of scales: filler, fines, filler+fines, etc. For the filler, the kerosene voids test was performed to determine the compacted voids content. The kerosene method has been reported to yield similar values to those measured by the Rigden apparatus (R^2 of 0.96) [11, 12], here they are treated as equivalent to the Rigden voids. The compacted voids for other scales were determined by AASHTO T 19 (dry rodded void content). The loose voids content for all scales was determined according to either AASHTO T 304 (filler, fines, and filler+fines) or AASHTO T 326 (materials with coarse aggregates).

5 TEST RESULTS

Results of temperature and frequency sweep tests are summarized with dynamic shear modulus, $|G^*|$, mastercurves in Figure 1 [1]. The modulus increases with the material length scale. This increase is not consistent between the different phases or with respect to temperature and frequency. The modulus is most affected by the changes occurring between the mastic and FAM scales. Between these two scales the material stiffens by a factor of 10 to 10,000 (depending on the specific condition of interest), and the time-dependence, which can be observed through the log-log slope of the mastercurve, qualitatively changes from liquid-like to solid-like. From the binder to the mastic and the FAM to the mixture the material modulus also increases, but the stiffness factor only varies between approximately 2 and 7 in both cases. These differences are statistically significant as the repeatability of the tests was very good, with coefficient of variations of all tests less than 10% and in many cases closer to 2–5%.

A compilation of loose and compacted void contents is shown for different particle size distributions in Table 3. These void contents are used to calculate the *SI* via Equation (2). The importance of gradation in determining the void content at the two compaction bounds can be clearly observed. For a fixed maximum aggregates size, the void content reduces as finer aggregates are included. This trend occurs even though the actual void content of these smaller scales may be larger than the scale that they are being added to. For example in the primary mixture, the 12.5 mm–0.6 mm range contains a compacted void content of 40.1% and the 0.3 mm–0.075 mm contains a compacted void content of 47.3%. However, when

these two are combined (12.5 mm–0.075 mm) the combination produces a compacted void content of 31.4%. This trend occurs in both materials.

6 APPLICATION OF STRUCTURALIZATION CONCEPT TO ASPHALTIC COMPOSITES

The first step in evaluating the existence of the *SI* is to examine how the *FC* concept applies across length scales. If *FC* is a sufficient index then these resulting curves should appear continuous with no major breaks or disruptions. The stiffening ratio for mastic is defined by taking the mastic $|G^*|$ as the numerator and the binder $|G^*|$ as the denominator. The stiffening ratio for the mixture and FAM is defined with by using the appropriate mastic $|G^*|$ as the denominator. This approach best matched the concepts of the microstructural hypothesis where the numerator is the $|G^*|$ of the target scale and the denominator is the $|G^*|$ of the material which coats the particles in this target scale [2, 3]. For the modulus ratio, test data was examined at many temperatures and frequencies, but was only compiled and presented at a few specific temperatures and at 18.85 rad/s. The trends shown are representative of all other conditions evaluated.

Figure 2 shows the results of this analysis for the primary mixture. Each data point represents one of the different mastic and FAM materials (Table 1). From this figure a consistent and smoothly varying curve is seen within the mastic phase and within the FAM phases. However, between the phases the curves are disjointed and do not form a consistent trend, which means that either *FC* is not an appropriate *SI* or that the entire concept of *SI* is flawed. *FC* may not be an appropriate *SI* because in taking the dry compacted density as the reference void content suggests that structural onset occurs at the densest possible dry aggregate configuration. However, one can clearly see a stable structure forming, i.e., one with contacting particles and internal load paths, at void contents greater than this value.

It is believed that the onset of a stable structure should be accompanied by a rapid change in mechanical properties, and that this rapid change can serve as a marker for structuralization onset. As seen in Figure 2 the mastic shows a bilinear relationship with respect to *FC*, and the point of inflection in this relationship indicates a structural change. This inflection can be used to identify the value of *B* by adjusting *B* until the intersection of the two bilinear curves corresponds to an x-value of 1. Since *B* does not depend on the scale, the inflection point can be used to define the $\%Voids_{str}$ and thus *SI* for all scales. This process is demonstrated for the primary mixture in Figure 3. The relationship between *FC* at structuralization onset, FC_S, and the *B* parameter is given in Equation (4). This *B* value can subsequently be substituted in Equations (2) and (3) to determine the *SI* value for each material. The analysis shows that *B* is 0.68 for the primary mixture and 0.50 for the secondary mixture. Thus, according to the discussion above it takes more compactive effort to reach a stable configuration for the secondary mixture than it does for the primary mixture. The AIMS data suggests

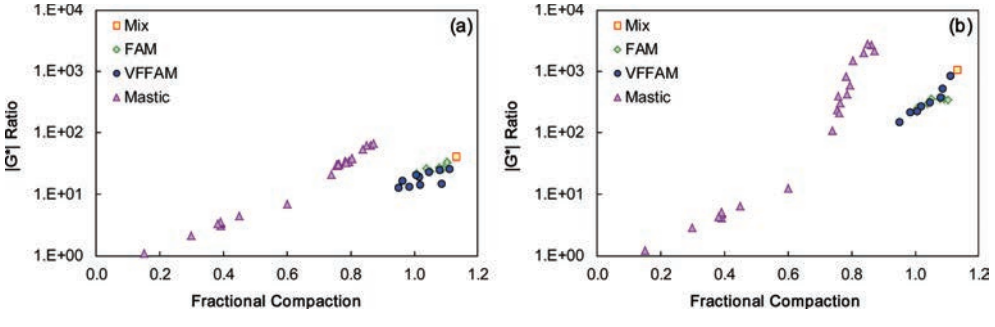

Figure 2. |G*| ratio of different characteristic length scales for primary mixture with respect to FC at; (a) 10°C and (b) 54°C.

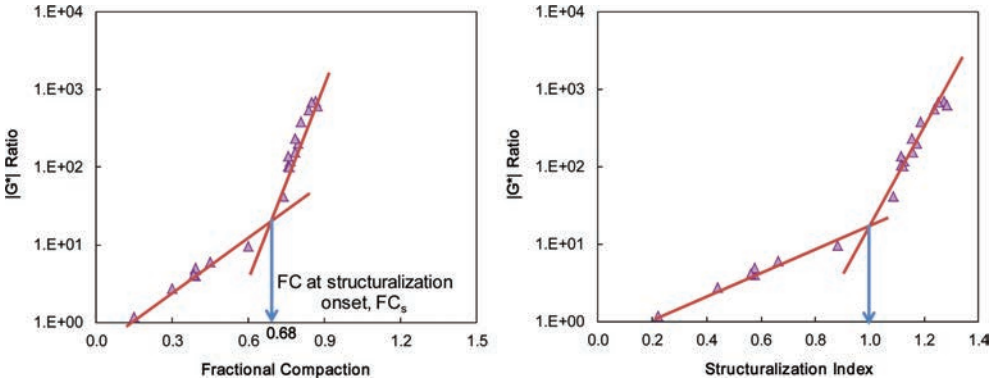

Figure 3. Identification of *B* parameter from measured mastic behaviors.

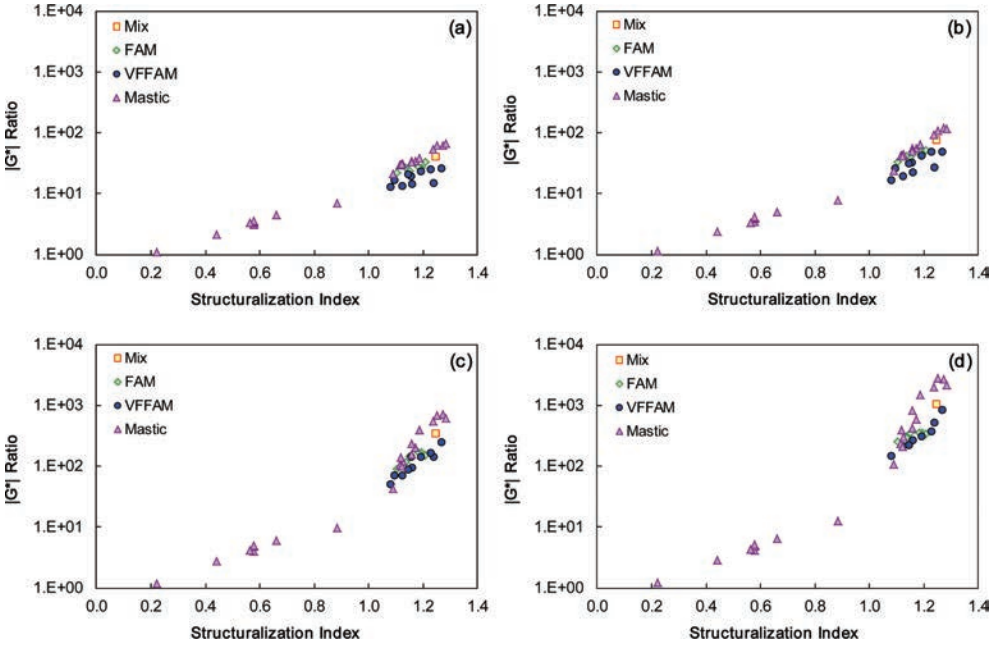

Figure 4. Structuralization plots for the |G*| ratio of the primary mixture materials at; (a) 10°C, (b)20°C, (c) 40°C and (b) 54°C.

that the primary mixture is more angular and so a higher compactive effort for the secondary mixture is not unexpected.

$$B = \frac{\left(1 - FC_s\right)\left(100 - \%Voids_{comp}\right)}{\%Voids_{loose} - \%Voids_{comp}} \tag{4}$$

The resulting modulus ratio plots using the *SI* are shown for the study mixtures in Figures 4 and 5. Note that modulus alone does fully capture the LVE response (and thus does not comprehensively prove a linkage between scales). The authors also examined the log-log slope of the measured data and although not shown here the same trends and continuous curves occur. The agreement is not perfect and it is surmised that the structuralization is only a first order approximation that may not be accounting for interactive effects between the

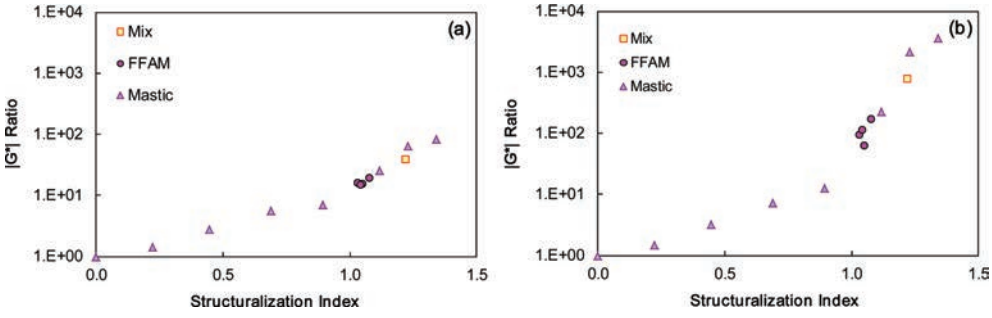

Figure 5. Structuralization plots for the |G*| ratio of the secondary mixture materials; (a) 10°C and (b) 54°C.

structure and asphalt binder or mastic and how this may affect the forces present at particle interfaces.

The fact that consistent temperature and frequency dependent slope (not shown in this paper) and modulus ratio curves could be defined across all scales for both study materials indicates that the assumptions put forth in the previous paragraphs are reasonably accurate. Independent evaluation and quantification of the aggregate characteristics aid in interpreting the reasonableness of the characterized *B* parameter. It should be noted that the authors evaluated many different potential indices to link the behaviours of these composites across length scales including some based on percolation theory. None of these methods produced as consistent of trend as the *SI* value defined here.

7 CONCLUSIONS AND SUMMARY

The reasonableness of internal structuralization as a linking concept for the mechanical behaviors of asphaltic composites across length scales has been evaluated. It is found that the traditional measure of structuralization, the *FC*, is not sufficient enough to describe the behaviors across length scales even though it can describe the effects of structure within a single scale. A new index, the structuralization index is subsequently postulated and defined based on a more general interpretation of the onset of structuralization and this index is found to capably explain the change in modulus and time-dependence of these composites across length scales. The existence of what is deemed to be a first order approximate linking index, which consists of a singular factor, *B*, and the void contents at different compaction efforts, suggests that a form of self-similar structuralization occurs in these composites. More study is needed to understand this phenomenon with better clarity. However, it appears based on this work and additional study that could not be presented within the limitations of this volume that this self-similarity is different than what is explained by existing statistical physics theories such as percolation.

ABSTRACT: Lowering production temperature in warm mix asphalt technology may lead to inadequate drying of aggregates, resulting in low-quality asphalt production. Due to difficulty in direct observation of drying and heating process and measurement of aggregate temperature inside the dryer, numerical analysis offers an alternative way to study heat transfer and aggregate temperature evolution. In this paper, coupled Computational Fluid Dynamics (CFD) and Discrete Element Method (DEM) is used to simulate aggregate movement and heat transfer in a simple drum. The effects of aggregate size and drum rotation speed on aggregate temperature evolution and fluid temperature on the heating efficiency are studied. The results show that coupled CFD-DEM technique is an appropriate approach to study aggregate movement and temperature evolutions in the drum directly. Small particles can be heated more easily than large particles. Determination of optimal drum rotation speed needs to consider particle movement models as well as resident time in a real drum with inclined angle. High fluid temperature could reduce heating time of particles to reach the target mixing temperature. The preliminary results may provide some guidelines for operating the mixing drum efficiently and designing drum to control quality of asphalt mixes and save energy.

Keywords: Coupled CFD and DEM, granular drying, rotation drum, heat transfer

1 INTRODUCTION

The increased awareness of sustainability has encouraged the use of low energy and low emission technologies for pavement design, such as Warm Mix Asphalt (WMA). WMA refers to a technology that reduces the mixing and compaction temperatures in order to lower energy consumption and reduce the emissions of greenhouse or other toxic gases [1]. However, one of the concerns of the use of low production temperatures for producing WMA is that the aggregate does not always dry adequately, which could lead to the susceptibility of the asphalt mix to moisture stripping or raveling [2–6].

In order to produce high quality, well-coated asphalt mixes, the aggregate particles need to be dried thoroughly and heated to mixing temperature, which can be achieved by counter-flow or parallel-flow drying in a plant. Currently the degree to which the aggregate is dried cannot be quantified precisely because it is not realistic to measure the aggregate temperature directly [7]. Therefore, a method of estimation of the degree of drying of the aggregates is needed to determine whether the aggregate is sufficiently dried before it is mixed with the asphalt binder. Based on the coupling of the Discrete Element Method (DEM) and Computational Fluid Dynamics (CFD), this study attempts to simulate the

heating process of aggregate as an essential step in estimating the degree of drying during the production.

The DEM is employed to simulate the movement of granular particles, and the CFD can model the behavior of a fluid, such as gas or liquid. Coupled CFD-DEM simulations have been used widely in many industry areas, such as studying the granular behavior in a fluidized bed [8], heat and mass transfer in a lime shaft kiln [9], and tablet coating in pharmaceuticals [10]. Therefore, a numerical simulation of the coupled CFD-DEM technique is a viable way to study the phenomena that occur inside an asphalt mix drum. The coupled CFD-DEM technique also shows a promising way to study aggregate behavior, such as moisture and temperature evolution, in the rotary drum dryer [7, 11].

In this paper, heat convection between hot gas and granular particles and heat conduction among particles are simulated to demonstrate the feasibility of the approach. A simple counter-flow drum model with four flights attached symmetrically around the inner chamber is used to demonstrate the aggregate particle movement and temperature evolution through the coupled CFD-DEM method. The effects of particle size, drum rotation speed, on aggregate temperature evolution, and fluid temperature on the heating efficiency are studied. The results could provide useful guidelines to optimize drum design and operation.

2 SIMULATION METHOD

The coupled CFD-DEM approach used in this paper is based on an open source program developed by Christian Doppler Laboratory [12] called the CFDEM project [13]. The CFD part of the simulations was conducted within OpenFOAM® [14], and the DEM part of the simulations was conducted by LIGGGHTS, an open source software package for modeling granular material based on LAMMPS, which is an open source molecular dynamics code developed by Sandia National Laboratories [15].

2.1 *Governing equations of the DEM*

The DEM was first developed by Cundall and Strack [16]. All of the particles in the computational domain follow Newton's laws of motion and are tracked in a Lagrangian way. The forces that act on the particles in this simulation include normal force and tangential force from the particle contacts, drag force from the fluid part, and gravity. The kinematic function is expressed as Eq. (1):

$$mi\frac{dv_i}{dt} = \sum_j F_{ij}^n + \sum_j F_{ij}^t + F_i^f + F_i^g \tag{1}$$

where F_{ij}^n is the normal contact force; F_{ij}^t is the tangential force; F_i^f is the drag force, and F_i^g is gravity.

Hertz-Mindlin contact model is adopted to calculate normal and tangential contact force [17]. Drag force is expressed as Eq. (2):

$$F_i^f = \frac{V_p^\beta}{\varepsilon_p}(u_f - u_p) \tag{2}$$

where β represents the interphase momentum transfer coefficient due to drag, which is calculated using a drag relationship proposed by Koch and Hill [18] that is based on the lattice-Boltzman simulation.

2.2 *Governing equations of CFD and CFD-DEM coupling*

The motion of a fluid phase is governed by the volume-averaged Navier-Stokes equations for compressible fluid, which can be written as Eqs. (3, 4):

$$\frac{\partial \alpha_f}{\partial t} + \nabla \cdot (\alpha_f u_f) = 0 \tag{3}$$

$$\frac{\partial (\alpha_f u_f)}{\partial t} + \nabla \cdot (\alpha_f u_f u_f) = -\alpha_f \nabla \frac{p}{\rho_f} - R_{sl} + \nabla . \tau \tag{4}$$

where α_f is the volume fraction occupied by the fluid; ρ_f is the fluid density; u_f is the fluid velocity; τ is the stress tensor for the fluid phase; and R_{sl} represents the momentum exchange with the particulate phase.

2.3 *Governing equations of heat transfer*

Particle temperature evolutions due to heat conduction among particles are shown as Eq. (5) [19]:

$$m_p c_p \frac{dT_{p,i}}{dt} = \sum \dot{Q}_{pi-pj} + \dot{Q}_{pi,source} \tag{5}$$

where $\dot{Q}_{pi-pj}$ is the rate of heat conduction flux by particle contacts; $\dot{Q}_{pi,source}$ is the rate of heat conduction flux by other sources; m_p, c_p $T_{p,i}$, are the particle mass, specific thermal capacity, and temperature respectively.

The model for heat convection between hot gas and particles is based on Li and Mason [20], which can be modeled by a solver of "cfdemSolverPisoScalar" developed by Christian Doppler Laboratory [21]. The rate of heat transfer Q_s from the gas to the particle can be calculated as Eq. (6):

$$Q_s = h_i A_i (T_g - T_{pi}) \tag{6}$$

where h_i is the heat transfer coefficient of the particles; A_i is the surface area of the particles; T_g is the gas temperature; and T_{pi} is the particle temperature.

2.4 *Drum geometry, simulation parameters and initial conditions*

In this study, a simplified drum with four flights is simulated, shown in Figure 1. The length of the drum is 1 m. Table 1 presents the parameters and initial conditions used in this simulation. As drum rotates, the flights pick up the aggregate particles that cascade due to gravity. Hot gas enters one end of the drum and exits from the other end where the aggregate particles enter. In order to study the effects of particle size, drum rotation speed, and fluid temperature on the heating efficiency, these three parameters are varied.

3 RESULTS AND DISCUSSION

3.1 *Particle movement and fluid characterization*

Figure 1 shows snapshots of the particle movement and temperature distribution at times of 1 s, 3 s, 25 s, and 60 s in the simulated drum with the rotation speed of 5 seconds Per Revolution (SPR). The particle size is 0.01 m in diameter, and the number of particles in the drum chamber is 13,500. This figure illustrates that the coupled CFD-DEM method is able to capture the escalation and cascading modes of the particle movement in the drum and the formation of veiling lift by the flights.

Also, the evolutions of the particle temperature can be observed directly from color of particles and studied by statistic data. Figure 2 shows the evolution of the maximum, minimum, and average temperature of two particles heated in the drum during 3600s under fluid temperature of 1000 K (727ºC). The initial temperature of the aggregate is set to 293 K (20ºC) and then is increased to temperature of 1000 K to reach the state of equilibrium with fluid temperature. It is seen that the aggregate temperature increases quickly at the early heating time, and then approaching to fluid temperature slowly.

Figure 3 shows the temperature and velocity of the fluid along the horizontal cross-section at 60 s. The arrows indicate the fluid flow direction. The temperature profiles show that the outlet temperature of the fluid is lower than the inlet temperature of the fluid due to the heat convection from the fluid phase to the particles. As for velocity, the gas at the center of the drum flows faster than the gas at the right edge of drum where the particle bed probably hinders the flow of fluid. Therefore, the coupled CFD-DEM method captures the mode of particle movement and fluid flow characterization.

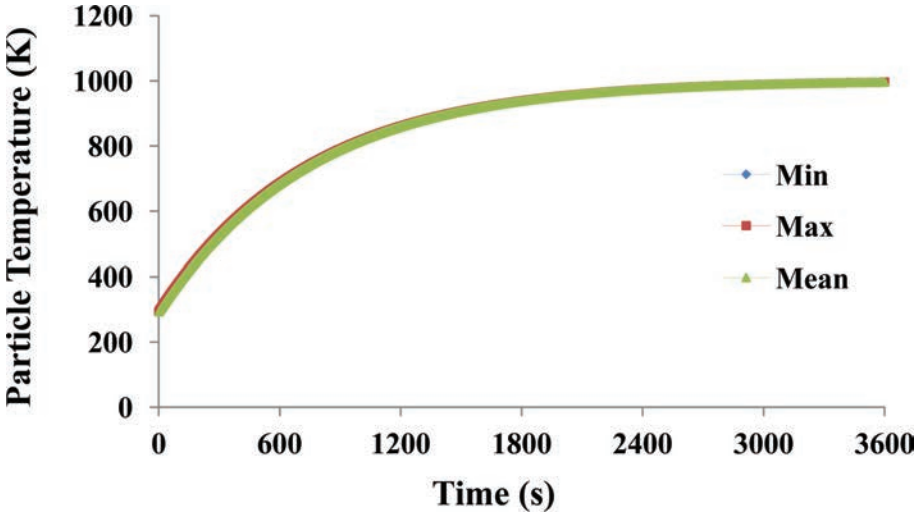

Figure 2. Particle temperature versus time.

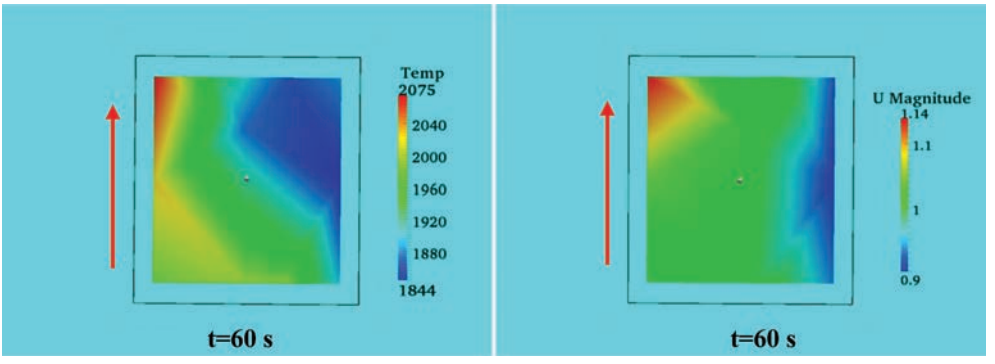

Figure 3. Profiles of fluid phase: temperature (left) and velocity (right).

3.2 *Effects of particle size*

In order to study the effect of particle size on the temperature changes of the particles, three particle diameters, 0.01 m, 0.02 m, and 0.03 m, are used for the simulation. The total mass of each size of particle is controlled equally to 20.5 kg. That is, the particle numbers used in the simulation are 13,500, 1,688 and 500 for the 0.01 m, 0.02 m, and 0.03 m particles, respectively. The fluid temperature is set to 2000 K (1727ºC). Figure 4 shows the relationship of particle temperature to particle size. It is seen that the small particles are much easier to heat than the large particles. A possible reason for this phenomenon is that the small particles have a large specific surface area, which is instrumental in absorbing heat energy from the hot gas and the heat conduction among the particles, which depends on the amount of contact area.

3.3 *Drum rotation speed*

Figure 5 illustrates the effect of the drum rotation speed on the particle temperature changes. Four different rotation speeds are used in the simulation: 0.8, 2, 5, and 10 SPR. It should be noted that smaller value of SPR means faster rotation speed. A comparison of the results of the rotation speeds of 2, 5, and 10 SPR shows that as the rotation speed increases, the

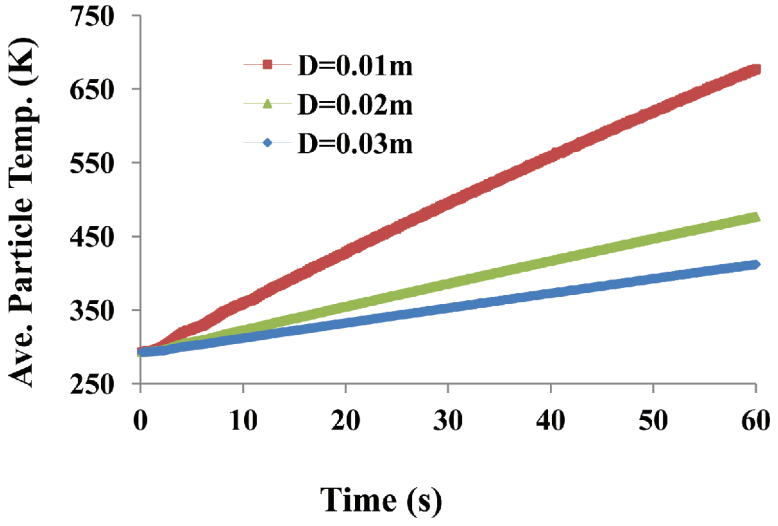

Figure 4. Average particle temperatures versus particle size.

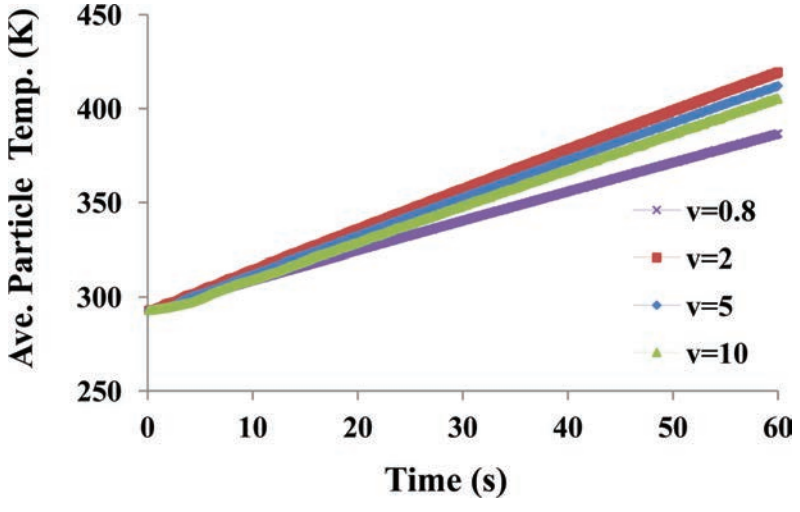

Figure 5. Average particle temperature versus rotation speed.

particles heat up faster. This phenomenon results from the veiling formation of the particles created by the flights in the drum. The fast rotation leads to more frequent exposure of the particles in the heat convection areas where the particles can be heated efficiently by the hot gas. Hobbs observed that a rapid increase in particle temperature corresponds to the start of veiling [7]. Therefore, a fast rotation speed is beneficial for heating aggregate particles quickly. However, this discussion is within the cascading mode of particle movement. If the rotation speed is set to 0.8 SPR, the mode of granular motion in this drum will be centrifuging without the veiling formation. In this case, the final temperature of the particles in centrifuge mode is lower than temperature of the particles in cascade mode. However, in a real drum with an inclined angle, although higher rotational speed might increase veiling frequency, it also will decrease the overall residence time. Therefore, determination of optimal rotation speed needs to consider balancing veiling frequency and residence time to achieve complete drying.

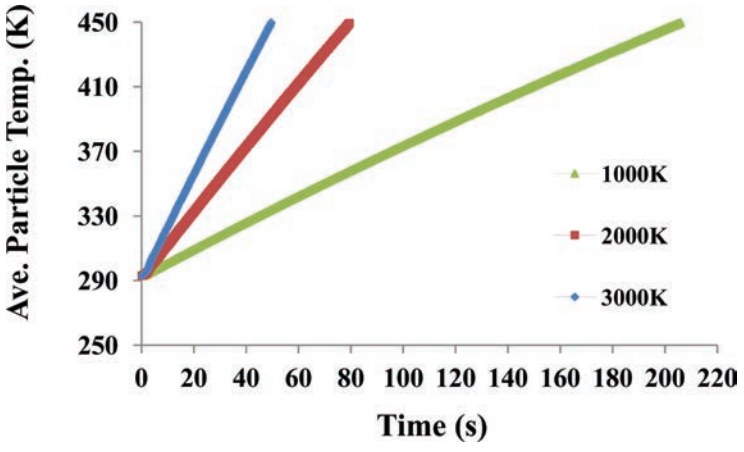

Figure 6. Average particle temperature versus heating time.

3.4 *Heating efficiency*

In agreement with common sense, higher fluid temperature will result in higher particle temperatures during the same heating time. If particles are designed to be heated up to certain mixing temperature, such as 450 K (177ºC), the heating time should be different under different fluid temperatures. Figure 5 shows heating time needed to heat particle to temperature of 450 K under different fluid temperature. For fluid temperature of 1000 K (727ºC), it takes 206 s to heat the particles to the target mixing temperature, and 80 s and 50 s under 2000 K (1727ºC) and 3000 K (2727ºC) respectively. It is as expected that shorter heating time is need under higher fluid temperature so that in an inclined drum operation, determining optimum heat time shall be based on fluid temperature and energy saving perspective, as well as without compromising the quality of hot mixes.

4 CONCLUSIONS

The adequate drying of aggregate particles is critical for WMA to achieve good performance. A methodology to quantify the drying process of aggregate is currently lacking. The coupled CFD-DEM technique is used here to study the aggregate movement and temperature evolutions in a simulated simplified rotating drum with flights. Hot gas is used to heat the aggregate while the drum is rotating. It is found that:

1. Particle size affects the heating efficiency. Small aggregate particles heat quickly compared to large particles, which is likely due to the relatively large specific surface area of the smaller particles.
2. With an increase in the drum rotation speed, the heating efficiency increases. However, an excessively fast rotation speed causes the particles to centrifuge, which reduces the heating efficiency. Determination of optimal rotation speed needs to consider particle movement model, and balance veiling frequency and residence time to achieve complete drying in a real drum with certain inclined angle.
3. Shorter heating time is needed under higher fluid temperature. Determination of optimum heat time shall be based on inlet fluid temperature and energy saving perspective, as well as without compromising the quality of hot mixes. This finding indicates the importance of the proper design of asphalt drums.

As a preliminary effort, this paper studies the feasibility of using the coupled CFD-DEM technique to simulate the drying process of aggregate. The simulation does not consider the heat transfer from the hot gas and particles to the drum wall, and the heat loss from the drum wall to the ambient environment. Also, a mass transfer and moisture evaporation model are

not included in this study. These factors will contribute largely to the heat transfer and temperature evolution of the particles in the drum. In addition, scale-up models should be used in the simulation, and experimental calibration needs to be carried out to verify the results from the numerical analysis.

ABSTRACT: It is well documented that performance of asphalt mixture is related to aggregate structure. The Dominant Aggregate Size Range-Interstitial Component (DASR-IC) model provides a framework of gradation-based parameters and associated criteria to link gradation characteristics and volumetric properties to aggregate structure, mixture properties, and field performance. Primary interlocking of coarser aggregate is characterized by DASR parameters, which have been used to establish performance-based criteria based on extensive field rutting data. Studies have also shown that mixtures with acceptable DASR criteria may result in acceptable cracking performance, indicating that IC characteristics strongly influence fracture resistance. Therefore, IC parameters have been used to establish and evaluate preliminary criteria for optimal cracking performance based on limited data. This paper presents the basis and early results for the evaluation and, if necessary, modification of IC criteria, through an extensive laboratory experiment. The challenge was to realistically isolate the effects of the IC, given that all DASR-IC components are interrelated. The results to date indicate that IC parameters have a strong effect on damage rate and fracture energy in a manner consistent with expected trends.

Keywords: Aggregate structure, gradation-based criteria, cracking performance, damage rate, fracture energy

1 INTRODUCTION

Asphalt mixture is a heterogeneous multiphase material comprising aggregates of various sizes, asphalt binder, and air voids. Thus, proportions and properties of the mixture constituents, as well as their chemical and physical interactions, dictate the content and spatial distribution, (generally referred to as the internal structure) of the mixture. Internal structure significantly influences asphalt mixture's mechanical properties and resistance to major distresses, such as rutting and cracking. Most mixture design methods recognize the importance of internal structure by imposing requirements for aggregate type, size, gradation, and volumetrics, as well as limits on density during compaction. For instance, aggregate gradation is generally selected to meet Superior Performing Asphalt Pavements (Superpave®) mix design specifications. However, Superpave® mixtures that meet all existing design criteria have exhibited highly variable cracking performance [1]. Research has not reached a consensus on rational design guidelines for achieving optimal cracking performance.

Research over the past ten years has emphasized on developing methods for quantitatively or qualitatively characterizing aspects of the internal structure of asphalt mixtures. With the development of computer technology, several researchers have used image analysis techniques to characterize mixture microstructure, and to directly quantify the internal structure distribution.

Researchers have also used digital imaging techniques to analyze digitized mixture images and quantitatively study the internal structure distribution of Hot Mix Asphalt (HMA). 2D images of the internal structure can be captured using a microscope and a camera, or through X-ray Computed Tomography (CT). X-ray CT is a unique nondestructive tool that obtains a series of 2D images of the internal structure of the specimen at fixed intervals through the entire thickness of the specimen, based on differences in density among the mix constituents. The system then combines this series of scanned images to produce a three-dimensional (3D) reconstructed image of the specimen's internal structure. Masad and Button summarized the ways in which imaging methods are used for characterizing and quantifying the internal structure of HMA [2]. The two main uses are performing aggregate orientation analysis [3, 4] and studying the size, connectivity, and distribution of air voids [5, 6]. Sefidmazgi, Tashman and Bahia used image analysis to implement a set of internal aggregate structure analysis features for asphalt mixtures, and proposed new indices to relate rutting performance to aggregate structure [7]. Specifically, they developed the iPas software, to quantitatively characterize the length and orientation of the stone-to-stone contact areas of asphalt mixtures. The software includes an Internal Structure Index (ISI) parameter function of contact length characteristics that correlates internal aggregate structure characteristics to mixture rutting performance.

Several theories have been proposed to characterize internal structure and link gradation to aggregate structure and mixture performance. In the early 1980s, the Bailey method was developed at the Illinois Department of Transportation with the main purpose of controlling the volumetric properties of mixtures during construction as a means of combatting the rutting of asphalt mixtures, while also maintaining proper durability characteristics. The Bailey method of mix design provides a set of tools to evaluate aggregate blends, to better understand the relationship between aggregate gradation and mixture voids, and design the aggregate structure in an asphalt mixture [8, 9]. The method is a systematic approach that provides aggregate interlock as the backbone of the aggregate structure and a balanced continuous gradation with adequate packing based on Voids in Mineral Aggregate (VMA) to complete the mixture and ensure optimal asphalt binder content. The design approach relies on coarse aggregate density as a measure of aggregate interlock. In addition the method defines gradation parameters that characterize packing of the aggregates and are related to air voids and VMA.

Numerous research projects have focused on characterizing aggregate structure and its relationship to mixture performance. In particular, several researchers have identified relationships between the primary coarse aggregate structure and mixture resistance to rutting based on interactive coarse particles (e.g., density, contact length characteristics). However, research has yet to properly characterize the volume within the interstices of the coarse aggregate structure. Recently, a conceptual and theoretical approach to evaluate aggregate structure based on packing theory named Dominant Aggregate Size Ratio—Interstitial Component (DASR-IC) model was developed at University of Florida, as described below, which is promising in addressing coarse aggregates structure and interstitial volume.

1.1 *DASR-IC model*

The DASR-IC model provides a framework for the design and modification of gradations to ensure that mixtures will have sufficient aggregate interlock to resist permanent deformation, as well as adequate durability and fracture resistance. According to the model, mixture behavior is influenced by two primary components: DASR, the coarse aggregate that forms the structural interactive network of aggregate and resists shear; and IC, the combination of fine aggregate, binder, and air voids, which fills the Interstitial Volume (IV) within DASR and resists primarily tension and to a lesser extent, shear. DASR can be composed of one size or multiple contiguous sizes of coarse particles. The composition can be determined by conducting particle interaction analysis based on packing theory. Particles larger than DASR will simply float in the DASR matrix and will not play a major role in the aggregate structure. On the other hand, particles finer than DASR are identified as the aggregates that do not interact with the coarser portion and fill the IV. Figure 1(a) illustrates these concepts.

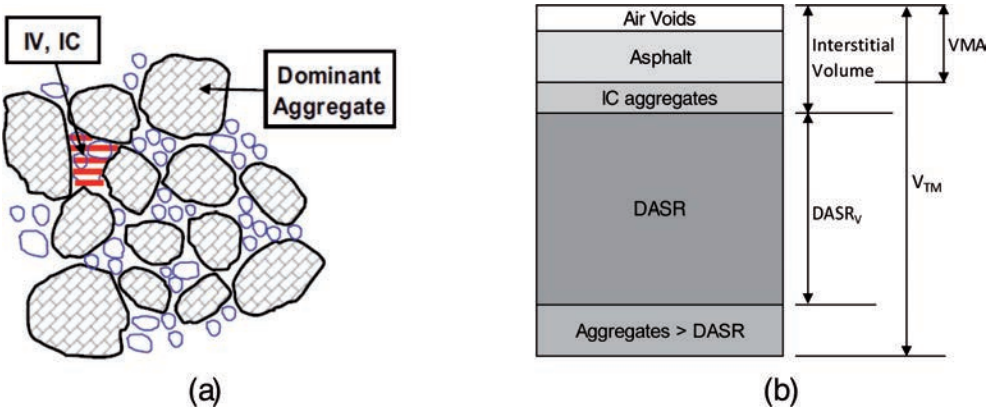

Figure 1. Schematic representations of the DASR-IC model.

Kim, Roque, and Birgisson indicate that the porosity of DASR can be used as a criterion to ensure contact between DASR particles and provide adequate interlocking [10]. Field and laboratory results clearly showed that DASR porosity can be used as an indicator of mixture resistance to permanent deformation (rutting). It is a well-known fact in soil mechanics that the porosity of granular materials should be no greater than 50% for particles to have contact with each other [11]. Porosity can be calculated for any single size, or any set of contiguous sieve sizes within a mixture, by assuming that a mixture has certain effective asphalt content and air voids for a given gradation and, therefore, VMA is comparable to the volume of voids in soil. Porosity can be calculated using the below equations.

$$V_{T(DASR)} = V_{TM} - V_{AGG>DASR} \tag{1}$$

$$V_{V(DASR)} = V_{ICagg} + VMA \tag{2}$$

$$\eta_{DASR} = \frac{V_{V(DASR)}}{V_{T(DASR)}} = \frac{V_{ICagg} + VMA}{V_{TM} - V_{AGG>DASR}} \tag{3}$$

where η_{DASR} = DASR porosity, $V_{V(DASR)}$ = volume of voids within DASR, $V_{T(DASR)}$ = total volume available for DASR particles, V_{ICagg} = volume of IC aggregates, V_{TM} = total volume of mixture, and $V_{AGG>DASR}$ = volume of particles larger than DASR (Fig. 1(b)).

Guarin indicates that IV bonds the coarse aggregate structure together, thereby providing resistance to tension, as well as a secondary structure to help DASR resist shear [12]. IC characteristics and properties strongly influence asphalt mixture cracking resistance. IC characteristics are expected to have a strong influence on key mixture properties, including fracture energy and creep rate as well as how they change with aging. IC should fill the IV, forming a secondary structure that helps resist deformation and fracture without disrupting the DASR structure. Guarin developed a new parameter, the Disruption Factor (DF), to determine the potential of fine aggregates to disrupt the DASR structure. The DF, which can be calculated as the ratio of potentially disruptive particles over the volume of DASR voids, is determined through a 3D packing analysis using spherical particles and single size DASR.

Studies have shown that mixtures with acceptable DASR criteria may or may not result in acceptable cracking performance, indicating that IC strongly influences fracture resistance [1]. For this reason, the DASR-IC model has been expanded to include Fine Aggregate Ratio (FAR) and Effective Film Thickness (EFT) parameters for more defined characterization of the IV. FAR (the ratio between the coarse and fine portions of the IC) is an indicator of the relative coarseness of the IC particle distribution. EFT (a durability-related measure of binder distribution in the IV) is calculated using the effective volumetric properties of fine

aggregate portion (i.e., passing 2.36 mm sieve size) of asphalt mixture using the following equation:

$$\text{EFT(microns)} = \frac{V_{be}}{\text{SA} \cdot W_T \cdot PF_{AGG}} = \left[\frac{P_b - \left(\frac{\text{Abs}}{100} \right) \cdot P_{AGG}}{\text{SA} \cdot PF_{AGG} \cdot G_b} \right] \times 1000 \quad (4)$$

where V_{be} = effective volume of asphalt binder, SA = surface area of fine aggregate, W_T = total weight of mixture, PF_{AGG} = percent of fine aggregate by mass of total mixture, P_b = percent of asphalt content by mass of total mixture, Abs = absorption, P_{AGG} = percent of aggregate by mass of total mixture, and G_b = specific gravity of asphalt binder.

Chun, Roque, and Zou [1] identified preliminary acceptable ranges of each parameter based on both laboratory and field data [12, 13] for optimal mixture property performance in terms of rutting and cracking:

- DASR porosity: 38–52% (48–52%: marginal)
- DF: 0.50–0.95
- EFT: 12.5–25.0 microns
- FAR: 0.28–0.36

Chun et al indicate that EFT, FAR, and the DF criteria can be used together to enhance the cracking resistance of asphalt mixtures [1]. However, the current IC parameters (EFT and FAR) were identified and evaluated using limited field data, and, therefore, may not fully characterize the interstitial volume, resulting in a need for further evaluation and possible modification of the IC criteria.

1.2 *Objectives*

The primary objectives of this study are:

- Develop an approach to evaluating IC criteria for cracking performance.
- Present the results of testing and analysis to date.

2 RESEARCH APPROACH

The DASR-IC model provides a framework of gradation-based parameters and associated criteria to characterize mixture structural characteristics and to link gradation and volumetric properties to field performance. The model uses (a) DASR porosity to ensure contact between larger particles within the mixture to provide suitable resistance to deformation, (b) DF to evaluate the degree of disruption of the IC on the DASR structure, (c) EFT to characterize binder distribution within the IV, and (d) FAR to estimate the relative coarseness of IC particles.

DASR porosity and DF criteria have been evaluated through a wide range of field and laboratory test results. Therefore, as long as the asphalt mixture design meets both criteria, it will have adequate coarse aggregate interlocking undisrupted by fine aggregates, which will ensure good rutting performance. EFT and FAR parameters and associated criteria play an important role in cracking performance; however, past research evaluated these elements with limited data, leaving a need for validation and refinement. This need led to the design of an experimental testing plan that will provide the data necessary to identify IC's effect on the cracking performance of asphalt mixture.

Given that all DASR-IC components are interrelated, realistically isolating the IC effects was challenging. The DASR porosity governs the coarse aggregate structure, which also affects the sizes and distribution of IV. Therefore, in order to isolate IC and its effects on performance, it was necessary to design first the coarse aggregate structure with adequate interlocking and then vary the fine portion of the gradation. This can be done by fixing the

DASR porosity and DF within the acceptable range, and then designing the IC gradation with varying EFT and FAR parameters.

This approach involved the design of mixture gradations that were not associated with actual mixtures; however, any alternative approaches involving only realistic mixture gradations would have required changing the gradation of the coarse portion in order to maintain the proposed ranges of IC parameters. This adjustment would have altered the DASR porosity and the DF, and would have led to complicated testing results involving the effects of both DASR and IC. Furthermore, it should be noted that the existing ranges for IC parameters were established using varying DASR characteristics representing varied levels of coarseness, which implies that the IC parameter criteria are applicable for varied DASR characteristics, as long as the mixture meets all gradation-based criteria. Therefore, the proposed approach appears to be viable for isolating IC and determining its effects on the cracking performance of asphalt mixtures.

2.1 *Materials and testing matrix*

In order to obtain the data necessary to meet the objectives of this study, an experimental testing plan was developed, which includes a wide range of mixtures subjected to different varying conditioning levels. Two aggregate types widely used in the state of Florida for road construction and rehabilitation projects were used to produce mixtures for laboratory testing: Georgia granite and Florida oolitic limestone. Two binder types: an unmodified binder (PG 67-22) and a polymer-modified binder (PG 76-22) were included in the testing plan to evaluate the interactive effects of binder type and interstitial volume characteristics. All mixtures were fine dense-graded and were designed using the Superpave® system with 12.5 mm Nominal Maximum Aggregate Size gradations and traffic level C, which corresponds to 3–10 million Equivalent Single Axle Loads over 20 years.

The DASR-IC model was used to design the range of mixtures to be tested. As stated previously, although a wide range of laboratory and field data was used to evaluate the DASR porosity and the DF, the acceptable ranges of EFT and FAR were determined based on limited data. For this reason, mixtures were designed by maintaining DASR porosity and DF values within the acceptable ranges, while broader ranges were used for EFT and FAR parameters. Two levels of DASR porosity within the acceptable range were selected for each aggregate type. Four different combinations of IC parameters were determined for each DASR porosity level by fixing the DASR and changing only the composition of the IC portion (particles smaller than the DASR), including one combination with both EFT and FAR outside (or near) the bounds, one with both parameters within the range, and the remaining two with either EFT or FAR near the bounds (Table 1). This led to eight gradations per aggregate type, as shown in Figures 2 and 3, respectively. Two binder types were adopted in this study. The optimal asphalt contents determined based on the unmodified binder for all sixteen gradations were employed to produce the other sixteen mixtures of the same gradations with the polymer-modified binder. As a result, a total of sixteen gradations and thirty-two mixtures were encompassed in this study.

These thirty-two mixtures were subjected to three conditioning levels in order to evaluate the changes in fracture properties at different ages and to assess the relationship between IV characteristics, cracking performance, and conditioning level, including (a) Short Term Oven Aging (STOA—AASHTO R30 [14]), (b) Long Term Oven Aging (LTOA—AASHTO R30 [14]), and (c) A combination of LTOA and Cyclic Pore Pressure Conditioning (CPPC). STOA simulates the aging effects that occur during the mixing and construction processes. LTOA simulates the aging of mixtures subjected to in-situ conditions of approximately 5 to 10 years. LTOA plus CPPC was employed to simulate the combined effects of oxidative aging and repeated internal water pressure [15]. Figure 4 shows the flowchart for the experimental testing program.

2.2 *Specimen preparation*

Specimens were produced for Superpave Indirect Tensile (IDT) tests at each of the three conditioning levels. All mixtures were designed using the Superpave mix design procedure. All

three mixtures were subjected to STOA and then compacted to 7% (± 0.5%) air voids using the Superpave gyratory compactor. For each type of mixture, two thirds of the compacted pills were further aged using LTOA. All pills were then sliced into specimens of the desired thickness (approximately 1.5 inches), and gage points were attached to each face of the prepared specimens for deformation measurements during the Superpave IDT tests described below. Next, half of the LTOA aged specimens were subjected to CPPC [15].

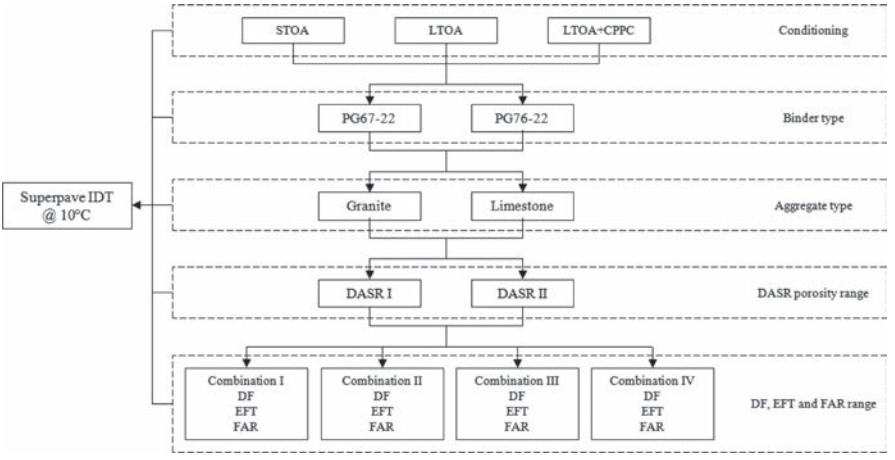

Figure 4. Flowchart for experimental testing plan.

2.3 *Superpave IDT*

Superpave IDT tests were performed at 10°C to obtain HMA fracture properties for each mixture at each conditioning level. The Superpave IDT is composed of a sequence of three tests (resilient modulus, creep compliance, and strength), from which damage and fracture-related mixture properties are determined, including resilient modulus, creep rate, and fracture energy limit [16–18]. Resilient modulus (M_R) is the ratio of the applied stress to recoverable strain when repeated loads are applied. It is a measure of the elastic stiffness of asphalt mixture. Creep rate is the rate of change of the creep compliance curve at 1000 seconds, which has been shown in prior work to be related to the rate of damage accumulation of a mixture. Fracture Energy limit (FE) is the total energy necessary to induce fracture, and represents the tolerance of the mixture to fracture.

3 PRELIMINARY RESULTS

Results to date obtained from Superpave IDT tests were used to evaluate the effect of the IV characteristics on asphalt mixture cracking performance. The main fracture properties of granite mixtures with unmodified binder subjected to STOA and LTOA conditions are summarized in Figures 5 and 6. More specifically, fracture energy limit and creep rate results are presented, since these properties have been found to be closely related to the cracking performance of the asphalt mixture. To further quantify the effects of IV characteristics on fracture resistance, the energy-based criterion called Energy Ratio (ER) was used, which includes an ER parameter and the associated minimum values of ER required for adequate cracking performance [19]. The ER parameter, defined as the ratio of Dissipated Creep Strain Energy limit ($DCSE_f$) over the minimum Dissipated Creep Strain Energy ($DCSE_{min}$) required for good top-down cracking performance, is expressed in the following equation:

$$\mathrm{ER} = \frac{DCSE_f}{DCSE_{min}} = \frac{a \times DCSE_f}{m^{2.98} \times D_1} \tag{5}$$

where

$$a = 0.0299\sigma^{3.1} \times (6.36 - S_t) + 2.46 \times 10^{-8} \tag{6}$$

where, σ (in psi) is tensile stress in the asphalt layer, S_t (in MPa) is tensile strength, $DCSE_f$ (in kJ/m^3) is dissipated creep strain energy limit, D_1 (in 1/psi) and m are power law parameters

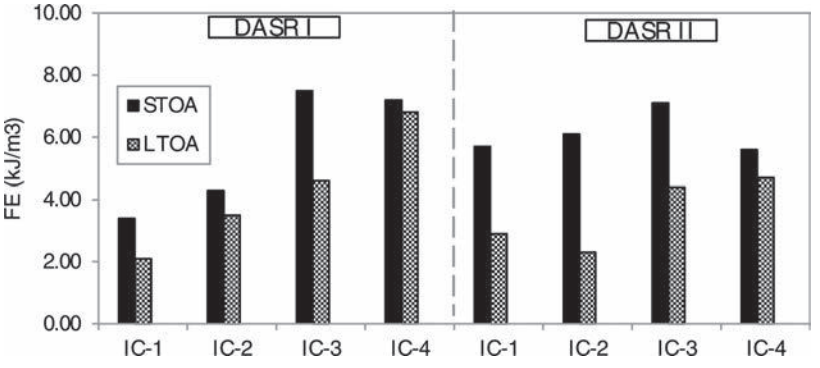

Figure 5. Effect of IV characteristics on FE (PG 67-22).

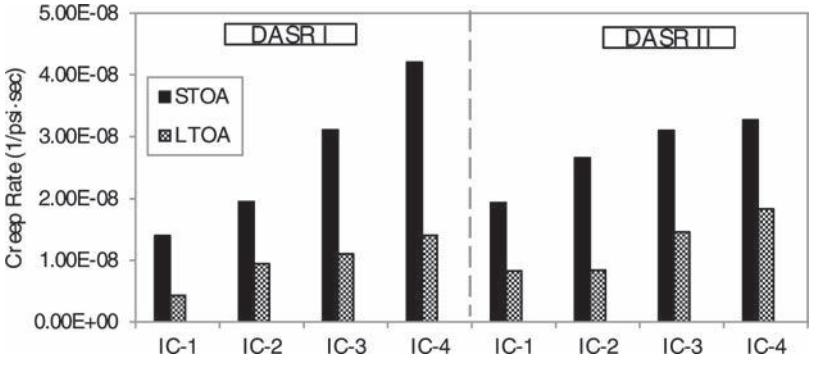

Figure 6. Effect of IV characteristics on creep rate (PG 67-22).

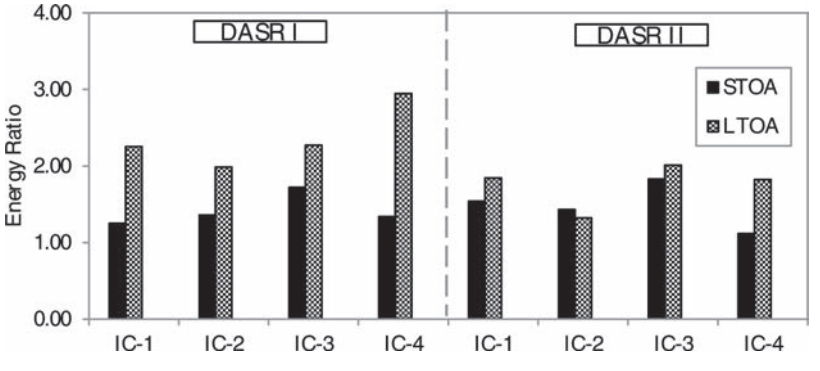

Figure 7. Effect of IV characteristics on ER (PG 67-22).

from creep compliance test. Figure 7 summarizes the effects of IV characteristics on ER. As shown in Figures 5 and 6, results indicate that different IC gradations within each DASR resulted in significant changes in mixture properties. In particular, the results of mixtures at STOA condition reveal that FE increased as IC coarseness increased (Fig. 5), which indicates an increase in fracture tolerance. A similar trend occurred in the creep rate results (Fig. 6), indicating that coarser IC gradation tend to accumulate damage at a faster rate. This trend was expected, as mixtures with coarse IC have higher asphalt content, as reflected by a higher EFT, and therefore a higher creep rate. Consistent with expectations, LTOA was able to

embrittle and stiffen all mixtures as manifested by loss of FE and decrease in creep rate. In particular, both IC-4 mixtures, which are characterized by the highest EFT and coarseness level for each DASR porosity level, exhibited a relatively small reduction in FE compared to the other mixtures but significant reduction in creep rate when subjected to LTOA. Results of further analysis, with respect to the effects of different IC gradations, indicate that both DASR porosity levels (i.e. DASR I and DASR II) of granite mixtures exhibited similar trends of changes in fracture properties at both heat oxidation levels.

The effects of IC characteristics on fracture performance were evaluated using the ER approach. A higher ER generally implies better cracking resistance, which relates to a higher FE and/or lower creep rate; however, it should be noted that a higher ER resulting from higher levels of heat oxidation does not necessarily imply better fracture performance since ER was calibrated based on pavement sections subjected to a similar level of oxidative aging. Therefore, ER was used in this research for relative comparison of the fracture performance of mixtures subjected to similar levels of heat oxidation. ER results indicate that both IC-3 mixtures with all four DASR-IC parameters within the preliminary acceptable ranges (i.e. IC-3 (DASR-I) and IC-3 (DASR-II)) outperformed the other mixtures under STOA conditions (Fig. 7). Under LTOA condition, ER was able to capture the behavior of IC-4, which exhibited the greatest increase in ER among all mixtures. This greater gain in ER of these two mixtures may be explained by the higher effective film thickness which helped retain the FE at a higher level.

4 DISCUSSION

As described above, preliminary testing results showed that FE increased as IC coarseness increased. These results indicate that IC coarseness significantly influences mixture cracking resistance, regardless of DASR porosity level. One possible explanation for this influence is that coarse IC aggregates filling the IV tend to leave more space among them, as indicated by higher asphalt content and higher EFT (Table 1), which decreases the stress concentration between IC aggregates. In order to achieve a better understanding of the relative effects of IC characteristics on stress and strain distribution within the IV, further studies using finite element models are concurrently being performed. The goal of this numerical analysis is to support the findings obtained from the laboratory study and to draw conclusions for a broader range of mixture gradations. A set of 2D linear elastic models using a schematic representation of the IV has been developed. Results to date showed that stress concentration along the gaps between IC aggregates decreased as IC coarseness increased. Details on the development of the finite element models, as well as complete results of numerical simulations, will be presented in a separate paper.

5 CONCLUSIONS

This study sought to evaluate the DASR-IC model with particular focus on the evaluation and possible modification of IC criteria. In order to isolate IC and its effects on mixture performance, the gradations included in the study were designed by fixing DASR porosity at two different levels within the acceptable range. The IV was then designed to encompass broad ranges for IC parameters (DF, EFT, and FAR). Based on the testing results to date, a summary of findings is presented as follows:

- Different IC gradations within each DASR resulted in significant changes in fracture properties of granite mixtures with unmodified binder.
- The trends of change in fracture properties (i.e., FE and creep rate) observed at STOA and LTOA conditions were almost the same for both DASR levels. In particular, both FE and creep rate increased as IC coarseness increased.
- LTOA caused the material to become stiffer and more brittle, which resulted in lower FE and decreased creep rate.

- ER results indicated that, for STOA condition, both IC-3 mixtures with all DASR-IC parameters within the preliminary acceptable ranges outperformed the other three mixtures regardless of DASR porosity level.
- Under LTOA condition, both IC-4 mixtures with the highest IC coarseness and the largest EFT for each DASR porosity level exhibited greater increase in ER than the others. This greater gain in ER of these two mixtures may be explained by the higher effective film thickness which helped retain the FE at a higher level.

ABSTRACT: It is well known that asphaltic materials present complicated viscoelastic behaviour that is significantly affected by the rate of loading and time as well as by temperature conditions. To improve accuracy in the analysis and design of asphaltic materials and pavement structures, the viscoelastic constitutive model has been considered by many studies. However, abundant experimental observations have presented nonlinear response of asphaltic materials at certain levels of stress and strain, and the nonlinear behaviour is not considered in the current pavement design methods. This study develops testing-analysis methods to rigorously define the stress-dependent nonlinear viscoelastic material characteristics at various stress levels. To this end, Schapery's nonlinear viscoelastic model is employed to characterize the nonlinear viscoelastic behaviour of asphaltic materials in two different length scales, i.e., mixture scale and component scale. The test and analysis results discussed in this paper provide a better understanding and identification of the true mechanical behaviour of asphaltic materials in pavements.

Keywords: Asphalt materials, nonlinear viscoelasticity, multiple scales, modeling

1 INTRODUCTION

An asphalt pavement is typically a multilayered system consisting of asphalt concrete, base, subbase, and subgrade layers. Multilayered elastic theory has been widely used for analysis and design of flexible pavements. As an example, the new pavement design guide, Mechanistic-Empirical Pavement Design Guide (MEPDG), has been developed and is currently under applications by many US states. The MEPDG basically uses layered elastic theory to determine the mechanical responses in conjunction with empirically developed failure criteria called transfer functions. Although the MEPDG employs various design parameters (climate, traffic, materials, etc.) to predict the performance of flexible pavements, it is known to be limited in its ability to accurately predict mechanical responses in asphaltic pavements. This limitation is due to the use of simplified structural analysis methods, a general lack of understanding of the fundamental constitutive behaviour and damage mechanisms for paving materials, and the use of circular tire loading configurations. Asphalt mixtures are typically considered viscoelastic; their stress and strain response is time-rate-temperature dependent. Therefore, the assumption of elasticity for an asphalt layer is misleading in predicting the performance of flexible pavements.

Recently, several studies [1–3] have conducted viscoelastic analyses that consider the asphalt layer as linear viscoelastic and the other layers as elastic, using the finite element method in two-dimensional (2-D) or three-dimensional (3-D) models for predicting the time-dependent

response of flexible pavement. However, nonlinear response was not taken into consideration for their models in spite of abundant experimental observations [4,5] that present nonlinear response of asphalt binders and mixtures at certain levels of stress and strain. When asphalt pavements are subjected to heavy truck loads, asphalt materials may present nonlinear viscoelastic behavior due to high stress (or strain) levels. Therefore, the nonlinear viscoelastic response of asphaltic pavement subjected to heavy truck loads should be taken into account for more accurate design and analysis.

The primary objective of this study is to investigate stress-dependent nonlinear viscoelastic characteristics of asphalt mixtures so as to identify the significance of nonlinear response for the more accurate analysis and design of asphalt pavements that are typically subjected to heavy vehicle loads. To that end, Schapery's single integral viscoelastic theory was applied with repeated creep-recovery tests in two different length material scales: the Fine Aggregate Matrix (FAM) scale and its corresponding asphalt concrete scale.

2 SCHAPERY'S NONLINEAR VISCOELASTICITY

Schapery's nonlinear viscoelastic single-integral constitutive model [6] for one-dimensional problems can be expressed in terms of an applied stress (σ), as follows:

$$\varepsilon(t) = g_0 D_0 \sigma + g_1 \int_0^t \Delta D\left[\psi(t) - \psi(\xi)\right] \frac{d\left(g_2 \sigma\right)}{d\xi} d\xi \tag{1}$$

where ψ is the reduced time given by:

$$\psi(t) = \int_0^t \frac{d\zeta}{a_\sigma} \tag{2}$$

where g_0, g_1, g_2, and a_σ are the nonlinear viscoelastic parameters associated with stress level, t is the time of interest, and ξ is the integration variable.

These nonlinear viscoelastic parameters are always positive and equal to 1.0 in linear viscoelasticity. It should be noted that Eq. (2) can include not only the stress effect but also other effects such as temperature, moisture, and physical aging with each shift factor. D_o and ΔD represent uniaxial instantaneous and transient creep compliance at linear viscoelasticity, respectively.

The uniaxial creep compliance in a form that combines the instantaneous and transient part can be expressed as a generalized power law, as follows:

$$D(\psi) = D_o + \Delta D(\psi) = D_o + D_c \psi^p \tag{3}$$

where D_o, D_c, and p values are material parameters representing the uniaxial linear viscoelastic creep behavior.

In the case of torsional shear loading, Schapery's nonlinear viscoelastic constitutive model can be expressed in terms of an applied shear stress (τ) and responsive shear strain (γ) with a different set of nonlinear viscoelastic parameters (with superscript *), as follows:

$$\gamma(t) = g_o^* J_0 \tau + g_1^* \int_0^t \Delta J\left[\psi(t) - \psi(\zeta)\right] \frac{d\left(g_2^* \tau\right)}{d\xi} d\xi \tag{4}$$

As in Eq. (3), the torsional creep compliance in a form combining the instantaneous and transient part can be expressed as follows:

$$J(\psi) = J_o + \Delta J(\psi) = J_o + J_c \psi^q \tag{5}$$

where J_o, J_c, and q values are material parameters representing the torsional linear viscoelastic creep behavior.

3 MATERIALS AND SPECIMEN FABRICATION

Three aggregates were selected and blended in this study: 16 mm limestone, 6.4 mm limestone, and screenings to produce an Asphalt Concrete (AC) mixture. All three aggregates are limestone with the same mineralogical origin. The Nominal Maximum Aggregate Size (NMAS) of the final aggregate blend was 12.5 mm. The asphalt binder used in this study was Superpave performance graded binder PG 64-28. With the limestone aggregate blend and the binder, a volumetric design of the AC mixture was accomplished; this resulted in a binder content of 6.0% by weight of the total mixture to meet the 4.0% target air voids and other necessary volumetric requirements. Along with the AC mix design, its FAM mix design was then conducted based on the volumetric mix design of its corresponding AC mixture. The FAM mixture consisted of the same PG 64-28 binder and fine aggregates passing No. 16 sieve (mesh size of 1.19 mm). The mix design of FAM was determined by considering that the coarse aggregates in the corresponding AC mixture could be separated from the FAM by virtually picking them out of the compacted AC mixture microstructure. Asphalt binder absorbed into coarse aggregates was subtracted from the total amount of binder used in the AC mixture, and the resulting remaining binder content was calculated to mix FAM. This approach resulted in a binder content of 8.0% by total weight of aggregates in the FAM mixture. A detailed description on specimen fabrication can be found elsewhere [7]. Table 1 illustrates gradation, bulk specific gravity (G_{sb}), and consensus properties (i.e., Fine Aggregate Angularity [FAA], Coarse Aggregate Angularity [CAA], Flat and Elongated [F&E] particles) of the aggregates used in this study.

As illustrated in Figure 1, AC and FAM specimens were fabricated to conduct the uniaxial and torsional creep-recovery tests, respectively. To fabricate AC specimens, a Superpave

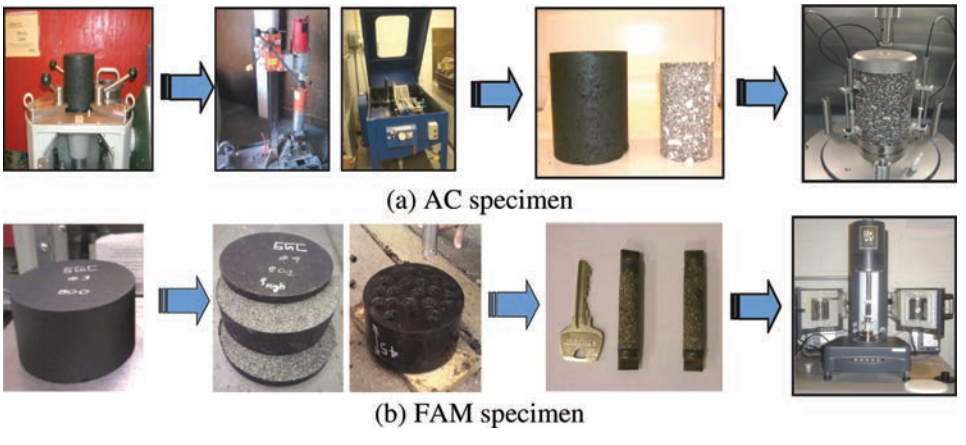

Figure 1. Specimen fabrication process for the repeated creep-recovery tests.

gyratory compactor was used to produce the cylindrical samples with a diameter of 150 mm and an approximate height of 170 mm. Then, the compacted samples were cored and sawn to produce testing specimens targeting an air void of 4% ± 0.5% with a 100-mm diameter and 150-mm height. To measure the axial displacement of the AC specimens, mounting studs were glued to the surface of the specimens so that three Linear Variable Differential Transformers (LVDTs) could be installed on the surface of the specimens through the studs at 120° radial intervals with a 100-mm gauge length. The AC specimen was then mounted in a mechanical testing station equipped with an environmental chamber for the uniaxial static creep-recovery tests.

Along with the AC mixture, the Superpave gyratory compactor was also used to produce a cylindrical FAM sample with a diameter of 150 mm and a height of 80 mm. The sample was then sliced into three pieces to obtain a middle section of 45 mm height. Then, cylindrical specimens 45 mm long and 12.25 mm in diameter were cored out of the middle 45 mm section of the bulk FAM sample. Special care was taken while coring, since the geometry and surface quality of the top and bottom parts of the core are very important when subjected to torsional loads. The FAM specimen was then installed into a rheometer to conduct torsional shear static creep-recovery tests in order to characterize viscoelastic deformation of the FAM mixture.

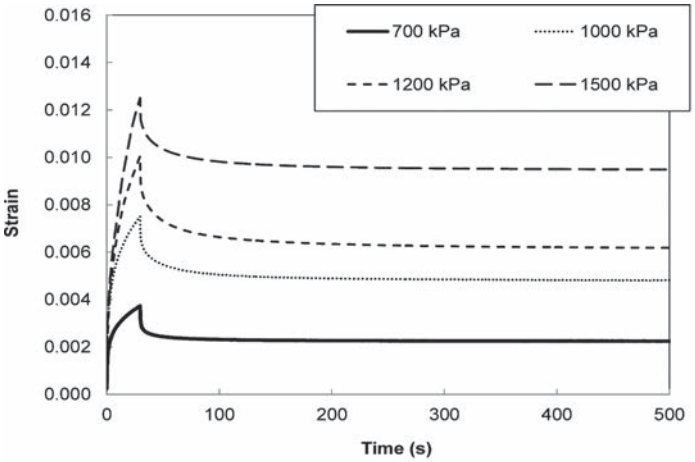
4 LABORATORY TESTS AND RESULTS

The static creep-recovery test was conducted on replicate specimens of AC mixture and FAM mixture at an identical testing temperature of 30 °C. Based on several preliminary tests conducted to find an appropriate creep loading time and recovery time, a creep stress for 30 seconds followed by recovery time of 500 seconds was applied to the specimens. The vertical deformation (in compression mode) from the AC specimens was monitored with the three LVDTs, while the torsional displacements (in pure shear mode) from the FAM specimens were measured with transducers installed in the rheometer. A large range of stress levels was applied to identify the level of (stress-independent) linear viscoelastic range and to characterize stress-dependent nonlinear behaviour of each mixture. Repeated preliminary tests indicated that the AC mixture was linear viscoelastic up to 700 kPa uniaxial creep stress, and the FAM specimens were generally subjected to linear viscoelastic behaviour up to 15 kPa torsional creep stress. In other words, nonlinear viscoelasticity starts when the stress level is greater than 700 kPa and 15 kPa for the AC specimens and the FAM specimens, respectively. Therefore, a creep-recovery curve at the threshold stress level within the linear viscoelastic range was used to find linear viscoelastic properties, and other creep-recovery curves obtained from higher stress levels than the threshold stress were used to characterize the stress-dependent nonlinear viscoelastic properties of each mixture.

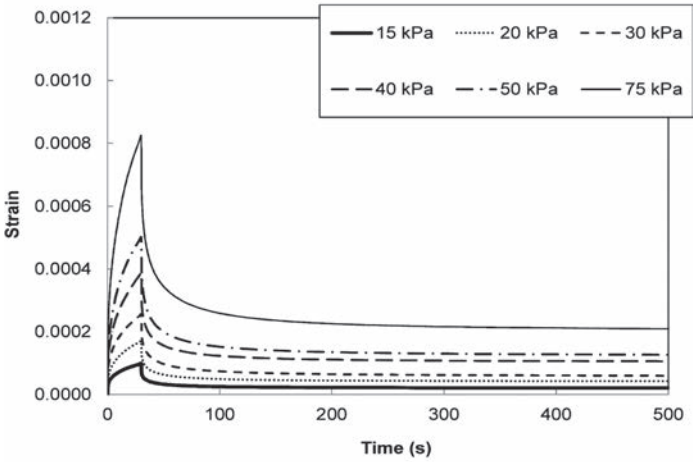
Figure 2 presents repeated creep-recovery test results obtained from the AC mixture and FAM mixture, respectively. Each strain curve at a specific creep stress level was averaged from three replicates. Test results between replicates were similar, so that the averaged curves presented in Figure 2 could be reasonably used to estimate deformation characteristics of each asphalt mixture. As shown in the figure, the higher stress level generated larger creep strain and provided less recovery at the testing temperature (30 °C).

5 CHARACTERIZATION OF NONLINEAR VISCOELASTIC PROPERTIES

The approach most often described in the literature to obtain nonlinear viscoelastic material properties is based on Schapery's procedure using numerical fitting of laboratory test data both in the linear viscoelastic range and in the nonlinear viscoelastic range at each stress level [8,9]. As mentioned earlier, the repeated creep-recovery test results were used to identify linear and nonlinear viscoelastic material properties. The procedure to define nonlinear viscoelastic properties starts with the identification of linear viscoelastic material properties



(a) AC mixture



(b) FAM mixture

Figure 2. Repeated creep-recovery test results.

using the test results at the threshold stress level. The linear viscoelastic properties are then used to find nonlinear viscoelastic properties by using creep-recovery test data resulting from higher stress levels than the threshold level. To better illustrate the characterization process, a schematic view of a single creep-recovery test is introduced in Figure 3 for a constant stress (σ_o) loading-unloading condition.

For the loading time period, (i.e., $0 < t < t_1$), Eq. (1) can be expressed as:

$$\varepsilon_c(t) = g_0 D_0 \sigma_0 + g_1 g_2 \sigma_0 \Delta D\left(\frac{t}{a_{\sigma_o}}\right) \tag{6}$$

For the unloading time period, that is, $t > t_1$, it can be expressed as:

$$\varepsilon_r(t) = g_2 \sigma_0 \left[\Delta D\left(\frac{t_1}{a_{\sigma_o}} + t - t_1\right) - \Delta D(t - t_1)\right] \tag{7}$$

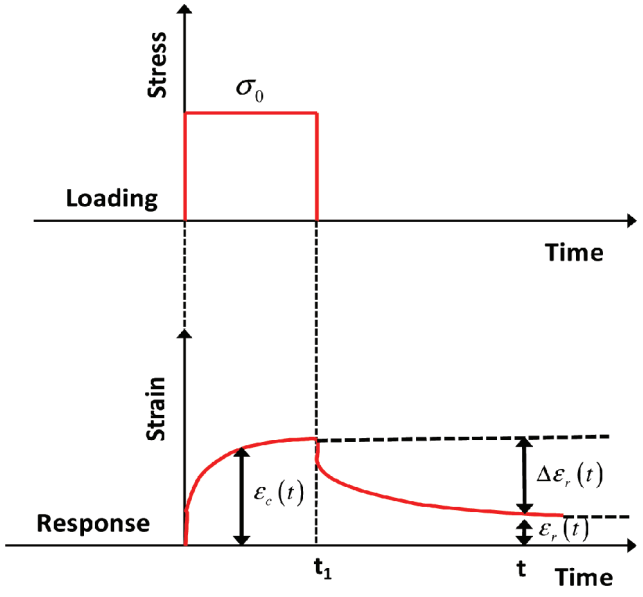


Figure 3. Schematic illustration of a single creep-recovery test.

The first step is to obtain linear viscoelastic material properties (D_o, D_c, and p for uniaxial creep and J_o, J_c, and q for torsional creep) from the generalized power law (Eq. (3), Eq. (5)) at the threshold stress level. Since the recoverable response is linear viscoelastic ($g_o = g_1 = g_2 = a_\sigma = 1.0$) at the threshold stress level, the recovered strain $\Delta\varepsilon_r$ shown in Figure 3 can be used to obtain the linear viscoelastic material properties. Linear viscoelastic material properties in the form of generalized power law are determined by minimizing errors between experimental measurements and predicted strains. Once the linear viscoelastic properties have been obtained, the nonlinear viscoelastic parameters at higher stress levels can then be determined. To do this, the recovered strains at higher stress levels than the threshold level are used again with the notion that the transient creep compliance is expressed in the form of a power law [8]. The resulting recovered strain $\Delta\varepsilon_r$ as a function of time is expressed as follows:

$$\Delta\varepsilon_r(t) = \varepsilon_c(t_1) - \varepsilon_r(t) = \alpha - \beta\left[\left(1 + a_{\sigma_o}\lambda\right)^n - \left(a_{\sigma_o}\lambda\right)^n\right] \tag{8}$$

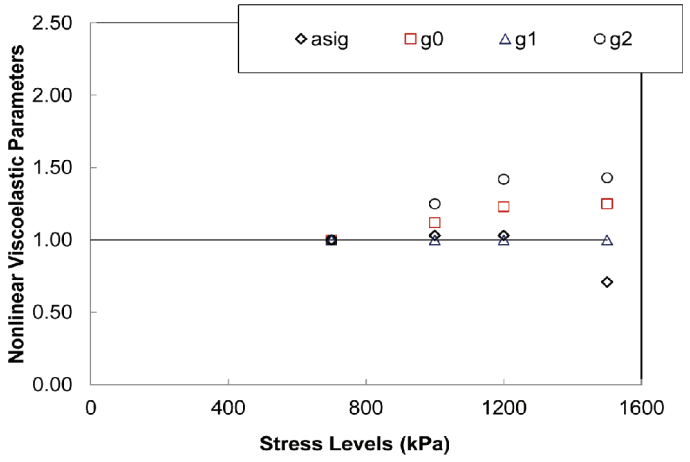
where

$$\alpha = g_0 D_0 \sigma_0 + g_1 g_2 D_c \sigma_0 \left(\frac{t_n}{a_{\sigma_0}}\right)^n \tag{9}$$

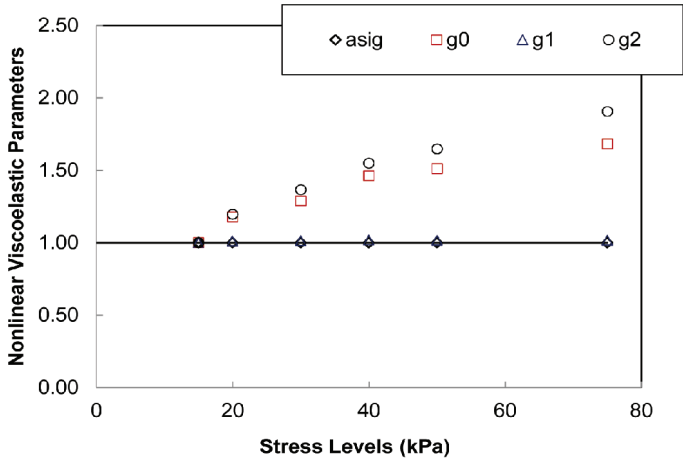
$$\beta = g_2 D_c \left(\frac{t_1}{a_{\sigma_0}}\right)^n \tag{10}$$

$$\lambda = \frac{t - t_1}{t_1} \tag{11}$$

Fitting Eq. (8) to the recovered strain data $\Delta\varepsilon_r$ can determine constants: n, α, β, and a_σ. It is also noted that n is almost stress-independent and can be obtained at a low stress level; therefore, the n value can be fixed as a material constant, and the values of α, β, and a_σ are obtained by repeating the fitting process. Next, from Eq. (10), g_2 is determined by minimiz-



(a) AC mixture



(b) FAM mixture

Figure 4. Nonlinear viscoelastic material parameters as a function of stress levels.

ing errors between experimental data and Eq. (10). Similarly, g_0 and g_1 are determined from Eq. (9). Based on this fitting process, all nonlinear viscoelastic parameters of the AC mixture and FAM mixture were found and are presented in Figure 4 plotted as a function of stress levels. The figures show that, for both AC and FAM mixture, parameter g_1 is not significantly related to nonlinearity, whereas other parameters such as g_0 and g_2 are affected by stress levels when the mixtures are subjected to nonlinear viscoelastic deformation. Both parameters generally increased as higher stresses were involved. Regarding a_σ, with the limited data available at the current stage, it does not seem to be highly related to the stress levels for both mixtures, except the value of AC mixture at the stress level of 1,500 kPa. However, this observation needs extended tests and relevant analyses to confirm.

6 SUMMARY AND CONCLUSION

This study developed testing-analysis methods to properly define the stress-dependent nonlinear viscoelastic material characteristics of asphalt materials. Schapery's single integral

viscoelastic theory was applied with repeated creep-recovery tests. Based on the test results and data analysis, the following bullet points summarize the conclusions that can be drawn:

- The repeated creep-recovery test and analysis method based on Schapery's single integral viscoelasticity were applied to both torsional FAM testing and uniaxial AC testing.
- Creep-recovery tests at varying stress levels were conducted to identify viscoelastic mixture characteristics. Test results were generally reasonable and repeatable, and analyses of test results were straightforward.
- Asphalt mixtures (in both length scales) clearly presented stress-dependent nonlinear viscoelastic responses at stress levels greater than the linear viscoelastic range. For both mixtures, nonlinear viscoelastic parameter g_1 did not show any significant nonlinearity, while parameters g_0 and g_2 increased with greater stresses. This indicates that the stress-dependent nonlinear viscoelastic behavior should be considered for the more accurate analysis and design of asphalt pavements that are typically subjected to heavy vehicle loads.
- With the test data and analysis results at this stage, a strong correspondence between the FAM and AC mixtures exits in their viscoelastic deformation characteristics. This implies that the viscoelastic characteristics of typical AC mixtures could potentially be estimated and/or predicted from the FAM testing, which can significantly reduce experimental-analytical efforts required to conduct AC testing. The authors currently investigate a correlation between the AC mixture and the FAM mixture. Any visible findings will be presented.
- This study was limited in its scope by testing only one type of asphalt mixture at one testing temperature (30 °C). A follow-up study is recommended to conduct the extended tests with different mixtures and testing temperatures to confirm the findings and observations obtained from this study.

Usage of advanced functions of Dynamic Shear Rheometer for the selection of a suitable binder for asphalt mixtures

Ondřej Dašek, Petr Hýzl, Michal Varaus & Pavel Coufalík
Faculty of Civil Engineering, Brno University of Technology, Veveří, Czech Republic

Petr Špaček & Zdeněk Hegr
Skanska a.s., Praha, Czech Republic

ABSTRACT: Asphalt pavements often have a tendency to creation of cracks and potholes, which can be associated with a decrease of the functional properties of asphalt binder. This decrease can be caused either by inadequate use of binders for the intended application, or undesirable change of binder properties during usage, most often due to excessive oxidative aging of asphalt binders in the asphalt mixtures.

One of the progressive functions of Dynamic Shear Rheometer (DSR) is the possibility to analyse the relaxation of shear stress of asphalt binders in dependence on time. This parameter is suitable to differ the appropriateness of the binder usage for the relevant application.

The results of advanced tests of Dynamic Shear Rheometer conducted on several types of asphalt binders, such as paving grade bitumen, polymer modified bitumen and asphalt rubber binder are introduced in the paper. The methodology describing the selection of the suitable binder for the presumed application using DSR device with the describing of Rolling Thin Film Oven Test (RTFOT) aging of binders is also presented.

Keywords: Bituminous binder, asphalt mixture, rheology, dynamic shear rheometer, relaxation of shear stress

1 INTRODUCTION

The relaxation of shear stress measured in the bituminous binder can become an important indicator of the level of material ability to diminish the imposed stress, as well as the quality of the modifying system. The ability to absorb the thermically induced stress is a significant property of the real bitumen layer that leads to the reduction of its cracking potential and can influence the transfer of tensile stresses in the bituminous mixture. This ability is primarily determined by the properties of the bituminous binder and bituminous film thickness that is used for the binder. The Czech systems of road testing specifications, particularly the technical regulations TP 151 [1] describe a method that enables the measurement of the aforesaid relaxation in bituminous mixtures. The test has proved to be very time-consuming and not always optimized in terms of instrumentation to ensure mutual consistency of inter-laboratory results. The basic idea for measuring the relaxation of shear stress of the bituminous binder using DSR is to describe the relaxation behaviour of the bituminous binder itself under given temperature conditions to predict the subsequent relaxation behaviour of bituminous mixtures, and thus to eliminate complex laboratory testing. When a bituminous binder shows a fast relaxation of imposed stress, the finished bitumen layer is assumed to have a reduced tendency to the formation and propagation of cracks. [2]

Table 1. Basic binder characteristics.

Binder	Penetration [0.1 mm]	Softening point [°C]
Paving grade bitumen 50/70	54	48.9
PmB 45/80-50	45	54.2
PmB 25/55-55	30	65.7
PmB 25/55-65	25	78.2
CRmB 25/55-60	38	62.3

2 MATERIALS USED

The following materials were chosen for laboratory testing: paving grade bitumen (gradation 50/70), three Polymer modified Bitumens (PmB) from the same producer (gradation 45/80-50, 25/55-55, and 25/55-65), and one Crumb Rubber modified Bitumen (CRmB, asphalt rubber) prepared in the laboratory by mixing paving grade bitumen 50/70 with 15.5% crumb rubber with a grain size of 0/1 mm (gradation 25/55-60). The basic properties of individual binders are given in Table 1.

3 APPLIED TEST PROCEDURES

To evaluate the properties of selected bituminous binders and the effects of ageing using the Rolling Thin Film Oven Test (RTFOT), empirical tests of binders (needle penetration according to the EN 1426 standard, softening point—ring and ball method according to the EN 1427 standard, and elastic recovery according to the EN 13398 standard) and a performance test of shear stress relaxation using DSR (dynamic shear rheometer) were chosen.

3.1 *Rolling Thin Film Oven Test (RTFOT)*

The Rolling Thin Film Oven Test is described in the EN 12607-1 standard. The ageing of bituminous binders is influenced by atmospheric oxygen only up to small thicknesses (approx. 50 μm); therefore, a rolling thin film of the binder is applied in the test. The test simulates binder ageing during the coating of aggregates in the mixing plant of bituminous mixtures. [3–5]

For the binder ageing test, an oven with a doubled wall and electric heating at a temperature of 163 °C is used. The binder is placed in eight cylindrical glass vessels supplied with heated air from a nozzle. The combined effect of heat and air is determined from the change of the binder weight in the vessels or from the change in the bituminous binder properties measured prior to and after the ageing. To describe the changes of properties, the tests of needle penetration, softening point or dynamic viscosity are used. The changes in binder properties after the ageing can also be expressed by rheological properties detected using a dynamic shear rheometer.

3.2 *Measurement of the shear stress relaxation in DSR*

There is a variety of rheometers, i.e. instruments to detect the rheological properties of materials. Rotary (oscillatory) rheometers (referred to as dynamic shear rheometers—DSR in road engineering) are complex instruments for characterising the rheological behaviour of a wide spectrum of materials. They are designed to describe the dynamic viscosity and also allow for measurements of the other rheological properties, i.e. in both stable shear and oscillating modes. For rheological measurements, the Kinexus rotational rheometer by Malvern was used in the Road Laboratory of Brno University of Technology, see Figure 1.

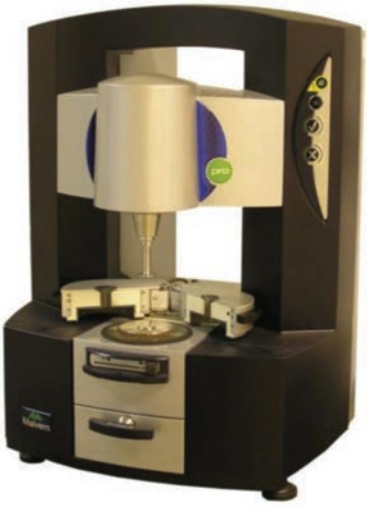

Figure 1. Kinexus rotational rheometer.

To determine the rate of shear stress relaxation in DSR, the following procedure has so far been used: at first, shear strain at a given shear rate is applied on the bituminous binder sample at a given temperature—the shear strain should be chosen in the linear viscoelastic region. For the whole testing period, the applied strain is maintained at a constant value. After the initial increase in shear stress that corresponds to shear strain and shear rate is achieved, the decrease in stress over time is monitored. The test result involves a relaxation curve of shear stress, which represents the dependency of shear stress decrease on time.

For ideally elastic materials, no shear stress relaxation will occur after the shear strain introduced, and the shear stress remains constant. In the case of a substance with ideally viscous behaviour, the internal stress will be eliminated practically immediately after the shear strain is introduced. When the shear strain is introduced to a viscoelastic material, a delayed relaxation of shear stress takes place, i.e. partial or full relaxation occurs after a certain period of time. The relaxation curve has an exponential shape, and the level of shear stress relaxation depends on the viscous component of the material.

When the shear strain is applied on a viscoelastic liquid, the complete relaxation of shear stress will be achieved (provided that the relaxation time is sufficient). For viscoelastic solids, no relaxation of shear stress to zero will take place even after a very long time interval. The relaxation curve will asymptotically near the final value referred to as equilibrium stress. This means that at least a part of the molecules are chemically or physically linked and, therefore, not able to move freely. At any moment of the test it is possible to determine the relaxation modulus as a ratio of instantaneous shear stress and set initial shear strain. [6]

4 TEST RESULTS

Below are presented the results of individual laboratory tests of binders and the description of the influence of the Rolling Thin Film Oven Test (RTFOT) on individual properties of tested bituminous binders.

4.1 *Needle penetration, softening point and elastic recovery*

The resulting values of needle penetration, softening point and elastic recovery of tested binders are given in Table 2, including the description of the influence of RTFOT ageing on the aforesaid characteristics. Paving grade bitumen showed the highest penetration value

Table 2. Basic binder characteristics prior to and after the short-term ageing (RTFOT).

	Penetration [0.1 mm]		Softening point [°C]		Elastic recovery [%]	
Binder	–	RTFOT	–	RTFOT	–	RTFOT

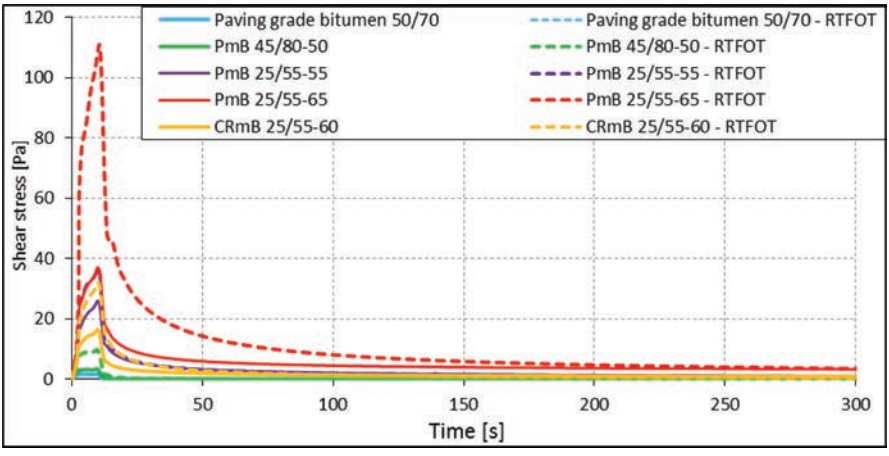

Figure 3. Relaxation of shear stress of individual binders (shear strain 1% after 10 s).

and the lowest softening point. Penetration of polymer modified bitumens decreases and the softening point increases with the increasing degree of modification of polymer modified bitumen. Short-term ageing resulted in a reduced penetration in all binders ranging from 3 to 19 penetration units. The PmB 25/55-55 showed the least influence of ageing on the value of penetration. The softening point of all binders increased due to RTFOT ageing by 3.1 °C

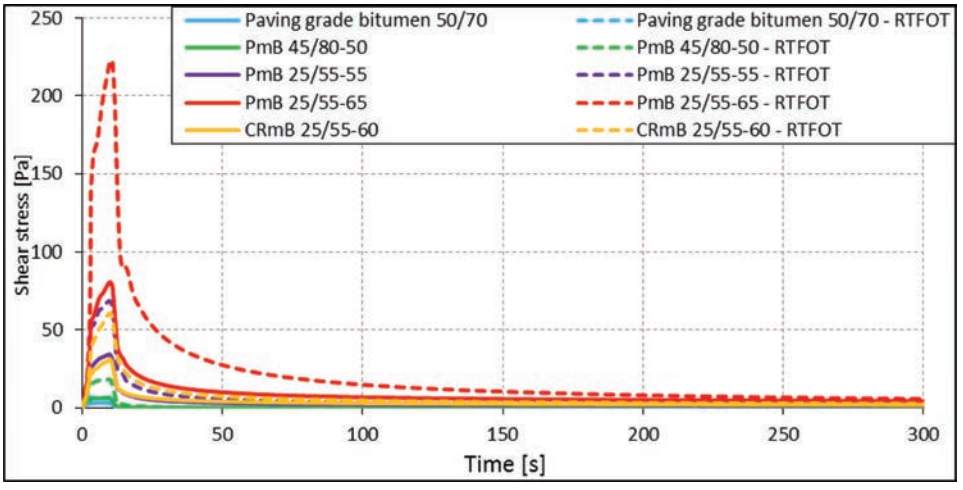

Figure 4. Relaxation of shear stress of individual binders (shear strain 2% after 10 s).

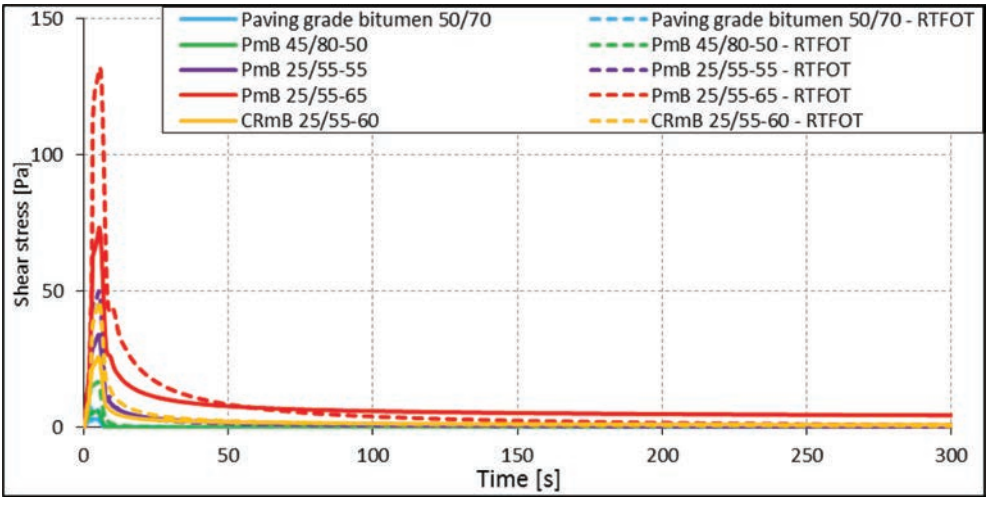

Figure 5. Relaxation of shear stress of individual binders (shear strain 1% after 5 s).

to 6.1 °C. The greatest change of the softening point value could be observed in case of crumb rubber modified bitumen. Naturally, the change in test values of the aged crumb rubber modified bitumen could be caused by the additional reaction of crumb rubber particles with bitumen at a high temperature. Due to ageing the elastic recovery decreased in the PmB 45/80-50 and CRmB 25/55-60 binders and increased in the two remaining polymer modified bitumens.

4.2 *Relaxation of shear stress*

The relaxation of shear stress of binders in DSR has been determined at a temperature of 50 °C using parallel measuring plates with a diameter of 25 mm and a gap size of 2.0 mm. The relaxation tests were carried out in the mode of controlled strain. The initial shear strain achieved a value of 1% and 2% of sample thickness, and the time to achieve the shear strain was 5 s, 10 s and 20 s, and a relaxation time 300 s was used.

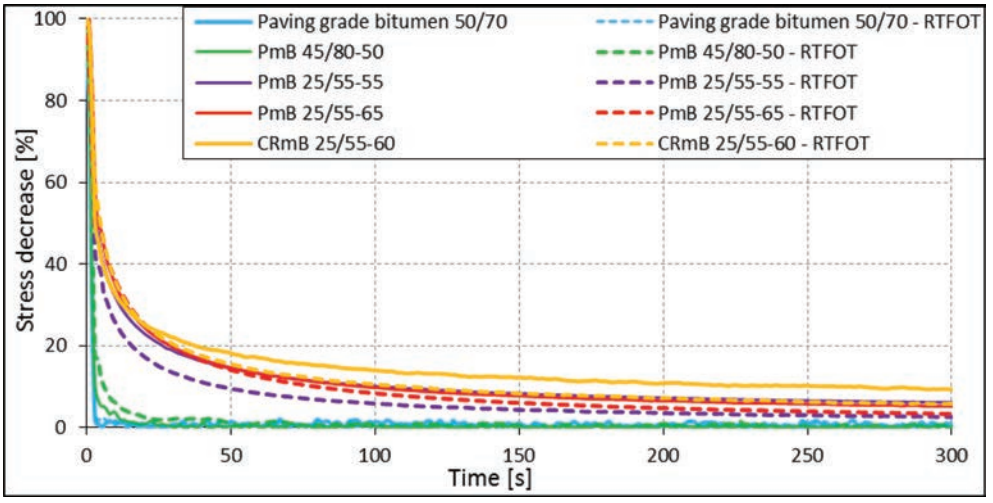

Figure 6. Decrease in shear stress of binders, in % (shear strain 1% after 20 s).

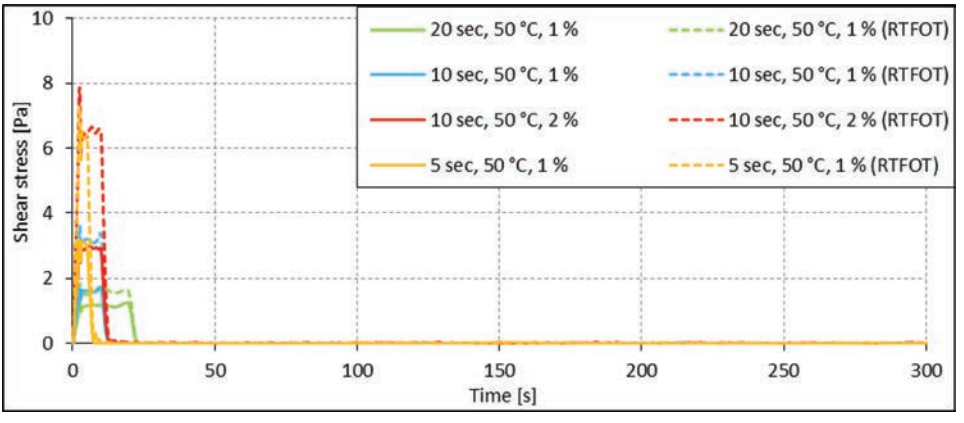

Figure 7. Relaxation of shear stress of paving grade bitumen 50/70.

Figures 2–5 compare the relaxation of shear stresses of individual binders depending on the time for various boundary test conditions. PmB 25/55-65 and paving grade bitumen 50/70 showed the highest and the lowest shear stresses, respectively. When testing the relaxation of shear stress of the paving grade bitumen 50/70 at 50 °C, the shear stress decreases practically immediately to zero once the shear strain ceased to be introduced on the bitumen sample. The negligible elastic response corresponds to great phase angles measured using the dynamic shear rheometer (80 ° to 85 °). Besides, when shear stress is introduced at 50 °C, the sample has already become flexible to such a degree that the pseudoviscosity of the plate/plate system is more likely to be measured. The decrease in shear stress of the PmB 45/80-50 sample was only slightly slower. For PmB 25/55-50, PmB 25/55-65 and CRmB 25/55-60, shear stress did not relax fully after 300 seconds; the relaxation curve is asymptotically nearing the final value (equilibrium stress). The RTFOT ageing caused an increase in initial maximum shear stresses of all binders. From Figure 6 it is obvious that the relaxation of shear stress is faster for aged binders than for non-aged ones when maximum shear stress equalling 100% is applied.

Figures 7–11 compare the relaxation curves of individual binders with various conditions applied during the testing of shear stress relaxation. The magnitude of maximum

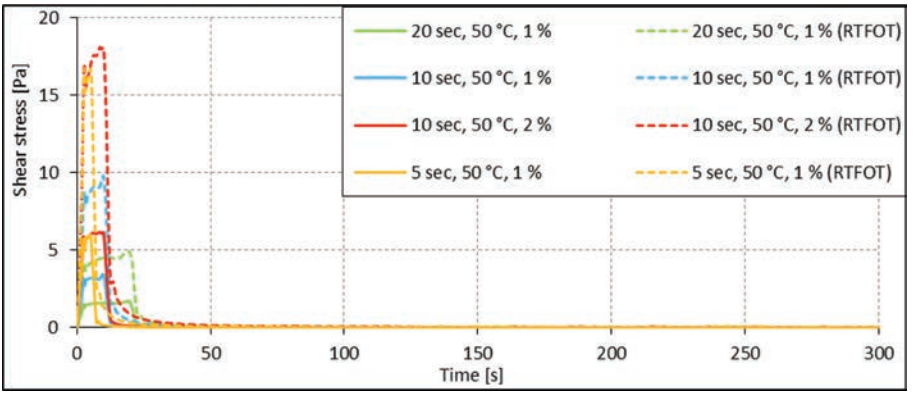

Figure 8. Relaxation of shear stress of PmB 45/80-50.

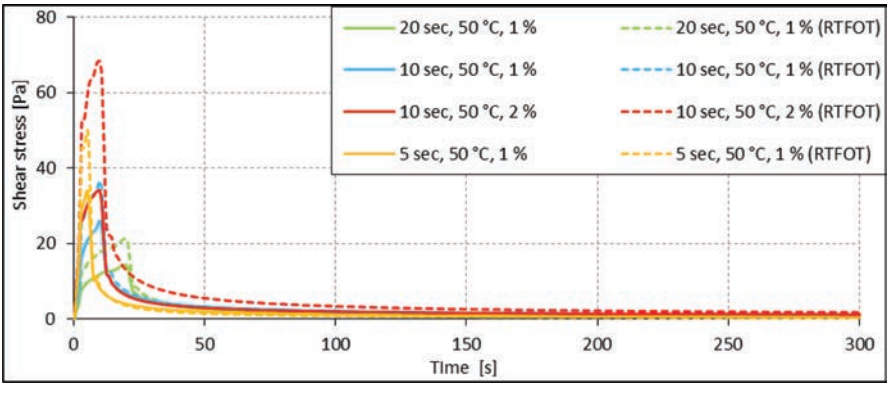

Figure 9. Relaxation of shear stress of PmB 25/55-55.

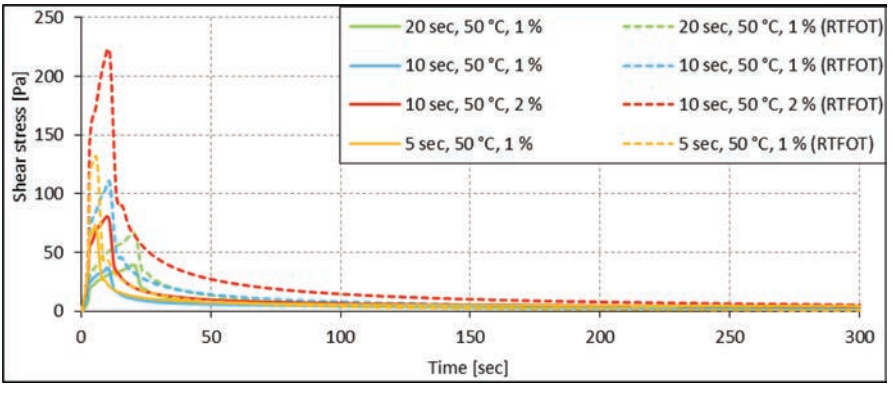

Figure 10. Relaxation of shear stress of PmB 25/55-65.

shear stress depends on the rate of shear strain change (shear rate). At the same shear rate, the loading line showed an approximately identical pattern (e.g. 1% after 5 s and 2% after 10 s). At a double shear rate, the produced shear stress also became doubled (e.g. 1% after 10 s and 2% after 10 s). The slowest relaxation of shear stress occurred in binders after a low shear rate had been applied (1% after 20 s), while the greatest

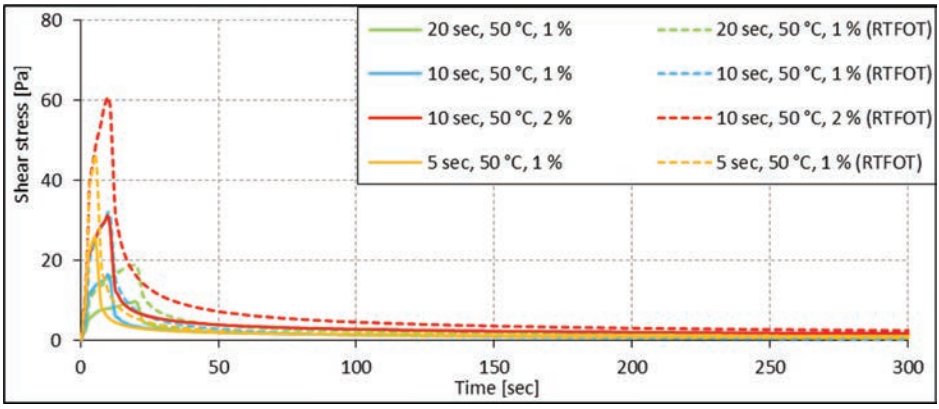

Figure 11. Relaxation of shear stress of CRmB 25/55-60.

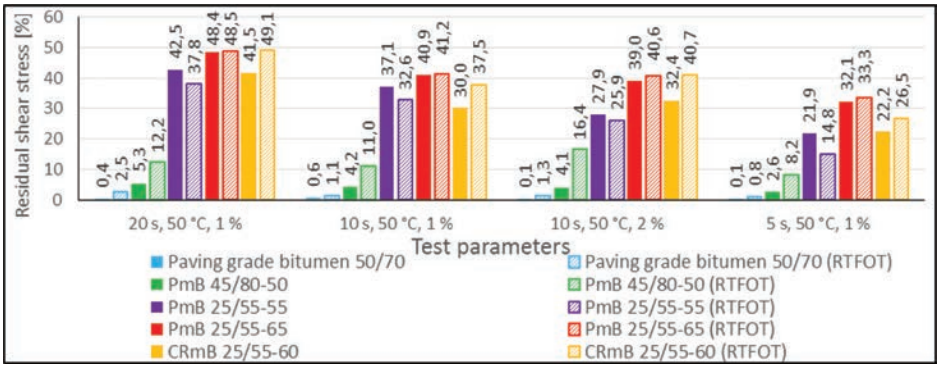

Figure 12. Residual shear stress of individual binders after 5 seconds of relaxation.

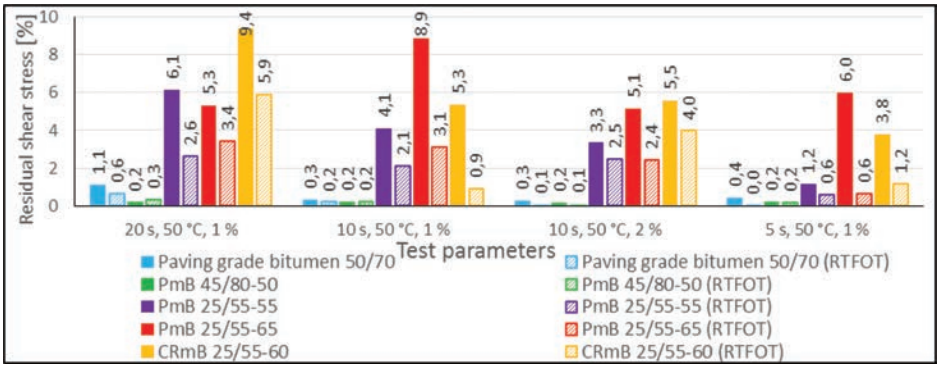

Figure 13. Residual shear stress of individual binders after 300 seconds of relaxation.

relaxation of binders was observed after a fast shear strain had been introduced (1% after 5 s).

Figure 12 summarizes residual shear stresses of binders after 5 seconds of relaxation in dependence on test conditions. Figure 13 shows residual values of shear stress of individual binders after 300 seconds of relaxation depending on the set test conditions. After 300 seconds

of relaxation, the crumb rubber modified bitumen CRmB 25/55-60 and polymer modified bitumen PmB 25/55-65 achieved the highest equilibrium stresses. Here again, the considerable influence of simulated ageing on the behaviour of bituminous binders could be observed. Probably due to crosslinking processes caused by thermo-oxidative reactions of radicals, the measured maximum shear stress increases and the percentage relaxation of shear stress of binders decreases in DSR.

5 CONCLUSIONS

The results of selected tests made on a spectrum of non-aged and RTFOT aged bituminous binders are presented in this article. For laboratory testing, 50/70 paving grade bitumen, three different polymer modified bitumens, and one crumb rubber modified bitumen (asphalt rubber) were chosen.

During the testing of shear stress relaxation in DSR made at 50 °C, the degree of modification system is likely to be employed. The relaxation of shear stress of binders has been determined in DSR at a temperature of 50 °C using parallel plates with a diameter of 25 mm and a gap size of 2.0 mm. The magnitude of maximum shear stress depends on the rate of shear strain change (shear rate). For PmB 25/55-50, PmB 25/55-65 and CRmB 25/55-60, shear stress did not relax completely after 300 seconds; the relaxation curve asymptotically approached the final value (equilibrium stress). The RTFOT ageing resulted in increasing the initial maximum shear stresses of all binders. When a maximum shear stress equalling 100% is applied, the relaxation of shear stress is faster in aged binders than in non-aged ones.

The relaxation of shear stress measured in the bituminous binder using DSR can be an important indicator of the level of material ability to diminish the applied stress, as well as the quality of the modification system. The basic purpose of the measurement of shear stress relaxation of bituminous binders using DSR is to describe the relaxation behaviour of the binder itself under given temperature conditions to predict the subsequent relaxation behaviour of bituminous mixtures. When a bituminous binder shows a fast relaxation of shear stress applied, it is assumed that the tendency of the finished bituminous layer to create and propagate cracks will be decreased.

Modern dynamic shear rheometers enable not only oscillation tests but also tests in stable shear flow as well as measurements of normal sample force to be carried out. The new test equipments allow for increasingly more precise descriptions of the behaviour of paving materials. In combination with the laboratory simulation of ageing, it is possible to describe the development of performance characteristics of bituminous binders and to predict their behaviour in a real pavement.

Possibilities of a hollow cylinder tester for asphalt mixtures

Eduardo J. Rueda, Silvia Caro, Bernardo Caicedo & Julieth Monroy
Department of Civil and Environmental Engineering, Universidad de los Andes, Bogotá, Colombia

ABSTRACT: The characterization of asphalt concrete materials continues being a crucial area of work in the field of pavement engineering. As part of the efforts to improve the current knowledge of this complex material, a novel laboratory equipment has been recently designed and constructed at Universidad de Los Andes (Bogotá, Colombia). This device, named "Hollow Cylinder Tester for Hot Mix Asphalt (HMA) materials" (HCT-HMA), is a multipurpose apparatus equipped with an environmental conditioning chamber and a versatile loading system able to apply axial and/or torsional loads. The main feature of this equipment is the geometry of the specimen, which consists of a 12.7 cm in height hollow cylinder with 2.54 cm wall thickness. This paper describes the components of the HCT-HMA and some of the possibilities of this device to characterize asphalt concrete materials. It is expected that this machine will provide new and valuable information regarding the complex response of asphalt mixtures.

Keywords: Asphalt mixture, hollow cylinder tester, mechanical characterization

1 INTRODUCTION

There exist several different standardized experimental methodologies that are applied worldwide to determine the mechanical properties of asphalt mixtures. Some of these techniques include, among others, the dynamic modulus test [1], the shear modulus test [2], and the indirect tensile test [3]. Most of these methodologies, however, are restricted to narrow stress paths. This situation constrains the acquisition of data regarding the response of the material under more complex conditions. For this reason, geotechnical and pavement engineers have found that the "Hollow Cylinder" methodology is an efficient tool to improve the possibilities of material characterization.

The hollow cylinder methodology has been used to study the properties of different materials, ranging from wood and metals to soils and polymers. The advantage of this methodology is that it enables the use of a wide range of stress paths that are typically limited in regular triaxial testing. This is partially due to the fact that the geometrical configuration of the specimens (i.e., hollow cylinders) promotes a more uniform stress distribution within samples subjected to torsional loading than that obtained in solid specimens. Additionally, as it will be explained in this paper, for the specific case of asphalt mixtures, this methodology could also be used to efficiently characterize the effect of environmental conditions on the mechanical response of the material.

Geotechnical engineers have used hollow cylinder testing procedures to study the response of clays and granular unbound materials subjected to the combined effect of axial and shear stresses (i.e., to simulate the rotation of principal stresses) [4]. The first experimental experience using this methodology intended to quantify the resistance of unconfined clays in pure shear [5]. Similar studies on clays continued with Geuze and Tan [6], and later by Saada and Zamani [7].

Based on the positive results obtained on clays, the use of the hollow cylinder methodology was expanded to study several effects of sands, including its undrained anisotropy behaviour,

liquefaction phenomena, and the effect of large amplitude vibrations on the shear modulus and damping of these materials [8], [9], [10]. Additionally, Di Benedetto et al. [11] used the hollow cylinder technique to describe the constitutive viscous and non-viscous behaviour of sand materials. Finally, a hollow cylinder machine was developed by the group of Geomaterials and Infrastructure Systems at Universidad de los Andes (Bogota, Colombia) to study the mechanical response of coarse aggregates used as part of base and subbase layers in pavement structures [12].

In contrast to the broad experience in geotechnical engineering, the application of hollow cylinder methodologies to characterize asphalt concrete is limited. The first experience was conducted in 1986 when a hollow cylinder apparatus was designed at the University of California at Berkeley to study the dynamic properties of asphalt concrete under axial and torsional loads [13] [14]. In 1999 the University of Illinois at Urbana-Champaing developed a new hollow cylinder apparatus to evaluate rheological properties of asphalt concrete like creep compliance, tensile strength and dynamic modulus [15]. In this case, however, the mechanism of load application consisted of applying pressure in the inner cavity of the hollow cylinder specimen. More recently, Brown et al. [16] at University of Nottingham designed a hollow cylinder apparatus to study the susceptibility of asphalt concrete to permanent deformation.

The experiences mentioned previously were the motivation for this work. This paper describes the characteristics of a new hollow cylinder machine, named "Hollow Cylinder Tester for Hot Mix Asphalt materials" (HCT-HMA), and explores some possible applications of the HCT-HMA to conduct novel characterization testing on this material. The HCT-HMA is a multipurpose device equipped with an environmental conditioning chamber and a versatile loading system able to combine different load applications.

This paper contains four sections. The first section presents the basic principles used in hollow cylinder tests. Next, the main features of the hollow cylinder device are described, followed by an explanation of the possibilities of the new machine to evaluate the performance of asphalt materials, as well as some calibration activities. Finally, the main conclusions of this work are presented.

2 HOLLOW CYLINDER TESTER FOR ASPHALT MATERIALS

The HCT-HMA is a laboratory equipment developed with the objective of conducting comprehensive characterization of asphalt materials. It was designed to test hollow cylinder samples in both torsional and axial loads. These loads can be applied using different combinations (e.g., axial and/or torsional load under monotonic, cyclic, and other conditions), at the point that the device can be used to reproduce tridimensional state of stresses that occurs in asphalt concrete materials subjected to moving loads. Additionally, it can be used to determine the linear and non-linear viscoelastic material properties of the mixtures, as well as to characterize its fatigue and permanent deformation susceptibility. In addition, the HCT-HMA was created to provide valuable information about the response of asphalt mixtures subjected to realistic field conditions. Within this context, the use of a hollow cylinder geometry accelerates environmental conditioning processes, due to the double exposed walls that characterize testing specimens. Therefore, the new HCT-HMA has been also designed to quantify the role of controlled environmental conditions, such as relative humidity and oxidation process, in the response of asphalt mixtures. Figure 1 illustrates the equipment and its components.

2.1 *Sample characteristics and fabrication procedure*

The specimen geometry for the HCT-HMA consists of a 12.7 cm height hollow cylinder with 2.54 cm wall thickness and 12.7 cm outside diameter. These dimensions were defined based on the recommendations provided by Saada and Townsend [17], who suggested a geometrical criterion shown in Eq. (1) to reduce the non-uniformity distribution of shear stresses.

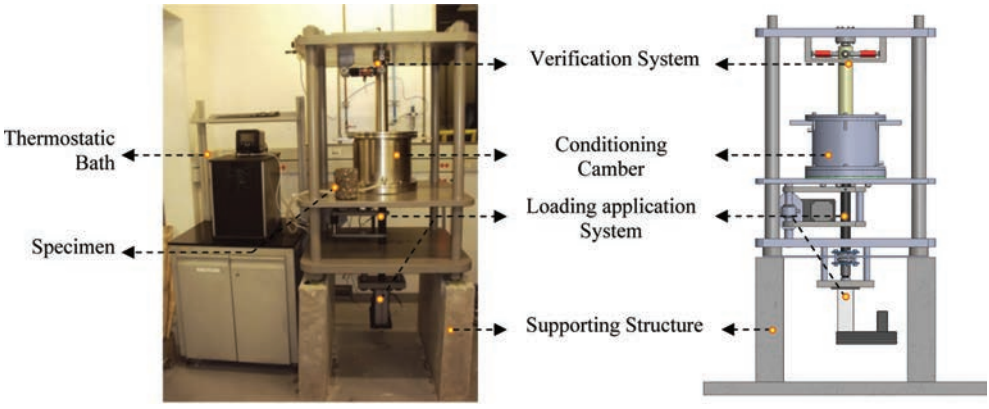

Figure 1. Hollow cylinder tester for hot mix asphalt materials: HCT-HMA.

Figure 2. (a) coring process, and (b) specimen geometry (centre).

According to these dimensions, the use of mixtures with a maximum nominal size of the aggregates equal or smaller than 12.5 mm (1/2 inch) is recommended.

$$\frac{r_{inner}}{r_{outer}} \geq 0.65 \text{ and } H \geq 5.44\sqrt{r_{inner} - r_{outer}} \quad (1)$$

where r_{inner} is the inner radius of the sample, r_{outer} is the outer radius of the specimen and H is the height of the sample.

The specimen preparation initiates with the fabrication of an asphalt mixture sample with 15 cm in height and 15 cm in diameter using the Superpave Gyratory Compactor. These samples are subsequently cored to remove the external shell of the specimen, using a 12.7 cm drill core, and to remove the inner cylindrical part of the specimen, using a 7.62 cm drill core. Finally, the hollow samples are trimmed 1 cm at the top and bottom edges of the specimen to produce smooth surfaces. Figure 2 presents the coring process and the final specimen configuration.

2.2 *Main components of the HCT-HMA*

Besides the testing specimen, the HCT-HMA has four main components: 1) a conditioning chamber, 2) a load application system, 3) a displacement and loading measurement system,

and 4) a software that controls the aforementioned component to perform specific operations. The following sections describe each one of these components.

2.2.1 *Conditioning chamber*

The conditioning chamber of the HCT-HMA is comprised of a base that holds the specimens between two rigid plates, and a pressure-temperature container able to generate specific environmental conditions (Fig. 3a and b). These environmental conditions are obtained by controlling the magnitude of the temperature, relative humidity and air pressure; parameters that can be applied either independently or simultaneously. Additionally, the conditioning chamber was equipped with a lifting system that was designed to displace the pressure-temperature container vertically in order to open or close the chamber (Fig. 3c).

The conditioning chamber has different subsystems to control each environmental parameter. Thermal conditioning, for example, is achieved by means of a thermostatic-bath that allows water, at a specific temperature, to recirculate through a double wall located within the container. The bath capacity ranges from –14 to 175 °C.

The chamber also has the ability to create environments that promote oxidative aging in asphalt mixtures. The aging subsystem consists of the application of high air pressure to the inner and outer parts of the specimen. The maximum pressure that can be applied to the specimen is 2000 kPa (20 Bar), which is similar to the value used in the Pressure Aging Vessel (PAV) procedure [18].

Finally, a constant relative humidity condition can be obtained within the chamber using a vapour equilibrium technique. This technique consists of locating a vessel containing a saturated saline solution outside the chamber. Depending of the salt used, the solution creates a controlled relative humidity environment that is transmitted into the chamber using a peristaltic pump.

2.2.2 *Loading application system*

The axial and torsional loads are applied to the specimen using the loading application system presented in Figure 4. This system has two electric linear actuators able to apply 20 kN. The actuators consist of a load cell and an accurate roller screw mechanism that permits the application of heavy loads at high speeds.

The system of axial loading application comprises an axial actuator with a stroke length of 6.0 cm and a force capacity of 20 kN. On the other hand, torsional loading is applied through an actuator connected to a 30.0 cm arm that is fixed to the extension shaft. The torsional actuator can apply a maximum torque of 6 kN-m.

2.2.3 *Displacement and loading measuring system*

In order to measure, verify and control all the variables and parameters involved in the characterization process, the HCT-HMA has a sophisticated instrumentation system that can be

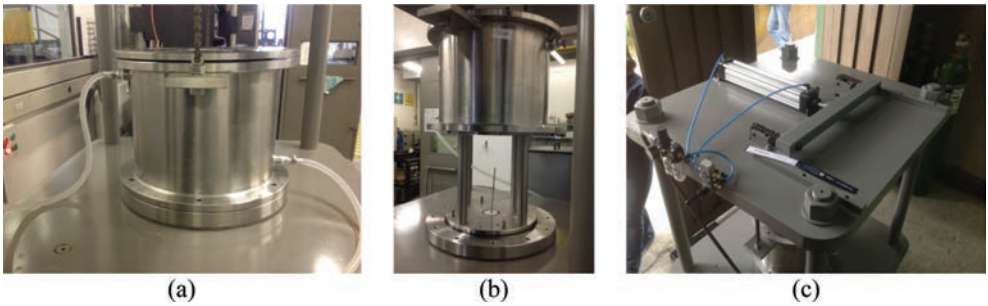

Figure 3. (A) HCT-HMA conditioning chamber, (b) base and pressure-temperature container in the highest position, and (c) lifting system.

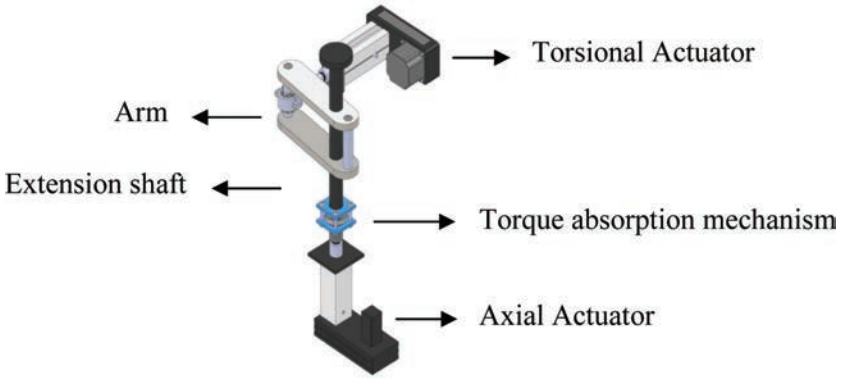

Figure 4. Loading application system.

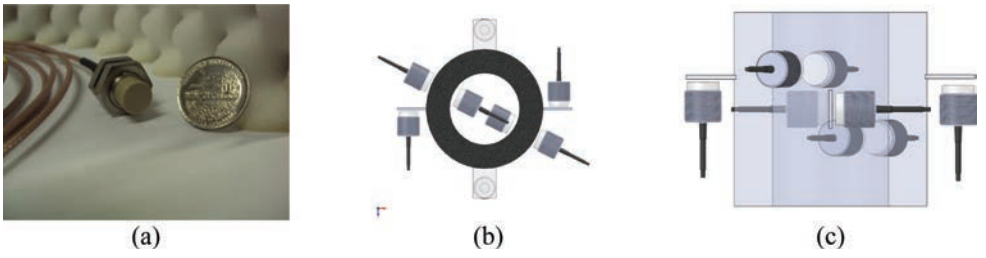

Figure 5. Positions of the displacement sensors: (a) eddy current displacement sensors, (b) top and (c) transverse view of the sensors located in the specimen.

divided into three components. The first component is in charge of measuring the specimen displacement, the second controls the environmental parameters and the last component is used to verify the magnitude of the applied loads.

The displacement measurement component consists of eight non-contact displacement sensors that use the eddy current principle (Waycon T3-G-KA with a precision of 0.006 mm). The displacement sensors are fixed at different points surrounding the specimen in accordance to the direction of measurements (Fig. 5). Thus, the axial strain is obtained using two sensors located at the top of the second third of the sample on either side (Fig. 5c). The measurement of the shear strain uses a similar technique. The difference in this case is the horizontal position of the sensors, since the radial displacement is measured in the inner and the outer walls of the sample by a pair of sensors that face each other.

The system designed to control the environmental conditions within the chamber and the testing specimen is composed by a couple of thermocouples (National Instruments 745691-01), moisture sensors (Honeywell HIH4602C) and pressure sensors (Futek QSH01450) (Fig. 6). These sensors are placed in the inner and the outer part of the specimen. The thermocouples are located in the walls of the sample to control the specimen's temperature, while the pressure and the moisture sensors are placed within the conditioning chamber to control the environment that surrounds the specimen.

Finally, two types of load cells are used to verify the magnitude of the load applied to the specimen. The applied axial load is measured using a "Pancake" load cell (Futek FSH01493). This cell has a maximum capacity of 22240 N and is able to resist tension and compression stresses. The applied torsional load is measured and verified using two "Tension-Compression" load cells (Futek FSH00711), based on the principle of a "pair of forces".

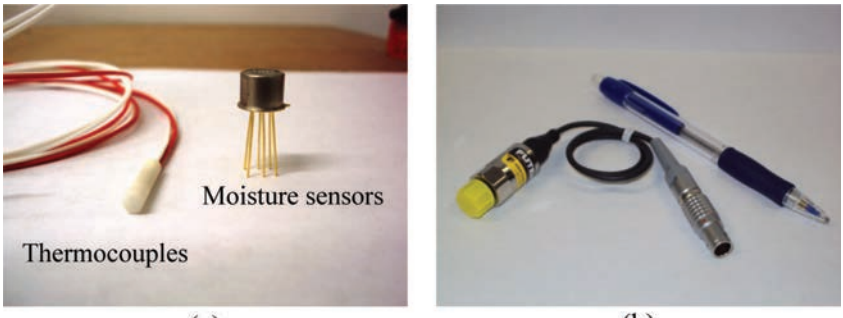

Figure 6. Components of the environmental control system: (a) thermocouples and moisture sensor, and (b) pressure sensor.

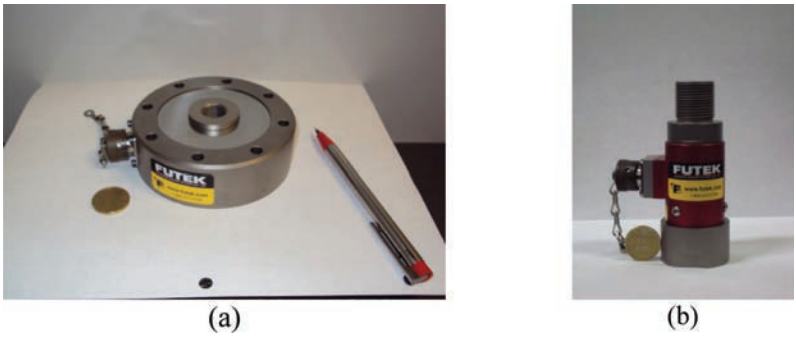

Figure 7. Load cells used to verify the axial and torsional loads: (a) pancake load cell, and (b) tension-compression load cell.

2.2.4 *Software to control the HCT-HMA*

As a complementary component of this equipment, a software was developed to enable communication between the HCT-HMA and the user. The HCT-HMA software was developed in the visual programming language "LabVIEW", and it contains four sections: 1) the "Settings" of the system, 2) the "Input Signal", in which the user can define the type of loading (e.g., cyclic axial load with certain amplitude and frequency) and the type of test (i.e., strain-controlled or stress-controlled), 3) the description of the "Previous Procedures" required before the experimental test initiates, and 4) the "Output Signal", in which the response of the material can be monitored in real time during the experiment.

3 POSSIBILITIES OF THE HCT-HMA

As observed in the previous sections, the HCT-HMA offers a wide range of possibilities for the characterization of HMA materials, as described in the following sections.

3.1 *Evaluation of viscoelastic properties of asphalt materials subjected to controlled environments*

Depending on the characteristic of the applied load, the HCT-HMA can be used to determine the linear and non-linear viscoelastic material properties of asphalt mixtures in the time and in the frequency domain (e.g., creep compliance, relaxation modulus and dynamic modulus).

Additionally, the use of the climatic chamber of the HCT-HMA enables the study of the influence of different environmental conditions (temperature, relative humidity, oxidative aging or a combination of them) on the viscoelastic properties of HMA materials.

3.2 *Evaluation of the performance and degradation of hot mix asphalt materials*

The HCT-HMA also provides the possibility to determine the fatigue life of asphalt mixtures and their susceptibility for permanent deformation. In the case of fatigue deterioration and failure, the equipment permits the characterization of this degradation process not only under the classical oscillatory axial stress/strain configuration, but also under oscillatory shear or torsional stress/strain. Besides, the equipment could be used to characterize the susceptibility of the material to permanent deformation using torsional shear stress configurations. In addition, the characterization of these deterioration processes using the HCT-HMA can be conducted under any defined environmental conditions. Thus, this machine can be used to evaluate the influence of environmental conditions on the performance and deterioration of the material (e.g., influence of moisture conditions or oxidative aging on the fatigue deterioration of asphalt mixtures).

4 CALIBRATION ACTIVITIES

Currently, the main structure of the HCT-HMA has been built, the components of the machine have been acquired, the task of verifying and calibrating the individual components of the machine has been finalized, and the assembling all the parts of the system has been completed. In terms of the verification of the HCT-HMA components, this task included the calibration of the load cells, the thermostatic bath, and the displacement, temperature, moisture and pressure sensors, among others activities. In the case of the thermostatic bath, for example, the calibration consisted of determining the maximum temperature that could be obtained within the conditioning chamber based on a temperature values assigned to the bath, as well as the time required for temperature stabilization within the chamber. Figure 8 presents the preliminary results of this calibration process.

Similarly, the operation of the load actuators, the capacity of the load cells to provide accurate values, and the correct response of the displacement sensors were also verified. In the case of the tension-compression load cell, for example, this was achieved by using a reference load cell and a servo-controlled press. The process consisted of applying a specific load using the servo press, verifying this load value with the reference load cell and comparing

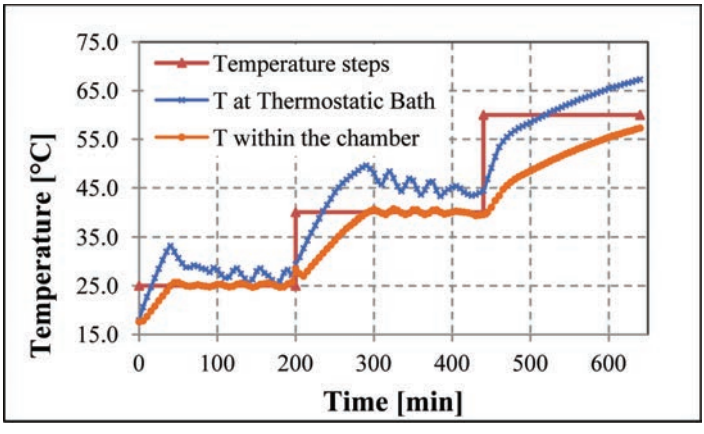

Figure 8. Calibration of the temperature at thermostatic bath and the temperature within the conditioning chamber.

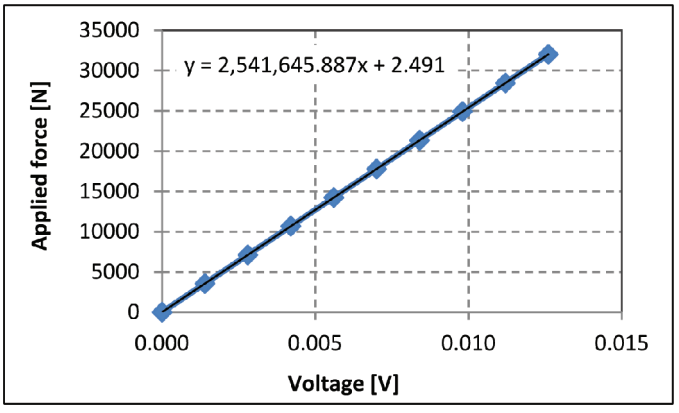

Figure 9. Calibration of the load cells (calibration parameters: K(N/V) = 2,541,645.8 and offset = 2.491 N).

it with the voltage values measured by the target cell. The final output of this procedure is the calibration constant (*K*) and its corresponding offset value, which in this particular case were defined as 2,541,645.8 N/V and 2.491 N, respectively (Fig. 9).

In the near future, several activities will be conducted on the recently assembled HCT-HMA to corroborate the proper operation of the machine. This includes, among others, checking the capacity of HCT-HMA to apply a requested load configuration, and verifying if the device can accurately measure the response of the specimen and capture this information using the developed software. Besides, it would be necessary to compare the results of the HCT-HMA machine with those obtained from standardized tests; for example, the dynamic modulus will be determine using both the HCT-HMA and the MTS testing system, in order to calibrate the testing procedure. Only after accomplishing these activities, it would be possible to design different experimental plans to conduct advance characterization of asphalt mixtures that, as mentioned previously, would include the relationship between the environment and the mechanical response of these materials.

5 CONCLUSIONS

This paper describes a new machine named "Hollow Cylinder Tester for HMA materials" or HCT-HMA. The machine counts with a versatile loading system and a sophisticated conditioning system that will improve the current testing possibilities to characterize asphalt mixtures. Among other characteristics, the HCT-HMA could be used to determine linear and non-linear viscoelastic properties and deterioration process of asphalt mixtures (e.g., fatigue and permanent deformation) that are subjected to a variety of environmental conditions and a wide range of stress paths (axial and/or torsional loads). Thus, the HCT-HMA will provide information regarding the role of different environmental parameters (i.e., temperature, relative humidity and air contact) in the deterioration of the HMA properties.

Currently, the calibration of most components of the machine (load application system, load verification system and environmental sensors) has been finalized, as well as the assembly of these components into the structure of the machine.

It is expected that the Hollow Cylinder Tester for Hot Mix Asphalt will became an efficient tool to achieve a more comprehensive characterization of the behaviour of this material.

ABSTRACT: This paper presents the details of a study conducted to evaluate rutting and cracking potential of mixes consisting of Reclaimed Asphalt Pavements (RAP). Texas (Type B) and Indian (DBM-2) mix specifications were reviewed and a mix design that meets both specifications was selected for evaluation purpose. Hot mix asphalt specimens consisting of 0%, 15%, 25% and 35% RAP were prepared in the laboratory using PG64-22 asphalt as a virgin binder. Design binder content of mix was estimated by conducting Superpave volumetric mix design. Performance of mixes was evaluated using dynamic modulus test, Hamburg wheel tracking device, and Texas overlay test. In addition, binder tests such as multiple stress creep recovery, linear amplitude sweep test and Complex modulus were performed on virgin as well as reclaimed binders to identify the influence of virgin and reclaimed binders on mix performance. Laboratory test results suggest that addition of RAP enhances rutting resistance in comparison to conventional mixtures, while cracking/fatigue resistance deteriorated. The results indicated that fatigue/cracking potential should be the governing factor in the selection of optimal percentage of RAP.

Keywords: Reclaimed Asphalt Pavement, fatigue, Texas overlay tester, binder rheology

1 INTRODUCTION

Reclaimed Asphalt Pavement (RAP) is asphalt concrete that has been removed from an existing pavement and is generally subjected to some degree of long-term aging as well as traffic loading. RAP can be recycled into new mixture by heating and mixing with virgin aggregate and asphalt binder. The recycling process can be conducted at conventional hot mix temperatures. The use of Reclaimed Asphalt Pavement (RAP) has become more prevalent with the rising cost of virgin materials and with the recent emphasis being laid on developing more environment friendly and sustainable roadways. Some studies [1–3] have shown that the percentage of RAP has a significant effect on the performance of asphalt mixture with RAP. To perform well in the field, the asphalt concrete overlay mixture must be both rut and reflective crack resistant. Thus, both rutting and reflective cracking must be considered during the mixture design. For the surface layer, rutting in the presence of moisture is the main concern, which has been successfully addressed in Texas using the Hamburg Wheel Tracking Test (HWTT). Though generally considered to be secondary to rutting in terms of its effect on performance, it is necessary that the issue of reflective cracking is given due consideration. The Overlay Tester is recommended for this issue in Texas. This paper presents the details of a study conducted to evaluate rutting and cracking potential of mixes consisting of Reclaimed Asphalt Pavement (RAP) material.

2 OBJECTIVE AND SCOPE

2.1 *Objective*

The main objective of this study is to evaluate the impact of RAP content on the properties of the final mixes in terms of resistance to rutting and fatigue cracking.

2.2 *Scope*

In this study, Texas (Type B) and Indian (DBM-2) mix specifications were reviewed and a mix design that meets both specifications was selected for evaluation purpose. Hot mix asphalt specimens consisting of 0%, 15%, 25% and 35% RAP were prepared in the laboratory using PG64-22 asphalt as a virgin binder. Design binder content of mix was estimated by conducting Superpave volumetric mix design. Performance of mixes was evaluated using dynamic modulus test, Hamburg wheel tracking device and Texas overlay tester. Rheological tests such as Dynamic Shear Rheometer, Multiple Stress Creep Recovery and Linear Amplitude Sweep Test were performed on PG64-22 and recovered binders to evaluate the influence of virgin and recovered binders on asphalt mixes.

3 MATERIAL CHARACTERISATION AND MIX DESIGN

3.1 *Virgin materials*

A single source of aggregate was used for this research. PG64-22 grade binder was used as virgin binder. Binders were aged as per SHRP protocols of short term and long term aging [4]. Dynamic Shear Rheometer (DSR) testing was completed on the virgin binder according to AASHTO TP5-93 [5]. The DSR testing produced rheological properties for the binders including and phase angle (δ). Master curves were developed for the complex modulus (G*) parameter using the results of rheological tests conducted using DSR on binders at different temperatures and frequencies.

Bending Beam Rheometer (BBR) testing was carried out on the virgin binder according to AASHTO T 313-09 [6] and creep stiffness (S) and slope (m) were determined. Tables 1 and 2 contain the rheological data obtained from the DSR and BBR tests respectively. The Performance Grade (PG) of the binder was confirmed according to AASHTO R-29 "Standard Practice for Grading or Verifying the Performance Grade of an Asphalt Binder" [7].

3.1.1 *Multiple stress creep recovery test*

The Multiple Stress Creep Recovery (MSCR) test is the latest development to the Superpave Performance Graded (PG) Asphalt Binders specification. Using the Dynamic Shear

PG64-22	148	0.301

Rheometer (DSR), a one-second creep load is applied to the asphalt binder sample. After the 1-second load is removed, the sample is allowed to recover for 9 seconds. The test is started with the application of a low stress (0.1 kPa) for 10 creep/recovery cycles after which the stress is increased to 3.2 kPa and repeated for an additional 10 cycles. The material response in the MSCR test is significantly different than the response in the existing PG tests. In the PG system, the high temperature parameter, G*/sinδ, is measured by applying an oscillating load to the asphalt at very low strain. Due to the low strain level, the PG high temperature parameter does not accurately represent the ability of polymer modified binders to resist rutting.

In the MSCR test, higher levels of stress and strain are applied to the asphalt, better representing the condition which occurs in pavements. By using higher levels of stress and strain the MSCR test captures not only the stiffening effects of the polymer, but also the delayed elastic effects. Results of MSCR test conducted on virgin PG64-22 binder are given in Table 3.

3.2 *RAP materials*

The RAP material was collected from Jobe mix plant, El Paso, TX. The basic tests conducted include the gradation, binder content and specific gravities. Table 4 shows RAP gradation. The binder from the RAP was extracted as per ASTM D 2172 [8]. The Rotavapor method was used to recover the binder from the solvent as per AASHTO T170 [9]. Average binder content in the RAP was found to be 4.2% (by weight of mix).

DSR test was conducted on the binder extracted from RAP. Test results are given in Table 5.

3.2.1 *Linear amplitude sweep test*

Linear Amplitude Sweep (LAS) test indicates the ability of asphalt binders to resist fatigue damage due to cyclic loading. The amplitude sweep test was conducted on PAV-aged virgin and RAP binders using dynamic shear rheometer at intermediate temperatures identified corresponding to a G*Sinδ value of 5000 kPa. The intermediate temperatures have been identified as 16°C and 22°C respectively for virgin and RAP binders.

Frequency sweep was performed at constant amplitude of 0.1% over a range of frequencies varying from 0.1 to 30 Hz. Complex modulus and phase angle were recorded at each frequency. Amplitude sweep was also run at the intermediate temperatures using oscilla-

tory shear at constant frequency of 10 Hz. Amplitude was varied from 0.1% to 30% [10]. Table 6 shows the Binder fatigue model parameters.

The binder fatigue performance parameter Nf can be estimated as

$$Nf = A(\gamma_{\max})^{-B} \tag{1}$$

where $\gamma_{\max}$ is the maximum expected binder strain for a given pavement structure and A and B are empirical coefficients derived from LAS test data. A and B values obtained for virgin, recovered binders (both PAV-aged) and at various RAP contents from are given in Table 6. From the results it shows that fatigue life of binder increases up to 25% RAP content.

3.3 *Development of master curve for DSR parameters*

The rheological nature of bituminous binders over wide temperature and frequency ranges can be characterized by Time-Temperature Superposition (TTS) [11]. TTS is the procedure of shifting of the test data collected at different temperatures to frequencies that correspond to a reference temperature, so that various curves can be aligned to form a single master curve applicable for a reference temperature.

In the present study, Williams-Landel-Ferry (WLF) relationship [12] given as Eq. (2) was used to estimate the shift factors.

$$\log f_{red} - \log f = \log \alpha_t = -\frac{C_1(T - T_{ref})}{(C_2 + T - T_{ref})} \tag{2}$$

where, f_{red} is the reduced frequency (Hz) at which the master curve should be read, f is loading frequency (Hz), T is the experimental temperature, T_{ref} is the reference temperature for which master curve is developed and C_1 and C_2 are empirical constants.

Master curve can be developed using different models. For low and intermediate temperatures, a generalized power law is suitable to describe the frequency dependant behavior of bituminous materials [13]. For a full temperature range, a sigmoidal fitting function is considered to be more appropriate [14]. In the present study, sigmoidal function, represented by Eq. (3), was used to develop the master curve for G* [15].

$$\log|G^*| = \delta + \frac{\alpha}{1 + e^{\beta - \gamma \log f_{red}}} \quad (3)$$

where, δ is minimum complex modulus, $\delta + \alpha$ is maximum modulus or span of the data, β and γ are respectively the location and slope steepness parameters of the sigmoidal curve, f_{red} is the reduced frequency obtained from shift factor (Eq. 2) and test frequency.

The experimental data was analysed using solver function of Excel spreadsheet to determine the values of C_1, C_2, α, β, γ and δ used in the Equations 2 and 3. The reference temperature was chosen to be 64°C. This temperature was selected to correspond to a high service temperature. Figure 1 shows the sigmoidal fit for PG64-22 binder.

3.4 *Asphalt concrete mix design*

Virgin aggregate, RAP and Virgin binder were collected from Jobe plant in El Paso. The asphalt content in the RAP was found to be 4.2%. Texas (Type B) and Indian (DBM-2) aggregate gradations were reviewed and a gradation that meets both specifications was selected for evaluation purpose. The gradation is shown in Figure 2. Mix specimens were prepared with

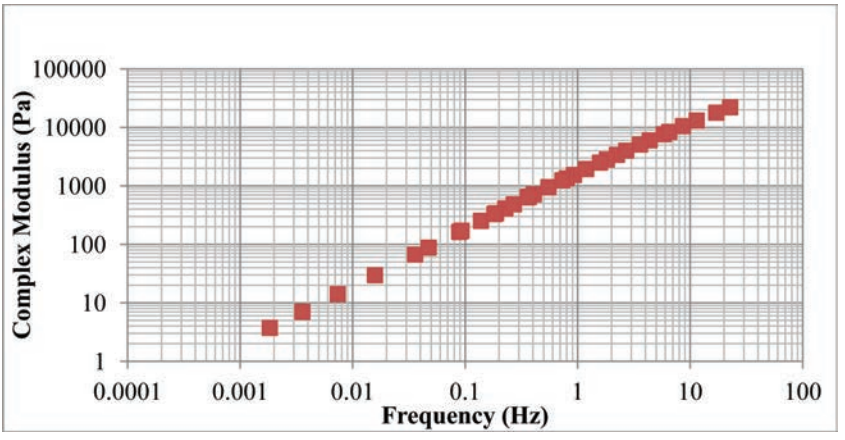

Figure 1. Complex modulus master curve for un-aged PG64-22.

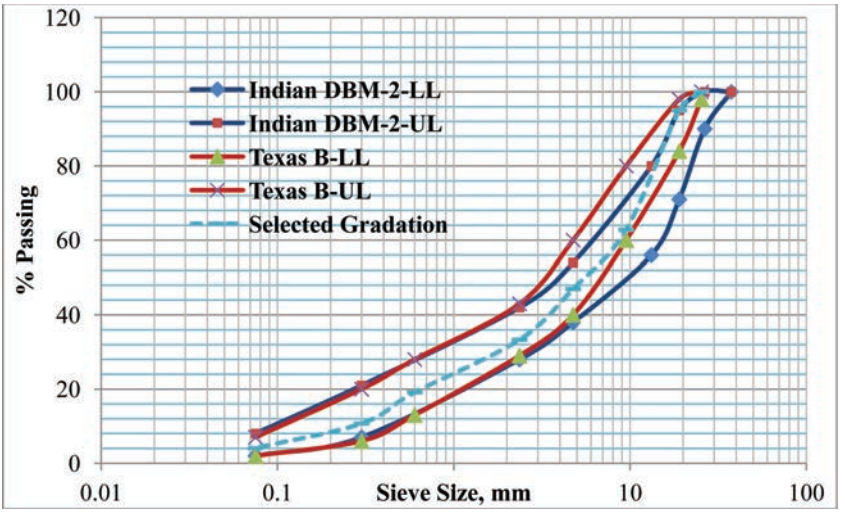

Figure 2. Selected aggregate gradation.

Table 7. Mix design parameters.

Mix type	OBC (%)	% binder replacement	VMA (%)	VFA (%)	Dust proportion
0% RAP	4.6	0	14.4	72	0.96
15% RAP	4.4	14.3	14.3	72.5	1
25% RAP	4.3	24.3	14.05	71	1.05
35% RAP	4.25	34.5	14.4	72	1.1

0, 15, 25 and 35% RAP content. A design compaction effort (design number of gyrations, N_{design}) of 50 was selected.

Virgin aggregates were batched by individual sieve size and heated at the mixing temperature for a minimum of 4 h before mixing. The RAP was batched as a stockpile and heated at the mixing temperature for 2 h before mixing. The RAP stockpile was heated for less time so that the RAP stockpile attained compaction temperature while minimizing aging of binder. The asphalt, aggregates, and RAP were mixed in a bucket mixer, short-term aged at the compaction temperature for 2 h, and then compacted using a Superpave Gyratory Compactor (SGC). After compaction, the bulk specific gravity of all specimens was measured using a Corelok vacuum sealing system according to ASTM D6752 (16). Design binder contents were selected to yield design air void content of 4% and to satisfy other volumetric parameters such as Voids in Mineral Aggregates (VMA) and Voids Filled with Asphalt (VFA) as per the Superpave mix design specifications (SP 2) [4]. Table 7 gives the mix design parameters for each of the RAP contents.

4 PERFORMANCE CHARACTERISTICS

4.1 *Dynamic modulus*

For linear viscoelastic materials, the dynamic modulus is defined by the stress-strain relationship under continuous sinusoidal loading. Temperatures, rate of loading, age, and mixture characteristics (i.e. binder stiffness, binder content, air voids, and aggregate gradation) are all factors that affect the dynamic modulus values of asphalt concrete. By applying a uniaxial sinusoidal load to a specimen and measuring the strain, the dynamic modulus of asphalt concrete can be calculated

$$E^* = \sigma/\varepsilon \tag{4}$$

σ = peak maximum stress
ε = peak maximum strain

The dynamic modulus test is conducted over a range of temperatures and frequencies. The Mechanistic-Empirical Pavement Design Guide—MEPDG (17) recommends performing the test at the following temperatures: –10°C, 4.4°C, 21.1°C, 37.8°C, and 54.4°C. For each temperature, the following frequencies should be tested: 25 Hz, 10 Hz, 5 Hz, 1 Hz, 0.5 Hz, and 0.1 Hz. The properties that are obtained from this test provide insight into the viscous properties of the material and can be correlated with in-service rutting measurements.

Individual dynamic modulus master curves for each group of samples are used as raw data to construct the master curves. An Excel Solver was used to develop master curves. Figure 3 shows the master curves for different asphalt concrete mixtures.

4.2 *Rutting characteristics*

The effect of high RAP content and production parameters on the rutting susceptibility of the mixtures was evaluated in accordance with AASHTO T324 'Hamburg Wheel-Track Testing of Compacted Hot-Mix Asphalt (HMA)' (18). Gyratory specimens were fabricated from loose lab-produced mixture to an air void level of 7.0 ± 1.0% as required by AASHTO T324.

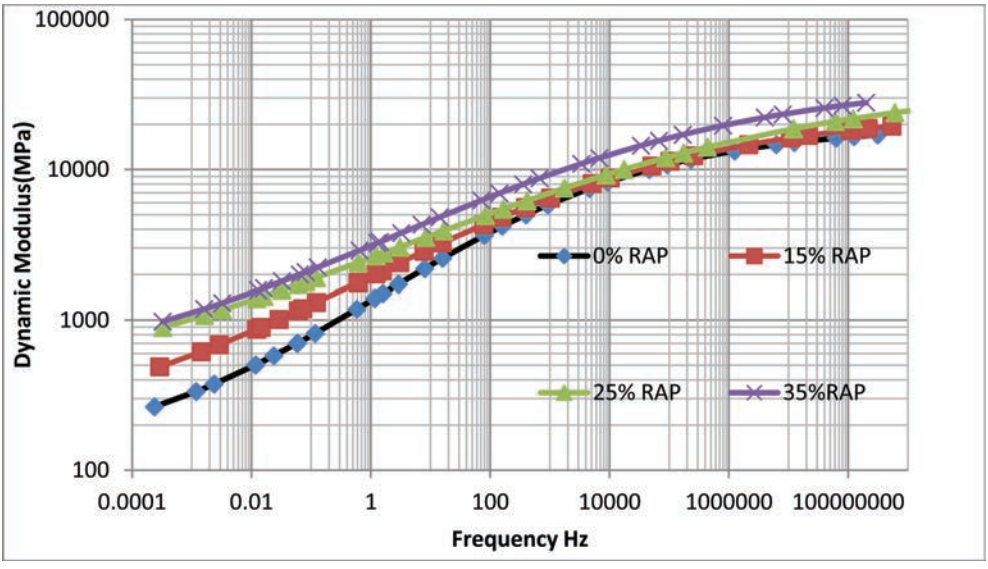

Figure 3. Dynamic modulus master curves.

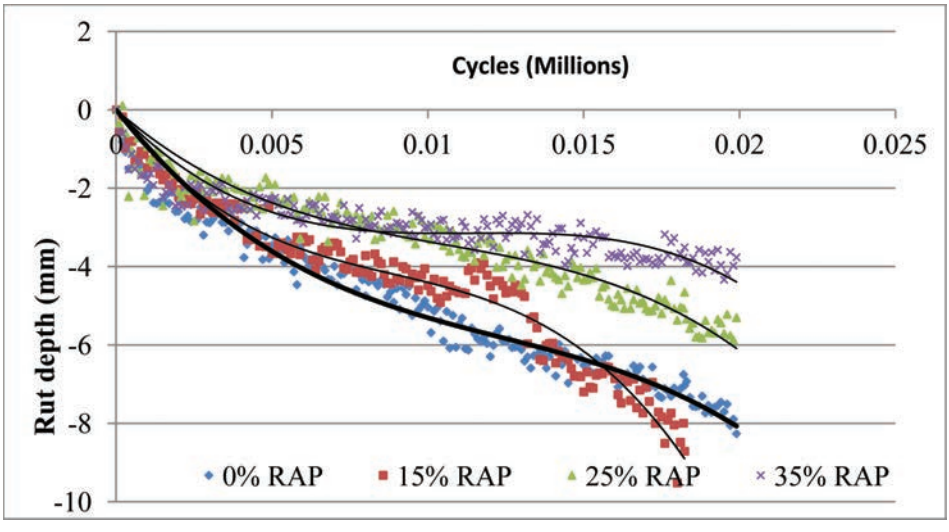

Figure 4. Rut test results at 50°C.

Testing in the HWTT was conducted at a test temperature of 50°C. Testing terminated at 20,000 wheel passes. Rutting potential of the mixes decreased as the amount of RAP in the mixture increased. Figure 4 shows the variation of rut depth with number of load passes.

4.3 *Fatigue characteristics*

Reflective cracking susceptibility of mixes with and without RAP was evaluated using the Texas Transportation Institute (TTI) Overlay Tester which was designed by F.P. Germann and R.L. Lytton in the late 1970's to simulate the opening and closing of joints or cracks. The device is a computer-controlled electrohydraulic system that applies repeated direct tension loads to HMA specimens. The machine features two steel blocks, one is fixed and the

other slides horizontally. The sliding block applies tension in a cyclic triangular waveform to a constant maximum displacement of 0.025 inches. The sliding block reaches the maximum displacement and then returns to its initial position in 10 seconds. Testing is performed at a constant temperature of 77 ± 3°F. This test method measures the number of cycles to failure. The overlay tester can be run on standard size samples, typically 6 in (150 mm) long by 3 in (75 mm) wide by 1.5 in (38 mm) high. These specimens can be prepared from either field cores or from Superpave Gyratory Compactor (SGC) molded specimens. During OT testing, the measurable parameters include the applied load, opening displacement, time, number of load cycles, and test temperature. All these data are automatically recorded in the computer attached to the OT machine as an Excel spreadsheet. The primary output of the OT test is the crack-resistance potential of an HMA mix, which is essentially quantified in terms of the number of cycles for the sample to fail (i.e., 93 percent drop of the first cycle peak load).

Fatigue test results are given in Figure 5. As different layers in the overlay have different critical issues, it is appropriate to set different criteria for each. Based on the substantial overlay tester results, TxDOT's specification on the HWTT [19], the preliminary criteria for the overlay tester and the HWTT, are presented in Table 8.

HWTT tests showed that rutting resistance increased with RAP percentage in the mix. However, the Texas overlay tester suggests that fatigue life will decrease with increase in RAP content. Based on data obtained from RAP mixtures, it is concluded that the maximum percentage of RAP is approximately 20% without the addition of rejuvenating agent. Fatigue life of binder increases up to 25% of RAP from LAS test, were results are shown in Figure 6.

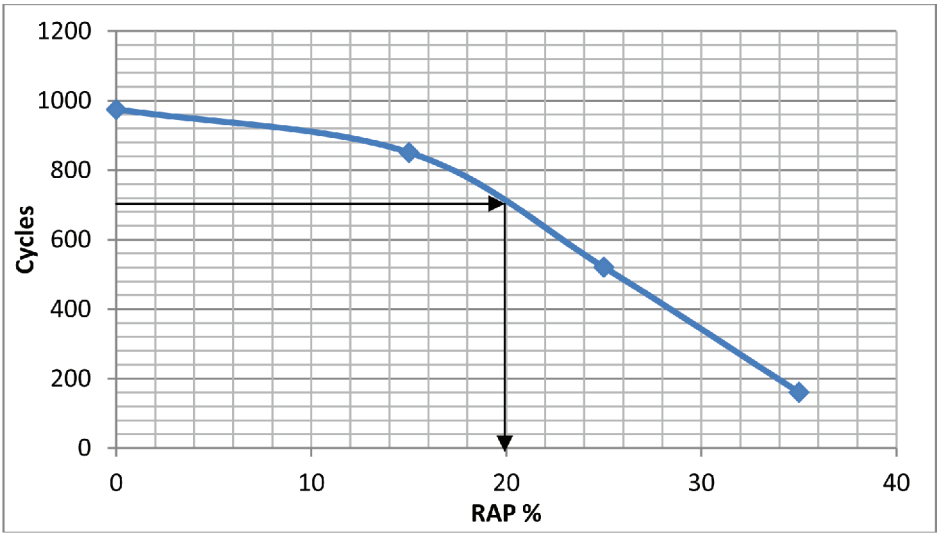

Figure 5. Variation of fatigue life with RAP content.

Table 8. Preliminary criteria for asphalt overlay mixtures.

Tests	Indicator	Bottom layer	Top layer
Overlay Tester @ 77 °F (25 °C) and 0.025 in opening	Reflective cracking life	750 cycles, min.	300 cycles, min.
HWTT @ 50 °C	Rut Depth (RD)	N/A	PG64-22, RD@10,000 < 12.5 mm PG70-22, RD@15,000 < 12.5 mm PG76-22, RD@20,000 < 12.5 mm

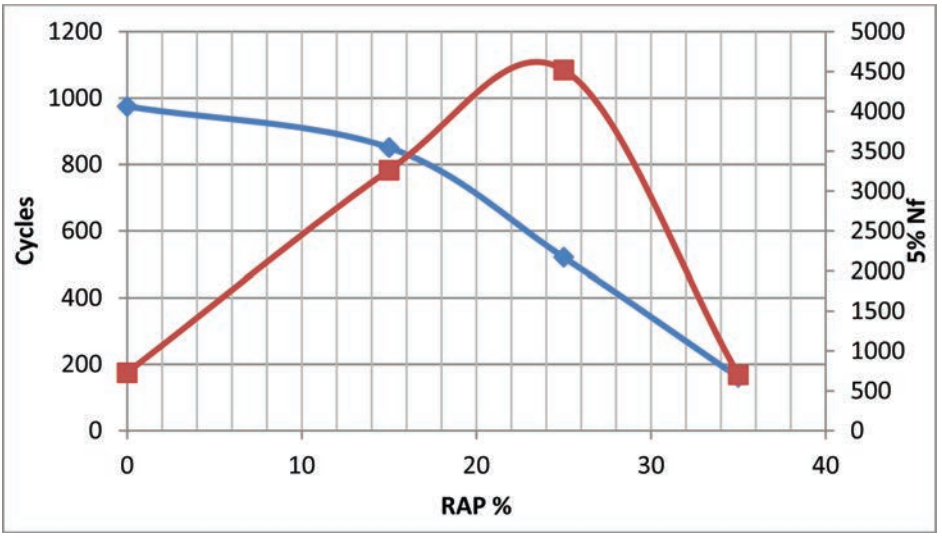

Figure 6. Fatigue life variations in binder and mix with RAP content.

5 CONCLUSIONS

The main objective of this work was to examine the effect of addition of RAP on the fatigue and rutting performance of asphalt mix. The significantly higher G*/Sinδ values of the binder extracted from RAP compared to those of virgin binder suggest that addition of RAP will improve the rutting performance of the mix. The higher dynamic values and the significantly better rutting performance of mixes with RAP determined using HWTT also prove the highly beneficial effect of adding RAP to reduce rutting in asphalt mix.

The relatively larger G*Sinδ values of RAP binder compared to those of virgin binder indicate that mixes with RAP are expected to have inferior fatigue performance. Linear amplitude sweep test results obtained for virgin and RAP binders show that mixes with RAP will have inferior fatigue performance for larger bending strains. Overlay tester results reveal that addition of RAP is likely to reduce the fatigue of the mix. 20% RAP appears to be an appropriate RAP content to be added to the mix from fatigue consideration.

Workability of WMA and WMA-RAP mixtures and relationship to field compaction

Mariely Mejias-Santiago, Jesse D. Doyle & John F. Rushing
U.S. Army Engineer Research and Development Center, Vicksburg, MS, USA

ABSTRACT: The terms workability and compactability have been applied to asphalt mixtures to describe the relative ease with which material can be placed, hand worked, or compacted. A number of methods described in literature have been investigated to quantify this parameter, including devices that measure the torque required to rotate a mixing paddle through a sample of asphalt mixture. An improved workability measurement device based on that concept is described in this paper. Data collected with this device for seventeen mixtures are presented. The mixtures included both Hot Mix Asphalt (HMA) and Warm Mix Asphalt (WMA). WMA was produced with Sasobit® additive, Evotherm™ 3G additive, and by asphalt binder foaming. Reclaimed Asphalt Pavement (RAP) contents of 25 and 50% were also investigated for HMA and WMA. Four of the mixtures without RAP, including HMA and one of each WMA, were produced at an asphalt plant and placed into test strips with full scale construction equipment. Compaction of the pavement mat was monitored by embedded thermocouples, and nuclear density gauge measurements were taken between successive roller compactor passes. The relationship between laboratory measurement of workability and the relative ease of field compaction is investigated.

Keywords: Warm Mix Asphalt, WMA, RAP, workability, compactability

1 INTRODUCTION

The workability of asphalt mixtures is related to the compaction properties of the mixture. The same material properties that affect the compaction characteristics of a mix also affect its workability. Workability of asphalt mixes has been defined by Celik and Atis [1] as the property that allows producing, handling, placing, and compacting a mixture with the minimum application of energy. It can also be thought of as a mixture's resistance to shear in an unconfined condition once movement of mix particles has been initiated. Workability can be defined from a field perspective as the asphalt mixture property that describes the ease with which the asphalt mixture can be placed, worked by hand, and compacted to the desired density [2]. Workability is affected by both aggregate properties and binder properties [3]. While the workability of asphalt mixtures is an important property in the construction of Hot Mix Asphalt (HMA) pavements, it has not been widely studied.

The primary purpose of this paper is to present test results from an asphalt mixture laboratory workability test device and to investigate its relationship to field compactability for HMA and Warm Mix Asphalt (WMA) mixtures. The secondary purpose of this paper is to investigate the laboratory workability of HMA and WMA mixtures containing 25 and 50% Reclaimed Asphalt Pavement (RAP).

2 LITERATURE REVIEW

One of the earliest laboratory studies of hot mix workability was conducted by Marvillet and Bougault [4]. They developed a device to measure workability of asphalt mixtures in the

laboratory. The device consisted of a heated and insulated testing chamber which held the hot mix and a mixing paddle that was inserted into the mix. The mixing paddle was rotated at a constant angular velocity, while the resistance of a spring was measured. The spring resistance was converted to a workability value that could then be used to compare mixture's relative workability. This measurement was then repeated at a series of temperatures to investigate the temperature dependence of the workability measurements. The workability value was defined such that as viscosity decreased and temperature increased, the workability value for the mixture would increase. The research results indicated that the workability measurements were strongly dependent not only on temperature and binder viscosity but also on aggregate shape (angularity) and particle size distribution (gradation) [4]. An increase in the filler content decreased the workability as well. Asphalt content was not found to significantly affect the measured workability values.

A study conducted by Gudimettla et al. (2003) expanded on the work of [4] in developing a device to measure asphalt mixture workability. The introduction of the Superpave mix design procedure and increased use of polymer modified binders reinforced the need for quantitative laboratory measurement of asphalt mixture workability. The researchers developed a prototype workability meter based on the designs of [4]. A workability index was determined from measurements of the torque required to rotate a paddle at constant speed (15 rpm) in a mixture sample. Data were collected for a range of temperatures as the sample was allowed to cool. The results indicated similar trends to the work previously done by [4]. Aggregate type was found to significantly affect the workability of mixtures; aggregate with high angularity exhibited lower workability values than semi angular aggregates. Workability was found to increase as the Nominal Maximum Aggregate Size (NMAS) was decreased. Mixtures made with polymer-modified PG 76-22 binder demonstrated significantly lower workability values than mixtures produced with neat PG 64-22 asphalt binder. Temperature also significantly affected workability values. Gudimettla et al. [3] suggested that the workability device they developed could be used to determine laydown and compaction temperatures for mixtures made with polymer modified asphalt binders but were unable to draw significant conclusions on what those temperature ranges should be based on the available data.

One purported benefit of WMA is the increased workability at lower (and at conventional) compaction temperatures. Bennert et al. [2] evaluated different methods to quantify workability for WMA. Of the six methods investigated (three binder and three mixture), the most rational rankings of data were obtained by binder lubricity testing, workability measurements with an Asphalt Workability Device (AWD) similar to the device developed by [3], and air voids of Marshall compacted specimens. Howard et al. [5] investigated workability of HMA and of mixtures with foamed asphalt and Evotherm™ 3G made at HMA temperatures. Workability was evaluated by the AWD on reheated samples of plant produced mixture. Results indicated that there was initially little difference in the mixtures, but that the mixture with Evotherm™ 3G additive remained more workable than the others after an extended haul time. Wang et al. [6] found the workability of WMA mixtures to be better than that of HMA and suggested that mixing and compaction temperatures can be established based on ranges of workability torque.

An additional purported benefit of WMA is the ability to improve workability for mixtures containing RAP. For a given virgin binder grade and mixing temperature, the addition of RAP generally decreases mixture workability [7, 8]. Austerman et al. [9] evaluated workability of WMA containing 10 to 25% RAP and observed improved workability with respect to HMA. Other researchers [10, 11] have evaluated workability of 100% RAP mixtures with WMA additives for in-place recycling applications and found improved workability relative to mixtures without the WMA additives.

3 EXPERIMENTAL PROGRAM

3.1 *Mixtures tested*

The asphalt mixtures used in the study consisted of an aggregate blend designed to meet Job Mix Formula (JMF) gradation requirements for a 12.5 mm nominal maximum aggregate size

mixture according to Unified Facilities Guide Specification 32-15-15.13, "Hot Mix Asphalt for Airfields". The aggregate blends used in this study are summarized in Table 1. The aggregate sources and blend used for the field produced mixtures (Gradation 1) were selected based on materials available for plant production. The base binder for all mixtures was PG 67-22 from a single refinery. Sasobit® was added at a rate of 1.5% of virgin binder mass and Evotherm™ 3G was added at a rate of 0.5% of virgin binder mass. Water added during foaming was 2% of binder mass and was not considered part of the binder mass for calculation of asphalt content. Asphalt mixtures were designed using 75 gyrations in a Superpave gyratory compactor to achieve 4.0% air voids. Additional mixture details are provided in [12, 13].

3.2 *Field compaction*

Data from full-scale field tests of ongoing research studies were used to evaluate field compaction of one HMA and three WMAs. The pavement structure consisted of 100 mm of asphalt concrete over 250 mm of limestone base course with a California Bearing Ratio (CBR) of 100 over a 300-mm-thick clay-gravel subbase course with a CBR of 30. The subgrade was high-plasticity clay and had an average CBR of 15. The test item was 15.2 m long and 3.7 m wide.

Asphalt for the full-scale tests was produced by APAC Mississippi, Inc. from a local drum mix plant in Vicksburg, MS, and delivered to the construction facility. Samples of the mixtures were collected from elevated platforms at the plant to verify that the mix design had been achieved. Plant production temperatures for the HMA and WMA were 143 °C and 121 °C, respectively.

The asphalt concrete pavement layer was constructed on a prepared crushed limestone base course using conventional paving equipment in two 50-mm lifts. The asphalt layer was placed with a Caterpillar AP655D asphalt paver. Breakdown rolling was performed using

a Caterpillar CB-534D XW vibratory steel-wheel asphalt compactor. An Ingersol Rand PT125R pneumatic roller was used for intermediate rolling. The steel-wheel roller with no vibration was used for finish rolling. A CRS-2 asphalt emulsion tack coat was applied between lifts. In-place volumetric properties are provided in the descriptions of each full-scale test. The average volumetric properties of the asphalt layer were determined from ten 100-mm-thick cores.

The asphalt mixtures were monitored during placement and compaction to determine the compaction behaviour. Data collected during these processes included temperature of the mixture during paving and compaction, density of the asphalt layer during compaction using a nuclear density gauge, and the number and type of roller passes required to achieve adequate mat density.

3.3 *Workability testing*

Mixture workability was evaluated using the Prototype Workability Device shown in Figure 1. This device was built specifically for this project by Instrotek, Inc., in Riley, NC, based on the work of [3]. The method consists of immersing a paddle into a sample of loose asphalt mixture and measuring the torque required to keep the paddle rotating at a constant speed within the sample. Workability is defined as the inverse of the measured torque.

The paddle configuration used had a roller attached to the shaft to push down the material that the auger normally moves up during the mixing process (Fig. 1). This configuration showed continuous sample remixing and did not create a shear plane through the mixture. A shear plane created within the sample would show a consistent workability (torque) over a given temperature range because of a lack of resistance [3]. This paddle configuration also

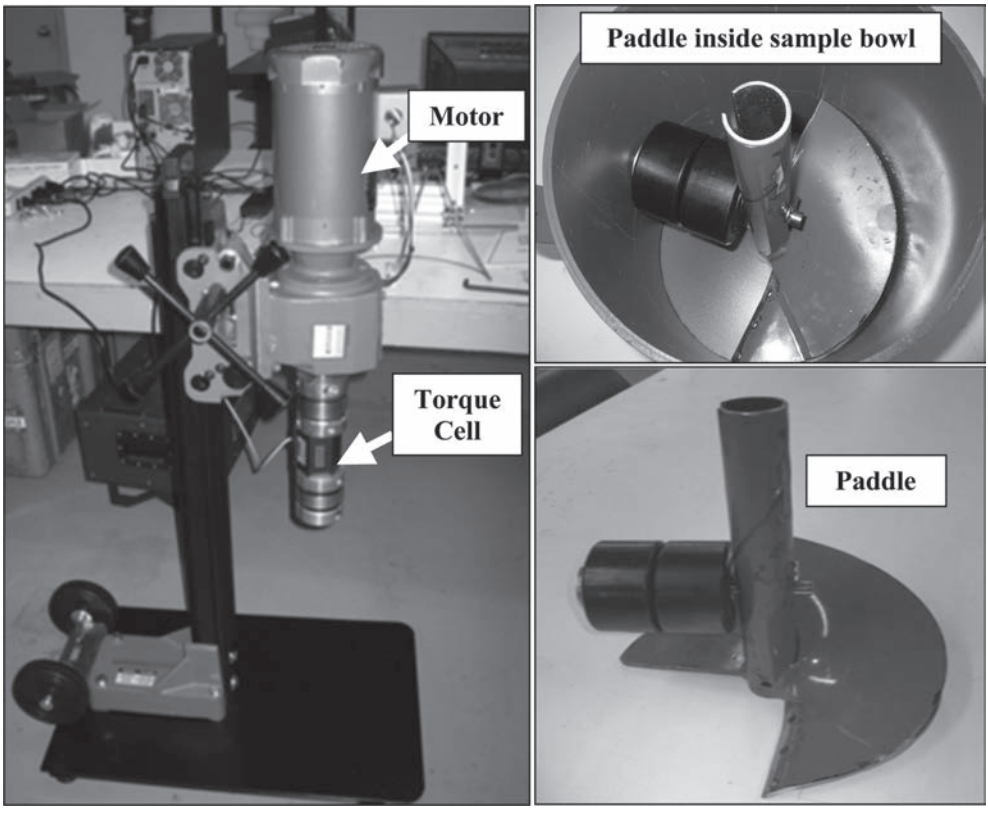

Figure 1. Prototype workability device.

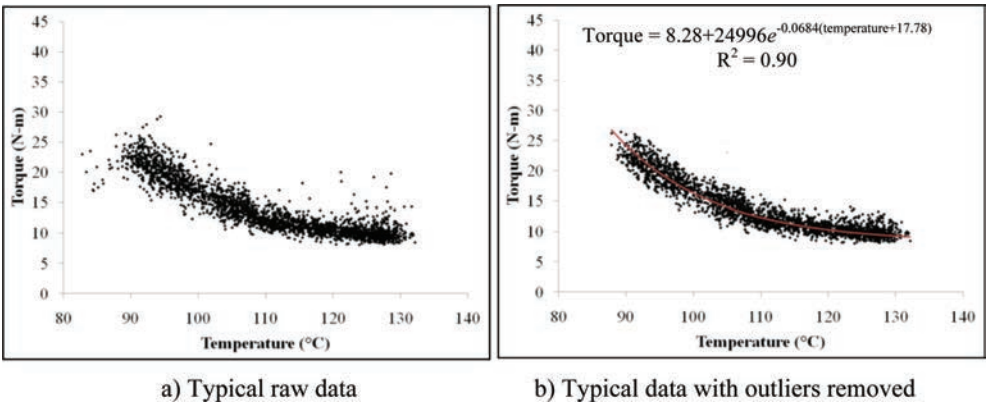

Figure 2. Typical data reduction from workability test.

provided a consistent temperature throughout the sample, and no aggregate breakage was observed. The sample bowl used was 25 cm in diameter and 28 cm deep and it is shown in Figure 1 with the paddle inserted.

For workability testing, two 11 kg samples per mixture were tested, and results were averaged to be used for comparisons. Laboratory-produced mixtures were prepared at a standard mixing temperature of 160 °C for HMA and 130 °C for WMA. For consistency, the field produced mixtures were reheated in the laboratory at the same temperatures prior to testing. For each test, the bowl and the paddle were heated to the corresponding mixing temperature. Each sample was placed into the bowl with the paddle already inserted inside the bowl, since the paddle configuration used did not allow for the opposite procedure of inserting the paddle in the sample mixture. The device was set to a constant rate of paddle revolution of 15 rpm as recommended by [3]. This rate was considered reasonable to produce a wide range of torque (workability) for the temperature range tested. Mixture temperature was measured using a miniature infrared sensor attached to the device. Torque and temperature were monitored and recorded continuously at a data collection rate of 48 Hz using a program written in National Instruments' Labview program.

Data reduction was performed using regressions between torque and temperature and evaluating standardized residuals for each test to identify outliers. Regressions were of the exponential form given in Eq. (1). Where: *Torque* = torque required to rotate the paddle, N-m; *Temperature* = mixture temperature, °C; and *a, b, c* = regression constants.

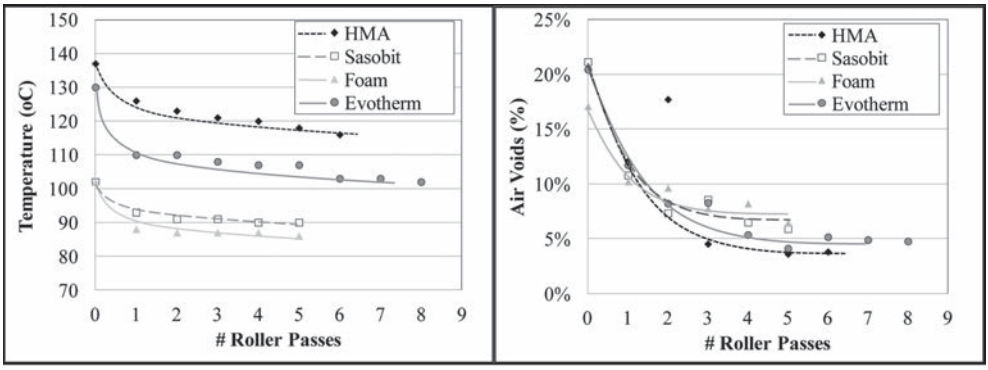
$$Torque = a + be^{-c(temperature+17.78)} \quad (1)$$

Figure 2 shows an example of the typical raw data from the workability device and the final data and regression model without outliers. The regression analysis and the identification of outliers through evaluation of standardized residuals were performed using the software Table Curve 2D. Once the data from each test were analysed, the final regression models of the two samples per mixture were averaged and used to compare the workability of the different mixtures.

4 RESULTS

4.1 *Field compaction*

Figures 3a and b show temperature and air void content measurements taken during break down rolling (vibratory steel wheel compactor). The air void content was determined using the wet density reading from the nuclear density gauge and the measured theoretical



a) Pavement Temperature b) Air Voids

Figure 3. Compaction measurements taken during break down rolling.

maximum density of each mixture. Density measurements were taken with a Troxler nuclear density gauge in backscatter mode. The values reported were adjusted so that the terminal air void content was equal to the average of the extracted cores. The temperature measurements are from thermocouples attached to small metal rods and embedded in the center of the surface layer immediately after paving. The temperature reading at the start of compaction is reported, along with the readings taken after different number of passes of the breakdown roller.

The roller pattern was very similar for each of the mixtures. The number of roller passes for breakdown rolling varied between five and eight on the different items. The HMA had the highest initial mat temperature of 137 °C. The Evotherm™ 3G mixture was produced hotter than expected, and compaction began with the mat temperature at 130 °C. The Sasobit® and foamed asphalt mixtures had initial mat temperatures of 102 °C.

Figure 3 shows that the temperature of the HMA was approximately 10 °C warmer than the Evotherm™ 3G and approximately 30 °C warmer than the Sasobit® and foamed asphalt during compaction. The air void content during compaction (Fig. 3b) was similar for the Sasobit® and foamed asphalt. These items did not densify as much as the HMA and Evotherm™ during breakdown rolling. The HMA had the lowest terminal air void content.

4.2 *Workability relationship to compactability*

Mixtures sampled during construction were reheated and tested using the workability device to determine how the laboratory measured torque values compared to field observations. The results of testing are given in Figure 4. The laboratory-produced HMA is also provided for comparison. Workability testing indicates a slight stiffening of the HMA produced in the asphalt plant as evidenced by higher torque values at equivalent temperatures. Mixture stiffening is known to occur during asphalt production. In addition, all field-produced mixtures were reheated in the laboratory prior to testing, which could have caused additional stiffening. The torque value measured for the HMA at the field placement temperature of 137 °C is 12.3 N-m. The measured torque value for the WMAs was 19.5, 11.3, and 18.5 N-m for the Sasobit®, Evotherm™ 3G, and foamed asphalt, respectively, at their field placement temperatures. These results indicate that the Evotherm™ 3G has similar or better workability than the HMA when 7 °C cooler. The foamed asphalt and Sasobit® exhibited reduced workability due to their low compaction temperature (102 °C).

Field compaction results directly correlate with the laboratory workability testing. The HMA and Evotherm™ 3G compacted to very similar air voids, even though the Evotherm™ was produced at a lower temperature. The air void content of the foamed asphalt and Sasobit® was approximately 2% higher with the same compaction effort. Their reduced workability at lower temperatures caused less densification to occur. Given that the density

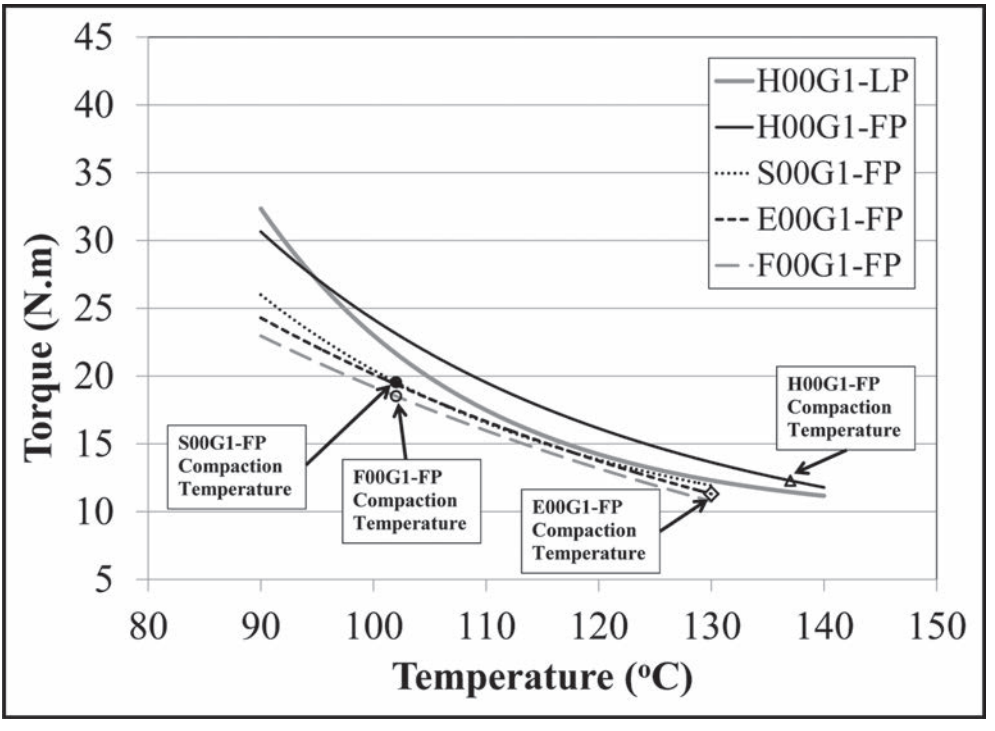


Figure 4. Workability test results from field mixtures.

of these mixtures was near the lower limits accepted by the construction specifications, the corresponding torque values measured for these mixtures can be used as a threshold for which to deem a mixture temperature suitable for compaction. An example would be to recommend laboratory torque values not exceed 20 N-m at the compaction temperature, which represents the minimum workability (maximum torque) measured on mixtures that still met minimum allowable field compaction requirements. Using this minimum workability limit, the minimum temperature for compaction of the HMA mixtures would be 110 °C, while for the WMA mixtures it would be 100 °C.

4.3 *Laboratory workability of HMA and WMA mixtures containing RAP*

Additional workability testing was conducted on laboratory-produced mixtures to evaluate the workability of mixtures containing RAP. RAP contents of 25% and 50% were evaluated in three WMA mixtures and one HMA. The results are presented in Figure 5a–c. The H00G1-LP mixture is also provided for comparison. At 0% RAP, the H00G2-LP mixture behaved very similarly to the H00G1-LP mixture. The differences in torque at a given temperature could be attributed to the difference in aggregate type and angularity. All the WMA mixtures were more workable than the two HMA mixtures at 0% RAP. Increasing the RAP content decreased the workability of all mixtures. However, WMA increased the workability at all RAP contents, which indicates that compaction temperature can be reduced when using WMA without compromising the workability.

The lower workability of all high-RAP mixtures as compared to the H00G1-LP mixture suggests that the minimum compaction temperatures need to be adjusted when RAP is used. To evaluate this, the workability data was examined to determine the temperature at which the torque was equal to 20 N-m. This is presented in Figure 5d. To meet the maximum torque requirement of 20 N-m the minimum compaction temperature needs to be increased by at least 10°C and 20 °C for 25% and 50% RAP mixtures, respectively, for both HMA and

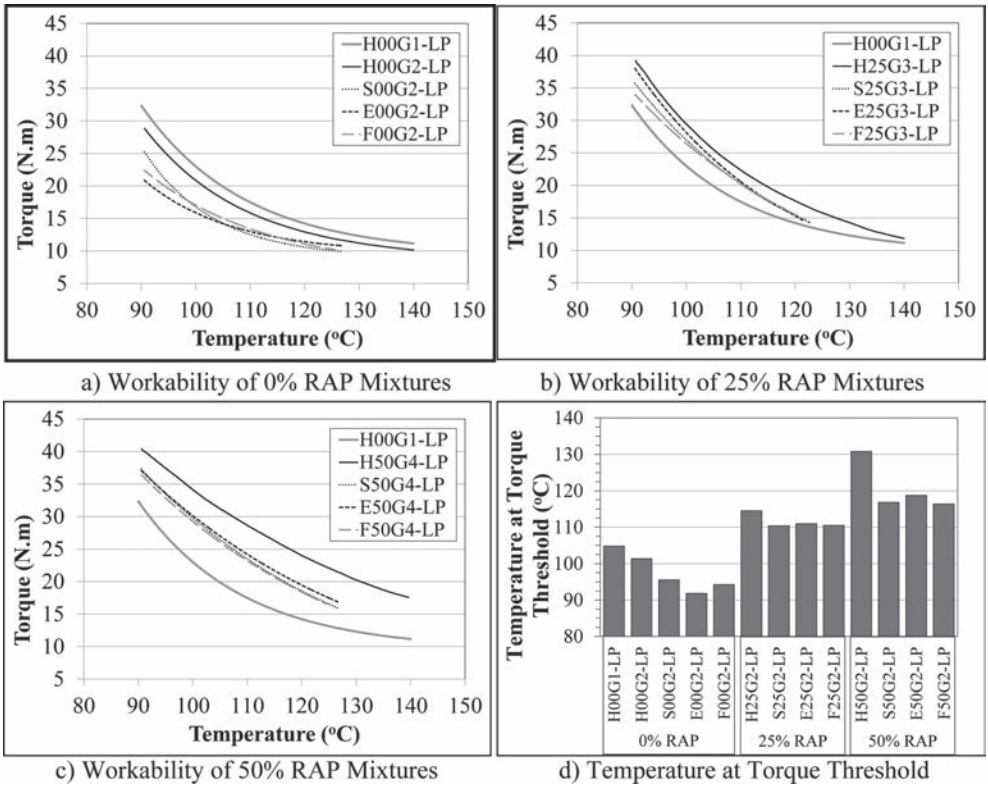

Figure 5. Laboratory workability of HMA and WMA mixtures containing rap.

WMA. For the mixtures evaluated in this paper, at 25% RAP, the minimum compaction temperatures of the HMA and WMA would be 120 °C and 110 °C, respectively. At 50% RAP, the minimum compaction temperatures of the HMA and WMA would be 130 °C and 120 °C, respectively.

5 SUMMARY AND CONCLUSIONS

In the field, WMA showed similar compactability to HMA when approximately 10 °C cooler and reduced compactability at lower temperatures. For example, Evotherm™ 3G compacted to air voids very similar to HMA, even though the Evotherm was produced and compacted at lower temperatures. When WMA was compacted at very low temperatures, as was the case for foamed asphalt and Sasobit®, the air voids were higher with the same compaction effort.

Field compaction results showed a direct correlation with the laboratory workability results. WMA showed to have similar workability to HMA when approximately 10 °C cooler. At temperatures cooler than these, WMA exhibited reduced workability. The reduced laboratory workability at lower temperatures causes less densification to occur in the field. Since the densities of the mixtures evaluated met the construction specifications, and since there is a direct correlation between the laboratory workability and field compaction, a maximum torque value of 20 N-m is recommended to be used as a threshold to estimate a mixture minimum compaction temperature. From the workability results on the field mixtures, the minimum compaction temperatures recommended for the HMA and the WMA mixtures are 110 °C and 100 °C, respectively.

High-RAP-WMA has better workability than high-RAP-HMA. However, overall the workability is reduced when RAP is added; this agrees with the results of [7, 8].

Therefore, for high-RAP mixtures (25–50% RAP), the minimum compaction temperatures need to be increased by 10–20 °C to meet the maximum torque recommendation of 20 N-m.

In general, workability results showed that the torque method evaluated is efficient in determining the workability of different mixtures and that the laboratory workability can be used to predict mixture compactability.

ABSTRACT: Cold recycling is one of the most employed rehabilitation techniques for asphalt pavements and it is becoming more and more important as the reduction of emissions becomes a priority in the reduction of the greenhouse effect. The main advantages of asphalt cold recycling techniques are the use of reclaimed materials and the lack of need to heat the aggregates to make the mixtures: these possibilities allow for reduced consumption of natural aggregates and emissions providing, at the same time, many technical and economical benefits. The reduction of emissions in the use of reclaimed materials is due to a reduction of transport, in particular that reduction is bigger when the reclaimed materials are used in place. Nevertheless, the so-called cold in place recycling has challenges to control the water content in the mixtures and of quickly achieving a sufficient bearing capacity to allow the completion of the re-paving work. Generally the solution is provided by the use of active fillers, mainly Portland cement, able to absorb water and stiffen the mixtures. Sometimes the in place working conditions make necessary (presence of clay soils) or suggest (high moisture content) the addition of lime, but its effect on cold mixtures performances is, at the moment, not completely understood.

In an effort to improve on-site performance of recycled mixtures, the authors developed an extensive research programme aimed to investigate the effects provided by the introduction of lime in cold recycled mixtures as active filler. The basic idea was to analyse the bearing performance of pavement layers made with bituminous emulsion cold recycled mixes with different blends of active fillers (cement, lime). This paper evaluates the short term bearing capacity of recycled mixtures: assessment provided are based on results of deflectometric tests carried out on a trial section specifically built in Italy, close to Florence. Tests have been undertaken using LWD (Lightweight Deflectometer) and FWD (Falling Weight Deflectometer) immediately after compaction and after 24 hours of curing. The obtained results, even though they need to be confirmed by the analyses of long-term behaviour, positively support the use of lime as an active filler.

Keywords: Cold Recycling, Lime, Lightweight Deflectometer, Falling Weight Deflectometer

1 INTRODUCTION

Asphalt mixtures are the most common materials employed in the road pavements around the world, so "how to employ?" and "how to manage?" the material produced in the demolition of damaged pavements at the end of the service life (the so-called RAP—Reclaimed Asphalt Pavement [1]) is one of the main issues for road agencies and road administrations.

Among the different options, the focus on cold recycling techniques is nowadays increasing due to the enormous contribution that they can give to increase sustainability of road constructions.

As reported in literature, the main benefits provided by cold recycling of asphalt pavements are, general, related to [2]:

- consumption reduction of natural materials;
- reduction of amount of waste materials to be disposed;
- reduction of energy consumption and greenhouse emissions due to cold production process.

In the case of in-place recycling another beneficial aspect of this technique is related to the reduction of heavy vehicle movements to provide fresh materials on construction site.

On the side of the advantages, the cold recycling techniques have to face the challenges related with mix design:

- the control of mixture's water content;
- quickly achieving a sufficient bearing capacity that allows completion of the repaving work.

Generally the solution is provided by the use of an active filler (a filler that chemically alters the mix properties): Portland cement appears to be the most used mainly due to the possibility to absorb the excess water, as a results of its setting reaction, and to quickly provide an increase of the mixture stiffness after compaction.

The in place recycling techniques in some situations may have some additional problems related to the specific pavement conditions. Two very common situations that engineers have to solve are the presence of clay soil inside of the granular materials of unbounded layer, mainly in during on site stabilization of distressed pavement, both with foam bitumen or bitumen emulsion, and when the amount of water greatly exceeds the optimum water content (or fluid content) for compaction. A practical solution frequently use in the work places to overcome these problems it is to add calcium oxide (quicklime) [3]. In the cases of clayey soils, the calcium oxide induces the flocculation of montmorillonitic components of soils making them insensible to the water. In the case of a large amount of water, the mechanism to dry the mixtures come from the reaction of hydration of calcium oxide to become calcium hydroxide with the production of a large amount of heat.

The question associated with this practical procedure is related to the global amount of active filler and whether the lime used for drying can be considered as an active filler? Or, in other words, can the lime be used instead of the cement or can the lime partially replace the cement in the global amount of active filler?

In general, limited literature exists regarding the effect on short and long term performance of cold recycled mixture made using different blends of active fillers including cement and lime. In an effort to assess the possible benefit of substitution of cement with lime in cold recycling, the Universities of Pisa, Parma, Stellenbosh and Nottingham designed and tested a full scale trial section to evaluate, under real traffic conditions, the short and long term performance of cold recycled mixtures made with multiple blends of active fillers.

Results presented in this paper are part of the extensive research work mentioned above and focussed on the short term performance of two bitumen emulsion recycled mixtures with and without addiction of lime to replace part of the mineral filler. Tests have been undertaken by means of Light Weight Deflectometer (LWD) and Falling Weight Deflectometer (FWD) immediately after compaction and after 24 hours of curing.

2 OBJECTIVE AND SCOPE

The objective of this research work is to investigate the influence of introducing lime as active filler in cold recycled mixtures on the short term bearing capacity of a bituminous emulsion recycled mixture.

A mixture made with 100% of RAP, with 1% of Portland cement by weight of aggregates as active filler was selected as a reference mixture and it was compared with a similar mixture where 2% (by aggregates weight) of lime was used to replace 2% of mineral filler (by weight of aggregates).

The bearing capacity of the two mixtures was investigated immediately after compaction with Light Weight Deflectometer (LWD) and 24 hours after compaction with Falling Weight Deflectometer (FWD). The possibility to use LWD immediately after compaction is related to the low stiffness of the mixtures: any component with binding action (cement, lime and emulsion) has no time to have a considerable effect hence the bearing capacity of the layer is mainly provided by the aggregate interlocking. After 24 hours of curing deflectometric tests were performed by means of FWD tests due to the achieved stiffness of recycled mixtures.

3 MATERIALS AND TRIAL SECTION CHARACTERISTICS

Trial section was built using two recycled mixtures with bitumen emulsion and different blends of active filler. Two different fractions of RAP aggregates have been selected to form the stone skeleton of the mixes: RAP fraction 0–10 mm and RAP fraction 10–20 mm. The two recycled mixtures had the same grading composition (100% RAP) and a cationic ultraslow setting bitumen emulsion was used as stabilizing binder. The total amount of filler in the mix was optimized to reach the OMMC (Optimum Moisture Mixing Content); the proportion of the three components, mineral filler, cement and lime, was optimized in order to investigate their influence on short term performances. Mixes were designed as reported in the following Table 1. The percentages of fillers, both active and mineral filler, should be considered as theoretical values; in the field a moderate variation occurs due to the inherent variability of recycled mixtures production process. For these reasons, the effective amount of fillers contained in the mixes are also presented.

To analyze the evolution in time of recycled mixtures performance, a specific trial section have been designed, realized and tested on a local road under construction near Florence (Italy). Recycled materials have been produced following the in-plant recycling techniques, laid with a paver and compacted using a combination tandem roller (front rubber tires and rear metallic drum). Dimensions of the trial section and pictures taken during construction process are hereinafter presented.

The trial section pavement at the moment of testing campaign consists of a 17 cm layer of recycled material over a lime stabilized subgrade (Fig. 2). The pavement will be completed with additional 4 cm of asphalt concrete wearing course type, to be laid directly over the recycled layer. The entire pavement structure were designed with the only aim to reach the

stress and strain distribution under load allowing researchers to clearly underline the different performances of the two investigated materials.

Test locations, both with LWD and FWD, were distributed to cover the entire trial section and can be shown in the subsequent schemes. Due to a fixed amount of material produced for the different mixtures and different paving layout (pavement shoulders, paver width setup, road curvature, etc.), the two sections have a different length and, consequently, a different number of test locations.

LWD tests were also carried out to characterize the subgrade of the pavement trial sections, prior to laying the recycled mixtures, in order to take into account the subgrade bearing capacity in data evaluation and to better understand test results carried out after compaction (zero curing). The test location used to characterize the pavement subgrade was exactly that used for the recycled mixture (Fig. 3). Results were also reported in the form of coloured maps for the entire trial field (Fig. 4—grid of data was created using the kriging algorithm) to underline the spatial variation of subgrade Surface Modulus

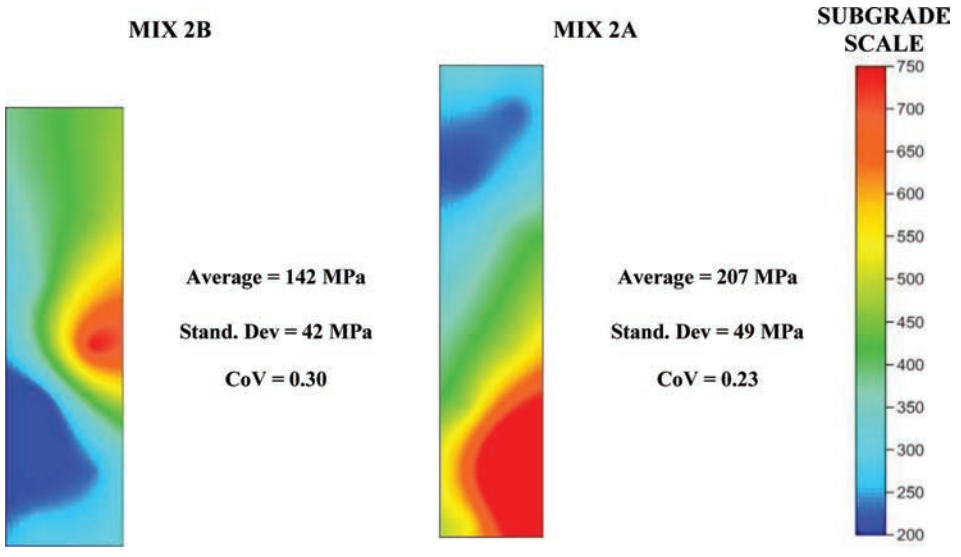

Figure 4. Colour maps of surface modulus for subgrade.

(Equation 1). Average value, Standard Deviation and Coefficient of Variation are also reported in Figure 4.

4 INVESTIGATION METHOD

4.1 *Light weight deflectometer LWD*

The dynamic load plate test in the form of Light Weight Deflectometer (LWD) was firstly introduced as mechanistic (or analytical) approaches to pavement engineering found increased support internationally, as a new method to determine the E-modulus of unbound and cement-bitumen stabilized materials in pavements [4].

The LWD testing device is used to characterize a half-space bearing capacity in terms of surface deflection and consequently through the Surface Modulus calculated using Boussinesq equation: stress distribution and Poisson's ratio is used to calculate elastic moduli. The effect on the calculated surface deflection modulus is seen from the equation:

$$E = \frac{f\ (1\ \nu^2)\ \sigma_0\ a}{d_0} \tag{1}$$

where the factor "f" (plate rigidity factor) is 2 for uniform distributions and π/2 for the rigid case, which may be more correct for cohesive materials, "a" is the load plate radius, "σ_0" and "d_0" are respectively the maximum value of the applied stress and the measured deflection.

During the field test with the LWD, an impact-like load is applied to the surface via a circular steel plate (load plate). The load set consists of a falling weight and a guide rod. After release, the falling weight slides down along the guide rod and hits a spring-damper element made of synthetic material.

A geophone installed in a centerplate hole records the speed of the ground subjected by the test load, allowing calculation of the plate displacement; at the same time, load applied during the impact is measured via a load cell. The data obtained can be used to estimate the surface modulus of the tested surface. The advantages of these types of instruments are the portability (small size and weight) and the speed of the tests, allowing the implementation for QC/QA on a large scale.

The Light Weight Deflectometer is becoming more and more used worldwide thanks to the new performance based approaches, such as the one introduced in UK with the IAN 73. In Italy, LWD on-site controls of compaction level are included since 2009 in the set of technical specifications for roadwork assigned by ANAS, the Italian Road Authority. LWD standard practice in the ANAS technical specifications are suggested to be used for embankment, granular foundation and cement stabilized layers; for cold recycled layers (in plant or in situ, with emulsion or foam bitumen) the LWD dynamic load plate test according ASTM E2583-07 is the only field test requested during construction.

In the present study short term bearing capacity of tested mixes was evaluated immediately after compaction by means of LWD (0 hours tests). Tests were carried out by applying a load able to induce on the surface a deflection higher than 100 μm in order to avoid problems due to the sensor accuracy [5].

4.2 *Falling weight deflectometer*

Today's most common testing equipment for evaluation of structural condition of pavements is the Falling Weight Deflectometer (FWD) which is a trailer-mounted device capable of transmitting a specified load to the pavement surface comparable with a heavy vehicle moving on the pavement with a speed ranging in the 60–80 km/h interval [6]. The falling mass, the spring system (rubber buffers), and drop height can each be adjusted to achieve the desired impact loading on the pavement. Vertical deflection peaks are measured at the centre of the loading plate and at multiple radial positions by a series of deflection sensors. The impulse load acting on the pavement causes a "wave front" of recoverable deformations, or deflections, that spread out from the centre of the load. Both the peak impulse load (force) and maximum vertical deflections of the "wave front" are measured at multiple radial distances from the load centerplate. These deflections, considered as a function of the applied impulse load, provide an indication of the structural strength of the pavement [7].

Since the theoretical approaches used to determine the stress–strain relationships in pavement layers calculate the deflections for given mechanical properties, it is necessary to make an inversion using a backcalculation tool. Several methods have been developed to backcalculate the mechanical properties of pavement; these methods vary in analysis type, material model, and optimization algorithm [8].

In the present study FWD tests have been undertaken after 24 hours of curing applying to the surface a pressure if about 1000 kPa. Centerplate deflection were used to calculate the Surface Modulus while the other deflection measurements allow the pavement layers modulus to be backcalculated following the structure presented in Figure 2. The pavement structure will be completed with the wearing course in the following months.

5 RESULTS AND DISCUSSION

Results of the test campaign are firstly presented in terms of Surface Modulus (Equation 1). This parameter can be defined as a measure of "Stiffness Modulus" based on the application of a known load at the top of the tested material. It can be considered a composite value with the contribution of all the underlying layers [9]; for LWD test, due to the load applied, the stiffness of the closest layer to the loading plate appear to be predominant. Regarding FWD a specific test setup able to reach a load corresponding to 1000 kPa was selected, rending the centreplate deflection, the one used to calculate Surface Modulus, significantly dependent on the stiffness of all the underlying layers. Results are reported comparing performances of the two mixes. Threshold values provided by technical prescription of Italian road authority ANAS are also reported: subbase layers realized with the in plant cold recycling technique should reach a Surface Modulus higher than 45 MPa after 4 hours from laying and compaction and higher than 170 MPa after 24 hours. These prescriptions are mainly devoted to evaluate the density achieved after compaction and avoid distresses due to the transit of delivery vehicles.

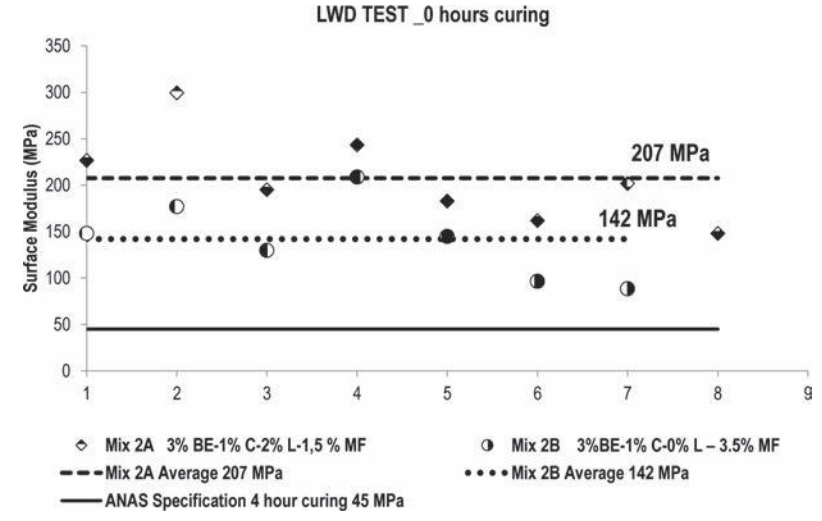

Figure 5. LWD surface modulus comparison.

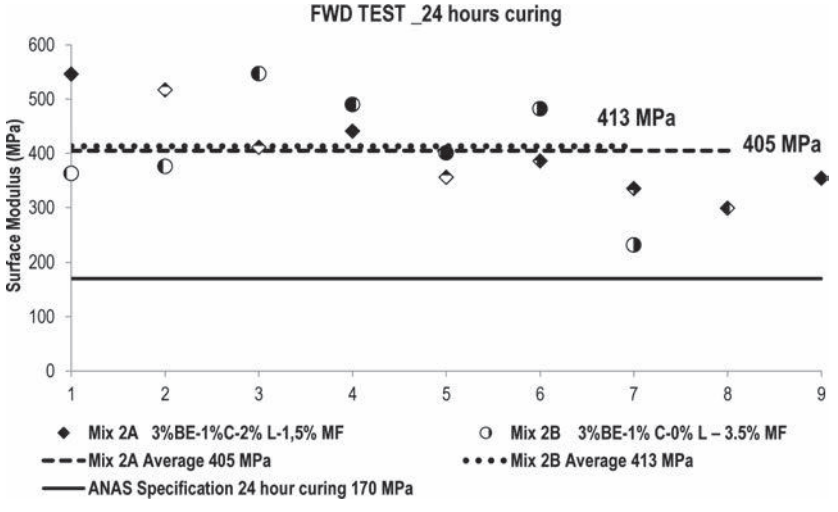

Figure 6. FWD surface modulus comparison.

In the subsequent pictures results of LWD tests are reported. The graph is organized plotting the Surface Modulus versus the number of test location (for example in the Mix 2A field 9 test location have been analysed).

The two mixes showed high values of Surface Modulus, both after compaction and after 24 hours of curing, more than two times greater than the threshold value required by ANAS technical specification. To better understand the spatial variation of LWD and FWD tests results, a colour map have been created for Surface Modulus using a specific spatial interpolation algorithm (grid of data was created using the kriging algorithm). Results are reported in the subsequent Figure 7 where x-axis represent the cross amplitude of the field and the y-axis the length of the field; average value, standard deviation and coefficient of variation (ratio of standard deviation and average value) are also presented.

FWD Deflection recorded after 24 hours from compaction have also been used to backcalculate the elastic equivalent modulus of the recycled layers. The pavement

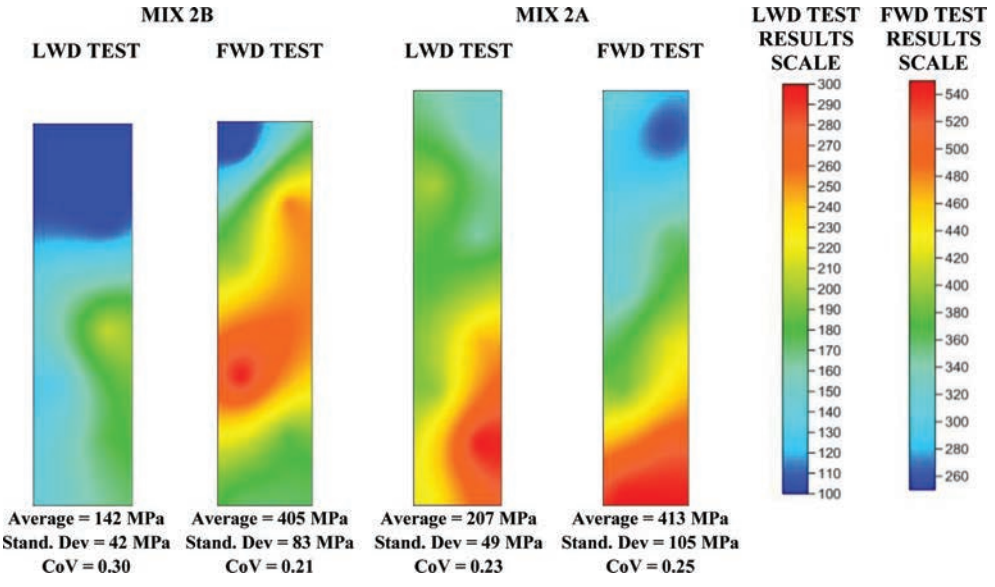

Figure 7. Colour map of surface modulus of recycled layers.

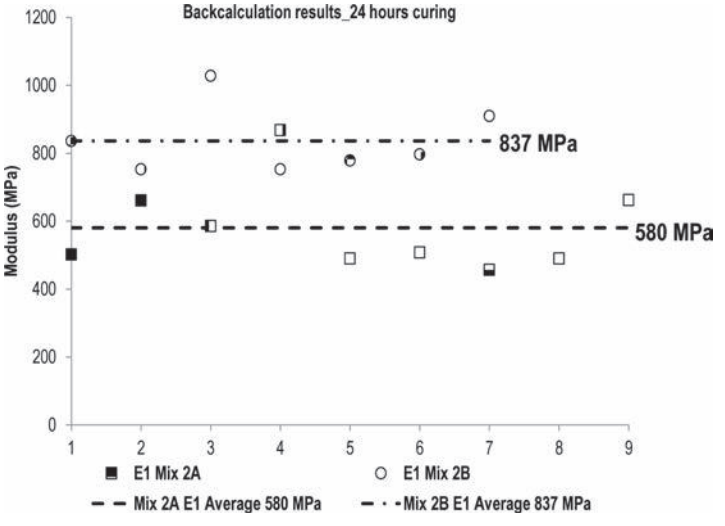

Figure 8. Comparison of E1 modulus of recycled mixtures from backcalculation process.

structure was assumed to be as reported in Figure 2 except for wearing course (laying of wearing course will be done in the next couple of weeks) and the Odermark-Buossinesq backcalculation method (MET Method of Equivalent Thickness) has been used. Results are subsequently reported in terms of modulus of recycled layer (E1) in order to separate the influence of the subgrade stiffness and then underline the recycled mixtures performance.

Results presented in Figure 8 can be considered an absolute measure of mixes stiffness after 24 hours of curing and allow to model the pavement response to applied loads. More information about that response will be provided by monitoring the stiffness evolution of the mix in the next month.

To provide a more detailed analysis and evaluate the influence of active fillers on mixtures strengthening, a comparison of modulus after compaction and after 24 hours of curing has been done, treating each mixture alone. To reach this goal the Surface Modulus calculated from LWD tests after compaction have been compared with the E1 modulus resulting from backcalculation of deflection recorded with FWD tests after 24 hours curing (FWD centreplate deflection after 24 hours of curing results too much dependent on subgrade stiffness than not useful to investigate the performance on the recycled mixture alone). In this regard it worth noting that, from a theoretical point of view, a Surface Modulus, which is a measure of the half space bearing capacity, cannot be compared with a layer modulus. Furthermore, the influence depth of the LWD tests can be assumed to be 1÷1.5·D (D = diameter of the loading plate) depending on different boundary conditions of the testing process. On the other hand, due to the stiffness of the materials, the deflection measured after compaction (LWD tests) appears to be strictly dependent on behaviour of only the upper layers, rending the Surface Modulus a preliminary indication on bearing capacity of the recycled layer alone.

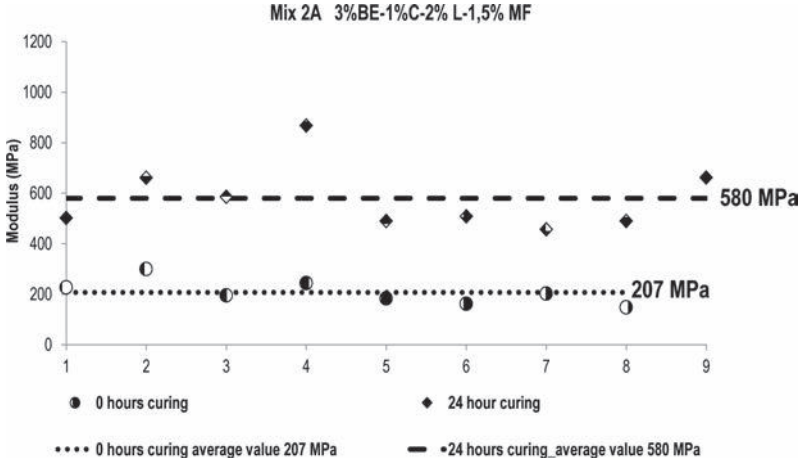

Figure 9. Comparison of modulus at 0 curing and 24 hours curing—mix 2A.

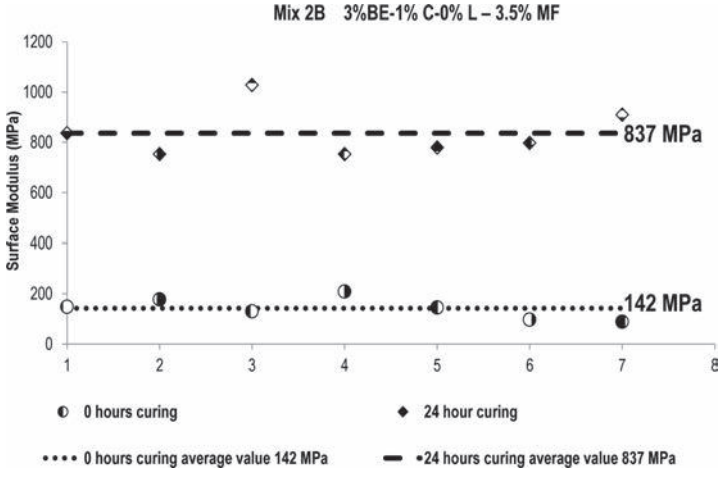

Figure 10. Comparison of modulus at 0 h curing and 24 h curing—mix 2B.

Results shows that a significant increase of mixtures stiffness occurs after only 24 hours of curing. Since the trial section is placed on a real road, no problems are recognized for the road authority to complete the pavement structure construction by placing the wearing course.

6 SUMMARY AND CONCLUSIONS

In this paper the short term performances of recycled mixtures made using different blends of active fillers have been analysed. The effect of using lime as active filler has been investigated by means of LWD and FWD tests after compaction and after 24 hours of curing.

Tested mixtures appear to perform well; threshold values provided by the ANAS technical specification significantly exceeded both after compaction and after 24 hours of curing.

As reported in the introduction, lime can be used to stabilize clay particles or to aid the drying process of RAP aggregates. Mix 2A can be considered to be this second situation with lime being used to substitute a certain amount of mineral filler (1% of cement is however added to the mix). In that case, comparing results to those obtained with a reference mix (mix 2B with only 1% of cement and no lime in the mix), no negative effect on material bearing capacity can be recognized due to the use of lime as active filler. On the other hand, lime seems to affect the strengthening process decreasing the rate of strength evolution in the mixes, even though tests carried out over a long term period will be needed to clarify this aspect.

To conclude, results obtained appear to be very promising regarding the short term performance of recycled mixtures. Further research is on-going with the aim to investigate the effect on long term performance of introducing lime in cold recycled mixture as active filler.

Performance evaluation of Cement Grouted Bituminous mixes

G. Manikantha Raju, D. Sita Rami Reddy & K. Sudhakar Reddy
IIT Kharagpur, Kharagpur, West Bengal, India

ABSTRACT: Cement Grouted Bituminous (CGB) mix is a semi flexible type of pavement material which essentially is an open graded (porous) bituminous mix grouted with cement mortar. CGB mixes have the advantages of both flexible and rigid pavements. This hybrid mixture provides good rutting and top-down cracking resistance. In the present study, an effort was made to evaluate the performance of CGB mixes. The study consists of selection of an appropriate gradation, design of cement mortar and performance evaluation of CGB mix. Performance of CGB and normal mixes was evaluated by conducting beam fatigue and static indentation creep tests. Correlations developed between the quantity of grout penetrating the mix with the air voids in dry aggregates and voids in mix will be useful for selecting suitable aggregate gradations. Different strength parameters of the mix improved significantly due to grouting. Resistance to moisture damage also improved. CGB mixes had much longer fatigue lives compared to unmodified mixes. Rutting performance of CGB mix, as observed in the static indentation creep test, was observed to be significantly better than that of normal mix. Results obtained from the investigations suggest that cement grouted bituminous mix can be a promising material for surface layers.

Keywords: Semi flexible, cement grouted, grouting, rut resistant, fatigue performance

1 INTRODUCTION

Bituminous (flexible) and concrete (rigid) are the two common types of pavement built. Flexible pavements are characterized by their lower initial cost, higher maintenance costs while rigid pavements have higher initial cost and longer life span. Concrete pavements require better construction skills and maintaining the joints in concrete pavement is also not easy. The main modes of failure in bituminous pavements are fatigue cracking, rutting and moisture damage of bituminous layers. Cement grouted bituminous mix, which is expected to have better rutting and moisture damage resistance, has been investigated in this study.

Cement grouted bituminous mix basically has two components: bituminous mix and cement grout. Aggregate gradation in the bituminous mix is selected in such a way that the mix will contain more voids compared to traditional dense-graded mixes. The volume of voids, thus created, will be sufficient for adequate quantity of grout to penetrate. Oliveira et al., [1] suggested that 25 to 35% voids are required in bituminous mix to allow proper penetration of cement grout. The cement grout is spread over the bituminous mix and made to flow through the voids of the bituminous mix. This type of grouted bituminous mix offers high rut resistance, fuel and oil spill resistance and acts as water impervious layer to underlying layers. It will also be free from the requirement of maintaining joints and offers a surface which has better wearing resistance.

The study methodology broadly consists of (i) design of gradation of aggregates by examining the relationship between the voids in the gradation and the quantity of grout penetrating the mix (ii) design of cement grout for proper penetration into the mix and for adequate strength of the grouted mix and (iii) evaluation of the performance of cement grouted bituminous mixes.

2 MATERIALS USED IN THE STUDY

2.1 *Aggregates*

Crushed coarse aggregate, fine aggregate and mineral filler used in this study were procured from the Shelda quarry in the state of West Bengal, India and these aggregates satisfy the requirements of the Ministry of Road Transport and Highways (MoRTH), Government of India [2].

Six trial gradations were chosen for the present study in which the first 3 gradations are selected in such a way that the fraction of filler retained between the following pairs of sieves: –0.6 μm to 0.3 μm, 0.3 μm to 0.15 μm and 0.15 μm to 0.075 μm is 1% for each pair and similarly the fraction of sand fraction retained between the following pairs of sieves: –4.75 mm to 2.36 mm, 2.36 mm to 1.18 mm and 1.18 mm to 0.6 mm is 2% for each pair of sieves. Fourth gradation has only 26.5 mm to 4.75 mm size coarse aggregates. Fifth gradation is similar to that of Surface dressing specified by MoRTH [2]. Sixth gradation is similar to bituminous macadam [2] aggregate gradation. Details of selected aggregate gradations are given in Table 1.

2.2 *Binder*

Two unmodified viscosity grade binders, VG-30 and VG-10, were used to study the effect of binder type on cement grouted bituminous mixes.

2.3 *Cement grout*

Cement used in the grout was satisfying the Specification as per IS-12269-1987 [3]. Sand used was graded as given in Table 2. Fly ash and Silica were used in the present study to increase the flow of cement grout at lower water cement ratio.

Table 1. Aggregate gradations used.

3 EXPERIMENTAL INVESTIGATIONS

3.1 *Void ratios in dry aggregate gradations*

The volume of voids available for cement grout penetration can be related to void ratio of dry aggregate gradations. For this, three different methods were adopted. In all the three methods the principle for finding the void ratios is similar. Only the volume and compaction effort is different. In Method 1, a three-liter metal cylindrical measure was taken and aggregates were filled in 3 layers. Each layer was tamped 25 times with a 16 mm diameter and 60 mm long steel rod. In Method 2, California Bearing Ratio test mould of volume 2250 cc was taken and aggregates were compacted in 3 layers by Marshall compaction hammer applying 25 blows over each layer. Method 3 consisted of determining the percentage voids in a manner similar to that adopted in method 2 but the Marshall hammer used for compaction has projections on the surface so that the compaction can be done more effectively. Void ratio in the compacted aggregate is computed using the bulk specific value of aggregates. The void ratios obtained with different gradations are tabulated in Table 3.

3.2 *Preparation of bituminous samples*

Cylindrical samples of bituminous mix were prepared using split Marshall mould. Effort was made to produce specimens of 50 mm height. The mixture of heated aggregates and binder was compacted by 25 blows of Marshall compaction hammer applied on one side only to have more air voids to facilitate penetration of adequate quantity of cement mortar. The quantity of binder required was estimated for each gradation separately based on the quantity required for a film thickness of 8 microns. Film thickness was estimated using the surface area factors given in Asphalt Institute manual MS-2 [4]. Binder contents adopted for different gradations are given in Table 4. Average volumetric parameters of the mixes produced with different gradations are also given in Table 4.

Table 3. Void ratios for different gradations.

	Void ratios by

1	4.43	2.714	2.204	26.1	18.8
2	4.43	2.718	2.159	27.7	20.6
3	4.43	2.724	2.031	33.1	26.7
4	1.26	2.769	1.979	31.5	28.6
5	2.03	2.774	1.890	36.7	31.9
6	6.65	2.657	2.212	25.2	13.1

3.3 *Grout penetration*

The amount of grout penetrating the specimen was obtained by measuring the weights of the specimen before and after grouting. The amount of grout penetrating different specimens prepared using different gradations is given in Table 5. The corresponding aggregate void ratio values computed by the three different methods are also given in the table. Water cement ratio of 0.75 and a cement:mortar proportion of 1:1 were used for preparing mortar. VG-30 binder was used to prepare bitumen mix specimens.

Table 5 indicates that the trends of variation of voids are similar for methods 2 and 3. Method 1 also gives nearly similar results with minor variations. In view of this, it has been decided to use the void ratio values obtained with method 3 for further analysis. The relationship between aggregate void ratio (obtained by method 3) and cement grout penetrated is shown in Figure 1.

3.4 *Effect of binder type on grout penetration and strength parameters*

Cement grouted bituminous mix samples were prepared with 3, 4 and 6 gradations. VG-30 and VG-10 binders were used. The samples were cured for 7 days and tested for Marshall stability and flow and Indirect Tensile Strength (ITS). Marshall and ITS parameters and the quantities of grout penetrated are tabulated in Table 6.

Mixes with VG3-0 binder yielded marginally more Marshall stability and ITS values compared to mixes having VG-10 binder. The amount of grout penetration is also slightly more with VG30 mixes.

4 GROUT

For increasing the flow of mortar, fly ash was introduced in the cement mortar. Three different fly ash contents, 0%, 10% and 20% by weight of cement, were used. Super plasticizer was also used in the water to increase the flow at lower water cement ratios. Trials were made with different water cement ratios for each fly-ash content. Water cement ratios of 0.68, 0.65 and 0.63 were found to be appropriate for 0%, 10% and 20% fly ash contents respectively. Details of compressive and flexural strengths of 7-day cured specimens prepared with different fly-ash contents are given in Table 7.

5 PREPARATION OF CEMENT GROUTED BITUMINOUS MIXES

Aggregates and bitumen were heated to the mixing temperature and were mixed uniformly and poured into split moulds at compaction temperature. The mix was compacted by Marshall hammer by applying 25 blows on one face only to have more voids to allow

4	34.5	1.8	1108	1093	98.62

Figure 3. Beam sample.

sufficient penetration of the grout. The mix was allowed to cool for one day. Next day, cement grout was prepared as per design proportions and was poured on the surface of the bituminous mix sample which was retained inside the mould and vibrated with electrical plate vibrator to allow the grout to penetrate into the voids of bitumen mix. The grouted bituminous samples were allowed to cure. Weights of the samples before and after the grout has penetrated were measured to determine the quantity of grout penetrated. Figure 2 shows the bituminous mix sample before grouting and after grouting.

6 PERFORMANCE TESTS ON CEMENT GROUTED BITUMINOUS MIXES

Tests conducted on the grouted bituminous mix samples are Marshall Test, Indirect tensile strength test, Fatigue test and Static indentation test. VG-30 binder, aggregate gradations 3 and 4, cement mortar (cement sand ratio of 1:1) and water-cement ratio of 0.65 were used to prepare the specimens. 10% of the sand was replaced by Silica fume. 10% of Cement was replaced by fly-ash. Super plasticizer was also used to improve grout penetration. Marshall Stability and flow, and indirect tensile strength were determined. Moisture damage test was also performed. The results are given in Table 8. ITS test was conducted at 25°C temperature.

The Indirect tensile strength values of the grouted bituminous mix are significantly larger compared to typical ITS value that can be expected for normal bituminous mixes. Retained ITS values are also high which shows that cement grouted bituminous mixes are less susceptible to moisture damage.

7 FATIGUE PERFORMANCE OF CEMENT GROUTED BITUMINOUS MIXES

Fatigue failure is one of the major load-related distresses experienced in pavements. Modulus of rupture values of different combinations of grouted bituminous mixes were determined by conducting flexure test on beams of 360 mm × 75 mm × 50 mm size. Samples were cured for 7 days in wet gunny bags after which they were removed from the moulds. Figure 3 shows a

grouted beam along with mould. Modulus of Rupture values were used to select appropriate stress levels for the fatigue test.

To evaluate the fatigue performance of the cement grouted bituminous mixes, beams were tested at different stress ratios. The load was applied at a frequency of 110 rpm. The test was conducted under constant stress mode. Fatigue failure of the cement grouted bituminous mix was identified as the point at which the specimen is unable to take any further load. The load was applied on top of the beam with a repeated load arrangement. Load was measured using a load cell. Fatigue equations were developed for the two aggregate gradations (3 and 4). Results of fatigue test are given in Table 9. Figures 4 and 5 show fatigue relationships between stress ratio and load repetitions to failure for gradations 3 and 4 respectively.

Fatigue relationship for cement grouted bitumen mix prepared using gradation 3 is given as Eq. (1).

$$N = 1136.56\left(\frac{1}{SR}\right)^{11.91} \tag{1}$$

Fatigue relationship for cement grouted bitumen mix prepared using gradation 4 is given by Eq. (2).

Table 9. Beam fatigue test results.

	No of repetitions to failure	
Stress ratio	Gradation 4	Gradation 3
0.965	1650	2200
0.911	5500	5720
0.857	6930	8800
0.804	19800	24420
0.750	39600	43120

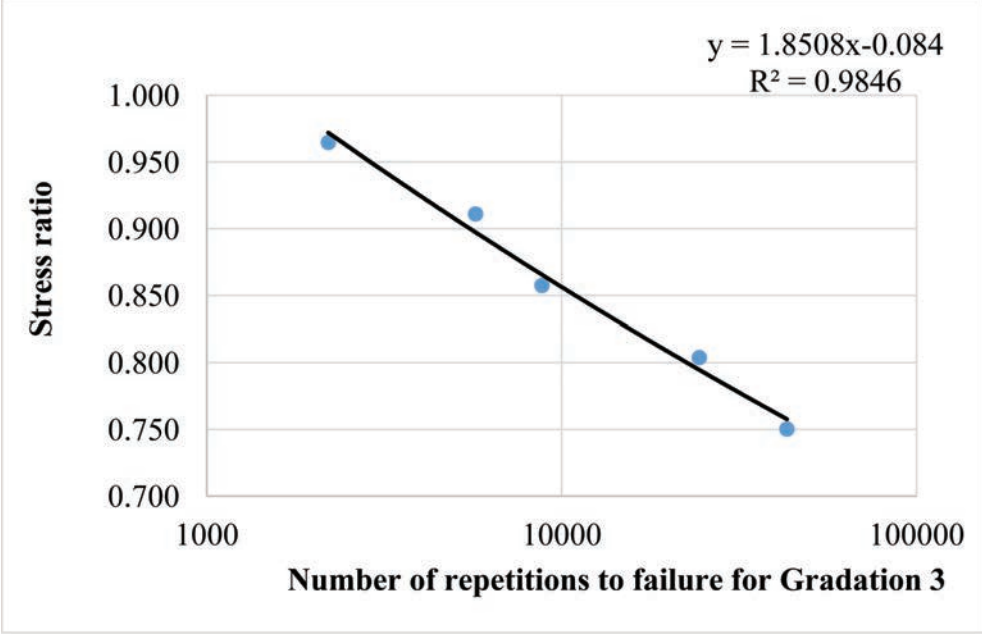

Figure 4. Stress ratio vs no of repetitions to failure for gradation 3.

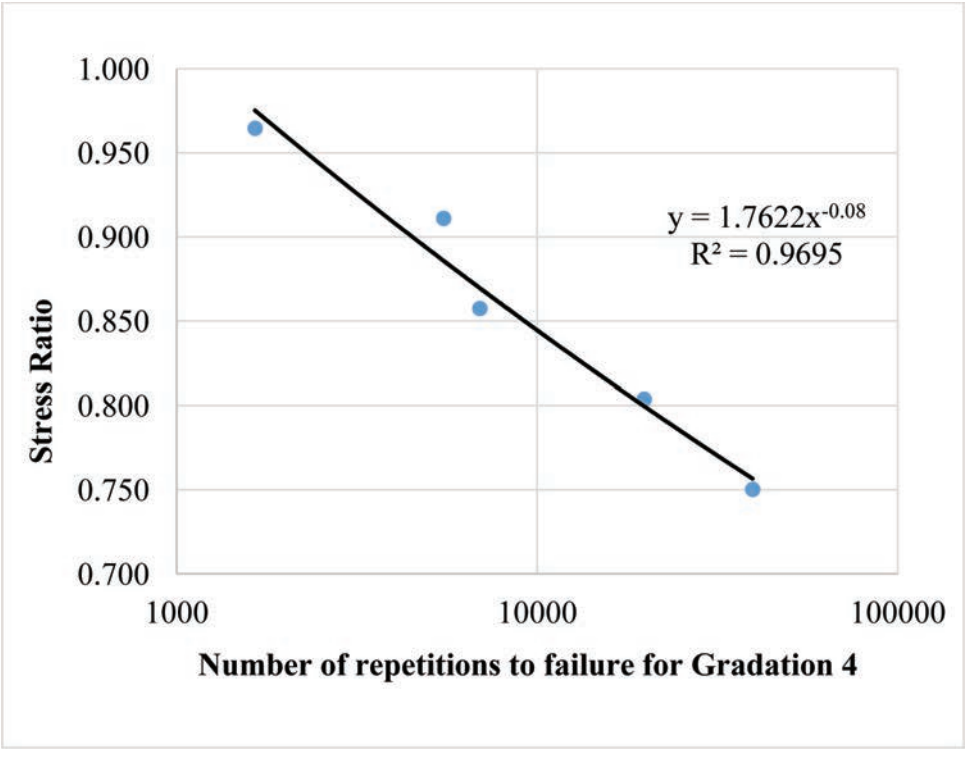

Figure 5. Stress ratio vs no of repetitions to failure for gradation 4.

$$N = 1190.30\left(\frac{1}{SR}\right)^{12.5} \tag{2}$$

8 ELASTIC MODULUS

Elastic modulus of grouted bituminous mix was obtained by measuring the mid-span deflection of the beam in the beam fatigue test. Average elastic moduli of the mix obtained with gradations 3 and 4 are 10575 and 10285 MPa respectively.

9 RUTTING PERFORMANCE OF BITUMINOUS MIXES

Cement grouted bituminous mixes are expected to have good rut resistance. Rutting performance test was conducted using static indentation test. This test was also conducted on traditional Bituminous Concrete (BC) mix for comparing with cement grouted bituminous mixes. This test was conducted at a temperature of 50°C.

9.1 *Static indentation test*

A variety of tests are used to evaluate the rutting resistance of bituminous mixes in laboratory. Creep test is the simplest one to study the permanent deformation characteristics of bituminous materials. In the present study, indentation test was used to determine the permanent deformation behavior of bituminous concrete mixes. In the indentation test [5], a constant load of 0.8 kN is applied through a loading plate of 38 mm diameter which produces a

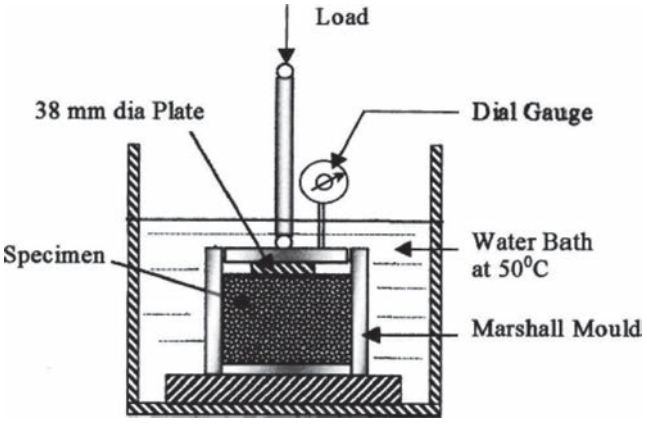

Figure 6. Schematic arrangement of static indentation test method.

Table 10. Static indentations test results.

Gradation type	Total deformation in 0.01 mm (TD)	Permanent deformation in 0.01 mm (PD)	Elastic deformation 0.01 mm (ED)	PD as % of ED	PD as % of TD
BC	35	7.5	27.5	27.2	21.4
Gradation 3	21	2	19	10.6	9.6
Gradation 4	23.5	2.5	21	11.9	10.6

vertical pressure of 700 kPa on one of the flat faces of a cylindrical specimen. A dial gauge was used to measure the vertical deformation of the specimen. Figure 6 shows the schematic arrangement of Static Indentation test method. The results of static indentation test are shown in Table 10.

It can be seen from Table 10 that not only the total deformation got reduced in grouted mixes but the permanent deformation components have also been reduced significantly.

10 CONCLUSIONS

The present investigation clearly demonstrated the superior performance of grouted mixes in terms of rutting, fatigue cracking and moisture damage. The following specific observations are made from the present study.

- The penetration of cement grout in the mix is directly proportional to the air voids in dry aggregates.
- The effect of binder hardness on grout penetration was very less.
- The Marshall stability and Indirect tensile strength values of grouted mixes are significantly larger than typical values obtained with normal mixes.
- High tensile strength ratio suggests satisfactory moisture resistance.
- The rutting performance of cement grouted bituminous mixes very high compared with that of normal bituminous mix.

Aging and constitutive modeling of asphalt mixtures: Research developments in Brazil

Lucas F. de A.L. Babadopulos, Jorge Barbosa Soares & Verônica T.F. Castelo Branco
Laboratório de Mecânica dos Pavimentos da Universidade Federal do Ceará (LMP/UFC), Departamento de Engenharia de Transportes, Fortaleza-CE, Brazil

ABSTRACT: The use of complex modulus for asphalt mixture characterization is still restricted to special projects in Brazil. Nevertheless it is recognized the importance of leveling ongoing national research efforts towards a new pavement design methodology with international state-of-the-art developments. The work presented herein concentrates on testing and analysis procedures for characterizing stiffness of asphalts mixtures considering its properties dependency on aging evolution. It uses an existing aging phenomenological model and it also proposes an aging experimental procedure. The referred model utilizes an internal state variable and four materials constants. Coupling the aging and well-established linear viscoelastic models, storage and loss moduli results at two different aging states are predicted. A simulation of the change in dynamic modulus with time (aging) is also presented to illustrate the potential of the modeling approach. This work is part of a continuing research at *Universidade Federal do Ceará*, at Fortaleza, Brazil, involving extended aging times, methodology, materials and further modeling efforts.

Keywords: aging, asphalt mixture, stiffness, complex modulus, modeling

1 INTRODUCTION

Asphalt mixture mechanical characterization in Brazil is today primarily based on resilient modulus and indirect tensile strength tests. There is still no national standard for fatigue or permanent deformation mixture characterization. In some specific situations, especially in road concessions to the private industry, controlled-stress diametral compression test at only room temperature is used for the former, and laboratory traffic simulators or dynamic creep (Flow Number) is used for the latter. Brazil is currently undergoing a national effort to develop its own mechanistic-empirical pavement design method, based on a national pavement material database and on the performance of test sections monitored around the country. A first version of the design guide is planned for 2016.

When it comes to mixture characterization in Brazil, the use of complex modulus is still restricted to academia and research centers. Therefore, it should not be considered in this first phase of the design method, which is being planned in such a way to be systematically updated. For that reason, it is recognized the importance of leveling the country's research with international state-of-the-art developments. In this context, the present work deals with the improvement of test and analysis procedures for the characterization of asphalt mixtures considering their properties dependency on aging evolution.

There is no worldwide consensus on a procedure for the characterization of fatigue in asphalt mixtures, although it is considered a major pavement distress. There is also no widely accepted aging model or experimental procedure to take into account this phenomenon in fatigue characterization, despite extensive literature comments on its influence. This paper is focused in modeling the behavior of asphalt mixtures under small strains, aiming at the stiffness characterization and at the incorporation of aging considerations. The authors believe

that the presented approach is an important step towards more sophisticated stiffness and fatigue characterization of mixtures in the Brazilian pavement design procedure. The research is part of a broader project related to the development of the new Brazilian mechanistic-empirical pavement design method. At this point, only data for early ages (2 days of aging) at two different temperatures (85 and 135ºC) were available. Aging was induced to loose asphalt mixture, in a procedure adapted from Partl et al. [1].

In literature, some works have presented viscoelastic models which included aging time as a variable (Daniel et al., [2]; Michalica et al., [3]) in addition to loading time (or frequency). However, these models are not conceived to allow easy coupling of aging to other mechanical characteristics of the asphalt mixture, such as viscoplasticity or damage. This has motivated the use of the aging phenomenological model proposed by Al-Rub et al. [4]. The referred approach couples aging to linear viscoelastic, viscoplastic and damage responses of asphalt mixtures. The model utilizes an internal state variable, whose evolution depends on oxygen availability, temperature, and four materials parameters. Those parameters are related to aging susceptibility, reaction kinetics, and aging history and temperature dependency. It allows to establish a relation between the difference of aging time and the difference of temperature in two different aging processes under the same oxygen availability. The material constants are obtained by minimizing model prediction square errors with respect to experimental results. Complex modulus results can be used to fit linear viscoelastic models at different aging states. The comparison between the linear viscoelastic parameters obtained at the different aging states allows the identification of the aging model parameters along with the linear viscoelastic parameters aging sensitivity. With the fitted aging model parameters, the nonlinear and the damage aging sensitivity can be estimated comparing experimental results obtained at different aging states, as shown by Al-Rub et al. [4]. This is the object of an ongoing research project conducted by the authors, and this paper presents the first aging results obtained. An aging experimental procedure is also proposed for asphalt mixtures herein as a contribution of the present research under development in Brazil.

2 LITERATURE REVIEW

2.1 *Linear viscoelasticity*

In this paper, mechanical analogs are used to fit linear viscoelastic models to experimental data. The Generalized Maxwell-Wiechert model was fitted to storage modulus following a Linear Least Squares Method, and then the Generalized Kelvin-Voigt model was generated by an interconversion procedure (Park and Schapery, [5]). These models are commonly referred to as Prony series models, and are often used to represent the linear viscoelastic behavior of solid continuum media, e.g., bituminous materials. The Maxwell-Wiechert model gives a Prony series for the relaxation modulus defined by the parameters E_∞, E_i's, and ρ_i's, while the Kelvin-Voigt does the same for the creep compliance, whose Prony series is defined by the parameters D_0, D_j's, and τ_j's. These properties are given in the time domain, and designated transient. However, it is more practical to perform experiments in the frequency domain, due to time consuming and difficulty with respect to linearity limits typical from time domain tests. In such case, the complex modulus (E^*) is used. For viscoelastic materials, the strain signal is delayed from the stress signal by a quantity known as the phase angle (φ). Using Euler's formula for complex exponentials, E^* is given by the ratio between stress and strain during a harmonic oscillation:

$$E^* = \frac{\sigma^*}{\varepsilon^*} = \frac{\sigma_0 e^{i(\omega t-\varphi)}}{\varepsilon_0 e^{i\omega t}} = \frac{\sigma_0}{\varepsilon_0} e^{i\varphi} = |E^*| e^{i\varphi} = |E^*|(\cos\varphi + i\sin\varphi) = E' + iE'' \quad (1)$$

where $i = \sqrt{-1}$.

$E' = |E^*| \cos\varphi$, known as the storage modulus, is associated to the stored portion of mechanical energy during harmonic loading. $E'' = |E^*| \sin\varphi$ is the loss modulus, associated

to the dissipated portion. The angular frequency ω represents the pulsation (rad/s), and it is directly related to the loading frequency f (Hz), as $\omega = 2\pi f$. The parameter $|E^*|$ is referred to as the dynamic modulus, although it does not deal with inertial properties. It grows with the increase in loading frequency and decreases with growing temperature. $|E^*|$, along with φ, describes the behavior of linear viscoelastic materials in the frequency domain.

For an asphalt mixture, a composite heterogeneous material, the interlocking provided by the aggregates provides to the phase angle a non monotonic trend with the change in temperature (or frequency). Generally, for low frequencies and high temperatures, φ grows with loading frequency, whereas for high frequencies and low temperatures the inverse occurs (Clyne et al., [6]; Flintsch et al., [7]). This phenomenon can be explained by the fact that the elastic behavior ($\varphi = 0°$) of the aggregates influences more the material's response when the asphalt binder is softer, i.e., at low frequencies and high temperatures. At those conditions, a decrease in frequency leads to a more elastic response, because aggregates participation in the material's behavior becomes more important: φ decreases.

Assuming the generalized Maxwell model, the storage (E') and the loss (E'') moduli are calculated from Eq. (2) and Eq. (3), respectively.

$$E' = E_\infty + \sum_{i=1}^{n} E_i \frac{\omega^2 \rho_i^2}{1 + \omega^2 \rho_i^2} \tag{2}$$

$$E'' = \sum_{i=1}^{n} E_i \frac{\omega \rho_i}{1 + \omega^2 \rho_i^2} \tag{3}$$

In this paper, a least squares optimization based on Eq. (2) was used with assumed relaxation times (ρ's) and long-term modulus (E_∞). It consists of the minimization of the Cost Function described by $C(E_i) = \left[E'_{experimental} - \left(E_\infty + \sum_{i=1}^{n} E_i \frac{\omega^2 \rho_i^2}{1 + \omega^2 \rho_i^2} \right) \right]^2$. This is presented in detail by Babadopulos [8] and it is analogous to equations provided in Silva [9]. The resulting equation from the optimization of the cost function leads to a system of linear equations. Eq. (4) summarizes the fitting procedure:

$$\sum_{i=1}^{n} \sum_{k=1}^{n} \left[\left(\frac{\omega k^2 \rho_i^2}{1 + \omega k^2 \rho_i^2} \right) \cdot \left(\frac{\omega k^2 \rho_j^2}{1 + \omega k^2 \rho_j^2} \right) \cdot E_i \right] = \sum_{k=1}^{M} \left[(E_k - E_\infty) \cdot \left(\frac{\omega k^2 \rho_i^2}{1 + \omega k^2 \rho_i^2} \right) \right] \tag{4}$$

The value of the long-term modulus (E_∞) is meant to be assumed lower than the lowest obtained modulus. Eq. (4) represents the algebraic linear system whose solution is the set of stiffness constants associated to the preestablished time constants in order to fit E' (frequency domain) experimental results using a linear least squares method. It is capable of considering all M experimental points (ω_k, E_k). The dummy variable (index) j represents the lines of the linear system to solve, and it varies from 1 to n (number of elements in the Prony series). Although E'' is not used in the fitting procedure, it can be used to verify the goodness of fit, comparing experimental to predicted results from Eq. (3). Then, the procedure proposed by Park and Schapery (1999) to interconvert the relaxation modulus discrete spectrum (E_∞, E_i's, ρ_i's) into a creep compliance discrete spectrum (D_0, D_j's, τ_j's) can be applied. Having both Prony series (relaxation and creep), allows one to model both strain input and stress input problems in linear viscoelasticity.

2.2 *Aging*

Since the production, asphalt binders are subjected to conditions which induce a change in their mechanical properties. Volatilization of light fractions produces physical aging. There is also oxidative aging, induced by irreversible chemical reactions of the binder with diffused oxygen in its volume. Binder aging is largely reported in the open literature, with relevant contributions made four decades ago (Lee and Huang, [10]; Lau et al., [11]; Petersen et al.,

[12]). On the other hand, constitutive modeling of asphalt mixtures aging is a relatively undeveloped subject. In Brazil, an attempt to include aging in constitutive modeling of asphalt mixtures is undergoing at *Universidade Federal do Ceará*. Different laboratory mixture aging methods are being considered, and mixture properties are subsequently obtained.

Al-Rub et al. [4] proposed a phenomenological mechanistic-based aging model which is conceptually similar to the chemical pressure- and temperature-dependent aging models for binders, which predict the basic carbonyl reaction rate. It establishes a general law for the evolution of an aging internal state variable and, then, couples its value to the effects of aging, i.e., change in mechanical properties such as viscoelastic, viscoplastic and damage characteristics. The general expression for the model is as follows:

$$\dot{A} = \Gamma^{\alpha}\theta^{k_1}(1-A)k_2 exp\left[-k_2\left(1-\frac{T}{T_0}\right)\right] \tag{5}$$

where A is the aging internal state variable, $\dot{A}$ its time derivative, θ is the normalized oxygen content (between 0 and 1), T_0 the reference aging absolute temperature, and T the actual absolute temperature. The four aging model parameters are the aging dependency on normalized oxygen content k_1, the aging history dependency k_2, the aging temperature dependency k_3, and the aging fluidity parameter Γ^{α}. The last one is given in s^{-1} and its inverse can be interpreted as a relaxation time for the aging process, i.e., time necessary for a fixed change in the original value of the aging variable. The aging internal state variable ranges from zero to 1, with $A = 0$ representing an unaged material, whereas $A = 1$ represents a completely aged material. This model can be simplified, assuming the material to be saturated ($\theta = 1$), $k_2 = 1$, and integrating it. The result is shown in Eq. (6).

$$A = 1 - (1 - A_0)e^{-ct} \tag{6}$$

where A_0 is the value of the aging state variable in the beginning of the aging process ($A_0 = A(t)_{t=0}$) and $c = \Gamma^{\alpha} exp[-k_2(1 - T/T_0)]$. The product $t' = ct$ can be seen as a reduced aging time, taking aging temperature into account. This simplified model is the one used to fit the experimental data in this paper.

The aging model can be coupled in the constitutive modeling of asphalt mixtures as shown by Al-Rub et al. [4]. For the coupling to linear viscoelasticity, the referred authors used the creep compliance discrete spectra at different aging states. In the present paper, the relaxation modulus discrete spectra were used. Eqs. (7a, 7b, 7c) represent the coupling between linear viscoelasticity and the aging of the material.

$$(E_{\infty})_A = (1 - A_0)^{-\alpha_1} \cdot E_{\infty}; (E_i)_A = (1 - A_0)^{-\alpha_1} \cdot E_i; \tag{7a,7b}$$

$$(\rho_i)_A = (1 - A_0)^{-\alpha_1} \cdot \rho_i \tag{7c}$$

The subscript A indicates the aged state. The model parameters represent the relaxation spectrum susceptibility with respect to aging (α_1 for the elastic modulus, α_2 for the transient modulus, and α_3 for the relaxation times).

3 MATERIALS AND METHODS

3.1 *Reference asphalt mixture*

The asphalt mixture investigated is a dense asphalt concrete with 12.5 mm nominal maximum aggregate size. The binder is classified by penetration as a 50/70. For the designed air voids content (4%), the required binder content was 6.0% (by weight). The resulting maximum theoretical density (Gmm) determined by the Rice test was 2.3915 g/cm³ (average results for three samples).

The materials tested in this paper are the reference unaged mixture (Age Zero), and two mixtures resulting from aging (designated Age 2, because of the 2 days aging time in the oven) at different temperatures (Age 2, 85ºC and Age 2, 135ºC). Testing different temperatures allows to identify the mixture aging sensitivity with respect to aging temperature, which constitutes a contribution with respect to the results originally presented by Al-Rub et al. [4], where aging temperature dependency was not evaluated. The Gmm changed with aging, resulting in 2.4025 g/cm³ for Age 2, 85ºC and 2.4017 g/cm³ for Age 2, 135ºC.

3.2 *Aging procedure*

Short-term aging was simulated at 150ºC, for 2 h. For the long-term aging simulation, aging was induced to the loose asphalt mixture, using a procedure inspired by a RILEM protocol described in the work edited by Partl et al. [1]. In order to normalize aging conditions, identical cooking trays (30 × 50 × 8 cm) containing asphalt mixture were maintained in the oven at the desired aging temperature. Equal quantities of material (three batches of 3.5 kg, i.e., 10.5 kg) were stored in each tray, in order to have always approximately the same height.

Sample preparation in the Superpave Gyratory Compactor was set to stop at a fixed height, targeting 150 mm, as the number of gyrations necessary to produce samples with 4% air voids could change due to the bitumen viscosity variation induced by aging. Final heights near to 150 mm were obtained, using approximately 2.630 kg of mixture to prepare each sample. Samples were not cored or cut, but used directly from gyratory compaction in the mechanical tests. For each aging condition (Age Zero; Age 2, 85ºC; and Age 2, 135ºC), 15 samples were prepared following the described procedure. The obtained mean air void contents were 4.3, 4.5 and 4.7%, respectively.

4 RESULTS AND DISCUSSION

In this section, the experimental results (dynamic modulus and phase angle) are described and compared. The procedure to fit the adopted linear viscoelastic and aging models is also described, and the resulting parameters are presented. A comparison is made between model prediction and experimental results. At the end, a brief aging simulation is performed, showing the estimated change of the mixture stiffness, according to the fitted aging model.

4.1 *Stiffness characterization*

AASHTO TP62-03 [13] was the test protocol adopted for HMA stiffness characterization. The results are shown in master curves for both $|E^*|$and φ, as indicated in Figures 1a and 1b, respectively. Mean results were obtained from four tests in samples of 100 mm diameter by

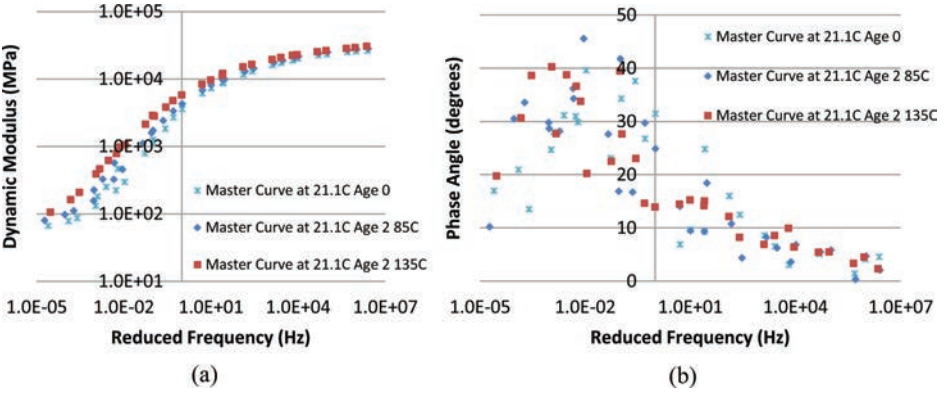

Figure 1. Dynamic modulus (a) and phase angle (b) master curves for the three tested aging states.

150 mm height, using three axial LVDTs mounted 120º apart on the surface of the sample, around its circumference. Fingerprint tests (short-time complex modulus tests, at very small strain amplitudes) were conducted in order to select the load pulse to be tested. A strain amplitude of 67.5 με was the target, expecting to reach strain amplitudes in the interval between 60 and 75 με. At this strain levels, linearity conditions should be respected and negligible strain dependency (nonlinearity) observed. The master curves for each aging state were obtained after horizontally shifting the isotherms, using a WLF Law (Williams et al., [14]).

In Figure 1a, it can be seen that $|E^*|$ gradually increases as aging evolves. In logarithmic scale (Fig. 1a), the dynamic modulus at low reduced frequencies (or high temperatures) seems to be much more affected by aging then at high reduced frequencies, as observed by other authors (Glover et al., [15]). This means that the percentage change in dynamic modulus is higher at low reduced frequencies. The scatter of φ results may not present a clear trend for the phase angle as aging evolves, as seen in Figure 1b, at least for the beginning of the aging process. The expected trend with respect to aging evolution was a decrease in φ.

4.2 *Linear viscoelasticity modeling*

The fitting procedure for linear viscoelasticity experimental data was the one presented in the Literature Review. At first, a pre-smoothing procedure using a sigmoidal function was tried, but significant prediction inaccuracy was observed for frequencies below 10^{-3} Hz at 21.1ºC. So, direct fitting to the data was used and resulted in acceptable results for the cases analyzed. One elastic term (long-term modulus, E_∞) and eleven transient terms (pairs E_i, ρ_i) were used to fit the storage modulus ($E'' = |E^*| \cdot cos\varphi$) experimental data. The same set of relaxation times (ρ_i), a decade apart one from another, was used for fitting all asphalt mixtures data, varying only the stiffness parameters (E_i's). The results are the discrete relaxation spectra of the tested asphalt mixture at different aging conditions, which describe its linear viscoelastic behavior, and can be used to simulate any kind of loading path that do not cause material nonlinearities (such as plasticity or damage). Then, the procedure proposed by Park and Schapery [5] to interconvert the relaxation modulus discrete spectrum (E_∞, E_i's, ρ_i's) into a creep compliance discrete spectrum (D_0, D_j's, τ_j's) was applied. The obtained discrete spectra (relaxation modulus and creep compliance) for the three aging states tested in this work are presented in Table 1.

The linear viscoelastic models summarized in Table 1 presented a satisfactory fitting to the experimental data. The good fitting was observed both for the storage modulus E' (fitting input) and the loss modulus E'' (not the fitting input), as seen in Figure 2. This indicates that linearity limits were respected during laboratory tests.

4.3 *Aging modeling*

In this section, the previously obtained viscoelastic models are considered as inputs for the aging modeling. In this work, aging modeling consists in determining the best set of parameters, with respect to experimental data, for the simplified model presented in the Literature Review: the reference temperature (T_0), the aging fluidity parameter (Γ^{α}), the initial aging state (A_0), the aging temperature dependency (k_3), and the relaxation spectra susceptibility with respect to aging (α_1 for the elastic modulus, α_2 for the transient modulus and α_3 for the relaxation times). The optimization of the aging oxygen availability dependency (k_1) and the aging history dependency (k_2) were not pursued for this work. They were assumed to be equal to 0.15 (as Al-Rub et al., [4] assumed) and 1 (to simplify calculation), respectively. The reference temperature (T_0) was taken as 21.1ºC.

The first step for the aging model fitting is the estimation of the values of the aging state variable (A), to which the aging process has led the asphalt mixtures to present at each aging condition. In this work, the initial aging state (A_0) was assumed to be zero, as Age Zero was taken as the beginning of the aging process. However, A_0 could be assumed to have a value different from zero, accounting for short-term aging (Al-Rub, [4]), and this would mean that the initial aging state occurred before the one referred to in this paper as Age Zero.

The parameter α_3, which accounts for the aging susceptibility of the relaxation time, was assumed to be zero ($\alpha_3 = 0$), as the magnitudes of the discrete spectra were obtained at exactly the same relaxation times, in a manner that they did not vary with respect to the aging state. As the elastic (E_∞) and the transient (E_i's) magnitudes did vary with respect to the aging state (A), the ratios between aged and unaged magnitudes were used as indicators of the aging state change. In addition, the aging susceptibility of the elastic and the transient relaxation magnitudes are given by α_1 and α_2, respectively.

Therefore, if the relaxation magnitudes are to be modeled using the unaged relaxation spectra and the aging model, the least squares method can be applied to minimize the error in the model prediction, varying the values of the aging state variable ($A_{2,85ºC}$ and $A_{2,135ºC}$) and the elastic and transient aging susceptibility. The procedure was carried out using Solver

and the obtained results were $\alpha_1 = 0.58$, $\alpha_2 = 0.94$, $A_{2,\ 85°C} = 0.228$ and $A_{2,135°C} = 0.449$. With the obtained aging state variable values ($A_{2,\ 85°C} = 0.228$ and $A_{2,135°C} = 0.449$), the aging model could be fitted by the determination of optimal $\Gamma^{\alpha</I>} = 9.95 \times 10^{-7}\ s^{-1}$ *and* $k_3 = 3.03$. The summary of the results is presented in Table 2.

Combining the aging model, whose parameters are presented in Table 2, with the linear viscoelastic model, whose parameters are presented in Table 1, one can represent all data of this paper. Figure 3 presents the comparison between experimental storage and loss moduli results at both aging states and the results predicted by the combination of Prony series and aging model.

It can be seen that the aging model, combined with the unaged discrete relaxation spectrum, can fit stiffness experimental data for asphalt mixtures, at least for early ages. Al-Rub et al. [4] used experimental data from the work done by Walubita [16], fitting an aging model for data covering up to 6 months of aging of compacted mixtures at 60ºC. Those authors evaluated two asphalt mixtures, obtaining Γ^{α} of 3.33 and $9.30 \times 10^{-7}\ s^{-1}$, i.e., the same order of magnitude found in the present paper. Al-Rub et al. [4] stated that Γ^{α} is used as an indicator of mixtures susceptibility to oxidative aging, because $1/\Gamma^{\alpha}$ could be regarded as a "relaxation time" for the aging. In this paper, temperature dependency was captured, because data was generated using aging at two different temperatures. Data for longer aging times will soon be available as part of the ongoing research effort at *Universidade Federal do Ceará*, at Fortaleza, Brazil.

4.4 *Aging simulation*

To present the main contribution of an aging model representing asphalt materials mechanical properties evolving with aging time, a few analytical simulations were performed. In the simulations the percent change in the Dynamic Modulus is presented as time passes during aging at a constant temperature. Different aging temperatures were evaluated, from 40 to 150°C. Results were summarized in Figure 4.

It can be seen that the fitted model predicts that a 40% increase in $|E^*|$ occurs at approximately 2.8×10^5, 2.4×10^5, 1.9×10^5, 1.1×10^5 and 0.9×10^5 s, for 40, 60, 85, 135 and 150°C, respectively. This corresponds to the following aging times, in days: 3.2, 2.8, 2.2, 1.3 and 1 day. For a given aging time, for example, 2 days, the predicted percent increases in $|E^*|$ are approximately 22, 26, 36, 68 and 75. In other words, it can be said that, based on some observations of the consequences of aging (change in moduli master curves in the case of this paper) at few aging states, a phenomenological aging model based on an internal state

Table 2. Result for the fitted aging model to the studied mixture.

Γ^{α} (1/s)	A_0 ( )	k_1 ( )	k_2 ( )	k_3 ( )	α_1 ( )	α_2 ( )	α_3 ( )	T_0 (ºC)

variable can associate aging time and aging temperature. The aging model predicts the value of the aging internal state variable (A) and it is then coupled to the aging consequences using the susceptibility parameters (α_i's). This gives the aging model the ability to predict the evolution of the mechanical properties, such as the Storage and the Loss Moduli, of asphalt mixtures. It is observed that this could be analogously done for viscoplasticity and damage as well, as presented by Al-Rub [4]. It is to be noticed that only two aging times were evaluated to this point of the research and could lead to prediction errors. A more comprehensive fitting will be produced with further data.

5 CONCLUSIONS

This paper uses an existing phenomenological model to study the aging effect on linear viscoelastic properties of asphalt mixtures. The referred aging model utilizes an internal state variable and four materials parameters. An aging experimental procedure inspired by a RILEM protocol is presented as part of a broader research effort under development in Brazil related to the country's new mechanistic-empirical pavement design method to be launched in 2016. Different aging temperatures allowed to identify the mixture aging sensitivity with respect to aging temperature, which constitutes a contribution with respect to the results originally presented by Al-Rub et al. [4], where aging temperature dependency was not evaluated. Concerning the aging model fitted in this paper, the material constants were obtained by minimizing square errors of the model compared to dynamic modulus experimental results at different aging states. A well-established procedure was used to fit the curves (Prony series) directly to experimental results (linear viscoelastic model), without pre-smoothing the data. The same relaxation times (ρ_i) were used for fitting all storage moduli (E')—aged and unaged mixtures—varying only the stiffness coefficients (E_i's). Combining the aging and the linear viscoelastic models, storage and loss moduli results at two different aging states were satisfactorily predicted. At the end, a simulation of the change in dynamic modulus with time (aging) was performed to show the potential of the coupled modeling approach. Data for extended aging times are being collected at *Universidade Federal do Ceará*, Brazil, and will be presented along with further modeling efforts in future papers by the authors and their research group.

Evaluation of the fatigue performance of asphalt mixtures with high RAP content

Amirhossein Norouzi, Mohammadreza Sabouri & Y. Richard Kim
Department of Civil, Construction and Environmental Engineering, Raleigh, NC, USA

ABSTRACT: Reclaimed Asphalt Pavement (RAP) has been used successfully in asphalt pavements at percentages up to 20 percent. The main problem that prevents transportation agencies from incorporating higher percentages of RAP is that high RAP contents may result in mixtures that are overly stiff and prone to fatigue cracking. In this study, the previously developed fatigue failure criterion for the Viscoelastic Continuum Damage (VECD) model, the G^R method, is used to evaluate the effect of incorporating high percentages of RAP on the fatigue cracking behavior of two different sets of plant-produced mixtures, referred to in this study as the VTe and MIT mixes. Incorporating high percentages of RAP into the VTe mixtures did not lead to a significant difference in fatigue resistance, which may suggest that the blending of RAP binder and virgin binder works as well as virgin binder alone. However, for the MIT mixtures, an increase in the percentage of RAP to 50 percent led to a considerable decrease in fatigue resistance, which was mitigated in this case with the use of a softer base binder.

Keywords: Reclaimed Asphalt Pavement (RAP), failure criterion, fatigue, damage

1 INTRODUCTION

During recent decades, the need for Reclaimed Asphalt Pavement (RAP) has increased. Some of the advantages of utilizing RAP include the preservation of the existing pavement profile, conservation of asphalt and aggregate resources, conservation of energy, and reduction in life-cycle costs [1]. However, many transportation agencies are not willing to use more than 10 percent to 20 percent RAP in Hot Mix Asphalt (HMA) [2]. One reason for this unwillingness is that RAP contains asphalt binder that has been aged, and incorporating higher RAP contents into HMA can produce mixtures that are stiffer than the same mixtures without RAP. Consequently, such mixtures would be less workable and more susceptible to field failure, such as fatigue cracking [3, 4]. Also, certain production factors, such as the RAP source, the virgin binder Performance Grade (PG), production temperature, and plant type, can affect the degree of blending RAP and virgin asphalt and consequently affect the performance of the resultant asphalt mixture [5].

Regardless of these concerns, Departments Of Transportation (DOTs) in the United States have been forced to increase the amount of RAP up to 50 percent in flexible pavements because of economic considerations, increases in the cost of asphalt binder, and environmental concerns.

Their primary objective is to encourage the use of recycled materials in the construction of highways to the maximum economical and practical extent possible with equal or improved performance [6].

Because fatigue cracking is one of the most common distresses in asphalt concrete pavements, it is extremely important to define or predict the fatigue cracking behavior of HMA in flexible pavement design and preservation. Therefore, an effective fatigue performance model is needed that can represent both fatigue damage growth and the fatigue failure criterion in

order to define the fatigue life of the pavement. Furthermore, in order to meet the demands for using RAP in HMA to the extent that is possible, the model should be able to incorporate RAP mixtures as well.

The Simplified Viscoelastic Continuum Damage (S-VECD) model is a continuum damage mechanics-based model that has been applied effectively to predict the performance of asphalt concrete mixtures under different loading conditions [7–12]. Zhang et al. [13] developed a new energy measure that represents the rate of damage growth using the S-VECD model and that can predict fatigue failure. However, Zhang et al. developed this approach based on controlled Crosshead (CX) mode of loading test data only. Later, Sabouri and Kim [14] applied Zhang et al.'s failure criterion to different modes of loading and found it to be mode of loading-dependent. They proposed a new failure criterion (the G^R method) that remedies the problems associated with Zhang et al.'s failure criterion. This new failure criterion is considered to be independent of mode of loading, strain amplitude, and temperature. According to this criterion, a characteristic relationship exists between the rate of change of the averaged released pseudo strain energy during fatigue testing and the final fatigue life, and is proved to be present in both RAP and non-RAP mixtures. This failure criterion combines the advantages of the S-VECD model and this characteristic relationship, which both originate from fundamental mixture properties.

Given the above considerations, the objective of this paper is to investigate the effect of incorporating high percentages of RAP in asphalt mixtures on the mechanical properties and the performance of those mixtures in terms of fatigue cracking using the S-VECD failure criterion and in comparison with standard (non-RAP) mixes.

2 MATERIALS AND SPECIMEN PREPARATION

2.1 *Materials*

For this study, a total of eight mixtures from two main sources were selected to be evaluated for their mechanical properties and fatigue performance. The first four mixtures are Superpave 9.5 mm plant-produced mixtures obtained from Pike Industries in Williston, Vermont (VT). These mixtures incorporate four different percentages of RAP: 0%, 20%, 30% and 40%. The VT mixtures are designated as VTeXXLC, with XX representing the percentage of RAP. The second source, Manitoba Infrastructure and Transportation (MIT), provided 16 mm plant-produced mixtures obtained from provincial Highway 8 in Manitoba, Canada. For the MIT mixtures, loose mixtures were sampled during paving of the top lift of each section at the project site. These sections were constructed in September 2009 and consisted of two 2-inch lifts with conventional HMA (i.e., 0% RAP), 15% RAP, and 50% RAP with no PG grade change for the new asphalt and 50% RAP with a PG grade change for the new asphalt.

2.2 *Binder*

PG 64-28 asphalt binder from a regional supplier was utilized for all the Vermont mixtures. The Manitoba mixtures that were evaluated in this study were manufactured using an asphalt binder of Pen grade 150/200. According to the study by Hajj et al. [15], the binder PG for the softer binder used in the Manitoba mixtures is specified as 52-34 whereas it is defined as 58-28 for the other mixes. Table 1 presents a summary of the properties of these eight mixtures.

2.3 *Specimen preparation*

All the specimens were compacted using the Superpave Gyratory Compactor (SGC) to a diameter of 150 mm and a height of 178 mm. To obtain specimens of uniform air void distribution, these samples were cored and cut to a 100 mm diameter and a height of 150 mm for the dynamic modulus tests and a height of 130 mm for the CX cyclic direct tension tests.

Table 1. Summary of mixture properties.

Mix type	Binder	Total AC (%)	RAP (%)	Compaction temp. (°C)	AV (%)
VTe00LC	PG64-28	6.5	0	149	6.0
VTe20LC	PG64-28	5.7	20	149	6.0
VTe30LC	PG64-28	5.1	30	154	6.0
VTe40LC	PG64-28	4.5	40	146	6.0
MIT-C	PG58-28	5.2	0	124	5.4
MIT-15R	PG58-28	5.2	15	124	4.9
MIT-50R	PG58-28	5.0	50	124	5.9
MIT-50RSB	PG52-34	5.0	50	129	5.7

The air void content was measured using the CoreLok method for each specimen before testing. All the samples selected for this study have the target air void of ±0.5%. All of the direct tension test specimens were glued to metal plates using DEVCON steel putty. Vertical deformations were measured using four Linear Variable Differential Transducers (LVDTs) with the gauge length of 70 mm at intervals of 90 degrees for both the dynamic modulus and CX cyclic tension tests.

3 TESTING METHODS

Two main tests were carried out in this study: (1) dynamic modulus tests were performed to determine the linear viscoelastic characteristics using the Asphalt Mixture Performance Tester (AMPT), and (2) CX cyclic direct tension tests were performed to determine the viscoelastic damage characteristics using the Material Testing System (MTS).

3.1 *Dynamic modulus testing*

Dynamic modulus testing was carried out in compression under load-controlled mode following the protocol given in AASHTO TP 79 [16]. The tests were performed for all mixtures at 4°C, 20°C, 40°C, and 54°C and at frequencies of 25, 10, 5, 1, 0.5, and 0.1 Hz. The load levels were specified by trial and error so that the strain amplitudes were between 50 and 75 microstrain to prevent damage to the specimens. The dynamic modulus (|E*|) values were fitted for the coefficients of the sigmoidal function and time-temperature shift factors by optimizing the dynamic modulus mastercurve. After determining the shift factors, the dynamic modulus was converted to the relaxation modulus, E(t), of the Prony series form to obtain a constitutive relationship between the strain and stress in the time domain. Finally, a power term, alpha (α), used in VECD theory, was calculated from the maximum log-log slope, m, of the relaxation modulus and time using the relationship, $\alpha = 1 + (1/m)$.

3.2 *Controlled Crosshead (CX) cyclic direct tension tests*

The CX cyclic direct tension tests were performed at 10 Hz at different temperatures based on the binder PG to determine the viscoelastic damage characteristics. All tests were performed at three to four different strain amplitudes (high, medium and low). The strain amplitudes were selected in such a way to create a spread of numbers of cycle to failure (N_f) in the range of 1,000 to 100,000 cycles. Fingerprint dynamic modulus tests were conducted to check the variability of the test specimens before running the CX cyclic direct tension tests. The dynamic modulus value measured from this test is specified as $|E^*|_{fingerprint}$ and is used to calculate the Dynamic Modulus Ratio (DMR) via Equation (1). $|E^*|_{LVE}$ is the linear viscoelastic dynamic modulus of the material at the particular temperature and frequency of the test. A DMR value in the range of 0.9 to 1.1 guarantees that the linear viscoelastic

properties obtained from the dynamic modulus tests can be used effectively in S-VECD analysis.

$$DMR = \frac{|E^*|_{fingerprint}}{|E^*|_{LVE}} \tag{1}$$

The fatigue failure for each of the specimens tested in the CX cyclic tests was determined by Reese's approach, which is based on the change in phase angle [17]. The phase angle increases until strain localization occurs, and then drops suddenly. This sharp decrease occurs around the failure point, which makes the determination of the number of cycles to failure accurate and consistent in a laboratory testing.

3.3 *Fatigue failure criteria*

The S-VECD failure criterion is based on the total released pseudo strain energy during a cyclic test. The maximum stored pseudo strain energy at each cycle reflects the material's ability to store energy at that particular time. As the damage grows, the material loses the stored energy for the same magnitude of applied pseudo strain due to the reduction in pseudo stiffness. The difference between the current stored maximum pseudo strain energy and the corresponding undamaged state is referred to as the *total released pseudo strain energy.*

The rate of change of the averaged released pseudo strain energy values throughout the history of the test is denoted as G^R. Sabouri and Kim [14] showed that G^R and the final fatigue life (N_f) are highly correlated, because the faster the damage accumulates, i.e., releasing higher amounts of energy during fewer numbers of cycles, the quicker the material should fail.

In order to minimize the effect of viscoplasticity, Sabouri and Kim suggested using the PG of the base binder to determine a proper testing temperature, as shown in Equation (2).

$$T(°C) \leq \frac{High\ temperature\ binder\ PG\ grade + Low\ temperature\ binder\ PG\ grade}{2} - 3 \leq 19°C \tag{2}$$

4 RESULTS AND DISCUSSION

Figure 1 presents the results of the linear viscoelastic characterization of the VTe and MIT mixes in both log-log and semi-log scales. The points in the graphs are the averaged dynamic modulus values of three replicates for each mixture. As Figure 1 (a) and (b) show for the VTe mixes, the addition of RAP into the VTe mixtures does not seem to have a significant effect on the dynamic modulus values, as no major differences are found in the dynamic modulus values when the RAP content is increased from 0 percent to 40 percent. On the other hand, as Figure 1 (c) and (d) indicate for the MIT mixes, incorporating RAP into the MIT mixtures has a more pronounced effect on the dynamic modulus values. In this case, the dynamic modulus values have increased significantly when 15% RAP is added to the mixture. One possible reason for this different behavior between the VTe and MIT mixes could be the greater difference in the PGs of the RAP binder and virgin binder in the MIT mixtures. The MIT RAP binder is PG 76-10 whereas the VTe RAP binder is PG 70-22.

Figure 2 presents the results of the S-VECD fatigue characterization of both the VTe and MIT mixtures. These plots illustrate how fast the material integrity (C) decreases as the damage (S) increases. These damage characteristic curves are each plotted up to the cycle when the phase angle starts to decrease. This cycle is considered to be the point of localization, i.e., the point where a single dominant macro-crack forms.

As Figure 2 (a) shows for the VTe mixes, all the C vs. S characteristic curves collapse almost on the same line, except for the 30% RAP mix for which the line stays a little above the

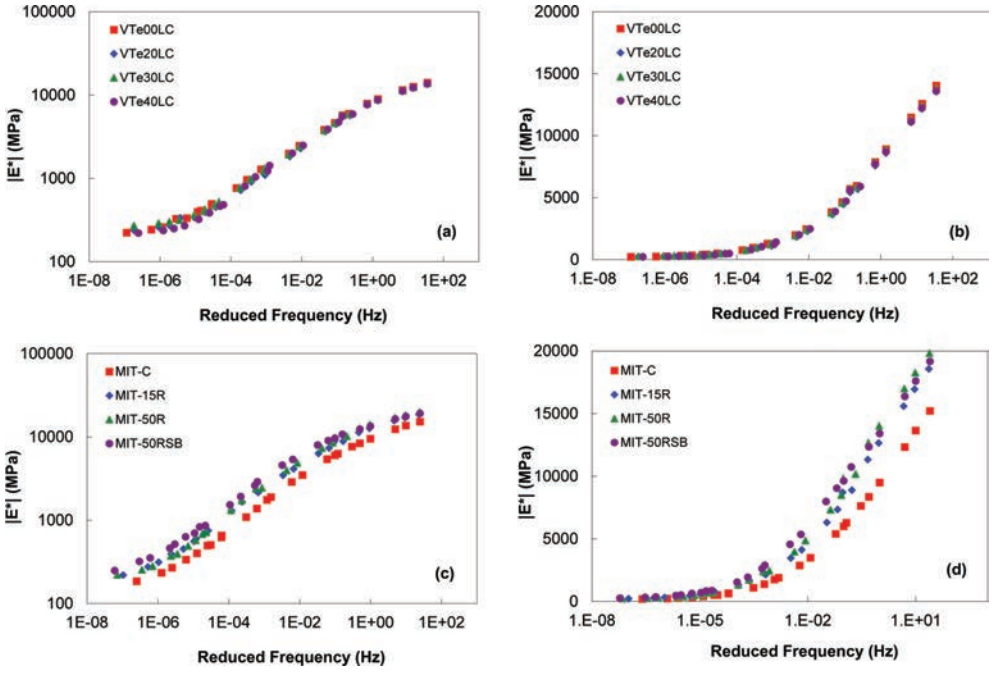

Figure 1. Dynamic modulus mastercurves: (a) VTe in log-log scale, (b) VTe in semi-log scale, (c) MIT in log-log scale, and (d) MIT in semi-log scale.

other lines. As Figure 2 (b) shows for the MIT mixes, the non-RAP mix and also the mix with soft binder show a rapid decrease in material integrity with an increase in damage compared to the mixtures with 15% and 50% RAP content.

The last point on each curve indicates the C value at failure (C_F). The results for the MIT mixtures confirm observations by Hou et al. [7] that suggest that the inclusion of RAP increases the material integrity at failure, though not to the same degree. The higher material integrity at failure value suggests that RAP mixtures cannot tolerate as much damage before failure as non-RAP mixtures. This ability is due to the mixture becoming more brittle once the RAP is incorporated into the mix. However, a comparison of only the damage characteristic curves cannot yield reliable information about the different mixtures' fatigue resistance, because the energy that is input by mechanical force is consumed not only in creating and propagating cracks in the material, but also in deforming the material. Therefore, it is important to include both stiffness and damage characteristics of a material when determining fatigue cracking resistance.

Figure 3 presents the characteristic relationships developed for both the VTe and MIT mixtures. A strong power law relationship exists between the failure criterion, G^R, and the number of cycles to failure, which is evident for all eight mixtures, according to the high coefficient of variance (R^2) values shown in Figure 3. One interesting observation to be made from Figure 3 (a) is the collapse of the failure criterion for all four VTe mixtures with different RAP contents. As discussed in the previous section, the dynamic modulus mastercurves and also the damage characteristic curves of this set of RAP mixtures are very close to those of the virgin mixture, indicating that the fatigue performance of the RAP and virgin mixtures would be similar. These similarities between the RAP and virgin mixtures seem to suggest that the materials (RAP binder grade, virgin binder grade, and type, etc.) and the mix design used for these RAP mixtures result in RAP mixtures with fatigue performance characteristics that are similar to those of the virgin mixture.

However, Figure 3 (b) demonstrates that incorporating high percentage RAP into the mix deteriorates the mixture fatigue resistance, as the failure criterion line for 15% RAP is a little

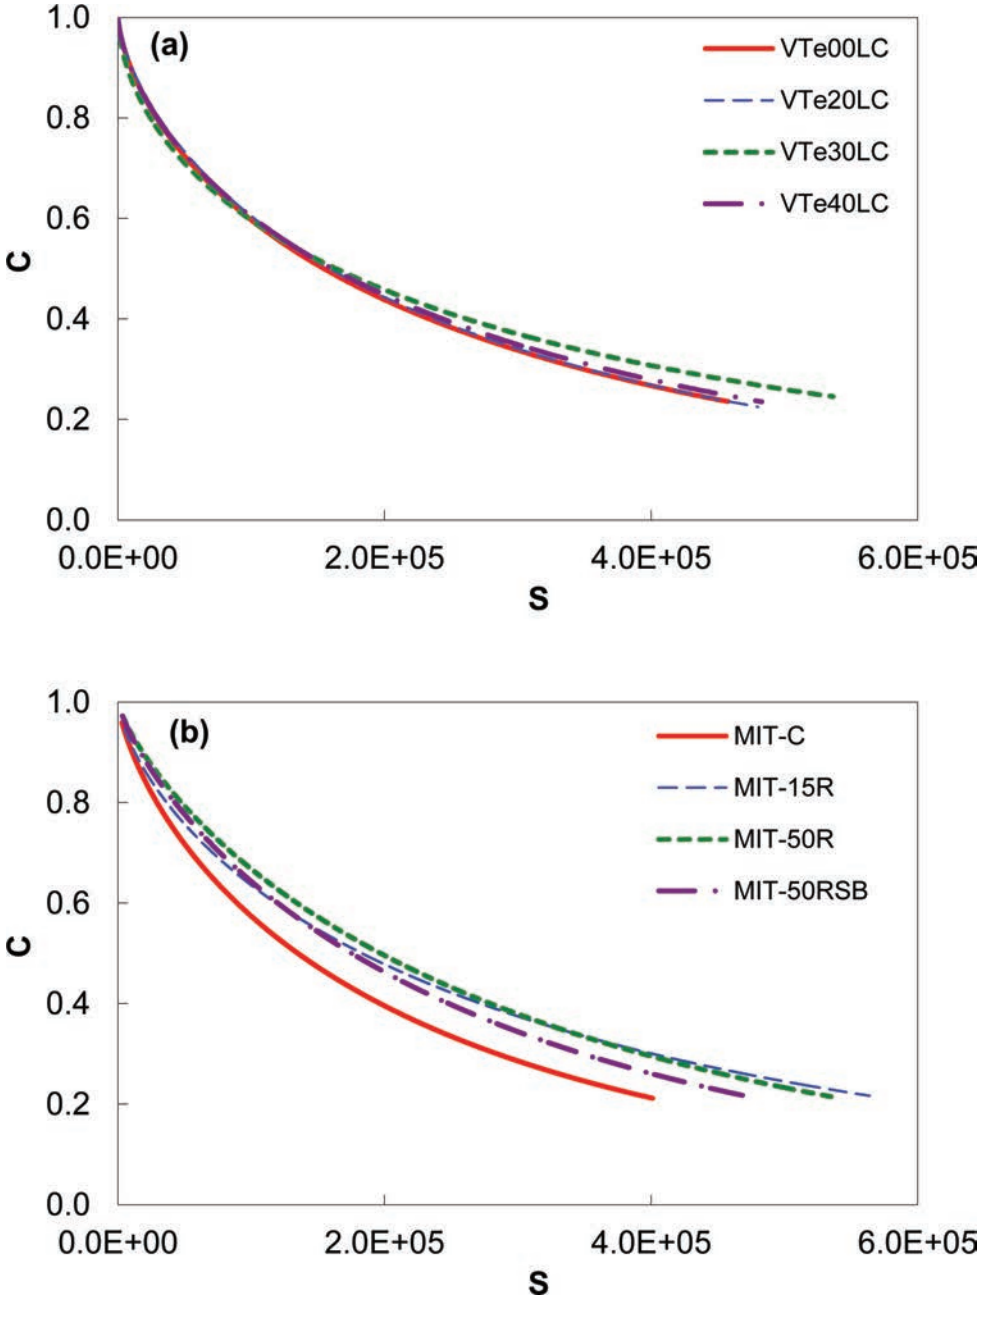

Figure 2. Characteristic curves for: (a) VTe and (b) MIT mixes.

below the virgin mix line, but the line for 50% RAP deviates from those two considerably, suggesting that at the same G^R value, the mix with 50% RAP results in fewer numbers of cycles to failure. This outcome may be due to the increase in the virgin binder stiffness as 50% aged binder is added to the mix, which makes the pavement system experience lower strains and consequently lower G^R values under the same loading history.

Another interesting observation from Figure 3 (b) is that the use of the softer binder (PG 52-34) can improve fatigue resistance, as the line for 50% RAP with the softer binder stays

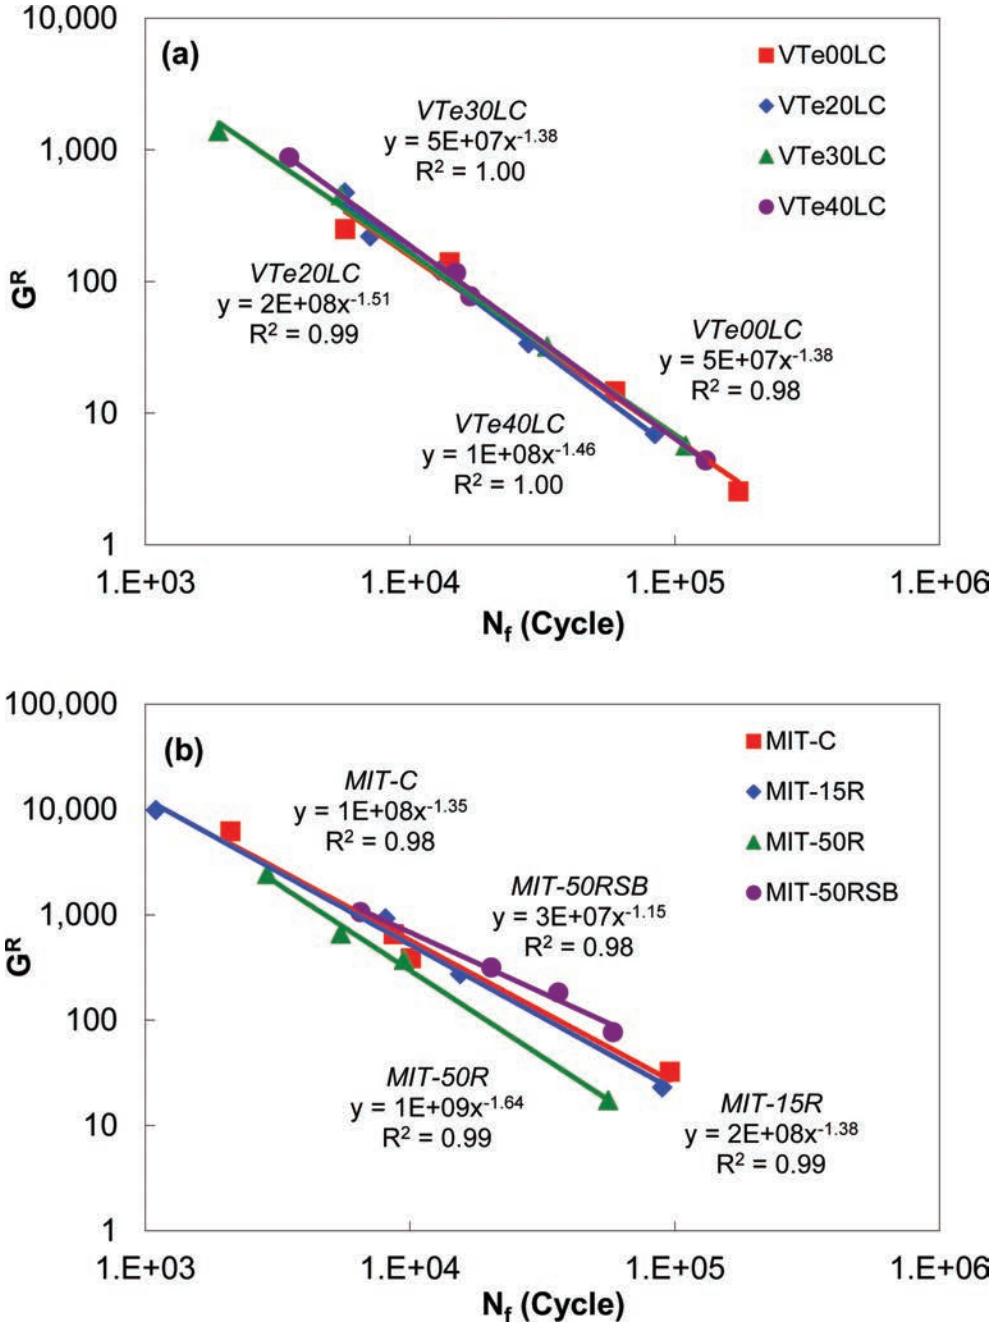

Figure 3. Relationship between G^R and N_f for: (a) VTe and (b) MIT mixes.

even higher than the line of the non-RAP mix. This finding suggests that using soft binder in high RAP content mixes can compensate for the decrease in fatigue resistance. Also, as expected, the MIT-C mix, which has the lowest stiffness (Fig. 1 (c)) and deepest fatigue characteristic curves (Fig. 2 (b)) among all the MIT mixtures with the same base binder, shows the best fatigue resistance, as its corresponding failure criterion line in Figure 3 (b) stays above the lines of the RAP mixtures with the same base binder.

5 CONCLUSIONS

This research conducted a laboratory evaluation of plant-produced mixtures from Vermont and Manitoba with RAP contents up to 50 percent. The impact of high RAP content on the fatigue cracking resistance of HMA mixtures was evaluated using a pseudo strain energy-based failure criterion. A different fatigue behavior trend was observed from the mixtures obtained from the two projects. The following summary presents the findings of this study for the evaluated mixtures.

- In general, the use of RAP, especially high RAP content, in HMA decreases the fatigue resistance, probably due to the addition of aged binder that stiffens the asphalt mixture.
- The data indicate no significant change in dynamic modulus values as the RAP content was increased for the VTe mixtures, whereas the mixture stiffness increased up to 25% when 15% RAP was added to the virgin MIT mix. One reason for this increase could be the difference in PG grades of RAP binders that were used in the VTe and MIT mixtures.
- The use of 50% RAP without a grade change for the virgin binder resulted in a reduction of the fatigue life of the MIT mixtures. However, the use of a softer virgin binder with the 50% RAP mixture improved fatigue resistance.
- Based on the findings of this study, it is concluded that it is possible to design high-quality HMA with up to 50% RAP that meets the desired fatigue resistance performance.
- This study's failure criterion (G^R) and the S-VECD model seem to be effective when used to compare the fatigue resistance of RAP and non-RAP asphalt concrete mixtures.

Three dimensional behaviour of bituminous mixtures in the linear viscoelastic and viscoplastic domains: The DBN model

Pierre Gayte, Hervé Di Benedetto & Cédric Sauzeat
ENTPE-University of Lyon, LGCB & LTDS (UMR 5513), Vaulx-en-Velin, France

ABSTRACT: Behaviour of bituminous mixtures is very complex. Their rheological properties depend on strain amplitude level and temperature. We can observe linear viscoelasticity properties for very small strain amplitudes and non-linearities for larger strain levels. Fatigue and rutting (permanent deformation) can appear for a great number of cycles. Moreover brittle or ductile failure can occur. All of these properties strongly temperature and time dependant.

The DBN (Di Benedetto-Neifar) model developed at LGCB laboratory (*University of Lyon/ENTPE "Ecole Nationale des TPE"*) aims at describing the complex behaviour of bituminous mixtures with an unified formalism. The model is also versatile and may be adapted to take into account some specific properties of bituminous materials. First, equations describing the whole three-dimensional DBN model in the linear domain are proposed. Then the visco-plastic formalism is introduced in the Elastic-Perfectly Plastic (EPP) case which is a simplified version of the model proposed for numerical finite element calculations.

Calibration of the model in the viscoelastic and viscoplastic domains as well as simulation are proposed based on experiments made at LGCB laboratory for different loading paths in the small and large strain domains.

1 INTRODUCTION

1.1 *Background*

Several external solicitations (mechanical, thermal, physical, chemical) can be identified when considering the behaviour of roadway structures. We can also observe that a coupling between these effects often appears. A main difficulty is then to model these effects (and their coupling) so as to be able to get a realistic performance prediction of bituminous pavements.

Mechanical properties of bituminous mixtures have to be modelled considering these four main properties [1–2]:

- Stiffness and stiffness evolution with time in the linear domain
- Fatigue and damage law evolution,
- Permanent deformation and accumulation of this deformation,
- Crack and crack propagation, in particular at low temperature.

Indeed they allow to characterize the structural effect of bituminous layers of the road and its evolution with time (not true for very thin surface layers). Being able to represent these properties is a way to model the behaviour of roads and then to indroduce this knowledge in pratical design methods using finite element methods.

Each of theses properties appears for a given domain of loading and corresponds to a specific type of behaviour for the mixtures. Thanks to Figure 1 it is possible to identify the domains corresponding to the different aspects introduced previously and the corresponding

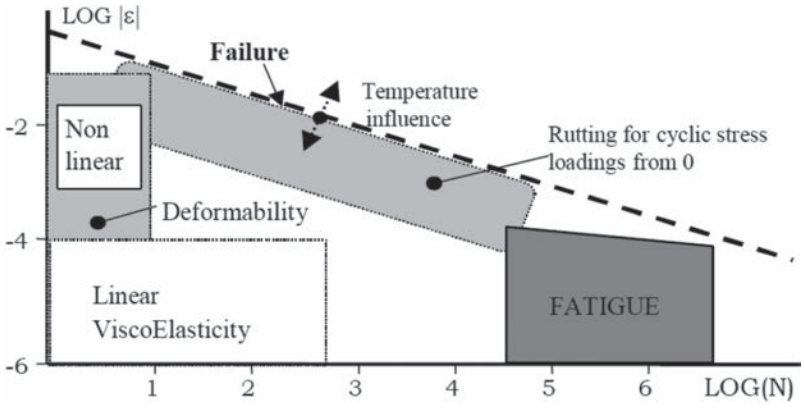

Figure 1. Domains of behaviour for bituminous mixtures (Strain amplitude (ε) above number of cycle (N)) by Di Benedetto (1990).

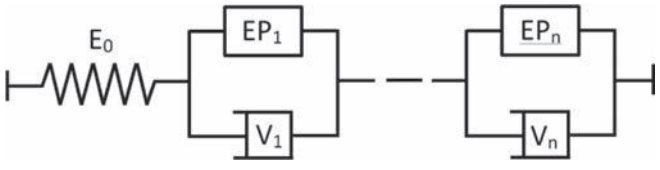

Figure 2. Analogical 1D representation of the DBN model.

"typical" type of behaviour for mixtures. Boundaries of domains are informative and transition from one domain to another is made in a smooth and continuous way.

1.2 *The DBN (Di Benedetto-Neifar) model*

Former works made at ENTPE (*Ecole Nationale des Travaux Publics de l'Etat*) leads to the development of the DBN model which is an attemp to describe with one formulation the different types of behaviour observed for bituminous mixtures. The main goal of this paper is to introduce a new version of the DBN model which aims at describing both the linear viscoelasticity and non linear domains. The general concept, equations and calibration process of the DBN model are more precisely described in [2]. Only the main aspects are recalled here.

This model is based on simple rheological elements and its calibration is made from experimental results on bituminous mixtures. Due to its high versatility this model is able to describe the behaviour in a wide range of strain amplitude, temperature and number of cyclic loadings. As a result this model can be very simple to use (linear viscoelastic domain) or more complicated (when introducing nonlinearity, fatigue) following required refinement.

The 1D representation of the DBN model is composed of one spring (modulus E_0) and n elementary bodies (each of them composed by an elastoplastic (*ie.* non viscous) body (EP) in parallel with a dashpot (linear V body) as shown on Figure 2. The number of elementary bodies can be chosen arbitrarily as the calibration procedure always needs the same number of constants. If n is high, simulations calculus are close to the experimental data. But also calculations take more time. Calibration of the n elementary bodies is made from parameters of the 2S2P1D model (also developed at LCGB-ENTPE) in the linear domain.

From the general structure of the model (Fig. 2) the total strain[1] $\underline{\varepsilon}$ is given by the sum of the strain in each body $\underline{\varepsilon_i}$ (Eq. (1)), while all bodies are subjected to the same stress $\underline{\sigma}$.

[1]Second order tensors are denoted with simple underline ($\underline{\varepsilon}$) and fourth order tensors with double underline ($\underline{\underline{M}}$).

Stresses in the EP_i and V_i body are denotedv $\underline{\sigma}_i^f$ and $\underline{\sigma}_i^v$ and verify the relationship (Eq. (2) and Fig. 3).

$$\underline{\varepsilon} = \sum_{i=0}^{n} \underline{\varepsilon}_i \tag{1}$$

$$\underline{\sigma} = \underline{\sigma}_i^f + \underline{\sigma}_i^v \tag{2}$$

1.3 *Visco-plasticity for body "i"*

Plasticity phenomenon appears when sollicitation applied to a given non viscous material create non-reversible deformations. A classical elastoplastic formulation is chosen to simulate plasticity. The yield surface $f(\underline{\sigma}_i^f) = 0$ (Fig. 4) is the limit between the elastic and the plastic domain for body EP_i. It is obtained from experimental tests. While the stress $\underline{\sigma}_i^f$ remains "inside" the yield surface only elastic strains occur in body EP_i. Once $\underline{\sigma}_i^f$ reaches the yield surface plastic (non-reversible) strains may appear involving viscoplasticity for body "i".

1.4 *Objectives*

The developments introduced in this article focus on the modelling of linear and non linear (deformability in Fig. 1) behaviours. Rutting and fatigue are not introduced yet. A simplified version of the DBN model is presented. This version is developped to facilitate introduction of the model in finite elements methods calculations considering that each EP_i body is Elastic-Perfectly Plastic (EPP) which means linear elastic (E) behaviour within the yield surface

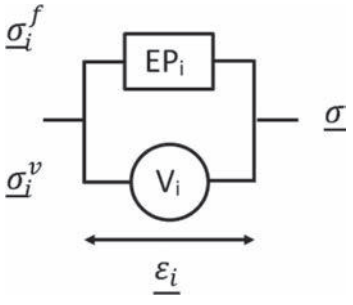

Figure 3. Representation of stress and strain in body "*i*".

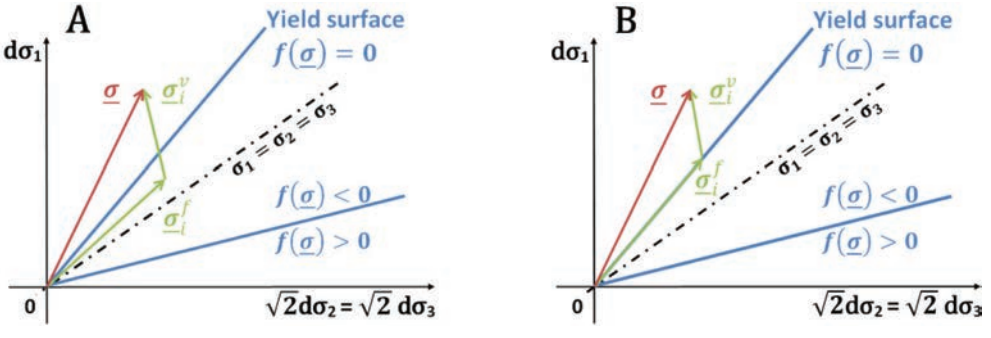

Figure 4. Representation of two possibles cases for $f(\underline{\sigma}) > 0$ considering $\sigma_2 = \sigma_3$ (A) elastic behaviour ($f(\underline{\sigma}_i^f) = 0$) and (B) visco-plastic behaviour ($f(\underline{\sigma}_i^f) < 0$).

and Perfect Plasticity (PP) for larger strain amplitudes. As explained previously the goal is to develop a rheological model which is able to correctly take into account some complex features of bituminous materials and simple enough to be implemented into a finite elements calculation software. Let's remind that it could be improved thanks to the high versatility of the model. Simple or more complex version can be considered depending on the studied phenomena.

2 FORMULATION OF EP_i BODIES FOR THE EPP (ELASTIC—PERFECTLY PLASTIC) VERSION OF THE DBN MODEL

Formulation of the EPP version of the DBN model is introduced for the 3D case. Figure 5 gives the analogical representation for the three-dimensional case.

2.1 *Elastic part of EP type body*

In the linear domain stress and strain of EP body are linked by the elastic tensor $\underline{\underline{M}}_i^e$ with components $M_{i_{mjkl}}^e$ using Equation 3

$$\varepsilon_{i_{mj}} = M_{i_{mjkl}}^e \sigma_{i_{kl}}^f \tag{3}$$

The elastic part of EP body is considered to be isotropic. Then elastic tensor can be written (Equation 4) as a function of the Young modulus E_i and the Poisson's ratio υ_i. These coefficients are both obtained from the optimisation process used in the unidirectional case from the 2S2P1D model. More details are available in [2] concerning the calibration process and experimental data needed.

$$M_{i_{mjkl}}^e = \frac{\left(1+\upsilon_i\right)\delta_{mk}\delta_{jl} - \upsilon_i\delta_{kl}\delta_{mj}}{E_i} \tag{4}$$

2.2 *Plastic strains of EP type body for the EPP version*

2.2.1 *General equations*

The stain $\underline{\varepsilon_i}$ of an EP_i body is considered as the sum of an elastic strain $\underline{\varepsilon_i^e}$ and a plastic strain $\underline{\varepsilon_i^p}$ (Fig. 5):

$$\dot{\underline{\varepsilon}}_i = \dot{\underline{\varepsilon}}_i^e + \dot{\underline{\varepsilon}}_i^p = \underline{\underline{M}}_i^{ep} \dot{\underline{\sigma}}_i^f \tag{5}$$

where $\dot{}$ denotes the objective time derivative. Equation (5) can be rewritten considering the elastoplasticity framework. Then for plastic loading it comes:

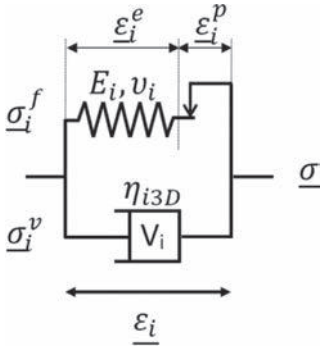

Figure 5. Analogical 3D representation of the EPP version of the DBN model.

$$\dot{\underline{\varepsilon}}_i = \underline{\underline{M}}_i^{ep}\,\dot{\underline{\sigma}}_i^f = \underline{\underline{M}}_i^{e}\,\dot{\underline{\sigma}}_i^f + \underline{\underline{M}}_i^{p}\,\dot{\underline{\sigma}}_i^f = \dot{\underline{\varepsilon}}_i^e + \dot{\underline{\varepsilon}}_i^p \tag{6}$$

And for unloading case:

$$\dot{\underline{\varepsilon}}_i = \underline{\underline{M}}_i^{e}\,\dot{\underline{\sigma}}_i^f \tag{7}$$

where $\underline{\underline{M}}_i^{ep}$ and $\underline{\underline{M}}_i^{p}$ are respectively the elastoplastic and the plastic tensors given by:

$$\underline{\underline{M}}_i^{ep} = \underline{\underline{M}}_i^{e} + \underline{\underline{M}}_i^{p} \tag{8}$$

$$\underline{\underline{M}}_i^{p} = M_i^p\left(\underline{n}_f \otimes \underline{n}_g\right) \tag{9}$$

And $\underline{n}_f$ and $\underline{n}_g$ are unit normal vectors to the yield surface f and the plastic potential surface g. M_i^p is the norm of the plastic tensor $\underline{\underline{M}}_i^p$ which is infinite because of the perfect plasticity property of the model. In this case Equation 6 can be rewritten:

$$\dot{\underline{\varepsilon}}_i^p = \underline{\underline{M}}_i^{p}\,\dot{\underline{\sigma}}_i^f = \dot{\varepsilon}_i^p\,\underline{n}_g \tag{10}$$

2.2.2 *Yield surface f*

The chosen yield surface is adapted from equations given by S. Maïolino in [3]. It is a general smooth, convex and cone-shaped function.

$$\begin{aligned} &f\left(R, L_s, I_0, I_1, J_2, J_3\right) \\ &= sign\left(I_1 + I_0\right)\left[L_s^2\left(I_1 + I_0\right)^3 R^3 - 3\left(L_s^2 - L_s + 1\right)\left(I_1 + I_0\right)J_2 R + 9\sqrt{2}\left(1 - L_s\right)J_3\right] \end{aligned} \tag{11}$$

where parameters R and L_S are respectively the "opening" and the "shape ratio" of the yield surface, I_0 gives the summit of the cone which is on the first trisect. I_1, J_2, J_3 are three invariants[2] of tensor $\underline{\sigma}^f$ (Fig. 6). This formulation of the yield surface needs to be calibrated for the case of bituminous mixtures.

From a series of triaxial compression and extension tests Di Benedetto and Yan [4] establish that the yield surface is a cone, whose axis is the trisect. Sections in deviatoric planes

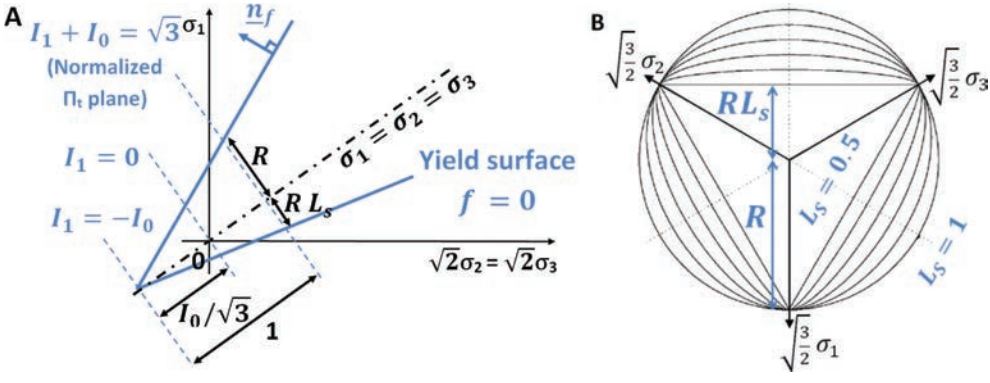

Figure 6. Representation of the yield surface (A) Section in the axis $\sigma_1 - \sqrt{2}\sigma_2 = \sqrt{2}\sigma_3$—(B) Section by the normal plane to the first trisect given by equation $I_1 + I_0 = \sqrt{3}$ in the principal axis.

[2] $I_1 = tr(\underline{\sigma}^f)$; $J_2 = tr(\underline{s}^{f^2})$, $J_3 = tr(\underline{s}^{f^3})$ where $\underline{s}^f = \underline{\sigma}^f - 1/3\,tr(\underline{\sigma}^f)$.

(perpendicular to the first trisect) are equilateral triangles (Fig. 7). It is supposed that yield surfaces of all bodies "i" have the same shape. From these considerations and using the function Eq. (11) the yield surface for bituminous material is proposed. The yield surface $f(\underline{\sigma}^f) = 0$ of the EPP version of the DBN model is then given by:

$$f\left(\underline{\sigma}^f\right) = \begin{cases} f^t\left(R_t, L_s, I_{0t,i}, I_1, J_2, J_3\right) & when\ I_1 \leq I_{p,i} \quad (12.1) \\ f^c\left(R_c, L_s, I_{0c,i}, I_1, J_2, J_3\right) & when\ I_1 > I_{p,i} \quad (12.2) \end{cases}$$

In order to approximate the Di Benedetto and Yan criterion (Fig. 7) with a smooth surface (to simplify computations) the shape ratio L_s has been chosen equal to 0.55 for each DBN body (Fig. 8). It remains the same for the two functions. Surfaces are thus given by continu-

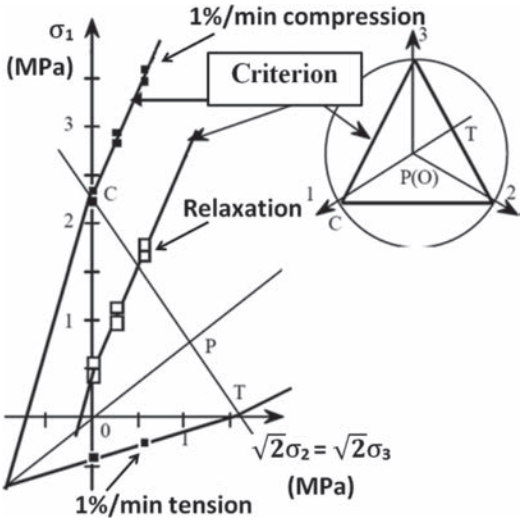

Figure 7. Failure stress for triaxial compression and tension tests at 1%/min and relaxation values (experimental data), and proposed failure surface (from [4]).

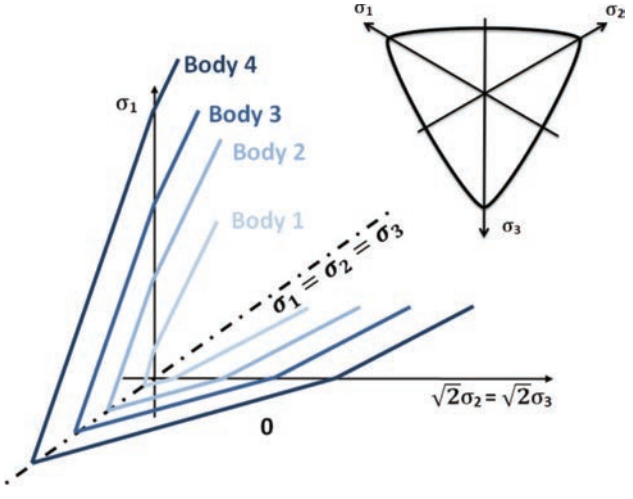

Figure 8. Representation (2D) of yield surfaces of the EPP version of the DBN model (only four EP bodies drawn).

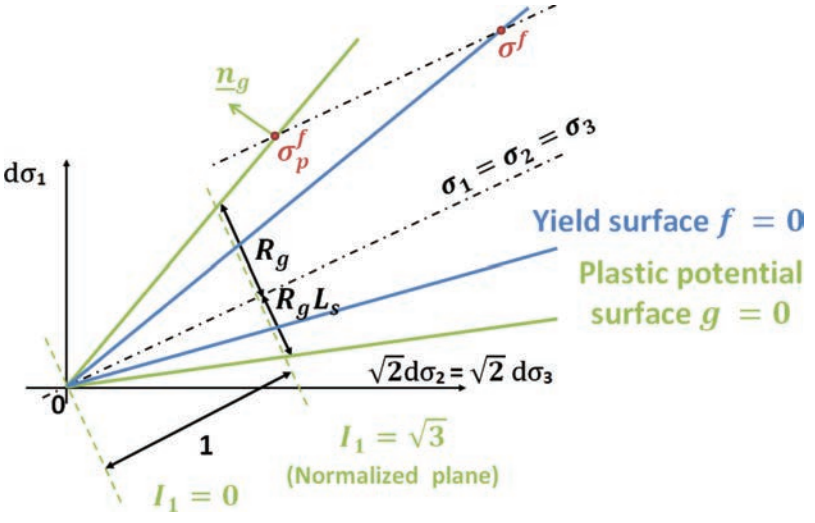

Figure 9. Representation of the plastic potential surface with parameters (R_g, L_{sg}).

ous and differentiable functions. Calibration of parameters R_t, R_c, $I_{0t,i}$, and $I_{p,i}$ is obtained from experimental data. R_t and R_c are not denoted with subscript "i" they take the same value for each EP_i body.

2.2.3 *Plastic potential g*

Direction of plastic strain is given by the unit normal vector to the plastic potential surface. In the EPP version of the DBN model introduced in this article it is decided to keep the same equation as the one used for the yield surface but with a different shape ratio L_{sg} and opening R_g.

$$g\left(R_g, L_{sg}, I_1, J_2, J_3\right) = sign\left(I_1\right)\left[L_{sg}{}^2\left(I_1\right)^3 R_g^3 - 3\left(L_{sg}{}^2 - L_{sg} + 1\right)\left(I_1\right)J_2 R_g + 9\sqrt{2}\left(1 - L_{sg}\right)J_3\right] \tag{13}$$

where I_1, J_2, J_3 are the three invariants of the tensors $\underline{\sigma}$. Parameters R_g and L_{sg} are obtained from experimental data of tension/compression tests by a calibration process. Poisson's ratios in tension and compression in the plastic domain are needed. R_g and L_{sg} are the same for each EP_i body. Then plastic potential surface is given by (Fig. 9):

$$g\left(R_g, L_{sg}, I_1, J_2, J_3\right) = constant \tag{14}$$

3 FORMULATION OF LINEAR V_i BODIES AND MAPPING RULE

3.1 *General V body behaviour*

Behaviour of V type body is given by:

$$\dot{\varepsilon}_{mj} = N_{i_{mjkl}}\, \sigma^v_{kl} \tag{15}$$

where $\underline{\underline{N}}_i$, with components $N_{i_{mjkl}}$, is the viscous rheological tensor which is a function of the temperature T. Thermo-susceptibility of bituminous material is thus taken into account in the model. It can be shown that the Time Temperature Superposition Principle is verified even in the nonlinear domain [2].

3.2 *Linear viscoelastic case*

This section deals with the LVE behaviour of V_i bodies *ie.* when $f(\underline{\sigma}^f) < 0$ or $f(\underline{\sigma}^f) < 0$ with no plastic strains ($\underline{\sigma}^f \cdot \underline{n}_f \leq 0$). A basic hypothesis formulated and interpreted in Di Benedetto (1987) is that the rate of the elastoplastic stress tensor ($\dot{\underline{\sigma}}^f$) is collinear and in the same direction as the viscous stress tensor ($\underline{\sigma}^v$) (Fig. 10). Considering this hypothesis and Eq. (15), let ζ_i be the ratio between norms of tensor $\underline{\underline{N}}_i$ and $\underline{\underline{M}}_i^e$:

$$\underline{\underline{N}}_i = \zeta_i \underline{\underline{M}}_i^e \tag{16}$$

Only one scalar is then needed to complete the description of the behaviour of the body V. The scalar parameter η_{i3D} is introduced:

$$\left\| \underline{\underline{N}}_i \right\| = \frac{1}{\eta_{i3D}} = \zeta_i \left\| \underline{\underline{M}}_i^e \right\| \tag{17}$$

where $\left\| \underline{\underline{A}} \right\| = \sqrt{A_{ij} A_{ij}}$ is the norm of tensor $\underline{\underline{A}}$. From equations 16 and 17 it comes:

$$\dot{\varepsilon}_i = \underline{\underline{N}}_i \underline{\sigma}_i^v = \zeta_i \underline{\underline{M}}_i^e \underline{\sigma}_i^v = \frac{\underline{\underline{M}}_i^e \underline{\sigma}_i^v}{\eta_{i3D} \left\| \underline{\underline{M}}_i^e \right\|} \tag{18}$$

Taking the case of a one dimensional loading (only σ_{11} is not nil), it comes:

$$\dot{\varepsilon}_{11i} = \frac{\sigma_{11i}^v}{\eta_{i3D} E_i \left\| \underline{\underline{M}}_i^e \right\|} = \frac{\sigma_{11i}^v}{\eta_i} \tag{19}$$

where η_i is the one dimensional viscosity constant of body "*i*". Then:

$$\eta_{i3D} = \frac{\eta_i}{E_i \left\| \underline{\underline{M}}_i^e \right\|} \tag{20}$$

Finally constant ζ_i which allows describing the whole behaviour of the V body is given by the relation:

$$\zeta_i = \frac{1}{\eta_{i3D} \left\| \underline{\underline{M}}_i^e \right\|} = \frac{E_i}{\eta_i} \tag{21}$$

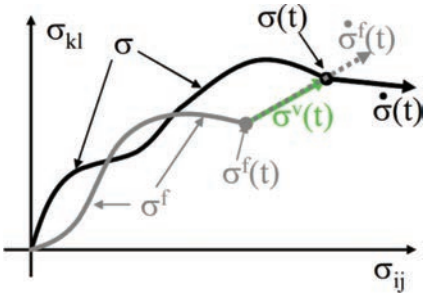

Figure 10. Evolution of the non-viscous (or elastoplastic) stress $\underline{\sigma}^f$ and of the viscous stress $\underline{\sigma}^v$ in the case without plastic strains (LVE behaviour).

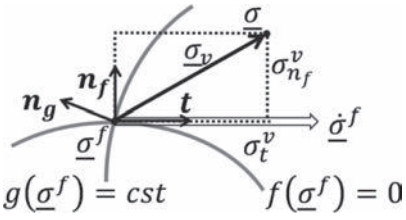

Figure 11. Representation of tensors when reaching the yield surface in the case of perfect plasticity.

3.3 *Viscoplastic case*

The EPP-version introduces a perfectly plastic model for EP_i bodies. This section deals with the viscoplastic case *ie.* $f\left(\underline{\sigma}_i^f\right) = 0$ with plastic strains $\left(\underline{\sigma}_v \cdot \underline{n}_f > 0\right)$. When non viscous stress $\left(\underline{\sigma}_i^f\right)$ reach the yield surface two complementary phenomena appear:

- As stress $\underline{\sigma}_i^f$ is on the yield surface the rate $\dot{\underline{\sigma}}_i^f$ can only be tangent to the surface $f\left(\underline{\sigma}_i^f\right) = 0$. In others words $\dot{\underline{\sigma}}_i^f$ is only pointing in the orthogonal directions of vector $\underline{n}_f$ which means $\dot{\underline{\sigma}}_i^f \cdot \underline{n}_f = 0$. Consequently $\dot{\underline{\sigma}}_i^f$ and $\dot{\underline{\sigma}}_i^v$ are no more collinear when plasticity is activated (Fig. 11).
- Plastic strain rate $\dot{\underline{\varepsilon}}_i^p$ is collinear to the unit normal vector $\underline{n}_g$ to the plastic potential surface. Its norm is denoted $\dot{\varepsilon}_i^p$ and given by the Mapping rule presented hereafter. Then $\dot{\underline{\varepsilon}}_i^p = \dot{\varepsilon}_i^p \underline{n}_g$.

From Equation 15 it comes:

$$\dot{\underline{\varepsilon}}_i = \underline{\underline{N}}_i \underline{\sigma}_i^v = \underline{\underline{N}}_i \left(\underline{\sigma}_{i\,n_f}^v + \underline{\sigma}_{i\,t}^v \right) \tag{22}$$

where $\underline{\sigma}_{i\,n_f}^v$ and $\underline{\sigma}_{i\,t}^v$ are respectively the projection of $\underline{\sigma}_i^v$ on the unit normal vector $\underline{n}_f$ to the yield surface and $\underline{\sigma}_{i\,t}^v = \underline{\sigma}_i^v - \underline{\sigma}_{i\,n_f}^v$. From this equation elastic and plastic part can be identified:

$$\begin{cases} \dot{\underline{\varepsilon}}_i^e = \underline{\underline{N}}_i \underline{\sigma}_{i\,t}^v \\ \dot{\underline{\varepsilon}}_i^p = \underline{\underline{N}}_i \underline{\sigma}_{i\,n_f}^v \end{cases} \tag{23}$$

Finally the norm of the rate of plastic strain is equal to:

$$\dot{\varepsilon}_i^p = \left\| \underline{\underline{N}}_i \right\| \left\| \underline{\sigma}_{i\,n_f}^v \right\| \tag{24}$$

And the expression of the rate of plastic strains is given by:

$$\dot{\underline{\varepsilon}}_i^p = \left\| \underline{\underline{N}}_i \right\| \left\| \underline{\sigma}_{i\,n_f}^v \right\| \underline{n}_g \tag{25}$$

4 EXAMPLES OF SIMULATION

Figure 12 presents the results of a complex modulus test performed on Mix6%5070[3] (from [5]) and the simulations with the linear viscoelastic model having continuum spectrum 2S2P1D [6] and the DBN model having 5, 15 and 25 bodies. The influence of the number of chosen elementary bodies "*n*" can be observed. The calibration procedure is presented in [5].

[3]Mix6%5070 is a mix with 6% (aggregate weight) of 50/70 penetration grade pure bitumen and a continuous 0/10 mm aggregates grading.

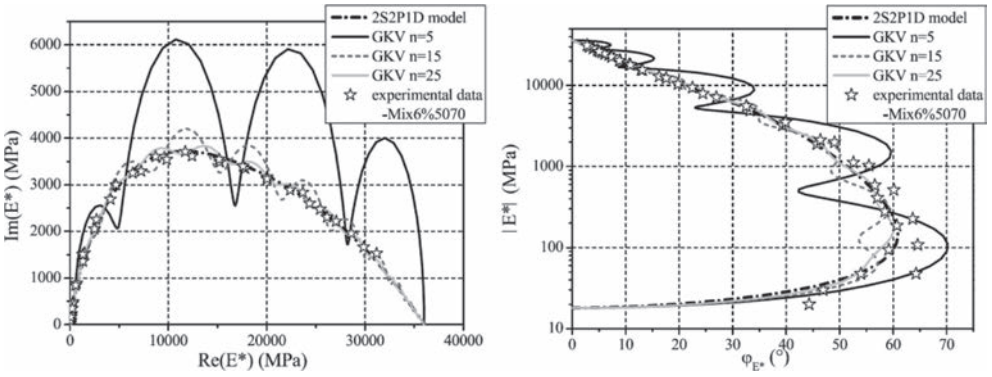

Figure 12. Experimental results of complex modulus test on Mix6%5070 and simulations with 2S2P1D and DBN models (5, 15, 25 elements)—Left: Cole-Cole diagram; Right: Black diagram—of complex modulus E* (from [5]).

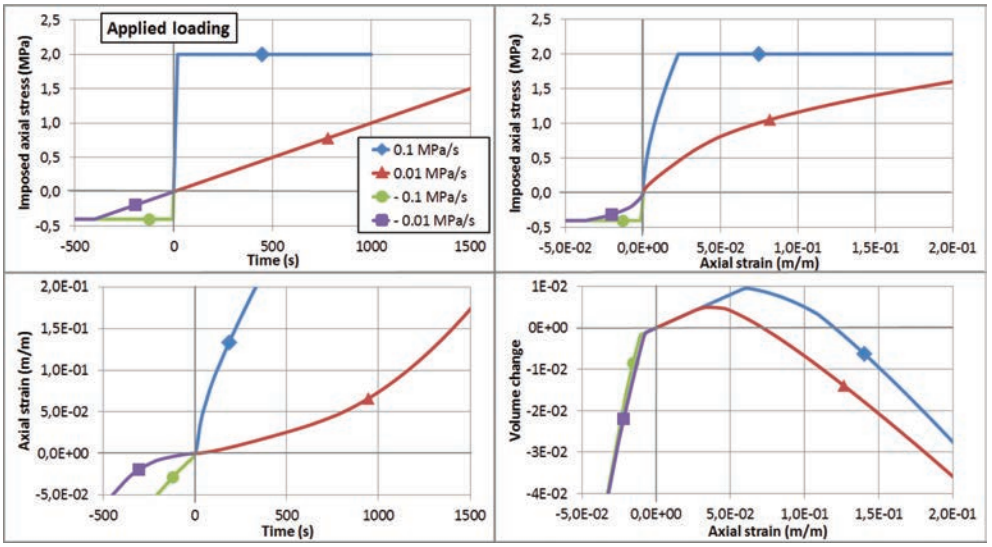

Figure 13. Simulations of compression and tension tests at two axial stress rates (0.1/0.01 MPa/s) followed by a creep period, using EPP version of the DBN model.

Results of a simulation based on the presented EPP version of the DBN model is plotted on Figure 13. Compression and tension tests are performed at two rate of stress (0.1/0.01 MPa/s) followed by a creep period. Calibration is made using 20 DBN bodies and is given in Annex A.

5 CONCLUSIONS AND PERSPECTIVES

This paper presents a version of the DBN model developed at LGCB laboratory (*ENTPE "Ecole Nationale des TPE"*) called the Elastic—Perfectly Plastic (EPP) version. DBN model is known to be versatile. This version is used to describe the linear viscoelastic and the visco-plastic domain. It can be upgraded to take into account more phenomena such as fatigue, rutting, brittle failure. Due to the limited number of pages these aspects are not developed in this paper.

The calibration of the EPP version of the BDN model needs twenty constants for the isotropic case. Nine of these constants are obtained in the small strain domain (linear viscoelastic behaviour) from the 2S2P1D model. Two constants are considered to stand for thermo-susceptibility of the material using the William-Landel-Ferry equation. The Time-Temperature Superposition Principle (TTSP) is respected in the linear and nonlinear domains. The plastic domain (yield and plastic potential surfaces) needs the last nine constants to be calibrated. Although few new constants are introduced this version has a good potential. Its formulation is easy-to-use. This law will be implemented further in a finite elements methods program.

Accelerated pavement testing for verification of DARWin-ME models for superpave pavements

Stefan Romanoschi
Department of Civil Engineering, University of Texas, Arlington, TX, USA

Mustaque Hossain
Department of Civil Engineering, Kansas State University, Manhattan, KS, USA

ABSTRACT: APT tests were conducted on 12 lanes of Superpave pavements with various thickness and mix design. The objectives of this research were to validate the pavement response models and fatigue relationship used in DARWin-ME. All pavement sections were instrumented with asphalt strain gages to measure transverse and longitudinal tensile strains and thermocouples for temperature measurements. Companion beam samples of the Superpave mix with the same air voids as the test lanes were tested in an IPC beam-fatigue test machine under controlled strain mode at three different strain levels till they reach 50% of the initial stiffness. The sections were loaded with a 100 kN (22.5-kip) single axle traveling at a uniform travel speed of 11.2 km/h (7 mph). The pavement responses were also independently calculated by the response software, JULEA. The results show that DARWin-ME structural response model for flexible pavements under-predicts the longitudinal strains at the bottom of the asphalt concrete layers, the structural response used for predicting alligator cracking. The computed strains were two to three times smaller than the measured strains. The laboratory beam fatigue test results show that a single model for the fatigue life of asphalt concrete, such as the one incorporated in DARWin-ME, does not effectively predict the fatigue life for all mixes.

Keywords: Superpave, DARWin-ME, fatigue life, Accelerated Pavement Testing

1 INTRODUCTION

The National Academy of Science, through its NCHRP Program, has developed a user-friendly procedure capable of executing mechanistic-empirical design while accounting for local environmental conditions, local highway materials, and actual highway traffic distribution by means of axle load spectra [1]. The resulting procedure was adopted by the American Association of State Highway and Transportation (AASHTO) as the new AASHTO design method (DARWin-ME) for pavement structures. It should be noted that all mechanistic design approaches produce "*theoretical structural designs*" that should be adjusted or *"calibrated"* to actual conditions using data originated from in-service pavement structures. DARWin-ME is a procedure with (i) national correlations to estimate selected inputs, (ii) national default values, and (iii) national calibration factors developed from the LTPP sites [2]. It is clear that all these need to be validated and/or calibrated for each specific state and/or region. Without region/state specific calibration, the new guide will be ineffective and of limited use for design purposes. Also, assessment of the design reliability can only be attempted after the guide has been calibrated and validated. This paper describes research work that aimed to contribute to the pavement performance models by conducting accelerated pavement tests at the Civil Infrastructure Systems Laboratory (CISL) Laboratory of Kansas State University. Due to the limited number of pavement sections that can be constructed and tested at CISL, the

research work focused on verification of the DARWin-ME models for representative flexible pavement structures in three Midwestern states: Iowa, Kansas and Missouri.

2 ACCELERATED PAVEMENT TESTING (APT) AT THE CIVIL INFRASTRUCTURE SYSTEMS LABORATORY (CISL)

The APT facility at CISL of Kansas State University is an indoor facility with about 651 m^2 (7,000 ft^2) of floor space [3]. The laboratory allows full-scale accelerated testing on pavement structures. The test pavements are constructed in three, 1.83 m (6.0 ft) deep test pits of varying width and 6.1 m (20 ft) in length. The accelerated loading is provided by the APT machine that can be moved on rails between the testing pits. The main components of the machine are the steel frame, which has two main girders with a 12.8 m (42-ft) center-to-center span; and the bogie, that is supported by the frame. The bogie is pulled back and forth by a rubber belt attached to an electric motor fixed on the frame. The wheel-load assembly consists of a single or tandem axle mounted on the bogie. Loading of the axle assembly is accomplished with a two hydraulic cylinders mounted on the bogie, above the single axle. The hydraulic pump pressurizes the oil in the hydraulic circuit and thus, the two cylinders push the bogie into the steel frame and the axle on the top of the test pavement. The cylinders also raise the bogie when uni-directional loading is applied. The axle load is controlled by the pressure in the hydraulic circuit. Load cells mounted on each wheel are used to measure the instantaneous wheel loads [3].

The bogie moves with a constant speed of 11 km/h (7 mph) on the test pavement; acceleration and deceleration are done outside the test area. The bogie takes approximately 5.8 seconds to complete its travel distance in one direction. In bi-directional loading mode, approximately 620 passes of the bogie are applied in one hour of operation, and about 100,000 passes in one week. The operation is typically stopped for several hours weekly for maintenance of the machine and measurement of pavement response and performance. Typically, two test pavements are constructed in each pit and loaded simultaneously with one wheel of the axle passing above each test pavement. The machine is equipped with a lateral wandering device that moves the entire frame in a lateral direction, with a maximum lateral wander of ±0.3 m (±12 inch). The lateral movement is applied in steps of 12.5 mm (0.5 inch) using screw jacks. A temperature-control chamber was built to encase the entire steel frame such that the temperature in the asphalt concrete layers could be controlled within ±3°C (±6°F). For this project, target testing temperatures were 20°C (68°F) and 35°C (95°F).

2.1 *CISL 14 experiment*

The objective of this experiment was to verify the models used in the Mechanistic Empirical Pavement Design Guide (now DARWin ME) for the design of new flexible pavements through Accelerated Pavement Testing (APT). Twelve experimental pavement structures were constructed and tested. Three pairs were 'fatigue cracking' sections aimed to study fatigue-cracking behavior of flexible pavements. The remaining three pairs were 'rutting' sections aimed to study rutting behavior of asphalt concrete pavements. In total, six Superpave HMA mixes were used, two for each of the three states. One 'fatigue-cracking' and one 'rutting' pavement were built for each mix.

Figure 1 shows an example of four test sections, a fatigue-cracking pair and rutting pair of test sections, built in two pits to test the two Superpave mixes of one state. The pavement sections were constructed in three layers: a Hot-Mix Asphalt (HMA) surface layer, a 0.15 m (6.0 in.) unbound granular base course, and a 1.5 m (5.0 ft), A-7-6 clay subgrade. The 'fatigue-cracking' sections had a 100 mm (4.0 in.) nominal thickness for the HMA layer and were loaded at a pavement surface temperature of 20°C (68°F). The 'rutting' sections had a 178 mm (7.0 in.) nominal thickness for the HMA surface layer and were loaded at a pavement surface temperature of 35°C (95°F).

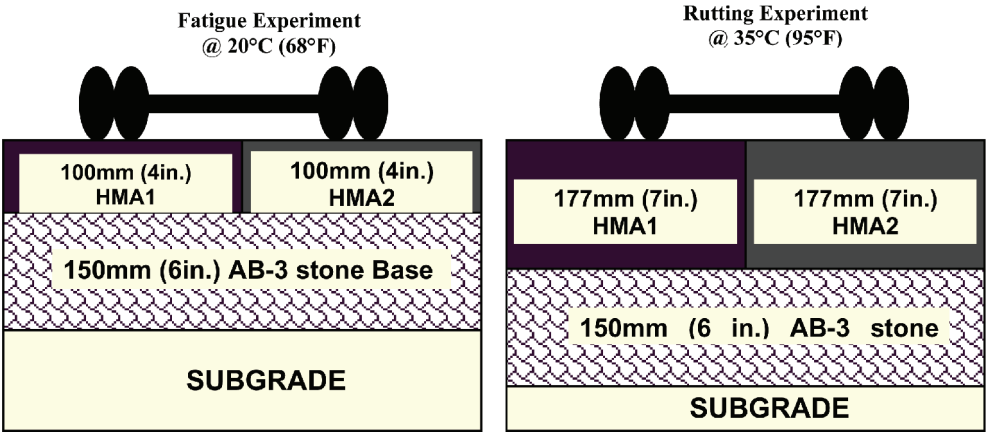

Figure 1. Cross section of the experimental pavement sections.

The sections were loaded with a 100-kN (22,500 lb) single axle applied at a uniform travel speed of 7 mph (11 km/hr). Lateral movement was provided by a lateral wandering device that moved the entire frame of the APT machine in the lateral direction, with a maximum lateral wander of ±0.305 m (±1.0 ft). Transverse profiles at the pavement surface were measured periodically during APT loading to record the evolution of rut depth with the number of load repetitions.

Instrumentation was embedded in the experimental pavement sections during construction. Strain gages were used to measure horizontal and vertical strains at the bottom of the HMA layer. Linear Variable Differential Transformers (LVDTs) were used to measure the dynamic and permanent vertical deformation in each layer. Pressure (stress) cells were used to measure the vertical compressive stress at the top of the subgrade layer. Thermocouples were used to measure the temperature at the surface and at two additional depth points in each pavement structure.

The Departments of Transportation (DOT) of Kansas, Missouri, and Iowa provided the mix designs for the six Superpave mixes used for test section construction. A local contractor, Schilling Construction Inc., constructed the pavement sections at CISL with materials transported from the three states. The six asphalt mixes consisted of a Kansas course mix (KS1) with 19-mm Nominal Maximum Aggregate Size (NMAS); a Kansas fine mix (KS2) with 12.5-mm NMAS; two 12.5-mm NMAS Missouri mixes with different binders (PG 70-22 for MO1 mix and PG 64-22 for MO2 mix), and two 12.5-mm NMAS Iowa mixes with the same binder but different design Equivalent Single Axle Loads (ESALs) (30 million for mix IA1 and 3 million for mix IA2). The mix design information, including aggregate gradation, PG binder grade, gravimetric binder content, and measured *in-situ* air voids can be found elsewhere [4].

3 FLEXURAL FATIGUE OF ASPHALT CONCRETE MIXTURES

In order to determine flexural fatigue properties of HMA mixes used for this research project, approximately 500 mm (20 inch) square slabs were cut from the HMA pads built outside the CISL laboratory with the mixes at the same time the experimental pavement test sections were constructed. The pads were compacted with the same rollers and at the same density as for the test sections. A Troxler nuclear density gage was used to measure the as-compacted density. Six beams were cut from each slab. Before testing, the beams were placed in the environmental chamber for at least two hours at 20°C (68°F), the test temperature. This test temperature was controlled by a heating and cooling unit and was maintained for all tested samples.

Each asphalt specimen was placed in the IPC beam-fatigue test machine and fixed in position with clamps (Fig. 2). After the input parameters were selected (dimensions of the beam, microstrain level, etc.) and all readings were zeroed, the fatigue test was started. After the test was initialized, the IPC beam-fatigue computer displayed the initial stiffness, measured after 200 cycles, and computed the termination stiffness as half of the initial stiffness. The applied cyclic load used was sinusoidal, with a frequency of 10 Hz and with no rest periods. The peak-to-peak load amplitude was recorded. The specimens were tested under controlled strain mode at three different strain levels: 100, 200, and 300 microstrain (10^{-6} in/in). Mixes KS1 and KS2 were also tested at 400 and 500 microstrain. Failure of the specimen was considered when the beam reached 50% of the initial stiffness.

The test loading time, cycle number, maximum and minimum applied load and deflection, tensile stress, strain, phase angle, flexural stiffness, modulus of elasticity, and dissipated energy data were recorded periodically. A typical test output, given in Figure 3, showed that

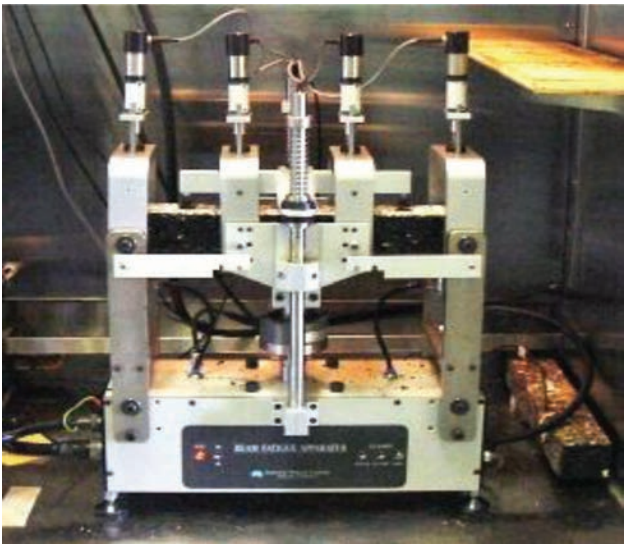

Figure 2. Beam fatigue testing apparatus.

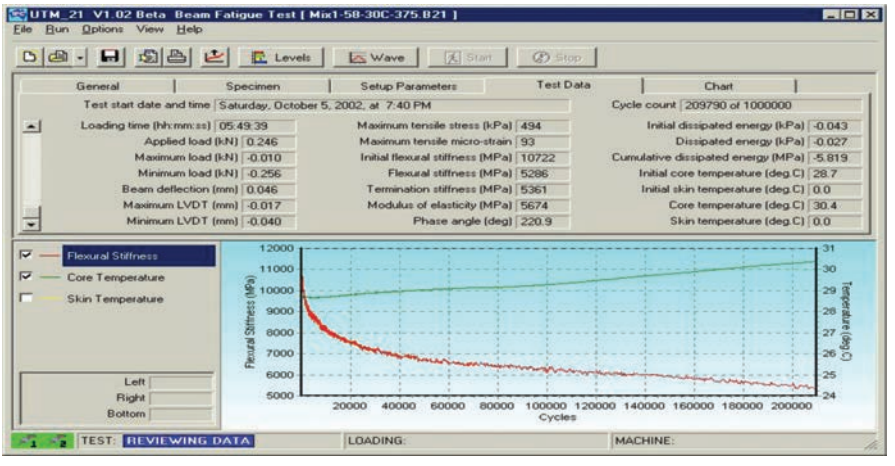

Figure 3. Typical output screen of beam fatigue test.

flexural stiffness decreased with an increasing number of loading cycles. This trend was observed for all beams tested in this experiment.

Some HMA specimens in this test did not reach the termination stiffness of 50% of the initial stiffness after maximum number of 2 million cycles, especially the specimens tested at low strain levels. For time consideration, these tests were stopped after 2 million loading cycles. This limited cycle number was input in to fatigue test control software as it was deemed that the stiffness data collected in the first 2 million cycles would allow estimation of the number of cycles to failure, considered as the number of cycles where the stiffness reaches half of the initial values. For these specimens an assumption was made that after 500,000 load cycles, flexural stiffness decreases linearly with the number of applied cycles:

$$S = b_0 + b_1 N \tag{1}$$

where
S = stiffness (MPa), N = is the number of cycles, and b_0 = is the intercept of the Y axis, and b_1 is the slope.

The final modulus, which is half of the initial modulus, has the following equation:

$$S_{fin} = b_0 + b_1 N_{fin} = 0.5 * S_{initial} \tag{2}$$

Therefore, the fatigue life N_{fin} was determined as follows:

$$N_{fin} = (S_{fin} - b_0)/b_1 \tag{3}$$

The coefficients b_0, b_1, R^2, and N_{fin} were computed using Microsoft Excel. A graphical example of the use of linear regression to estimate the number of cycles to failure for the specimens that did not fail up to 2 million cycles is shown in Figure 4.

The number of cycles to failure was also calculated considering an exponential evolution of the stiffness with the number of cycles, as follows:

$$S = c\ N^d \tag{4}$$

The coefficients c and d were computed using Microsoft Excel from the stiffness data recorded during the first 2 million cycles. Then, the number of cycles to failure, N_{fin}, was calculated. However, engineering judgment dictated that the linear regression provided a much

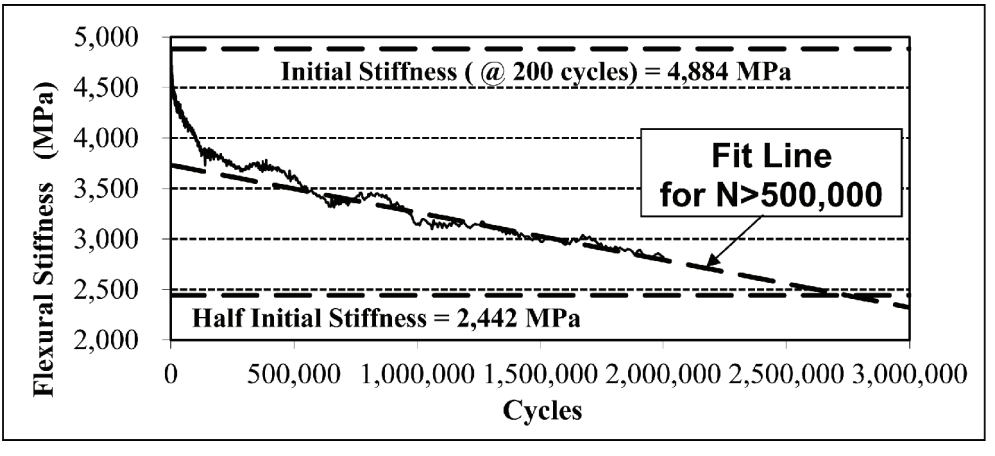

Figure 4. Estimation of loading cycles to failure by extrapolation.

better fit than the exponential model, and therefore, the fatigue lives obtained with the linear model were used for further analysis.

Models expressing the relationship between the number of cycles to failure and loading strain were developed after the number of cycles to failure was determined for each tested sample. Table 1 presents, for each of the six mixes subjected to flexural fatigue tests, two models relating the number of cycles to failure and loading strain. The models are very similar from a mathematical standpoint. However, a slightly better fit is obtained with Model 1.

Figure 5 shows, on the same chart, the Model 1 fit curves for all six mixes. The figure indicates that for loading stains higher than 100 micro-strains and at 20°C (68°F), HMA mix

Table 1. Models relating the number of cycles to failure and loading strain.

Mix	a	b	c	R-squared
Model 1: $N = a * (micro\text{-}strain)^b$				
KS1	1.61E+11	–2.10978		0.922867
KS2	9.41E+08	–1.06065		0.374794
MO1	3.71E+10	–1.53314		0.357193
MO2	4.77E+10	–1.72622		0.763139
IA1	1.09E+13	–2.82145		0.635796
IA2	1.29E+12	–2.61847		0.947428
Model 2: $log_{10}(N) = a + b * log_{10}(micro\text{-}strain)$				
KS1	11.19836	–2.07084		0.866162
KS2	8.963334	–1.0955		0.446746
MO1	10.57472	–1.54622		0.592261
MO2	10.68022	–1.7123		0.816795

IA2	12.0887	–2.60335		0.921726
Model 3: $N = 10^M * a * (strain)b * (E^*)^c$				
	7.89	–1.59697	0.070324	0.09
Model 4: $log_{10}(N) = M + log_{10}(a) + b * log_{10}(strain) + c * log_{10}(E^*)$				
	8.44	–1.6095	0.045636	0.330

Note: E^* is measured in MPa.

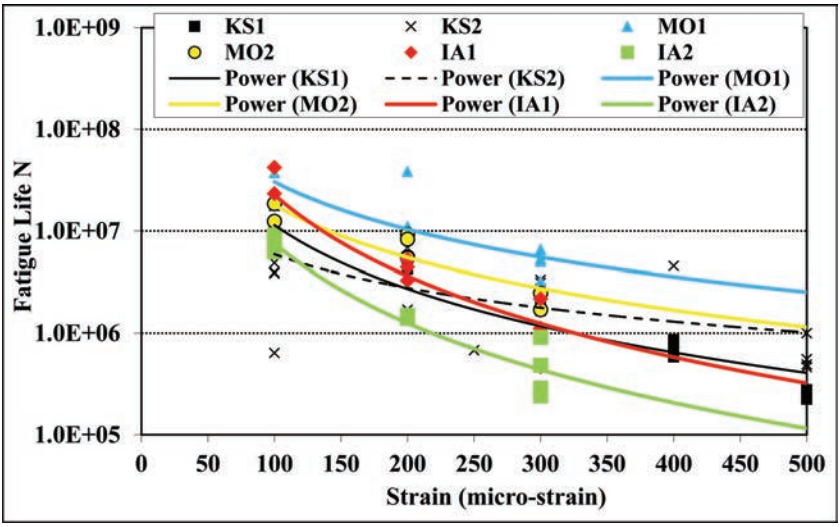

Figure 5. Flexural fatigue lives predicted by model 1.

MO1, with a polymer-modified binder, has the highest fatigue life, while mix IA2 has the shortest fatigue life. The difference in fatigue life increases with increased strain level.

In order to incorporate the effect of mix stiffness and volumetric properties, two overall fatigue models (Models 3 and 4) were developed from the fatigue data recorded on all samples. These models are similar to Equation 5 (shown later), the fatigue model incorporated in AASHTO DARWin ME, with $M = 4.84*[V_b/(V_a + V_b) - 0.69]$. A better fit of the overall model was obtained for Model 4.

4 FATIGUE CRACKING

CISL test sections were monitored to observe surface cracking every time the pavement response and surface profile measurements were performed. The only crack observed was for section KS2-4 at 1,300,000 passes of the APT machine; no other cracks were observed on other 11 sections. That crack was in the longitudinal direction, was located very close to the centerline of the section, and had a length of approximately 1.06 m (27 inches). The crack grew to approximately 1.08 m (43 inch.) in the following 100,000 load repetitions. However, the crack was not observed anymore when the next measurements were performed at 1,500,000 load repetitions, and after that.

5 MEASURED STRAIN AT THE BOTTOM OF THE HMA LAYER

Strain values were recorded for at least four cycles (eight passes) of the CISL APT machine, at a sampling frequency of 100 Hz. Recording was started when the axle was at the west end of the travel and had started traveling east. Strain measurements were performed for two lateral positions of the wheels: (1) Position 0: The symmetry axis of the wheel was right above the gages and the tires were straddling the gages. (2) Position +6: With one tire passing right above the strain gages; the symmetry axis of the wheel was 0.15 m (6 inches) to the side from the location gages. Figure 6 shows and example of measured strain signals. Figures 7 and 8 show the evolution of measured strains with the number of applied passes.

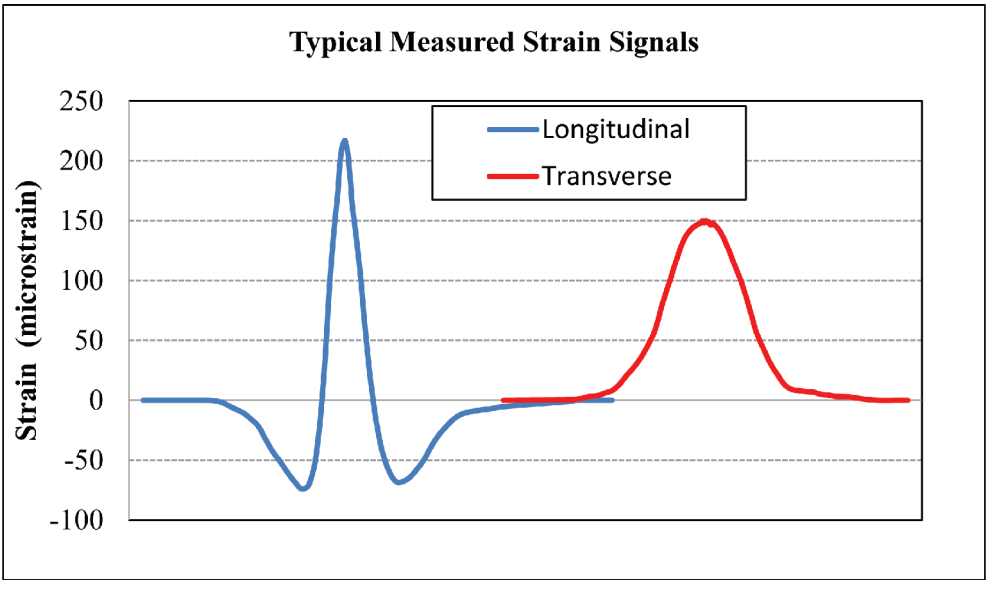

Figure 6. Typical signals for the measured horizontal strains at the bottom of the asphalt concrete layer.

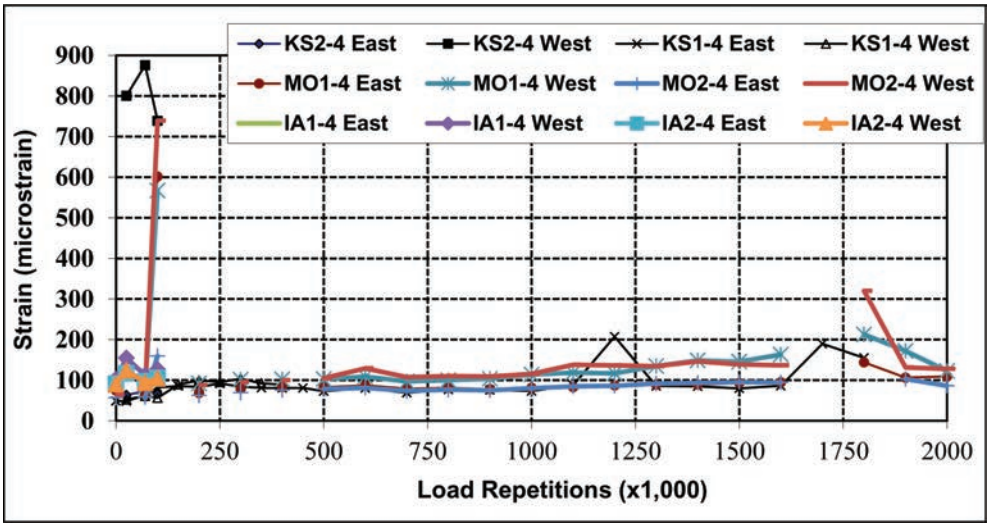

Figure 7. Transverse strains for the fatigue-cracking sections (4″ HMA).

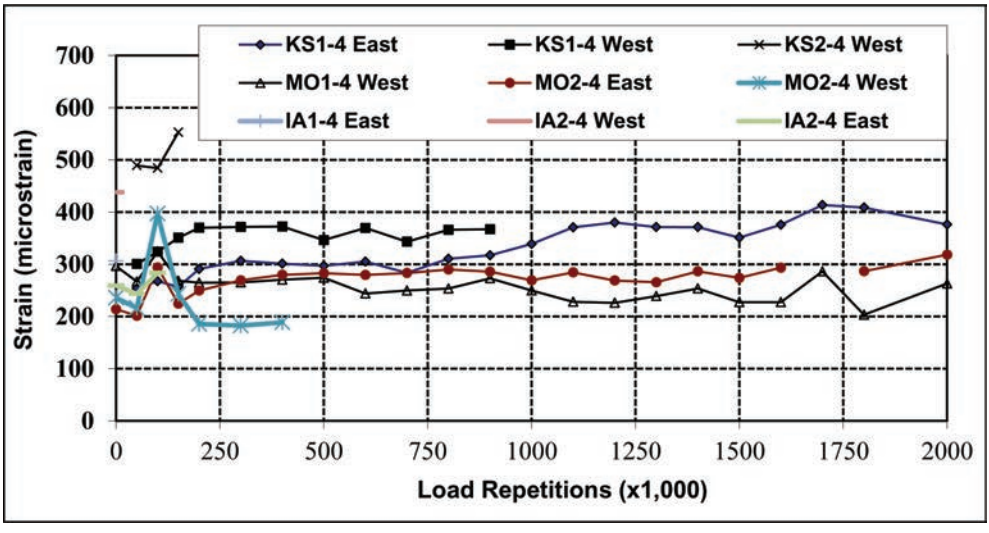

Figure 8. Longitudinal strains for fatigue cracking sections.

A few observations can be made regarding the measured strains at the bottom of the HMA layer:

- The measured longitudinal strains are almost always larger than the corresponding transverse strains.
- In the Kansas fatigue-cracking sections, the longitudinal strains recorded before loading commenced were very high. However, once loading commenced, the recorded strains were comparable to but remained higher than those recorded for the other fatigue-cracking sections.
- Differences between corresponding strains measured by replicate gages (east and west) installed in the same test sections can be significant, in many cases larger that the difference between corresponding strains measured on two sections with mixes from the same state.

- In general, when two mixes of the same state are compared, the ranking of the corresponding measured strains matches the expected ranking. Strains measured on the KS1, MO1, and IA1 sections are smaller than those measured on the KS2, MO2, and IA2 sections.
- For most cases, strains measured after the first 200,000 load repetitions seem to remain stable, exhibiting only small fluctuations after that.

6 VERIFICATION OF PAVEMENT RESPONSE MODEL

The response model that calculates the stresses and strains that develop in the pavement structure under truck wheel loading is of paramount importance in the MEPDG (predecessor of DARWin ME software) model since distresses and thus, pavement performance, are estimated based on the computed stresses and strains. The MEPDG software does not yield computed stresses and strains as outputs. Rather the software output contains accumulated fatigue-damage parameters for bottom-up fatigue cracks. This fatigue damage is calculated from the value of the longitudinal strain found at the bottom of the asphalt concrete layer in incremental fashion using Miner's law [1]. The fatigue model calculates the allowable repetitions to failure as

$$N_f = 0.00432 * k_1' * C(1/\varepsilon_t)^{3.9492}(1/E)^{1.281} \quad (5)$$

where
ε_t = longitudinal strain at the bottom of the asphalt concrete layer;
E = stiffness of the asphalt concrete;
$C = 10^M$ and $M = 4.84*[V_b/(V_a + V_{bef}) - 0.69]$;
V_a and V_{bef} = air voids and effective binder volumetric content (%); and
k_1' = a parameter that depends only on the thickness of the asphalt layers.

For each of the 12 months, the total duration of simulated APT trafficking used in this study, the MEPDG output obtained listed the fatigue damage in percentages, the number of trucks passing over the designed pavement structure, and the estimated stiffness of the asphalt concrete layers. Simulation of the APT testing was conducted with MEPDG software for level 1 and 3 analyses, at a 50% reliability level. In both analyses, all pavement materials were assumed to be linear elastic. However, the value of the modulus of asphalt concrete was selected depending on the speed of loading. Since the number of trucks in the simulations was the same as the number of axle passes in the APT experiment, it was possible to compute the damage calculated by the MEPDG model for a single pass of the APT axle for each month. The damage values were then used to "back-estimate" the longitudinal strain at the bottom of the asphalt concrete with Equation 5.

Figure 9 shows the correspondence between the measured longitudinal strains and the corresponding values "back-estimated" from the MEPDG output in the level 1 and level 3 analyses. The figure suggests that for the "rutting" sections, the measured strains were between two and three times higher than the computed strains, at both levels 1 and 3. For the thinner sections, the computed strains were closer to the measured strains in some cases, but in many cases they were two to three times higher than the measured strains. This suggests the algorithms for computing the response in the MEPDG model should be reviewed and further validated. The under-prediction of strains may result in under-designed pavement structures for fatigue resistance.

In addition to back-estimating the longitudinal strains from the MEPDG software output, the MEPDG-calculated pavement response was obtained by performing runs with the JULEA software. JULEA is the linear-elastic model incorporated in the MEPDG software for computing response of new flexible pavement structures. The JULEA software models the wheel load as uniformly distributed over circular areas.

The calculation of the theoretical strains with the JULEA software was done assuming the loading configuration shown in Figure 10. The figure also shows the points where the stresses

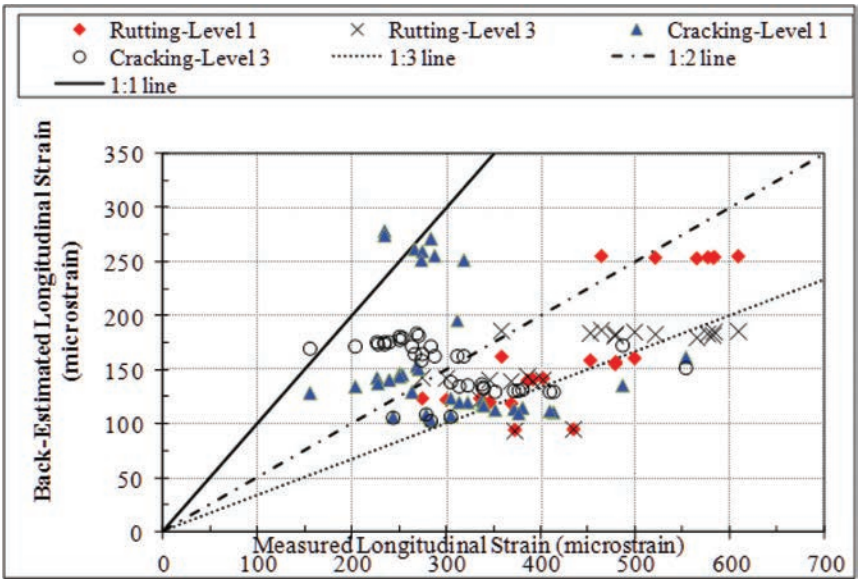

Figure 9. Measured and back-estimated longitudinal strains.

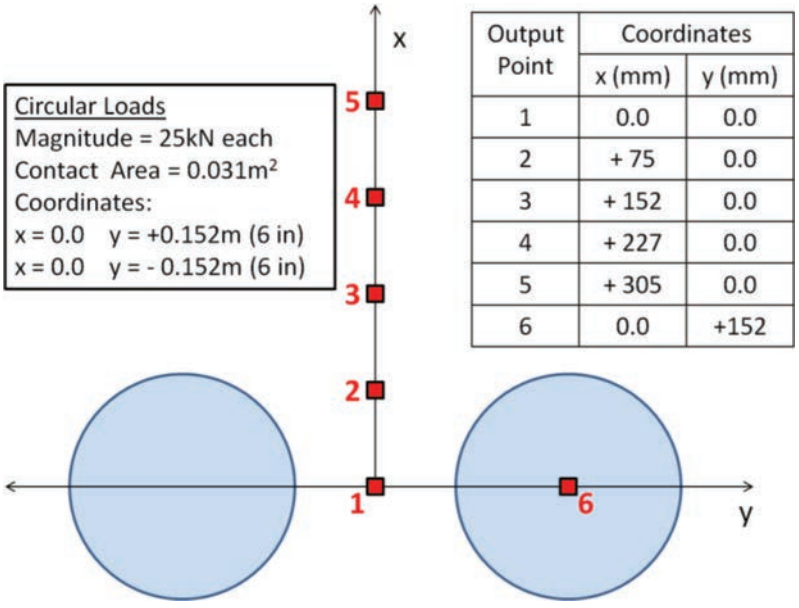

Output Point	Coordinates	
	x (mm)	y (mm)
1	0.0	0.0
2	+ 75	0.0
3	+ 152	0.0
4	+ 227	0.0
5	+ 305	0.0
6	0.0	+152

Figure 10. Loading model for JULEA calculations.

and strains were computed (output points). The layer moduli were the same as those used in the MEPDG inputs for Level 3 design analysis [5].

Results of the JULEA calculations are shown in details elsewhere [5]. They suggest the following:

- The computed maximum longitudinal strains at the bottom of the HMA layer are not always in between the two wheels. Depending on pavement layer thickness and stiffness, they can also develop right underneath the center of one circular loading area.

- Longitudinal strains computed by JULEA are different from those back-estimated from the MEPDG output. This suggests that the MEPDG software code should be reviewed.
- With a very few exceptions, the longitudinal strains computed by the JULEA model and back-estimated from the MEPDG output are smaller than the corresponding measured strains. This can lead to severe under-estimation of the fatigue damage for the bottom-up cracking and thus, to over-estimation of the fatigue cracking lives of the flexible pavement structures.

7 CONCLUSIONS

The following can be concluded from this research study:

- The MEPDG structural response model for flexible pavements under-predicts the longitudinal strains at the bottom of the asphalt concrete layers, the structural response used for predicting fatigue/alligator cracking. The computed strains were two to three times smaller than the measured strains.
- The laboratory beam-fatigue tests performed at 20°C (68°F) indicate that a single model for the fatigue life of asphalt concrete, such as the one incorporated in MEPDG, does not effectively predict the fatigue life of all mixes.
- The experiment could not verify either the bottom-up or top-down fatigue-cracking models incorporated in the MEPDG, since only one of the twelve tested sections exhibited cracking. Moreover, the longitudinal crack that appeared in that section healed before the load repetitions ended.
- With a very few exceptions, the longitudinal strains computed by the JULEA model and back-estimated from the MEPDG output were smaller than the corresponding measured strains. This can lead to severe under-estimation of the fatigue damage for the bottom-up cracking and to over-estimation of the fatigue-cracking lives of the flexible pavement structures.

Asphalt Pavements – Kim (Ed)

Power law viscoelastic contact model for Discrete Element Method simulation of asphalt binder

Bo Peng & Linbing Wang
Virginia Tech, Blacksburg, VA, USA

ABSTRACT: The Discrete Element Method (DEM) has been extensively used for modelling the behavior of asphalt concrete, cement concrete and other geomaterials with discontinuous structure. As one of the most important materials for pavements, asphalt has very complex characteristics. Unlike existing linear viscoelastic contact models, this paper provides a detailed exploration of the contact model for thin film power-law creeping materials based on C.Y. Chueng's work. This model is aimed at simulating the thin film asphalt layer between two aggregates, which is a common structure in asphalt mixture. The new contact model was implemented on software PFC 3D and is numerically verified. Experiments with specimens containing a thin film asphalt between two aggregates are employed to validate the new contact model.

Keywords: Discrete Element Method, contact model, power law viscoelastic, viscoelastic, thin film

1 INTRODUCTION

Asphalt, an adhesive, low-cost and waterproof material discovered as early as 3800 B.C., is extensively used in pavement construction. However, asphalt is also acknowledged as a complex material which is not able to be well analysed by solid mechanics directly, because of its inelasticity, temperature sensitivity, load sensitivity and complex polymer structure. Some theoretical models have been developed for asphalt, such as dynamic models, temperature dependence models, and pressure dependence models. For more practical applications, the linear viscoelastic model is widely used in DEM, especially when it comes to asphalt mixtures.

DEM was proposed by Cundall in 1979 [1]. Since then, the method has been studied worldwide. DEM can be applied in a varied range of research, including soil and rock simulation, fluidization of cohesionless and cohesive particles flow, confined or unconfined particle flow, particle packing, compaction of particles, etc. The advantage of DEM is that it can simulate heterogeneous materials through discretization. Setting different parameters to the contributing materials in the simulation helps to distinguish their interaction. Those characteristics ensure DEM is a good method to simulate asphalt concrete (AC), which consists of various components such as asphalt binder, aggregates and air void.

In DEM, a contact model is the key to defining material and interaction type within a specimen. As the most frequently used DEM platform to develop asphalt application, Particle Flow Code (PFC) [2] has implemented several contact models, such as the linear elastic model [3], Hertz model [4], and soft-placement model; however, there are only two viscoelastic contact models—the linear viscoelastic and the Burger model, which are all linear models. Because of that, most recent asphalt simulation problems studied, such as prediction of mixture dynamic modulus [5], creep stiffness [6], mixture failure [7], are all based on linear viscoelastic contact models.

Asphalt is a complex material, and a linear viscoelastic model might not be accurate enough to describe its behavior. In this case, a high-order non-linear contact model is needed to improve simulation results. Considering the fact that asphalt often exists as a thin film layer between aggregates in mixture, the primary objective of this research is to develop a rational power law viscoelastic contact model. A corresponding DLL file that can be used as contact model and applied directly into PFC 3D is developed. The DEM simulation results are verified by theoretical results, and force-displacement simulation results from the contact model are validated with experiments.

2 POWER LAW CONTACT MODEL

2.1 *Theoretical model*

Asphalt binder is usually considered as a viscous fluid at relatively high temperatures, and an elastic medium at relatively low temperatures. In the temperature range of pavement, asphalt is regarded as a viscoelastic material. A viscoelastic model is usually comprised of an elastic part and an energy dissipation part, which is presented by a spring and dashpot. There are two types of common combinations—the Kelvin model which connects spring and dashpot in parallel and the Maxwell model which connects spring and dashpots in series. Different combinations of the Maxwell and Kelvin models can be assembled to come up with various viscoelastic models.

To simulate the complexity of a real viscous material, a nonlinear Maxwell model that theoretically assumes unidirectional flow in a uniform passage was developed by C.Y. Chueng and D. Cebon in 1997 [8]. This solution is aimed at acquiring the relationship between force and displacement of a thin-film asphalt layer sandwiched between two aggregates. Simplifying the two aggregate surfaces as two parallel rigid planes, the specimen employed is shown in Figure 1. Chueng verified his solution in compression, shear and combined compression and shear by comparison with experimental results. The following theoretical content is based on a paper of Chueng's in 1997 [8].

This solution assumes that the width of the layer is much larger than the height of the layer. As Figure 1 shows, *2a* is the width, *2h* is the height and *2l* is the length. Due to the large aspect ratio, *a*/*h*, this model can be regarded as a plane strain problem. Influenced by surrounding temperature and the characteristics of creeping material itself, pure bitumen in a thin film would follow a power-law relationship as:

$$\frac{\sigma'_{ij}}{\sigma_0} = \frac{2}{3}\left(\frac{\dot{\varepsilon}_e}{\dot{\varepsilon}_0}\right)^{1/n} \frac{\dot{\varepsilon}_{ij}}{\dot{\varepsilon}_e} \tag{1}$$

where σ_{ij} is the deviatoric stress tensor; $\dot{\varepsilon}_{ij}$ = strain rate sensor; $\dot{\varepsilon}_e$ = effective strain rate; and σ_0, $\dot{\varepsilon}_0$ are constants, which are related to the ambient temperature. If $n = 1$, then this solution

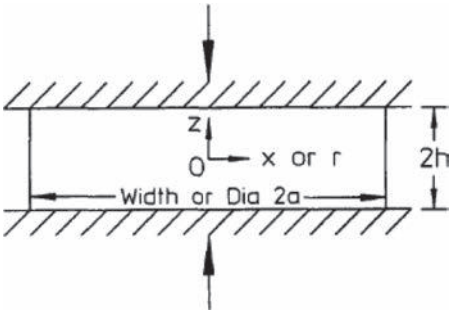

Figure 1. Geometry information of the thin layer [8].

becomes linear viscosity; while in the case of $n > 1$, the power law creep behaviour is assigned to the material layer. Parameter n is also related with temperature. Using the equation above, the constitutive equation can be written as:

$$\sigma_{xx} - \sigma_m = \frac{2}{3}\frac{\sigma_0}{\dot{\varepsilon}_0^{1/n}}(\dot{\varepsilon}_e)^{(1-n)/n}\left(\frac{\partial \dot{u}}{\partial x}\right) \tag{2}$$

$$\sigma_{zz} - \sigma_m = \frac{2}{3}\frac{\sigma_0}{\dot{\varepsilon}_0^{1/n}}(\dot{\varepsilon}_e)^{(1-n)/n}\left(\frac{\partial \dot{w}}{\partial z}\right) \tag{3}$$

$$\tau_{xz} = \frac{1}{3}\frac{\sigma_0}{\dot{\varepsilon}_0^{\frac{1}{n}}}(\dot{\varepsilon}_e)^{\frac{1-n}{n}}\left(\frac{\partial \dot{u}}{\partial z} + \frac{\partial \dot{w}}{\partial x}\right) \tag{4}$$

where σ_m is the mean stress. Besides the constitutive condition, the equilibrium conditions are:

$$\frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \tau_{xz}}{\partial z} = 0 \tag{5}$$

$$\frac{\partial \sigma_{zz}}{\partial z} + \frac{\partial \tau_{xz}}{\partial x} = 0 \tag{6}$$

Then, let's take a look at strain rate sensor for this situation:

$$\dot{\varepsilon}_{ij} = \begin{bmatrix} \partial \dot{u}/\partial x & 0 & 1/2\left(\partial \dot{u}/\partial z + \partial \dot{w}/\partial z\right) \\ 0 & 0 & 0 \\ 1/2\left(\partial \dot{u}/\partial z + \partial \dot{w}/\partial z\right) & 0 & \partial \dot{w}/\partial z \end{bmatrix} \tag{7}$$

where $\dot{u}$ is the deformation rate in x direction, and $\dot{w}$ is the deformation rate in z direction.

Because of the large aspect ratios in the thin film model, $\partial \dot{u}/\partial z$ strain rate would be much larger than the deformation rates in other directions. Therefore, the strain rate tensor can be rewritten as:

$$\dot{\varepsilon}_{ij} = \begin{bmatrix} 0 & 0 & 1/2\left(\partial \dot{u}/\partial z\right) \\ 0 & 0 & 0 \\ 1/2\left(\partial \dot{u}/\partial z\right) & 0 & 0 \end{bmatrix} \tag{8}$$

The effective stress in the case can be simplified as:

$$\dot{\varepsilon}_e = \left(\partial \dot{u}/\partial z\right)/\sqrt{3} \tag{9}$$

Simplify the Eq. (4) and equilibrium Eq.(5) by Eq.(9), we can get:

$$\frac{\tau_{xz}}{\sigma_0} = \left(\frac{1}{\sqrt{3}}\right)^{(n+1)/n}\left(\frac{|\partial \dot{u}/\partial z|}{\dot{\varepsilon}_0}\right)^{1/n}\operatorname{sign}\left(\frac{\partial \dot{u}}{\partial z}\right) \tag{10}$$

$$\frac{\partial P}{\partial x} = \frac{\partial \tau_{xz}}{\partial z} \tag{11}$$

where $P = -\sigma_m$. Because of the symmetry of structure, $\partial\tau_{xz} = 0$ when $z = 0$ and ignorance of the changing of pressure in the direction of z, the combination of the Eqs. (10, 11) can be written as:

$$\frac{\partial \dot{u}}{\partial z} = \left(\frac{\sqrt{3^{n+1}}\dot{\varepsilon}_0}{(n+1)\sigma_0^n} \right) |Z|^n \left| \frac{\partial P}{\partial x} \right|^n \operatorname{sign}\left(\frac{\partial P}{\partial z} \right) \tag{12}$$

The boundary conditions include $\dot{u} = 0$ at $z = \pm h$, $P = 0$ at the location $x = \pm a$, and:

$$F = 2l\int_{-a}^{a} P\, dx \tag{13}$$

where F is the force load on the surface.

For the overall thin film, compression of the material would lead to a flow from the center to the sides. Take $\dot{Q}$ as volumetric flow in the x-direction, the flow equation is:

$$\frac{\dot{Q}}{2l} = -2\dot{h}x \tag{14}$$

Consider the boundary condition and flow equation, then integrate the Eq.(12), the viscoelastic material force-displacement relationship is obtained as:

$$\frac{dh}{dt} = -h\dot{\varepsilon}_0 \left(\frac{1}{n+2} \right) \left(\frac{2n+1}{n} \right)^n \left(\frac{\sqrt{3}}{A} \right)^{n+1} \left(\frac{F/(4al)}{\sigma_0} \right)^n \tag{15}$$

where a and l are the relevant width and length of the layer; here, only h is a variable, other parameters are all constant. Regarding $\sigma_n = F/4al$, $\dot{\varepsilon}_n^v = -\dot{h}/h_0$, Eq. (15) can be rewritten as:

$$\dot{\varepsilon}_n^v = \dot{\varepsilon}_0 \left[\left(\frac{1}{n+2} \right) \left(\frac{2n+1}{n} \right)^n \left(\frac{\sqrt{3}}{A} \right)^{n+1} \right] \left(\frac{\sigma_n}{\sigma_0} \right)^n \tag{16}$$

Eq. (16) shows the pure viscosity of a material when elasticity is taken into consideration. The constitutive model is composed of a spring in series with the nonlinear dashpot denoted as:

$$\dot{\varepsilon}_n^0 = \dot{\varepsilon}_n^e + \dot{\varepsilon}_n^v = \frac{\dot{\sigma}_n}{E_n} + \dot{\varepsilon}_0 \left[\left(\frac{1}{n+2} \right) \left(\frac{2n+1}{n} \right)^n \left(\frac{\sqrt{3}}{A} \right)^{n+1} \right] \left(\frac{\sigma_n}{\sigma_0} \right)^n \tag{17}$$

where $\dot{\varepsilon}_n^0$ is the total strain which includes elastic and viscous parts. This is the microscopic constitutive model for a thin film viscoelastic material.

2.2 *DEM contact model development*

On the basis of Eq. (17), a constitutive contact model is deduced to apply in the DEM:

$$\dot{u} = \frac{\dot{f}}{E_n} + \dot{\varepsilon}_0 \left[\left(\frac{1}{n+2} \right) \left(\frac{2n+1}{n} \right)^n \left(\frac{\sqrt{3}}{A} \right)^{n+1} \right] \left(\frac{f}{\sigma_0} \right)^n \tag{18}$$

where u is the contact deformation between two spheres and f is the contact force. Then applying a backward difference approximation of a finite difference scheme, we can obtain the final equation applied in the DEM contact model:

$$\frac{u^{t+1} - u^t}{\Delta t} = \frac{f^{t+1} - f^t}{\Delta t \times E_n} + \dot{\varepsilon}_0 \left[\left(\frac{1}{n+2} \right) \left(\frac{2n+1}{n} \right)^n \left(\frac{\sqrt{3}}{A} \right)^{n+1} \right] \left(\frac{f^{t+1} + f^t}{2\sigma_0} \right)^n \tag{19}$$

where u^{t+1} is the current contact overlap which has been updated by Newton's Second Law automatically; u^t and f^t are obtained from the previous time step; and f^{t+1} is the only unknown variable—a contact force, needed to be calculated through contact model in the current time step. Therefore, Eq.(19) is a solvable equation that can be applied in DEM directly.

This power law user-defined contact model is written into PFC 3D with the C++ language. After the key equation—Eq.(19)—is written into the interface between C++ and FISH, which is the official coding language for PFC 3D, a DLL file is generated by compiling the C++ project, and this DLL file allows the new contact model to be loaded in PFC 3D directly. When the user contact model is running, the updated contact force would be obtained through Eq.(19) using the velocity, displacement and force in the previous time step and the Newton method is applied to solve the high order equations.

2.3 *Numerical verification*

To verify this contact model, a PFC 3D model of two fixed balls with constant overlap is developed, as shown in Figure 2. The computed normal contact force changing with time is recorded in the DEM simulation, and the analytical results are compared with computed results. In this case, since the overlap u is a constant, Eq.(19) can be simplified as:

$$\dot{f} = -kf^n \tag{20}$$

where $k = E_n \dot{\varepsilon}_0/\sigma_0^n [(1/n+2)(2n+1/n)^n(\sqrt{3}/A)^{n+1}]$.

Take $n = 2$ as test case, the analytical solution for Eq.(20) would be:

$$f(t) = \frac{1}{kt + (1/F_0)} \tag{21}$$

where F_0 is the initial contact force when $t = 0$.

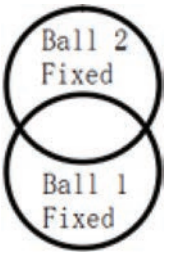

Figure 2. DEM verification model.

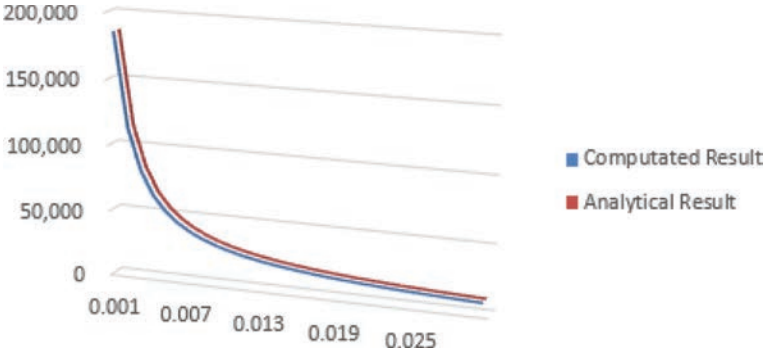

Figure 3. Comparison between computed result and analytical result.

The red line in Figure 3 shows the analytical results calculated by Eq.(21), and the blue line is the contact force obtained from the two fixed ball model in PFC 3D. Analytical results and computed DEM results from the power law contact model match well, verifying the power law's solution is successfully integrated into the DEM contact model. Both lines demonstrate that the force vanishes to zero with time, which is consistent with a viscosity material under constant loading.

3 EXPERIMENT VALIDATION FOR CONTACT MODEL

3.1 *General experiment description*

In order to develop the experimental situation consistent with power law theory—a thin film layer between two rigid planes, a sample is prepared as a thin film asphalt sandwiched between two cubic aggregates. Unakite aggregates are used in this experiment. In comparison with the stiffness of asphalt, the stiffness of Unakite aggregates is very large and can be considered as rigid. PG70-33 binder is used in the tests. After the binder was heated to 300 °F, a slight amount of softened binder was positioned over one aggregate, and another aggregate is used to cover the other surface of asphalt binder immediately. When the temperature goes down, asphalt shrinkage is inevitable. To neutralize the tension caused by shrinkage during the asphalt cooling down, the sample is pressed gently. This pressure assists in the formation of a thinner and more evenly distributed asphalt layer.

The size of the sample is mainly limited by the size of container in SKYSCAN 1174. The SKYSCAN is a micro X-ray CT machine that has the capability to measure dimension information of specimen, such as the asphalt thickness, asphalt width and aggregate size. The X-ray picture for a sample is shown as Figure 4.

Besides measuring dimensions, SKYSCAN also has a micro-processor, which controls the application of torsion, tension and pressure. After asphalt samples are placed in the loading stage, a uniaxial compression load is applied to samples from top and bottom stages. Because of the high energy of X-ray, the temperature within the machine will slightly increase. In this case, it is very important to finish the tests as soon as possible to keep testing times the same. Testing parameters are set through software controlling the X-ray system. With a constant speed of 0.7 μm, the force-displacement relationship is recorded during uniaxial compression process.

3.2 *Experiment parameter and data analysis*

To verify the correctness and accuracy of power law contact model, two sets of tests are performed. The parameters are provided in Table 1.

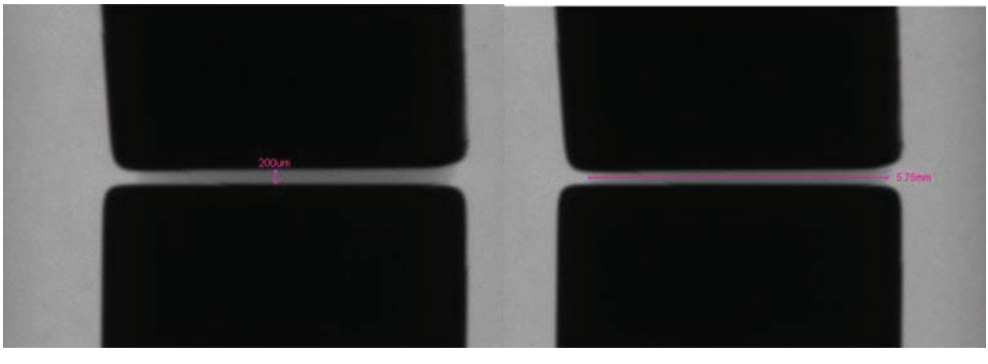

Figure 4. Test sample.

Table 1. Sample information.

	Thickness of asphalt lay (μm)	Width of asphalt lay (mm)	Aspect ratio of asphalt layer	Aggregate material	Plane size of stone (mm)
Experiment 1	156	3.92	25.13	Unakite	4.29*4.29
Experiment 2	156	3.5	22.44	Unakite	4.29*4.29

After the force-displacement data is obtained from SKYSCAN, a curve fitting method is applied to obtain the parameters of the contact model in Eq.(19). To simplify the process, three reorganized parameters are estimated:

$$a_1 = E_n$$
$$a_2 = \frac{\dot{\varepsilon}_0}{\sigma_0^n}$$
$$a_3 = \left[\left(\frac{1}{n+2}\right)\left(\frac{2n+1}{n}\right)^n\left(\frac{\sqrt{3}}{A}\right)^{n+1}\right]$$

The curve fitting solution employs an Ordinary Differential Equation (ODE) solver and a fmincon function in MATLAB to find the minimal difference between experimental results and computational ODE results. To acquire accurate fitted curve and estimated parameters, the initial values of the parameters are very important. Without a reasonable initial value, the fmincon function has a high possibility to find a local minimum, whereas only the global minimum is the desired answer. Supposing $n = 2$, this process will only obtain material-related parameters a_1, a_2, because a_3 can be directly calculated when the geometry information is known.

To evaluate the accuracy of power law model, material parameters a_1, a_2 estimated from test 2 and geometric parameter a_3 from test 1 are applied in DEM model, which is used for comparison with experimental data 1. Vice versa, DEM data by a_1, a_2 from test 1 and a_3 from test 2 are compared with experimental data 2.

In Figures 5 and 6, the blue dashed line presents the experiment results, the green dots represent the fitted curve where the material parameters are obtained from the same test and the red line demonstrates the numerical results with material parameters from another experiment. For the experimental data, the general trend of force-displacement obeys the viscoelastic law, which is near elastic at the beginning, and gradually plateaus. In terms of how well the power law model fits with the experimental results, an average error is calculated—average absolute value of force difference between experimental data and power law numerical data:

$$F_{err} = \frac{1}{n}\Sigma_{i=1}^{n} \mid F_{simulation} - F_{experiment} \mid \tag{22}$$

and relative error percentage is defined as force error divided by maximum experimental force after its increasing rate stabilized:

$$P = F_{err}/F_{stable} \tag{23}$$

The detailed results are shown in Table 2. The columns in the table represent the experiment results used for comparison, and the rows describe the data sets used for material parameters estimation, which are applied to numerical results. As the table shows, errors are relatively small when the same test data is used for parameter estimating and error testing—7.8% for test 1 and 3.36% for test 2. The maximum numerical force error is 5.3 N, after divided by the stable force in the experiment—30.1 N, the relative error does not exceed 17%.

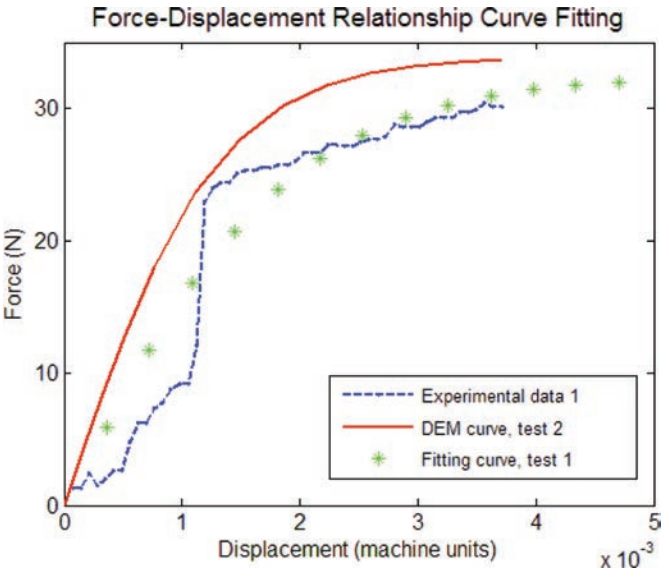

Figure 5. Experiment, numerical, DEM results for experiment 1.

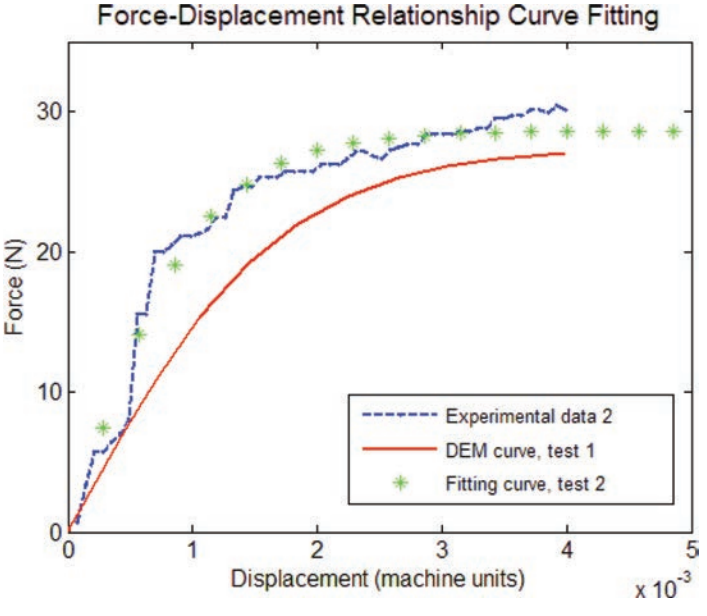

Figure 6. Experiment, numerical, DEM results for experiment 2.

Table 2. Error information between experiment results and DEM results.

Parameter from test data	Force error (N)		Error percentage	
	Test 1	Test 2	Test 1	Test 2
Test 1	2.357	5.314	7.83%	17.65%
Test 2	3.551	1.0117	11.80%	3.36%

There are several reasons that cause the error. First, the two planes of aggregates sandwiched asphalt binder are not strictly parallel to each other. Second, the friction of aggregate surface is not large enough to ensure the theoretical boundary condition. Third, the lateral deformation in both directions along the plane is not even.

4 CONCLUSION AND FUTURE WORK

As a new alternative contact model for asphalt binder simulation, the power law model shows a good potential to solve thin film asphalt problems. With the corresponding power law DLL file generated by C++ code, the new contact model is able to be loaded directly into PFC 3D to apply to more complex problems. However, some interesting problems are also raised during this research. How does film thickness influence the accuracy of power law model? How does aggregate stiffness and friction affect experimental results? What is the force (stress) range that the power law model is good for? Can we use more parameters to calibrate power law model and improve model accuracy? This paper provides a foundation for further exploration and future work.

ABSTRACT: Dynamic response is an important indicator in estimating long-term performance of a pavement structure. To obtain dynamic responses, field measurement is a direct and realistic method. In this study, a multidirectional strain measurement is performed in a highway section paved by two structures: an inverted pavement and a semi-rigid pavement. Accelerated loads are imposed by a full-scale Mobile Load Simulator (MLS). A comparison on dynamic responses from the two structures is made. Two loading positions, central and eccentric loading, are performed alternately. The strains are measured by strain gauges. The results show the maximum tensile strain at the bottom of asphalt mixture in the inverted pavement is higher than that in the semi-rigid pavement at both loading positions. It is concluded that the bottom-up fatigue crack would be the potential failure mode of inverted pavement since the introduction of graded crushed stone interlayer decreases the material stiffness under asphalt mixture. Crack observation from the inverted pavement confirms this failure. The measurement under various axle amplitudes shows that there is a good agreement between strain increments and tire contacted pressure increments. Therefore, when the heavy vehicles are concerned, the tire contacted pressure, rather than the load amplitude, should be the primary parameter in fatigue prediction.

Keywords: Dynamic response, inverted pavement, strain gauge, MLS, ALF

1 INTRODUCTION

Reflective cracking is a common distress type in semi-rigid asphalt pavement. Crack often occurs in the semi-rigid base, and then extends to the pavement surface subsequently. To eliminate reflective cracking, inverted pavement was advanced as an alternative pavement structure. An unbound aggregate interlayer on top of the semi-rigid base was used to prevent surface asphalt pavement from cracking. Extensive studies have been conducted to evaluate the performance of inverted pavement.[1] However, the use of inverted pavement is still limited by the lack of field experiments. Question arises from contractors about whether the long-term performance of the inverted pavement is superior to that of the semi-rigid pavement when the total thicknesses are the same. Since the unbounded interlayer exhibits a nonlinear constitutive relationship under loading, current design methods are unsuitable for the analysis of inverted pavements. Therefore, there is an urgent requirement to make a field comparative study between the inverted pavement and the semi-rigid one.

The dynamic response of field test has always been a prevailing and efficient indicator in evaluating the performance of a pavement structure.[2–4] In these field tests, the responses were

commonly collected under the load of a specific truck.[5–6] It will provide a realistic reflection of multi-axle configuration. However, it is not an alternate opinion for long-term load application. In contrast to vehicles, the Accelerated Loading Facility (ALF) provides a cyclic load with high stability. Previous ALF tests performed on special built test sections.[8–10] As the advancement of movable ALF, the equipment is able to move at a maximum speed of 1 km/h under its own power. As a result, a long-term field test could be performed on real road. MLS-66 is one of this movable ALF which designs and manufactures in South Africa. As a single axle dual-tire version of TxMLS, this machine implements a unidirectional wheel load with six load units. The maximum loading rate is up to 6000 times/hour which is the highest one among all the ALFs. Since MLS is much smaller than that of TxMLS, it is convention to perform tests on field. Given the advantages above, MLS66 is an appropriate machine for field test.

2 OBJECTIVES

The objective of this study is to provide field performance data for both semi-rigid pavement and inverted pavement. An accelerate pavement test on semi-rigid pavement and inverted pavement has been carried on in field section in Liaoning, P.R. China. The multidirectional dynamic responses have been collected and compared under the loads from MLS66. The differences on mechanical response and potential failure mode are highlighted. It also provides data to understand the pavement responses under variable loading amplitude.

3 TEST ROAD DESIGN AND INSTRUMENTATION

3.1 *MLS66 accelerated loading facility*

Figure 1 shows the appearance of the new full-scale accelerate loading faculty MLS66. Before test, its four corner jacks were adjusted to the correct working height.

Figure 2 shows the loading system. Inside the machine, six sets of bogies were assembled to a loading system. Each bogie is consisted with two set of hydraulic actuator, and a pressurized nitrogen accumulator to control the load application on pavements. Dual tires representing half of an axle are installed on each bogie. A guide rail carrying the six bogies is linked by chains. The bogies driving by chains perform a circular movement along rail in the vertical cross section (as shown in Fig. 2(a)). Therefore, a continuous unidirectional load is created in pavement of 6.6 m length under the equipment. Since the hydraulic system on each bogie runs individually, a repeated load spectrum with up to six load amplitudes (G1–G6) would be provided by MLS66.

3.2 *Pavement structure*

Figure 3 shows the two pavement structure being tested. The first one is the semi-rigid pavement. The semi-rigid pavement is consisted of a 17.5 cm asphalt mixture course, a 40 cm

Figure 1. Appearance of the MLS66 facility.

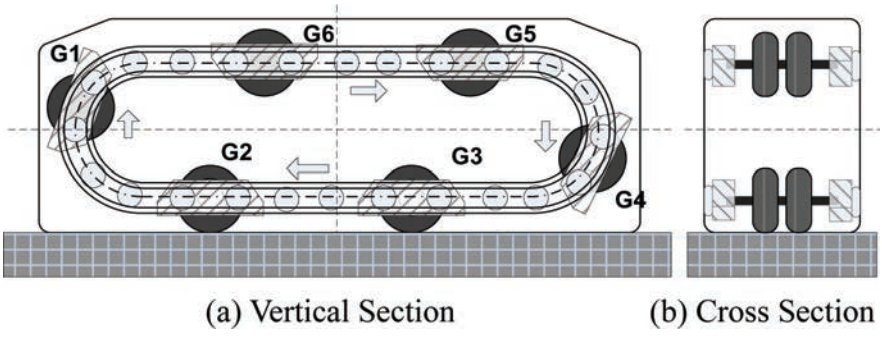

Figure 2. Load system of MLS66 facility.

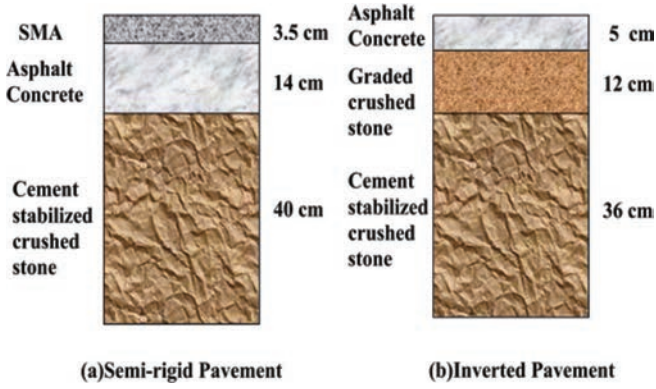

Figure 3. Structures of two kinds of pavement.

semi-rigid base and 15 cm graded sand subbase. The structure has been widely used in case of heavy load traffic in highway construction of China. The typical failure mode of this structure is reflective cracking. The second is the inverted pavement. A 12 cm unbounded stone under the surface course is advanced as the interlayer. Under the interlayer, there is a 36 cm semi-rigid base. A 5 cm layer of flexible pavement was placed over the interlayer.

The test field is located at an unopened highway section. All of the pavements were constructed on prepared subgrade with its modulus above 70 MPa. All construction works were followed the requirement of local specification.

3.3 *Device instrumentation*

The arrangements of devices are shown in Figure 4. It is to be noticed that the two pavement structures are total different. Therefore, the devices were instrumented at the bottom of each layer to obtain the maximum tensile strain for each material. Strain gauges were instrumented during the pavement construction. To measure the dynamic responses at different layers, the devices lined up along the direction of travel at the bottom of asphalt mixture layer and base layer separately. In the surface layer, FBG-FRP (Fiber Bragg Grating-Fiber Reinforced Polymer) sensors were used to measure the vertical strain, and PP-OFBG (Polypropylene-Optic Fiber Bragg Grating) sensors were used to measure the longitudinal and transversal strains. In the base layer, only longitudinal and transversal responses were measured. All devices were aligned along the track of loading wheels. In the asphalt mixture layer, a 600 mm distance between the sensors was kept to avoid interference. In the base layer, the distance was 900 mm. The construction of test road and the instrument of the gauges were done alternatively. The work of Timm et al.[11]

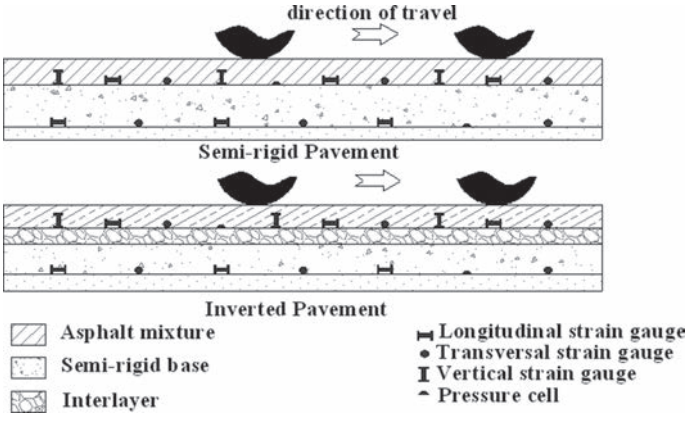

Figure 4. Arrangements of sensors in two kinds of pavement.

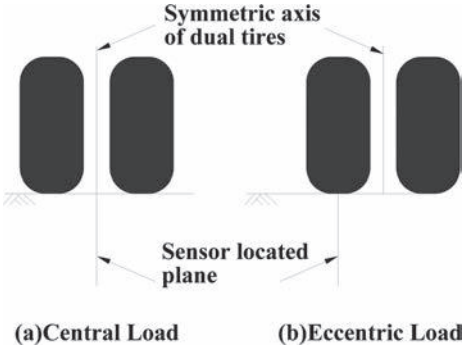

Figure 5. Two loading positions.

was referenced as a guide for the instrumentation in order to prevent the device from damage.

The data acquisition system was capable of recording fast dynamic responses up to 200 Hz. The frequency is accurate enough to obtain successive dynamic responses. Since the amount of data was huge, a three-minute dynamic response was recorded for every one hundred thousand load application.

3.4 *Load applications*

Figure 5 shows the two kinds of transversal load location for field test. In the first one, the symmetric axis of dual tires is right on the top of the plane strain devices located (central loading). In the second one, the symmetrical axis of a single tire is right on the top of the device plane (eccentric loading).

In order to simulate the traffic flow consisted by various load levels, a spectrum with multiple amplitude axle loads was imposed. The loads of six wheels G1 to G6 were set to three different values as shown in Table 1. G1 represents half of a 100 kN rear axle of a truck. G2 and G3 represent half of a rear axle in a 30% and 50% overloaded truck, respectively. The tire contacted area for each load level was measured. The measured contacted areas A, and the calculated tire contacted pressures P are all listed.

In spite of the increments of wheel load range from 30% to 50%, the increments of contacted area are 21.2% and 40.5%, respectively. The increments of tire contacted pressure are only 3% and 7%, respectively. The increment of axle amplitude results in a significant

Table 1. Parameters of six loading units (G1 to G6).

Items	G1	G2	G3–G6
Load L/kN	50	65	75
Percentage/100%	1	1.3	1.5
Contacted area A/mm^2	51876	62854	72893
Tire pressure P/MPa	0.96	0.99	1.03
Percentage/100%	1	1.03	1.07

increment in tire contacted area. Compared to the tire contacted area, the increments of tire pressure are not significant.

4 TEST RESULTS

An accumulated loading over 2.2 million times has been applied on each pavement. From all the results, the primary-stage dynamic responses, which are taken as the first quarter of the entire data, are focused on for the following analyses. During this stage, the primary densification is finished and the pavement is still undamaged. Therefore, data from this stage is appropriate to represent the normal working condition of pavement.

4.1 *Dynamic responses of semi-rigid pavement*

Figure 6 shows the three directional dynamic responses at the bottom of asphalt mixture in one load cyclic from two load locations. In each cycle, six peak values appear in terms of the six loading units. The difference in peak-value time is caused by the different longitudinal locations of sensor. In the transversal direction, strain was compressive under central loading. Then it changed into a tensile one under eccentric loading. The results show there is a switch in strain from negative to positive while the loading point moves transversal from the inner to the outer side. When the wheel moves towards and away from the sensor, the longitudinal strain exhibits a compression-tension-compression response. The maximum tensile strain is discovered when tire is directly on top of sensor. The maximum vertical compression strain is found under central loading. Since in all conditions, the maximum tensile strain is less than 100×10^{-6}, fatigue cracking would not start from the bottom of asphalt mixture.

Figure 7 shows the dynamic responses at the bottom of semi-rigid base. Unlike asphalt mixture, the responses of cement stabilized stone are not time-dependent. The strain curves are symmetry when wheel moves towards and away. The strain responses at the bottom of cement stabilized stone layer are wider than that of asphalt mixture. The value from central loading is higher than that from the eccentric loading because of the superposition of two loading regions. The maximum tensile strain is 169.1×10^{-6} from longitudinal direction. Since the tensile strain at the bottom of semi-rigid base is higher than that at the bottom of asphalt mixture, the bottom of semi-rigid base would be the location where reflective cracks start.

4.2 *Dynamic responses of inverted pavement*

Figure 8 shows the three directional dynamic responses in inverted pavement. Similar shapes of curve are observed. That means the load creates the same compressive or tensile strain in inverted pavement as it does in semi-rigid pavement. However, there are significant differences among strain values. The result shows that the tensile strains in inverted pavement were much higher than those in semi-rigid pavement in longitudinal and transversal direction. The maximum value is 543.9×10^{-6} from transversal direction under 50 kN load. The high tensile strain will be the reason of fatigue cracking in inverted pavement. Based on the result, we may conclude that transversal crack would be found at the bottom of the asphalt mixture under long-term cyclic loads.

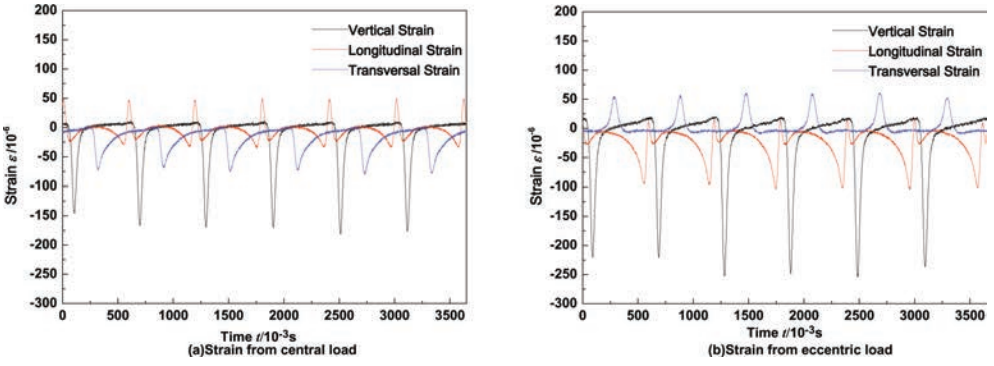

Figure 6. Strains at the bottom of asphalt mixture in semi-rigid pavement.

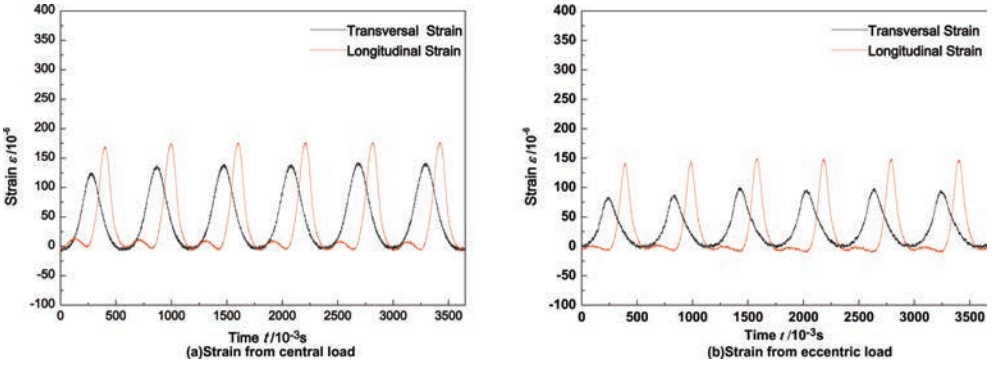

Figure 7. Strains at the bottom of base in semi-rigid pavement.

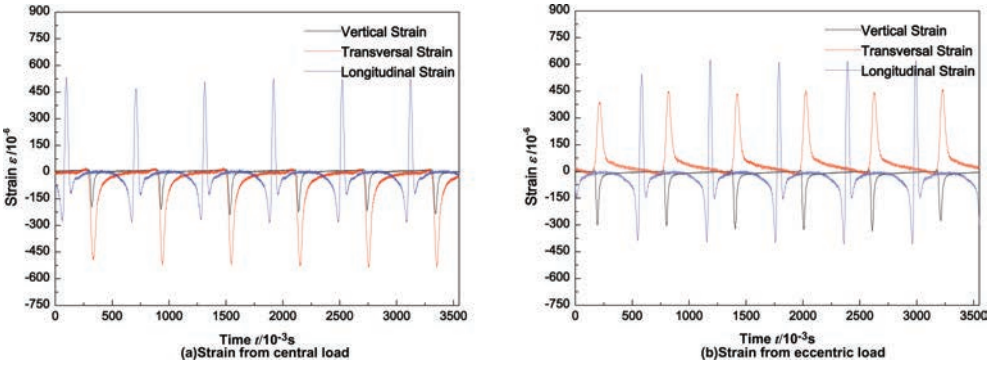

Figure 8. Strains at the bottom of asphalt mixture in inverted pavement.

4.3 *Crack observation*

At the end of the test, when 2.2 million equivalent load passes have been imposed in the semi-rigid pavement, the observation showed that the pavement was still undamaged. The results show that the fatigue life of semi-rigid pavement is much higher than 2.2 million times. While the same numbers of load have been exerting on the inverted pavement, surface cracks were observed after 1.7 million passes from the 8 m^2 loading area (6.6 m*1.2 m). Distress surveys were taken to reveal the growth of cracks. Figure 9 shows the relationship between

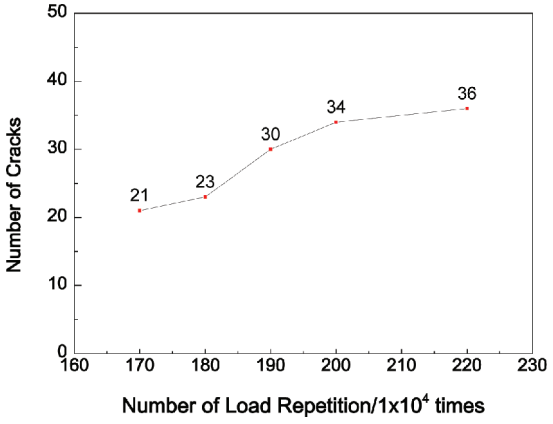

Figure 9. Numbers of cracks vs. load repetitions in inverted pavement.

the number of cracks and the number of load repetition. The result shows that the crack density was 0.9 m/m^2. For all the 36 cracks, 82% of them were transversal crack. This observation shows a good agreement with the result predicted based on the field-measured strain in the inverted pavement.

5 DISCUSSIONS

Based on the field-measured dynamic responses, the critical mechanical state of both pavements was obtained. Figure 10 shows the three-dimensional strain vectors at the bottom of asphalt mixture for both pavements. The compressive or tensile status of bulk strain is also shown.

The introduction of interlayer causes the differences between mechanical statuses. In semi-rigid pavement, since the stiffness of cement stabilized stone is close to that of asphalt mixture. The asphalt mixture and semi-rigid base bend together. The bottom of the cement stabilized stone layer bears higher tensile strain than the asphalt mixture layer does. Since the thickness of base layer is greater than asphalt mixture, the bottom of asphalt mixture will be in compression which will not initiate crack. The crack may start from the base layer, and it may result in reflective cracking.

In the inverted pavement, the introduction of interlayer increases the differences in modulus between the top two layers. In inverted pavement, the asphalt mixture is in a mechanical state of bending. The bottom of asphalt mixture bears majority of tensile stress. The results suggest that transverse fatigue crack may initiate at the bottom of asphalt pavement. The percentage of transversal crack in all cracks (Fig. 9) has confirmed this result. Since inverted pavement is vulnerable to fatigue load, it would be appropriate for highway with low traffic volume. The indicator of strain at the bottom of asphalt mixture would be decisive in the pavement design. The fatigue failure could be avoided by increasing the thickness or increasing the tensile strength of asphalt mixture.

The relationship between contacted pressure and field measured strain is analyzed. Table 2 shows strain ratio collected from 16 gauges under different axle loads. Based on the result, the average strain under 65 kN load and 75 kN are 1.07 and 1.11 times as the strain under 50 kN load, respectively. The results show that, the field measured strain is in good correlation with the contacted pressure, regardless the non-linear behavior of materials. Therefore, an accurate estimate of fatigue responses should be made in considerate contacted pressure, rather than load level. If the enlarged contacted area is ignored, the calculation based on a fixed contacted area would be overestimated the fatigue strain when overload is concerned.

It is to be noticed that the heavier loads affect the pavement through two aspects: higher contacted pressure and larger contacted area. The increment in contacted pressure will

Note: $\varepsilon_{50\,kN} = \varepsilon_{G1}$, $\varepsilon_{65\,kN} = \varepsilon_{G2}$, $\varepsilon_{75\,kN} = (\varepsilon_{G3} + \varepsilon_{G4} + \varepsilon_{G5} + \varepsilon_{G6})/4$.

decrease the fatigue life of pavement by generating a higher tensile strain. The way contacted area affecting fatigue growth is complex and needs further studies.

The distress survey, as well as the measured tensile strain, shows that the inverted pavement is more vulnerable to fatigue cracking compared to semi-rigid pavement. The result is found to be different with the conclusion drawn by Rasoulian et al.[1,12] The difference causes from the pavement configuration. Rasoulian replaced the semi-rigid layer by crushed limestone base. In China, an important issue confronting the contractors is the soft subgrade. To eliminate the pavement damage induced by soft subgrade, a thick semi-rigid base was commonly used. When the inverted pavement was constructed, a 36 cm semi-rigid base was kept. After the introduction of interlayer, the asphalt mixture was replaced by graded crushed stone. Since the thickness of asphalt mixture decreased, the inverted pavement was sensitive to fatigue load. The fatigue performance of inverted pavement would be improved when the thickness of asphalt mixture increases.

6 CONCLUSIONS

Directly measured dynamic responses have been obtained from field test of semi-rigid and inverted pavement. Comparison shows that the maximum tensile strain exists in the longitudinal direction of the inverted pavement. The transversal crack would result from the

maximum tensile strain. This corresponding type of cracks was discovered during the test. Since the inverted pavement is sensitive to the load application, the thickness design is vital indicator for inverted pavement.

The results show that, in both pavements, the vertical compression strain under eccentric loading is higher than that under central loading during a cyclic period. A sign convention of transversal strain may result while the measurement point moves transversal from the inner side to the outer side. A compression-tensile-compression pattern is observed in longitudinal strain during the procedure of load wheel moving towards and away from the sensor.

The results under different load amplitudes show that the strain responses have a directly impact from the tire contacted pressure rather than load level. The estimation without consideration of contacted area would lead to inaccuracy of fatigue life. The tire contacted pressure should be the primary concerned in estimating fatigue strains.

ACKNOWLEDGEMENT

The authors would like to express their thanks to the Liaoning Department of Transportation for the support in field construction, to fellows of the Communications Research Institute of Liaoning Province for adjusting test equipment and accomplish the field test. The authors also want to acknowledge all others not mentioned here who contributed to this project.

ABSTRACT: An experimental program to compare pavement responses caused by new-generation Wide-Base Tires (WBT) with the conventional Dual-Tire Assembly (DTA) is presented. Four pavement sections were built, tested, and instrumented at two test sites: two sections at Florida DOT facility and two sections at UC-Davis. H-type strain gauges at the bottom of the Asphalt Concrete (AC) and pressure cells on top of the base and the subbase were installed at each test site. Instrumentation also included surface foil gauges in Florida and a multi-depth deflectometer at UC-Davis. All sections were subjected to the same test loading: five tire loads (26.2, 36.2, 44.4, 62.1, and 79.9 kN) and four tire inflation pressures (552, 690, 758, and 862 kPa) at three temperatures using the two types of tires considered. In addition, two cases of differential tire inflation pressures were included for DTA (552/758 and 414/758 kPa). Pavement responses to a tire loading of 44 kN and tire inflation pressure of 758 kPa for both tires are presented. Data analysis and impact of tire type on pavement responses is discussed. This paper is part of the pooled-fund project TPF-5(197), The Impact of Wide-Base Tires on Pavement Damage: A National Study.

Keywords: New-generation wide-base tires, accelerated pavement testing, pavement instrumentation, pavement responses

1 INTRODUCTION

The use of Wide-Base Tires (WBT) as an alternative to the conventional Dual-Tire Assembly (DTA) has advantages for trucking operations (fuel economy, hauling capacity, and tire cost and repair) and the environment (gas emission and tire recycling) [1]. The First-Generation (FG-WBT) was introduced in North America in the early 1980s, but it proved to be more detrimental than DTA to flexible pavements [2–6]. The new-generation WBT (NG-WBT) began to be used in 2000, and some research has been performed comparing the damage caused to Asphalt Concrete (AC) by WBT with damaged caused by DTA. What follows is a short summary of the main studies that experimentally compared WBT and DTA.

Major research was conducted at Virginia Tech to assess the pavement damage caused by different tire types and axle configurations [7–10]. Twelve pavement structures were built, heavily instrumented and tested with DTA (275/80R22.5) and NG-WBT (445/50R22.5). During the first test session (May 2000) and based on strain at the bottom of AC, it was determined that NG-WBT produced almost the same fatigue damage as DTA. For vertical

compressive stress, the difference between DTA and NG-WBT decreased with depth, even though it was higher for NG-WBT near the surface. Similar results were obtained during November 2000 and July 2001.

The effect of different tire types has also been studied in Canada [11]. An experimental section with a thickness of 4 in was built at Laval University in Québec City, and it was instrumented to measure longitudinal and transverse strains at different levels as well as vertical strain. It was found that at an inflation pressure of 106 psi, DTA produced less strain at the base than the WBT, and 455/55R22.5 produced less strain than 385/65R22.5. By contrast, when the tire inflation pressure was increased to 130 psi, 385/65R22.5 and 455/55R22.5 produced lower vertical strain than that of the DTA. In addition, WBT provided better performance with regard to rutting.

DTA and WBT were mechanically compared by the National Center for Asphalt Technology (NCAT) in 2006 [12]. A pavement section 6.73 in thick was subjected to accelerated pavement testing using two types of tires: 275/80R22.5 and 445/50R22.5. The test section was instrumented with longitudinal and transverse strain gauges at the bottom of the AC layer with pressure cells on top of the base and subgrade. The readings from the instrumentation were compared with analytical results calculated with WESLEA software. The study concluded that there is insignificant difference between WBT and DTA in the horizontal strain at the bottom of the AC layer and the stress on top of the subgrade.

Response of and damage to pavement by DTA and WBT have been also compared in pavements with different thicknesses [13, 14]. Flexible pavement sections with thicknesses varying between 6 and 16.5 in were instrumented and tested at the Advanced Transportation Research Engineering Laboratory (ATREL) at the University of Illinois at Urbana-Champaign. Thermocouples and strain gauges (two longitudinal and one transverse) were installed. The test sections were subjected to moving loads (5 and 10 mph) using conventional DTA (11R22.5), NG-WBT (455/55R22.5), and FG-WBT (425/65R22.5). The measurements showed that the lowest longitudinal strain at the bottom of the AC is created by DTA. Also, WBT-425 presented a higher response than WBT-455 for all testing conditions. Based on the experimental measurements, it was possible to conclude that WBT-425 is the most damaging tire with regard to fatigue cracking, followed by WBT–455.

A similar study focusing on the damage caused by DTA and WBT-455 on roads with low traffic volume was conducted by Al-Qadi and Wang [15]. Three sections with the same surface layer (75- and 125-mm thick) but different base thickness (200, 300, and 450 mm) were instrumented and modeled. The investigation found that WBT caused more damage than DTA to roads with low traffic volume.

The results of an additional study of WBT and pavement damage were published in 2009 by Greene et al. [16]. The focus of that project was to evaluate pavement rutting. Two types of pavement were subjected to accelerated loading until a rut depth of 12.5 mm was reached. The type of tire with the greatest number of passes to create a 12.5-mm rut depth was the DTA, while WBT-425 required the fewest. In addition, WBT-455 required a similar number of repetitions as DTA on an open-graded surface and slightly less on a dense-graded one. Based on the readings of two surface sensors installed 125 mm from the edge of the tire, it was concluded that WBT-425 generated the highest surface transverse strain. Finally, WBT-445 was found to cause more rutting damage than DTA and WBT-455, while the damage caused by WBT-455 and DTA were similar.

Although solid research has been conducted, no final conclusions have been drawn about pavement performance when WBT and DTA are considered. This paper discusses the instrumented pavement sections subjected to accelerated loading that are part of the pooled-fund project TPF-5(197), The Impact of Wide-Base Tires on Pavement Damage: A National Study. This pooled-fund study approaches the problem in a holistic way, using tools such as an advanced numerical model, artificial neural networks, and pavement instrumentation. The details of the pavement structures as well as their instrumentation are described. In addition, the typical reading of installed sensors is provided along with some results for a specific loading case [44 kN (10 kips) applied load and 758 kPa (110 psi) tire inflation pressure].

2 TEST SECTIONS

2.1 *Pavement structure*

2.1.1 *Pavement structure at Florida DOT*

Two pavement structures were built and instrumented at Florida DOT's State Materials and Research Park in Gainesville (test pit and test track section). The structure under the AC layers is the same for both sections: A-3 subgrade according to the AASHTO classification method: 305 mm of a mixture of limerock and subgrade soils on top of the subgrade; and 267 mm of limerock base directly underneath the AC layers.

The AC layers are different for each structure. The section on the test track has an existing 38-mm-thick AC with PG 67-22 binder and 12.5-mm Nominal Maximum Aggregate Size

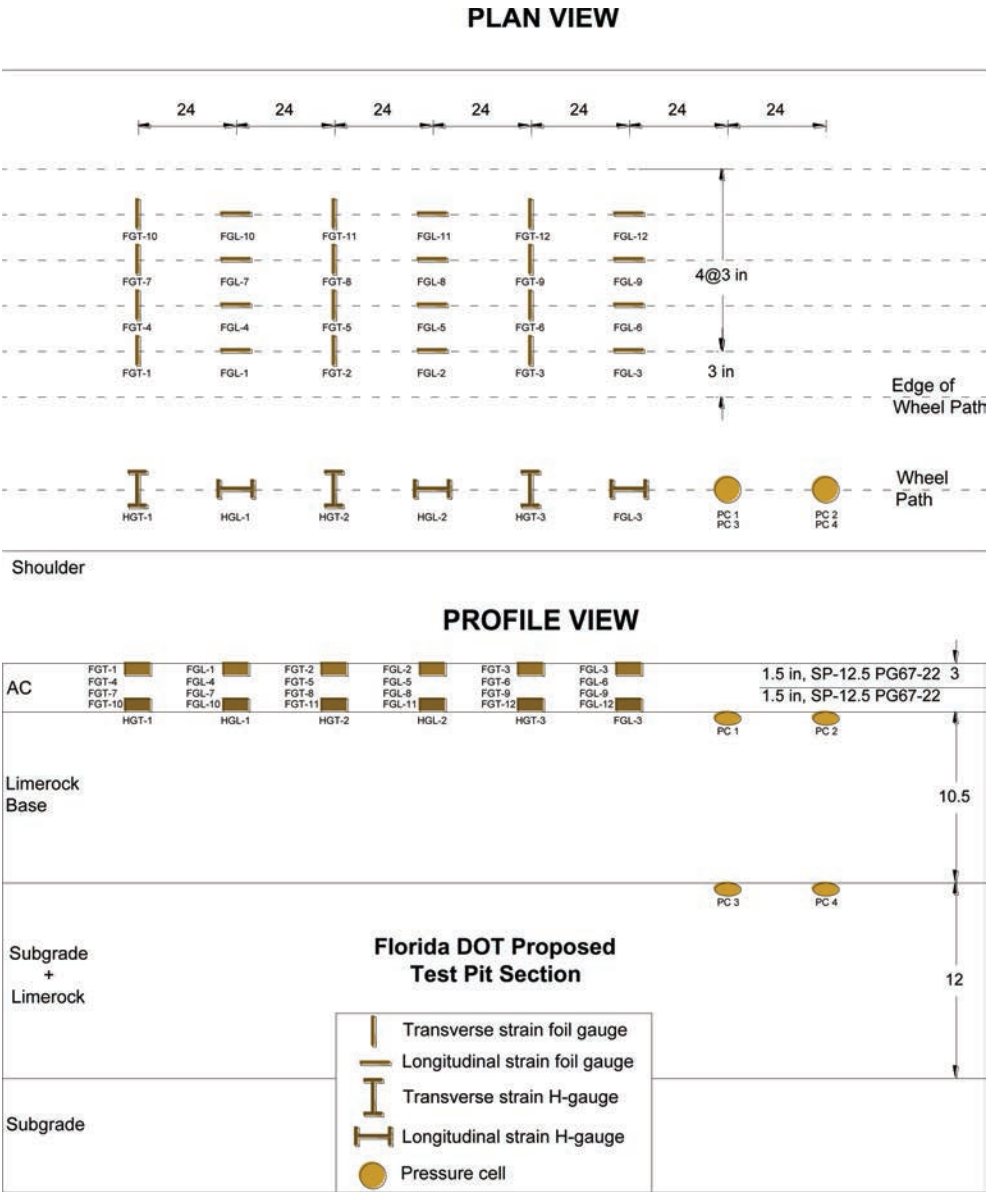

Figure 1. Pavement structure and instrumentation for the test pit section at florida DOT facility.

(NMAS), which is overlaid by two lifts of AC. The first lift is 38-mm-thick, and the surface lift is 25-mm-thick of 4.75-mm NMAS. The binder for these two layers was PG 76-22, and the NMAS was 12.5 and 4.75 mm, respectively. The thickness of the AC layer of the section in the test pit was 76 mm and was built using two lifts of equal thickness. The AC of the test pit has a NMAS of 12.5 mm and PG 67-22 binder. Figure 1 details the pavement structure of the test pit section.

2.1.2 *Pavement structure at UC-Davis*

As with the sections in Florida, the layer configuration under the AC is the same for the two pavement structures built and instrumented at UC-Davis. The top 200 mm of the clay subgrade were ripped and recompacted, and the thickness of the base was 270 mm. Between the AC and the base layer, 250 mm of recycled base were constructed. The two sections differ in the thickness of the AC layer: one at 60 mm, and the other at 120 mm. In addition, the AC layer contained 15% RAP.

2.2 *Instrumentation*

2.2.1 *Florida DOT*

Three types of sensors were used to measure pavement responses of the test sections built at the Florida DOT facility: 48 foil strain gauges, 12 H-type strain gauges, and four pressure cells. The foil gauges were installed on the surface of the pavement and were arranged in six sets. Each set was placed 610 mm in the traveling direction, and it was composed of four foil gauges. At the same time, each of these four gauges was located every 76.2 mm perpendicular to the wheelpath (see Fig. 1). The H-type strain gauges were placed at the bottom of the AC of each section in the longitudinal (traffic) and transverse direction. As in the case of the foil gauges, the separation between two consecutive H-type strain gauges was 610 mm. Finally, four pressure cells were installed in the test pit section: two at the interface between the AC and base and two on top of the subbase.

2.2.2 *UC-Davis*

H-type strain gauges, Multi-Depth Deflectometers (MDD), pressure cells, and thermocouples were installed in the pavement sections at UC-Davis. For the thick section, four strain gauges were installed at the bottom of each lift (eight total). Out of these four, two were installed in the longitudinal direction and two in the transverse. In addition, two pressure cells were placed at the recycled-base/existing-base and AC/recycled-base interfaces. In the case of the thin section, six strain gauges (three in each direction) and one pressure cell were placed at the bottom of the AC. Both sections were equipped with MDD to measure deflection at various locations in the pavement structure.

3 LOADING

All pavement structures were subjected to accelerated loading using the same testing matrix. The values of applied load and tire inflation pressure were intended to cover a wide range, varying from very low (552 kPa and 26.8 kN) to very high (862 kPa and 80.0 kN). In addition, differential tire inflation pressure was considered in the case of DTA. All the values used in the testing matrix are summarized in Table 1.

The described testing matrix was performed at three temperatures at each testing site: Florida at 25°C, 40°C, and 55°C (77°F, 10°F4, 131°F); and UC-Davis at 20°C, 35°C, and 50°C (68°F, 95°F, 122°F). Furthermore, the load was applied unidirectionally at the Florida DOT site and bidirectionally at the UC-Davis site. Test at different offsets With Both Tires (WBT and DTA) were also performed at UC-Davis for a specific case: temperature = 50°C (122°F), tire inflation pressure = 552 and 862 kPa (80 and 125 psi), and load = 44 kN (10 kip). The offsets were 178 and 305 mm. The location of the tires with respect to line of sensors was different

Table 1. Experimental matrix for tire contact stress measurement.

414/758**					
552/758**					

*1 kPa = 0.145 psi; 1 kN = 0.225 kip; **Differential tire inflation pressure (DTA only).

at each testing site. At UC-Davis, the center of each of the tires matched the line of sensors, while at the Florida site, the edge of each tire was placed 76 mm from the first longitudinal foil gauge (which means that the center of the tires did not line up with the line of sensors).

4 TYPICAL READINGS

Typical readings of the sensors installed in Florida are presented in Figure 2. Because the instrumentation in both testing sites differs only with regard to the MDD, these measurements are considered to be representative of all the sections. The curves shown correspond to the sensors in the test pit section for DTA with an applied load of 44 kN (10 kip) and tire inflation pressure of 758 kPa (110 psi).

Figure 2a presents the variation of the longitudinal strain at the bottom of the AC with time. Three distinctive segments of the plot can be clearly distinguished. In the first one, the tire creates compressive longitudinal strain as it approaches the sensor. When the tire reaches the strain gauge, tensile strain is generated and the maximum longitudinal strain is experienced by the pavements. When the tire leaves the sensor, compressive strains are read once more. The variation with time of the transverse strain at the bottom of the AC does not exhibit compressive strain (see Fig. 2b). There is a chance that the strain gauge experiences compressive strain if the tire does not travel on top of the line of sensors (with offset). Good repeatability was observed in at least two of the three strain gauges installed in each direction. It should be noted that the alignment of the sensors plays a significant role in the uniformity of their readings, and this alignment might easily be altered during installation of the sensor and compaction of the AC layers.

Figure 2c and 2d show the change of the surface strain in the direction of traffic and perpendicular to traffic (negative sign indicates tension). The area directly underneath the tire has high compressive stresses in the in-plane directions. This creates high compressive strains in the longitudinal and transverse directions at the points close to the surface and in the vicinity of the contact patch. The longitudinal surface strain decreases as the distance transverse to the traffic direction increases until its value completely vanishes, as illustrated in Figure 2 where the peak of each curve decreases as the location of the foil gauge changes from 76.2 mm to 304.8 mm. This is not exactly the case for the transverse surface strain, where the highly compressed zone close to the tire becomes tension before the magnitude of the strain becomes zero. In summary, longitudinal surface strain magnitude monotonically decreases from the loaded area, while transverse surface strain changes its sign before becoming zero. As a consequence, at some points on the pavement surface, the sign of the peak transverse and longitudinal surface strain are opposite, as seen in Figure 2c and 2d. Furthermore, the peak increases when the location of the foil gauge changes from 76.2 mm to 152.4 mm. The reason for this behavior cannot be gener-

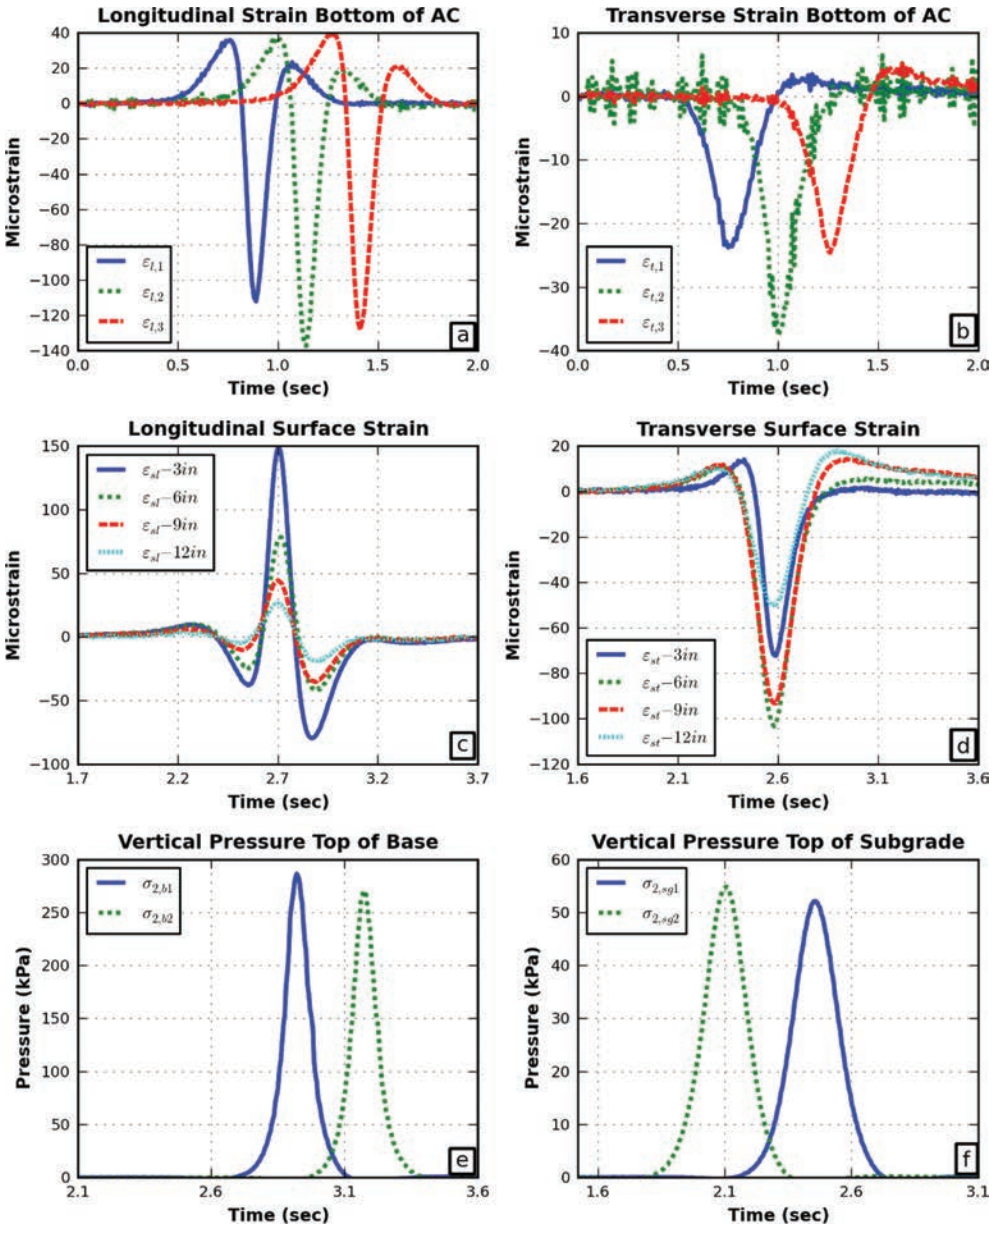

Figure 2. Typical measurements of florida DOT's instrumentation: (a) longitudinal strain at the bottom of the AC; (b) transverse strain at the bottom of the AC; (c) longitudinal strain at the pavement's surface; (d) transverse strain at the pavement's surface; (e) vertical pressure on top of the base; and (f) vertical stress on top of the subgrade.

alized because it might change for a different pavement structure, loading condition, and sensor location.

Finally, Figure 2e and 2f present the typical readings of the pressure cells on top of the base and subbase. The readings from this type of sensor are commonly used to determine the loading time and how this load duration changes with depth. As can be seen in the figure, not only does the peak decrease with depth, but the loading time also increases.

5 COMPARISON OF WBT AND DTA

The comparison between the measurements of both tire types at 44 kN (10 kips) applied load and 758 kPa (110 psi) tire inflation pressure is presented in Figure 3. The longitudinal and tensile strain at the bottom of the AC in Florida and the longitudinal tensile strain at the bottom of each lift in Davis are shown in Figure 3a and 3b, respectively. In each of these cases,

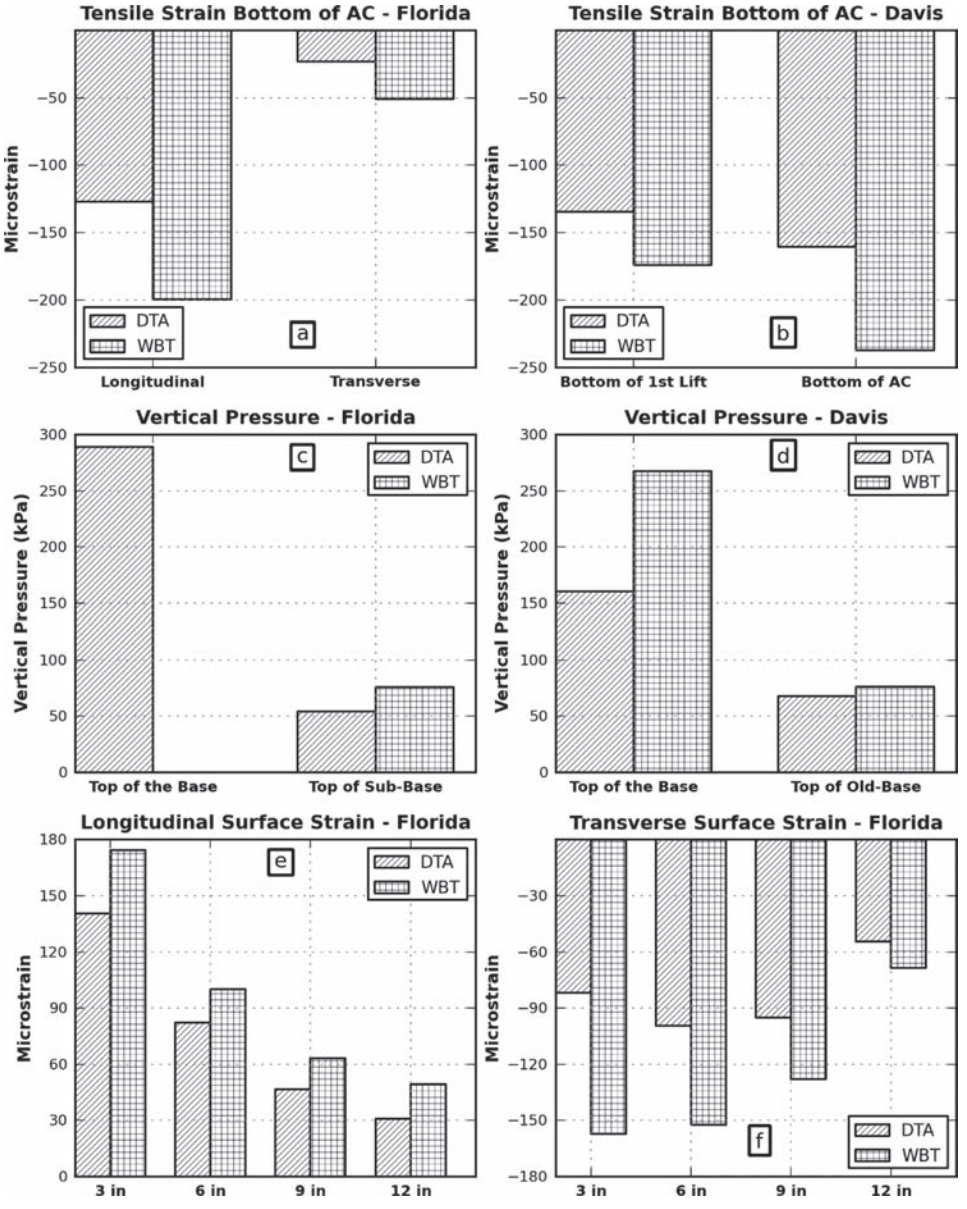

Figure 3. Experimental measurements for 44 kN applied load and 758 kPa inflation pressure: (a) longitudinal and transverse tensile strain at bottom of AC in Florida; (b) longitudinal strain at bottom of each lift in Davis; (c, d) vertical pressure on top of the base and subgrade for both sections; and (e, f) longitudinal and transverse surface strain at various distances from tire's edge in Florida.

WBT created more strain than DTA. Analysis of the load-transfer mechanism of the tires considered in this research showed that the contact area of WBT is smaller (not to mention that there is a spacing between the tires of the dual assembly), although the contact length is longer for WBT. However, the maximum vertical contact stresses are similar for both tires for the specific loading case considered [17]. This indicates that the distribution of the applied load is more concentrated for WBT than for DTA, which translates into higher longitudinal and transverse tensile strains in the AC.

It is important to consider that strain gauges read strain at a single point, and the strain might not be maximum at any specific point. This fact is more relevant in the Florida section, where the center of the DTA was not aligned with the line of sensors. To find the actual maximum, a calibrated finite element model can be developed, so all the points in the pavement structure can be analyzed.

Figure 3a and 3b also show a higher longitudinal strain compared with the transverse. In the extreme case of circular contact area subjected to uniform vertical contact stresses, the strain in both directions would be equal at any depth under the center of the tire–pavement contact patch. However, this is not the case for the actual tire–pavement contact. Relevant differences are seen in the strains along the longitudinal and transverse directions, indicating that the circular contact area with uniform pressure in the vertical direction only is not a good approximation for pavement analysis.

Figure 3b compares in-plane tensile strains at two depths, and it can be seen that the difference between WBT and DTA increases with depth. This result can be explain by taking into account the area used by each tire to distribute the applied load. Because WBT load distribution is more localized, its effects have a greater variation with depth. This is observed not only with the longitudinal tensile strain but also with the vertical pressure (see Fig. 3d). On the contrary, DTA not only has greater contact area but also is composed of two tires with space between them. As a consequence, depth has a greater influence on longitudinal tensile strain that is caused by WBT than DTA.

This argument cannot be generalized to other loading conditions, responses, or pavement structures. A good example of this caveat is the vertical pressure. As can be seen in Figure 3d, the difference between the vertical pressures caused by each tire decreased with depth, indicating that the effects of tire–pavement contact become less relevant as the vertical distance from the pavement surface increases. It is worth noting that the measurements of the deepest pressure cells in each section were not very different, as can be inferred from the readings on top of the subbase and on top of the old base in Florida and Davis, respectively.

The variation of the longitudinal and transverse surface strains with the distance perpendicular to the traveling direction for WBT and DTA is presented in Figure 3d and 3e, respectively. As briefly discussed above, there is a highly compressed zone caused by the confinement provided by the pavement structure surrounding the area where the tire is in contact with the pavement. The longitudinal surface strain decreases from the highly compressed region around the tire–pavement contact zone until it becomes zero without changing to tension. In contrast, the transverse surface strain changed from compression under the tire to tension before fully vanishing away from the tire. This finding suggests that there is a point with maximum surface transverse tensile strain.

The shape of the variation of the longitudinal surface strain from the tire's edge is very similar for both tires. This is not the case, however, for the transverse surface strain. After analyzing readings for DTA, it was seen that the mentioned transverse surface strain is higher at 152.4 mm than at 76.2 mm from the tire's edge and then decreases until it vanishes. This result indicates that the transverse foil gauges are in the zone in tension; it also indicates that the first gauge is located before the peak tensile strain and the other three after. Conversely, for the case of WBT, all the foil gauges are located after the peak transverse tensile surface strain. Because all foil gauges are located at the same distance from each tire's edge, it can be concluded that the peak transverse tensile strain is located closer to the WBT.

In general, Figure 3d and 3e show higher surface strains for WBT than for DTA. Because the tire–pavement contact stresses are more localized for WBT (smaller contact area and single tire), a point at a fixed distance from the edge of each tire will experience higher surface

strain from WBT than from DTA. The difference between the strain values from tires is higher in the transverse direction than the longitudinal one. It is worth recalling that loading was carried out by maintaining the distance from the tire's edge to the closest foil gauges at 76.2 mm.

6 CONCLUSIONS

Pavement structures, instrumentation, and loading details of four accelerated pavement testing sections that are part of the pooled-fund project TPF-5(197), The Impact of Wide-Base Tires on Pavement Damage: A National Study were discussed. In addition, the typical readings of the sensors used, along with some results for a specific loading case (applied load = 44 kN and inflation pressure = 758 kPa) were provided and analyzed.

The results presented indicate that WBT create greater responses than DTA on the pavement at the studied locations (longitudinal and transverse tensile strains on the surface and at the bottom of the AC, and vertical pressure) and for the loading case that was considered. It is concluded that depth has greater influence on the measurements caused by WBT than DTA. It was also observed that the stress/strain state near the contact between the tire and the pavement is a relevant factor in pavement behavior close to the surface and at the surface itself.

It should be emphasized that the results discussed in this paper are not conclusive. The findings are from only a portion of extensive tests performed at a wide range of temperatures, loads, and tire inflation pressures and currently being analyzed.

ACKNOWLEDGMENT

This paper discusses some results from an ongoing pooled-fund study, DTFH61-11-C-00025: The Impact of Wide-Base Tires on Pavement—A National Study. The project is being conducted in cooperation with the Illinois Center for Transportation; the U.S. Department of Transportation, Federal Highway Administration; Rubber Manufacturers Association, and the following state departments of transportation: Illinois, Minnesota, Montana, New York, Ohio, Oklahoma, Texas, and Virginia. The feedback and input of the following are greatly appreciated: David Lippert, Shongtao Dai, Dan Hill, Wes Yang, John Bowman, Brian Diefenderfer, and Larry Buttler. This project is managed by Eric Weaver, who has been instrumental in providing directions and input.

Effect of geotextile-reinforced base on fatigue life of Hot-Mix Asphalt pavement

Milad Saghebfar, Mustaque Hossain & Nassim Sabahfar
Department of Civil Engineering, Kansas State University, Manhattan, KS, USA

ABSTRACT: Geotextiles have been widely promoted for pavement structures over the past 30 years. Previous studies show that a geotextile placed at the subgrade-base course interface of a paved road can increase the number of load repetitions before rutting failure. Thus, reduction of base and/or asphalt thickness may be possible. However, there is a lack of well-instrumented full-scale experiments to investigate effect of geotextile reinforcement on other possible mechanisms of pavement failure like fatigue of the Hot-Mix Asphalt (HMA) layer. In this study, full–scale accelerated pavement testing was done on eight pavement test sections. Six out of these eight sections had base layers reinforced with different types of woven geotextiles. The reinforced sections and the control sections (with unreinforced base) were paved with Superpave HMA layers. Base and subgrade materials were the same for all sections while some test sections had different asphalt and base layer thicknesses. Each test section was instrumented with six H-bar strain gages at the bottom of the HMA layers to measure longitudinal and transvers strains. The mechanistic response of each section was monitored and analysed at the selected number of wheel passes. Predicted fatigue lives of the test sections were calculated based on the Asphalt Institute and Shell models. Results indicate that fatigue life of test sections did not increase due to geotextile reinforcing although rutting performance of some reinforced sections did improve. This may indicate geotextiles may not improve fatigue performance of HMA layers in pavements.

Keywords: Geotextile, Hot-Mix Asphalt, fatigue life, Accelerated Pavement Testing

1 INTRODUCTION

One of the persistent problems involved with Hot-Mix Asphalt (HMA) pavements is fatigue cracking. The repeated traffic loads result in tensile stress repetitions in the bound layers. Under these repeated strains, fatigue cracks initiate at locations where the largest tensile strains and stresses develop. These critical locations depend on many factors such as pavement structural configuration, layer stiffness, and load configuration (area of load distribution, magnitude of stresses at the tire-pavement interface, etc.). After crack initiation at critical locations, repeated traffic loads can cause the cracks to propagate throughout the entire layer. These cracks allow water infiltration, which can negatively affect pavement performance. Many pavement structural models assume that cracks initiate at the bottom of the asphalt concrete surface layer and then propagate upward. These cracks are aptly named bottom-up fatigue cracks. The newly released AASHTO mechanistic-empirical design procedure (DARWin ME) considers the alligator cracking as bottom-up fatigue cracking [1]. DARWin ME also recognizes another type of fatigue cracking, now known as top-down cracking, which are longitudinal cracks in the wheel path. The cause of top-down cracking is highly debated but they do seem to exist, especially in hot-weather locations and pavement constructed on moisture sensitive subgrades [1].

Classical fatigue analysis directly correlates the fatigue life of asphalt mixtures with the critical pavement responses (stresses or strains). A number of fatigue analysis approaches

have been proposed by researchers over the last few decades. The point of failure is normally defined as the moment at which the stiffness of the specimen is reduced to a certain value [2]. While dissipated energy theory was introduced by Hopman and Pronk [3] in the fatigue analysis, dissipated energy ratio was used to describe the fatigue damage of asphalt mixtures. Ghuzlan et al. [4] and Shen and Carpenter [5] developed models that can predict the fatigue life from material properties and loading conditions. Kim et al. [6] and Lundstrom [7] applied Viscoelastic Continuum Damage (VECD) approach to simulate the damage evolution under cyclic loading tests. According to SHRP-A-404, pavements with different mix stiffness, thickness, subgrade modulus, air void and asphalt content exhibit different fatigue behaviour [8]. A literature review was done by Carpenter [9] on fatigue cracking models. In the majority of models, the number of load applications to fatigue crack appearance (N_f) is related to the strain at the bottom of the HMA layer (ε_t). Thus, this strain was measured and analyzed in this study to assess fatigue life of HMA pavements under accelerated pavement testing.

2 ACCELERATED PAVEMENT TESTING (APT)

The Civil Infrastructure Systems Laboratory (CISL) at Kansas State University is one of only six such university-owned facilities in the nation that is capable of testing large-scale asphalt and concrete pavement sections under full-scale loading. CISL houses an Accelerated Pavement Testing (APT) machine and three pits for constructing test sections. The reaction frame of the APT machine covers a distance of 12.8 m and applies axle load with air-bag suspension on dual tires. The wheel assembly is belt driven by a 20-HP electric motor, while the load is controlled by hydraulic pressure. The pits are each approximately the same size at 6.1-m long, 4.9-m wide, and 1.8-m deep [9].

Loading mechanism at CISL APT can be controlled via hydraulic pressure, tire pressure, and test speed. In this testing, an 80-kN single axle load with air-bag suspension was applied on dual tires. Tire pressure was 627 kPa and testing speed was 11 km/h. The APT machine has the ability to wander laterally during passes simulating realistic traffic load distribution across the lane. A ±150 mm wander was applied in a truncated normal distribution. The number of passes for one full wander cycle is 676.

2.1 *Test sections*

Two pits at CISL were divided into two lanes each for a total of four lanes. In the first series of tests, each lane had a length of 6.1 m (20 ft.), width of 2.45 m (8 ft.) and depth of 1.83 m (6 ft.). In the second series of tests, the width of the test sections was increased to simulate expected geotextile behavior (full-width mobilization) in the field. In the second test series, each section had a length of 3.05 m (10 ft) in the direction of trafficking and 4.9 m (16 ft) width in the direction perpendicular to traffic. The second series configuration was created to accommodate the full-width of the geotextiles. Figure 1 shows the cross sections of the test pavements.

Sections A and E are the unreinforced (control) test sections with a deep (305 mm) crushed aggregate base. Other test sections have crushed aggregate bases with varying thickness and reinforced with different types of woven geotextiles. HMA, base course aggregate and subgrade materials for all sections were the same but their thicknesses varied.

2.2 *Material properties*

2.2.1 *Subgrade*

An AASHTO A-7-6 clay was used in subgrade construction. The maximum dry density of the subgrade soil was 1.61 g/cm^3 at an optimum moisture content of 21%. However, 24% moisture content was used to produce a CBR of 2.6 (corresponding subgrade resilient modulus of 4,700 psi). The subgrade was placed and compacted in five lifts. Dynamic Cone Penetrometer (DCP) testing was done on each lift to evaluate subgrade strength.

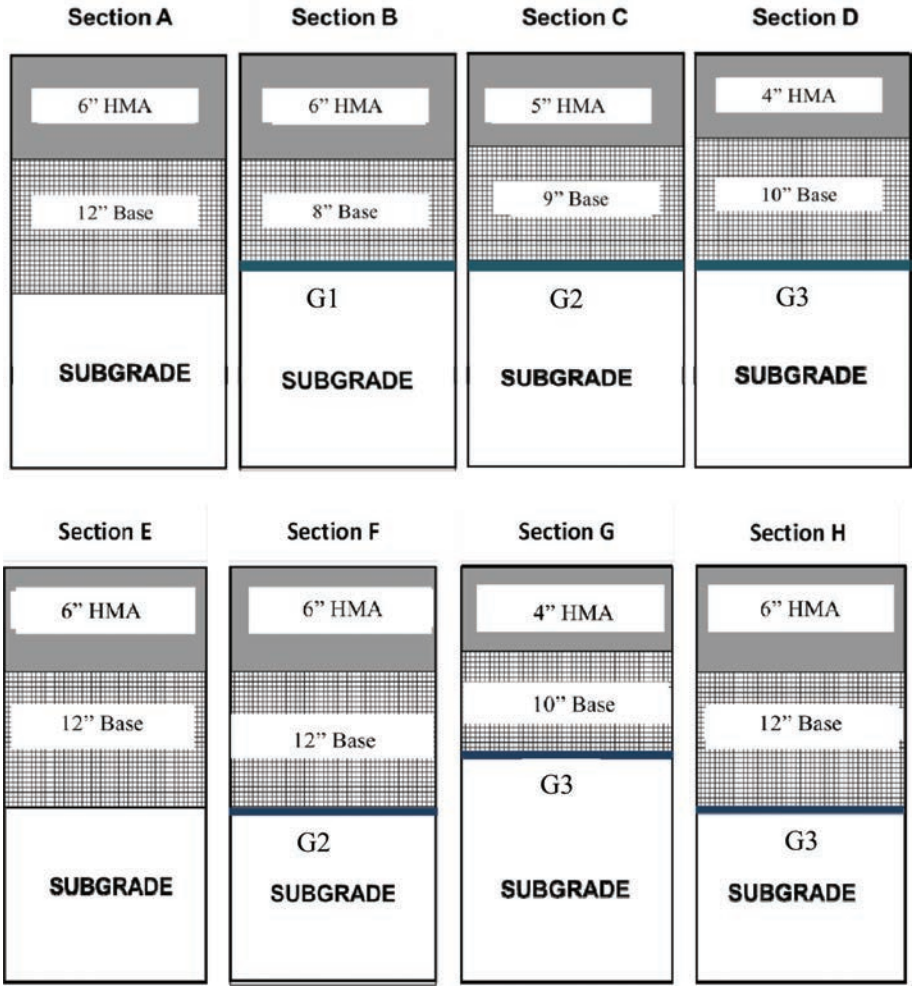

Figure 1. Cross sections of the test pavements.

2.2.2 *Base course*

Well-graded crushed limestone, known as AB-3 in Kansas, was used as the base layer material for all sections. The AB-3 had a mean particle size of 4.4 mm, coefficient of curvature of 1.55 and coefficient of uniformity of 21. The optimum moisture content of the base material was 10.2% and the maximum dry density was 2.13 g/cm^3. Base course layers were compacted at 95% of the maximum dry density. DCP and Light Falling Weight Deflectometer (LFWD) tests were done to assess layer strength and stiffness, respectively, to ensure base courses for the test sections are comparable.

2.2.3 *Hot-Mix Asphalt (HMA)*

All sections were paved with a 12.5-mm Nominal Maximum Aggregate Size Superpave mixture with fine gradation. This HMA mixture with 25% of Recycled Asphalt Pavement (RAP) materials is known as SR-12.5 A by the Kansas Department of Transportation (KDOT). A PG 58-28 virgin binder was used in SR-12.5 A.

2.2.4 *Geotextile*

Three types of woven reinforcement/stabilization geotextiles were used. The geotextiles were composed of high-tenacity polypropylene yarns, which are woven into a network such

that the yarns retain their relative position. The wide width tensile strengths of the geotextiles based on ASTM D4595 testing are shown in Table 1. Geotextile type G1 was used in section B and G2 was used in sections C and F. Sections D, G and H were reinforced by geotextile G3.

2.3 *Instrumentation*

2.3.1 *Sensor preparation*

Each section was equipped with six strain gages (three in the longitudinal and three in the transverse direction) and two thermocouples. Sensors were placed just below the HMA layer and under the wheel path. A Data Acquisition (DAQ) system was used to collect instrument responses. The DAQ system interfaced with a PC equipped with LabVIEW 2009 through a simple USB 2.0 connection. The strain gauge responses were recorded for a full wander cycle (676 passes) each time. The top 20 peak strain measurements were averaged.

Four types of strain gages were used to measure strain in the hot mix asphalt: foil strain gages; strain coils; and H-bar gages. Foil strain gages are placed in carrier blocks or extracted pavement cores [11]. Among different types of strain gages, H-bar gages are more accurate and have been successfully used in previous experiments [12,13]. In this study, PML-60-2 L strain gages from Tokyo Sokki Kenkyujo Co. were used. Each strain gage was connected to two aluminium rods (Fig. 2). Strain gages come with wires; however the original wires cannot tolerate the high temperature of asphalt during construction. Thus, conductor wires of 22 AWG types with braided shields were soldered to the H-bars. The solder was covered by

a heat shrinking sheath. Then the resistance of the gages was checked to make sure it was close to 120 ohms. The calibration factor provided by the manufacturer was used as the gage factor.

2.3.2 *Data acquisition system*

A compact DAQ (cDAQ) system from National Instruments was used for data collection. The cDAQ system allows multiple interchangeable modules to be used with an electronic chassis, with a simple USB interface and a Personal Computer (PC). For this setup, three types of terminal block modules were used with the cDAQ-9178 chassis. A thermocouple module (NI 9211, 4 channel, +/–80 mV, 24 bit differential analog input), two quarter-bridge input modules (NI 9235, 120 ohm, 8 channel, 24 bit, 2.5 ex) and an analog input module (NI 9205, 32 channel, +/– 10 V, 16 bit) were installed in the chassis for data collection during the experiments. The quarter-bridge modules complete the Wheatstone bridge circuit for the strain gages as shown in Figure 3. Applying the necessary excitation voltage, and the strain gage factor can be applied via software.

The cDAQ system interfaced with a PC equipped with LabVIEW 2009 through a simple USB 2.0 connection. A custom Virtual Instrument (VI) was constructed in LabVIEW in order to collect necessary data for the study. The VI creates a *.csv file (or appends onto an existing file) with specified column headers and then acquires data from the cDAQ system at a rate of 100 readings per second using the built-in DAQ Assistant VI. The pulse for each sensor is displayed in a chart (in pairs to show sensors which lie under the moving wheel on the same chart, to simplify the observation). The data for each sensor is output to a specific column in the *.csv file created (or appended to it). This file is continuously saved and after the VI is stopped, the file may be opened and viewed. Figure 4 shows this acquisition and display process. Within the DAQ Assistant VI settings, the input from a strain gage is read as strain gage input and the correct strain gage factor is applied.

3 TEST RESULTS

Six H-bar strain gages were placed at different locations in each test section to measure longitudinal and transvers strains at the bottom of the HMA layer. Results are shown in Tables 2 and 3. Average longitudinal and transverse strains at the bottom of the HMA layer are plotted in Figures 5 and 6. These strain responses fluctuate widely up to about 100,000 repetitions. This is most likely due to the consolidation of the HMA and base

400,000	2	746		1	585	

layers. After about 100,000 repetitions, the results were analyzed and showed a clear trend among the sections. In the first test, both transverse and longitudinal strains at the bottom of HMA are lower in the control section (Section A) than in the reinforced sections (sections B, C and D). Control and Section B have the same HMA thickness (150 mm). Strain at the bottom of the HMA layer in the control section is less that for the geotextile-reinforced Section B.

In the second test, the thinnest section (section G) experienced highest transverse and longitudinal strains. After 200,000 repetitions of loading, both transverse and longitudinal strain in the control section (section E) and test sections F and H (reinforced sections, thickness same as the control section) are very close. Thus, geotextile reinforcement at the interface of the base and the subgrade did not reduce strains at the bottom of the HMA layer.

4 FATIGUE LIFE

In the majority of fatigue life models, the number of load applications to fatigue crack appearance (N_f) is related to the tensile strain at the bottom of the asphalt layer (ε_t) and elastic modulus of asphalt layer (E_1). The Asphalt Institute expressed following formula as failure criterion for fatigue cracking [15]:

$$N_f = f_1(\varepsilon_t)^{-f_2}(E_1)^{-f_3}$$

f_1, f_2 and f_3 are constants determined from fatigue tests. Table 4 shows f_1, f_2 and f_3 values suggested by the Asphalt Institute and Shell models.

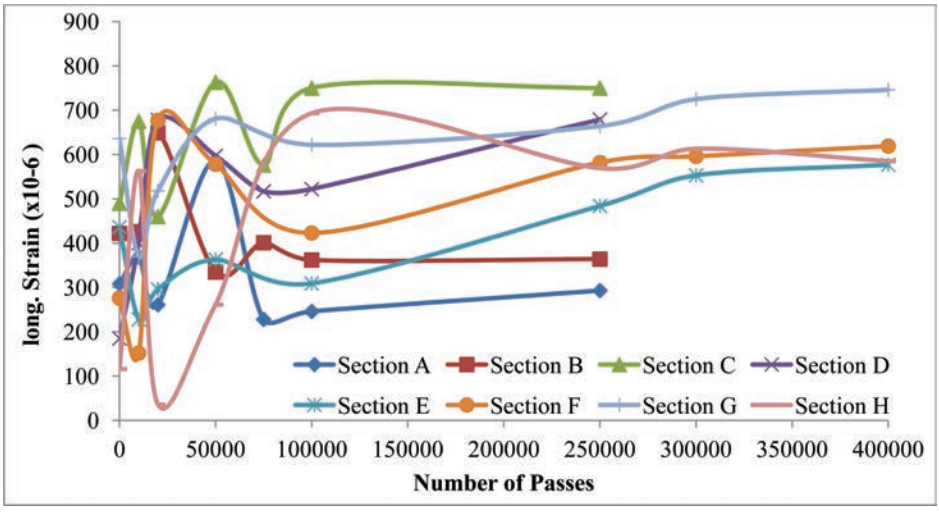

Figure 5. Longitudinal strains at the bottom of HMA.

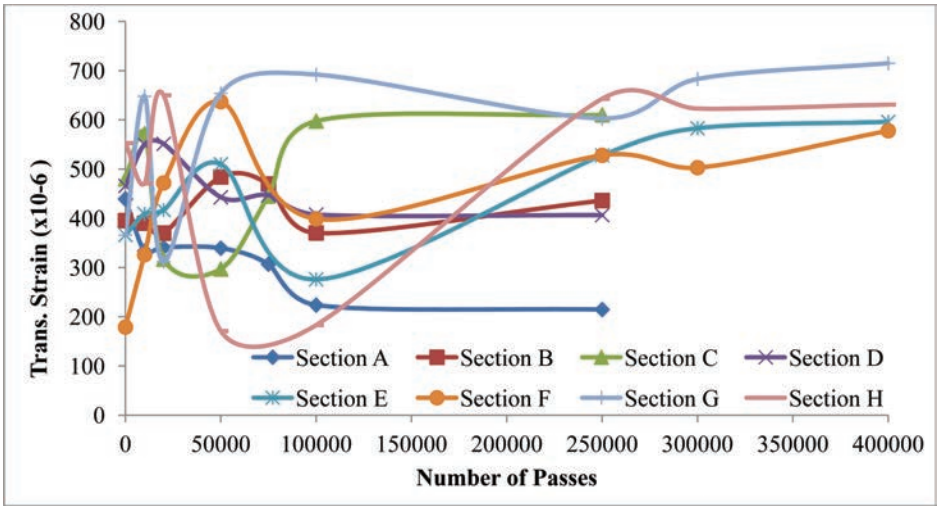

Figure 6. Transverse strains at the bottom of HMA.

Table 4. Parameters in fatigue cracking models [15].

Parameters	Asphalt institute	Shell
f_1	0.0796	0.0685
f_2	3.291	5.671
f_3	0.854	2.363

In this study, fatigue lives of the test sections were calculated based on the measured strains at the bottom of HMA layer and layer moduli were back calculated from FWD testing. FWD testing was done after construction of the test sections, and also after 250,000 and 400,000 wheel load repetitions. Table 5 shows the predicted remaining fatigue life of test sections for 676, 250,000, and 400,000 wheel load repetitions.

Table 5. Predicted fatigue life.

	Remaining fatigue life after 676 load repetitions			
Section A	300	308	602,048	640,740
Section B	300	422	213,574	107,425
Section C	307.3	490	127,967	43,499
Section D	300	185	3,222,474	11,537,778
Section E	300	436	191,823	89,274
Section F	300	270	928,610	1,352,039
Section G	308	636	54,139	9,859
Section H	300	316	553,326	554,023
	Remaining fatigue life after 250,000 load repetitions			
Section A	300	293	709,562	850,446
Section B	300	364	347,430	248,455
Section C	313.3	750	31,012	3,718
Section D	314	679	42,939	6,500
Section E	366	484	114,782	30,862
Section F	325	582	69,247	14,363
Section G	325	664	44,876	6,801
Section H	325	569	74,592	16,326
	Remaining fatigue life after 400,000 load repetitions			
Section E	300	577	76,282	18,223
Section F	310	619	58,862	11,322
Section G	325	746	30,590	3,514
Section H	305	585	71,880	16,209

After 676 repetitions, strain at the bottom of the HMA layer in the section D was less than other sections, so predicted fatigue life for this section is higher than other sections. When consolidation of the HMA and base layers had completed and strains were recorded, there appeared to be no significant improvement in fatigue life of the test sections constructed with a geotextile. In both experiment series, remaining fatigue life for the unreinforced section (section A or E) was higher than the reinforced sections after 250,000 and 400,000 repetitions.

4 CONCLUSIONS

Eight test sections including six geotextile-reinforced sections and two unreinforced control sections were subjected to full-scale accelerated pavement testing. Transverse and longitudinal strains at the bottom of the HMA layer were measured at regular loading intervals. Predicted fatigue life for the test section was calculated based on the Asphalt Institute and Shell models. Apparently, HMA fatigue life was not increased by using a geotextile reinforcing layer below the base. Therefore, geotextile-reinforced bases did not improve the fatigue resistance of these sections. It is expected that a reinforced HMA layer will results in lower strain at the bottom of the HMA layer, and that in turn will increase the fatigue life.

ABSTRACT: Stiffness of pavement subgrade materials that is commonly determined by the resilient modulus parameter is an important component in the mechanistic design of flexible pavement structures. Environmental effects such as seasonal variations in pavement moisture content can considerably influence this material property which should be properly considered in any realistic pavement design. The seasonal changes in moisture condition affects the stress state in the subgrade due to changes in the matric suction which is an important stress state variable in unsaturated soil mechanics. In this study, a modified test procedure and a predictive resilient modulus model that takes into account the subgrade soil matric suction as a stress state variable is presented. Two different silty sand subgrade materials were tested in unsaturated conditions using a series of Repeated Load Triaxial (RLT) tests. The tests were performed under various matric suctions (moisture contents) to enhance the understanding of its effect on the resilient modulus. The results showed a considerable influence of the moisture content (matric suction) on the subgrade resilient modulus. The resilient modulus data together with the suction measurements were used and a set of parameters for the enhanced predictive model were developed. This model accounts for seasonal variation of subgrade material stiffness by incorporating suction as a stress state variable.

Keywords: subgrade, resilient modulus, unsaturated soil, matric suction, environmental effects, moisture content

1 INTRODUCTION

The Swedish Traffic Administration has initiated a research program to develop a comprehensive Mechanistic-Empirical analysis and design procedure of pavements. The aim is to develop and calibrate enhanced design models for flexible pavement structures that are calibrated for the materials, construction practices, traffic loads and climatic conditions of the road network in Sweden.

One of the important input parameters in the analysis and design of any flexible pavement structure is the stiffness of the unbound layers. This material property is widely characterized by the resilient modulus (M_R), which depends on many factors such as gradation and texture, stress state, compaction energy, dry density, number of load cycles and moisture content [1].

Large part of the road network in Sweden consists of relatively thin flexible pavement structures that are located in cold regions. These pavement structures are subjected to significant seasonal variations in pavement environmental condition that influences the material properties and pavement performance. In unbound pavement materials and subgrade soils, moisture content is known to be the major environmental factor which can be affected by seasonal changes in water table condition, water infiltration from precipitation as well as the frost-thaw action.

Since moisture content in unbound pavement materials is one of the main factors that have a significant role in their mechanical response, proper consideration to this factor should be given in any sustainable pavement design approach. As a consequence, the essential role of the environmental factors has been substantially emphasized in the latest design guide procedures in pavement engineering [2,3].

Over the recent years, a number of experimental studies has been carried out to understand the influence of moisture content on the resilient response of pavement unbound materials and to develop models that can properly predict this parameter and its variation due to seasonal effects [4–8]. Most of the models developed from these studies are based on triaxial testing on unbound materials at different moisture contents and use a total stress approach. These models incorporate an environmental factor that represents the influence of the changes in the moisture content on the resilient modulus for the set of stress levels applied during the triaxial testing.

From unsaturated soil mechanics, it is known that variations in the moisture content of fine-grained subgrades (seasonal environmental variations) result in changes in the stress state of the soil which is explained by changes in the soil matric suction, which is the pressure difference between the pore-air and the pore-water phases in the soil matrix. Therefore, a more rational approach to incorporate seasonal effects in the resilient modulus predictive models would be to consider matric suction as a fundamental variable in the stress state of the subgrade soil [9–11].

The overall objective of this study was to investigate the influence of moisture content on the mechanical response of silty sand subgrade materials and to further calibrate model parameters of a suction-dependent resilient modulus model.

In this study, two different silty sand subgrade soils were tested. Silty sand subgrade materials appear frequently in Nordic countries due to the heterogeneous sedimentation process of glacial origin. The proposed model was validated and the regression parameters were determined for the silty sand subgrade soils commonly found in Sweden.

The materials were tested at the Arizona State University (ASU) Geotechnical Laboratory using a custom built advanced triaxial cells and control units. The system enables full control/measurement of pore-water and pore-air pressure of the cylindrical test specimen during the Repeated Load Triaxial (RLT) test. The load sequences used for this purpose were in accordance to the NCHRP 1-28A [12] protocol "Harmonized Test Methods for Laboratory Determination of Resilient Modulus for Flexible Pavement design" after some modifications to the procedure that would allow for testing soil in unsaturated conditions with matric suction control. More details on the modification to the NCHRP 1-28A loading procedure and triaxial cell control unit can be found in Cary and Zapata (2011) [11].

2 MODELING OF RESILIENT MODULUS

It is widely recognized that the resilient modulus can properly characterize the mechanical stiffness of pavement unbound materials and subgrade soils. This parameter is measured under conditions representative of the stress state and the environment that is experienced by the unbound materials in the pavement system. Many researchers have proposed mathematical models that describe the stress dependence of the resilient modulus using a total stress approach. These models are mainly developed from curve fitting of the laboratory triaxial data and do not directly account for environmental factors [1].

To overcome this drawback, Cary and Zapata (2011) [11] proposed an enhanced resilient modulus model that accounts for seasonal environmental variations by incorporating matric suction as stress state variable. They obtained sets of regression constants from triaxial experiments on granular base and subgrade materials that are commonly used in the state of Arizona. Their proposed model is presented in Eq. (1):

$$M_R = k_1 p_a \left(\frac{\theta_{net} - 3\Delta u_{w-sat}}{p_a} \right)^{k_2} \left(\frac{\tau_{oct}}{p_a} + 1 \right)^{k_3} \left(\frac{(\psi_{m_0} - \Delta\psi_m)}{p_a} + 1 \right)^{k_4} \quad (1)$$

where,
p_a = atmospheric pressure (here chosen as 100 kPa)
$\theta_{net} = \theta - 3u_a$ = the net bulk stress (θ = bulk stress = $\sigma_1 + \sigma_2 + \sigma_3$ and u_a = pore-air pressure)
Δu_{w-sat} = pore-water pressure build up under saturated condition ($\psi_m = 0$)
τ_{oct} = octahedral shear stress = $1/3\sqrt{(\sigma_1 - \sigma_2)^2 + (\sigma_1 - \sigma_3)^2 + (\sigma_2 - \sigma_3)^2}$
ψ_{m_0} = initial matric soil suction and $\Delta\psi_m$ = relative change in soil matric suction with respect to ψ_{m_0} due to pore-water pressure build up under unsaturated condition ($\Delta u_{w-sat} = 0$)
$k_1 \geq 0, k_2 \geq 0, k_3 \leq 0$ and $k_4 \geq 0$ are regression constants.

In RLT tests, the principal stresses acting on the specimen are: $\sigma_1 = \sigma_3 + \sigma_d, \sigma_2 = \sigma_3$ and $\sigma_3 = \sigma_c$ where σ_c = confining pressure and σ_d = deviator stress. Therefore, $\theta = \sigma_d + 3\sigma_c$ and $\tau_{oct} = \sqrt{2}/3\ \sigma_d$.

3 TEST MATERIAL INDEX PROPERTIES

Two silty sand subgrade soils commonly encountered in Sweden were selected for testing in this study. The subgrade soils were obtained from two different sites in Sweden; the southern part (near Torpsbruk in the Småland province) and the northern part (near Luleå in Norrbotten province) of the country. Wet sieve analysis, specific gravity, maximum dry density, optimum moisture content and Soil-Water Characteristic Curve (SWCC) tests were performed on the selected materials. A summary of the test results is presented in Table 1. Figure 1 shows the grain size distribution curves for the subgrade soils used in this study.

The SWCC for the subgrade materials were determined using the Fredlund SWCC device which is an oedometer-type apparatus for applying matric suctions from near zero values up to 1500 kPa under various stress paths [13]. A saturated ceramic stone with a High Air Entry (HAE) value of 500 kPa was used for this test, which allowed applying suction values up to 450 kPa. This was found to be suitable for the non-plastic subgrade soils tested. The subgrade soils specimens were compacted in the brass ring of the apparatus to reach the maximum dry density that was obtained from the standard Proctor test and then were fully saturated. Thus, the drying paths of the SWCCs for the subgrade soils were obtained by applying air pressure to the specimens. For each soil, the equilibrium moisture contents at six different matric suctions were measured. These graphs were further used to apply the matric suction levels required to reach the target moisture contents for the resilient modulus tests. The SWCCs and test apparatus are presented in Figure 2.

Table 1. Summary of the subgrade soil index properties.

Subgrade soil	USCS class.[1]	Passing No. 200 (%)	Max. dry unit weight (kN/m³)[2]	Opt. moisture content. (%)	Specific gravity	Plasticity index
Luleå	SM	42.2	19.6	10.1	2.68	Non plastic
Torpsbruk	SM	27.4	20.3	7.6	2.67	Non plastic

4 EQUIPMENT SETUP AND TESTING SYSTEM

The triaxial cell and control unit for unsaturated soils testing at ASU is a custom-built electro-hydraulic system with fully digital servo controllers that is capable of adjusting pore-water and pore air pressure of the soil specimen during the test. In the triaxial cell, the bottom platen is built-in with a 500 kPa HAE ceramic disk similar to the one used in the Fredlund SWCC device. The top loading platen is built-in with a porous stone that allowed for application of air pressure to the specimen. In order to eliminate erroneous diffusion of air bubbles that might be trapped in the lines and under the bottom ceramic disk, the bottom platen is also equipped with a flushing device. For the confinement of the specimen during the test, air was used. The vertical deformations on the test specimen were measured using two Linear Variable Differential Transformers (LVDTs) mounted directly on the studs that were buried into the specimen during the compaction process. Schematic overview of the triaxial system is depicted in Figure 3.

5 TRIAXIAL SPECIMEN PREPARATION

Preparation of the specimens was in accordance with the NCHRP 1-28A test protocol [12]. In order to obtain a homogeneous mix, the subgrade materials were thoroughly mixed at

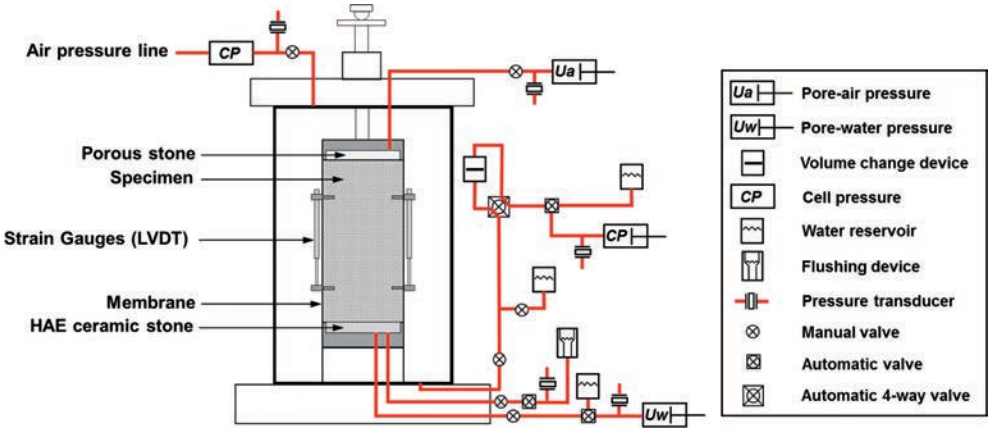

Figure 3. Schematic overview of the triaxial testing system at ASU.

Table 2. Target degrees of saturation, corresponding moisture contents and calculated matric suctions for resilient modulus testing of the subgrade soils.

	Luleå subgrade				Torpsbruk subgrade

[1]Measurement corresponding to the optimum moisture content.

their optimum moisture content and stored in a sealed container in a controlled temperature room for approximately 48 hours. Subsequently, the materials were compacted to reach their maximum dry density as per the standard Proctor tests. These specimens were cylindrical and were 102 mm in diameter and 203 mm in height (4 × 8 inch). The two subgrades were tested at 4 different moisture contents with two replicates that add up to a total number of 16 successful tests. The four different target moisture contents for resilient modulus tests were the optimum moisture contents as well as the moisture contents corresponding to 30, 50 and near 100% degrees of saturation.

In the preconditioning process, to reach the target moisture content for the resilient modulus tests, the specimen were compacted at optimum moisture content and subsequently, they were either saturated or dehydrated to the target moisture content. This was controlled by regular measurement of the weight of the specimens. Once the specimen was close to the target moisture content, the latex membrane was assembled and the specimen was stored in a moisture-sealed bag for about 24 hours. During this period, the specimen was intermittently turned over upside down to retain the homogeneity in moisture distribution.

The specimen was then mounted on the triaxial cell pedestal. Any possibly entrapped air under the ceramic stone and in the connection lines was flushed out and after applying a suitable confinement pressure the target matric suction value was imposed. In this procedure, under the applied matric suction, the specimen is supposed to absorb or release water unless moisture equilibrium is reached. This was the last phase of the moisture equilibration process. Once the equilibration process was completed, the resilient modulus test was started.

It should be mentioned that the specimens could have reached the desired moisture content by only performing the last part of the equilibration process mentioned above (only applying suction to the compacted specimen that correspond to the target moisture content). However, this would be a relativity long process due to the dimension of the specimen and the fine content of the soils. Therefore and as stated earlier, preconditioning of the specimens was performed prior to the final equilibration phase which expedited the process.

6 TEST RESULTS

Examples of the resilient modulus test results for the two subgrade soils are presented in Figures 4 and 5. These figures show the resilient modulus changes with respect to changes in the bulk stress and the moisture content (degree of saturation) of the specimens. Higher moisture contents correspond to lower matric suction values in the subgrade. It should be mentioned that loading sequences for the two subgrades were not fully identical. In the NCHRP 1-28A test protocol [12], loading sequence procedure for the resilient modulus testing of subgrades are divided into two different procedures; Procedure Ib for granular subgrades and Procedure II for fine-grained subgrades. According to the test protocol specification, the Torpsbruk subgrade is categorized as granular subgrade and the Luleå subgrade is categorized as fine-grained subgrade. The specifications for the material classifications and the corresponding test sequences can be found in NCHRP 1-28A [12]. Figure 4 shows variations in the resilient modulus for the two subgrades with respect to changes in degree of saturation and bulk stress. The data plotted in this figure correspond to cyclic deviator stress of 28 kPa.

As expected, increase in the bulk stress resulted in increase in the resilient modulus and increase in the moisture content (matric suction reduction) resulted in decrease in the resilient modulus. It can be observed that both subgrades exhibited higher sensitivity to the bulk

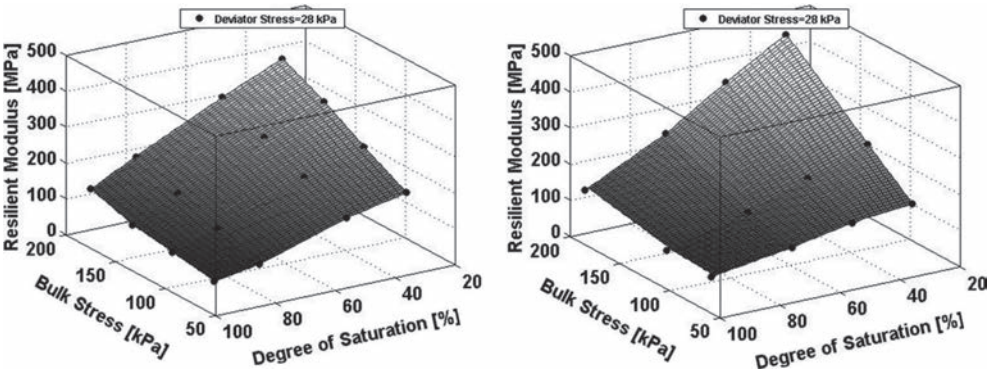

Figure 4. Examples of data; resilient modulus variations with change in moisture content and bulk stress for Luleå Subgrade (Left) and Torpsbruk Subgrade (Right).

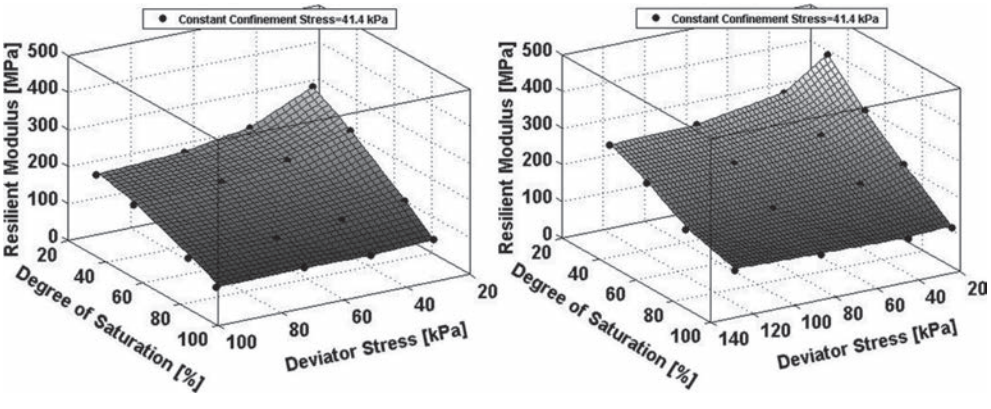

Figure 5. Example of data; resilient modulus variations with change in moisture content and deviator stress under constant confinement stress (41.4 kPa) for Luleå subgrade (left) and Torpsbruk subgrade (right).

stress values at lower degree of saturations. That is, at lower degrees of saturation, resilient modulus of the subgrade increased at higher rate with increase in the bulk stress.

Figure 5 illustrates variations in the resilient modulus as a function of changes in degree of saturation and deviator stress. The data in these figures correspond to a constant confinement stress of 41.4 kPa. From these figures, it can be seen that the subgrades generally exhibited a softening behaviour with respect to increase in the deviator stress. For a constant confinement stress, increase in the deviator stress resulted in decrease in the resilient modulus. However, this softening behaviour was diminished as the moisture content of the subgrade was increased. At high degree of saturations, the magnitude of the deviator stress had no or insignificant influence on the resilient modulus.

7 MODEL PARAMETERS

The regression parameters for the model presented in Eq. (1) were calculated by least square curve fitting on the resilient modulus test data. In total, 123 data points for the Luleå and 150 data points for the Torpsbruk subgrade that correspond to different combinations of stress invariants and matric suctions were used for this statistical analysis. The Solver function in Microsoft Excel was used for the model parameters optimization. The coefficient of determination (R^2) and the adjusted coefficient of determination (R^2_{adj}) were also calculated to evaluate the goodness of fit for the proposed model. The calibrated model parameters and the goodness of fit statistics are summarized in Table 3. Figure 6 shows the prediction results from the Cary and Zapata model presented in Eq. (1) together with the measurements for the two subgrade materials.

The regression of the test data yielded R^2_{adj} values of 0.76 and 0.78 for Luleå and Torpsbruk subgrades, respectively. This is considered to be good for unbound subgrade materials which

Table 3. Resilient modulus model regression parameters for the subgrade soils.

	Model parameters				Goodness of fit	
	k_1	k_2	k_3	k_4	R^2	R^2_{adj}
Luleå subgrade	1489	0.746	–2.633	0.434	0.761	0.759
Torpsbruk subgrade	1524	0.774	–1.470	0.475	0.785	0.784

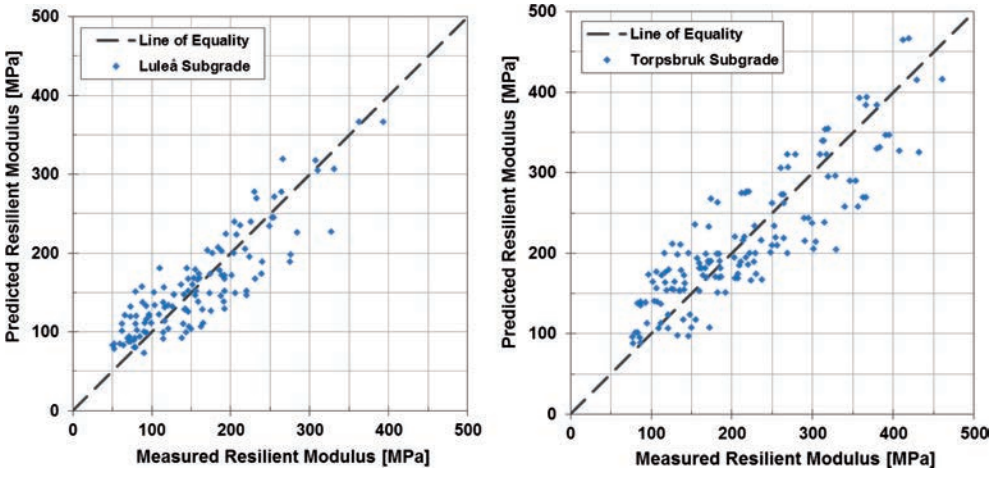

Figure 6. Actual versus predicted resilient modulus obtained from the Cary and Zapata model for Luleå subgrade (left) and Torpsbruk subgrade (right).

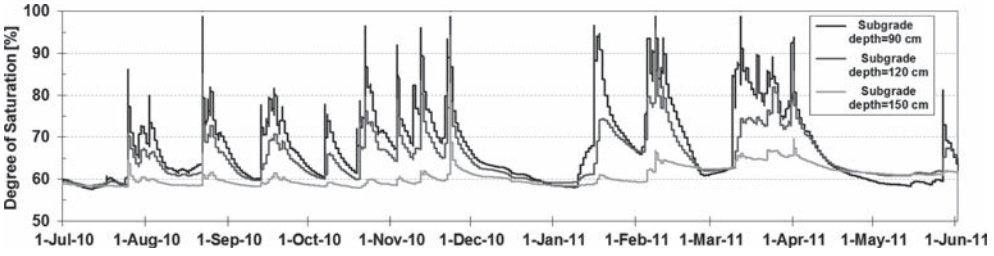

Figure 7. Degree of saturation variations in the subgrade soil of a road structure in torpsbruk (measurements from the unpaved shoulder of the pavement).

generally show high data scatters in experimental tests such as the resilient modulus. From the graphs plotted in Figure 6 and given the goodness of fit parameters presented in Table 3, it can be concluded that the proposed model that includes matric suction as a fundamental stress variable might be a realistic approach for taking into account effect of change in the environmental conditions.

8 FIELD MOISTURE VARIATION IMPACT ON RESILIENT MODULUS

In the recent years, considerable improvements have been made in techniques and instrumentations that can measure in-situ moisture content of pavement unbound layers. Often, considerable variation in the moisture content has been observed, mainly due to water infiltration after heavy rainfalls and spring thaw action in cold regions. This has called the attention of the researchers to further investigate moisture effects on the performance of the pavement structures.

Figure 7 shows variations in degree of saturation in the subgrade layer of the test road section in Torpsbruk (southern Sweden), over a one year period (July 2010 to June 2011). The Torpsbruk subgrade soil samples that were used in this study were taken from this road section. This figure is based on in-situ measurements from two moisture rods, each consisting of four moisture probes [14]. Figure 7 shows the considerable variation in the subgrade moisture content particularly in the upper section. The subgrade degree of saturation deviates from an equilibrium state of approximately 60% to more than 90% due to the autumn heavy rainfalls as well as the thawing action in the spring. From the Torpsbruk subgrade SWCC presented in Figure 2, this change in moisture content corresponds to matric suction variations from about 35 kPa to about 5 kPa. Concerning the impact on the resilient modulus of the subgrade, for a confinement stress of 27.6 kPa and a deviator stress of 13.8 kPa, increase in the degree of saturation from 60% to over 90% resulted in resilient modulus decrease from 205 MPa to 118 MPa. This corresponds to 42% reduction in the resilient modulus.

9 SUMMARY AND CONCLUSIONS

Proper accounting for the environmental effects on the resilient modulus of the unbound materials can result in more cost effective pavement design. Variation in the moisture content of unbound materials is known to be the major driving factor for seasonal changes in the resilient modulus.

Any change in the moisture content affects the soil matric suction that can be considered as an independent stress state variable in the resilient modulus prediction models of subgrade soil materials. Several resilient modulus tests were conducted on two silty sand subgrade soils and at four different degrees of saturation (matric suctions). The test data were then used to determine regression parameters of a model that take account of matric suction as a stress state variable. The prediction model showed a relatively good correlation with the

experimental data. Given the goodness of fit of the prediction model, it can be concluded that considering matric suction as a stress state variable that incorporates environmental effects into the resilient modulus predictive model might be a rational approach.

Reconstructing the field moisture variations of the Torpsbruk subgrade that was monitored over a one-year period revealed 42% reduction in the resilient modulus when the moisture content increased from the natural equilibrium state during heavy rainfalls and the spring thaw. This illustrates the importance of the environmental effects and the necessity for developing models that can properly account for the seasonal environmental variations.

It is believed that a more extensive database with more tests and materials is required to validate the approach and improve or calibrate the model presented in this study. The major concern for this methodology is that triaxial systems that are capable of measuring matric suction under cyclic loading are mainly limited to research institutes. The authors recommend more research works to be carried out to further develop the approach that is believed to be a step forward to a realistic pavement design.

ACKNOWLEDGEMENTS

This study was sponsored by the Swedish Transport Administration (Trafikverket) and the Fredrik Bachmans memorial foundation (Stiftelsen Fredrik Bachmans Minnesfond). The authors wish to thank Peter Goguen, laboratory manager, and Kenneth Witczak, laboratory coordinator, at Arizona State University, School of Sustainable Engineering and Built Environment for their technical support and assistance.

Influence of saturation and repeated loading on mechanical behavior of permeable asphalt pavement

Yusuke Kawaguchi, Shinichiro Nakashima & Norikazu Shimizu
Yamaguchi University, Tokiwadai, Ube, Japan

ABSTRACT: In this study, a cyclic plate load test was conducted for a pavement model in the laboratory to evaluate the mechanical behavior of permeable asphalt pavement with different degrees of saturation. A four-layer pavement model was prepared, and 49 kN was loaded repeatedly through a steel plate, 300 mm in diameter, at a frequency of 1.0 Hz. A total of 100,000 repetitions were applied alternating the saturation conditions of the model between drained (dry) and saturated (wet). The test results showed that the repeated loading under a saturated condition caused a remarkable increase in the elastic deformation of the pavement surface. The normal stress on the subgrade surface showed a decrease in the saturating process, and changed to an increase in the following loading process. Based on a series of elastic analyses for a simple three-layer model, softening of the subbase course and the subgrade occurred in the saturating process, followed by softening of the subbase course and the surface course in the repetition process.

Keywords: permeable asphalt pavement, saturation degree, mechanical behavior, repeated plate load test, elastic multi-layered analysis

1 INTRODUCTION

Permeable asphalt pavement is a special type of pavement that allows rainwater to pass through it, as shown in Figure 1, thereby reducing the runoff from a site. This type of pavement has been applied to areas with light traffic, such as parking lots and sidewalks, since the mid-1970s. However, recent changes in storm water regulations, established to counteract urban flooding in Japan [1], have prompted us to expand the application to areas with heavier traffic.

In the practical application of permeable asphalt pavement to roadways with heavy traffic, mechanical durability is of great concern. On the one hand, many researchers [e.g., 2–10] have

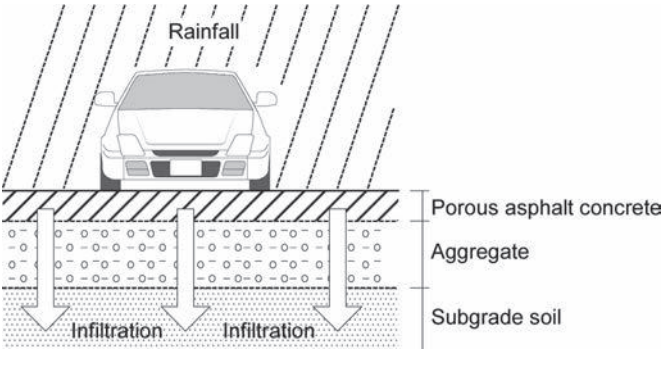

Figure 1. Typical structure of permeable asphalt pavement.

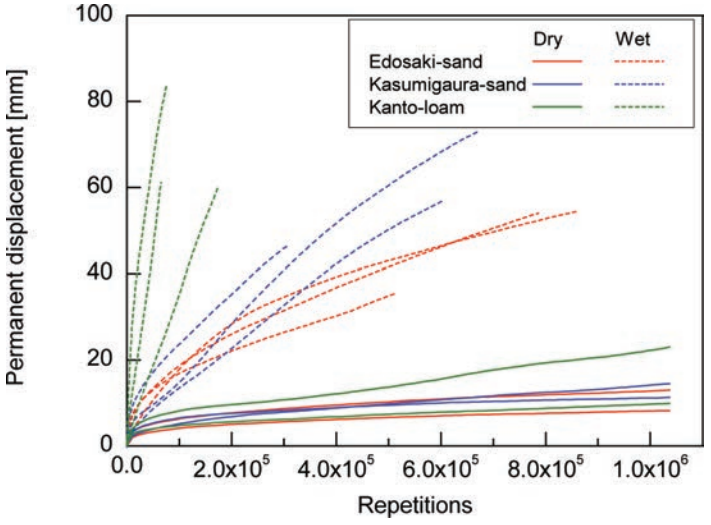

Figure 2. Permanent displacement of loading surface by repeated plate load test for permeable asphalt pavement models with different subgrade materials and different saturation conditions.

reported the negative effects of water saturation on the stiffness and the strength of unbound granular materials through material tests. Therefore, we can easily expect the premature failure of pavement structures, if the thickness of the permeable pavement is designed in the same way as conventional (impervious) asphalt pavement. On the other hand, the results of some field tests [11] that have been conducted on real roadways in service indicate no notable damage to the permeable pavement sections relative to the impervious pavement sections within a period of several years. Therefore, for the proper assessment of permeable asphalt pavement on roadways with heavy traffic, further tests and simulations are needed using reasonable layered models under properly controlled mechanical and hydrological boundary conditions.

The authors [12, 13] have developed indoor cyclic plate load testing equipment to evaluate the performance of permeable asphalt pavement sections with different subgrade materials and different saturation conditions. The results of the model tests have revealed that under a highly saturated condition, rutting (permanent deformation of pavement surface) grew over a few times or more rapidly than under a dry condition, as shown in Figure 2. Based on the test results, the authors of this paper conducted an additional model test to study the deterioration mechanism of permeable asphalt pavement. The degree of saturation was controlled in the middle of the load repetitions by raising and lowering the water level in the model. A series of elastic analyses was also carried out for a simple three-layer model. Based on the experimental and analytical results, we will discuss the influence of the saturation degree and the load repetitions on the mechanical behavior of permeable pavement.

2 OUTLINE OF MODEL TEST

An indoor cyclic plate load testing device was used in this study. Figure 3 shows the cross section of the pavement model. This model was a 1 m × 1 m cylinder, consisting of a 50-mm-thick surface course, a 50-mm-thick base course, a 200-mm-thick subbase course and a 600-mm-thick subgrade. The bottom layer (100 mm) was a filter layer (a mixture of crushed gravel and coarse sand) that allows water to flow smoothly into and out of the model.

A repeated load, namely, a 1.0 Hz sine-wave load ranging from 0.1 to 49 kN, which results in a loading pressure of 694 kPa, was applied through a steel rod on the load plate that sits on the model surface. The load plate was a steel plate, 50 mm in thickness and 300 mm in diameter.

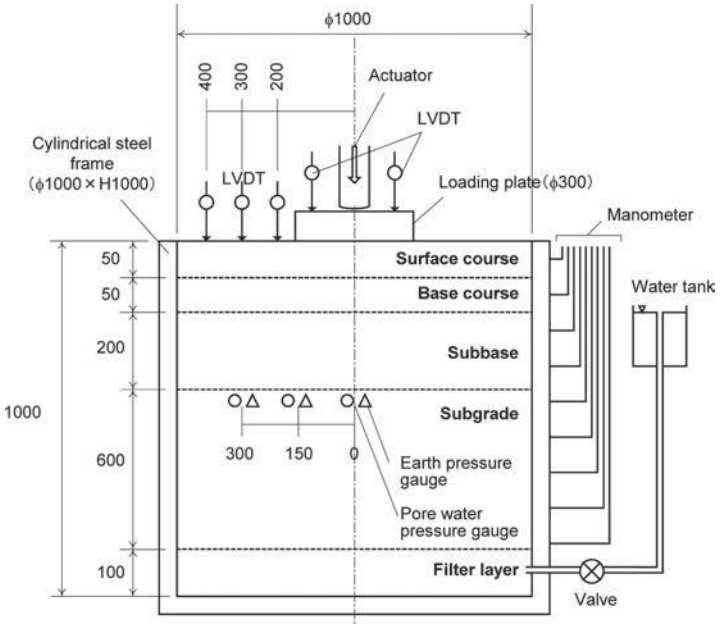

Figure 3. Cross section of permeable pavement model.

The pavement materials and their conditions are shown in Table 1. They were chosen based on the Japanese interim manual for permeable asphalt pavement design [14]. The subgrade soil was local Masa sand, a well-graded type of sand with gravel having a CBR-value of 27.1% in the laboratory.

The construction procedure for the model is shown in Figure 4. The compaction ratios (relative densities) of the subgrade and the subbase course were 90% and 95%, respectively, under their optimum moisture contents. After the completion of the subgrade preparation, pressure gauges and piezometers were installed within the subgrade (about one centimeter below the subgrade/subbase interface) at three locations, or along the centerline (X = 0 mm) and 150 and 300 mm away from the centerline. After the load plate was placed on the pavement surface, two LVDTs were set on the plate to monitor the vertical displacement; another three LVDTs were set on the pavement surface 200, 300 and 400 mm away from the centerline to monitor the surface deformation.

Figure 5 illustrates the test procedure. 20,000 repetitions under a drained (dry) condition and the same number under a saturated (wet) condition were alternated, and consequently, 100,000 repetitions were done in total. In the saturating process, we raised the water level of the model over two weeks, providing water from the model bottom, until the water level reached the base/subbase interface. In the draining process, we released the outflow valve and kept it open for over two weeks. No loading was conducted during the saturating/draining processes.

Before and after every 20,000 repetitions, a Static Plate Load (SPL) test was carried out, as indicated by "K" in Figure 5, using the same equipment as in the repeated plate load test. The aim of the SPL test in this study was to monitor the change in stiffness of the pavement model throughout the experiment. Relatively smaller loads (5, 10 and 20 kN) were applied in the SPL test to minimize the plastic deformation of the model, and the modulus of pavement reaction K_{30} was calculated using the following equation:

$$K_{30} = P/A\ s \tag{1}$$

where P = applied load (5, 10 and 20 kN), A = area of the loading plate (70,650 mm^2) and s = vertical displacement of the loading plate.

3 EXPERIMENTAL RESULTS

Figure 6 presents the entire histories of the measurements. Figures 6(a) and (b) show the permanent displacement and the resilient displacement, respectively, of the load plate and the pavement surface (outside of the load plate) obtained from the LVDT measurements. Here, the permanent displacement is defined as the residual component of the vertical displacement that remains after unloading, while the resilient displacement is defined as the displacement amplitude at each loading cycle. From Figure 6(a), the permanent displacement of the load plate shows a continuous increase. However, contrary to our previous experiments shown in Figure 2, we cannot find a remarkable difference in the increasing ratio between the dry and the wet cases. One reason is that the number of repetitions in this study was so small (less than one-tenth of the previous experiments) that plastic deformation was not generated visibly in the pavement model within this range of repetitions. Figure 6(c) shows the normal stress on the subgrade by the earth pressure gages. This figure shows that the pressure acting on the subgrade in this experiment was about half the amount of the loading pressure by the load plate (694 kPa). Figure 6(d) shows the excessive pore water pressure within the subgrade by the piezometers. We can see that pore water pressure was activated in the saturated cases, but that the amount is less than 0.2% of the loading pressure by the plate load and that it shows stability during the repetitions.

Figure 7 presents a comparison of the growth of the resilient displacement of the load plate and the normal stress on the subgrade within each set of 20,000 repetitions. The resilient displacement of the load plate in the wet cases increased more rapidly than that in the dry cases. Also, the normal stress on the subgrade showed a significant increase with the repetitions in the wet cases, while the stress remained constant (or showed a small decrease) in the dry cases. From these results, we find that repetitions under a wet condition increase the elastic deformation of the pavement model, which results in the increase in pressure acting on the subgrade surface.

Figure 8 shows the results of the SPL tests that were conducted before and after each set of 20,000 repetitions. From Figure 8(a), overall, the modulus of pavement reaction K_{30} gradually dropped with the progress of the test, which implies the deterioration of the stiffness of the

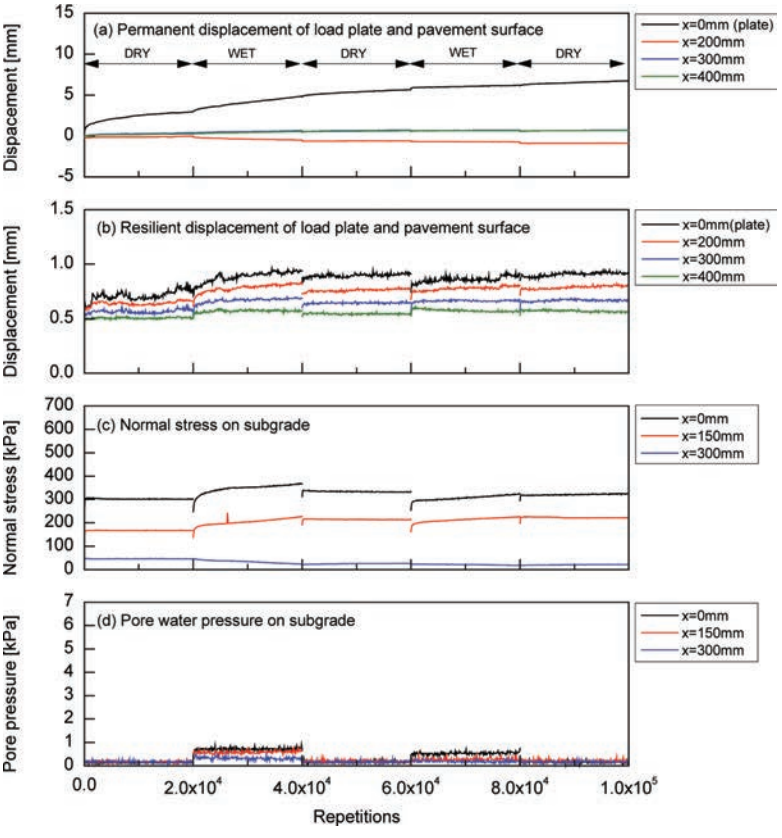

Figure 6. Histories of measurements by repeated plate load test.

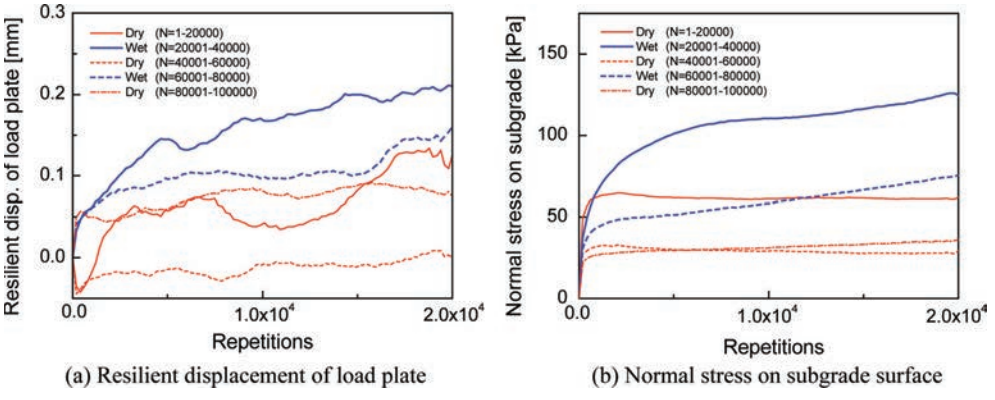

Figure 7. Change in resilient displacement of load plate and normal stress on subgrade within each 20000 repetitions.

pavement model. At the same time, we can clearly see that modulus K_{30} largely dropped after experiencing 20,000 repetitions under a wet condition, and it recovered after draining. On the other hand, K_{30} did not show any remarkable change after 20,000 repetitions under a dry condition or following the saturating process. Figure 8(b) shows the normal stress on the subgrade along the centerline when 20 kN was applied in the SPL tests. From this figure, we can see that

Type of external impact	Displacement of plate		Normal stress on subgrade
	Permanent displacement	Resilient displacement	
a) 20000 repetitions under DRY condition	Small increase	Small increase	Small increase
b) 20000 repetitions under WET condition	Small increase	Increase	Increase
c) Saturating (from dry to wet)	–	Small increase	Decrease
d) Draining (from wet to dry)	–	Decrease	Decrease

the normal stress on the subgrade largely increased after experiencing 20,000 repetitions under a wet condition, while the change was small under a dry condition. In addition, the normal stress on the subgrade showed a decrease after both saturating and draining processes.

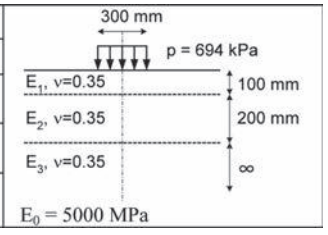
Table 2 summarizes the changes in the vertical displacement of the load plate and the normal stress on the subgrade at each stage of the experiment. The growth of the permanent displacement with repetitions seems reasonable, but the reasons for the changes in the resilient displacement and the normal stress on the subgrade are not clear. They might be associated with the change in the elastic behavior of the pavement. Therefore, we carried out a series of elastic analyses in the following section to evaluate which layer was softened (or hardened) by the loading and saturating/draining processes.

4 SIMULATION OF MODEL TEST USING ELASTIC-LAYERED THEORY

Based on the traditional layered elastic theory, a simple three-layer model was analyzed. As shown in the right column of Table 3, the model consists of a top layer, 100 mm in thickness,

Table 3. Simulation model and cases of elastic analysis.

	Case name					
	HHH	HSH	SSH	HHS	HSS	SSS
1st layer AC (E_1)	E_0	E_0	0.1 E_0	E_0	E_0	0.1 E_0
2nd layer Subbase (E_2)	E_0	0.1 E_0	0.1 E_0	E_0	0.1 E_0	0.1 E_0
3rd layer Subgrade (E_3)	E_0	E_0	E_0	0.1 E_0	0.1 E_0	0.1 E_0



which represents the asphalt concrete layers in the experiment, a second layer, 200 mm in thickness, which represents the subbase course, and a bottom layer, with a half-space, which represents the subgrade. A circular uniformly distributed load of 694 kPa, 300 mm in diameter, was loaded on the surface of the top layer. The aim of this analysis was to understand the pavement response (resilient displacement of the pavement surface and normal stress on the subgrade) associated with the elastic moduli of the layers. Therefore, to simplify the problem, only two kinds of elastic moduli were used, E_0 = 5000 MPa (relatively hard) and 0.1 E_0 (relatively soft). Poisson's ratio was 0.35 for all the layers. Table 3 shows the calculation cases. Regarding the model with all layers E_0 (HHH) as the basic model, the elastic moduli of part or all of the layers were replaced with the soft value (0.1 E_0). For example, model HHS has a hard modulus (E_0) in the top and second layers and a soft modulus (0.1 E_0) in the third layer.

Figure 9 presents the analytical results of the vertical displacements of the top surface. The displacements were normalized by the value of the basic model (HHH) at the load center (X = 0 mm). The red plots indicate the models with "soft" subgrade, while the black plots indicate the models with "hard" subgrade. The figure shows that the displacement of model HHH is smaller than that of any other models. This means that the surface displacement always increases if the elastic modulus of any layer is reduced. The figure also shows that the red and the black plots exist separately forming each group at X = 500 mm or farther. This means that the elastic modulus of the subgrade determines the spread of the surface deformation. Moreover, from a comparison of the results of the three models, HHS, HSH and SHH, if the elastic modulus of just one layer is reduced, the softening of the upper layer brings about a larger displacement at the load center (X = 0 mm).

Figure 10 shows the normal stresses on the subgrade. The plots for model HHH exist just behind those for model SSS, because their stress levels are completely consistent with each other. Regarding the normal stress of the subgrade surface along the load center (X = 0 mm), all the red plots are lower than the black plots. This means that if the elastic modulus of the subgrade is reduced, the normal stress of the subgrade surface always decreases. At the same time, the figure shows that the normal stress of the subgrade surface shows an increase in the cases where the elastic modulus of the AC or the subbase course is reduced. From the analytical results, we find that a reduction in stress of the subgrade surface indicates the softening of the subgrade material, while an increase in stress indicates the softening of the upper layers (AC and/or subbase course).

Based on the above analytical results, we try to explain the experimental phenomena shown in Table 4. Here, we select the results of the elastic behavior, or the resilient displacement of the load plate and the normal stress on the subgrade. Firstly, in the process of repeated loading under a dry condition, the elastic moduli are thought to change little at all layers, because the resilient displacement of the pavement surface and the normal stress of the subgrade surface were almost the same during the process. Next, in the process of repeated loading under a wet condition, both the pavement surface displacement and the subgrade surface stress rose in the experiment. This corresponds to the analytical results of model HSH or SSH or to a reduction in the elastic modulus occurring only at the subbase or at both the subbase and the AC layers, while maintaining the subgrade elastic modulus. Through the saturating process of the experiment, the resilient displacement increased a

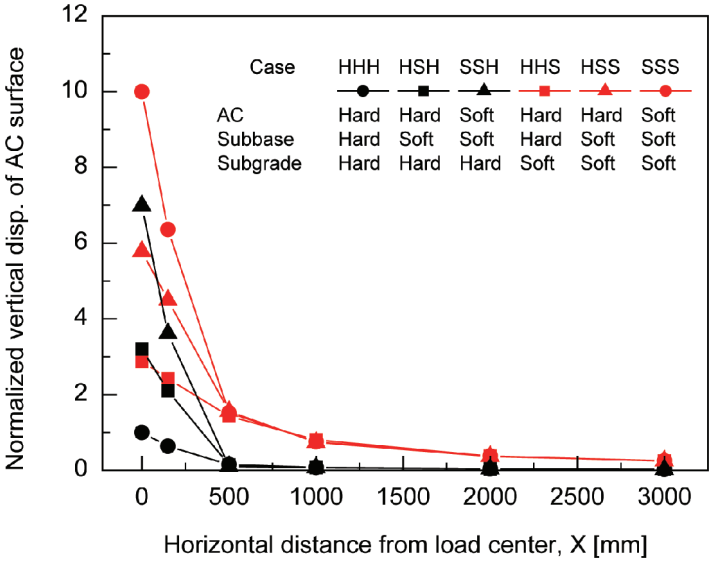


Figure 9. Vertical displacement of model surface by elastic analysis.

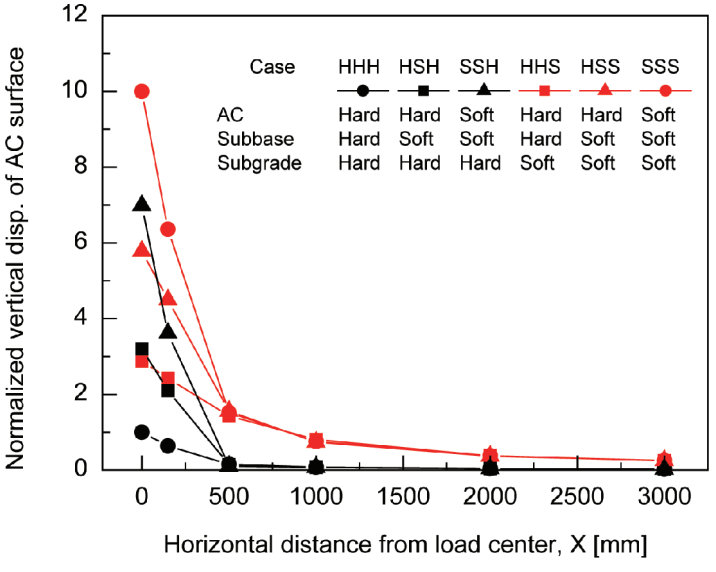

Figure 10. Normal stress on subgrade surface by elastic analysis.

little and the subgrade stress decreased. This corresponds to model HSS or HHS or to the elastic modulus of only the subgrade or both the subgrade and the subbase decreased. Finally, draining was the only process during which the resilient displacement showed a decrease. Based on the analytical results, this indicates that an increase in the elastic modulus occurred at a layer during the draining process. On the other hand, the subgrade stress decreased in the draining process of the experiment. Considering the analytical fact that hardening of subgrade caused an increase in subgrade stress, it can be said that the increase in elastic modulus occurred not at the subgrade, but at the upper layer or at the subbase and/or the AC layer.

Table 4. Possible reasons for experimental results.

Type of external impact	Experimental results (table 2)		Possible reason for experimental result estimated from elastic analysis
	Resilient displacement of pavement surface	Pressure on subgrade surface	
a) 20,000 repetitions under DRY condition	Small increase	Small increase	Small decrease in stiffness of ACor subbase
b) 20,000 repetitions under WET condition	Increase	Increase	Decrease in stiffness of AC or subbase
c) Saturating (from dry to wet)	Small increase	Decrease	Decrease in stiffness of subbase and subgrade
d) Draining (from wet to dry)	Decrease	Decrease	Increase in stiffness of AC or subbase

5 CONCLUSIONS

In this study, a cyclic plate load test has been conducted for a permeable pavement model in the laboratory to grasp the deformational characteristics of permeable pavements under saturated and unsaturated conditions. A series of elastic analyses was also carried out for a simple three-layered model to evaluate the model test results.

From the results of the model tests, in the cases of the saturated pavement model, the resilient displacement of the pavement surface and the normal stress on the subgrade surface grew progressively larger with the load repetitions, while they were almost stable in the unsaturated cases. Based on the elastic analyses, this means that the load repetitions under saturated conditions caused the softening (elastic modulus reduction) of the subbase course or the AC layer, while the subgrade remained relatively stable.

The results of the static plate load tests showed that the saturation of the model brought about a significant drop in the normal stress on the subgrade surface against a static load, with a constant modulus of pavement reaction K_{30}. The analytical results explained this drop as a reduction in elastic modulus occurring at the subgrade or at both the subgrade and the subbase course. On the other hand, the draining water from the model resulted in an increase in the modulus of pavement reaction K_{30} and a decrease in the normal stress on the subgrade surface against a static load. The analytical results explain this as an elastic modulus recovered in the draining process.

From the above results, it is evident that the subbase course is a key layer of permeable pavement because its mechanical properties change remarkably due to the water flow into and out of the pavement and the load repetitions.

Utilization of municipal solid waste Incinerator Bottom Ash Aggregate in asphalt mixture

Dong Liu, Lihan Li & Huajie Cui
Key Laboratory of Road and Traffic Engineering of Ministry of Education, Tongji University, Shanghai, P.R. China

ABSTRACT: The objective of this paper is to analyze the physical and chemical properties of natural weathered municipal solid waste Incinerator Bottom Ash Aggregate (IBAA) within 6 months, and in the following the physical properties of asphalt mixture containing different amounts of IBAA as aggregate substitution. The Marshall mix design method was carried out to determine the design asphalt content. Dynamic creep test, moisture susceptibility test, and low-temperature bending test were performed to evaluate the engineering properties of mixture. Results showed that the weathering treatment increased the apparent density and decreased the pH, water absorption and crushing value of IBAA. The most obvious changes occurred in the first 3 months. Results showed that IBAA improved the resistance of permanent deformation, water resistance and anti-crack performance of asphalt mixture containing IBAA no more than 30%. It is recommended that IBAA be subjected to weathering treatment for at least 3 months before being used, and the amount of IBAA be limited to 30%, by total weight of the aggregate to ensure satisfactory pavement performance.

Keywords: Incinerator Bottom Ash Aggregate (IBAA), asphalt mixture, weathering treatment, properties, mixing amount

1 INTRODUCTION

Incinerator Bottom Ash Aggregate (IBAA) is the most common by-product after incinerating municipal solid waste in combustor facilities. It is estimated annual production of IBAA is 2 million tons in Shanghai, China. Although landfill may cause ground-water contamination due to inadequate monitoring system, it is the most common treatment measure in Shanghai at present. However, there is not enough space for landfill. Besides, the mining of aggregate is becoming an ecological problem as the demand for aggregate is increasing rapidly due to rapid infrastructure activities in Shanghai. IBAA has a potential for utilization in road construction [1,2]. Such utilization would decrease the amount of IBAA for landfill and the natural aggregate used, which avoids the damage to the environment.

The major chemical components of IBAA are silica (SiO_2), alumina (Al_2O_3), ferric oxide (Fe_2O_3), and lime (CaO). According to the previous researches [3,4], freshly quenched IBAA has a high reactivity, mainly because of high contents of amorphous and highly reactive silica and lime. During the natural weathering process, some of the chemical and mineralogical characteristics undergo significant changes including oxidation, dissolution and precipitation, carbonation, and the neoformation of clay-like minerals. As a consequence, the properties of IBAA may change. However, there are few studies about the properties of IBAA undergoing natural weathering treatment. Researches have proven that a one-to-three month exposure to natural weathering decreases dramatically the release of heavy metals from IBAA [3,4]. Natural weathering is the most cost-effective treatment method [5].

Regarding the utilization of IBAA in asphalt mixture, a number of trails have been conducted. In these studies, different amounts of IBAA were used as an aggregate substitute.

Chen [6] evaluated the engineering properties of asphalt mixture containing IBAA up to 40%. It is recommended that the mixing amount of IBAA be limited to 20% in base course and 10% in surface mix to ensure satisfactory pavement performance. Garrick [7] used up to 32% IBAA. Walter [8] recommended using IBAA up to 40–55% with an asphalt content of 5.5–6.5%. Based on previous research works, it can be concluded that IBAA is potential material which can be utilized in asphalt mixture. However, there is no consistent conclusion about the amount of IBAA could be used and the pavement performance of IBAA-mix. More researches should be done to understand the properties of IBAA and its mixture.

The main focus of the present investigation was directed towards the weathering treatment of IBAA and properties of asphalt mixture containing IBAA. The aim of this paper is to evaluate the properties of weathered IBAA and asphalt mixture containing 0, 10, 20, 30 and 40% IBAA by aggregate weight in terms of:

1. pH value, crushing value, apparent specific gravity and water absorption of IBAA with different weathering time;
2. Marshall properties, permanent deformation, moisture susceptibility and anti-crack performance of asphalt mixture containing IBAA.

2 MATERIALS AND METHODS

2.1 *Materials*

2.1.1 *IBAA*

IBAA used in this study were derived from a single incinerator in Shanghai. It was stored and weathered outdoor. During the weathering process, the IBAA was turned over several times a week with a shovel to ensure homogenization of the moisture content and to improve the air contact. The sieve sizes of IBAA were shown in Figure 1. To understand the effect of weathering treatment on IBAA, basic properties of IBAA were tested at different time. Specific gravity test (JTG E42, T0328-2005), water absorption ration (JTG E42, T 0330-2005) and crushing value test (JTG E42, T0350-2005) were carried out according to China standard. The pH was determined for the suspension after 24 h equilibration period with liquid-to-solid ration of 5.

2.1.2 *Aggregate and mineral filler*

The basalt aggregates and mineral filler were chosen from local engineering. Four different sizes of basalt aggregate were used, and they were 0–4.75 mm, 4.75–9.5 mm, 9.5–13.2 mm and 13.2–19 mm, respectively. The sieve sizes of basalt aggregate and mineral filler were shown in Figure 1. Table 1 gives the basic physical properties of basalt aggregates and mineral filler.

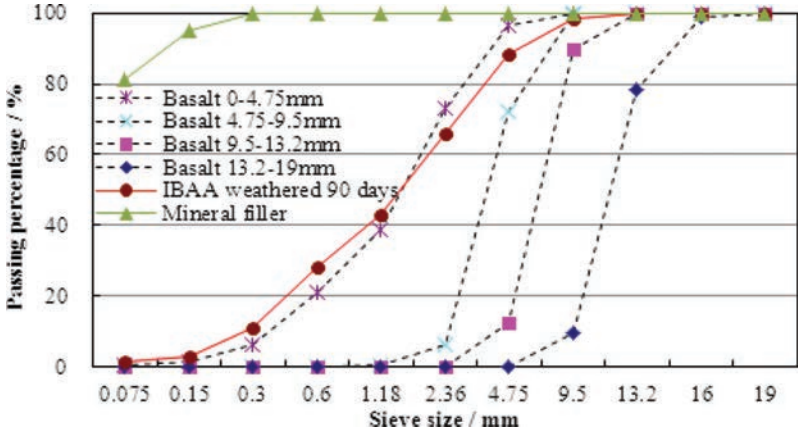

Figure 1. Gradation curves of basalt aggregate, mineral filler and IBAA.

Table 1. Basic properties of basalt aggregate and mineral filler.

Properties	Basalt aggregate/mm				Mineral filler
	0–4.75	4.75–9.5	9.5–13.2	13.2–19	
Apparent specific gravity (g/cm^{-3})	2.911	2.776	2.776	2.823	2.720
Absorption (%)	–	2.65	2.52	1.93	–
Crushing value (%)	–	21	22	22	–

Table 2. Basic properties of AH-70.

Properties	Measured values	Requirements
Penetration at 25°C (0.1 mm)	75.2	60~80
Ductility, 5 cm/min, 15°C (cm)	>100	≥100
Softening point (°C)	48.2	44~54

Table 3. Basalt aggregate and IBAA blending percentages.

IBAA blending percentages (%)	Percentage in the aggregate blend (%)				
	Basalt aggregate				Mineral filler
	13.2–19 mm	9.5–13.2 mm	4.75–9.5 mm	0–4.75 mm	
0 (Control)	37	13	6	35	9
10	37	12	7	25	9
20	37	10	8	17	8
30	37	9	9	7	8
40	37	8	8	0	7

All properties of basalt aggregates and mineral filler satisfied the requirement of Chinese norm JTG F40-2004.

2.1.3 *Asphalt binder*

Base asphalt (AH-70) was used to prepare asphalt mixture. All the testing results of AH-70 were shown in Table 2 and within specification (Chinese norm JTJ052-2000) limits.

2.1.4 *Mixture design*

IBAA was used as a substitute for natural aggregate in asphalt mixture. Basalt aggregates and IBAA were blended to meet the China specification. AC-16 asphalt mixture was used in this study. The contents of IBAA used were 0, 10, 20, 30, and 40% by mass of the total mix, whereas the 0% IBAA-mix was used as the control group. This resulted in the blending percentages shown in Table 3 and the gradation curves of mixture shown in Figure 2. Mix design was carried out according to the Marshall mix design method (ASTM D 1559) at different IBAA substitution ratios. Air voids, Voids in the Mineral Aggregate (VMA), Voids Filled with Asphalt (VFA), Marshall stability and flow value of marshal specimens were used to decide the optimal asphalt content of asphalt mixture. The optimum asphalt content was determined considering 4% of air voids.

2.2 *Pavement performance test*

2.2.1 *Dynamic creep test*

Dynamic creep tests were conducted to characterize the deforming resistance of asphalt mixture. The specimens of 100 mm in diameter and 100 mm in height were prepared and

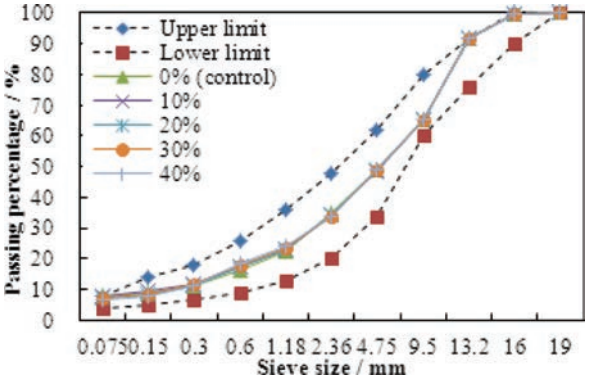

Figure 2. Aggregate blend gradation curves for different IBAA content.

then tested at 60°C. The tests were carried out using MTS 810 to apply axial stress to specimens.

The conditions under which the unconfined dynamic uniaxial creep test is performed are: (a) preloading for 10 min at 0.01 MPa, as a conditioning stress; (b) haversine wave stress pulse for 7200 s with frequency of 1 Hz (by allocating 100 ms for pulse width and 900 ms for rest period); (c) maximum axial stress was 100 kPa. During the test, the accumulated strain of specimens was calculated by Eq.(1). The growth rate of creep strain of asphalt mixture also shows the resistance of asphalt mixture to permanent deformation, which was calculated by Eq.(2).

$$\varepsilon = h/H_0 \quad (1)$$

$$s = \Delta\varepsilon/\Delta n \quad (2)$$

where ε is the accumulated strain of specimen during the test time, 1 mm/mm; h is the axial deformation, mm; and H_0 is the initial specimen height, mm; s is the growth rate of creep strain during the test time, ε/time; Δε is the accumulated strain between 3600 loading cycles to 7200, 1 mm/mm; and Δn is the loading cycles, time.

2.2.2 *Moisture susceptibility test*

Tensile Strength Ration (TSR, water freeze at –18°C for 16 h and thaw at 60°C for 24 h as a cycle) of Marshall specimens were tested at the loading rate of 50 mm/min according to JTG E20-2011 of China.

2.2.3 *Low-temperature bending test*

In order to investigate the low-temperature flexibility of asphalt mixture, the three-point bending beam test was conducted. According to JTG E20-2011 of China, specimens of 250 mm × 30 mm × 35 mm were prepared. And the tests were carried out using MTS 810 to apply stress to specimens with span length of 200 mm at the loading rate of 50 mm/min at –10°C. Failure strain of asphalt mixture was calculated based on the bending deflection of beams.

3 RESULTS AND DISCUSSION

3.1 *IBAA properties*

The pH values of IBAA as a function of weathering time were given in Figure 3. As can be observed, the pH value decreased rapidly with weathering time up to about 90 days, and then levelled off. The freshly quenched IBAA had a high pH of 12.4, which was controlled by the formation and solubility of portlandite according to the previous studies [3,4]. Atmospheric CO_2 was absorbed by the alkaline IBAA in the following time. After weathering time of 90 d, the pH value of IBAA maintained at about 8.4.

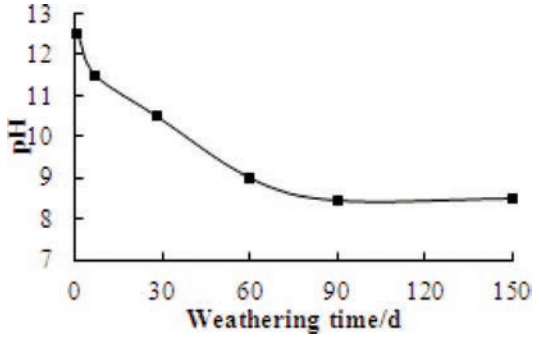

Figure 3. pH of IBAA with weathering time.

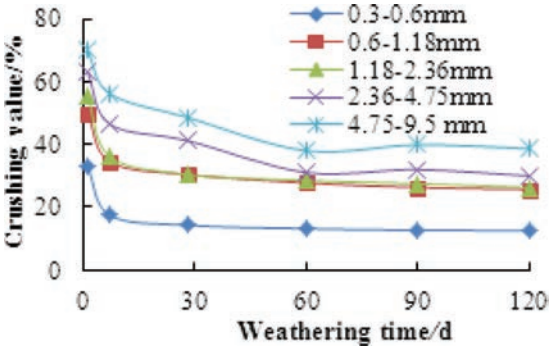

Figure 4. Crushing value of IBAA.

Table 4. Specific gravity and water absorption of IBAA.

	Apparent specific gravity (g/cm^{-3})		Water absorption (%)	
	Weathering time (d)		Weathering time (d)	
IBAA	1	90	7	180
0–2.36 mm	2.280	2.433	–	–
2.36–4.75 mm	2.404	2.410	8.5	8.2
4.75–9.5 mm	2.403	2.577	9.4	8.7

Crushing value reflects the crushing strength of aggregate. Figure 4 shows the variation of crushing value of IBAA with different particle sizes during weathering. As can be observed, the natural weathering treatment decreased the crushing value of IBAA. The formation of neoformed phases including calcite, gypsum, and ettringite improved the mechanical properties of IBAA. Figure 4 also shows that the IBAA with smaller particle size had a lower crushing value, which means its ability of resisting crushing was better. Crushing value of IBAA larger than 4.75 mm is over 30%. Because of low strength of coarse IBAA, the asphalt mixture containing coarse IBAA is expected to show low strength. This is why particle size of IBAA larger than 9.5 mm was not chosen to be used in the asphalt mixture in this study.

Table 4 shows the specific gravity and water absorption of IBAA. It illustrates that IBAA had higher water absorption and lower apparent specific gravity contrast to natural aggregate (Table 1). Meanwhile, with the weathering time, the neoformed phases filled the porous structure of IBAA, and this resulted in the decrease of absorption and the increase of specific

gravity. The higher water absorption of IBAA will lead to the higher design asphalt content of asphalt mixture, which will increase the cost of asphalt mixture. Therefore, it is recommended that IBAA be subjected to weathering treatment for at least 3 months before being used in asphalt mixture.

3.2 *Volumetric properties of mixture*

The Optimal Asphalt Content (OAC) and Marshall properties of prepared asphalt mixture are presented in Table 5. IBAA increased the OAC due to the higher absorptivity relative to natural basalt aggregate. The OAC increased linearly with about 0.67% increase for every 10% IBAA replacement. The addition of IBAA caused increase in VMA and VFA. The Marshall stability of mixture with IBAA was higher than control mixture. The Marshall stability increased with the increase of mixing amount of IBAA no more than 20%. While IBAA was more than 20%, the Marshall stability decreased. The flow value remained within the range of 2.3–4.0 mm for the different mixes. All Marshall properties satisfied the China specification except the VFA of IBAA-mix.

3.3 *Pavement performance*

3.3.1 *Dynamic creep test*

The results of dynamic creep test at 60°C are shown in Figure 5 and Table 6. As seen in Figure 5, the accumulative creep strain of asphalt mixture increased with load cycles. 10% IBAA-mix had the lowest accumulative creep strain. Meanwhile, the growth rate of creep strain of 10% IBAA-mix was lowest, which means that the accumulative creep strain of 10% IBAA-mix grew slowest and it had the strongest resistance to permanent deformation. 40% IBAA-mix both had the highest accumulative strain and growth rate of creep strain.

Table 5. Marshall properties of mix.

Parameters	IBAA content (%)					China specification
	0	10	20	30	40	
Optimal asphalt content (%)	4.0	4.8	5.7	6.3	6.6	–
Air voids (%)	4.1	4.0	4.0	3.9	4.0	3.5~5
VMA (%)	15.7	16.4	18.4	20.5	25.0	≥13.5
VFA (%)	70.5	75.0	77.8	82.8	86.2	65~75
Marshall stability (kN)	8.7	10.2	11.1	10.4	10.2	≥8
Flow value (mm)	3.6	2.4	4.0	2.3	3.3	1.5~4

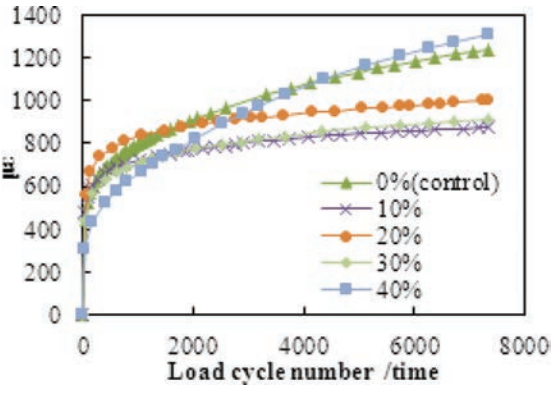

Figure 5. Accumulated strain versus load cycle number.

Table 6. Dynamic creep test results.

	Mixtures with different IBAA contents (%)				
Index	0	10	20	30	40
ε/(10^{-6})	1227	878	999	913	1305
s/(με/time)	3.35	1.05	1.11	1.32	4.57

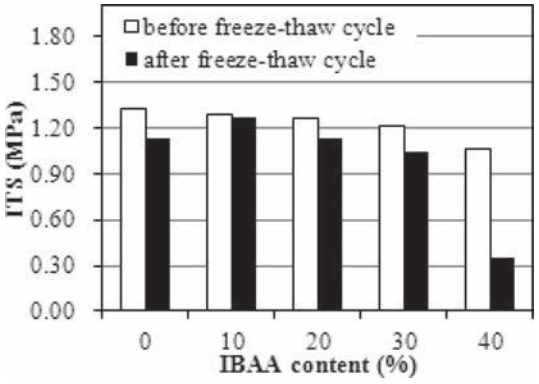

Figure 6. ITS of asphalt mixture.

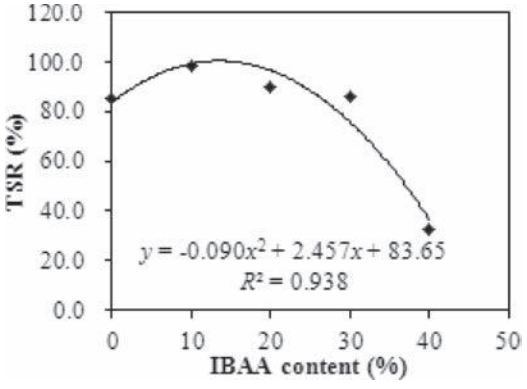

Figure 7. TSR versus IBAA content.

This proved that the asphalt mixture containing IBAA had stronger resistance of permanent deformation at high-temperature than control asphalt mixture except 40% IBAA-mix.

3.3.2 *Moisture susceptibility test*

Indirect Tensile Strength (ITS) test results before and after freeze-thaw cycle are given in Figure 6. As shown in Figure 6, the ITS values of asphalt mixture before freeze-thaw cycle decreased with the increase of IBAA percentages. Meanwhile, the ITS values after freeze-thaw cycle increased from 0% to 10% IBAA replacement. At higher IBAA substitutions, similar to the asphalt mixture before freeze-thaw, a gradual decrease was noticed. Figure 7 illustrates the TSR value of asphalt mixture. It shows that the TSR of 10% IBAA-mix was higher than the control mixture. 20% IBAA-mix was approximately the same with the control mixture. At higher IBAA replacements, the TSR value declined significantly. The TSR value of 40% IBAA-mix was only 32.9%, which could not satisfy the Chinese specification.

Table 7. Failure strain of asphalt mixture.

Mixtures with different IBAA contents (%)	0	10	20	30	40
Failure strain/(10^{-6})	2523	2691	2944	3196	3288

3.3.3 *Low-temperature bending test*

Results of bending test at −10°C are shown in Table 7. Failure strains of asphalt mixture increased with the increase of IBAA percentages. This means the asphalt mixture containing more IBAA showed better anti-crack properties at low temperature. However, this doesn't mean more IBAA should be used in asphalt mixture to improve its resistance to crack. The more IBAA used in mixture, the more asphalt will be used. It is easy to understand that the more asphalt provide better flexibility of mixture at low temperature. Considering the more asphalt will cost much more, it is not economical to improve mixing amount of IBAA just for enhancing anti-cracking property of asphalt mixture.

4 CONCLUSIONS

On the basis of the results of this study, the following conclusions are made:

1. The natural weathering treatment of IBAA deceased the chemical activity (pH value), and improved the physical properties including the decrease of water absorption and increase of crushing strength. Natural weathering time of 90d was necessary for IBAA being used in asphalt mixture.
2. Optimal asphalt content of mixture increased with the increase of IBAA used. The IBAA resulted in the higher VMA, VFA, Marshall stability, and lower flow value than natural aggregate.
3. Asphalt mixture containing IBAA had stronger resistance of permanent deformation at high-temperature than control asphalt mixture except 40% IBAA-mix.
4. Mixtures containing IBAA no more than 30% met the requirement of moisture susceptibility. Mixture containing 40% IBAA had poor moisture susceptibility.
5. Asphalt mixture containing more IBAA showed better anti-crack properties at low temperature due to more asphalt used.

On the basis of the performance analysis in this study, it is recommended that the mixing amount of IBAA is no more than 30% in asphalt mixture.

An investigation into the effects of accelerated curing on Cold Recycled Bituminous Mixes

Chibuzor Ojum, Kranthi Kuna, Nick H. Thom & Gordon Airey
Nottingham Transportation Engineering Centre (NTEC), The University of Nottingham, Nottingham, UK

ABSTRACT: Compared to Hot Mix Asphalts (HMA), the behaviour of Cold Recycled Bituminous Mixes (CRBM) is more complex due to the presence of water in the mix. CRBMs develop strength and stiffness with time and this relates to the rate at which curing occurs in the mix. Various accelerated laboratory curing and conditioning regimes exist for CRBM and are used in a variety of ways by researchers although the underlying question remains: how realistic are these curing and conditioning regimes in simulating pavement conditions as experienced in the field? The ideal curing regime for these mixture types would be to simulate conditions similar to those experienced in the field. Most accelerated curing regimes fail to reproduce the actual condition of the mix that is expected in the pavement and tests are therefore conducted at superior conditions. This results in overestimating the mix performance in the field. This is especially true when the fundamental properties of the CRBM are compared with other mixes such as HMA and Warm Mix Asphalt (WMA). Hence, there is a need to develop a curing regime that simulates as realistically as possible actual pavement conditions. This paper investigates the need for accelerated curing and the degree of acceleration that is realistic by studying different curing regimes and their effect on mechanical and performance behaviour of CRBMs. The experimental design is carefully selected in such a way that the curing conditions include regimes that are followed by different highway agencies and also conditions that are expected to simulate different climatic zones. The investigation includes both bitumen emulsion and foamed bitumen treated mixes with and without cement.

Keywords: Bitumen emulsion, foamed bitumen, cold recycled bituminous mixes, accelerated curing, performance testing, field performance

1 INTRODUCTION

There are significant benefits of incorporating Reclaimed Asphalt Pavements (RAP) in the production of bituminous mixtures and these benefits include considerable savings in cost, energy and environmental gains that arise as a result of the reduction in the disposal of waste materials from rehabilitation and maintenance of road structures. The mechanical and performance properties of CRBM are intimately related to the curing condition [1]. The strength development of CRBM is very important as it is dependent on the rate at which curing occurs. This plays a major role in relation to traffic opening time and the long term performance of the road [2]. The absence of well-established and defined specifications for CRBM that realistically simulate pavement conditions as experienced in the field has resulted in varied curing regimes being used that can potentially overestimate the performance of the asphalt pavement. Therefore knowledge of the most appropriate curing regime is crucial. The research presented in this paper highlights the need for accelerated curing and the effect on degree of acceleration by examining different curing regimes and how they affect the mechanical and performance properties of the CRBM by direct comparison of mixtures produced using bitumen emulsion and foamed bitumen with and without cement.

2 MATERIALS

The materials used are typical of those used in recycling of asphalt pavements for road applications. The RAP was sourced from a contractor engaged in CRBM production. The RAP was characterised prior to mix design and the gradation ascertained in accordance with BS EN 933-2:2012. A composition analysis was conducted and the binder in the RAP was separated using a fractionating column in accordance with BS 598-102:2003. The residual binder content of the RAP was obtained as 5.5%. The gradation of the RAP including that of the extracted RAP aggregate is shown in Figure 1. The virgin aggregate used comprised limestone supplied in nominal sizes as follows: 20 mm, 14 mm, 10 mm, 6 mm, dust (0.075 mm–4 mm) and filler.

Further to this, to ascertain if the bitumen in the RAP could be classified as "active" or "inactive", an indicative test was conducted currently under investigation by the International Union of Laboratories and Experts in Construction Materials, Systems and Structures (RILEM). This involved conditioning a sample of RAP for 4 hours at 70°C followed by the manufacture of three 100 mm diameter by 63.5 mm high specimens using Marshall Compaction with 50 blows per face. After compaction, Indirect Tensile Strength (ITS) tests in accordance with BS EN 12697-23 were carried out at 20°C and then in wet conditions, soaked at 20°C for 24 hours. If the soaked ITS ≤ 100 kPa or the specimens do not hold together at 70°C, the RAP is considered to be inactive. For comparison, the test was also conducted with RAP conditioned at 140°C. In all cases, the values exceeded 100 kPa indicating that the binder in the RAP used in the study can be classified as active. The results are presented in Figure 2.

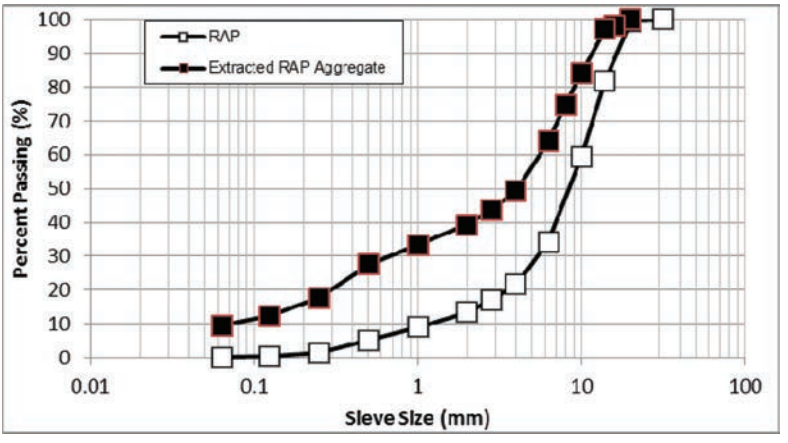

Figure 1. Aggregate gradations of RAP and residual RAP after binder extraction.

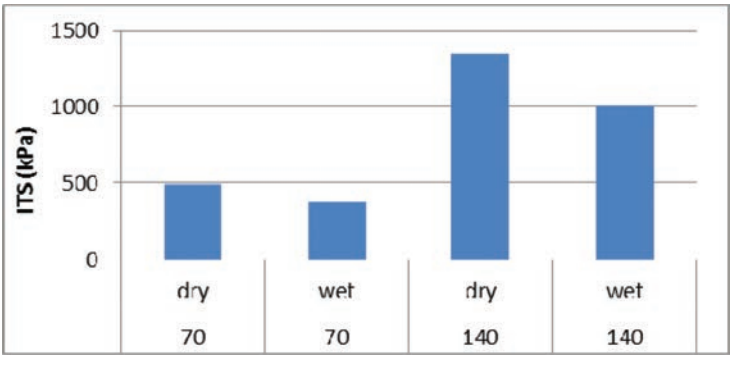

Figure 2. Test to ascertain state of binder in RAP.

Table 1. Bitumen emulsion formulation and properties.

Property	Value
Particle surface electric charge	Positive
Binder level (%)	60
Water level (%)	40
Softening point (°C)	52
Penetration (dmm)	47
Density (g/cm³)	1.016

The bitumen emulsion used is a cationic bitumen emulsion containing 60% bitumen and 40% water. The formulation and properties of the bitumen emulsion are shown in Table 1. The penetration grade for the foamed bitumen as supplied was obtained as 70/100 with specific gravity of 1.03 and softening point of 45°C. The cement used conformed to CEM II/A-L 32.5 R in line with BS EN 197-1.

3 EXPERIMENTAL PLAN

3.1 *Introduction*

It is a well-established fact that curing has a significant effect on the mechanical and performance properties of CRBM [3]. This research aimed to provide a valid investigation into the behavior of CRBM taking into account (1) the effect of temperature, curing conditioning and curing duration (2) the influence of cement with different curing regimes and (3) the difference in terms of the mechanical and performance properties of CRBM between bitumen emulsion and foamed bitumen. Table 2 states the plan for the experimental study.

3.2 *Mix design procedure*

The composition of aggregates used in the research study comprised 50% RAP and 50% virgin aggregates. The limits and gradation used are as depicted in Figure 3. The aggregate gradation limits are based on Table 9/12 Zone C of the UK Manual of Contract Documents for Highway Works Volume 1 Series 900 Clause 948 [4]. To further optimise the aggregate gradation, a fuller curve was targeted in order to obtain the gradation that gives the maximum density and ensures smaller particles are adequately packed together with larger particles thereby reducing voids and creating better particle to particle contact, stability and better water resistance for the produced mixtures.

Tables 3 and 4 state design parameters used as obtained from mix design studies conducted on both mixture types. It should be noted that the residual binder content for the bitumen emulsion mixtures is 3.25%. In both cases, the mix proportions are typical of those used in reality.

3.3 *Specimen preparation*

100 mm diameter CRBM specimens were produced using bitumen emulsion and foamed bitumen. Mixing for the bitumen emulsion mixtures was done using a Sun & Planet mixer while the foamed bitumen mixtures were produced in a dual shaft pug mill mixer using a Wirtgen WLB 10 S foam rig. The specimens were compacted using a Coopers Gyratory Compactor in accordance with BS EN 12697-31, at a constant pressure of 600 kPa, a speed of 30 rpm, an angle of gyration of 1.25° and 110 gyrations for all cores prepared. The selection of 110 gyrations was made following comparisons with specimens made using modified Proctor compaction. After compaction, the specimens were left in the mould for 24 hours

4 TESTING METHOD AND RESULTS

4.1 *Stiffness modulus and ITS test results*

4.1.1 *Introduction*

In this study, the stiffness modulus was determined using a servo-pneumatic testing machine (NU-14) by applying indirect tension to the cylindrical specimens. A rise time of 124 ms and a target horizontal deformation of 5 μm were used. Ten conditioning pulses were applied to the specimens followed by five test pulses. The measurements were repeated along two diameters and the average stiffness values calculated. The test was conducted at 20°C according to BS EN 12697-26 specifications. Three specimens were tested in each condition.

The ITS test involved applying compressive loads to the samples between two loading strips which creates tensile stresses along the vertical diametric plane causing a splitting failure [5]. The test was conducted at 20°C using the INSTRON test equipment located at the Nottingham Transportation and Engineering Centre (NTEC) in accordance with BS EN 12697-23. In each case, the same three specimens used for ITSM testing were also tested for ITS.

4.1.2 *Effect of curing conditioning*

Figures 5–7 present stiffness modulus results as obtained for CRBM produced using bitumen emulsion and foamed bitumen conditioned for 28 days at three different temperatures with and without the inclusion of 1% OPC. The results as seen in Figures 5–7 show that the Fully Wrapped (FW) specimens had the lowest stiffness values especially those cured at 5°C with values of 929 MPa and 648 MPa respectively for both bitumen emulsion and foamed bitumen mixtures with 0% OPC. The highest stiffness values for the FW mixtures with 0% OPC were observed on specimens cured at 40°C with values of 1791 MPa and 1554 MPa for bitumen emulsion and foamed bitumen. At all curing temperatures, UnWrapped (UW) specimens with 0% OPC reached a stiffness 2–2.5 times the FW specimens.

ITS test results are presented in Figures 8–10. The trend observed for the ITS test results is identical to that for stiffness. The lowest strength values were observed also for the FW specimens cured at 5°C for both bitumen emulsion and foamed bitumen. At 0% OPC, UW specimens achieved 1.5–2.5 times the strength of FW specimens.

4.1.3 *Temperature influence on curing*

The influence of curing temperature on the stiffness modulus and strength development of the mixtures is illustrated in the case of 0% OPC specimens in Figures 11–12. The stiffness modulus and strength development increases with increase in curing temperature. This was evident irrespective of the curing conditioning employed. Higher curing temperatures resulted in higher rates of stiffness and strength increase which led to higher maximum values.

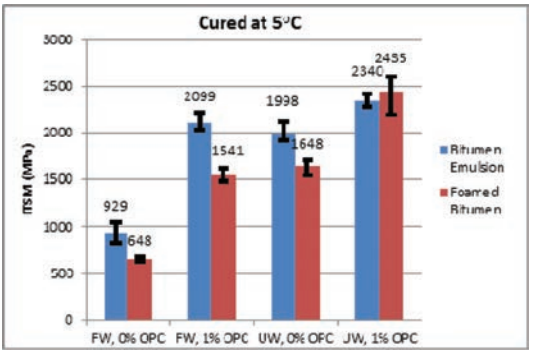

Figure 5. ITSM of specimens cured at 5°C.

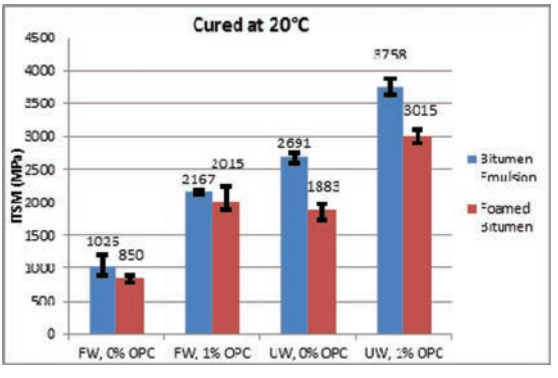

Figure 6. ITSM of specimens cured at 20°C.

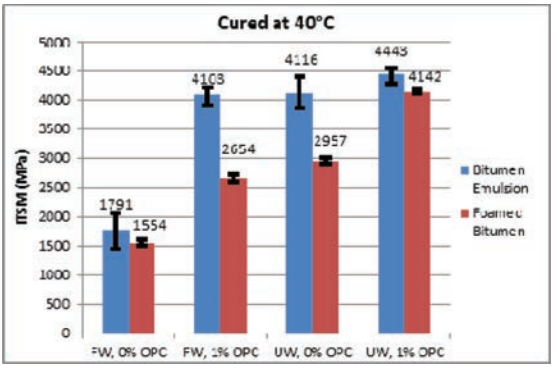

Figure 7. ITSM of specimens cured at 40°C.

A major phenomenon occurring during the curing process is moisture loss. As shown in Figures 13 and 14, there is naturally a significant difference between FW and UW specimens particularly with bitumen emulsion. Nevertheless, it is apparent from the relatively modest difference between final water contents at different curing temperatures that moisture loss is not the only mechanism involved in 'curing'. High temperature is clearly responsible for additional strength/stiffness gain, possibly by facilitating binder adhesion during the curing process.

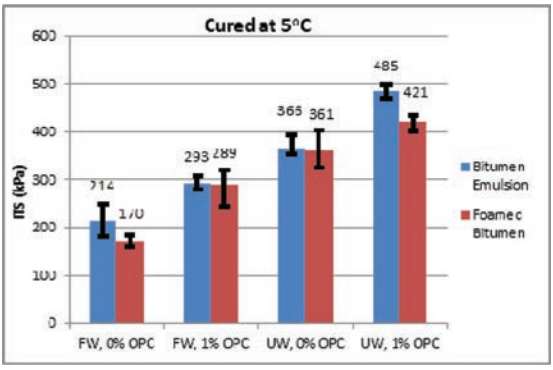

Figure 8. ITS of specimens cured at 5°C.

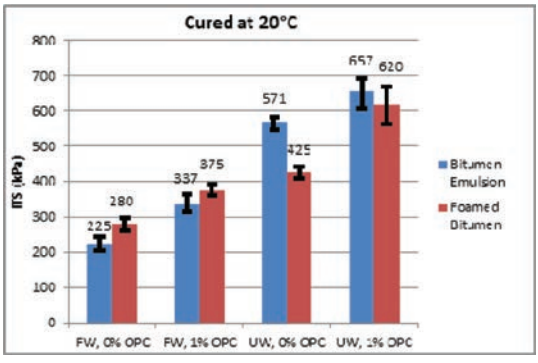

Figure 9. ITS of specimens cured at 20°C.

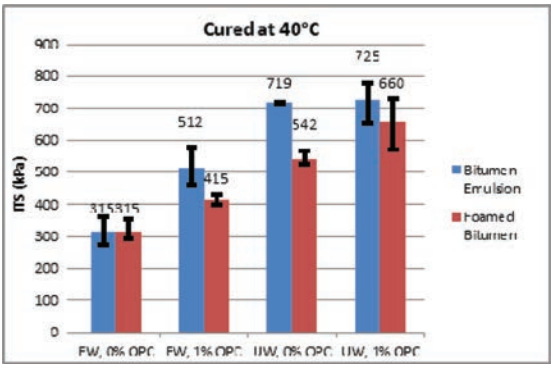

Figure 10. ITS of specimens cured at 40°C.

4.1.4 *Influence of cement*

The addition of cement increased the stiffness and strength at all curing temperatures for both FW and UW conditions. This increase is partly due to the removal of water from the system during hydration and partly due to the formation of cementitious bonds. In terms of stiffness, the addition of 1% OPC to FW specimens increased the 28 day values to those of 0% OPC UW specimens, illustrating the usefulness of cement in countering adverse weather during curing. The effect in terms of strength was slightly less but still significant.

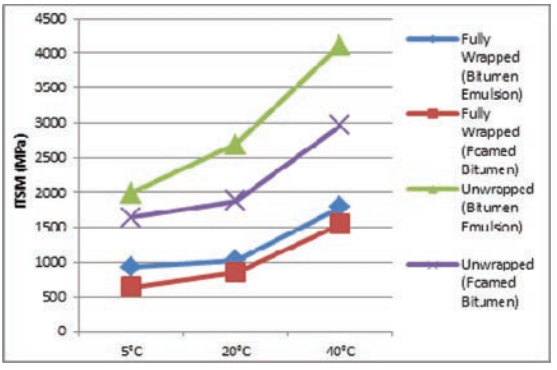

Figure 11. Stiffness trend.

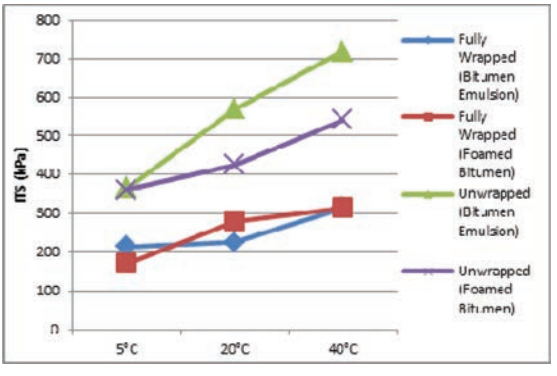

Figure 12. Strength trend.

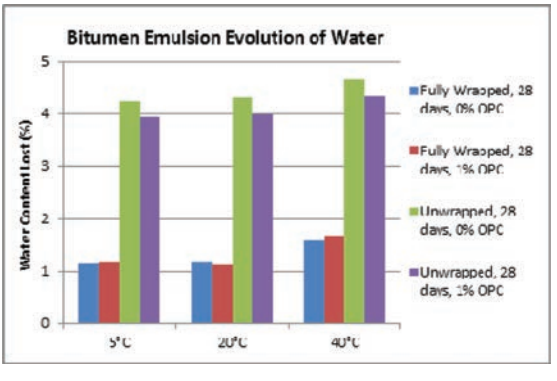

Figure 13. Bitumen emulsion moisture evolution.

Addition of cement to UW specimens also led to strength and stiffness increase. However, it is noticeable that with curing at 40°C, the effect of cement is minor. This suggests that its primary role, at least at 1%, is to remove water and facilitate bitumen bond formation rather than to create cementitious bonds.

4.1.5 *Influence of curing time*

This can be seen in Figures 15 and 16 where the 3 day and 28 day data are compared. Typically, it may be found that the stiffness values for the FW specimens, cured at 40°C for 3 days were

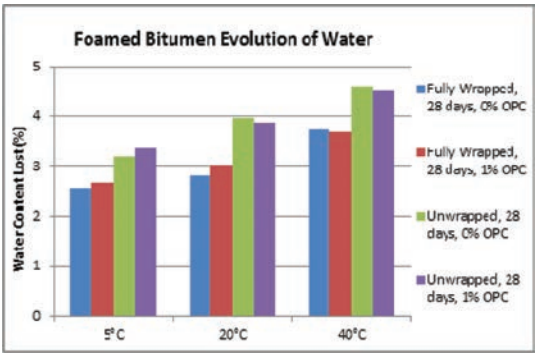

Figure 14. Foamed bitumen moisture evolution.

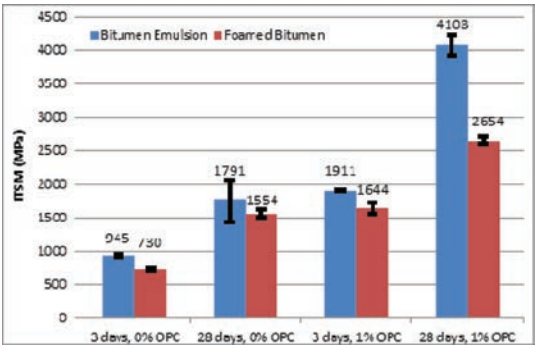

Figure 15. ITSM (3 days and 28 days).

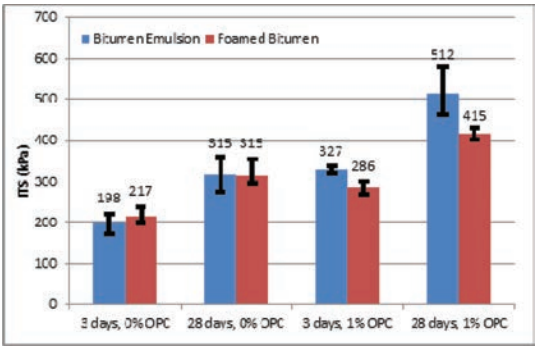

Figure 16. ITS test results (3 days and 28 days).

about 50% of those achieved at 28 days and with respect to the ITS results, the proportion is about 70%.

The combination of 7 days partially wrapped and 14 days fully wrapped (COMBO) was introduced to simulate typical field conditions with a surface course applied 7 days after construction of the base layer and trafficking commencing 14 days later. Figures 17 and 18 below compare this curing condition to the 28 day curing period of FW and UW curing conditions at 20°C. It is observed that in every case, the COMBO lies in between the FW and UW curing conditions. This reinforces the view that 28 days UW may result in an overestimate of actual performance and also suggests that 28 days FW may be appropriately conservative.

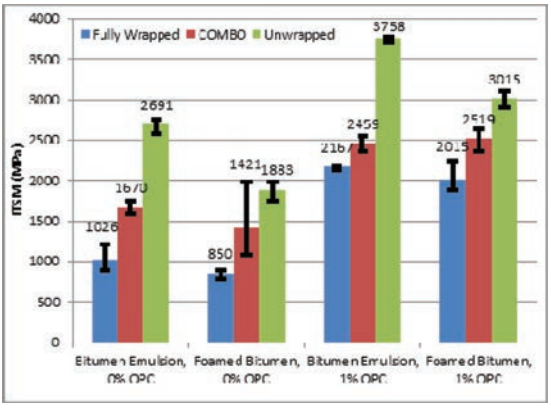

Figure 17. ITSM (COMBO).

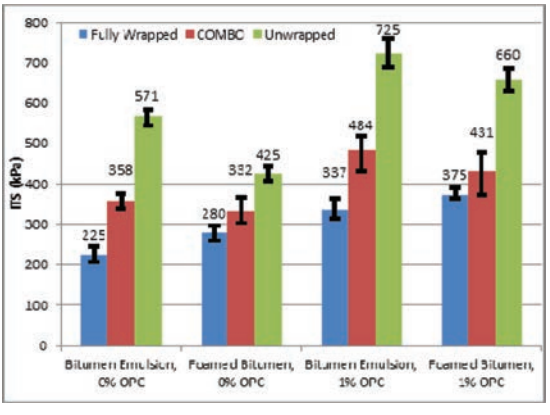

Figure 18. ITS (COMBO).

4.1.6 *Comparison of bitumen emulsion and foamed bitumen*

On average, it is clear that the emulsion specimens were generally stiffer and stronger than the foamed bitumen specimens. However, it should be noted that the grade of bitumen used in the emulsion was harder, reflecting common practice since hard binders tend not to foam so effectively. The binding effectiveness was probably similar in both cases since there was no significant difference between the two binders in terms of the relative effect of temperature, time, curing condition (FW or UW) or cement addition. Thus, in these cases, the two binders may be considered as having extremely similar types of action.

4.2 *Resistance to repeated loading*

To complete this study the resistance to permanent deformation was carried out using the Repeated Load Axial test (RLAT) in accordance to BS DD 226 as the guide. Test specimens were subjected to repeated load axial pulses that simulate loading conditions in road pavements. The parameters used are stated below:

- Conditioning stress: 10 kPa
- Conditioning period: 600 s
- Test stress: 100 kPa
- Test duration: 1800 pulses
- Test temperature: 30°C

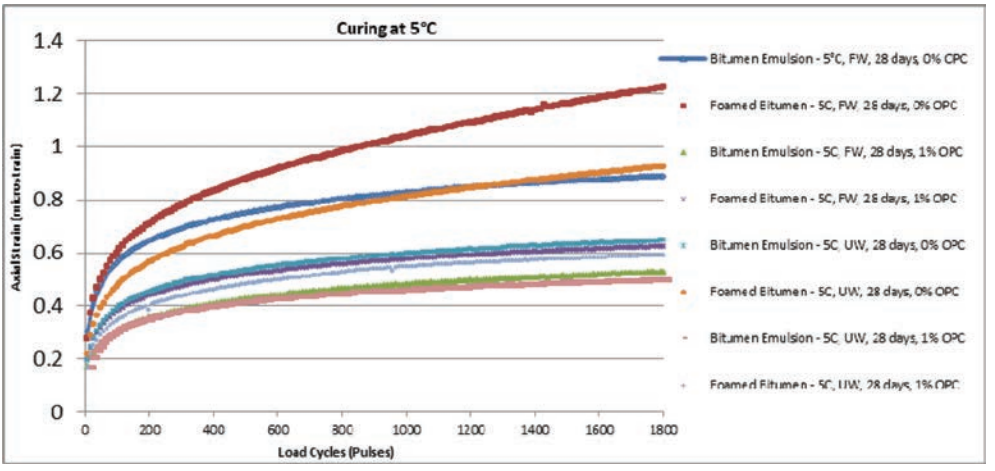

Figure 19. Permanent deformation at 5°C.

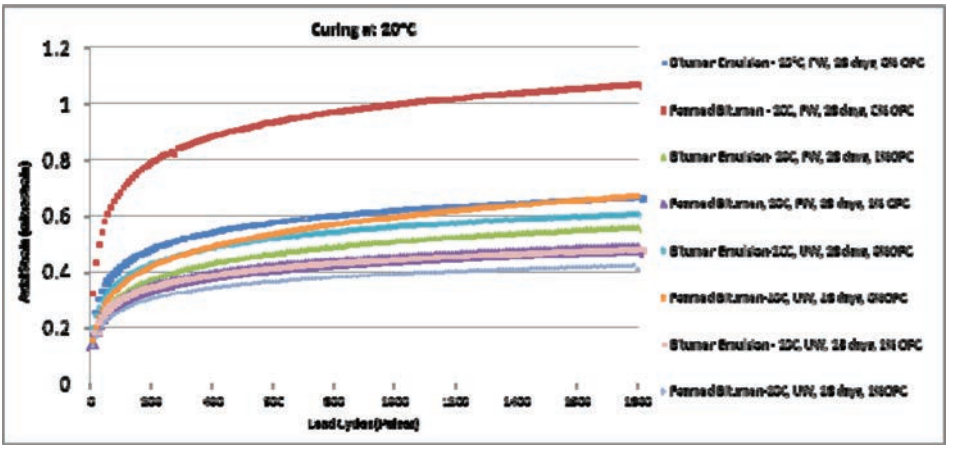

Figure 20. Permanent deformation at 20°C.

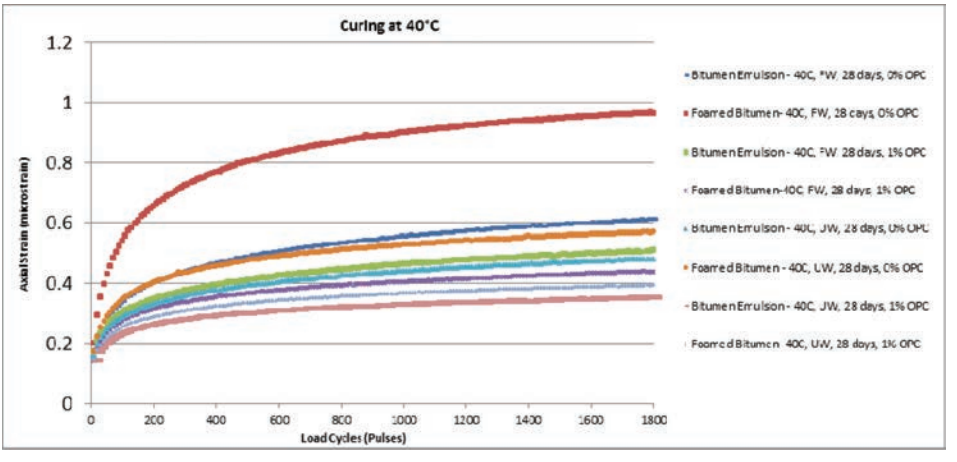

Figure 21. Permanent deformation at 40°C.

Analysing the permanent deformation results as presented Figures 19–21, the effect of curing temperature is moderate while the addition of cement greatly affects the performance of the CRBMs. Overall, the UW CRBMs had better resistance to deformation at the different temperatures but the difference is relatively slight. Similarly, the CRBMs produced with bitumen emulsion outperformed those produced with foamed bitumen as expected due to their harder binder.

5 CONCLUSIONS

The suite of tests carried out on CRBMs for this paper has resulted in several interesting conclusions with practical repercussions, namely:

- Curing temperature dramatically affects the rate of curing and the 28-day strength and stiffness values despite final water contents being similar.
- The ratio of 28-day stiffness results of specimens cured unwrapped to those cured fully wrapped is typically 2–2.5, independent of curing temperature. The equivalent indirect tensile strength ratio is 1.5–2.5.
- The inclusion of 1% cement in the fully wrapped case leads to strength and stiffness results approximately equal to those of unwrapped specimens without cement, suggesting that 1% cement addition is an appropriate means of avoiding the effects of adverse weather during curing.
- Strengths and stiffness results at 3 days are approximately 50–70% of those at 28 days, illustrating the danger of damage due to early trafficking.
- A 2-stage curing regime intended to simulate site practice produced strength and stiffness data that lay between the wrapped and unwrapped 28-day results.
- The behaviors of emulsion-bound and foamed-bitumen bound materials were very similar in terms of the relative effects of curing time and temperature, specimen wrapping and cement addition. However, the emulsion bound materials had consistently better performance as expected due to the harder grade of binder used.
- Exactly the same trends appeared from tests for permanent deformation resistance as for strength and stiffness.

ABSTRACT: The practice of incorporating Reclaimed Asphalt Pavement (RAP) into Hot Mix Asphalt (HMA) is common within the paving industry as a cost effective source of quality paving binder and aggregate. These mixtures incorporate already aged asphalt binder into new mixtures, which can impact the performance of the mixture in the field in terms of cracking, rutting and aging. This paper presents the results of a forensic study on cores from 23 year old pavements; the objective was to determine if a difference in aging between high and low RAP mixtures existed. Binders were extracted and recovered from field cores taken along New Hampshire Department of Transportation (NHDOT) paving projects that were constructed in 1987. This included 35% RAP mixtures from I-93 and virgin and low RAP mixtures along I-89. Field cores were obtained from the travel and shoulder lanes of the pavement sections and asphalt binder was extracted and recovered from different depths in the pavement structure. The results indicate that the 35% RAP mixtures age more uniformly through depth and between travel and shoulder lanes compared to the virgin and 15% RAP mixtures.

Keywords: High RAP, recycling, aging, extracted binder, field cores

1 INTRODUCTION

Hot Mix Asphalt (HMA) is comprised of three main components: aggregate, asphalt binder and recycled materials. While recycled materials can come from several different sources, the most commonly used in HMA is Reclaimed Asphalt Pavement (RAP), which is asphalt concrete from millings or plant waste that is processed for inclusion in new mixtures. RAP is a source of paving quality asphalt binder, as well as paving quality aggregate. The primary concern with use of RAP is the asphalt binder, which has been aged and is stiffer and more brittle than a virgin binder, which may lead to a higher susceptibility to cracking in the field. Based on experience and research, transportation agencies have been comfortable using 15–20% RAP (by total weight) in their mixtures [1–4] before any modifications to the mixture, such as changing binder grade, are required to offset the impact of the RAP binder.

Many research projects have evaluated the performance of asphalt mixtures containing various amounts of RAP compared to virgin mixture performance [1–8]. However, most of the research has been conducted on laboratory mixtures or field mixtures that have been in place for only a few years. This paper presents the results of a forensic analysis on 23 year old field cores that contained 35% RAP in the surface and intermediate binder layers. Companion virgin or low RAP (15%) field cores were also obtained. The binders were extracted and recovered from the field cores and tested in the laboratory to determine if the high RAP

mixtures aged differently than the low RAP or virgin mixtures in the field. The aging that occurred along the depth of the core as well as comparison between travel and shoulder lane cores are evaluated in this study.

2 MATERIALS AND METHODS

2.1 *Field cores*

Field cores were obtained from 23 year old pavements in two locations: Interstate 93 and Interstate 89 in New Hampshire. The I-93 cores contained 35% RAP; the I-89 surface cores were a virgin mix and the intermediate course contained 15% RAP. An intermediate course pavement of that age with virgin mix was not available, so the comparisons are between high and low/no RAP mixtures. The mixtures used a ¾ in. maximum aggregate size gradation with AC-10 binder. More details on the mixtures can be found in [9]. The two pavement sections had Average Daily Traffic (ADT) counts of approximately 20,000 vehicles per day for I-93 and 36,000 vehicles per day for I-89.

Volumetric information for the cores is presented in Table 1. The field cores had a large range in air void contents, with average values varying significantly at the surface between the travel and shoulder lanes and between the surface and intermediate layers.

2.2 *Asphalt binder extraction and testing*

The asphalt binder was extracted and recovered from three layers of each field core: the top 0.5 in., the next 1.0 in., and the next 1.0 in. For most of the cores, the top two layers were surface course materials and the bottom layer was the intermediate course. The exception is the I-89 travel lane middle layer that contains both surface and intermediate course material. Figure 1 shows the extraction layers and mixtures with depth, where the surface course is indicated in light grey and intermediate course is indicated in dark grey, and each unit

Table 1. Average volumetric properties of field cores.

Location	RAP Content (% by total weight)	Min. Air Void	Max. Air Void	Ave. Air Void	Ave. VMA	Ave. VFA
I-93 Travel surface	35%	1.1%	4.2%	2.2%	15.7	88.8
I-93 Travel intermediate		3.6%	6.5%	5.1%	17.5	69.4
I-93 Shoulder surface	35%	3.6%	4.0%	3.8%	16.7	77.1

I-89 Shoulder surface	0%	6.6%	8.6%	7.6%	20.1	62.4
I-89 Shoulder intermediate	15%	4.3%	5.9%	5.1%	17.0	70.1

Figure 1. Schematic of layer and binder extraction depths.

represents 0.5 in. The binder was extracted from each layer following AASHTO T-164 using trichloroethelyne as the solvent and recovered following AASHTO T-170.

Binder testing included the Bending Beam Rheometer (BBR) (AASHTO T 313), Direct Tension Test (DTT) (AASHTO T 314) and Dynamic Shear Rheometer (DSR) (AASHTO T 315) testing. Only one specimen was tested at each location and depth, so a typical statistical analysis could not be performed. In order to quantify the differences between binder results, percent differences were calculated to compare stiffness, m-values and critical cracking temperatures. To compare the shear modulus and phase angle master curves, a ratio of the modulus and phase angle values at various reduced frequencies were calculated and plotted on a log scale. The control specimens for percent differences are displayed as the numerator in the legend of each graph.

3 RESULTS AND DISCUSSION

3.1 *Naming scheme*

The specimen name starts with the route number from which the sample was cored, followed by a "T" or "S" for travel lane or shoulder lane, respectively, followed by a number which indicates the % RAP in the layer, followed by a "t", "m", or "b" for the top 0.5 in., middle 1 in., and bottom 1 in. respectively. Binder specimens that contained a mixture of surface and intermediate course binder are noted with a "*" at the end of the name.

3.2 *BBR M-Value and stiffness*

Figure 2 presents the BBR stiffness measured at several temperatures while Figure 3 through Figure 5 present the percent difference comparisons at –18C for the stiffness values. Figure 6 shows the m-value results at different temperatures and Figure 7 through Figure 9

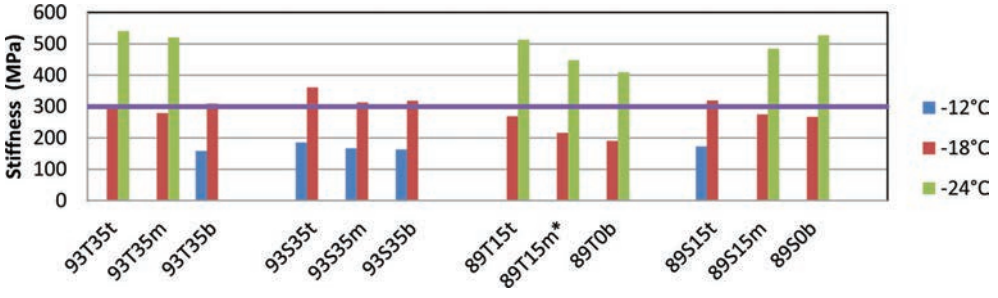

Figure 2. Stiffness of all binder specimens.

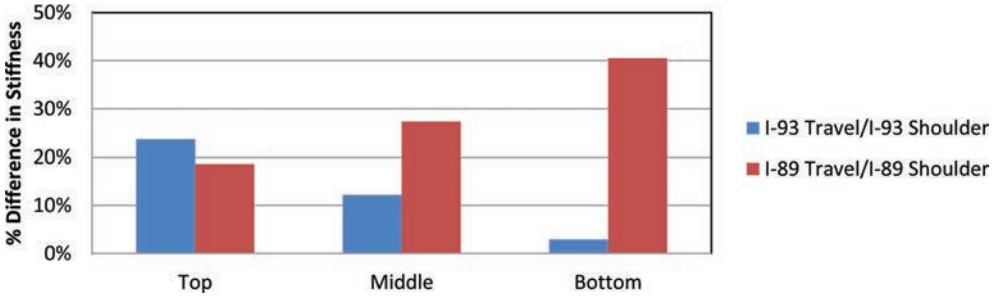

Figure 3. Percent difference between stiffness of travel and shoulder lanes with depth.

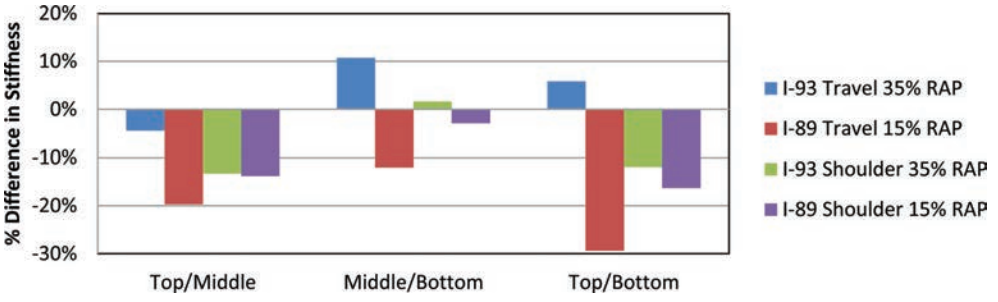

Figure 4. Percent difference between stiffness of lanes with depth.

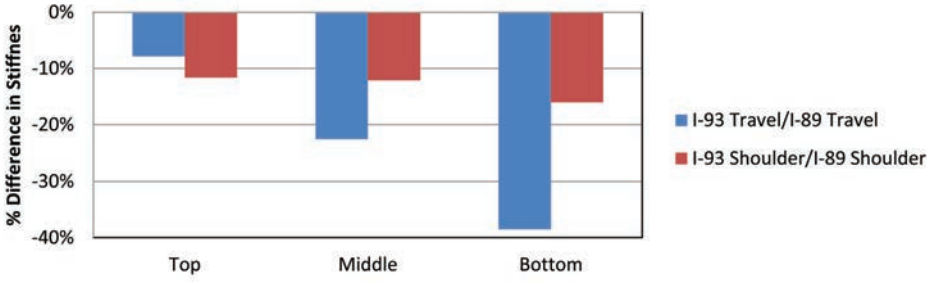

Figure 5. Percent difference between stiffness of high and low RAP with depth.

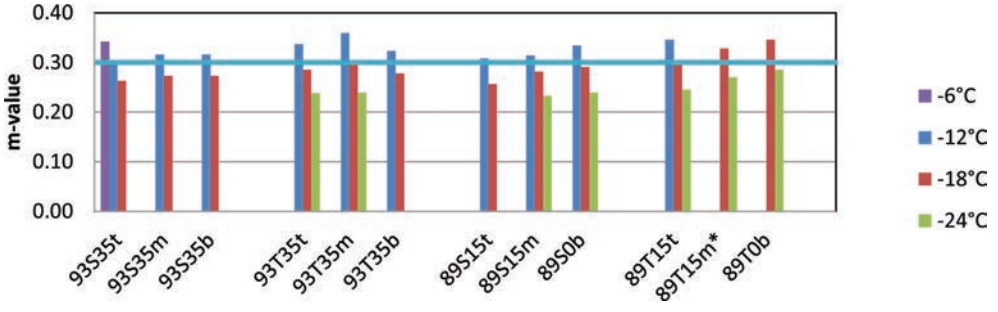

Figure 6. M-Values for all binder specimens.

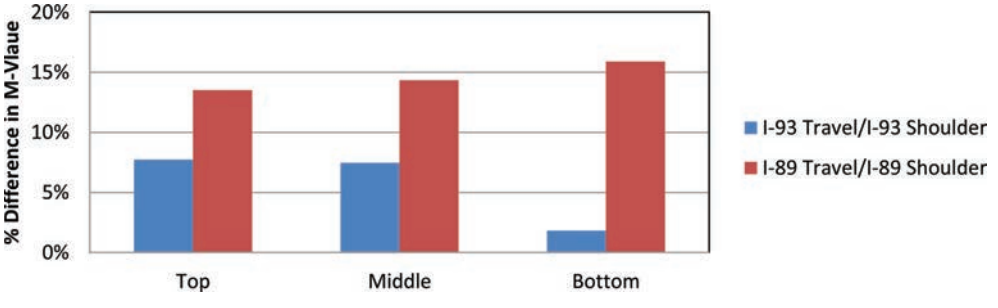

Figure 7. Percent difference between M-Value of travel and shoulder lanes with depth.

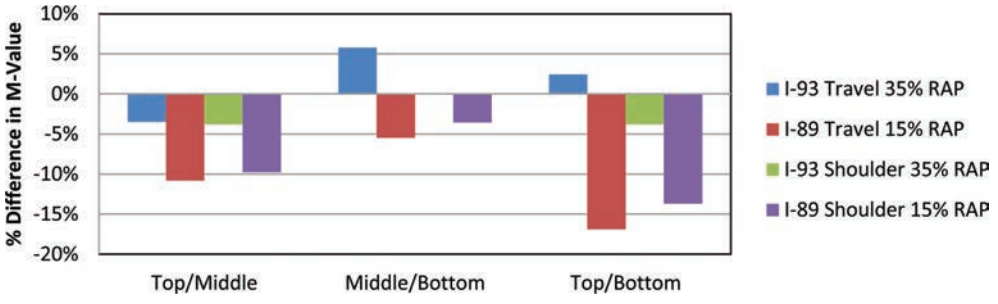

Figure 8. Percent difference M-Value of lanes with depth.

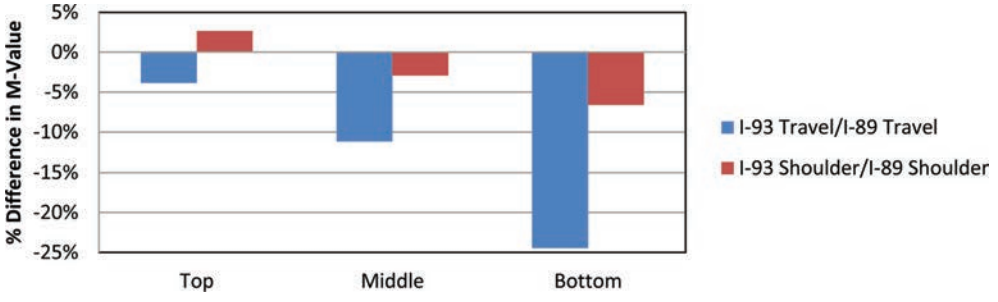

Figure 9. Percent difference between M-Value of high and low RAP with depth.

present the percent differences at –18C for the m-value results. In both cases, there is a larger percent difference among the low RAP cores compared to the high RAP cores between lane types. The low RAP cores have a much higher percent difference throughout lane types than the high RAP cores. There is an increasing percent difference with depth between the RAP contents and a much greater variability in the low RAP cores, especially with depth from the surface particularly in the travel lane. The results indicate that high RAP cores aged differently from the low RAP cores because the low RAP cores have greater changes in stiffness and m-value through the pavement depth and between lane types.

It is expected that the high RAP cores have higher stiffness and lower m-value due to the already aged binder. Increased exposure to oxidation at the surface is expected to cause higher stiffness at the surface and decrease through the middle and bottom layers. The m-value is expected to increase through the middle and bottom layers. Traffic action is shown to decrease the effects of aging at the surface, so it is probable that there are lower stiffness values in the travel lane compared to the shoulder lane, and higher m-values in the travel lane. Higher air voids are shown to increase the aging process by allowing oxygen to flow through the pavement layers, however, since the higher air voids were in the intermediate course it likely had less of an impact. The stiffness and m-value trends follow the predicted behaviors, indicating these specimens are good candidates for determining if RAP has an impact on aging as there are no unexpected trends.

3.3 *Critical cracking temperature*

Critical Cracking Temperature (CCT) values were calculated following AASHTO MP 1a-04 and are presented in Figure 10. Figure 11 through Figure 13 present the percent differences between CCT value results. Similar to the stiffness and m-value results, there is a larger percent difference between low RAP cores compared to the high RAP cores. This larger difference in CCT values in the low RAP cores is observed when comparing depth from surface

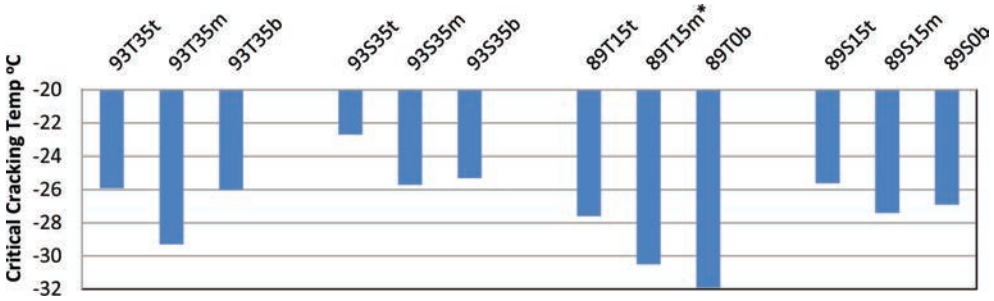

Figure 10. Critical cracking temperature of all binder specimens.

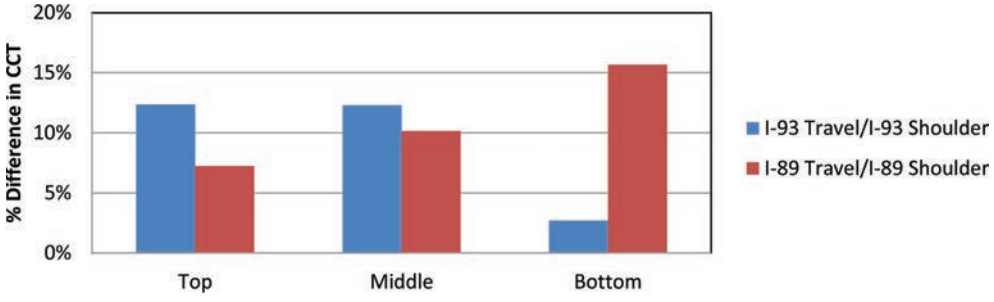

Figure 11. Percent difference between CCT of travel and shoulder lanes with depth.

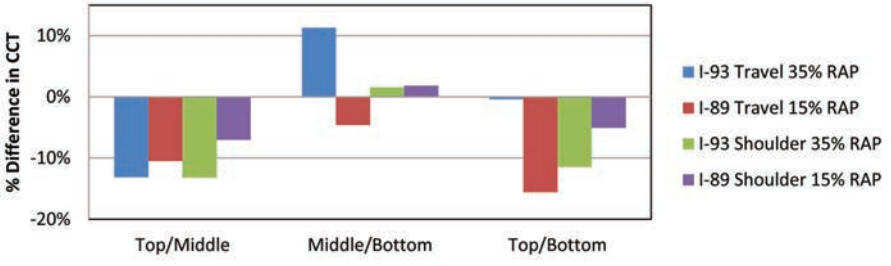

Figure 12. Percent difference CCT of lanes with depth.

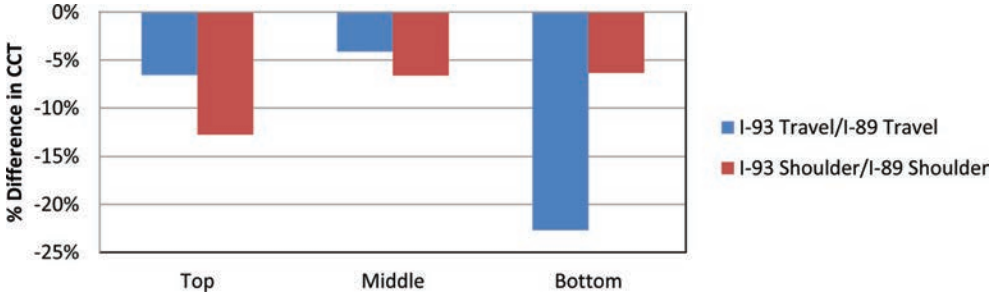

Figure 13. Percent difference between CCT of high and low RAP with depth.

and when comparing lane type. It is important to notice the high RAP mixture middle specimens for both lanes had lower CCT values than the top and bottom depths, which caused an increase in the percent difference that is not observed in the previous results from stiffness and m-value. The top and bottom layers of the high RAP cores, however, have similar CCT values that are consistent with previous results which may indicate the middle layer is an outlier. These results indicate that the high RAP cores have aged more uniformly during their service life when compared to low RAP cores both with depth and lane type.

It is expected that the high RAP cores have higher CCT than the low RAP cores due to the already aged binder. Increased exposure to oxidation at the surface is expected to cause higher CCT at the surface and decrease through the middle and bottom layers. The CCT values trends follow expected behaviors with respect to traffic and air void content, indicating these specimens are good candidates for determining if RAP has an impact on aging as there are no unexpected trends.

3.4 *Dynamic shear modulus |G*|*

Figure 14 presents the dynamic shear modulus, |G*|. In general, the master curves follow trends observed from the stiffness, m-value and CCT results, with the top sections having highest (stiffest) master curves and stiffness decreasing with depth and RAP content. The shoulder lanes also have stiffer master curves than the travel lanes. Air void contents were not consistent, which may have affected aging over the lifespan of the pavement, however the air voids are lowest at the surface, decreasing the impacts of aging in the intermediate layers.

Figures 15 and 16 present ratios of the |G*| master curves (20°C reference temperature) by depth, lane type and RAP content. The legend indicates the numerator and

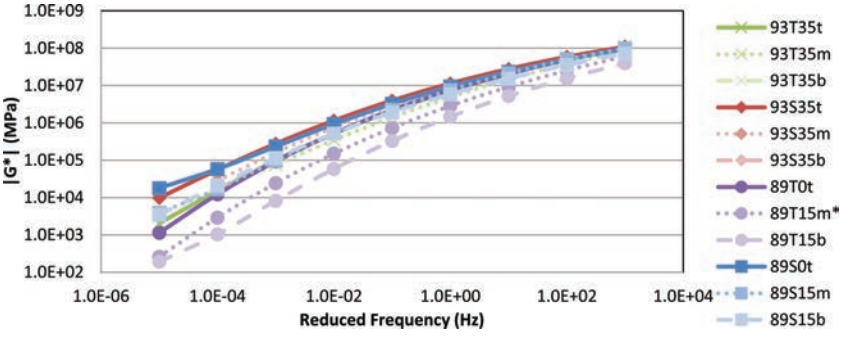

Figure 14. Summary of all binder's |G*| master curves.

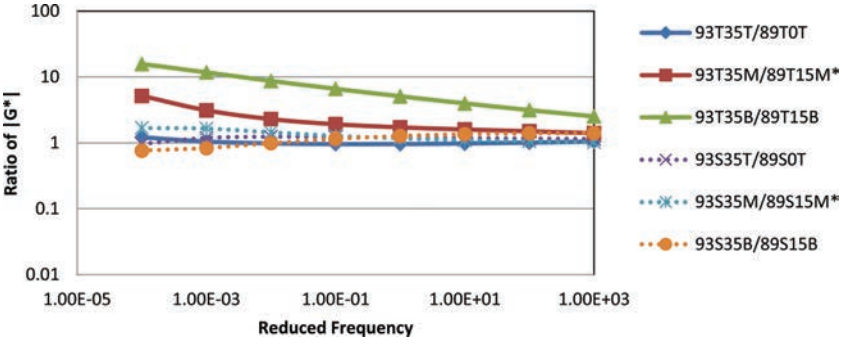

Figure 15. Ratio of |G*| for travel and shoulder lanes.

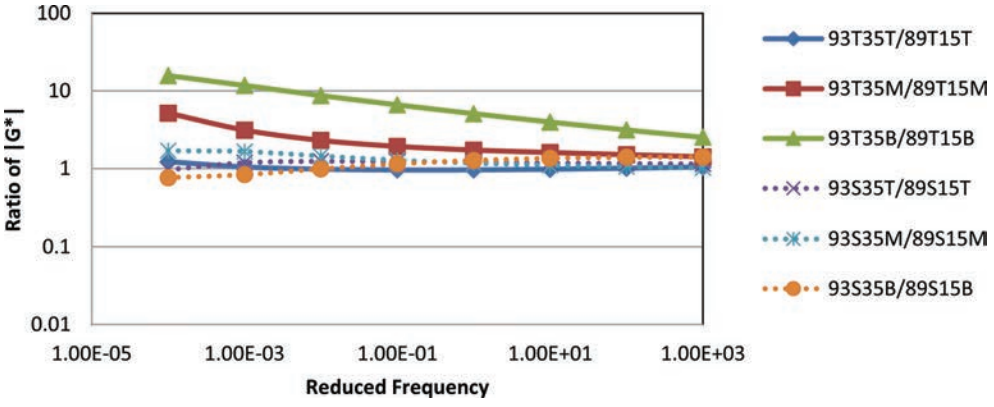

Figure 16. Ratio of |G*| for high RAP and low RAP cores.

denominator in the ratio. With few exceptions, the low RAP mixtures have larger ratios, indicating a larger difference in stiffness. At all depths and frequencies the ratio of high RAP specimens are close to 1, indicating very similar stiffness while the low RAP travel lane ratios are close to 12 times greater between the top and bottom specimens and close to 5 times greater for the shoulder lane at low frequencies. This greater difference suggests the low RAP mixtures are not aging uniformly with depth, while the high RAP mixtures are aging at a more similar rate. There is also more uniform aging indicated between shoulder and travel lane for the high RAP mixtures when compared with the low RAP mixtures.

4 SUMMARY AND CONCLUSIONS

The research goal for this project was to determine if high RAP mixtures age differently than mixtures with low or no RAP. Field cores that had been in service for 23 years with varying amounts of RAP were obtained. The binder was extracted and recovered from surface and intermediate courses and tested for shear modulus, phase angle, stiffness, m-value and critical cracking temperature. The binder testing, in general, yielded trends among RAP contents, lane types and depths that were consistent with previous research, with increase in stiffness at the surface, in the shoulder lanes compared to travel lanes, and in high RAP mixtures compared to low RAP mixtures.

By quantifying the difference between the high and low RAP performance using percent differences and ratios, the following conclusions are drawn regarding the effects of RAP content on aging based on the pavements evaluated in this study:

- High RAP mixtures appear to age differently than low RAP mixtures;
- High RAP mixtures have more uniform properties along pavement depth and between shoulder and travel lanes than low RAP mixtures.

While this research, as well as previous research, has shown that high RAP mixtures are stiffer and thus more susceptible to cracking than low RAP or virgin mixtures, this research has also shown that they age at a more uniform rate. It is also indicated that aging in the high RAP mixtures cause smaller differences from initial conditions over time. Oxidation of the RAP material that occurred during its initial service life is likely the reason for the smaller changes observed. Knowing that high RAP mixtures will age less over time means that transportation agencies can better predict material properties over design life, and thus better predict pavement performance.

5 RECOMMENDATIONS FOR FUTURE WORK

The following items are recommendations for future work to evaluate the effect of high RAP on asphalt pavement performance in field aged mixtures:

- Include test sections of wider range of RAP contents;
- Evaluate initial mixture and binder performance;
- Evaluate mixture and binder performance at regular time intervals throughout pavement service life; and
- Eliminate as many sources of error between test sections possible by selecting roadways with similar ADT and consistent aggregate gradation, layer thickness and air void content.

ACKNOWLEDGEMENTS

The authors acknowledge NHDOT for providing funding for this work and Materials and Research Bureau of NHDOT for performing much of the binder extractions and binder testing for this project.

Resistance to permanent deformation of base courses asphalt concretes made with RAP aggregate and steel slag

Marco Pasetto

Nicola Baldo
Chemistry, Physics and Environment Department, University of Udine, Udine, Italy

ABSTRACT: The results are presented of a laboratory investigation aimed at analyzing the rutting susceptibility of asphalt concretes with Reclaimed Asphalt Pavement (RAP) aggregate and Electric Arc Furnace (EAF) steel slag, used at different proportions (up to 70% of the weight of the aggregates), in partial substitution of limestone aggregates. The experimental study has been focused on the characterization of the physical-mechanical properties of the marginal materials, as well as on the mix design and the permanent deformation evaluation (by means of Creep Recovery Tests, Repeated Load Axial Tests, Wheel Tracking Tests) of bituminous mixtures for road asphalt concrete base courses. Since the requisites for acceptance in the Italian Specifications and Standards have been satisfied and given the positive mechanical performance (indirect tensile strength at 25°C on dry samples up to 2.35 MPa, depending on the mixture), it has been verified that the marginal aggregates investigated can be used as substitution of the lithic materials in the base courses, also with very high content (up to 70% on the weight of the aggregates).

Keywords: Base course asphalt concrete, steel slag, reclaimed asphalt pavement, permanent deformation resistance

1 INTRODUCTION

The accumulation of permanent deformations at high working temperatures and heavy loadings leads to the formation of surface ruts, i.e. longitudinal hollows with raised edges. This can be caused by the poor shear strength of the asphalt that forms the surface layer of a flexible pavement.

Resistance to permanent deformation in a bituminous mix is mainly influenced by the compaction level of the mixture, binder's rheological properties and content [1], and factors connected with the aggregate (angularity, particle size distribution, shape of the grains, texture, etc.) [2, 3]. For this reason, the use of unconventional aggregates deserves a particular attention in the design of bituminous mixtures, especially in the case of heavily trafficked pavements (e.g. in motorways and airport pavements).

The paper presents the results of a laboratory study aimed at verifying the influence of different types of aggregates (two recycled plus a natural one) on the permanent deformation resistance of base courses asphalt concretes.

Two artificial and recycled aggregates were used in the study: Electric Arc Furnace (EAF) steel slag, and Recycled Asphalt Pavement (RAP) aggregates. The use of these materials in the construction of transport infrastructures appears to be particularly promising. Although applications of each type of un-conventional aggregate for road pavements have been widely tested [4–7] in the past, their simultaneous utilization in an integrated lithic matrix of

bituminous mixtures for pavement layers is still the subject of research aimed at evaluating suitability and economy of the application.

2 MATERIALS

The artificial and recycled aggregates (EN 13043) considered in the study were what are known as marginal materials [8–11]; more specifically they are EAF steel slag and RAP aggregate. The marginal aggregates used in the study were supplied by different private companies in northern Italy, while the natural aggregate (limestone and sand) derived from a quarry in the same area.

The grading curves of the aggregates reported in Figure 1, show that the 10/15 mm fractions of the EAF slag and limestone had an almost identical particle size distribution, while a relevant difference can be noticed between the 15/20 fractions: the first slag had a finer composition that the corresponding fraction of the limestone. The 5/10 mm fraction of the EAF slag presented an intermediate grading distribution. RAP and natural sand represent the fine aggregates.

Table 1 reports the physical-mechanical properties of the aggregates, as well as the specific road test protocols adopted.

The Los Angeles test showed a good resistance of the EAF slag to abrasion and friction, with a LA coefficient lower than the acceptance requisites of SITEB—Italian Society of Bitumen Technologists Specifications [12], set at 25%. The Los Angeles coefficient of crushed limestone, as well as that of RAP aggregate, are higher than SITEB's threshold, with differences of 20% and 8%, respectively. The mechanical resistance of the marginal aggregates is anyway higher than that of the natural ones.

The cleanliness, expressed in terms of Equivalent in Sand, resulted extremely good for all the aggregates and largely above the minimum SITEB threshold, fixed at 50%. Both the limestone and the marginal aggregates, namely EAF slag and RAP, presented satisfactory

morphological properties, given that the Flakiness Index values were consistently below the maxim requisite limit, fixed by SITEB at 25%. All the marginal aggregates resulted as practically unaffected by the action of water, presenting non-determinable Atterberg Limits (Liquid Limit and Plastic Limit), as prescribed in the Italian technical regulations. The particle densities of the RAP aggregates are quite similar to those of the natural materials, but decidedly lower than those of the steel slags.

By Italian Law, the steel slags considered are "non-hazardous, special non-toxic and non-noxious" refuse; their pH resulted equal to 11.5. The chemical composition of the EAF slags have been analyzed with XRF (X-ray fluorescence); their toxicological characteristics were checked in terms of initial concentrations of heavy metals, measured with the ICP-AES methodology (Inductively Coupled Plasma—Atomic Emission Spectrometer), whilst their leaching was determined by the TCLP (Toxic Characteristic Leachability Procedure) given in Appendix A of Standard UNI 10802, following the method in Standard EN 12457-2.

The slags, in terms of oxides, contain a prevalence of FeO (30.4%) and CaO (27.7%), as well as SiO_2 (17.5%), MgO (6.6%) and Al_2O_3 (4.8%). The SiO_2/CaO ratio characterizes the EAF slag as a substantially alkaline aggregate and therefore suitable to guarantee the necessary adhesion with the weakly acid bitumen. With regard to the initial concentration of heavy metals (Table 2), the steel slags present higher contents of vanadium, zinc and chromium, the

latter predominating over all the other metals; anyhow it is less than 0.4% of the total volume of slags.

The results in Table 2 demonstrate that, for the steel slag, the release of heavy metals by leaching is within the limits of the environmental regulations in force in Italy (Legislative Decree no. 152/2006). Therefore, given that the constituents of the mixtures do not present toxicological problems, it was considered unnecessary to proceed with leaching tests on asphalt specimens.

The steel slags investigated in the present research have been seasoned by the producer, exposing the material to weather for a period of at least six months, so that the unbound fraction of calcium oxide can be stabilized naturally, without being subject to a volumetric expansion. However, a volumetric stability test on the EAF slags, according to the Standard EN 1744/1 part 15.3, has been performed and it showed a null expansion after the 168 hours requested by the protocol. Lastly, neither the natural aggregates nor those of fusion demonstrated any problems of affinity with the bitumen, with no stripping of the grains coated with binder after 24 hours of immersion in water at 25 °C.

Cold extraction (by centrifugation) of the bitumen of the RAP aggregate revealed a binder content of 4.3% (EN 12697-1) on the weight of the aggregate. The extracted bitumen showed a penetration of 15 mm/10 at 25 °C (EN 1426) and a softening point, with the Ring & Ball Method, of 74 °C (EN 1427); it is therefore a decidedly aged and particularly hard binder. A conventional bitumen (50/70 dmm pen) was used as virgin binder for all the mixtures in the experiments.

RAP aggregates were preheated at mixing temperature for 2 hours, before the mixing. The virgin bitumen, RAP and the other aggregates (namely limestone and steel slags), have been mixed together in a heated lab mixer for one minute.

3 MIXTURES

Five mixes were designed with an integrated slag-RAP-limestone lithic matrix (S0R2, S0R4, S3R0, S3R2, S3R4) and one, used as control, with only natural aggregate (S0R0). Artificial and recycled aggregates were used up to 70% of the weight of the total aggregate.

3.1 *Grading and composition of the mixes*

The particle size distribution of the mixes with artificial and recycled aggregates was optimized with reference to the design grading envelope of SITEB [12] for asphalt concrete base courses, in order to identify a curve as close as possible to its centre, but compatible with the availability of the different aggregates in the sizes necessary to construct this "ideal" grading. For the control mix (all natural) various amounts of marginal materials are substituted by limestone with an equivalent grading fraction.

Table 3 reports the grading composition of the bituminous mixtures and proportions of the components, whereas the corresponding grading curves are presented in Figure 2. The design grading curves (Fig. 2) are all within the reference grading envelope [12] for base course asphalts with maximum aggregate size of 20 mm.

3.2 *Optimization of the mixture*

The volumetric mix design, according to CIRS-Italian Ministry of Infrastructure Specifications [13], based on the gyratory compaction procedure and the Indirect Tensile Strength (ITS) test at 25°C, on both dry and wet cylindrical samples, was used for the optimization of the bituminous mixtures. Regarding the main test parameters, a speed of 30 revs/minute, a pressure of 600 kPa, an angle of rotation of 1.25° and a diameter of the mould of 150 mm, were used in the gyratory compaction.

The Optimum Bitumen Content (OBC) for each mixture was determined in correspondence to the residual air voids content (Va) at 10, 100 and 180 revs, of 10–14%, 3–5% and

Table 3. Aggregate type and particle size distribution of the mixtures.

Mix composition	Fraction [mm]	Quantity [%]					
		S0R0	S0R2	S0R4	S3R0	S3R2	S3R4
Crushed limestone	5/10	25	15	12	29	21	14
	10/15	20	20	20	–	–	–
	15/20	12	12	11	–	–	–
Sand	0/2	40	30	13	38	26	12
RAP aggregate	0/10	–	20	40	–	20	40
EAF steel slag	10/15	–	–	–	10	18	18
	15/20	–	–	–	20	12	12
Filler (additive)	–	3	3	4	3	3	4

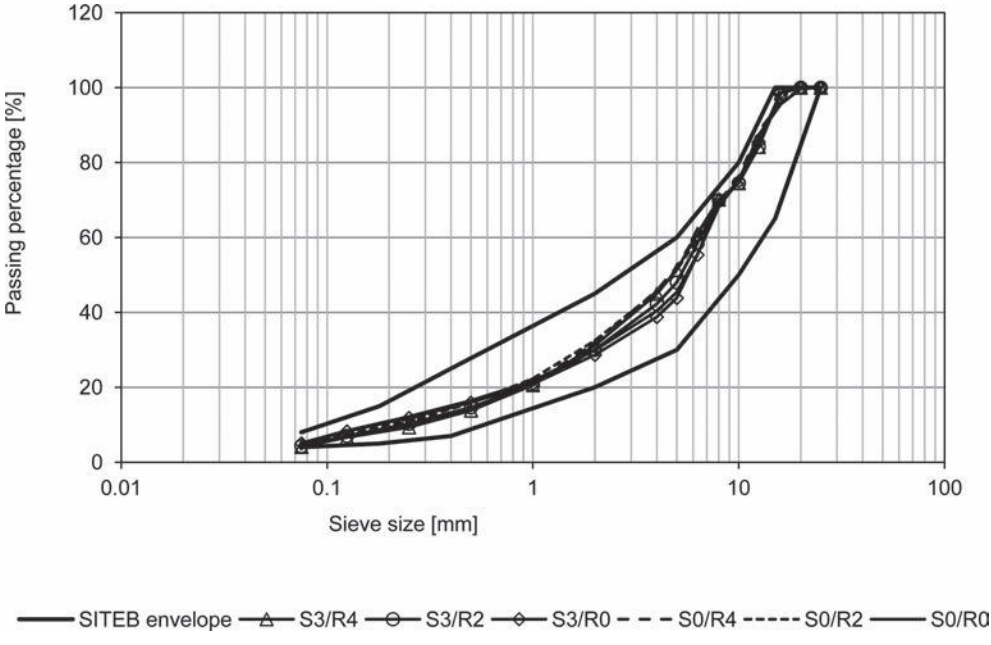

Figure 2. Design grading curves of the mixes.

over 2%, respectively [13]. The binder content determined regards the virgin bitumen added to the granular mixtures, therefore, for the mixes containing RAP aggregate, the total bitumen content is given by the sum of the aged bitumen of the RAP and the OBC.

The Tensile Strength Ratio (TSR) has been computed as the ratio between the indirect tensile strength of the specimens treated by means of 15 days of immersion in a thermostatic bath at 25 °C (ITS_{wet}) and untreated (ITS_{dry}), respectively. The ITS_{dry} and the TSR values of the mixtures prepared with the optimum bitumen content should result higher than 0.6 MPa and 75%, respectively, in order to fulfill the CIRS acceptance requisites.

For each of the 6 asphalt concretes, different mixtures were analyzed, in which, having defined the type of aggregate and grading composition, the amounts of binder were varied at intervals of 0.25% on the weight of the aggregate. To support the phase of mix design, four gyratory specimens were produced for each mix. The results of the mix design procedure are summarized in Table 4, which details for each material: OBC, Air Voids (Va) at 10, 100 and 180 revs, bulk density at 100 revs, ITS for dry and wet conditions.

Table 4. Mix design results.

Mixtures	OBC (%)	Va @ 10 res (%)	Va @ 100 res (%)	Va @ 180 res (%)	Bulk density (g/cm^3)	ITS dry (MPa)	ITS wet (MPa)	TSR (%)
S0R0	4.75	13.24	4.96	2.95	2.410	1.62	1.35	83
S0R2	3.90	13.09	4.89	2.89	2.433	1.88	1.61	86
S0R4	3.00	12.91	4.78	2.81	2.469	2.35	2.06	88
S3R0	4.85	12.20	4.27	2.48	2.626	1.74	1.46	84
S3R2	4.00	12.02	4.18	2.39	2.661	1.90	1.73	91
S3R4	3.10	11.88	4.03	2.27	2.714	2.18	2.01	92

The total bitumen content resulted to be within the typical range of base courses asphalt concretes, namely 4.5–5.5% by weight of the aggregates [12, 13], for all the mixes. As it was expected, the greater the RAP content, the lower the virgin bitumen content that is necessary in order to optimize the mixture made with RAP aggregate.

The bulk density of the mixtures was obviously heavily affected by the integration of the EAF slags in the aggregate skeleton, given the high grain densities of the steel slag particles.

The Air Voids requisites prescribed by CIRS mix design procedure, at 10, 100 and 180 revs, were completely satisfied, for all the mixes. The ITS values in dry conditions, resulted largely above the CIRS acceptance requisite (at least more than double) for all the asphalt concretes, as well as the ITS on wet samples, always higher than the 75% of the correspondent ITS dry value (up to 92%, depending on the mix composition), so coming to the conclusion of the acceptability of these base courses asphalt concretes.

The mixes with marginal aggregates showed improved ITS values, with respect to the reference limestone-only asphalt concrete (S0R0), varying from 7% to 53%, depending on the dry/wet condition and on the mix composition; the mixture made with 30% EAF slag and 40% RAP (S3/R4) was characterized by the highest mechanical strength and moisture damage resistance. The rough texture of the steel slags, as well as the presence of a bitumen film on the RAP particles (aged binder), enable a strong adhesion between the new bitumen added to the mixes and the marginal aggregates grains, that allows, to the optimized asphalt concretes, to achieve consistent mechanical strength. Moreover, the greater the RAP content, the higher the ITS value.

4 PERFORMANCE TEST PROGRAMME

Creep Recovery Tests (CRT, BS 598 Standard) and Repeated Load Axial Tests (RLAT, BS 226 Standard) at 40°C, as well as Wheel Tracking Tests (WTT, EN 12697-22 Standard, procedure B) at 60°C, have been performed on the six asphalt concretes optimized in the mix design procedure, in order to investigate the permanent deformation resistance of the mixes at high temperature. The CRTs were conducted setting both the loading time and rest period at 3600 s, respectively, and with a constant uniaxial stress equal to 100 kPa. The same stress level (100 kPa) have been applied also for the cyclic uniaxial stress in the RLAT, for 3600 pulses, with loading and unloading times were fixed at 1 s. Both the CRTs and RLATs were performed on cylindrical specimens prepared by gyratory compaction, whereas for the WTT, 300 mm × 400 mm × 50 mm slabs produced by a laboratory compacting roller, were used.

4.1 *Permanent deformation test results and discussion*

Figures 3–5 report the evolution of the permanent deformation curves during the tests conducted (CRT, RLAT and WTT respectively); the evolution of the permanent deformation, for all the mixes, is that typical of visco-elasto-plastic materials: a first phase with a decreasing creep rate, and a second with a constant creep rate can be clearly distinguished. For the CRT it is also possible to appreciate the recovery of the visco-elastic deformation after unloading.

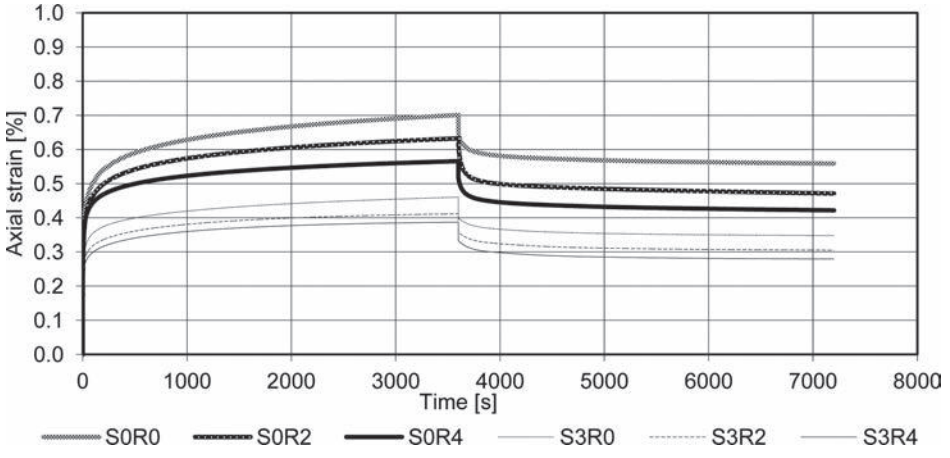

Figure 3. Permanent deformation curves by CRT.

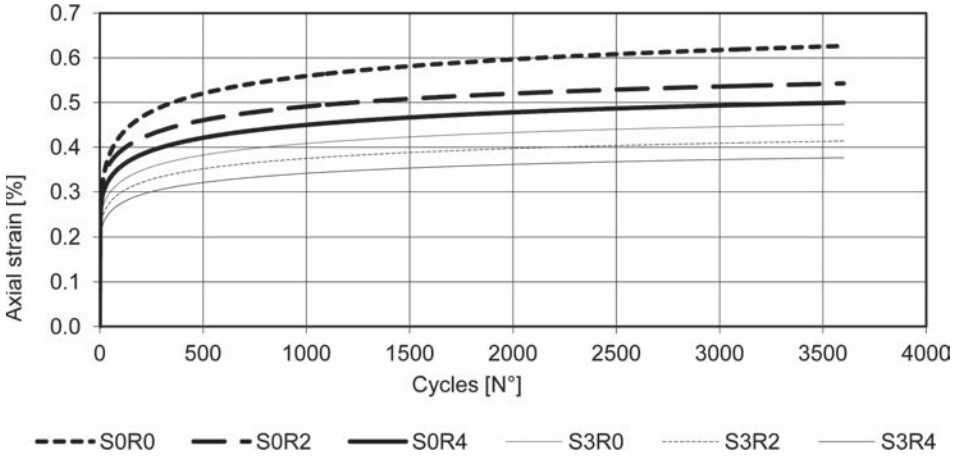

Figure 4. Permanent deformation curves by RLAT.

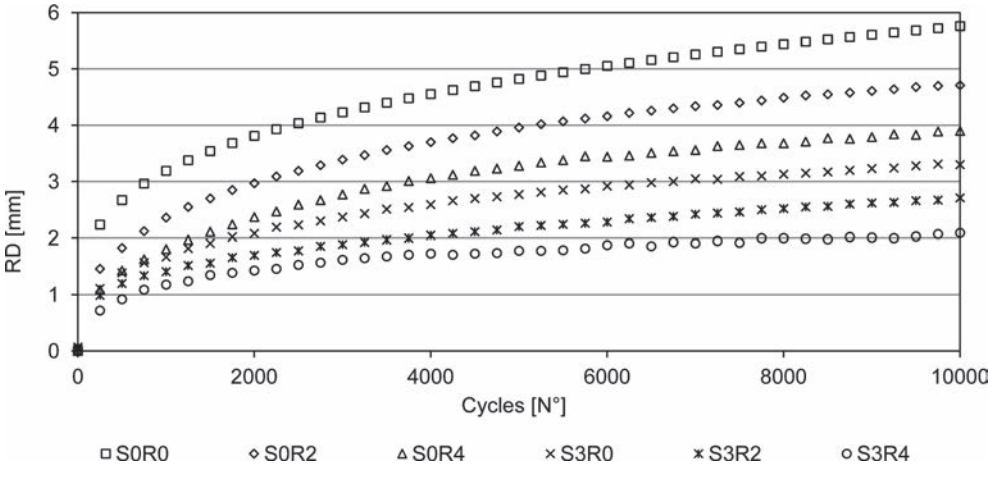

Figure 5. Permanent deformation curves by WTT.

Table 5 reports the permanent deformation for CRT and RLAT (unitary axial strain—ε_p), as well as for WTT (Rut Depth—RD), for each mixture; the Creep rate (for CRT and RLAT) and the Wheel Tracking Slope (for WTT) are also indicated. The Creep rate has been computed as the ratio between the cumulative axial strain in a defined range of load applications and the width of the interval (evaluated between 1,800 and 3,600 s for CRT; 1,800 and 3,600 cycles for RLAT). Similarly, the Wheel Tracking Slope (WTS) was determined as the ratio between the cumulative rut depth in a defined range of load applications and the width of such interval (evaluated between 5,000 and 10,000 cycles in the test period).

Given that the Standards in force provide no reference for defining the minimum value required for mixture's acceptance and that the permanent deformation tests are strongly influenced by the compaction technique, the results have to be evaluated in comparative rather than absolute terms, in order to identify, primarily, the influence of the marginal aggregates.

The asphalt concretes made with recycled aggregates showed lower permanent deformations, as well as lower Creep rate and WTS, than the mixtures with limestone, in all the tests (CRT, RLAT, WTT). The polyhedric shape, high angularity and rough texture of the EAF slag enhances the high internal friction and therefore a better densification condition of the base courses asphalt concretes, with a benefit for the resistance to permanent deformations. The integration of the RAP in the aggregate skeleton of the mixtures allows to substantially reduce the magnitude of the permanent deformations, as observed in all the tests, especially for the highest RAP content, namely 40%. The permanent deformation reduction of 33%

Table 5. Permanent deformation test results.

Mixtures	ε_p CRT [%]	Creep rate—CRT [microstrain/sec]	ε_p RLAT [%]	Creep rate—RLAT [microstrain/10^3 cycles]	RD [mm]	WTS [mm/(10^3 cycles)]
S0R0	0.559	0.022	0.626	0.020	5.77	0.198
S0R2	0.471	0.018	0.543	0.015	4.74	0.150
S0R4	0.422	0.013	0.500	0.014	3.88	0.124
S3R0	0.348	0.012	0.451	0.012	3.31	0.106
S3R2	0.305	0.008	0.414	0.011	2.70	0.102
S3R4	0.279	0.007	0.376	0.010	2.07	0.062

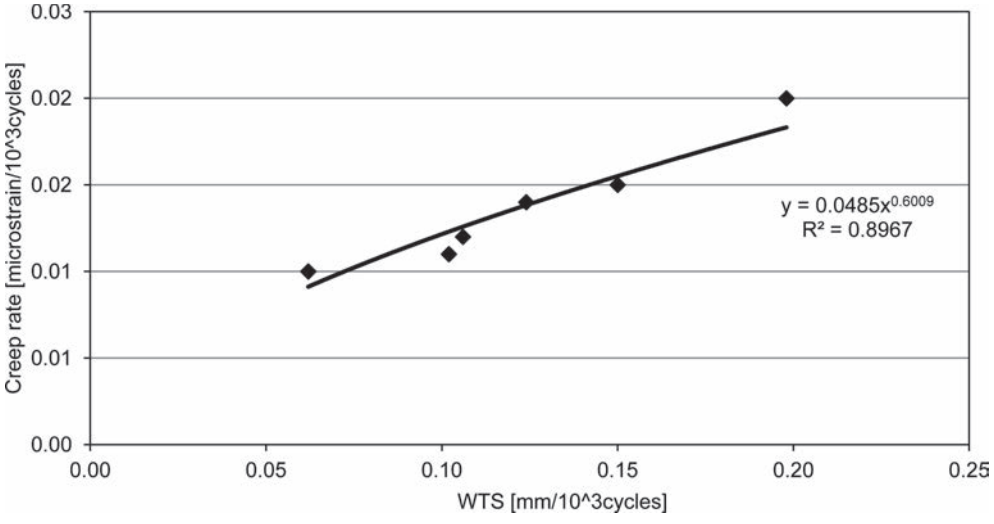

Figure 6. Correlation between the WTS and the Creep rate by RLAT.

recorded for the mix S0R4, with respect to the mix S0R0, is further increased for the mix S3R4 containing 30% EAF slags; in this case the rut depth recorded is less than half and the wheel tracking slope is about a third.

Even if Ozen et al. [14] have found a poor correlation between RLAT at 40°C and LCPC wheel tracking test at 60°C, for the mixtures investigated in this study it has been verified a satisfactory correlation between the Creep rate of the RLAT and the Wheel Tracking Slope of the WTT (Fig. 6), so confirming previous results of others researchers [11]. The data interpolation, by means a power function, gives good value of the coefficient of determination R^2 (0.89) and demonstrates a reasonable congruence between RLAT and WTT analysis, in spite of different test temperatures and stress level involved and the absence of confinement in the RLAT protocol adopted. However, further research and a larger data set are needed in order to formulate a conclusive judgment about the possibility to identify an effective correlation between RLAT and WTT data.

5 CONCLUSIONS

The marginal aggregates studied have shown physical-mechanical characteristics substantially equivalent to those of natural stone aggregates usually used in transport infrastructure construction and no hazardous leaching behaviour.

The experimental results are extremely satisfactory for all the mixtures made with marginal aggregates, especially for those prepared with RAP, in terms of both road technical acceptance requisites (Air Voids, ITS), and permanent deformation resistance.

The limited axial deformation registered during the Creep Recovery Tests and Repeated Load Axial Tests, lead to the conclusion that the RAP mixes have a little aptitude to develop excessive permanent deformations.

The Wheel Tracking Test, representative of loading conditions with slow channelled traffic at high temperature, has furtherly confirmed an extremely positive overall performance of the mixtures, in terms of rutting resistance.

The mixes with RAP and steel slags were characterized by low water damage, thus demonstrating a good durability.

Of the five mixes with marginal aggregates, S3R4, made with 30% EAF steel slags and 40% RAP, showed to be the best in all the mechanical and performance tests.

Effect of asphalt binder content and grade on transverse field cracking performance of Minnesota's Roadways

Eshan V. Dave, Chelsea Hanson & Benjamin Helmer
Department of Civil Engineering, University of Minnesota Duluth, Duluth, MN, USA

Luke Johanneck
Office of Materials and Road Research, Minnesota Department of Transportation, Minnesota, MN, USA

ABSTRACT: Cracking is a major distress mechanism in asphalt pavements. Thermal cracking is especially prevalent in Northern Minnesota and other areas with cold climates. Developing asphalt mix designs that are more resistant to cracking distresses is necessary to reduce maintenance and rehabilitation expenditures. The present study involves analysis of over 32,000 asphalt mixes and approximately 12,000 field sections available from Minnesota Department of Transportation (MnDOT).

The main objective of this work is to identify the effects of asphalt binder content and binder grade on the actual field cracking performance. A comprehensive database has been developed that includes mix design information (design traffic level, mix size, binder type, wear versus non-wear course), mix volumetrics and gradation (air voids, voids in mineral aggregates, voids filled with asphalt, adjusted asphalt film thickness, percent passing on control sieves, recycled fractions), and actual field performance data from MnDOT's pavement management system.

This database has made it possible to quantify the effects of binder content and grade on the actual field performance. A series of statistical tests were conducted to determine if significant relationships exist between the binder content and grade, and the field cracking performance. The results show that both binder content and grade have a significant effect on the transverse cracking of pavements and for Minnesota the PG XX-34 grade may be better suited than the PG XX-28 binder grade.

1 INTRODUCTION

One of the main causes of asphalt pavement degradation in cold climate regions, specifically in the northern United States and Canada, is transverse cracking [1,2]. This is caused by the pavements contracting when they are subjected to low temperatures. The asphalt concrete also becomes brittle as well during the cooling process. The combination of both the thermal contraction and embrittlement of the asphalt mixture lead to transverse cracks forming and propagating within the pavement structure. These cracks lead to decreased serviceability of the pavement to the public. Current asphalt mix design specifications are highly based on mix volumetric measures and require no laboratory performance test as a means to predict field cracking performance of asphalt mix designs [3]. A laboratory performance test to supplement existing asphalt mix design specifications is needed to improve the performance of asphalt pavements throughout their lifetime. Pavement performance data has also been used as a means to improve ways of predicting field performance of asphalt pavements and refining the mix design process [4,5].

Analysis of the effect of mix design parameters (asphalt film thickness, voids in mineral aggregate, asphalt binder grade) on field cracking performance is also an important aspect of improving asphalt pavement performance. Creating a comprehensive database that includes both mix design information and pavement performance data will allow for continued analysis of mix design parameter effects on asphalt pavement field performance in the future. This continued improvement will refine the mix design process and result in pavements with decreased transverse cracking.

2 DATA SOURCES

The data sources that were combined to construct a comprehensive database of asphalt mix design parameters and pavement field cracking performance were obtained from MnDOT's Office of Materials and Road Research (OM&RR). The data was received in the form of Microsoft Excel spreadsheets. Four primary data sources were available. These data sources are comprised of:

1. Mixture Design Reports (MDR)
2. Laboratory Information Management Systems (LIMS)
3. Pavement Management Systems (PMS).

2.1 *Data mapping*

The computer software program used in this study to compile and build the comprehensive database of both mix design parameters and field performance data was Microsoft Access. This software program allows for importing different sets of data, such as Microsoft Excel Spreadsheets, and combining or "linking" the multiple data sets together into one comprehensive database. The five data sources described previously are imported as "Tables" into Access. The combination of these tables into one Access file creates a comprehensive database. This newly formed database allows for vital information from different sources to be combined together in one list. This list of data can then be used for analysis. For this study, asphalt mix design parameters from the LIMS data source were combined with the field performance data for conducting statistical analysis.

The "linking" of data sources will be referred to as "data mapping" throughout the rest of the report. The records that are common across various data sets are used for "linking" them. These common records are referred to as "mapping parameters". These are the means by which multiple data sources are combined together to allow for specific information to be extracted from each source. They also allow for traversing throughout multiple data sets when looking for specific mix parameters or field performance quantities. Searches conducted within Access for certain parameters are referred to as queries. These mapping parameters can be seen in Table 1.

The focus of this paper will be the field cracking performance of asphalt pavements and the effect of mix parameters on this distress measure. A description of the mapping parameters used to extract this data can be found in the following text of the report.

Table 1. Mapping parameters related to different data sources.

Data source	Mapping parameter
Material Data Records (MDR)	MDR, Mix Design
LIMS Database	Project Number (SP), MDR, Mix Design
Pavement Management Systems (PMS)	Route Type, Route Number, Year, Pavement Section Reference Points
Geographic Information Systems (GIS)	Route Type, Route Number, Year, Pavement Section Reference Points, Project Number (SP)

3 FIELD CRACKING PERFORMANCE

The field cracking performance was expressed in the form of twelve different measures of transverse cracking. The scope of this paper is limited to the transverse cracking amounts.

3.1 *Calculation of field cracking performance measures*

The PMS data source contains all of the field performance (distress) data, specifically cracking performance of different pavement sections. Information pertaining to route types (Interstates, State highways, and US highways) and route numbers are included in this data source which contains 188 unique routes. The distress information includes transverse cracking, longitudinal cracking, rutting, raveling, patching, and longitudinal joint deterioration. Due to the main focus of this study pertaining to cracking of asphalt pavements, only transverse and longitudinal cracking were included in the statistical analysis phase, and only the transverse cracking results are included in this report. Inclusion of this data source into the database allows for the ability to track the effect of different mix design parameters on field performance of the pavement over several years. This data contains information recorded between year 2004 and 2011.

The transverse cracking data in the PMS data is collected based on the severity of the cracks, namely low, medium and high. For each severity level, the data is reported in terms of percent cracking (% cracking). Percent cracking is calculated as 2 times the number of cracks per 500 feet length of the survey section. For purposes of conducting a statistical analysis between amount of cracking and laboratory tests as well as asphalt mix parameters, a number of measures of field cracking performances can be calculated. In this study, the researchers looked at transverse cracking amounts in two primary ways: (1) total cracking; and, (2) total weighted cracking. Total cracking is sum total of low, medium and high severity cracks, whereas weighted cracking amount is arbitrary cracking amount with weight factors of 1, 2 and 4 applied to low, medium and high severity crack amounts.

The total cracking and total weighted cracking amounts for a given PMS section for each year of distress survey can be used to calculate additional cracking measures that are representative of field cracking performance. This paper includes the results pertaining only to transverse cracking rates and results. These measures for transverse cracking are described in Table 2.

3.2 *Data mapping with transverse field cracking*

For cracking distress data that was combined and analysed with mix design information, the PMS data source needed to contain a mapping parameter that is common with the LIMS data source. The PMS data source contains distress information, it is the only source of field cracking data in the comprehensive database. Without a common mapping parameter between the LIMS and PMS data sources, no analysis of cracking data with mix parameters could be conducted. An illustration depicting this linking of mapping parameters together is seen in Figure 1.

The combining of the PMS and GIS data made it possible to pair and extract transverse cracking distress data with its respective project number. This project number then was used to link this data with mix parameter data, which was needed to statistically analyse and investigate any relationships between the transverse cracking amounts and mix design parameters. This is shown in Figure 2.

3.3 *Statistical analysis and presentation of results*

Once the data was exported from the database, it was able to be input to the SAS software. The analysis that was run on the data was an LS Means analysis. This type of analysis allows for investigating effects of multiple variables. An LS Means analysis was chosen as the proper analysis to run on the selected data. The null hypothesis in the LS Means analysis

Table 2. Field cracking measures.

Measure	Description	Unit
Maximum Total Transverse Cracking Amount (MTCTotal)	Maximum transverse cracking amount (low + medium + high) of all survey years for a pavement section normalized against number of years for which pavement section has been in service.	% cracking/year
Maximum Total Weighted Transverse Cracking Amount (MTCWeighted)	Maximum weighted transverse cracking amount (low + 2*medium + 4*high)/6 of all survey years for a pavement section normalized against number of years for which pavement section has been in service.	% cracking/year
Maximum Total Transverse Cracking Rate (MTCRTotal)	Maximum increase in total transverse cracking amounts (low + medium + high) between any two consecutive years of service.	% cracking/year
Maximum Total Weighted Transverse Cracking Rate (MTCRWeighted)	Maximum increase in total weighted transverse cracking amounts (low + 2*medium + 4*high)/6 between any two consecutive years of service.	% cracking/year
Average Total Transverse Cracking Rate (ATCTotal)	Difference between maximum and minimum total transverse cracking amounts (low + medium + high) divided by number of years that pavement section has been in service.	% cracking/year
Average Weighted Total Transverse Cracking Rate (ATCWeighted)	Difference between maximum and minimum total weighted transverse cracking amounts (low + 2*medium + 4*high)/6 divided by number of years that pavement section has been in service.	% cracking/year

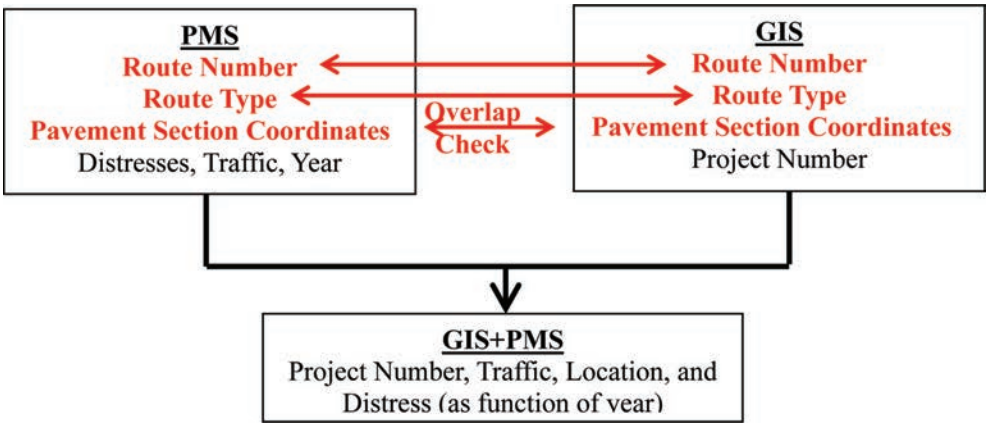

Figure 1. Linking and combining of PMS and GIS data sets in microsoft access.

is that the binder content and/or binder grade have no effect on the field cracking performance indicator (such as, MTCTotal). A p-value of > 0.05 indicates it can be said with 95% confidence that the null hypothesis is correct. A p-value of < 0.05 indicates that it can be said with 95% confidence that the null hypothesis is not true, and it can be rejected. This means that the binder content and/or binder grade does have a statistically significant relationship with field cracking performance.

To further investigate the effects of binder content and/or binder grade on the extent of transverse cracking, the data was converted to a normalized frequency. This was accomplished by first distributing the binder content in discrete intervals. Next, the data for all

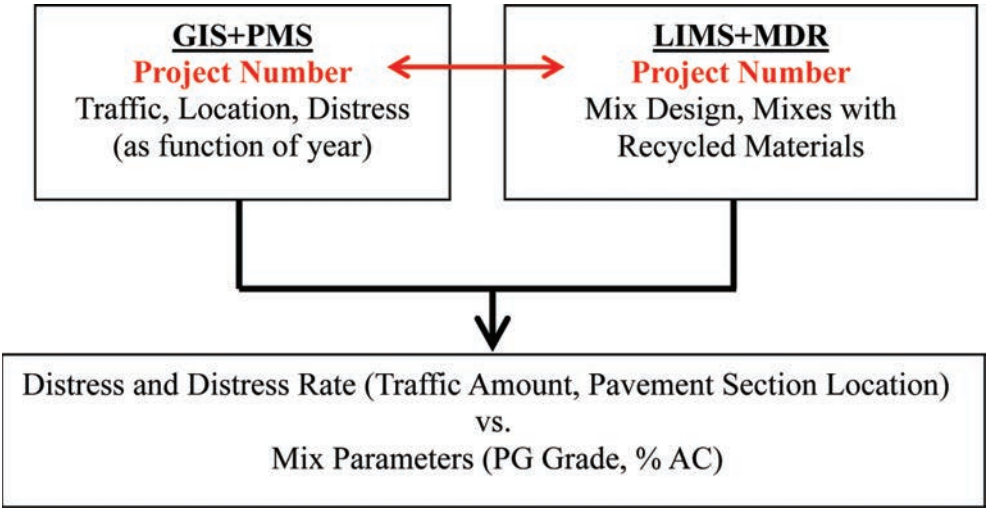

Figure 2. Linking and combining of PMS and GIS data sets to mix design parameter data.

pavement sections in each interval of binder content or each binder grade were analysed to determine the percent of sections that have no cracking (MTCWeighted of 0%/500 ft./year) and ones with cracking at 10, 20, 30, 40 and 50%/500 ft./year respectively. The database consists of very few pavements with cracking amounts above 50%, therefore cracking amounts above this percentage were not considered. Thereafter, the normalized frequencies for each of the cracking amounts were plotted for each interval of binder content and each binder grade.

4 TRANSVERSE CRACKING AND MIX DESIGN PARAMETER ANALYSIS

4.1 *Asphalt binder amount (percent binder)*

The asphalt binder contents were determined using chemical extraction and ignition oven methods. The binder contents were then used to determine their effects on the measures of transverse cracking. The statistical analysis for asphalt binder contents determined using both methods are presented in Table 3 and Table 4. The results show that irrespective of the measurement method, the asphalt binder content has significant effect on the amount of field cracking.

In order to further evaluate this effect, the MTCWeighted data was analyzed to determine the normalized frequencies. The normalized frequencies of the transverse cracking amounts for various ranges of asphalt binder contents are plotted in Figure 3 for chemical extraction and Figure 4 for ignition oven methods. In general, the results show a greater percent of pavements are free of transverse cracks for mixes with higher asphalt binder content. The data for mixes with greater than 6.0% asphalt binder content as determined using chemical extraction is the only outlier. The plots also show that the number of pavements with 20, 30 and 40%/500 ft./year cracking increase as the amount of asphalt binder in mixes decrease. Specifically, the asphalt mixes with binder contents between 4.0 and 4.5% represent almost 10% more pavements with 20 and 30%/500 ft./year cracking as compared to other mixes.

4.2 *Asphalt binder grade (PG, PGLT and PG spread)*

The asphalt binder grade (PG), the low temperature grading of the binder (PGLT) and the spread between the high and low temperature grading (PG Spread) information was used

Table 3. Effect of asphalt binder content (chemical extraction) on measures of maximum field cracking.

Cracking measure	*p*-value	Field cracking is related to percent binder?
MTCWeighted	<0.0001	Yes
MTCTotal	<0.0001	Yes
MTCRTotal	0.0005	Yes
MTCRWeighted	<0.0001	Yes

Table 4. Effect of asphalt binder content (ignition oven) on measures of maximum field cracking.

Cracking measure	*p*-value	Field cracking is related to percent binder?
MTCWeighted	<0.0001	Yes
MTCTotal	<0.0001	Yes
MTCRTotal	<0.0001	Yes
MTCRWeighted	<0.0001	Yes

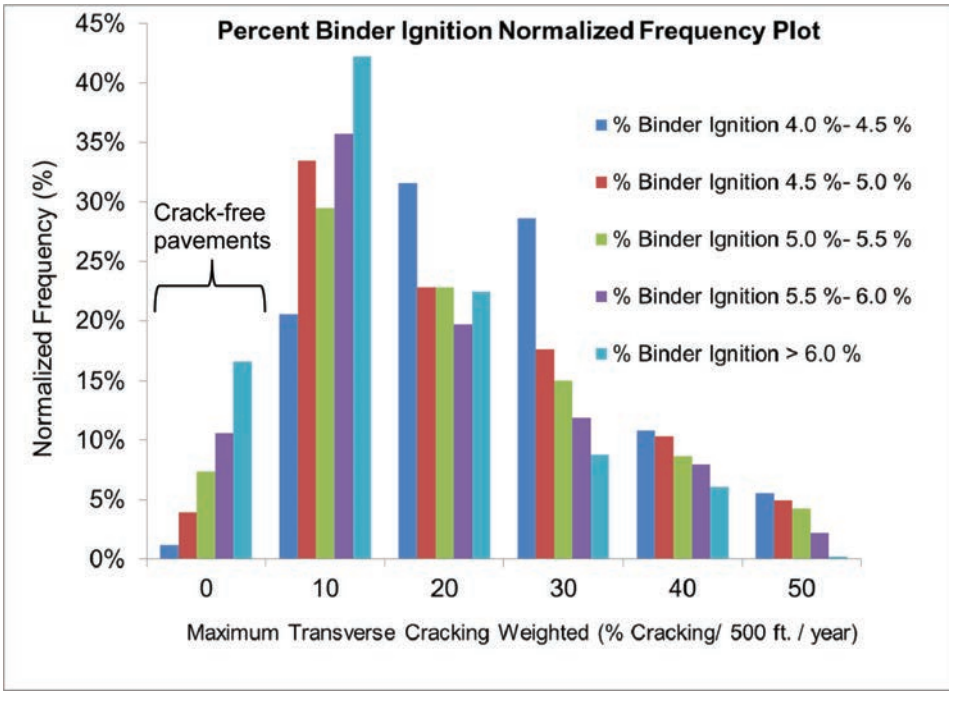

Figure 3. Normalized frequency plot of asphalt binder content (chemical extraction) with various ranges of weighted maximum transverse cracking amounts (MTCWeighted).

to conduct a statistical analysis. The results from the statistical analysis conducted to determine whether different field cracking measures depend on the asphalt binder grade and its derivatives are presented in Table 5, Table 6, and Table 7. The results show that the asphalt binder grade has a significant effect on the amounts and rates of transverse cracking.

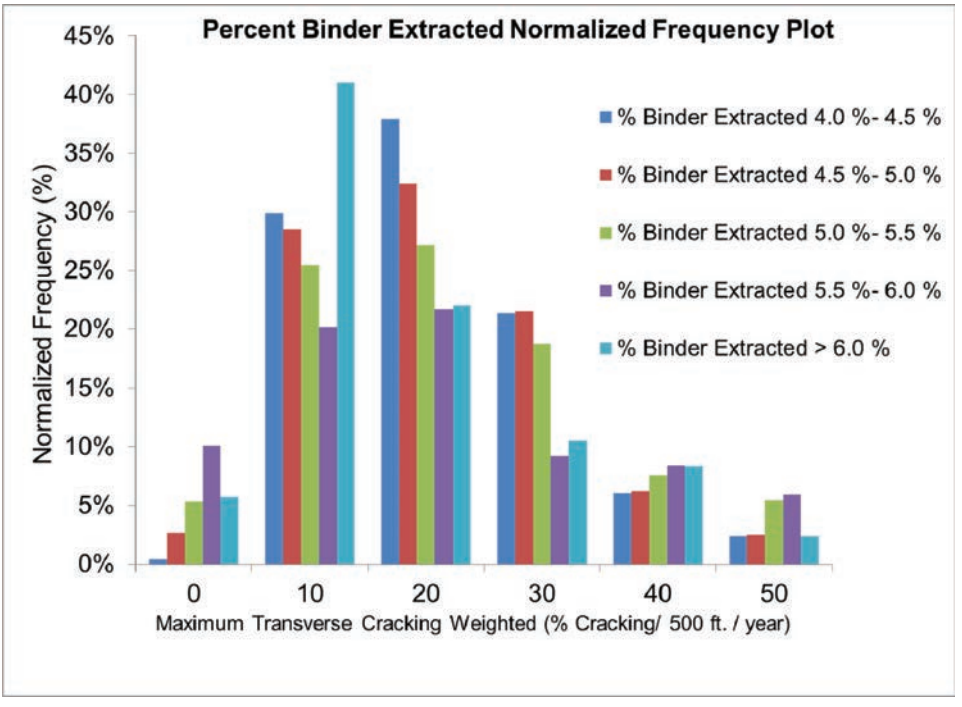

Figure 4. Normalized frequency plot of asphalt binder content (ignition oven) with various ranges of weighted maximum transverse cracking amounts (MTCWeighted).

Table 5. Effect of asphalt binder grade (PG) on measures of maximum field cracking.

Cracking measure	*p*-value	Field cracking is related to PG?
MTCWeighted	<0.0001	Yes
MTCTotal	<0.0001	Yes
MTCRTotal	<0.0001	Yes
MTCRWeighted	<0.0001	Yes

Table 6. Effect of asphalt binder low temperature grade (PGLT) on measures of maximum field cracking.

Cracking measure	*p*-value	Field cracking is related to PGLT?
MTCWeighted	<0.0001	Yes
MTCTotal	<0.0001	Yes
MTCRTotal	<0.0001	Yes
MTCRWeighted	<0.0001	Yes

Similar to analysis of previous mix parameters, in order to determine the effects of asphalt binder grade on the amount of cracking, the PGLT data was used to generate normalized frequencies of the maximum weighted transverse cracking (MTCWeighted). The frequencies are plotted for PGLT of –28 and –34 °C. These two were selected as a majority of pavements

Table 7. Effect of spread in asphalt binder grade (PG Spread) on measures of maximum field cracking.

Cracking measure	*p*-value	Field cracking is related to PG Spread?
MTCWeighted	<0.0001	Yes
MTCTotal	<0.0001	Yes
MTCRTotal	<0.0001	Yes
MTCRWeighted	<0.0001	Yes

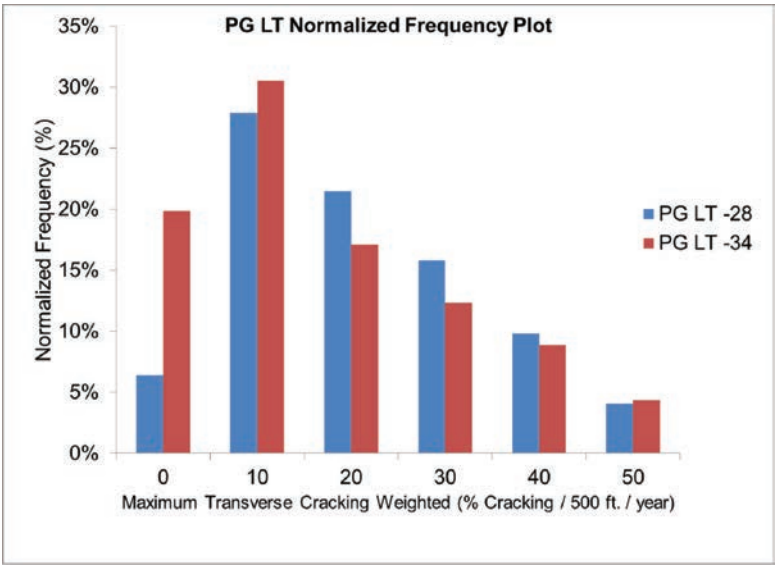

Figure 5. Normalized frequency plot of asphalt binder low temperature grade (PGLT) with various ranges of weighted maximum transverse cracking amounts (MTCWeighted).

in the database represent these types of binders. The results are plotted in Figure 5. The results show that a significantly greater amount of pavements are crack free when containing mix with PGLT of -34. Furthermore, a larger number of pavements with higher transverse cracking amounts (20, 30 and 40%/500 ft./year) have mixes with PGLT -28 binder.

5 CONCLUSIONS AND RECOMMENDATIONS

This study undertook task of combining various data sources corresponding to the asphalt mix designs and pavement performance that are available to Minnesota Department of Transportation into a single comprehensive database. The findings from this study resulted in several conclusions regarding the effects of mix design parameters on field cracking performance of asphalt pavements. The focus of this paper is on the evaluation of the effects of asphalt binder content and the asphalt grade on transverse cracking performance of the highways.

The key conclusions that can be drawn from the results presented herein are:

- The amount of asphalt binder, both calculated by means of chemical extraction and ignition oven, showed significant effect on transverse field cracking performance.
  - Mixes with higher asphalt contents corresponded to a greater percent of pavements with low transverse cracking. Specifically with pavements containing 20, 30, or 40 (%/ 500 ft./year), the cracking amounts are higher for with mixes containing low amounts of asphalt binder.

- The PG binder grade, PGLT, and PG Spread do have an effect on transverse cracking amounts.
  - Mixes with PGLT -34 have higher amounts of transverse crack free pavements as compared the mixes with PGLT -28. A higher amount of 20, 30, and 40 (%/ 500 ft./ year) cracking occurred for mixes with PGLT -28 binder.
- Asphalt binder grade has a significant effect on the pavement cracking performance. Mixes containing -34 asphalt binders have significantly greater amount of crack-free pavements as compared to mixes containing -28 binders. Fewer percent of pavements with significant amounts of transverse cracking are represented by mixes with -34 binder grades as compared to those with -28 binder grades.
- The amount of asphalt binder has a significant effect on field cracking performance. The mixes with higher asphalt content showed lower amounts of cracking.

Generating a comprehensive database and the subsequent statistical analysis in context of field cracking performance helped make several observations regarding future recommendations. The key recommendations from the research efforts of this study are as follows:

- The asphalt binder amount and grade play an important role in the cracking performance of bituminous pavements and overlays. The asphalt binder grade recommendations along with the potential for use of a minimum asphalt binder amount in the specifications should be reevaluated. The future tasks of the current project will provide additional information on this topic through field and laboratory evaluation of several pavement sections.
- The data analysis presented herein did not normalize the field cracking performance measured against the amount of traffic. The future data analysis should consider this effect to determine if the cracking amounts and rates are significantly affected by traffic level and whether the effects of mix design parameters on cracking are altered by the effects of traffic.

Temperature effects on Warm Mix Asphalt performance

Venon Jalali, James R.A. Grenfell & Andrew Dawson
Nottingham Transportation Engineering Centre, Department of Civil Engineering, The University of Nottingham, University Park, Nottingham, UK

ABSTRACT: Over the past few years, several Warm Mix Asphalt technologies have been developed to help lower asphalt production temperatures by up to 30°C. As part of this research, two different technologies were investigated; a wax additive using Sasobit and a chemical additive using Rediset LQ. The rheological behaviour of the base binders and the base binders with each additive was investigated over a range of temperatures using both a Dynamic Shear Rheometer (DSR) at lower temperatures and a rotational viscometer at higher temperatures. Then by performing the Dynamic Contact Angle (DCA) test using the Wilhelmy Plate apparatus, the effect of these additives was looked at in terms of the Surface Energy components of the binders.

Keywords: Warm Mix Asphalt (WMA); compaction temperature; rheology; surface energy

1 INTRODUCTION

Warm Mix Asphalt (WMA) refers to bituminous mixtures which are produced at temperatures approximately 25°C to 55°C lower than the typical production temperature of Hot Mix Asphalt (HMA) for the purposes of energy saving and lowering greenhouse gas emissions. However, as a replacement material for conventional HMA, WMA should have similar strength, durability and performance characteristics [1].

During the mixing, delivery or compaction processes, if the mixture's temperature drops below the minimum allowable production temperature at which adequate compaction can be achieved, then serious problems are expected. In the case of WMA mixtures, the effects of temperature decline on the properties of mixture may be more complicated than in HMA due to the presence of additives. This can refer to several factors such as the lower level of ageing in WMA binder due to the lower production temperatures, the effect of additives on the rheological, physical and mechanical characteristics of the binders, binder-aggregate adhesion properties and subsequently, the resultant mixture mechanical performance and properties [2].

The aim of this research is to study the effects and implications of temperature decline during mixing, delivery, placement and compaction phases on the mechanical performance of Warm Mix Asphalt along with the determination of the fundamental reasons for such performance changes.

2 MATERIALS IN USE

2.1 *Bitumen modifiers*

2.1.1 *Sasobit®*

Sasobit is a product of the Sasol Wax Company in South Africa. It is a crystalline, long chain aliphatic polymethylene hydrocarbon wax with a general formula of C_nH_{2n+2} whose carbon

chain length ranges from C_{45} to C_{100} plus. Sasobit results from coal gasification and is a by-product from the synthetic petrol production process called Fischer-Tropsch. Having a melting point of about 100°C, it can be totally dissolved in bitumen at above 115°C. Sasobit can be either in the form of a white powder or granules pills [3,4].

It is said that when added to the bitumen for producing WMA mixtures, it decreases the viscosity and improves the lubrication, both of which result in improving the mixture workability and compactability at temperatures lower than HMA [1,5]. According to the research of Liu et al. [5] adding 3% Sasobit to the binder can reduce the asphalt production temperature by 15°C.

When Sasobit cools down, it begins to crystallise at 110°C and below its congealing point, it forms regularly distributed, microscopic, stick-shaped particles. Such a crystallisation results in increasing the stiffness of the binder and the resistance against deformation. At service temperatures, Sasobit forms a lattice structure in the binder that provides stability for the mixture [6,7].

2.1.2 *Rediset® LQ 1102 CE*

Rediset LQ is a chemical Warm Mix Asphalt liquid additive which has recently been developed by AkzoNobel. It is said that it allows the production and compaction of asphalt pavements at temperatures typically 20 to 30°C lower than conventional HMA. The surfactants in Rediset LQ modify the properties of the binder in such a way that readily allows it to bond with the active sites on the aggregate surface. The surfactants also reduce the surface tension of the asphalt binder, which enables efficient coating of asphalt binder on the aggregate surface. This property enables the binder to readily coat the aggregate and eventually increases the workability of the mix and allows the mix to be more compactable at lower temperatures [8]. According to the producer, it will not change the penetration grade of the binder.

2.2 *Pure bitumen and modified binders*

The main neat binder used in this research was bitumen 70/100 pen made from blending 53.4% bitumen 160/220 pen with 46.6% bitumen 30/45 pen. The base neat binders which were used only in the case of supplementary tests were a 160/220 pen and 30/45 pen bitumen. The modified binders in the current research include Sasobit-modified and Rediset LQ-modified binders each of which have been produced by adding three different dosages of Sasobit (2, 3 and 10% of the weight of binder) and Rediset LQ (0.4, 0.5 and 0.6% of the weight of the binder) respectively to each of the three different neat binders.

The bituminous blends and modified binders have been prepared and made in accordance with BS EN 12594:2007 [9]. However, some modifications have been applied to the recommendations in bitumen sample preparation in terms of bitumen's heating temperature and time. Heating time and temperature for the modified binders have been considered the same as the base binder and not according to their softening point.

3 BINDER TESTS

In order to determine the physical, mechanical and rheological behaviour and behavioural characteristics of the binders and also to study the binding, coating and surface energy properties, a comprehensive matrix of laboratory tests has been devised and performed as shown in Table 1.

3.1 *Penetration grade and softening point determination*

The penetration grade and softening point tests were performed in accordance with BS EN 1426:2007 [11] and BS EN 1427:2007 [12], respectively, in order to have the basic physical characteristics of the binders and the effect of each additive and its dosage on the properties. The test specifications are as shown in Table 1 and the results are presented in Table 2. It can

Table 1. Binder testing matrix.

Test	Standard name	Standard no.	Test device	Description
1. Pen grade determination	Determination of needle penetration	BS EN 1426: 2007 [11]	Penetrometer	Test temperature = 25°C
2. Softening point determination	Determination of the softening point-ring and ball method	BS EN 1427: 2007 [12]	Ring and ball aparatus	N.A.
3. Brookfield viscometry	Determination of dynamic viscosity of bituminous binders using a rotating spindle apparatus	BS EN 13302: 2010 [13]	Brookfield viscometer	Temperature swept from 90°C to 180°C with 10°C intervals, meter reading = (50 ± 10)% spindle size = SC4-34
4. Bitumen wax content	Determination of the paraffin wax content-part 1: method by distillation part 2: method by filtration	BS EN 12606-1: 2007 [16]	Standard laboratory distillation and filtration setup	N.A.
5. Brookfield viscometry	Test methods for viscosity determinations of unfilled asphalts using the brookfield thermosel apparatus	SUPERPAVE ASTM D4402 [14]	Brookfield viscometer	Temperature swept from 90°C to 180°C with 10°C intervals, rotational speed = 20 rpm shear rate = 6.8 s^{-1} spindle size = SC4-27
6. Frequency-temperature sweep	Determination of complex shear modulus and phase Angle-Dynamic Shear Rheometer (DSR)	BS EN 14770: 2012 [17]	Bohlin's CVO Dynamic Shear Rheometer (DSR)	Frequency swept from 0.1 Hz to 10 Hz over the temperature range of 10°C to 75°C with 10°C intervals
7. DCA	Dynamic contact angle measurement	[18]	Wilhelmy plate	Test temperature = 23°C ± 2°C

be seen that while adding Rediset LQ has nearly no effect on penetration grade and softening point of the binders, adding Sasobit significantly increases the softening point and decreases the penetration grade.

3.2 *Brookfield viscometry test*

In order to study the effect of the additives on the rheological behaviour of the binders, Brookfield viscometry tests have been performed on the binders over the temperature range of 90°C to 180°C. This was done to investigate the viscosity of the binders at high temperatures and to study the changes in binder rheology in the presence of the additives around the mixing and compaction temperatures. It was also done to justify or find the correct production temperature of the WMA.

The Brookfield viscometry test in this research was performed twice, based on two different Standards, BS EN 13302:2010 [13] and ASTM D4402 [14]. The reason for this has been the considerable difference between the results of the test based on BS EN 13302:2010 [13] for the Sasobit-modified binders, with those of the NCAT Report 05-06 [3], Yero et al. [15] and Liu et al. [5], which had been done in accordance with the ASTM Standards.

BS EN Standards validate choosing any rotational speed (rpm) for the spindle at which the meter reading remains between 10% and 100%. In the current research, BS EN-based Brookfield viscometry has been performed by using spindle SC4-34. At each temperature,

the rotational speed was set to the value at which the meter reading stays between 10% and 100% with the preferred value of about (50 ± 10)%. However, SUPERPAVE (ASTM) recommends using spindle SC4-21 or SC4-27, rotating at a speed of 20 rpm to apply a shear rate of 6.8 s^{-1}. In this research the SUPERPAVE-based Brookfield viscometry has been performed using spindle size SC4-27.

From the test results, it can be observed that just after Sasobit's melting temperature (transition point), the viscosity of the modified binder drops and the viscosity curve shifts down afterwards. However, it seems that at the temperatures lower than the transition point the crystallisation phenomenon in the wax structure results in an increased viscosity of the binder. As can be seen in Table 3 and Figures 1 and 2, according to the Brookfield viscometry test results performed based on BS EN 13302:2010 [13], the viscosity of the 70/100 pen bitumen was not reduced as much as it could reduce the mixing and compaction temperature by 25°C as promised in NCAT Report 05-06 [3] or even by 15°C as shown by Liu et al. [5]. Even increasing the dosage of Sasobit up to 10% by the weight of the binder and also performing the test on both the 30/45 pen and the 160/220 pen binders did not show the promised level of reduction in the viscosity of the binders.

Therefore, in order to make sure about the repeatability of the results, the test was repeated again but this time, based on ASTM D4402 [14]. However, referring to the results of ASTM-based Brookfield viscometry test, as shown in Table 4 and Figures 3 and 4 it can be seen that using 3% Sasobit can decrease the mixing and compaction temperature by up to 10°C which is still less than the amount reported in the NCAT Report 05-06 [3], work by Liu et al. [5] and as promised by the producer.

It seems that according to the results, the ASTM-based Brookfield viscometry should be more reliable. The reason for such a difference in the test results could be due to the greater turbulent flow of the bitumen between the inner wall of the apparatus cup and the surface of the spindle in the BS EN-based test. Due to the greater gap between the inner wall of the cup and the surface of the spindle in the BS EN-based test compared to the ASTM-based test, the rotational flow of bitumen around the spindle will be less laminar and more turbulent at high temperatures and rotational speeds. This turbulent flow can result in applying some additional unwanted friction on the surface of the spindle and therefore show a greater value of the binder viscosity than it really is.

For the Rediset LQ chemical additive, nearly no effect on the viscosity of the binder can be seen, which was expected from the specifications according to the material producer.

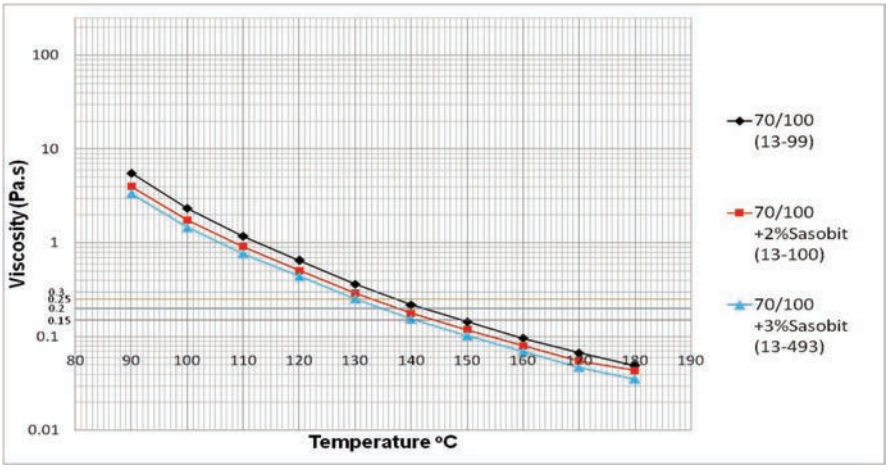

Figure 3. ASTM-based brookfield viscometry test results (Sasobit-modified binders).

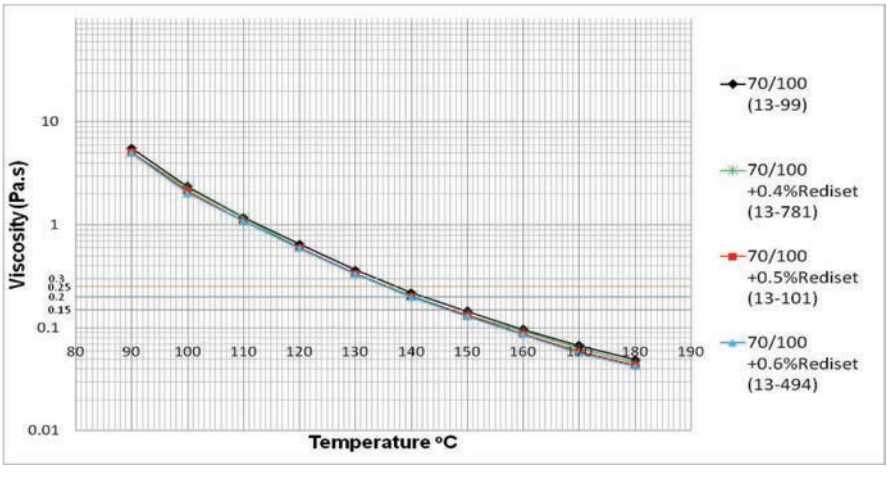

Figure 4. ASTM-based brookfield viscometry test results (Rediset LQ-modified binders).

3.3 *Bitumen wax content test*

In order to understand these differences, the Bitumen Wax Content test was performed on the base binders in accordance with BS EN 12606-1:2007 [16], because it was predicted that the bitumen might have been already waxy and adding more wax to the existing amount in the bitumen might have no significant effect. In the other words, bitumen samples might have been waxy, themselves, therefore, decreasing their viscosity sensitivity to the extra wax content. However, the Bitumen Wax Content test showed that the base bitumens were non-waxy types. As they contained no more than 0.06% and 0.02% of Paraffin wax for the 160/220 pen and 30/45 pen, respectively.

Thus, the unexpected results (small decrease in the viscosity of the modified binders compared to their neat bitumen) of Brookfield viscometry test might have been because the bitumen samples had nearly no wax initially and originally. Eventually, the added Sasobit (wax) might have been consumed by the non-waxy bitumen to increase its wax content to a normal balanced level.

To check this theory, it was necessary to add more Sasobit to modify the pure bitumen samples and 10% Sasobit-modified binders were produced. However, performing the same

Brookfield viscomety test on the 10% Sasobit-modified bitumen grades did not result in any significant decrease in the viscosity of the binders.

3.4 *Frequency-temperature sweep test*

The mechanical properties of the binders were studied by investigating their rheological behaviour by performing the Frequency-Temperature Sweep test using a Dynamic Shear Rheometer (DSR) over a range of different temperatures (5°C to 80°C) and frequencies (0.1 Hz to 10 Hz). The test was performed in accordance with BS EN 14770:2012 [17]. It should be mentioned that the rheological behaviour investigations have been carried out for two main reasons. Firstly, to study the mechanical properties of the binder itself in the presence of additives at different temperatures and loading frequencies and secondly, in order to have sufficient fundamental support to analyse and interpret the mechanical behaviour of the

resulting mixtures at the operating temperatures. This will also allow linking the behaviour of the mixtures to the mechanical properties of their corresponding binders at the mixing and compaction temperatures at which the mixtures mechanical behaviour will be formed.

The Frequency-Temperature Sweep test, which has been characterised in Table 1, has been performed in strain-controlled mode applying a maximum strain value of 0.5%, 0.4% and 0.3% for 0%, 2% and 3% Sasobit-modified binders respectively to remain within the Linear Visco-Elastic Region (LVER). For the Rediset LQ-modified samples, the LVER has been set to the same value as for the neat binder. The results of the Frequency-Temperature Sweep tests are shown in Figures 5 and 6.

From the test results, it can be concluded that adding Sasobit increases the complex shear modulus (G*) and decreases the phase angle of the binders, while the Rediset LQ has nearly no effect on the parameters.

Adding 3% Sasobit to the 70/100 pen bitumen increases its complex shear modulus by nearly 8 times at about 10°C and 1.5 times at about 75°C. Adding 2% Sasobit has increased the complex shear modulus by about 3 times at 10°C and nearly 1.5 times at about 75°C.

3.5 *Dynamic Contact Angle test (DCA)*

This test has been performed to find out the changes in the values of the Surface Energy (SE) components of the binders, which may be caused by the additives. The measured values, when combined with the ones of aggregate, will be used to calculate the Bonding Energy. This is used to evaluate the work of adhesion when combined with aggregates and also to calculate the work of de-bonding in the presence of water in order to estimate the moisture sensitivity of the resulting mixtures.

Also, according to the Brookfield viscometry test results, as the viscosity issue may not be the only factor which is affected by Sasobit, the DCA test has been performed to find out the reasons why a lower production temperature of WMA can be used when Sasobit is added. Therefore, it is predicted that Rediset LQ should change the surface tension of the bitumen if it has no effect on the rheological issues such as viscosity.

The DCA test has performed using a DCA Analyser apparatus (Wilhelmy Plate method) according to NTEC laboratory protocol [18]. In order to increase the precision of the results, five slides per binder sample were prepared to perform the test by the use of three different probe liquids: water, glycerol and di-iodomethane. The test results and data can be found in Table 5.

Referring to Table 5, the relatively high value of the γ^{LW} component, which is representative of the Van der Waals non-polar interaction forces, confirms that the tested neat bitumen is basically a non-polar material as it naturally is. However, in contrast with the slightly acidic behaviour which is normally expected from any neat bitumen, the higher value of γ^- (basic component) compared to γ^+ (acidic component) indicates that the neat bitumen is slightly basic in nature. This means that this bitumen can give better adhesion if it is used with acidic aggregates (e.g. Granite).

In the case of the Sasobit-modified binders, it can be observed that adding Sasobit has decreased the non-polar component as well as the basic characteristics of the modified binder in comparison with the neat bitumen. At the same time it increases the acidic component of SE which can result in a better adhesion of the Sasobit-modified binders with a basic aggregate (e.g. Limestone).

According to the results reflected in Table 5, Rediset LQ has not changed the non-polar component of SE significantly. However, it has considerably decreased both γ^+ and γ^-, which can result in a better moisture resistance.

4 CONCLUSIONS

- While adding Rediset LQ has nearly no effect on the Penetration Grade and Softening Point of the binders, adding Sasobit significantly increases the Softening Point and decreases the Penetration Grade.

- According to the Brookfield viscometry test results which was performed based on BS EN 13302:2010 [13], the viscosity of the 70/100 pen bitumen was not reduced as much as it can lower the mixing and compaction temperature by 25°C as promised in the NCAT Report 05-06 [3] or by 15°C as shown in Liu et al.s research. Increasing the dosage of Sasobit up to 10% by the weight of the binder and performing the tests on the both base bitumen grades did not show the promised significant reduction in the viscosity of the binders.
- The results of ASTM-based Brookfield viscometry test showed 3% Sasobit can decrease mixing and compaction temperature by up to 10°C which is still less that the amount reported in NCAT Report 05-06 [3], the research of Liu et al. [5] and promised by the producer.
- Rediset LQ chemical additive has nearly no effect on the viscosity of the binder, which was expected from the specifications of the manufacturer. In fact, this additive, has nearly no influence on the rheological and mechanical properties of the binder.
- Adding Sasobit increases G* and decreases the phase angle of the binders while Rediset LQ has nearly no effect on the mentioned parameters.
- Adding 3% Sasobit to 70/100 pen bitumen increases its complex shear modulus by nearly 8 times at about 10°C and 1.5 times at about 75°C. Adding 2% Sasobit increased the complex shear modulus by about 3 times at 10°C and nearly 1.5 times at about 75°C.
- Adding Sasobit decreases the non-polar component as well as the basic characteristics of the modified binder in comparison with the neat bitumen. It also increases the acidic component of SE which can result in a better adhesion of the Sasobit-modified binders with a basic aggregate (e.g. Limestone).
- Rediset LQ does not affect the non-polar component of SE significantly. However, it has considerably decreased both γ^+ and γ^-, which can result in a better moisture resistance.

5 FUTURE WORK

Mixture compaction trials will be carried out for the different binder compositions over a range of temperatures to investigate the effect of temperature reduction on the compacted material properties. Stiffness, fatigue, rutting and water sensitivity tests will be performed in order to characterise the mechanical properties of the resulting mixtures which will be mixed at recommended mixing temperature and compacted at a number of temperatures lower than the recommended compaction temperature.

Binding/coating quality of the mixtures and also the post-failure structure of the tested mixtures will be observed through SEM or X-Ray CT to support the mechanical test results.

Finally, it is planned to develop approaches and guidelines to improve the mechanical deficiencies and reduce the potential distresses resulting from the time delay and temperature decline between mixing and compaction.

ABSTRACT: The warm asphalt mixture process using foam asphalt technology allows mixing and compaction at lower temperature. Nevertheless the higher air void content and incomplete coating of large aggregates are issues that need improvement to reach the properties of hot mix asphalt. In order to improve the understanding and characterization of the bitumen foam, X-ray radiography was used to investigate the formation and decay of bitumen foam in 2D representation. Image segmentation analysis was used to determine the foam bubble size distribution as a function of time. The impact of water content on the process has been studied for two penetration grade bitumen. The water content showed considerable influence on the foam quality in terms of expansion ratio and bubble size distribution. Increasing the water content in the foaming process leads to a quicker collapse of the bubbles and favors coalescence of individual bubbles.

Keywords: Foamed bitumen, expansion ratio, half-life, X-ray radiography, image segmentation analysis

1 INTRODUCTION

Foamed asphalt technology, which allows lower mixing temperatures, has been used successfully in many countries. Energy saving, decreased emissions of fumes and odor, extending the paving season, compaction aid for stiffer mixes … etc., are main advantages of the foam asphalt (warm mix asphalt) over the conventional hot mix asphalt. Foam asphalt produced at ambient temperature needs improvement to reach the properties of hot mix asphalt for heavy duty roads. Higher void content and incomplete coatings of large aggregates are the main reasons for its lower performance. Foam bitumen is a mixture of air, water and bitumen. It is produced through the injection of small quantities of water typically 1–6.0% regarding the mass of the

bitumen into hot penetration grade bitumen (160–180°C) in an expansion chamber. The bitumen expands to about 5–15 times its original volume [1] and forms a foam, which is highly efficient in wetting and coating the surface of fine particles [2]. As the foam collapses most of the water is lost in the form of steam, leaving residual bitumen with properties similar to the original bitumen [3]. The time that the expanded bitumen takes to settle to half its expanded volume is called the half-life, τ [4]. The half-life is used to explain the stability of the foam bitumen in general. The desirable value of the half-life is difficult to determine since the addition of water varies the half-life. The Expansion Ratio (ER) is determined by taking the ratio of expanded volume in the foamed state to the non-foamed volume of bitumen in the container.

Foam bitumen allows to construct asphalt pavements at reduced temperature in terms of mixture production, transport, laying and compaction [5]. Reducing production and compaction temperatures by using WMA (Warm Mix Asphalt) in place of HMA (Hot Mix Asphalt) is environmentally beneficial since it decreases fuel or energy consumption, reduces emissions of CO_2 and reduces smoke from mixing plant and improves working conditions at the paving site [2, 6].

Foams may be classified as dry or wet depending on the liquid (bitumen) content, which is represented by the liquid volume fraction *f*. The amount of liquid may range from less than 1% to about 30% [7]. These characterizes only about the foamability of liquid foam (two-phase systems) in general. The higher the gas fraction the better the foamability. In the dry foam the films forming the interface between bubbles are not spherical since these bubbles are made of polyhedral cells [8].

Coarsening is a change of bubble morphology which mainly occurs in two way: by the rupture of the film between two adjacent bubbles or cells and or by gas diffusion driven Ostwald ripening [9]. The rupture of thin films is related to the drainage (redistribution of liquid) and stability of foam films [7], whereas the Ostwald ripening is caused by inter-bubble gas diffusion by which liquid foam comes in to thermodynamic equilibrium, where one large bubble is energetically more favorable than two smaller bubbles [10]. Because of the above mentioned processes, bubbles smaller than the average size shrink, while large bubbles become larger resulting in an increase of the average size of the bubbles over time [11].

Usually foam bitumen is characterized by two empirical parameters called expansion ratio and half-life. The two parameters only describes the volumetric property of the foam bitumen. However the relation of these parameter to foam properties, such as foam morphology, bubble size distribution, drainage, coarsening, … etc. remained still unclear due to the difficulty to study the unstable foam and its black color. Usually expansion ratio and half-life are determined using a foam ruler. However, foam bitumen is very unstable when foamed at higher water content and the measurement of the expansion using the foam ruler can be inaccurate.

Moreover, the rheology and stability of the foam are mainly depending on the foam's bubble size distribution and gas liquid fraction [12]. To determine the growth rate of bubbles in dry foam, the bubble size and shape are crucial. For wet foam the influence of the bubble shape is less significant since the bubble shape are expected to be more spherical [7]. Hence, determination of the bubble size distribution in foam is crucial for a better understanding of the foam properties and the stability of the foam. However, there is no work on how the foam bitumen is formed during the foaming process, how it changes with time and which mechanisms are responsible for this. The present paper intends to help in closing this gap.

The main objective of the study is to characterize the morphology of foam bitumen bubbles and the evolution of bubble size distribution with time during the foaming process for different foam bitumen parameters using X-ray radiography analysis. Hence, the influence of the water content and bitumen temperature on two different types of penetration grade bitumen has been studied.

2 EXPERIMENTAL METHOD

The foam bitumen was produced using a WLB10S lab foamer. To study the dynamic process of foam formation and decay, a special X-ray setup has been constructed. The idea was to cre-

ate a 2D cross-section through a container that is filled with foam. As shown in Figure 2(a), between X-ray source and detector, a test box was placed according to the field of view required for the experiment. The test box consisted of two parallel plate produced from a wooden frame and covered with silicon coated paper, having a size of 297 × 210 mm × 10 mm. An extension pipe made of fiber reinforced plastic, having internal diameter of 8 mm and length of 2000 mm was connected to the outlet nozzle of the lab foamer to take the foam bitumen in to the test box.

Both horizontal and vertical axis of the X-ray field of view had a resolution of 205 µm. The images were taken at 14.7 frames/s. The study was done for two types of bitumen of different origin. Bitumen A (supplied from Nynas, Germany) had a penetration value 80*0.1 mm and softening point of 45.3°C and the other harder bitumen type B (supplied from Grisard AG, Switzerland), had a penetration of 51*0.1 mm and softening point of 51.1°C.

Influence of the water content was investigated for 1 and 4% water content (W.C.) by weight of the bitumen in combination with 160°C foaming temperature as shown in Table 1.

Analysis of bubble size distribution was done for each experiment at three particular characteristic moment of time as shown in Figure 1, which includes

1. The time when the foam is close to maximum expansion, h_{max}. This corresponds to 4.2 s starting from the time of spraying.
2. The time at half of the expansion height, $h_{max}/2$; in this case the moment of time depends on the expansion height, i.e. the value is different for all different kinds of foaming conditions.
3. The time at the end of the decaying process, this time frame also depends on the water content and temperature of the bitumen.

As shown in Figure 2 (b) the total field of view of the X-ray was 195 mm*176 mm. In a single experiment hundreds of images were taken, since there is a limitation on showing all the results specific points selected. A rectangular section of 164.0 mm by 57.4 mm for foam analysis at the bottom of the images for analysis of bubble size distribution with time. In some cases the maximum expansion height of the foam was measured using a ruler at the end of the experiment, since the foaming height was above X-ray field of view. Zero time corresponds to the starting of the spray, when the foam comes out of the extension tube.

Table 1. Experimental plan.

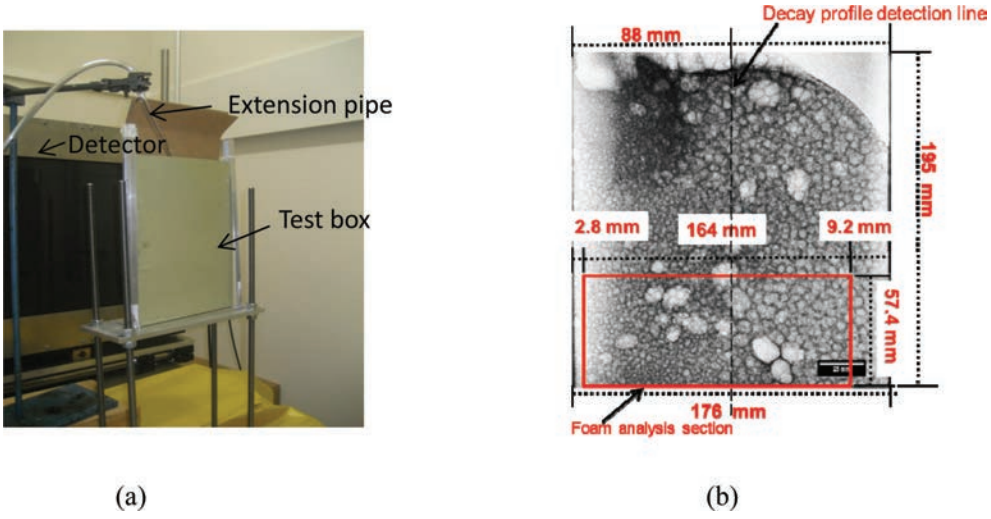

Figure 2. (a) Foam bitumen X-ray setup (b) X-ray analysis section, image at 5.2 s for 1% W.C at 160°C bitumen temperature for bitumen type "A".

3 DATA ANALYSIS

For the characterization of the bubble size distribution, an algorithm was developed using Matlab to perform image segmentation and bubble detection. Image thresholding was applied to find the boundary of the vapor and bitumen phase. Defining the boundary of bitumen and vapor was not trivial in the image segmentation due to possible overlapping of the bubbles as well as the noise from the X-ray measurements. After confirming the detection of possible bubbles from image segmentation, each bubble was counted and numbered from left to right within the image analysis section. For bubble detection, the minimum bubble size for image segmentation was set to 0.2 mm^2 which corresponds to approximately five pixels. Bubble sizes below this limit were not considered in this analysis.

4 RESULT AND DISCUSSION

4.1 *Influence of the water content on foamed bitumen bubble size distribution*

The foam bitumen decay profiles shown in Figure 3 (a) and (b) were determined by taking a cross section at the center of the field of view as indicated in Figure 2 (b) using "Fiji" image analysis software. As it is expected increasing the water content leads to higher expansion height for both investigated bitumen as indicated in Figure 3 (a) and (b). The expansion height was higher for the softer bitumen "A" compared to the harder bitumen "B" for the same water content. The pressure produced by water vapor inside the bubbles is counter balanced by forces of the thin film of each bubble, which has a direct relation to surface tension and viscosity. Hence for the same amount of water content, bitumen "A" has a higher expansion due to its lower viscosity and surface tension.

In order to understand the influence of the water content on the morphology of bubbles, 1% W.C. and 4% W.C. at 160°C foaming temperature are compared for bitumen "B" as shown in Figures 4 and 5. Enormous polydispersity of bubbles was observed during the foaming process as indicated in Figure 4 (a) and the coarsening continued even for longer period. The main destabilization mechanism of foam with viscous liquid matrix in the wet condition is coarsening [10, 13]. In the case of bitumen "B" it is found that the major decaying or destabilizing mechanism was coarsening and bursting of bubbles at the foam bitumen surface. Coarsening is caused by rupture of films between two adjacent bubbles. In addition

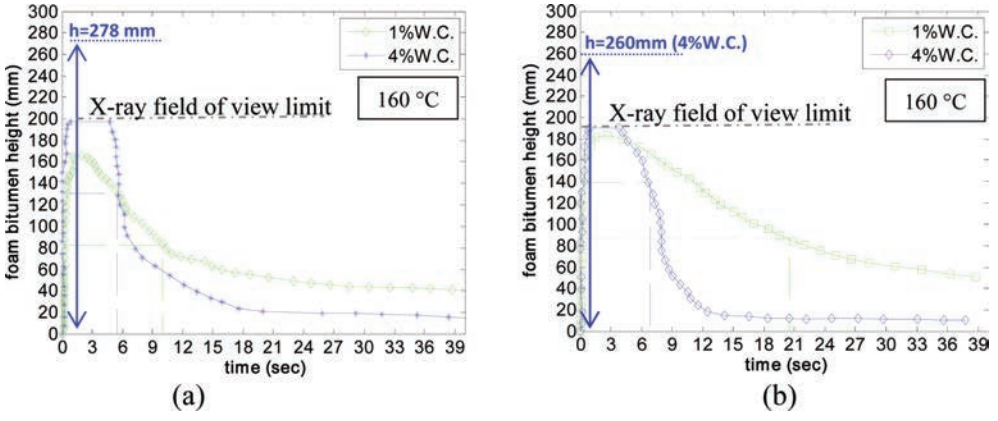

Figure 3. The foam bitumen height in the parallel plate during the decay process (a) bitumen "A" (b) bitumen "B" in the field of view.

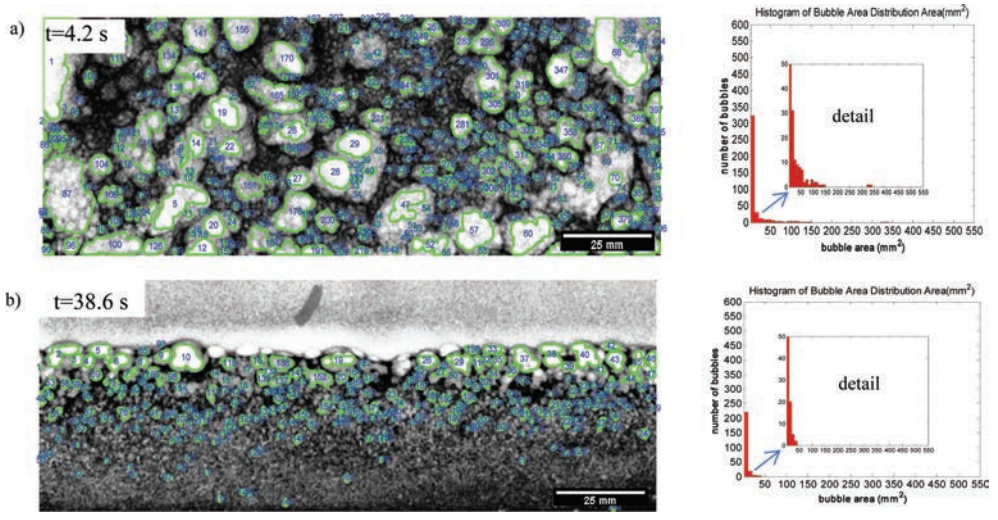

Figure 4. Foam bitumen bubble size distribution in the foam analysis section at different decay times, t_1 and t_3 (1% W.C., Bitumen "B", 160°C Temperature).

to this redistribution of the gas in bubbles, such as Ostwald ripening can cause coarsening [14]. Because of the polydispersity of foam bitumen, pressure difference between the inside and outside of the bubbles surface; a consequence diffusion of vapor occurs during the decaying process, hence Ostwald ripening can cause coarsening as well.

The surface energy which is proportional to the interaction surface area of the bubbles enables the individual bubbles to take up shape minimizing the surface energy [13]. Moreover, the surface tension tends to minimize the contact surface of bitumen and vapor, which leads to quicker coarsening. Increasing the viscosity and minimizing the surface tension plays a big role in stabilizing the foam and reducing the quick collapse of foam [12, 15]. Therefore, high surface tension can be one of the reasons for the quick collapse of bitumen "B". The surface energy of the foam will decrease with time as the foam decays.

Rising of the bubbles to the surface, in addition to subsequent drainage causes creaming [13]. This is also true in the case of bitumen type "B" where drainage of liquid bitumen from relatively dry zone of foam bitumen, near the surface towards the wet region was observed at the end of decaying process as shown in Figure 5 (b). The variation of liquid (bitumen) con-

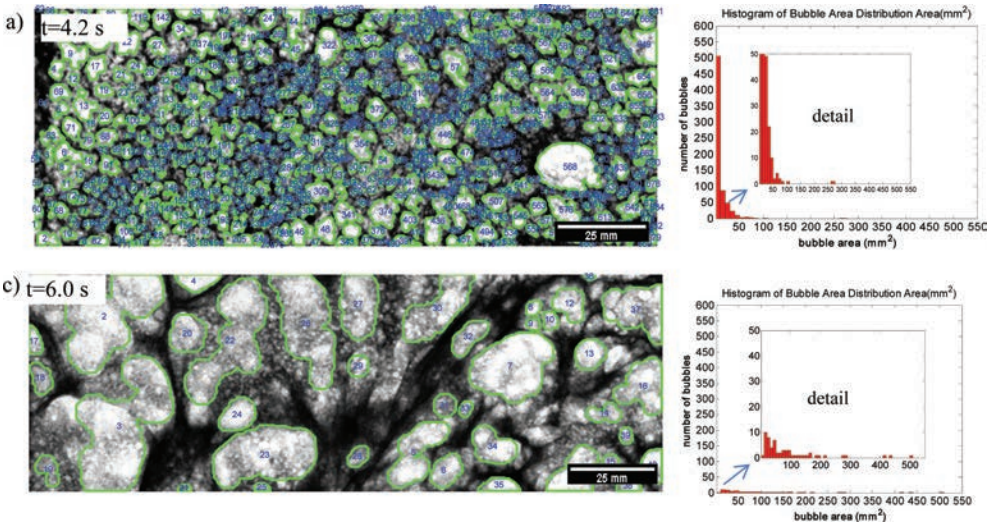

Figure 5. Foam bitumen bubble area distribution at different decay times, t_1 and t_3 (4% W.C., bitumen "B", 160°C temperature).

tent from the top surface to the bottom creates a density profile that helps the foam to remain in equilibrium under gravity [13]. During the experiment the sequence of images showed that liquid bitumen drained through the plateau borders during the decay process.

In the case of 4% W.C. the polydispersity of the bubbles is also significant, as shown in Figure 5 (a) and (b). The bubbles become larger and fewer during the decay process due to coalescence, triggered by excess pressure from the foam producing water. This made the 4% W.C. foam less stable compared to 1% W.C. as indicated in Figure 3 (b). Since heat exchange occurs between water and bitumen during the foaming process, more energy is required to evaporate the water. Hence, increasing the water content decreases the temperature of foam in general, therefore the viscosity of the bitumen will increase even at the beginning of the foaming process. The increase of the viscosity minimized the creaming effect compared to the foam with 1% W.C. Nevertheless the excess pressure from higher water content produces vapor that leads to quick collapse.

As presented in Figure 6 (a) and (b), for these characteristic moment of time the cumulative number of bubbles in percentage are plotted from the histograms. The cumulative bubble size distribution in Figure 6 (a) indicated that less water content produce smaller bubbles. In the case of 1% W.C. for bitumen type "A", the number of smaller bubbles (0.2–10 mm^2) decreased immensely during the decay process and the number of larger bubbles increased. This indicates the growth of smaller bubbles over time during the decay process. In the case of 4% W.C. the bubbles size distribution change was less after the half of the expansion height. For instance the number of smaller bubbles at 6.9 s (half of the expansion height) was comparable to the 9.6 s (one fourth of the expansion height). From observation during the experiment drainage of bitumen within this time range was less compared to bitumen "B" shown in figure 4(a), rather the bubbles were growing and coarsening due to surface tension effect. In addition fast coalescence was observed during the decay process. As shown in figure 6 (b), the influence of the water content on the bubbles size distribution at the beginning of the foaming process (4.2 s) was less for bitumen type "B". Nevertheless, as presented in figure 4 (a) and 5 (a) the morphology of the bubbles was different. At the end of the decay, bubbles remaining close to the surface of the foam were smaller in size compared to the 4% W.C. In this case, the decay of the foam appears to depend much on gas loss by diffusion into the surface of the foam including a gas loss due to bursting cell walls located at the foam surface.

From observing of the image sequences, the decay mechanism of bitumen type "A" for 1% W.C. and 160°C foaming temperature is mainly caused by coalescence, drainage and gas

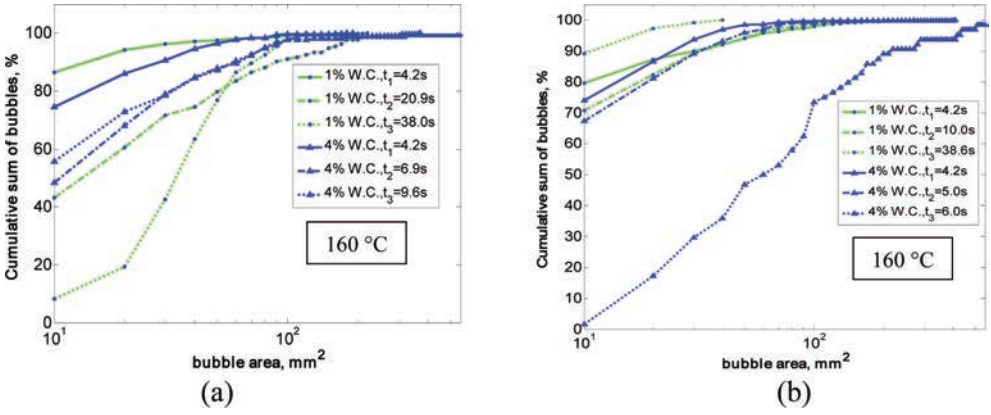

Figure 6. Cumulative sum of bubble area vs. number of bubbles (a) Bitumen "A" (b) Bitumen "B".

loss from bursting bubbles located on the surface of the foam; Whereas bitumen type "B" was more influenced from bitumen drainage and resulting separation between the dry foam of the surface and the wet zone at the bottom of the foam for 1% W.C. and 160°C foaming temperature. Therefore the decaying mechanism for bitumen type "B" was influenced by significantly creaming effect it was followed by the loss of gas through diffusion at the surface the bursting bubbles on the surface of the foam. Moreover, in the case where 4% W.C. and 160°C foaming temperature was used both bitumen types were influenced mainly from quick coalescence of individual bubbles.

5 CONCLUSIONS

Foam bitumen decay was found to be a dynamic process of coarsening of the foam bitumen bubbles. The coarsening takes place in a fraction of a second creating impacts on adjacent bubbles and eventually leading to sudden bubble coalescences. In all experiments it was observed that there is a redistribution of bubble size during the decaying process. During the decay of the bubble size distribution became progressively larger with time for 160°C bitumen temperature. In general, at the beginning of the foam formation, majority of the bubbles are small in size (0.2–10 mm^2) and the foam is relatively monodisperse, at latter stage the bubbles became polydisperse. Comparing different foaming conditions, it was observed that the majority of the bubble size distribution ranged between bubble area of 0.2–10 mm^2 regardless of the water content. For the harder bitumen "B" the cumulative bubble area and number of bubbles were less influenced by the water content at 160°C foaming temperature as compared to the softer bitumen "A". During the decaying process, at a time t_2 and t_3, bitumen "B" at 1% W.C. had a high percentage of small bubbles area (0.2–10 mm^2) compared to bitumen "A" for 1% W.C. Hence, the morphology and bubble size distribution depended on the origin of the binder.

The evaluation of foam bitumen formation and decaying mechanism with X-ray analysis was helpful to understand the influence of water on the foaming of bitumen from the experimental point of view. Understanding the decaying mechanism is certainly useful to identify and optimize the stabilizing mechanism. For instance at lower water content (1% W.C.) and 160°C foaming temperature uniform bubble size distribution was found but the foam was decaying due to drainage, creaming and bubble burst at the foam surface. Different literatures suggested that this decaying mechanism can be improved by increasing the viscosity of the bitumen and reducing the diffusion of gas between bubbles. Similarly other experiments performed in this research can be used to improve the different stabilizing mechanism of foam bitumen.

Formation and decaying of foamed bitumen is a complex mechanism which certainly needs further attention and research efforts. However, principles found and shown here appear

promising and may serve as an element for both more reliable practical tools for assessing foaming and decaying mechanisms of foam bitumen. This also helps to improve theoretical understanding and characterization of foam bitumen.

Evaluating the effects of Sasobit on characterization and workability of asphalt mixes containing reclaimed asphalt binders

Faramarz Safazadeh
Sharif University of Technology, Tehran, Iran

Ali Vahabi
Isfahan University of Technology, Isfahan, Iran

ABSTRACT: Use of Reclaimed Asphalt Pavement in HMA[1] is beneficial by reduction of initial costs. But the higher stiffness of aged binder may lead to workability issues in the field, therefore use of large percentages of RAP[2] impacts the HMA properties. Utilizing Sasobit is a solution to use more RAP at a relatively lower temperature in HMA mixes. This study investigates the effects of 2 percent Sasobit on the reduction of compaction temperature by measuring low shear viscosity and workability of mixtures containing RAP binder. Low and intermediate temperature properties of RAP binder using mix designs were compared to properties of artificially aged binders. Virgin binder was aged in PAV to make artificial RAP binder. Comparison between physical parameters of RAP binder and binder aged in PAV[3] was done and it was found that about 40 hours is sufficient for simulating the aging of RAP binder and making artificially aged binder. Results of this study on artificial RAP show that utilizing Sasobit is a feasible way to make HMA which contain 25% RAP. Utilizing RAP and Sasobit together in a HMA project would lead to select softer virgin asphalt binder with a lower performance grade.

Keywords: Recycling, reclaimed asphalt binder, HMA, WMA[4], mortar

1 INTRODUCTION

Asphalt recycling became popular since 1970s with shortage of resources, increase in binder price and environmental issues. Also utilization of RAP in HMA decreases the costs of disposals. The higher the percentage of RAP utilized in a job, the greater is the savings. Incorporating Warm Mix Asphalt (WMA) technologies like Sasobit into HMA mixes conserves fuel by reducing compaction and mixing temperature and will improve the flow of asphalt [1]. Both Aged binder from RAP and Sasobit will have some effects on resultant binder. For compensating the change of rheological binder properties caused by the aged binder and Sasobit, a virgin binder with a lower Performance Grade (PG) will be used [2].

To date, extraction with solvents and recovery of RAP binder is the only method to obtain binder from aggregates for physical characterization. The reaction of asphalt binder and solvent while in solution can alter the physical properties of the recovered asphalt binder like binder hardening. Residual solvent often remains in the recovered asphalt binder at the

[1]Hot Mix Asphalt.
[2]Reclaimed Asphalt Binder.
[3]Pressure Aging Vessel.
[4]Warm Mix Asphalt.

completion of the recovery process, which alters the physical properties of the asphalt binder. Also there would be possibilities that Asphalt binder is not completely extracted from the aggregate, leaving strongly adsorbed material that may have significantly different bulk physical properties than the remainder of the recovered asphalt binder [3]. To determine low temperature characterization of RAP binder properties, researchers have developed mix designs and back calculation of binder properties [4].

The higher stiffness of aged binder may lead to workability issues in the field, therefore use of large percentages of RAP impacts the HMA properties. Utilizing Sasobit is a solution to use more RAP at a relatively lower temperature in HMA mixes [5–7]. Sasobit lower the viscosity of asphalt, making the end product attaining sufficient workability and having the ability to be compacted to the desirable air void [5].

Workability is known as the ability of the asphalt mixture to be easily handled, placed, and be compacted. Measuring the workability of HMA mixtures is a matter of interest and many agencies determine mixture workability based on subjective visual field observations and other methodologies. To date, limited research has been conducted to identify a methodology to quantify HMA workability.

The concept behind workability testing devices for HMA appears to have begun with Marvillet and Bougault in 1979. Instrotek, Inc. took their ideas and developed the prototype equipment.

The general concept that they developed involved measuring the torque required to push a paddle through a bituminous mixture at different temperatures. Because the torque required moving the paddle would increase as the temperature decreased, a measurable indication of the workability of the mixture was determined [8].

The objectives of this study were to:

1. Investigate rheological properties of Warm Mix Asphalt (WMA) binders containing artificially long-term aged binder.
2. Evaluate the workability of mixtures that incorporate RAP and WMA technology.

2 EXPERIMENTAL PLAN AND TESTS

Addressing the need for non-solvent based RAP binder characterization, two procedures for simulating the aging of RAP binder is presented in this paper. At first virgin binder is aged in PAV for several hours (20, 25, 35 and 40 hr). Low and intermediate temperature properties of RAP binder using mix designs and back calculation of binder properties is compared to properties of artificially aged binders. At last there is a comparison between reduction of compaction temperature of mixtures containing RAP by considering workability index and binder viscosity. Figure 1 shows a flow chart of the experimental design used in this study. As been said artificially RAP is produced by aging the virgin binder in the PAV. The period of time being in the PAV for aging is determined by comparison between physical parameters of RAP binder and binder aged in PAV

1. Comparison between IDT[5] of HMA species containing RAP and IDT of HMA species containing burned RAP (RAP aggregates) and binder aged in PAV.
2. Comparison between stiffness of binder aged in PAV and extrapolated stiffness of RAP binder computed by Sweirtz et al. method.

Single gradation was used to make HMA species for IDT. For meeting the gradation requirement, the ASTM-D3515 specification (12.5 mm Nominal Maximum Aggregate Size Job Mix Specification) is used.

For this comparison RM denotes asphalt mixes prepared with virgin binder and RAP, while PM denotes asphalt mixes prepared with virgin binder, burned RAP and binder aged

[5]InDirect tension test.

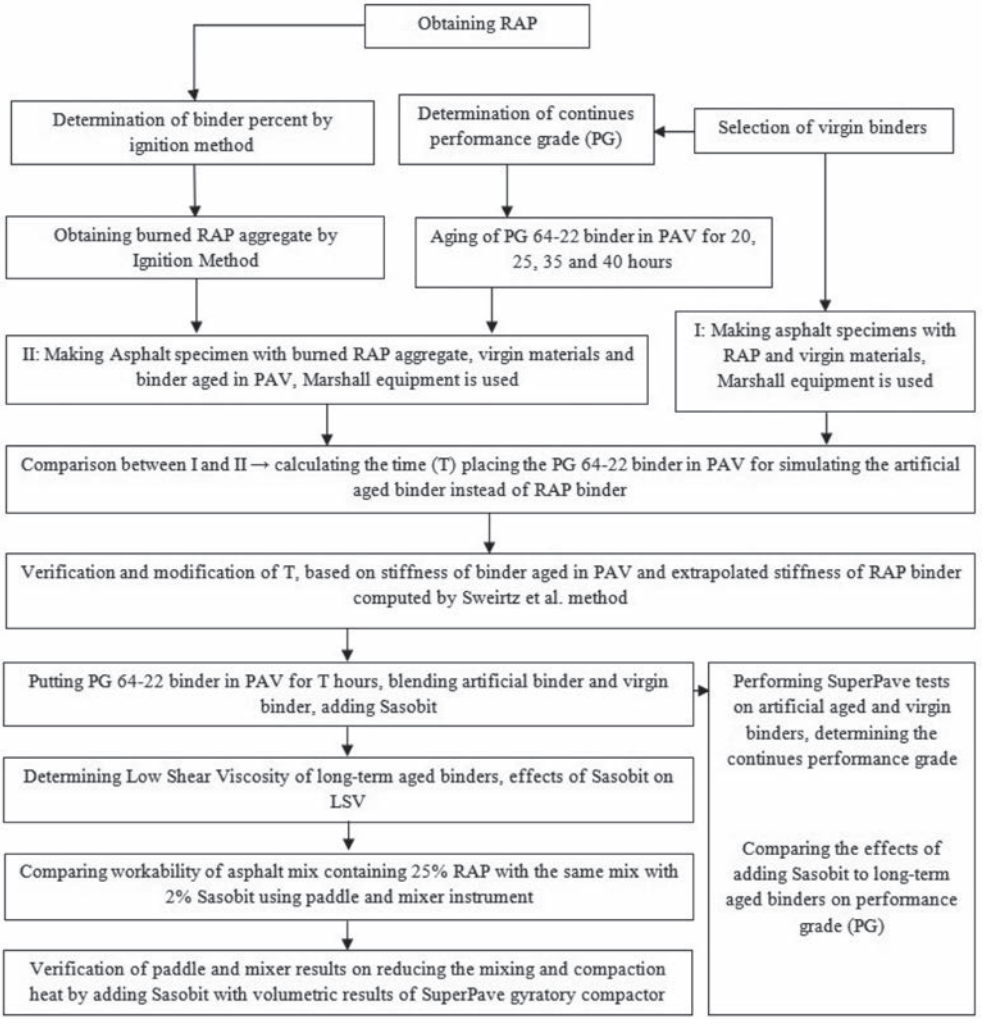

Figure 1. Diagram of experimental plan.

in PAV instead of RAP binder. For determination of asphalt content of RAP, it was ignited in furnace at 540°C in accordance with ASTM-D 6307-98 [9]. In order to create a mix design of 4% air voids, several different mixes were prepared and the air voids were calculated. The percent air voids was determined by modification to AASHTO T269 by determining the bulk specific gravity (G_{mb}) and theoretical maximum density (G_{mm}) of the mixes.

In the second method developed by Sweirtz et al. the proposed analysis procedure will require the preparation of two mortar samples from one RAP source and one fresh binder sample. SRAP denotes mortar sample that contains RTFO binder and R100 (passing No. 50 and retained on No. 100 sieve) RAP while RRAP denotes mortar sample that contains RTFO binder and burned R100 RAP. Both the total binder content and gradation of the mortar samples is equal, meaning that any difference in properties between the SRAP and RRAP mortar can be attributed to the RAP binder contained within the SRAP mortar. The analytical procedure is based on the assumption that the effect of RAP binder on the continuous grading curve for the fresh binder will simply be a shift in stiffness or m-value. The shift between the stiffness of SRAP and RRAP at –12°C and –18°C remains constant; respectively the same shift at the critical time (60 seconds) would be applied to the fresh binder at –12°C and –18°C. Based on this method the stiffness of fresh binder blended with

RAP binder is calculated and stiffness of RAP binder can be extrapolated on a diagram of stiffness and percent of RAP binder. With comparison between stiffness of RAP binder and virgin binder aged in PAV, the time of aging is predicted.

3 RESULTS AND DISCUSSIONS

In Figure 2 force—displacement curve is shown in order to compare the total fracture energy and fracture energy to failure [10]. In this figure RM mixes show less displacement in their maximum tensile strength in comparison with PM mixes. Therefore, for more simulating PM40 is placed in 135°C for about 2 hours in order to increase asphalt absorption by aggregates.

Table 1 presents indirect tensile strength properties of each specimen. It was observed that virgin binder aged around 40 hours in PAV can be used instead of RAP binder and its effects would be observed through SuperPave asphalt binder tests.

In Figure 3 stiffness of SRAP and RRAP mortar samples, containing 4, 7 and 10 percent RAP binder measured by BBR test at −12°C and −18°C are shown. Making mortar samples with higher percentages of RAP binder because of poor workability of them was impossible.

For a given temperature, higher percent of RAP binder have higher shift between the stiffness of SRAP and RRAP because of high stiffness of RAP binder in comparison with binder that is aged in RTFO. In BBR test stiffness reduces with time but the shift between

60	92.6	1.97	0.0093	1.976	94.6

1—log stiffness RTFO + 4% RAP binder = log stiffness RTFO binder + δ.

SRAP and RRAP is constant except mortar samples which contain 10 percent RAP binder at −18°C. This could be of non-uniform or non-homogeneous blend of mortar binders and the sensitivity of stiffness in low temperatures. In Tables 2 and 3 stiffness of binder aged in RTFO and 4 percent RAP binder through applying the shift at the critical time (60 seconds) is calculated. Other cases are performed like the previous state.

After determining the stiffness of binders containing RAP binder at each temperature, stiffness of RAP binder is extrapolated on a diagram of stiffness and percent of RAP binder (Fig. 4). Then extrapolated stiffness at each temperature is compared with stiffness of virgin binder aged in PAV to estimate the time for stimulating the aging of RAP binder (Fig. 5). The resultant time is averaged between two temperatures and about 40 hours is quite enough for stimulating the aging of RAP binder and making artificially aged binder.

Continues performance grade of two virgin binders (PT[6] 60-70 and PT 85-100) and the artificial aged binder through SuperPave tests are presented in Table 4. Based on these continues performance grades, allowable percentage of RAP binder blending with virgin binder to obtain the binder which is specified by the agency depending on the project location and conditions can be represented by the following equation:

$$RAP = \frac{(T_{\text{Blend}} - T_{\text{Virgin}})}{(T_{\text{RAP}} - T_{\text{Virgin}})} \tag{1}$$

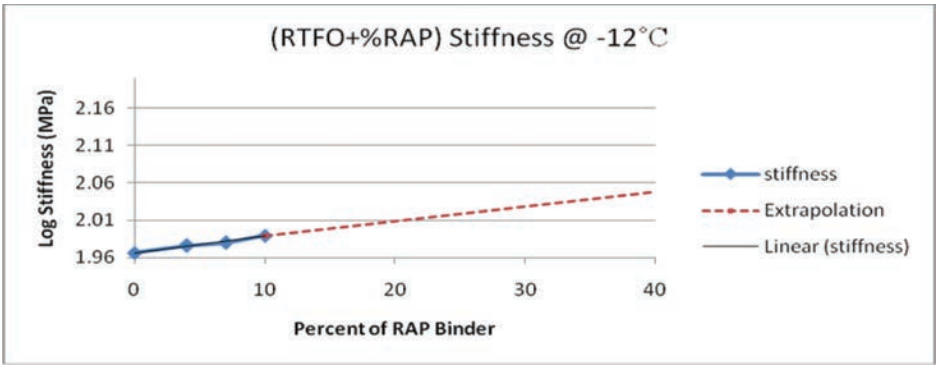

Figure 4. Stiffness of blended binder containing RAP binder.

where T_{virgin} is the critical temperature of the virgin asphalt binder; T_{blend} is the critical temperature of the blended asphalt binder; %RAP is the percentage of RAP to be used in the HMA expressed in decimal; and TRAP is the critical temperature of the recovered RAP binder. To satisfy the low-temperature grade of PG 64-22 when the virgin PT 60-70 binder is utilized, allowable percentage of RAP binder is 32% and when virgin PT 85-100 binder is utilized, 40% is the allowable percentage of RAP binder.

In Table 5 and 6 performance grade of 25% RAP blended with virgin binder and the influence of adding 2% percent Sasobit to this blend is presented.

SuperPave tests show that utilizing softer binder will help to have better performance in low temperatures and this will justify the increase in allowable percentage of RAP. From Table 5 it is observed that by adding Sasobit the performance grade of the blend will be PG 70-16. And for Table 6 it's PG 70-22, therefore adding Sasobit to the softer virgin binder is more economical by improving the performance grade from PG 66-22 to PG 70-22.

Viscosities of asphalt binder at different shear rates are obtained and by fitting Cross-Williamson, low shear viscosity is determined. The Cross-Williamson model is:

$$\eta = \eta_{\infty} + \frac{\eta_0 - \eta_{\infty}}{1 + (k\dot{\gamma})^n} \tag{2}$$

where η_∞ is the terminal viscosity, η_0 is the zero shear viscosity; k and n are constant models and $\dot{\gamma}$ is the shear rate. In this research low shear viscosity for virgin PG 64-22 binder, virgin binder with 25% artificial RAP and the same blend with 2% Sasobit is obtained. Table 7 presents viscosities at different shear rates at 145°C for virgin binder with 25% artificial RAP and all parameters by fitting Cross-Williamson are presented in Table 8. Other states are obtained likes this; for all of them mixture and compaction temperatures based on low shear viscosities are presented in Table 9.

Accuracy and validity of LSV is upon to measuring the viscosities near zero shears and also the model that is used for fitting. Viscosity is measured by the rotational viscometer as specified in AASHTO T-316 (TP48). Figure 6 presents viscosity curves at each shear rate for virgin binder with 25% artificial RAP. In Figure 7 low shear viscosity vs. temperature for virgin PG 64-22 binder (Pen 60-70), virgin binder with 25% artificial RAP and the same blend with 2% Sasobit is shown. Virgin binder containing 25% artificial RAP with 2% Sasobit has the biggest absolute value slope of reducing LSV; thus it could be concluded that it has temperature sensitivity. Also it could be seen that adding 25% artificial RAP to virgin binder increase its sensitivity to temperature. Viscosity at each shear rate in a constant temperature is measured and data which is fitted by Cross-Williamson shown in the next column. Different between measured and fitted viscosity is shown by dη and smaller the total square

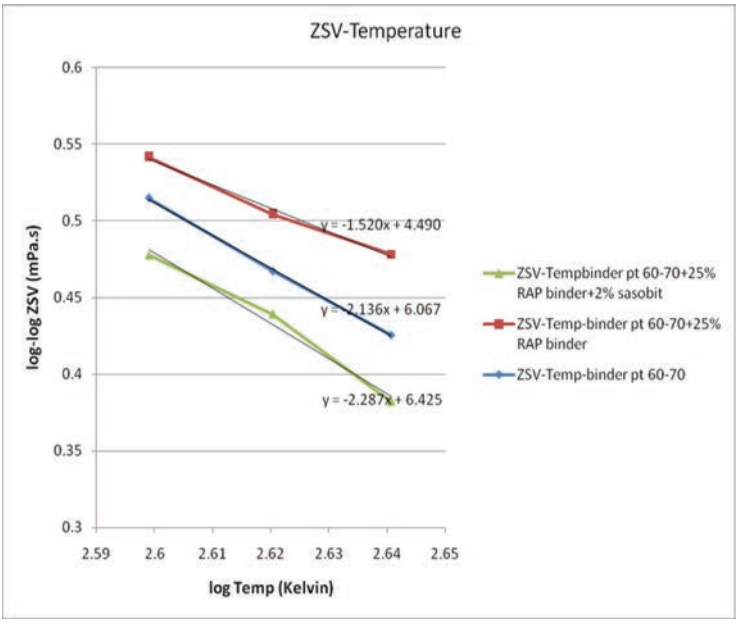

Figure 7. Low shear viscosities vs. temperature.

of that shows the accuracy of fitting. Brookfield apparatus Viscometer used in this study could measure viscosities that required torques between 1 to 100 LV; therefore by using spindle No. 27 viscosities at lower shear rates could be taken.

Another way for determining or make comparison between temperatures of mixture and compaction of asphalt mixes is evaluating the workability of the mix. For measuring workability a workability meter device is built in this study (Fig. 8). Device tools include a motor, a gearbox that reduces the rotating rate of the shaft from 1400 to 23.3, a shaft and two paddles at the end of the shaft, an instrument for measuring the torque and a bucket for mixing the asphalt according to what is made by Instrotek, Inc [8]. The more torque that asphalt mix causes to the device, it means that the mix has less workability. Evaluating the workability

110	31.9	0.031	28	0.036

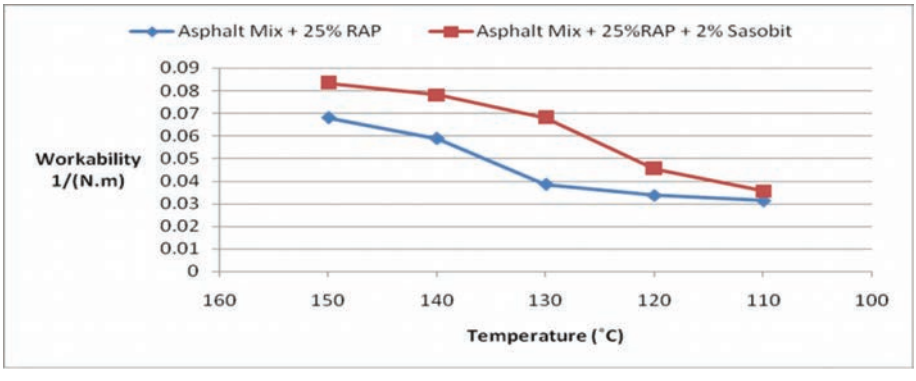

Figure 9. Graphs of workability.

criterion by this device is the reverse value of the torque. Asphalt mixture containing 25% RAP in comparison with the same mixture with 2% Sasobit are made and their workability are evaluated and presented in Table 10.

In Figure 9 the graphs of workability and temperature are shown, obvious improvement of workability by adding 2% Sasobit and about 20°C reduction in mixture temperature are seen. For confirmation of the workability evaluation, asphalt mixture with the same properties are made and compacted by SuperPave gyratory compactor in 150°C. Comparison is

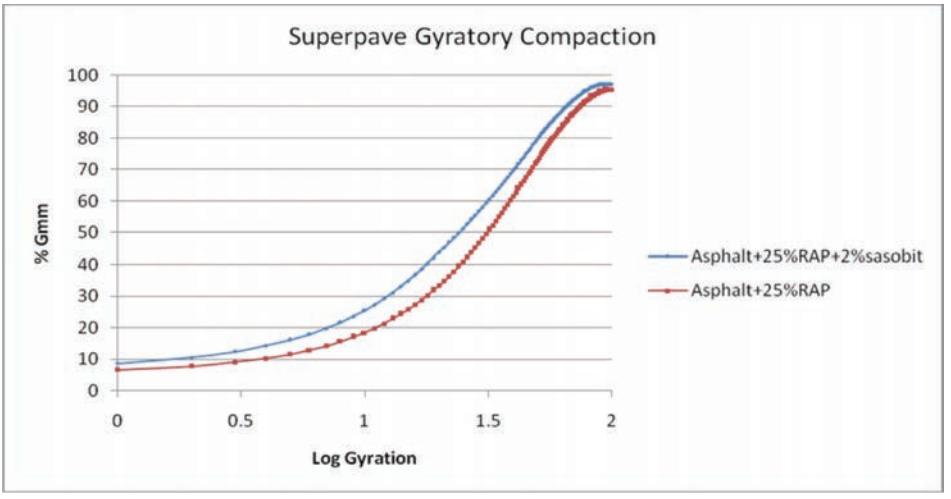

Figure 10. Graphs of % Gmm in SGC.

done based on the air trapped in the asphalt mix and it shows the capability of the asphalt compaction (Fig. 10). For better comparison, gradation and G_{mm} of two mixes are the same. Adding 2% Sasobit to the asphalt mix will improve the compact ability and reduces the air tapped from 4.5% to 2.8%. Thus it shows that the workability device compared two mixes approximately right.

4 CONCLUSION AND RECOMMENDATIONS

Based on this study, the following conclusions and recommendations can be made

1. Virgin binder aged around 40 hours in PAV can be used as artificial aged asphalt binder and its effects on stiffness and total fracture energy would be the same with RAP asphalt binder.
2. SuperPave tests show that utilizing RAP and Sasobit together in a HMA project would lead to select softer neat asphalt binder with a lower performance grade.
3. Using Sasobit with a softer neat asphalt binder is practical way of increasing allowable percent of RAP binder.
4. Use of Sasobit with asphalt binder at a mixing temperature of 130°C produced mixes with workability and compatibilities that are lower but close to those of a mix with virgin asphalt binder, mixed at 150°C.
5. There seems to be a significant advantage in using Sasobit in reducing temperature for using asphalt binder in recycling of HMA. The important advantages of using Sasobit are in terms of reduction of temperature and hence associated fuel cost and emissions, and the ability to recycle HMA at a lower temperature. This ability would lead to more widespread use of Reclaimed Asphalt Pavement.
6. Field project to evaluate Sasobit mixes with HMA should be initiated. The use of 2% Sasobit with asphalt binder is recommended.

ABSTRACT: Although foaming, viscosity reduction and surface-active agents are now commonly used technologies to produce Warm Mix Asphalt (WMA), the mechanisms of such technologies are still not well understood. That is why this study aims to understand surface-active additives mechanism to further improve the chemistry of such additives. Literature shows that the studied additives have only a slight impact on the viscosity and allocates them lubricant and adhesion promoting properties. In order to evaluate possible reactions of WMA additives with mineral substrates and/or bitumen components, tribological experiments were conducted on the linear alternative tribometer available at the Laboratory of Tribology and System Dynamics (LTDS). Several parameters able to act on the friction coefficient were tested. Then Scanning Electron Microscopy with Energy Dispersive X-ray Spectroscopy (SEM-EDX) and X-ray Photoelectron Spectroscopy (XPS) will be used to show evidence of a tribo-chemical film on the aggregates surface. On the other hand, quantification of the bitumen containing additives-aggregate interaction was evaluated at mixing temperature by using the sessile drop method with several kinds of minerals.

Keywords: Warm Mix Asphalt additives mechanism, tribological film formation, surface tension measurements

1 INTRODUCTION

Over 100 Mt of bitumen are worldwide consumed every year, mainly for asphalt pavement applications [1]. Traditional asphalt concretes are composed of about 95 weight percent of aggregates and 5 percent of binder (bitumen). Because of its viscous-elastic properties at room temperature, bitumen should be heated to further coat the aggregates. In practice, for a better coating, both aggregates and bitumen are heated. This mixture is classically called Hot Mix Asphalt (HMA). It is traditionally manufactured at temperatures range from 150°C to 200°C and from 100°C to 135°C during the mixing and compaction steps respectively.

According to more severe regulations and with the aims to be more competitive, to improve the safety of workers, to reduce both costs and fuel consumption and to decrease pollutant (Polycyclic Aromatics Hydrocarbons, NOx, SOx, greenhouse gas) emissions, asphalt manufacturers try to reduce the asphalt mix temperatures without (significantly) affecting the properties of the mixes. For the last twenty years, manufacturers experiment Warm Mix Asphalt (WMA) technologies whose mixing temperatures are lower, typically ranged from 100°C to 140°C.

Literature reveals the existence of many different technologies, which are now commonly used to produce WMA. Some of them are called foaming technologies and results of the presence of water in the mix. Above 100°C, this small amount of water is responsible of a global mix volume expansion which improves the mixture workability [2–4]. Presence of water results of Water Based Process or is due to foaming additives such as zeolites. Others are called Non-Foaming (NF) technologies. Different kinds of NF-WMA are already available on the market and they do not contribute to the workability improvement in the same way: waxy components are thought to decrease the binder viscosity; others are thought to act as surface active agents [2–4].

In our work we are concerned by the question: "How do WMA non-foaming additives improve the workability of asphalt concretes?" The mechanisms by which they act are indeed currently not well understood.

Furthermore binder viscosity is a key parameter to explain the asphalt mix workability; so much that it has longtime been the only parameter into account. But it has been shown than some of the NF-WMA only slightly reduce the binder viscosity and it is believed that this small reduction cannot fully explain the reduction of temperatures for producing WMA rather than HMA [5].

Recently, tribological experiments have proved that WMA are effective in improving the bitumen lubrication of contact aggregate-aggregate [5–7]. Thus lubrication is a mechanism which can also contribute to improve the workability of asphalt concretes. In this study, we proposed to evaluate how WMA agents act on the binder viscosity, on the lubrication properties when two mineral surfaces are in contact and if they can improve the wettability.

2 EXPERIMENTATION

2.1 *Materials*

2.1.1 *Bitumen*

To understand how the addition of WMA additives to neat bitumen can improve the workability of the final asphalt mix a 35/50 neat bitumen was studied. The neat bitumen was provided by TOTAL. Some of its properties are summarized in Table 1. Three NF WMA additives with various chemistry were studied. Bitumens references are listed in Table 2.

2.1.2 *Aggregates*

Asphalt mixes are made of aggregates of various sizes, shapes, roughness, chemical/mineralogical compositions etc. To simplify the study flat samples of various materials were used to represent different kinds of aggregates: glass, limestone, marble and granite. Flat samples were polished prior the tests. Samples were provided by a marbler as 6 cm × 3 cm × 0.5 cm plates. More details are listed in Table 3.

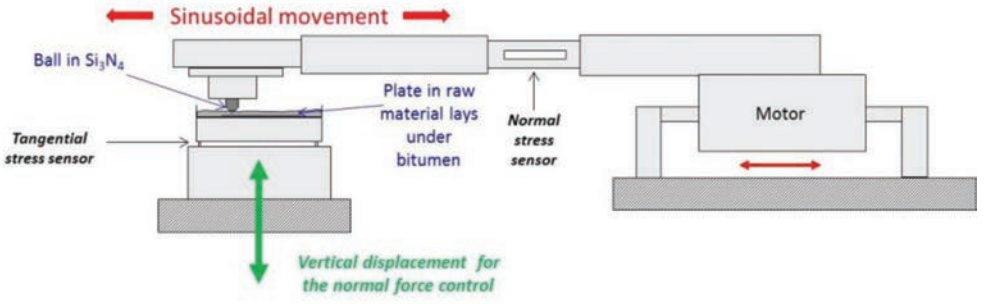

Figure 1. Ball on flat reciprocating tribometer.

2.2 *Test methods*

2.2.1 *Bitumen viscosity measurements*

A Brookfield rotational viscometer was used to determine the viscosity of virgin and WMA binders at three different temperatures (80°C, 100°C and 120°C). Then, the value at 160°C was extrapolated by semi-logarithmic regression between 100°C and 120°C. The temperature is controlled by the mean of a Peltier bottom plate.

2.2.2 *Tribological measurements*

To determine whether WMA additives are able to improve the lubricant properties of bitumen by reducing the friction coefficient of two in-contact aggregates, a pin on flat linear reciprocating tribometer was used (Fig. 1). A Si_3N_4 ball of radius 6.35 mm was chosen to slide against the mineral flats presented in section 2.1.

The experimental parameters consist in sliding distance and frequency of 10 mm and 0.1 Hz respectively, of a 50 N normal load (which creates a mean pressure of 0.7 GPa). 1600 cycles or more are generally performed during an experiment and the temperature was 120°C. Measured parameters are temperature, normal force (L), tangential force (T) and displacement. The Coefficient Of Friction (COF also noted µ) is then defined as COF = T/L (= µ).

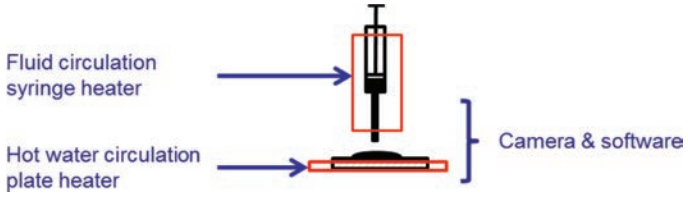

Figure 2. Scheme of the tensiometer.

Prior to experiments, mineral plates are washed three times ten minutes in a water ultrasonic bath and dried in an oven at 100°C overnight (to remove dust contaminations). Then both ball and plates are rinsed with heptane, acetone and propan-2-ol under ultrasonic conditions. Two hours before a tribological experiment, bitumen is heated at 140°C in an oven.

2.2.3 *Contact angle measurements*

Sessile drop experiments were performed in order to evaluate if WMA additives promote a better bitumen coating of aggregates. The tensiometer has been modified to allow high temperature contact angle measurements (Fig. 2). Prior experiments, all bitumens are heated at 180°C in an oven for 1 h 30 in order to pump bitumens in the syringe. In the same time, flats are washed with white-spirit and heated at 90°C thanks to the water circulation plate heater. Then the full bitumen syringe is clamped on the tensiometer and heated at 150°C via the oil circulation flat heater. After one hour, experiments are performed.

Experiments consist in laying a drop of bitumen on the mineral flat. Then, due to capillary effects, bitumens drops spread out on the plane. A camera records the process; a dedicated-software analyzed pictures by fitting the shape of the drops and gives contact-angles values. A minimum of five drops by flat sample are laid. Drop putting down is made manually. This leads to relative important initial contact angles variability.

3 RESULTS AND DISCUSSION

3.1 *Asphalt binder viscosity*

As expected, Figure 3 reveals that bitumen viscosity significantly decreases with temperature. On this figure, it can be seen that WMA additives are effective in decreasing the control binder viscosity; they acts as flow improvers. At 120°C, the most important control binder viscosity reduction is obtained by adjunction of additive D. In this case, a 27% decrease was measured. However, the control binder viscosity is reduced by 90% when temperature gets from 120°C to 160°C. As confirmed by literature review, NF-WMA agents' viscosity can therefore not fully explain the workability of WMA.

3.2 *Tribological behavior*

First friction experiments in various speed conditions have shown that, due to the relatively high viscosity of bitumen, a liquid film can be formed in the contact. Then, it is possible to distinguish 2 situations: friction with hydrodynamic film formation, friction in boundary lubrication conditions (without a liquid film in the contact).

3.2.1 *Experiments conducted in hydrodynamic lubrication regime*

Figure 4 presents results from the tribological experiments performed with glass flats. It can be seen that the COF decreases with increasing temperatures (due to viscous effects) and the curves shape confirms that experiments are conducted in the hydrodynamic range where a full film separates the ball and the flat and where the film thickness depends on the viscosity of the lubricant (bitumen in the present case). Some experiments conducted

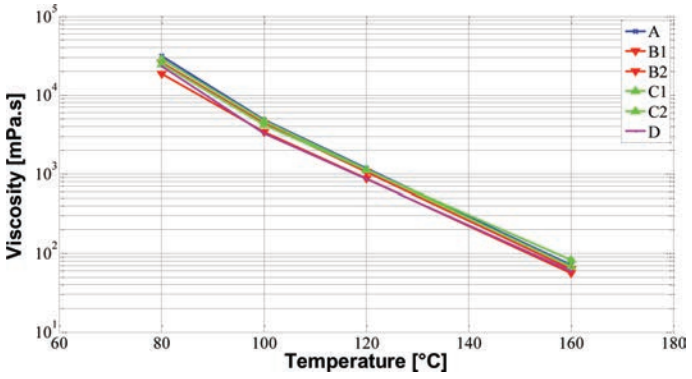

Figure 3. Viscosity of bitumen as a function of temperature; effects of WMA agents.

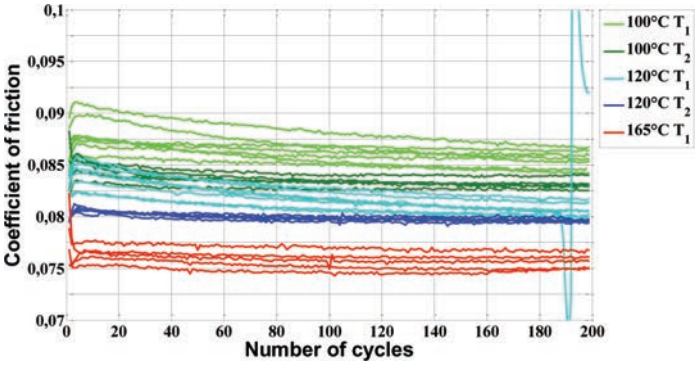

Figure 4. COF as a function of number of cycles in the case of a Si_3N_4 ball sliding against a glass flat.

at various frequencies (0.1 Hz, 0.5 Hz, 1 Hz and 2 Hz) confirm the hydrodynamic hypothesis.

This graph also reveals a time dependence of μ which can be attributed to a diffusion time of some chemical species to the sliding surfaces. The fact that the diffusion seems quicker at elevated temperatures seems corroborate this hypothesis.

One the other hand, experiments performed on glass samples at 120°C reveals that WMA agents do not modify the COF of the control bitumen under hydrodynamic conditions. This seems coherent with the fact that WMA agents imply small reduction of the binder viscosity (i.e. tribological experiments are not able to significantly differentiate these small viscosity variations).

We conclude that the sliding contact of a Si_3N_4 ball against perfectly smooth glass flat samples in presence of bitumen and with the experimental parameters we used are conducted in the hydrodynamic range where viscosity play a key role: enough to bring out the temperature influence but not strong enough to show the WMA additives influence. However this result does not imply that WMA agents do not get lubricating properties.

By using rougher materials, experiments can be performed under mixed or boundary conditions and should help to reveal the impact of WMA additives.

3.2.2 *Experiments conducted in boundary lubrication regime*

3.2.2.1 Limestone

Figure 5 shows results from tribological experiments conducted with limestone flats. This graph compares the mean COF of the control binder and those of the binder modified with various WMA chemical additives. Results seem relatively reproducible.

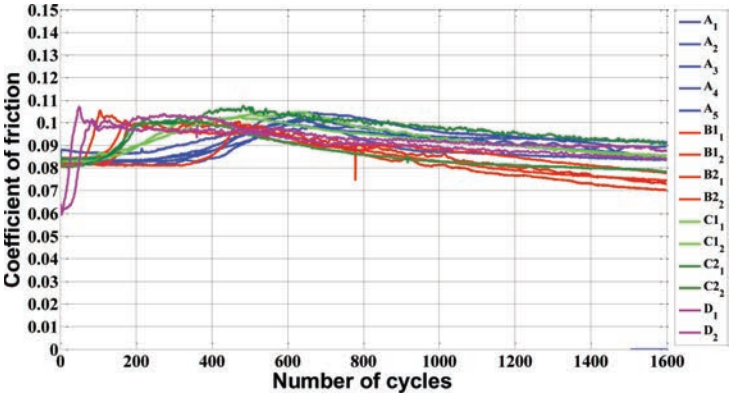

Figure 5. COF as a function of number of cycles in the case of a Si_3N_4 ball sliding against a limestone flat with bitumen in the contact.

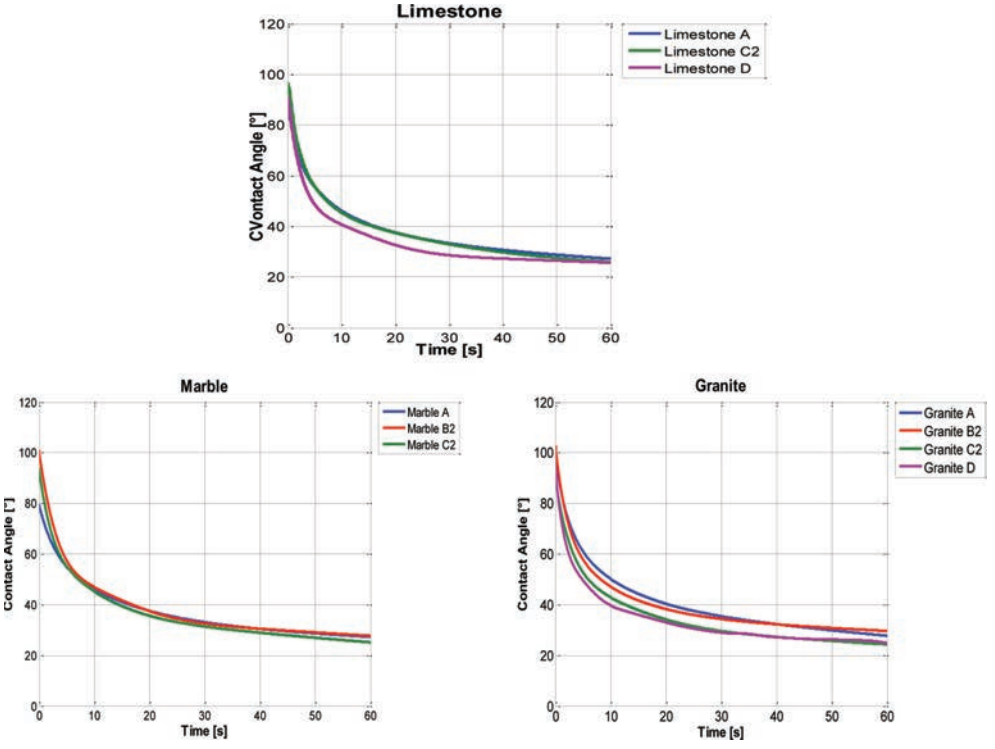

Figure 6. Contact angle measurements of bitumen droplets on various materials: limestone, marble and granite.

The control binder gets an initial 0.083 COF value for the 300 first cycles. Then μ increases up to 0.1. This increase is thought to correspond to wear of the plate. After that, the COF decreases and reaches a steady state with μ-values of 0.09.

WMA agent D leads to low value of COF in the early stage (μ = 0.06) and do not seem to act in the final stage where μ is equal to the COF-value of the control binder. It can also be noticed that wear occurs after a short initial period. This behavior suggests that this kind of components quickly move to the surface aggregate and is removed when wear occurs.

One can also suppose that the initial film thickness is thinner due to the presence of wax resulting in the short wear-induction time.

Contrary to bitumen D, bitumen containing Additive 1 do not promote COF modification in the early stage but seem to induce a COF reduction in the final stage.

3.3 *Bitumen-aggregates wettability*

Thermo-dynamical contact angle and the time necessary to reach this steady state are usually the two sought factors in wetting experiments. In some cases, the steady state time is short but it could sometimes be very long. Moreover, in our study, the bitumen's and the flat's temperatures are 150°C and 90°C respectively. That means the steady state is reached when the whole system is at 90°C and when the contact angle becomes constant. However, when the drop temperature falls from 150°C to 90°C, bitumen viscosity is dramatically increased. This can lead to very long equilibrium time (t_{eq}). That is why, our experiments were stopped at t = 40s which can further be called t_{eq}.

Figure 6 shows contact angles as a function of time for several bitumens and different kinds of plate's material. The drop spreads out very quickly for the fifteen first seconds. It could be attributed to the time at which the drop reaches the thermic equilibrium.

Plots reveal that marble and limestone plates, which are very similar in chemical composition and in roughness, get very similar contact angles at t_{eq}. On the opposite, the final contact angle measured with granitic samples is much higher confirming a better affinity of bitumen for limestone rather than granite substrates [8].

These graphs also reveal that bitumens with WMA-agents get lower contact angle than the control binder, especially in the case of granite materials.

Curves of bitumen D present rapid decrease initial contact angle to final contact angle values. This result confirms that Additive D moves to the surface of aggregate.

4 CONCLUSIONS AND PERSPECTIVES

In this study, we have shown that WMA-additives can play various roles:

- They slightly decrease the viscosity of bitumen. However, this minor phenomenon is not sufficient to explain why WMA are so workable at 120°C.
- They do not affect the COF in the hydrodynamic lubrication range (due to the small variations in binders viscosity).
- They are efficient in slightly decreasing the COF in the boundary lubrication range. This fall appears in different stage of the sliding experiments depending on the WMA-agents and on the nature of the sliding substrates.
- They facilitate the coating of aggregate as proved by contact angle measurements.

For a better understanding of the WMA additives mechanism, X-ray Photo-electron Spectroscopy (XPS) have to be used to show evidence of a tribo-chemical film on the aggregates surface.

Tribological experiments with other aggregate materials, granite and marble plates are in progress, in order to precise the role of the aggregate nature.

Study on integrated application and durability of two warm-mix asphalt techniques

Liping Liu, Xiaofei Gao, Zhoucong Xu & Lijun Sun
Key Laboratory of Road and Traffic Engineering of the Ministry of Education, Tongji University, Shanghai, China

ABSTRACT: Warm-mix asphalt technique has been widely adopted by road departments in an increasing number of countries and regions due to its advantages in energy efficiency, environment protection, asphalt aging prevention, extended construction seasons, improvement of working environment for the workers and prompt opening to traffic. At present a number of warm-mix asphalt techniques have emerged. Performance of warm-mixed mixtures varies with mechanism and process of warm-mix techniques. Study shows that compared with hot mix technique, some warm-mix techniques such as warm-mix technique by adding organic viscosity reducers significantly improve stability of the mixture under high temperature, while other warm-mix techniques like surfactant-based warm-mix asphalt significantly improve the anti-fatigue performance. Therefore, the two warm-mix asphalt techniques were applied integrally to different asphalt layers on Shaoguan-Ganzhou Expressway based on their respective characteristics. 200 m test section was paved and tested in terms of compaction, evenness and other performance parameters. The test results demonstrate that all technical parameters of warm mix asphalt reach hot-mix asphalt standards. In addition, laboratory accelerated aging test on the warm and hot mix mixtures were conducted, and the durability evaluation reveals that compared with hot-mix asphalt mixture, warm-mix asphalt is more durable.

Keywords: Warm-Mix Asphalt, surfactant warm-mix asphalt technique, organic viscosity-reducing warm-mix asphalt technique, integrated application, durability

1 INTRODUCTION

Warm-mix asphalt mixture is a general term for a new kind of asphalt mixture whose construction temperature is between that of hot-mix and cold-mix (normal temperature) temperatures with performances equal to that of hot-mix asphalt mixture. Its working temperature can be 30–60°C lower than that of hot-mix asphalt mixture. It has such advantages as energy efficiency, environment-friendliness, asphalt aging prevention, extended construction season, improvement of working environment for workers and prompt opening to traffic. Therefore, warm-mix technique has aroused great interest of road workers worldwide since it emerged, and has become a hot topic for road technique researches in recent years[1,2,3,4]. At present, plenty of warm-mix techniques or products have emerged in international market, out of which warm-mix technique by foaming asphalt, surfactant-based platform warm-mixing technique and warm-mixing technique by adding organic additive etc. are representative[5,6]. The process of warm-mix varies with warm-mix mechanism of different warm-mix techniques. So do the results. The paper focuses on Surfactant-based platform warm-mixing technique and warm-mixing technique with addition of SAK organic viscosity reducers. The two warm-mix techniques were applied in different asphalt layers on Shao-Gan Expressway in consideration of their respective advantages[7]. The post-construction compaction effect and evenness and other performances were tested and compared to those of hot-mix asphalt mixture. Also,

long-term durability of the two warm-mix asphalt mixtures were evaluated through laboratory accelerated aging test and compared to that of hot-mix asphalt mixture. This paper will expound in these two aspects.

2 EVALUATION ON DESIGN AND PERFORMANCE OF MIXTURES PRODUCED BY TWO WARM MIXING TECHNIQUES

Different warm-mix asphalt techniques have different effects on performance of asphalt mixtures. The organic viscosity reducer-based SAK technique (abbreviated as S-WMA) and surfactant-based Evotherm technique (abbreviated as E-WMA) are adopted herein. Design and performance of mixtures at Gradation AC-20C and Gradation AC-13C were compared and evaluated. 70# common asphalt was used for Gradation AC-20C in the middle asphalt course, and SBS modified asphalt was used for Gradation AC-13C in the upper asphalt course. The dose of SAK added was 3% of the mass of asphalt. The dose of Evotherm DAT-H5 added was 11% of the mass of asphalt (effective ingredient: 0.5%). These two mixtures are mixed and moulded under temperature 30°C lower than that of hot-mixing.

2.1 *Comparison on performance of WAC-20C by two warm mixing techniques*

Granite and 70# common asphalt were used for Gradation WAC-20C. Warm-mix asphalt mixtures were prepared by SAK technique and Evotherm technique respectively. See Table 1 for composition of Gradation WAC-20C. The optimum asphalt-aggregate ratio and relevant parameters of asphalt mixture designed are as shown in Table 2. Results of mixtures performance test are as shown in Tables 3 and 4. Here, performances of the mixtures evaluated include stability of asphalt mixture at high temperature, crack-resistance at low temperature, water damage resistance and fatigue resistance. Relevant test methods and standards were executed per Technical Specification for Construction of Highway Asphalt Pavements (JTG F40-2004).

It can be seen from the above table that when 70# common asphalt was adopted, the optimum asphalt-aggregate ratio of both warm-mix techniques was 5.2%, 0.3% higher than that of hot-mix asphalt mixture at the same Gradation.

It can be seen from Table 3 that asphalt mixture prepared by SAK warm mix technique was significantly superior in terms of dynamic stability, while surfactant-based warm mix technique was significantly superior in terms of performance at low temperature. Water stability of both was inferior to hot-mix asphalt mixture. To improve their water stability, appropriate amount of cement or hydrated lime were added into mixtures prepared by the warm-mix

The original gradation	75.3 (0.89/0.67)	76.7 (0.90/0.69)	87.7
1% cement was added	86.9 (0.84/0.73)	74.7 (0.83/0.62)	–
1% hydrated lime was added	83.5 (0.97/0.81)	65.8 (0.79/0.52)	–

Note: the left parenthesized values indicate splitting-strengths before thawing, while the right parenthesized values indicate splitting-strengths after thawing.

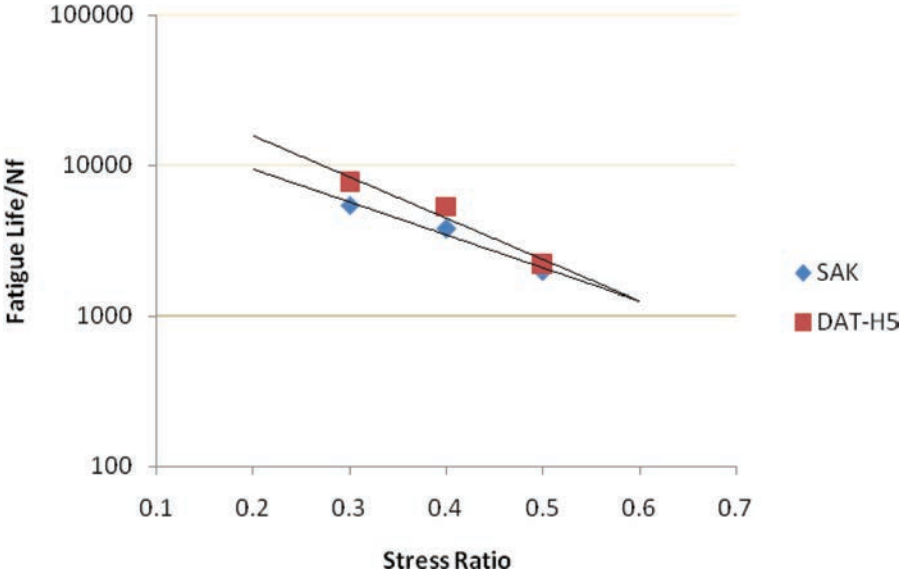

Figure 1. Fatigue curve of AC-20C mixture prepared by two warm mix techniques.

techniques respectively, in other words, 1% mineral powders in the gradation was substituted with cement or hydrated lime in equivalent mass. See Table 4 for test results.

It can be seen from Table 4 that TSR of S-WMA was significantly improved and has been close to that of hot-mix asphalt mixture after cement or hydrated lime was added. So both 1% cement and 1% hydrated lime can improve water damage resistance of S-WMA. For E-WMA, the water damage resistance drops slightly after cement was added, while TSR of E-WMA drops significantly after hydrated lime was added. Therefore, cement or hydrated lime shall not be used as admixture in production of E-WMA.

Fatigue resistance of asphalt mixture can be evaluated based on fatigue life of mixture at different stress ratios, the fatigue curve of which is as shown in Figure 1.

It can be seen from the fatigue curve that fatigue resistance of mixture prepared by Evotherm warm mix technique was higher than that of mixture prepared by SAK warm mix technique at the same stress ratio.

2.2 *Performance comparison of WAC-13C prepared by the two warm mixing techniques*

In Gradation WAC-13C, diorite was used as coarse aggregate, limestone as fine aggregate, and SBS modified asphalt as binding material. Warm-mix asphalt mixtures were prepared by SAK technique and Evotherm technique respectively. See Table 5 for composition of Gradation WAC-13C. The optimum asphalt-aggregate ratio and relevant parameters of asphalt mixture designed are as shown in Table 6. Results of performance test of the mixtures are as shown in Table 7.

It can be seen from the above table that when SBS modified asphalt was adopted, the optimum asphalt-aggregate ratio of both warm-mix techniques was 5.4%, 0.2% higher than that of hot-mix asphalt mixture at the same Gradation.

It can be seen from Table 7 that when SBS modified asphalt was adopted, stability of both Warm-mix asphalt mixtures at high temperature, particularly S-WMA, was higher than that of hot-mix asphalt mixture; Maximum flexure tensile strain of both Warm-mix asphalt mixtures at low temperature was slightly different but higher than HMA. Different from common asphalt, water damage resistance of both Warm-mix asphalt mixtures, particularly E-WMA technique, was higher than that of hot-mix asphalt mixture. Similar to WAC-20C, Fatigue life of WAC-13C was also compared. See Figure 2.

It can be seen from the fatigue curve that for modified asphalt, fatigue resistance of AC-13C mixture prepared by Evotherm warm mix technique was obviously higher than that of SAK warm mix technique at same stress ratio.

3 INTEGRATED APPLICATION OF TWO WARM MIXING TECHNIQUES IN PROJECTS

Considering respective advantages of two warm mixing techniques, the organic viscosity reduction technique and surfactant-based technique were integrally applied in Shaoguan-Ganzhou Expressway with total length at 200 m. Organic viscosity reduction—based warm-mix technique was used in the middle asphalt course due to its outstanding stability at high temperature; while surfactant-based warm-mix technique was used in bottom asphalt course due to its relatively fine fatigue resistance; and Evotherm modified asphalt warm mixing technique was used in surface asphalt course due to its excellent comprehensive performance. The test road structure is as shown in Table 8.

After construction, evenness, compactness, surface texture depth, friction coefficient, water permeability coefficient and rebound deflection were tested for the upper surface courses, and evenness, compactness, water permeability coefficient and rebound deflection were tested for the middle and bottom surface courses. See Tables 9 and 10 for the result.

It can be seen from the test results that when warm-mix asphalt mixture technique was adopted, all construction quality test indexes can fully meet corresponding technical requirements of hot-mix asphalt mixture technique.

4 EVALUATION ON DURABILITY OF TWO WARM MIXING TECHNIQUES

Gradation AC-13C warm-mix asphalt mixture was prepared by the two warm mixing techniques. The warm-mix asphalt mixtures undergo accelerated aging test, and then their high temperature performance after short-term aging and water damage resistance, crack resistance at low temperature and fatigue resistance after long-term aging were tested, studied and compared to those of hot-mix asphalt mixture to evaluate durability of warm-mix asphalt mixture.

4.1 *Stability of warm-mix asphalt mixture at high temperature after short-term aging*

The newly warm-mix asphalt mixture was placed in the baker at 135°C to age for 4 h before formation to simulate aging of asphalt mixture during construction. After short-term aging,

Table 8. Integrated application scheme of two warm mix techniques.

Structural course	Thickness and type	Remarks
Upper asphalt course	4 cm WAC-13C	SBS modified asphalt, surfactant-based warm-mix technique
Middle asphalt course	6 cm WAC-20C	SBS modified asphalt, organic viscosity reduction warm-mix technique
Bottom asphalt course	15 cm WAC-25F	70# common asphalt, surfactant-based warm mix technique

Table 9. Summary of test results of upper asphalt course (WAC-13C).

Type of structure	Evenness standard deviation (mm)	Surface texture depth (mm)	Friction coefficient (BPN)	Water permeability coefficient (ml/min)	Deflection (0.01 mm)	Average thickness (mm)	Compactness (%)
WAC-13C	0.85	0.79	68	51.3	15.3	41.0	93.7
Technical requirement	⩾1.2 mm	/	>45	⩾120 ml/min	/	–10% of designed value	≥93

Table 10. Summary of test results of middle and lower asphalt courses.

Type of structure	Evenness standard deviation (mm)	Water permeability coefficient (ml/min)	Deflection (0.01 mm)	Average thickness (mm)	Compactness (%)
WAC-20C	1.15	87	17.55	52.5	94.3
WAC-25F	1.37	Not leaky	25.38	162.0	96.9
Technical requirements	⩾1.5 mm	⩾120 ml/min	/	–8% of design value	≥93

Table 11. Comparison on stability of different mixtures at high temperature after short-term aging.

Type of mixture	HMA	S-WMA	E-WMA
Post-aging dynamic stability/time/mm	6826	21352	18652
Pre-aging dynamic stability/time/mm	5187	6568	5384

stability of asphalt mixture at high temperature was evaluated through rutting test, the results of which are as shown in Table 11.

It can be seen from above table that dynamic stability of different mixtures was significantly improved after short-term aging, particularly dynamic stability of warm-mixed mixture was improved by 2 to 3 times of the hot-mix asphalt mixture. So short-term aging contributes to improving rutting resistance of warm-mix asphalt mixture.

4.2 *Water stability of warm-mix asphalt mixture after long-term aging*

Specimen prepared with warm-mix asphalt mixture having undergone short-term aging test was placed in a baker at 85°C and heated for 5d in a ventilated manner to simulate status of the asphalt mixture after years. After long-term aging, water stability of asphalt mixture was evaluated through freeze-thaw split test (T0729-2000), the results of which are as shown in Table 12.

Table12 indicates that water damage resistance of all asphalt mixtures drops obviously after long-term aging, out of which organic viscosity reduction based warm mixing technique was slightly better. But generally speaking, water damage resistance of warm-mix asphalt mixture after long-term aging was equivalent to that of hot-mix asphalt mixture.

4.3 *Crack resistance of warm-mix mixture at low temperature after long-term aging*

The specimen after long-term aging also undergoes bending test at low temperature (–10°C). The test results are as shown in Table 13.

The above table indicates that crack resistance of different asphalt mixtures drops obviously after long-term aging, particularly the hot-mix asphalt mixture, while the organic viscosity reducer based warm mixed technique was relatively better.

4.4 *Fatigue resistance of warm-mix asphalt mixture after long-term aging*

Also post-long-term-aging specimen was tested on its bending fatigue life at low temperature in controlled stress method. Fatigue performance of different asphalt mixtures after long-term aging was reflected by remaining fatigue life of mixtures at different stress levels. Fatigue curves of different asphalt mixtures after long-term aging are as shown in Figure 3.

Table 12. Comparison on water stability of different mixtures after long-term aging.

Type of mixture	HMA	E-WMA	S-WMA
Pre-aging TSR (%)	92.4	95.8	90.6
Post-aging TSR (%)	77.1	76.7	79.8

Table 13. Comparison on performance of different mixtures at low temperature after long-term aging.

Type of mixture	HMA	E-WMA	S-WMA
Pre-aging maximum flexure tensile strain/με	12891	9876	9736
Post-aging maximum flexure tensile strain/με	3984	5999	7963

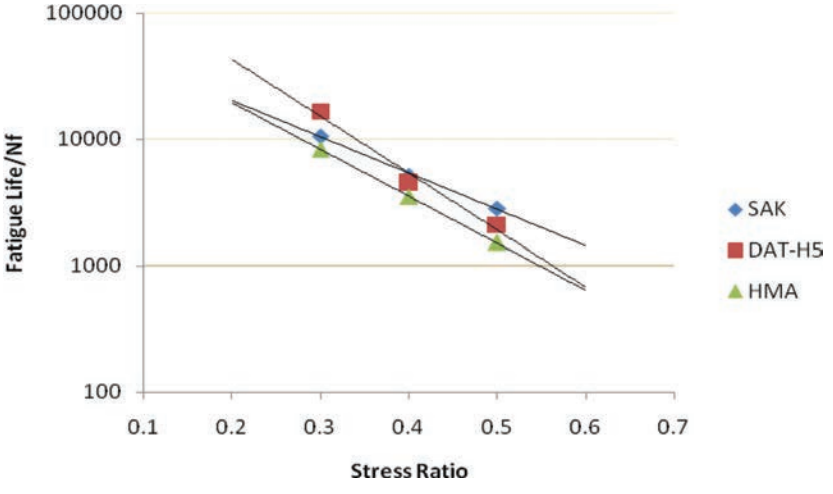

Figure 3. Fatigue curves of different asphalt mixture after long-term aging.

It can be seen from Figure 3 that fatigue resistances of two warm-mix asphalt mixtures were higher than that of hot-mix asphalt mixture under the same long-term aging conditions. By comparing the two warm-mix asphalt mixtures, it can be seen that remaining life of surfactant-based warm mix technique turns from advantageous to disadvantageous with increase of stress level, in other words, it drops quickly.

5 CONCLUSION

1. Different warm-mixing techniques have different effects on mixture performance, and can be used for particular purposes. Asphalt mixtures prepared by surfactant-based warm mixing technique shows great fatigue resistance and can be primarily used on occasions requiring better anti-fatigue capability. Modified asphalt can be used in surface courses as it shows good overall performance. Asphalt mixtures prepared by organic viscosity reducer based warm mixing technique was prominently stable under high temperature and can be primarily used on occasions requiring better stability under high temperature, e.g., the middle surface course.
2. Where common asphalt was used, water damage resistance of mixtures prepared by both warm mixed techniques drops significantly. For organic viscosity reducer based technique, 1% cement or hydrated lime can be added to substitute for mineral powder to improve water damage resistance of the mixture; but this method does not work on surfactant-based WMA technique, and even has counteraction.
3. The two WMA techniques were applied to different asphalt layers of Shaoguan-Ganzhou Expressway based on their respective performance. 200 m test section was paved and tested in terms of compactness and evenness. The test results demonstrate that all technical parameters fully meet technical requirements of HMA at the same gradation.
4. The two warm-mix asphalt mixtures undergo indoor accelerated aging and performance test for durability evaluation. Compared to hot-mix asphalt mixture at the same Gradation, they were superior in terms of low temperature performance and anti-fatigue property.

Characterization of bituminous layers interfaces: From the mechanical behaviour to the modelling

Ktari Rahma, Leandry Ismaelle, Millien Anne, Fouchal Fazia, Pop Ion-Octavian & Petit Christophe
GEMH Laboratory, Civil Engineering and Durability, University of Limoges, Egletons, France

ABSTRACT: Even if, for composite materials, many experimental studies as well as behavior laws have been developed, evaluation of the behavior of interfaces between pavement layers is an actual scientific lock. The current French design method only takes into account interfaces, as conventional perfect bonding or slipping plane. In order to understand the behavior of the interface or interphase, the photomechanical tools are unavoidable. Global and local analysis, determined by two methods, includes tracking markers and Digital Images Correlation (DIC). The feasibility of this approach is presented for a direct tensile test on double-layered asphalt pavement specimen. The results (roughness, adhesion) will be input as parameters of a damage model interface.

Keywords: Interface, image analysis, field measurements, roughness, damage model

1 INTRODUCTION

In road construction, multi-layer composite material making up a road structure are subjected to traffic loading and environmental impacts. Sustainable development needs repairs works or fortification works. Proposed solutions use bituminous materials for the surface layer with optimized mechanical characteristics; layers are finer and finer. This strategy leads to an increase of thermo mechanical stresses on a part close to the surface of the pavement including more and more interfaces between pavement layers especially treated layers with hydraulic or hydrocarbon binders. Associated pathologies to layers unsticking are observed despite the obligation to use a sticking by interposition of a brush layer in tack coat. Sizing road method only considers sticking or a perfect sliding in interfaces conditions. International studies are based on mechanical responses for traction or shearing under monotone or fatigue stress [1, 2, 3, 4, 5]. Obtained results show a direct dependence between the stress, residual dosage of the brush layer and the applications conditions in the building site. Moreover, modelling of interfaces mechanical performances is not studied much in scientific publications. It is mainly expounded models based on elasto-plastic local laws like Mohr-Coulomb. This paper deals with the feasibility of a local approach based on the optical techniques use. This approach will allow the modelling parameters like damage variables and roughness profile.

2 MATERIALS AND FORMULATION: DESCRIPTION OF THE COATED

The tested material comes from an experimental board which has been made in relation to the RILEM ATB&SIB project [4]. It concerns a double-layered asphalt pavement. The lower and the upper layers consisted of an asphalt mixture type AC 12 with binder 35/50 content 4.75% (EN 13108-1), separated by a tack-coat SBS modified emulsion 50/70, binder

Penetration @ 25°C [dmm]	EN 1426	55 ÷ 65
Viscosity @ 160°C [Pa · s^{-1}]	EN 12595	0.200 ÷ 0.800
Softening point [°C]	EN 1427	65 ÷ 75
Breaking point (Fraass) [°C]	EN 12593	<–18

residual: 210 g/m^2. The particle sizes of the mixture are shown in Figure 1. Typical parameters of tack-coat emulsion are presented in Table 1.

3 EXPERIMENT INVESTIGATION

Simple traction tests have been realized with a plane-parallel form specimen (Fig. 2). To ensure the bonds between specimen and machine, metallic items are stock on the specimen surface (Fig. 2). Those items are screwed up on the electro mechanic press axis. The trial machine submits the specimen to a displacement speed about 0.5 mm/min. During feasibility tests, mechanical data and images speed acquisition are about a measurement per second. Experiment temperature is equal to room test temperature (22°C).

4 GLOBAL HOMOGENEOUS ANALYSIS

Global measurement fields are obtained on the one side by mark tracking using a software named DEFTAC developed by the scientific team PEM of P' Institute of Poitiers and on the other side by digital images correlation using another software named CORRELA developed by the same team [9]. To use the marks tracking method, white mark are placed on the items on both sides of the specimen (Fig. 2). This technic is based on the tracking of those marks in each acquired image by calculating their geometric center weighted by the light intensity. During the test position centers allow the global vertical variation ΔUy. Quotient between ΔUy and the initial specimen length is defined as the conventional deformation ε_{yy}.

Digital Images Correlation (DIC) consists in matching two images of the specimen plan surface. Those images correspond to two distinct mechanical states of the specimen. The first one is the reference state and the second the deformed state.

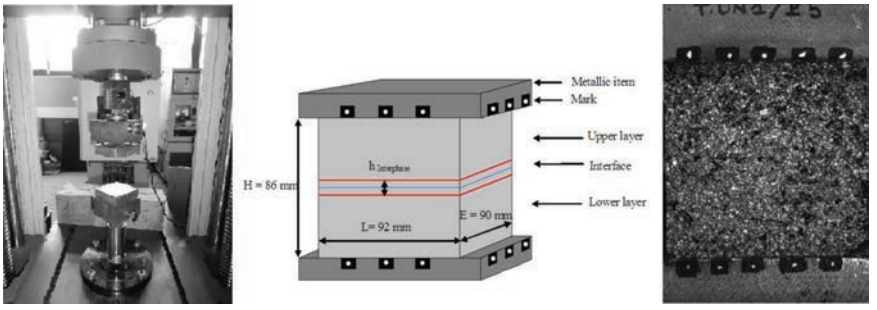

Figure 2. Trial machine, specimen geometry and preparation of surfaces for image analysis.

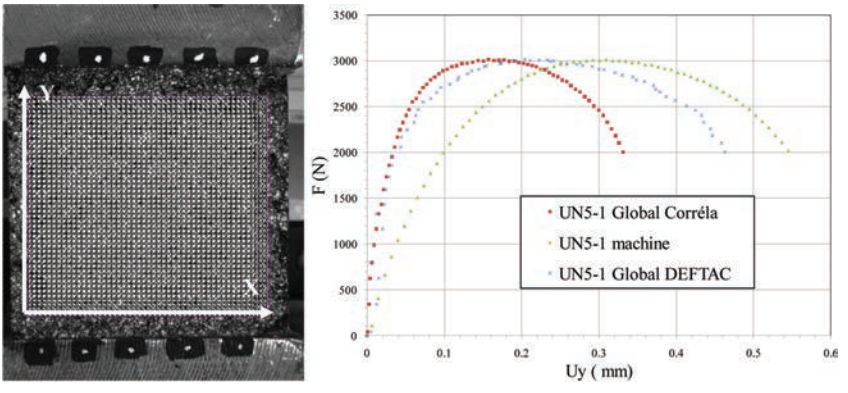

Figure 3. Global fields a) study area (reference, markers and correlation grid) b) overall load–displacement curve.

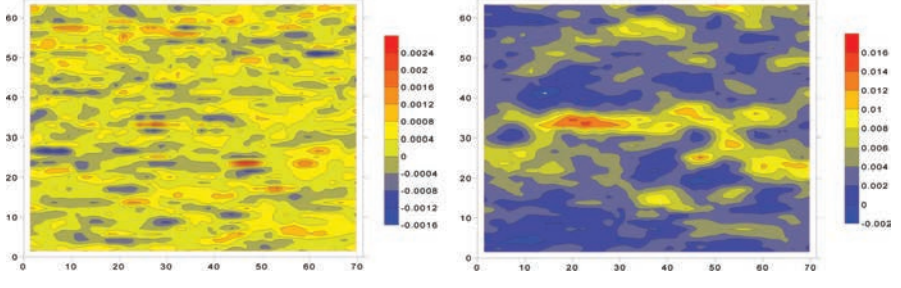

Figure 4. Global fields of strain ε_{yy} a) picture 13 b) picture 60.

When the image pattern of the deformed state is perfectly overlapped with those of the reference state image, displacements are determined.

Generally, pattern is either the objet natural texture, either an artificial pattern like painting projection. In this study case, specimen surface texture is not adequate, so a speckle is projected on its surface.

A correlation study is achieved with a rise of =0.202 mm/pixel and the correlation windows size is about 8 × 8 pixels (the shift is equal to 2 pixels). Global fields for each method cited above and the study area included the reference, markers and correlation grid are presented in Figure 3.

Two fields are presented on Figure 4: as the maximal stress is obtained for the 41st picture, the first field (a) corresponds to the initial linear part of the global stress-strain curve.

It allows the visualization of material heterogeneity. The second presented field has been captured after the stress pic and shows the strain localization on the interphase.

5 LOCAL ANALYSIS

Different evolution curves are plotted. It concerned the vertical displacement versus the vertical position for each picture. Figure 5 presents an example of results for a vertical line located in the middle of the analyzed specimen face. Those curves are used to evaluate the interphase local strain and the interphase size. In this study the interphase is 2.5 mm. Local strain is defined as the guiding coefficient of each curve median segment. In Figure 5, the observed local strain scatter in the neighborhood of the interface/interphase for different curves shows the roughness effect and the material heterogeneity.

6 COMPARISON OF LOCAL ANALYSIS WITH GLOBAL ANALYSIS

Figure 6 is the global and local curves over lapping. It shows difference of the behavior between the global specimen (usual data) and the interface (DIC data). The beginning of this difference seems to be early.

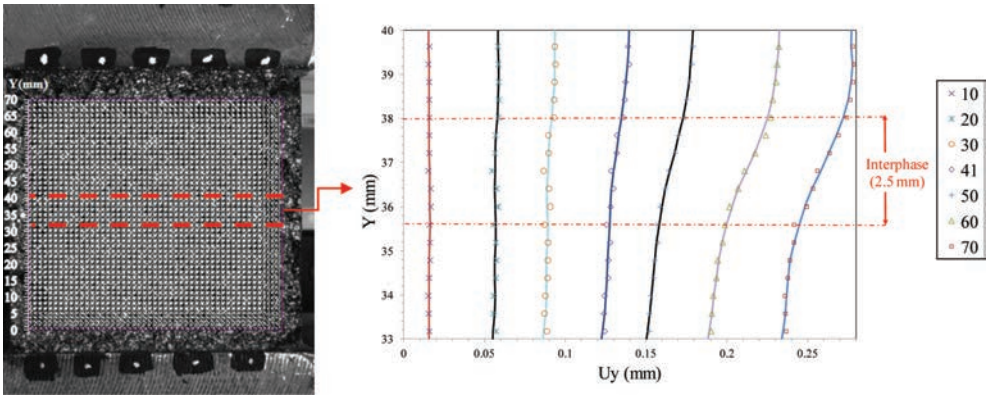

Figure 5. Localization of the interface during the essay with a correlation windows size 8 × 8 pixels.

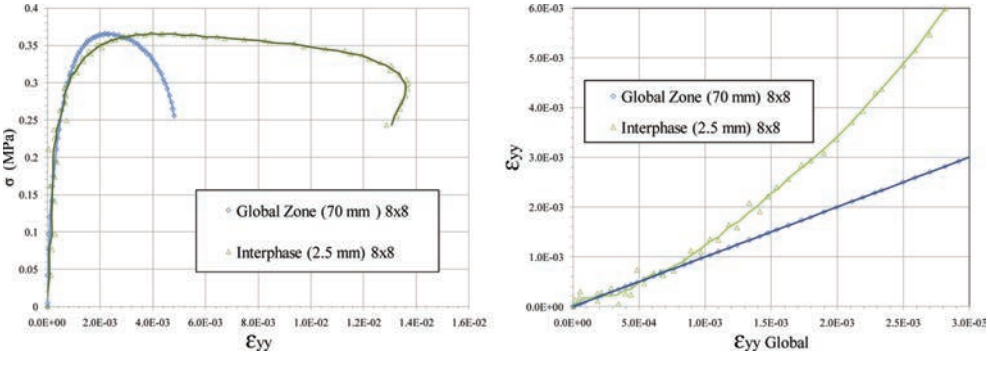

Figure 6. a) superposition of global and local behavior curves: Stress–strain curve—b) focus on the localization of the interface.

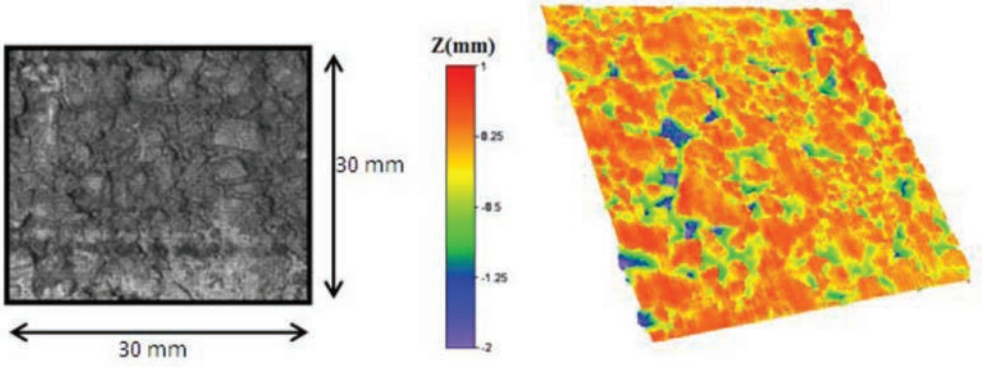

Figure 7. a) Sample before break—b) profile of interface roughness to the initial state.

Table 2. Average roughness of the study area.

	Initial state	Post break
Ra (mm)	0.32	0.50
Rq (mm)	0.44	0.67

7 MORPHOLOGY AND INTERFACE ROUGHNESS

Fringe projection principle is the same as shadow moiré which allows the visualization and the direct calculation of the relief of a studied object surface. For this study, a reference volume is employed instead of a reference plan for more accuracy [13]. The basic principle of the optical technique consists of projecting a pattern of fringes and in recording an image of the object from another point of view with a CCD camera. Even if the surface to be analyzed does no present large discontinuities, a specific image analysis is used to determine the phase of deformed pattern on the relief object surface [9]. For that purpose, the software Light 3D, developed by PEM team research of the GMSC department of the P' Institute of Poitiers, has been used.

Before the measurement, the surface to study must be prepared: white paint projection is carried (Fig. 7-a). Figure 7-b shows the rough state surface at the initial condition. The aim of this study is to introduce roughness parameters or roughness curves in a model.

To analyze the surface roughness, the roughness average (Ra) and the root Mean Square Roughness (Rq) are calculated in Table 2 [14, 15, 16]. Those parameters come from the ISO 4288 Standard (1996). For this specimen, partial statistic results are presented in following table. A global increase of means roughness can be observed due to the grain wrenching after breaking.

The local study performed with DIC method, presented in section 5, allows determining the thickness interphase which is close to 2.5 mm. This value is similar to the roughness value (Table 2).

8 INTERFACE MODELLING

The homogenization method consists of describing the average behavior for equivalent material by taking into account the microscopic parameters for each component.

In this study, homogenous model is proposed for the bituminous material. It's considered as a one-dimensional composite cell. The interphase is described by two material layers shown in Figure 8. Both layers are characterized by the same thickness.

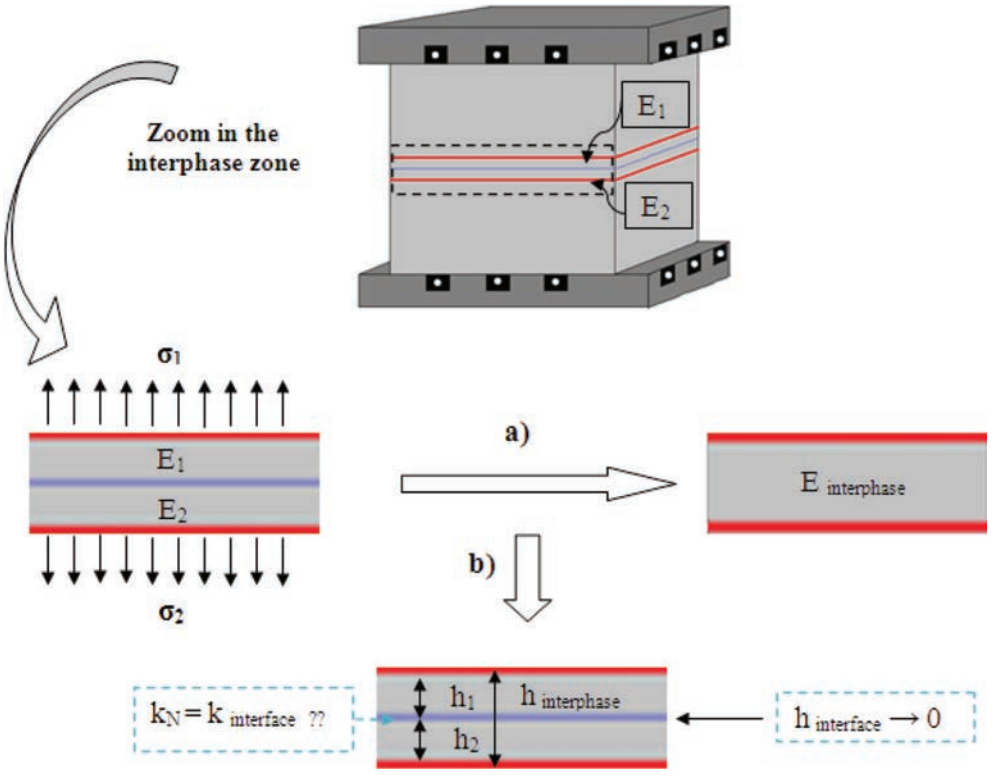

Figure 8. a) Homogenizing a bituminous double layer materials in parallel b) interface modelling.

Young's modulus for the upper layer in the samples is $\mathbf{E_1}$ and for lower layer is $\mathbf{E_2}$. These parameters are measured in two areas located on each side of the interface. Both thickness areas are equal to 13.5 mm chosen as they are greater than a grain size.

Also, Young's modulus secant $E_{interphase}$ can be determined experimentally from the stress-strain curves (see Fig. 6-a).

Young's modulus results for the different materials are given in Figure 9, for the maximum and minimum uncertainty bars of measurement for the experimental study.

This model allows us to calculate Young's $E_{interphase}$ modulus (Fig. 8-a) for the homogeneous material. The interphase behavior shown in Figure 9 is described in the following equations.

$$\sigma_{interphase} = E_{interphase} \times \varepsilon_{yy}^{interphase}, \sigma_1 = E_1 \times \varepsilon_{yy}^{1}, \sigma_2 = E_2 \times \varepsilon_{yy}^{2} \quad (1)$$

The equilibrium of the interphase involves Eq. (2):

$$\sigma = \sigma_{interphase} = \sigma_1 = \sigma_2 \quad (2)$$

The sum of the displacements U_y^1 and U_y^2 in the direction of y, calculated for the first and the second layer must be equal to the total material *"interphase"*

$$U_y^{interphase} = U_y^1 + U_y^2 \quad (3)$$

$$h_{interphase} = h_1 + h_2 \quad (4)$$

which: ε_{yy}^1, ε_{yy}^2: Mean strain in the upper and the lower layer respectively.
U_y^1, U_y^2: Relative displacement for each layers.

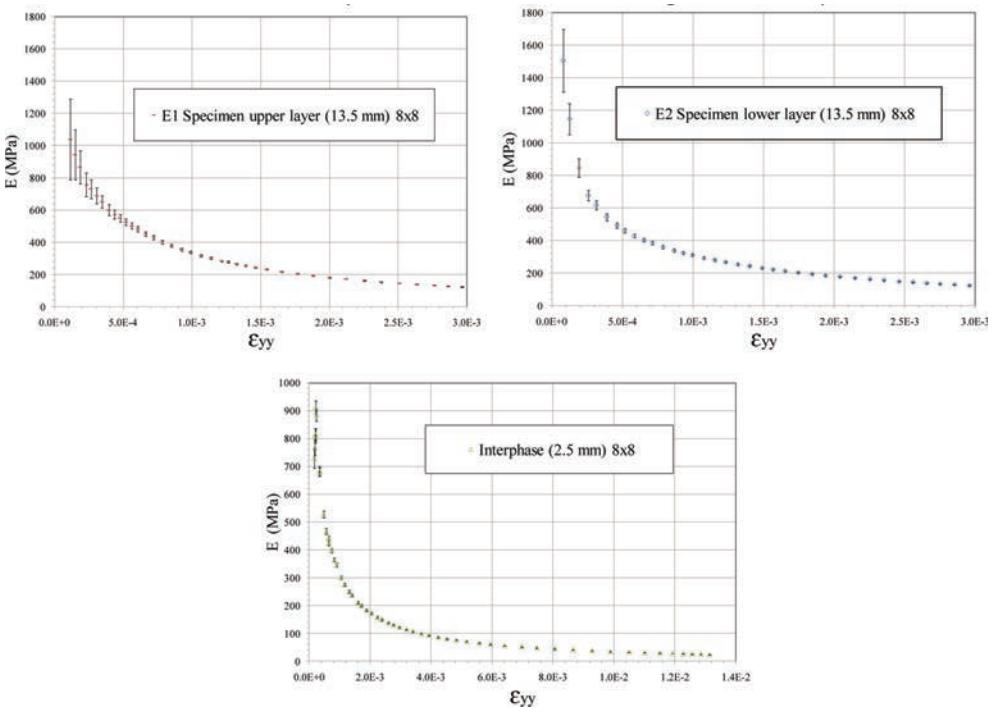

Figure 9. The secant modulus for the different materials: E_1 for upper layer, E_2 for lower layer and $E_{interphase}$ for interphase zone.

Finally Young's interphase modulus is obtained by Eq. (5)

$$E_{interphase} = \frac{E_1 \times E_2 \times (h_1 + h_2)}{E_1 h_2 + E_2 h_1} \tag{5}$$

The results shown in Figure 10, present Young's modulus $E_{interphase}$ measured (including the interface behavior) and calculated (perfectly bonded layers). It enables the user to get by difference of both curves the interface behavior.

If we opt for finite element modeling, we need to assume joint finite element (thickness tend to zero). The linear elastic joint behavior is reminded in Eq. 6.

$$\sigma_{interface} = k_{interface} \times [U_y] \tag{6}$$

where: $[U_y]$ is the relative normal displacement of the interface.

Now, if we include the interface behavior in Eq. (3) we get Eq. (7)

$$U_y^{interphase} = U_y^1 + U_y^2 + [U_y] \tag{7}$$

The normal stiffness k_N of the interface is then deduced from Eq. (1, 6, 7):

$$k_N = \frac{E_{interphase} \times E_1 \times E_2}{E_1 \times E_2 \times (h_1 + h_2) - E_{interphase} \times E_2 \times h_1 - E_{interphase} \times E_1 \times h_2} \tag{8}$$

The interface stiffness result is given in Figure 11-a. We can see with the error bars that incertainty depend on the level of displacement measurements. So for k_N calculation, we consider only displacements that are more than one micrometer in order to have an acceptable accuracy.

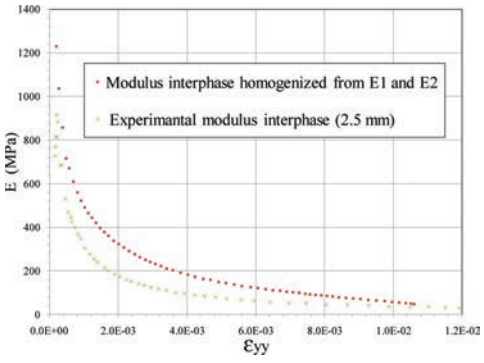

Figure 10. Comparison of the interphase modulus: experimental modulus data and modulus homogenized from E_1 and E_2.

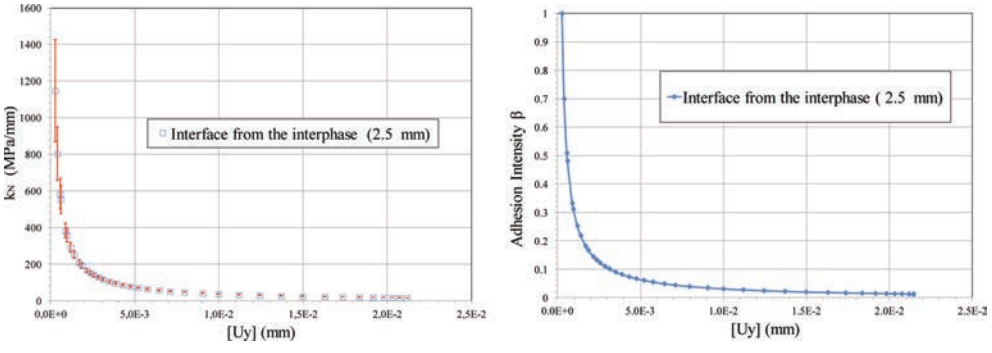

Figure 11. a) Normal interface stiffness b) evolution of the adhesion intensity with the relative displacement at the interface.

In the case of the modeling RCCM type [10, 11], the adhesion intensity variable β introduced by Fremond [12] can be experimentally determined from the normal stiffness of the interface (Fig. 11-b).

9 CONCLUSION AND PERSPECTIVES

This study confirms the possibility to determine the interface thickness by localization and to identify the parameters of the interface behavior such as roughness, stiffness, adhesion intensity. The goal of this work is to develop an interface modeling for the pavement structures by using the previous main parameters. This analysis concern only bonding test with tensile loading. Other tests are performed with shear loading in order to get a better understanding interface behavior such as interlocking effect depending on roughness for instance.

Comparison of asphalt fatigue characteristics under different control modes

Hong Zhang, Liyan Shan, Yiqiu Tan, Yichen Feng & Hongsen He
School of Transportation Science and Engineering, Harbin Institute of Technology, Nangang District, Harbin, Heilongjiang, China

ABSTRACT: Fatigue cracking is a common form of distress in asphalt pavement. The ability of asphalt binder to resist accumulation of fatigue damage can have a profound effect on the service life of asphalt pavements. However, the fatigue characteristics of asphalt binder depend heavily on the loading modes. That is the fatigue characteristic of asphalt binder under controlled-stress mode is totally different from that under controlled-strain mode. The issue affects the establishment of universal fatigue evaluation index of asphalt binder. This study focused on analysing the fatigue performance difference between under controlled-stress and controlled-strain mode. The fatigue characteristics of two kinds of asphalt binders under different loading control modes were compared. And the fatigue performances relationship under different control modes was founds. Further, a method to transform accumulated dissipated energy curve from one loading mode to the other was proposed.

Keywords: asphalt binder, fatigue, controlled-stress mode, controlled-strain mode

1 INTRODUCTION

Fatigue cracking is one of the primary distresses in asphalt pavements. As one of the most important components of asphalt mixture, asphalt binder plays a critical role in the fatigue performance of asphalt mixture even asphalt pavement. So the fatigue characteristics of asphalt binder have always been focused in the past few decades.

The fatigue behavior of asphalt binder is complex as it is affected by many factors, such as temperature, loading level, loading control mode and so on. Among these, loading control mode is one of the most important effect factors. The fatigue behavior of asphalt binder under controlled-stress mode is totally different from that under controlled-strain mode. And the fatigue life rankings of different asphalt binders under different control modes are contradictory evaluated by the same index, which makes it different to choose binders with better fatigue performance. The common practice in fatigue analysis is to employ the controlled-strain mode for asphalt materials that are used in thin pavements and controlled-stress mode for asphalt materials used in thick pavements (1). However, changes in the structural design of pavements and complex traffic loading make it difficult to identify pavement systems that adhere strictly to either controlled-strain or controlled-stress conditions.

In order to address this problem and better evaluate the fatigue performance of asphalt binders, some researchers have attempted to unify the results from controlled-strain and controlled-stress modes of testing for the same asphalt materials using different methods. Monismith et al. (2) corrected for the mode of loading by introducing a mode factor in analysis of fatigue testing. Van Dijk et al. (3,4) were the first to suggest to use the dissipated energy concept to analyze fatigue behavior. During the fatigue process the material is damaged and energy is dissipated. Bonnetti, K.S. et al. (5) used K_1 (slope) and K_2 (intercept) for the curve of N_{p20} (the number of cycles at which the dissipated energy ratio shows 20% deviation from the no-damage ratio) versus initial dissipated energy per cycle to define fatigue performance

and it showed that these two values were not highly affected by the loading mode. Ghuzlan and Carpenter (6) attempted to unify the results from different control mode by using the ratio of the change in dissipated energy between consecutives cycles (i and i + 1) to the dissipated energy in the first of the consecutives cycles (i). There is a constant plateau value in the curve of the ratio versus the number of load cycles, which was independent of the mode of loading. Based on that energy principle, Shen and Carpenter (7) established a PV (plateau value) fatigue prediction model for asphalt mixture. Kim et al. (8) used the elastic–viscoelastic correspondence principle proposed by Schapery (9) to derive damage functions and stress–strain relationships for asphalt mixture under controlled-strain and controlled-stress cyclic loadings. After it has been successfully used for mixture, some researchers (10, 11) applied the theory to asphalt binder, and it showed that some binders did follow that and some not. Based on the elastic–viscoelastic correspondence principle, Kim et al. (12) also employed the concept of Dissipated Pseudo Strain Energy (DPSE) to evaluate the fatigue cracking life of Fine Aggregate Matrix (FAM) using the Dynamic Mechanical Analyzer (DMA). Masad et al. (13) separated the DPSE due to the change in phase angle (W_{R1}) and pseudo stiffness (W_{R2}) and permanent deformation (W_{R2}) and unified the results of the controlled-strain and controlled-stress modes of loading by the ratio of W_{R3} to W_{R1}. Based on the same theory and the principles of fracture mechanics, Castelo Branco et al. (14,15) also developed the crack growth index, and proved that this index can quantify fatigue cracking in an asphalt mixture independent of the mode of loading. Bhasin et al. (16) quantitatively compared different energy methods to characterize fatigue in asphalt materials, and showed the advantages and disadvantages of different methods. All these methods focus on unifying the results from different loading control modes in form, but the fatigue behavior difference still needs to be studied and the fatigue performance relationship between different control modes is seldom studied.

Based on the above analysis, the fatigue performances of two kinds of asphalt binders in different control modes were studied by analysing the dynamic modulus curve and accumulated dissipated energy curve. The relationship between the performances in these two kinds of control modes was established. Further, a method to transform accumulated dissipated energy curve from one loading mode to the other was proposed.

2 MATERIALS AND TEST METHODS

Two neat asphalt binders were selected for this study. For the remainder of this paper, these materials are labeled as generic binders A and B. Both of the materials are standard, unmodified asphalt binders. A is 60~80 "penetration" asphalt, and B is 80~100 "penetration" asphalt, according to the Chinese penetration grade. These binders were both aged in a rolling thin-film oven (i.e., RTFO-aged) prior to testing to simulate the effects of mixing and compaction. Laboratory testing was performed using a TA Instruments DHR-2 rheometer. All tests were conducted with an 8-mm diameter parallel plate geometry and 2-mm gap setting. Two types of test were conducted: stress sweep test and fatigue test. At least three replicates were performed for each condition. Although not shown in this paper, the variability for these tests is generally less than 10 percent.

2.1 *Stress sweep test*

Before the fatigue tests were conducted, the stress or strain levels for these experiments were chosen from the results of stress sweep test, as shown in Figure 1. The strain increases linearly with increase in stress level at first and increases sharply when the stress level gets to some level. When the strain is 3%, the stress is 0.3 MPa for binder A at 20°C, 0.25 MPa for binder B at 20°C, 0.14 MPa for binder A at 25°C and 0.11 MPa for binder B at 25°C. 0.3 MPa and 3% for binder A at 20°C, 0.25 MPa and 3% at 20°C for binder B, 0.14 MPa and 3% at 25°C for binder A, and 0.11 MPa and 3% at 25°C for binder B are named couples of loadings. In order to compare the fatigue performance of the studied asphalt binders in different loading

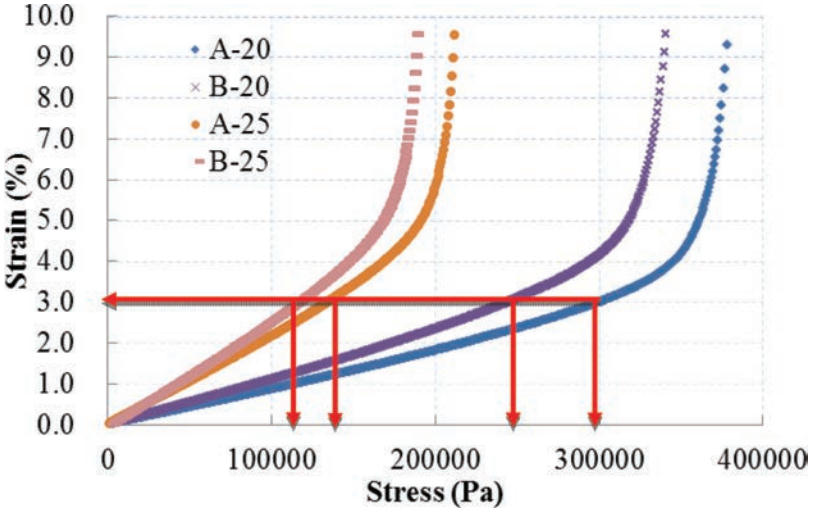

Figure 1. Stress sweep test results for the studied binders.

modes, it is necessary to choose the couples of loading. To round up or down the stress level a little bit, 0.3 MPa at 20°C and 0.15 MPa at 25°C were chosen for binder A, and 0.25 MPa 20°C and 0.1 MPa at 25°C were chosen for binder B. Besides that, In order to study the fatigue performance of the asphalt binders in different stress levels, the stress levels of 0.1 and 0.2 MPa at 25°C for binder A and 0.15 and 0.3 MPa at 20°C for binder B were also chosen.

2.2 *Fatigue test*

Because fatigue is generally a concern at intermediate temperatures, these tests were conducted at 20°C and 25°C. The fatigue tests were conducted in both controlled-stress and controlled-strain modes with a 10 Hz continuous sinusoidal loading until the dynamic modulus of the specimens gets to smaller than 20% of the initial value.

3 RESULTS AND ANALYSIS

3.1 *Analysis of the dynamic modulus curves in different loading modes*

Figure 2 presents the fatigue characteristics of the studied asphalt binders in terms of dynamic modulus versus number of cycles. In Figure 2, the data series that are labelled A-0.1 MPa indicate that the tested binder is A and the controlled stress is 0.1 MPa, with similar meanings for the other data series labels. Figure 2 shows that the dynamic modulus value decreases slowly at first, but then the degradation accelerates quickly as the specimen approaches failure in controlled-stress mode. In controlled-strain mode, the dynamic modulus value decreases slowly at first, then decreases quickly and decreases slowly again after attaining about 30% of its initial value. The figure also shows that the fatigue performance of asphalt binders worsens with an increased input magnitude and also with an increase in temperature.

If the fatigue process is divided into two phases (the demarcation point is the point after where the dynamic modulus decreases quickly), it is meaningful to find that if the strain and stress levels are a couple of loading, the curve in the controlled-stress mode almost coincides with the curve in the controlled-strain mode in the first phase. For example, 0.3 MPa and 3% are the couple of loading for binder A at 20°C, and the A-0.3 MPa dynamic modulus curve overlaps with the A-3% dynamic modulus curve at 20°C in the first phase. Same phenomenon can be found for another couple of loadings. It means that the effect of strain and the effect of stress are the same as in the first phase. Furthermore, under those conditions, the fatigue

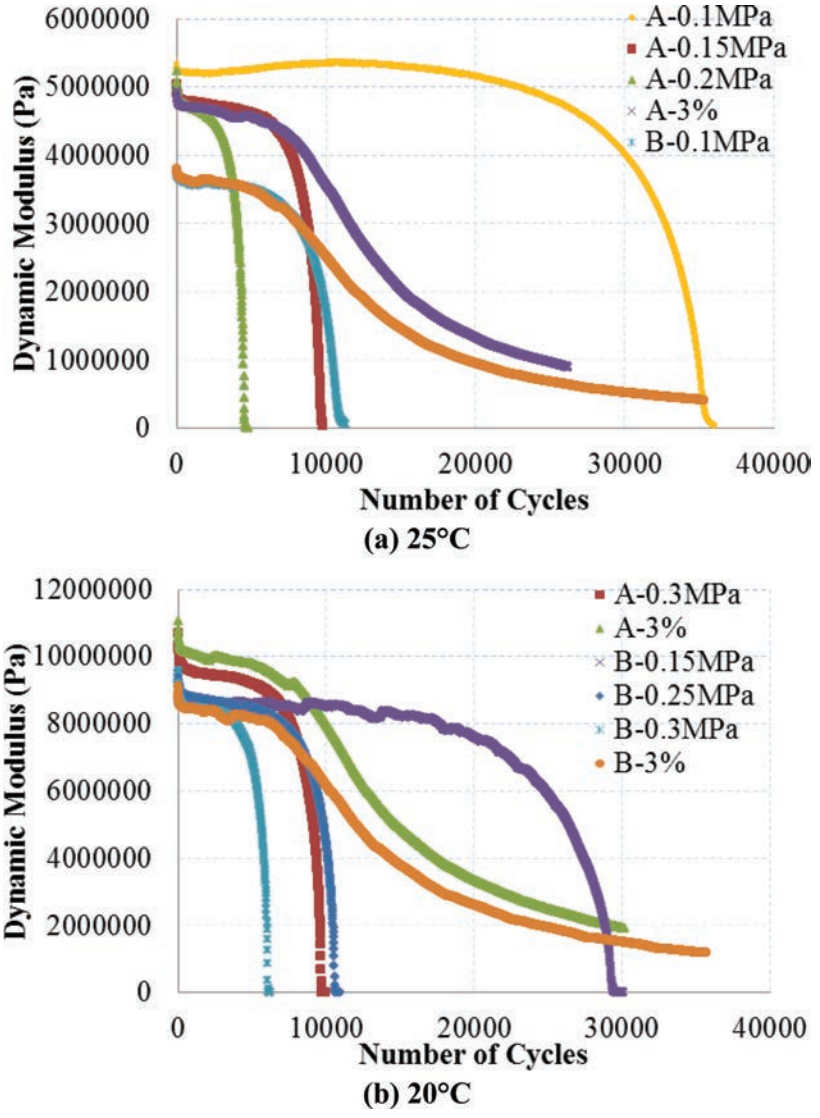

Figure 2. Fatigue performances of the studied binders.

behavior of the asphalt binders is the same in different control modes. The main differences between the fatigue behavior of the asphalt binder in controlled-strain mode and controlled-stress mode are in the second phase of the fatigue process. In controlled-stress mode, the dynamic modulus value decreases quickly in the second phase, but in controlled-strain mode, the dynamic modulus value decreases slowly. This phenomenon leads to the fatigue life of the same asphalt binder being different in different control modes evaluated by the same index.

3.2 *Analysis of the dissipated energy in different loading modes*

In order to compare the fatigue performance of asphalt binders in different loading modes and find the relationship between them, the dissipated energy of the binders under the couple of loading was studied.

The equation to calculate dissipated energy is shown as follow in Equation (1). After integrating Equation (1), Equation (2) was obtained. The dissipated energy per cycle changes

with increase in number of cycles. The accumulated dissipated energy is the sum of the dissipated energy from cycle one to cycle n, as shown in Equation (3). It can also reflect the fatigue performance of asphalt binders.

$$w_i = \oint \tau(dt)d\gamma(t) = \oint \tau(t)\frac{d\gamma(t)}{dt}dt \quad (1)$$

$$w_i = \pi\tau\gamma\sin\delta \quad (2)$$

$$W_n = \sum_{i=1}^{n} w_i \quad (3)$$

where: w_i = dissipated energy (Pa);
τ = shear stress (Pa);
γ = shear strain (%);
δ = phase angle;
W_n = accumulated dissipated energy (Pa).

Figure 3 presents the dissipated energy changing law of the asphalt binder A and B in terms of accumulated dissipated energy versus number of cycles. It shows that the accumulated dissipated energy increases with increases in number of cycles under both controlled-stress and controlled-strain modes. In controlled-stress mode, the accumulated dissipated energy increases linearly first then the increasing ratio increases when the dissipated energy accumulates to some level. In controlled-strain mode, the accumulated dissipated energy increases linearly first same to that in controlled-stress mode. After the dissipated energy accumulates to some level, the increase ratio decreases with increases in number of cycles. The curve of

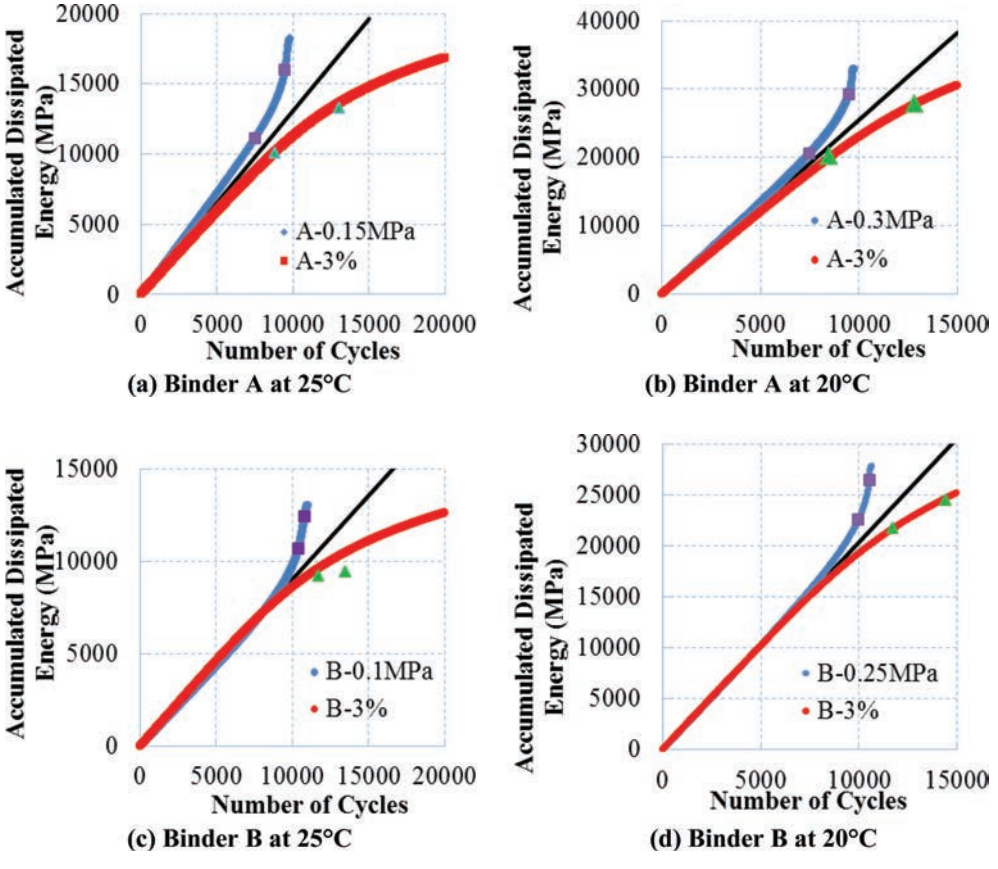

Figure 3. Accumulated dissipated energy under the four couples of loading.

accumulated dissipated energy versus number of cycles under controlled-stress mode almost coincides with that under controlled-strain mode in the linear part. Besides that, the curve of accumulated dissipated energy versus number of cycles under controlled-stress mode and that under controlled-strain mode seems to be symmetrical.

In order to prove these two kinds of curves were symmetrical or not, three steps were taken. First, the symmetrical axis was chosen and plotted. It is chosen based on the coincided part of the two curves. It is the linear line that goes through the coincided part (black linear line), as shown in Figure 3. Second, two points in the non-linear part of the controlled-stress curve were chosen, and the symmetrical points were calculated, as shown in Figure 3 and Table 1. Finally, the calculated points were compared to the points in the controlled-strain curve, and the symmetry was proved. It should be noted that the x-axis scale and y-axis scale are not the same, so the two points seems to be not symmetrical. But they are symmetrical in fact.

As shown in Table 1, the values in "In controlled-stress curve" column are the points selected by the authors, and two points were select for each condition. By calculating, the symmetrical points of the selected points can be found, as shown in "Calculated symmetrical points" column. The point in the controlled-strain curve that is the most closet to the calculated symmetrical point was found as shown in "In the controlled-strain curve". The symmetry of the controlled-stress curve and the controlled-strain curve was studied by comparing the values in the last two columns in Table 1. It can be seen in the table that the values in these two columns are very close. For example, for point 2 of binder A at 25°C, the calculated symmetrical point is (13008.48, 1.33×10^{10}) and the real point in controlled-strain curve is (13001.8, 1.36×10^{10}), these two points are very close, same to another points, except for point 1 at 25°C for binder B. For that point, the calculated symmetrical is (13455.97, 0.95×10^{10}), but the real point in the curve is (13448, 1.05×10^{10}). The differences between the y values of these two points are a little big but not huge. Based on the whole results, it can be say that the controlled-stress curve is symmetrical to the controlled-strain curve. If the controlled-stress curve was obtained, the controlled-strain curve can be obtained by symmetry calculation and vice verse.

3.3 *Accumulated dissipated energy curves transformation from one loading mode to the other*

Known from the analysis of the above, the controlled-stress curve is symmetrical to the controlled-strain curve. If the controlled-stress curve was obtained, the controlled-strain curve

Table 1. Calculated results for the symmetry.

Binders	Temperature	Point	Symmetrical axis	In controlled-stress curve	Calculated symmetrical points	In controlled-strain curve
Binder A	25°C	Point 1	$y = 1.3 \times 10^6 x$	7500.42, 1.11×10^{10}	8795.06, 1.01×10^{10}	8792.18, 1.01×10^{10}
		Point 2		9500.26, 1.60×10^{10}	13008.48, 1.33×10^{10}	13001.8, 1.36×10^{10}
	20°C	Point 1	$y = 2.55 \times 10^6 x$	7504.36, 2.06×10^{10}	8465.48, 2.02×10^{10}	8460.77, 1.98×10^{10}
		Point 2		9500.38, 2.92×10^{10}	12854.40, 2.78×10^{10}	12858.40, 2.78×10^{10}
Binder B	25°C	Point 1	$y = 9.0 \times 10^5 x$	10401.5, 1.07×10^{10}	11692.98, 0.92×10^{10}	11698, 0.96×10^{10}
		Point 2		10806.7, 1.24×10^{10}	13455.97, 0.95×10^{10}	13448, 1.05×10^{10}
	20°C	Point 1	$y = 2.04 \times 10^6 x$	10005.2, 2.26×10^{10}	11743.72, 2.18×10^{10}	11744.4, 2.17×10^{10}
		Point 2		10555.1, 2.65×10^{10}	14458.03, 2.46×10^{10}	14462.4, 2.47×10^{10}

can be obtained by symmetry calculation and vice versa. In this part, a method to transform accumulated dissipated energy curve from one loading mode to the other was proposed and three steps were taken as follows.

First, the accumulated dissipated energy curve of one controlled mode was got from fatigue experiments, and a function was chosen to fit the curve. For controlled-stress mode, the function which was shown in Equation (4) was used to fit the accumulated dissipated energy curve, and Equation (5) was used to fit the accumulated dissipated energy curve of controlled-strain mode.

$$W_{fit-stess} = \frac{w_0 \times (10t)}{\left(1 - \frac{t}{t_R}\right)^{1/(\nu+1)}} \tag{4}$$

$$W_{fit-stain} = w_0 \times (10t) \times \left(1 - \frac{t}{t_R}\right)^{1/(\nu+1)} \tag{5}$$

where: $W_{fit-stress}$ = fitted accumulated dissipated energy of controlled-stress mode (Pa);
$W_{fit-strain}$ = fitted accumulated dissipated energy of controlled-strain mode (Pa);
w_0 = initial dissipated energy without damage (Pa);
t = time(s);
$\left(1 - t/t_R\right)^{1/(\nu+1)}$ = damage evolution function;
t_R, ν = material parameters, obtained by fitting.

Second, the symmetrical axis was chosen and plotted based on the coincided part of the curve. The expression of the symmetrical axis was shown in Equation (6).

$$y = kt \tag{6}$$

where: $k = 10 \times w_0$;
w_0 = initial dissipated energy without damage (Pa).

If two curves are symmetrical about a straight line the expression of which is as Equation (6) shows, and the functional relationship of one curve is $y = f(t)$, then the functional relationship of the other curve is as Equation (7) shows.

$$\frac{2kt + (k^2 - 1)y}{1 + k^2} = f\left(\frac{2ky - (k^2 - 1)t}{1 + k^2}\right) \tag{7}$$

So on the basis of knowing the functional relationship of accumulated dissipated energy curve in one mode which was shown in Equation (4) or Equation (5), the functional relationship of accumulated dissipated energy curve in the other mode can be measured. Take the case of the controlled-stress mode, if the functional relationship of accumulated dissipated energy curve in controlled-stress mode was known, the functional relationship of accumulated dissipated energy curve in controlled-strain mode was shown in Equation (8).

$$\begin{aligned} \frac{2kt + (k^2 - 1)W_{measure-strain}}{k^2 + 1} = 10w_0 \times \frac{2kW_{measure-strain} - (k^2 - 1)t}{k^2 + 1} \\ \times \left(1 - \frac{\frac{2kW_{measure-strain} - (k^2 - 1)t}{k^2 + 1}}{t_R}\right)^{-1/(\nu+1)} \end{aligned} \tag{8}$$

where: $W_{measure-strain}$ = measured accumulated dissipated energy of controlled-strain mode (Pa).

Third, give the values of t and get the values of $W_{measure-strain}$. Because Equation (8) was a nonlinear equation, the values of $W_{measure-strain}$ were calculated by Matlab software. The results of the measured $W_{measure-strain}$ were shown in Figure 4.

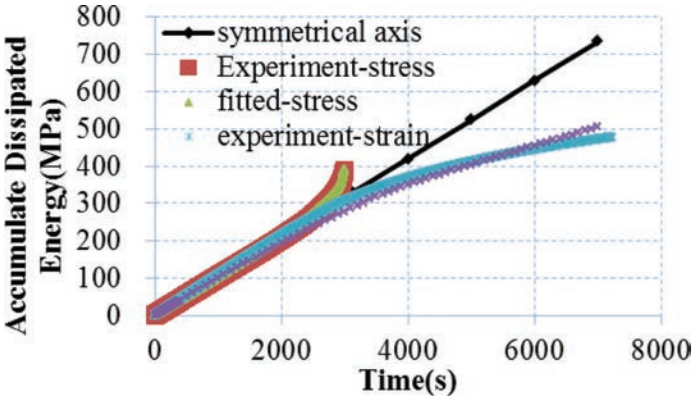

Figure 4. The measured results of accumulated dissipated energy of controlled-strain mode.

As shown in Figure 4, the fitted curve of accumulated dissipated energy in controlled-stress mode ("fitted-stress") is coincident with the experimental data ("experiment-stress"), which is indicated that Equation (4) can fit the accumulated dissipated energy in controlled-stress mode well. On the other hand, the measured curve of accumulated dissipated energy in controlled-strain mode ("measured-strain") is also relatively consistent with the experimental data ("experiment-strain"), which further demonstrates that the controlled-stress curve is symmetrical to the controlled-strain curve.

4 CONCLUSIONS

This paper analyses and compares the differences in the fatigue behavior of asphalt binders in different loading control modes in terms of dynamic modulus and accumulated dissipated energy. The fatigue behaviour relationship between different control modes is found. And the differences are explained by the cross-sections in different control modes. Based on the results presented, several conclusions can be drawn:

1. If the controlled stress and controlled strain is a couple of loading, the fatigue curves of asphalt binders in different control modes are the same in the first phase.
2. If the controlled stress and controlled strain is a couple of loading, the accumulated dissipated energy curve of asphalt binders in controlled-stress mode is symmetrical to that in controlled-strain mode.
3. The method to transform accumulated dissipated energy curve from one loading mode to the other proposed by the article is practicable.

To confirm these findings, more asphalt binders including modified asphalt binders should be tested and analyzed in the future.

Moisture sensitivity of interlayers between conventional and porous asphalt mixes

Emiliano Pasquini, Fabrizio Cardone & Francesco Canestrari
Università Politecnica delle Marche, Ancona, Italy

ABSTRACT: The use of geocomposites obtained combining bituminous membranes with reinforcing geosynthetics represents a promising option for asphalt pavement application. Thanks to their waterproofing effect, such geocomposites could be successfully used also underneath porous surface layers as an alternative of bituminous tack coat. In this sense, one of the major issue related to the use of geocomposites at the interface between porous surface layers and binder courses is the prolonged contact with drained rainfall water. Given this background, a specific research study was carried out in order to evaluate the moisture sensitivity of interlayers positioned between traditional dense graded asphalt concretes and porous asphalt concretes. Particularly, two geocomposite materials produced combining an elastomeric membrane with a polyester textile and a fiberglass grid, respectively, were investigated along with a traditional reference interlayer obtained by applying hot polymer modified asphalt at the interface. In order to evaluate moisture sensitivity of such interlayers, shear tests were carried out in both dry and wet conditions on double-layered samples prepared in the laboratory. Experimental results showed that the prolonged action of the water did not produce loss of performances of studied interlayers in terms of interface shear strength.

Keywords: Geocomposites, asphalt pavement, interface shear properties, moisture sensitivity, porous asphalt

1 INTRODUCTION

Nowadays, Porous Asphalt Concrete (PAC) is successfully worldwide used on the main highway systems as wearing course or overlay on top of existing pavements in order to improve the surface performance. PACs are bituminous mixtures characterized by a discontinuous grading (high amount of coarse aggregates and low sand and filler content), thus creating an open structure with high air void content (usually ≥ 20%). The particular arrangement of the voids is such that rainwater can drain through a system of interconnected voids to the sideways of the road pavement, thus improving wet weather driving conditions (reduced hydroplaning and splash & spray along with improved skid resistance). Moreover, the high air void content also allows the reduction of traffic induced noise emissions [1–4].

Despite its safety and environmental benefits, PAC can suffer and expose underlying asphalt courses to significant moisture damage due to its open structure, leading to a weakening and hence shortened durability of entire pavement [5–8]. Therefore, an adequate bituminous interlayer with waterproofing function is necessarily required underneath porous surface courses in order to prevent infiltration of water through underlying layers.

In this context, the use of geocomposites obtained by combining a bituminous membrane with a reinforcing geosynthetic can represent a promising option for interlayer systems. In fact, they simultaneously act as waterproofing barrier to control water flow as well as reinforcement systems improving structural response of pavements [5, 9–14].

This paper illustrates a part of an ongoing wider research project which aims at developing an optimized reinforced membranes for asphalt pavement applications on the basis of a performance-related approach [15, 16].

Particularly, the present research evaluated the use of specified geocomposites produced combining an elastomeric bituminous membrane with two different reinforcement types. Such materials could be placed underneath porous surface layers for waterproofing purpose as an alternative of traditional bituminous interlayer. The effectiveness of studied products was investigated in the laboratory with regard to the moisture sensitivity of interface shear behavior of layered systems.

2 MATERIALS AND METHODS

2.1 *Asphalt concrete*

In the present research, double-layered slabs were prepared in the laboratory. The lower layer consisted of a dense graded (conventional) mix AC20 prepared with limestone aggregates (D_{max} = 20 mm) and SBS polymer modified bitumen dosed at 4.0% by the weight of the aggregates. Whereas the upper layer consisted of an open graded (porous asphalt) mix PA 16 prepared with basaltic aggregates (D_{max} = 16 mm) and the SBS polymer modified bitumen dosed at 4.9% by the weight of the aggregates. The gradations and the main properties of the bitumen used for both mixtures are shown in Figure 1 and in Table 1, respectively.

2.2 *Interlayer systems*

Three different double-layered systems were considered depending on the type of interlayer material used: a bituminous material and two geocomposite systems. The reference interface configuration was prepared with an SBS polymer modified binder classified as PMB 45/80-70 according to EN 14023. Hot bitumen dosed at 0.6 kg/m^2 was applied at the interface of the double-layered slabs.

On the other hand, the studied geocomposites, having a thickness of 2.5 mm, were obtained combining an elastomeric bituminous membrane, modified with Styrene-Butadiene-Styrene (SBS) synthetic copolymers, and two different reinforcing materials (Fig. 2). The reinforcing materials were a polyester nonwoven textile and a fiberglass grid characterized by a square

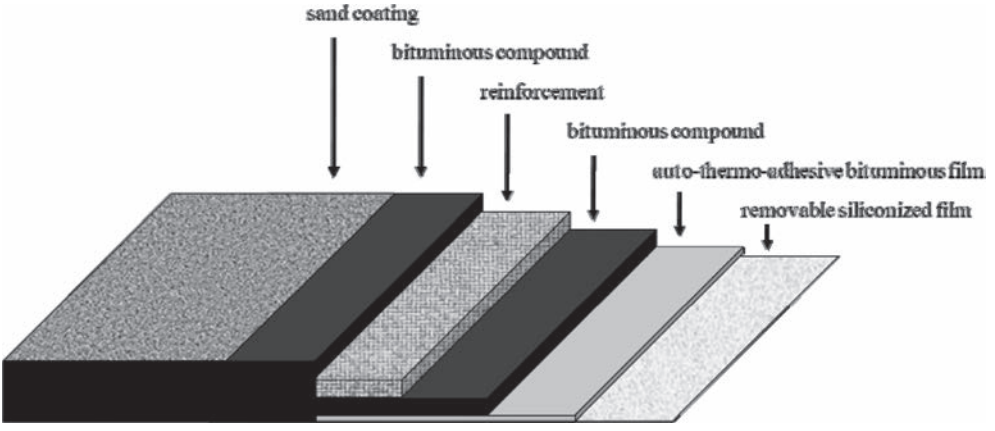

Figure 2. Typical cross-section of reinforced geomembrane.

12.5 mm mesh. It is worth mentioning that the upper side of both geocomposites was coated with a fine sand ($D_{max} < 0.5$ mm) whereas the lower side was characterized by an auto-thermo-adhesive SBS-modified bituminous film (Fig. 2).

2.3 *Laboratory specimen preparation*

Double-layered slabs with a plan dimension of 305×305 mm^2 were compacted in the laboratory by means of a Roller Compactor (EN 12697-33).

Each slab was prepared following different phases. First, the lower layer (binder course) was compacted with a thickness of 40 mm, assuming a target of 8.0% air void content. After cooling of slab at room temperature for 4 hours, depending on the required interface configuration, the appropriate interlayer system (hot bitumen or geocomposite) was applied. Then, a 40 mm thick upper layer (porous asphalt) was compacted with a target air void content of 21.0%. Finally, the compaction direction was marked on the slab surface in order to perform the shear tests in the same direction.

From each double-layered slabs, five 95 mm diameter cylindrical specimens to be evaluated by means of Ancona Shear Testing Research and Analysis (ASTRA) tests were obtained by coring.

2.4 *ASTRA test*

The ASTRA test allowed the evaluation of the interlayer (hot bitumen or geocomposites) influence on the interface shear behavior of the corresponding layered systems.

The ASTRA device (Fig. 3), compliant with the draft European Standard prEN 12697-48 and the Italian Standard UNI/TS 11214, is a direct shear box, similar to the device used in

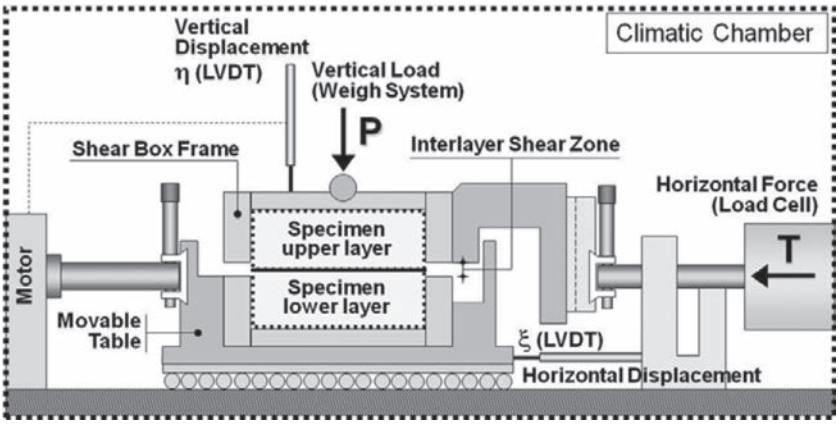

Figure 3. Scheme of ASTRA equipment.

soil mechanics, and the whole apparatus is located in a climatic chamber with temperature and relative humidity control. Single specimen, prepared in laboratory or cored from the field, is installed in two half-boxes (upper and lower) separated by an unconfined interlayer shear zone and the lower half-box is free to move with a fixed rate [17, 18]. During the test, a constant horizontal displacement rate of 2.5 mm/min occurs while a constant vertical load, normal to the interface plane, is applied on the upper half-box in order to generate a given normal stress (σ_n).

This test returns a data-set where interlayer shear stress (τ), horizontal (ξ) and vertical (η) displacement are reported, allowing the calculation of the maximum interlayer shear stress (τ_p), for each specimen. ASTRA tests, carried out at various stress levels σ_n, allow a complete assessment of failure and residual properties (post-peak) of interfaces to be obtained [17]. Previous studies [17, 18] have shown how residual friction, inner cohesion, dilatancy and tack coat adhesion affect the interlayer shear resistance in multi-layered bituminous systems.

3 EXPERIMENTAL PROGRAM

Three interface configurations were obtained using different interlayer materials. The reference configuration, prepared with hot applied bitumen at the interface, is hereafter named as REF whereas the configurations characterized by the presence of the geocomposites are labeled as GPT in the case of geocomposite reinforced with a nonwoven polyester textile and GFG in the case of the geocomposite reinforced with a fiberglass grid with a square 12.5 mm mesh.

The research aims to identify the studied geocomposites as suitable solution, alternative of bituminous tack coat, for interface waterproofing. Moreover, the geocomposites can assure anti-pumping and anti-reflective cracking performance. Because of prolonged contact between geocomposites (placed at the interface between porous surface layers and binder courses) and drained rainfall water during service life of pavement, the use of such geocomposites was evaluated in terms of moisture effects on interlayer shear properties.

To this end, ASTRA interface shear tests on cylindrical specimens cored from double-layered slabs were carried out at 20°C under three normal stresses ($\sigma_{n1} = 0.0$ MPa, $\sigma_{n2} = 0.2$ MPa and $\sigma_{n3} = 0.4$ MPa) performing three repetitions for each test configurations (Table 2).

The moisture sensitivity of interlayer systems was evaluated by carrying out shear tests on both dry and water exposed samples. Each sample of specified interface configurations was divided into two subsets: dry (9 specimens) and wet (9 specimens). Before testing, the dry subsets and the wet subsets were conditioned for 15 days at 20°C in air and fully immersed in water, respectively.

GPT	3	3	3	3	3	3
GFG	3	3	3	3	3	3

4 RESULTS AND ANALYSIS

The overall results of ASTRA tests are presented in Table 3 in terms of envelope characteristic parameters, where c_0 is the pure shear resistance, Φ_p is the peak friction angle, c_r is the pure shear resistance after the failure and Φ_r is the residual friction angle. These values come from the peak and friction envelopes, obtained as linear regression of the representative shear data measured applying different normal stresses σ_n (0.0, 0.2 and 0.4 MPa). The statistical overall quality of the adopted linear regression models is showed in Table 4 in terms of Standard Errors (SE) of c_0, c_r, Φ_p and Φ_r as well as of τ_p and τ_r.

First of all, it is interesting to note that tested double-layered systems exhibited a certain pure shear resistance after failure ($c_r \neq 0$), unlike results obtained in previous researches on different grid-reinforced and unreinforced interfaces [17, 19–21]. According to Canestrari et al. [22], this "residual cohesion" is provided by the presence of the thick bituminous interlayer which obstructs the real contact between the asphalt layers. This finding seems to be confirmed by the fact that the two layers of the specimens were still held together by the bituminous interlayer after testing.

Moreover, it was possible to note that the shear failure did not affect the interface between the interlayer and the asphalt layers but it was located within the interlayer: the deformable bituminous film caused the asphalt layers to slip each other without breaking and determined the residual cohesion of the double layered systems. Thus, in this case, also the residual friction angles Φ_r were influenced by interlayer characteristics in opposition to what found in several studies [17, 19–21] of unreinforced and grid-reinforced systems. In fact, such researches demonstrated that, once the failure condition is reached, the residual friction properties can be considered as an intrinsic characteristic of the asphalt materials. This assumption is still valid if a real contact between the two layers is allowed whereas it seems not applicable in the presence of interlayers.

Figure 4 illustrates peak envelopes for each testing condition. Results show that the reference configuration REF offered the highest shear resistance. This experimental finding proves that the presence of a reinforced membrane at the interface inevitably reduces the bonding between the asphalt layers, according to several previous investigations carried out on reinforced interfaces using various experimental devices [12, 16, 19, 20, 22–25].

On the basis of such results, the application of studied geocomposites has to be carefully verified for interfaces located close to the road surface where the shear stresses transmitted by vehicles remain still high. In fact, a too much low shear strength at the interface could imply the risk of debonding and consequent slippage between the wearing and the binder courses causing both structural and functional damage to the pavement. In any case, it can be asserted that GFG can be successfully applied for asphalt layers reinforcement (at least underneath the binder course); in fact, it was demonstrated, through static three-point bending tests, that the application of GFG geocomposite is able to provide an enhanced damage resistance of the double layered reinforced systems as regard to GPT geocomposite. On the other hand, the geocomposite GPT could be preferred to GFG thanks to the lower interface debonding as long as the required reinforcing contribution is limited.

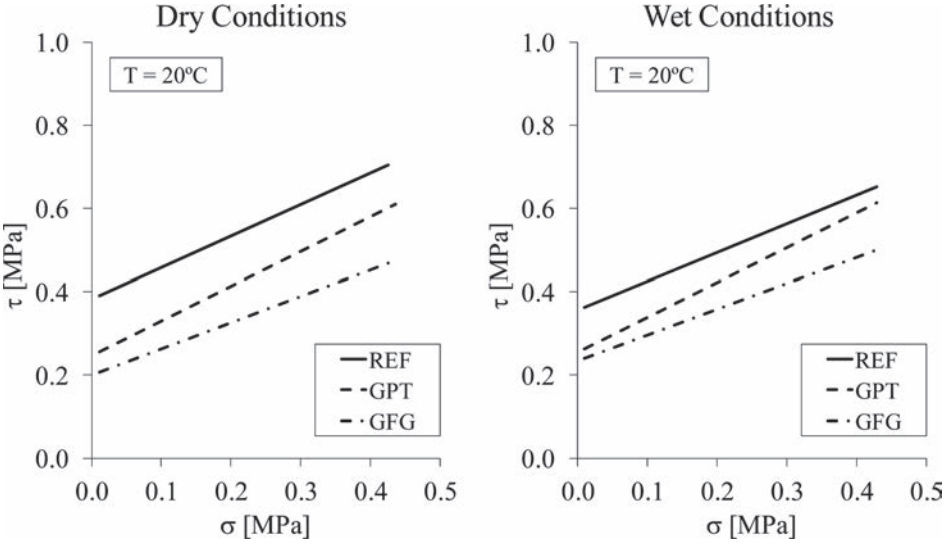

Figure 4. ASTRA test peak envelopes: dry (left) and wet (right) conditions.

As far as the water resistance of studied interlayers is concerned, the comparison between dry and wet configurations for each studied interlayer is shown in Figure 5 in terms of the peak envelopes. Results proved that only the reference interlayer REF exhibited a certain performance decrease due to the water exposure whereas interface treated with geocomposites GPT and GFG demonstrated identical or even improved performances in wet conditions. However, the difference between dry and wet conditioned samples was negligible and hence not directly related to real damage due to water. Thus, it can be asserted that the application of the studied geocomposites did not imply an increase in moisture sensitivity at the

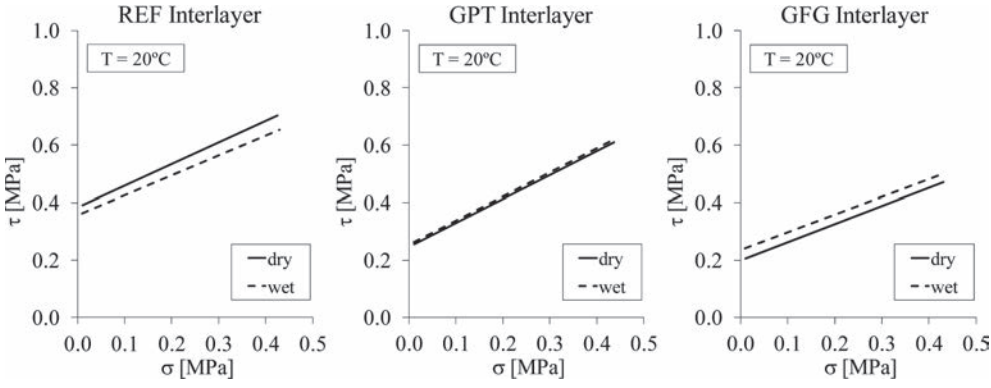

Figure 5. ASTRA test peak envelopes: moisture sensitivity of studied interlayers.

corresponding interfaces with respect to a traditional interlayer (hot applied polymer modified bitumen). It is also right to point out that, for a better comprehension of the moisture sensitivity of studied interlayers, a more severe water conditioning (e.g. higher temperature and/or time, repeated dry/wet cycles, etc.) should be selected for further studies in order to emphasize the water damage at the interface.

5 CONCLUSIONS

The research described in this paper has the objective of evaluating the potential application of reinforced membranes underneath porous surface layers as an alternative of traditional bituminous interlayer. An SBS polymer modified binder and two geocomposites were considered as interlayer systems. The geocomposites consisted of an elastomeric bituminous membrane reinforced with a polyester nonwoven textile (geocomposite GPT) and a fiberglass grid (geocomposite GFG), respectively. The effectiveness of studied products was investigated in the laboratory with regard to the moisture sensitivity of interface shear behavior of layered systems.

ASTRA tests carried out in dry and wet conditions allow the following conclusions to be drawn:

- Studied interlayers exhibit a "residual cohesion" after failure provided by the presence of a thick bituminous film which obstructs the real contact between the bituminous layers;
- The installation of geocomposites at the interface inevitably leads to lower interface bonding between the asphalt layers reducing peak strength. Particularly, geocomposite GPT showed slightly higher performances than GFG;
- The application of the studied geocomposites did not imply an increase in moisture sensitivity of the corresponding interfaces with respect to a traditional interlayer.

It is worth clarifying that, in order to avoid debonding and consequent slippage between the wearing and the binder courses due to the high shear stresses transmitted by vehicles, the application of studied geocomposites close to the road surface should be carefully designed as a function of predicted stresses and strains at the interface. In this sense, further studies evaluating the shear stresses typically generated as a function of the interface depth are currently in progress with the aim of a theoretical validation of the use of interlayers.

As far as results presented in this study concern, it is possible to state that the geocomposite GPT could be preferred to GFG thanks to the lower interface debonding as long as the required reinforcing contribution is limited.

Finally, as far as water sensitivity concerns, it is right to point out that the difference between dry and wet conditioned samples was negligible. Thus, for a better comprehension of the moisture sensitivity of studied interlayers, a more severe water conditioning should be selected for further studies.

ABSTRACT: Glass fiber grids or "geogrids" are geocomposite materials frequently employed in asphalt pavement design as reinforcement interlayer to delay the occurrence and propagation of cracks. This paper presents the study and the characterization of the fatigue behavior of a standard asphalt concrete and of the composite made of the asphalt concrete and a glass fiber grid. The aim of this study is to characterize the fatigue behavior of the different structures, to compare them and to quantify the increase in fatigue life due to the geogrid. This is achieved with the four point bending tests performed in the laboratory. The fully reverse fatigue tests were carried out on two different types of specimens: A non-reinforced asphalt concrete beam and a reinforced asphalt concrete beam with two fiber glass grids. The analytical damage model of Castro-Sanchez is calibrated on the bituminous mixture and on the geogrid reinforced bituminous mixture and we discuss the accuracy of this model. The reinforcement role of the glass fiber grid is evidenced by the four point bending test results and supported by the modeling results.

Keywords: fatigue cracking, asphalt concrete, geogrid, four point bending test, analytical damage model

1 INTRODUCTION

The service life of an asphalt pavement depends on its performance under the action of traffic loads and thermal stresses. The phenomenon known as "fatigue cracking" happens under the repeated loads induced by traffic and it is one of the major causes of pavement deterioration [2]. Fatigue cracking is initiated where the tensile stresses are significant, generally at the bottom of the asphalt surface course. One of the methods used to delay this phenomenon is to use a coated glass fiber grid called "geogrid" at the interface between surface course and base course. The geogrid is bonded to the base course with bitumen emulsion. The complex made of asphalt concrete and geogrid has a very good behavior under fatigue loading, delaying the fatigue crack initiation and propagation. In this way, the geogrid works as reinforcement of the asphalt concrete surface course, subjected to fatigue loading.

In this paper, we study the fatigue behavior of the complex made of an asphalt concrete and a geogrid. The study is organized in five sections as follow:

– Section 2 presents the materials and the sample preparation steps.
– Section 3 describes the fatigue test procedures and experimental device.
– Section 4 presents the Four Point Bending (4PB) fatigue tests results.
– Section 5 presents the simulation of the number of cycles at failure with the Castro-Sanchez damage model.

2 MATERIALS AND SAMPLE PREPARATION

2.1 *Tested materials*

The tested asphalt concrete is a standard Semi-Coarse Asphalt Concrete (SCAC) 0/10 class III according to the European classification [3], with the elasticity modulus of 9 GPa, obtained in four point bending tests performed at $T = 15°C$ with $f = 10$ Hz. The aggregate gradation is presented in Figure 1. The bituminous mixture is composed of the following aggregate fractions: 40.68% of 0/4 mm, 9.46% of 4/6 mm, 42.58% of 6/10 mm, 1.89% of filler and 5.39% bitumen 35/50.

The geogrid used as a reinforcement is the coated glass fiber grid CIDEX 100 SB of 6D Solutions, represented in Figure 2. The product is an elastic composite made of warp and filling yarns and nonwoven parts of polyester fiber (mesh: 40×40 mm^2). Both yarn types are made of continuous glass fiber and SBS resin. The mechanical strength at failure of this geogrid is 100 KN/m. In practice, the geogrid is bonded to the pavement layers by applying 600 g/m^2 of bitumen emulsion.

2.2 *Sample preparation*

Two types of samples are made in laboratory [3], respectively: Non-Reinforced (NR) and reinforced (R) asphalt samples. There are five steps in the making process of the reinforced asphalt slabs, as follows:

A. The compaction of the first asphalt concrete layer of 50 mm height,
B. The insertion of a geogrid with a bitumen emulsion applied at ambient temperature (23°C)

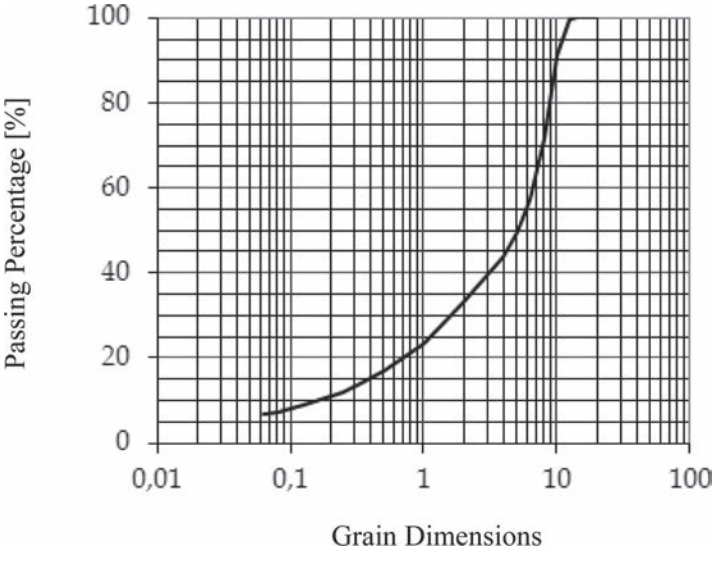

Figure 1. Aggregate gradation of SCAC 0/10 class III.

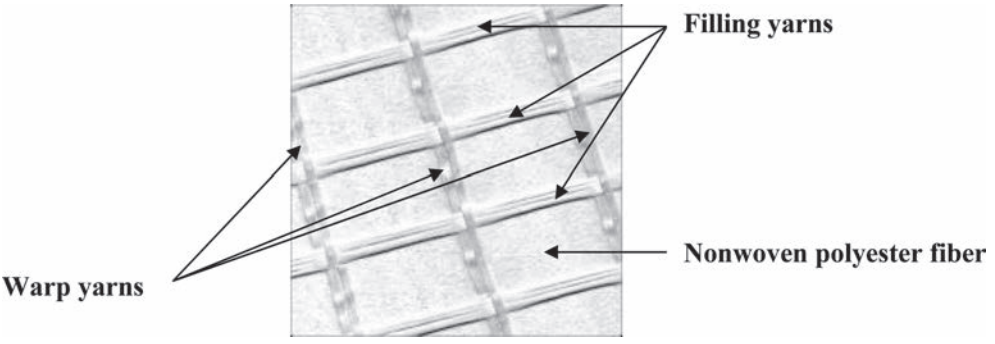

Figure 2. Geogrid CIDEX 100 SB, 6D Solutions.

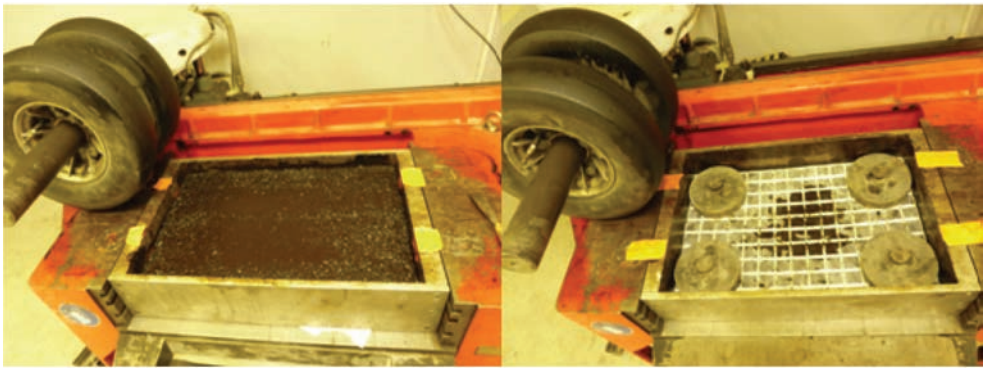

Figure 3. Fixation of the glass fiber grid with bitumen emulsion on the compacted asphalt layer, Epsilon laboratory.

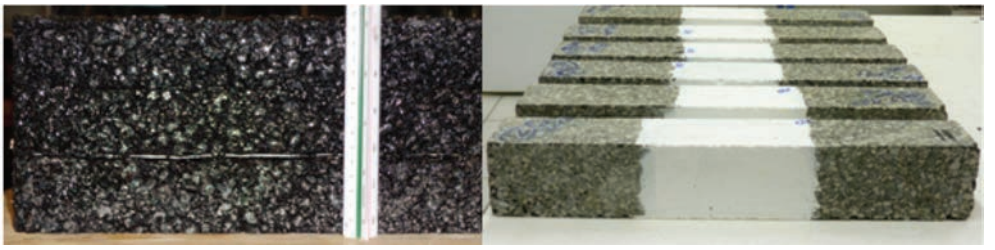

Figure 4. Reinforced asphalt slab and beams.

C. The compaction of the second asphalt concrete layer of 50 mm height,
D. The insertion of a second geogrid with a bitumen emulsion applied at ambient temperature (23°C),
E. The compaction of the third asphalt concrete layer of 50 mm height.

The slabs have the dimensions $600 \times 400 \times 150$ mm^3 (length × width × height). A quantity of 600 g/m^2 of bitumen emulsion was used to insert each geogrid in the R specimens. For the NR specimens, only 300 g/m^2 of bitumen emulsion was used between the asphalt layers. Once the slab is removed from the roller compactor mold, two blocks made of the same asphalt mixture are fixed with araldite at both ends of the slab (minimum 15 mm thickness each) in order to obtain a total slab length of 630 mm. The last operation is sawing the slabs. From each slab we

obtain three beams of $630 \times 100 \times 100$ mm^3. The reinforced asphalt beam vertical section from the bottom to the top is: 25 mm asphalt concrete layer, geogrid with bitumen emulsion, 50 mm asphalt concrete layer, geogrid with bitumen emulsion and 25 mm asphalt concrete layer.

3 FATIGUE TESTS PROCEDURES

The fatigue tests are performed using a four point bending device, specially designed for this study. The standard 4PB device was adapted to the dimensions of the samples, according to the standard [1]. The fatigue tests are fully reverse four point bending tests, performed with a controlled strain, with a frequency of 25 Hz at 10°C temperature [1]. In the French pavement design method [2], the admissible tensile strain at the bottom of asphalt layers is calculated in function of the tensile stress leading to failure after 1 million cycles in a standardized fatigue test with $f = 25$ Hz at $T = 10$°C. The tests are performed with the two types of beams presented in section 2: reinforced (R) and Non-Reinforced (NR) asphalt beams.

3.1 *Four point bending testing device*

The standard fatigue device corresponds to asphalt beams of $400 \times 50 \times 50$ mm^3. These dimensions are not sufficient to test the reinforced asphalt beams presented in section 2. The fatigue device was design to test asphalt beams of $630 \times 100 \times 100$ mm^3.

3.2 *Four point bending test configuration*

Figure 5 shows the principle of the fully reverse four point bending (4PB) test with sinusoidal waveform [1]. In the fully reverse 4PB bending test, the beam is bent from the initial position to the position corresponding to the amplitude of deflection in both senses of tension and compression. Failure happens in an area of uniform moment corresponding to the central part of the beam, between the two load lines.

The deflection is constant and the response of the material is the force, which decreases with the number of cycles. The imposed strain of 135 μm/m corresponds to a constant deflection of 0.1035 mm. This value was chosen to obtain a fatigue life for the non-reinforced asphalt mixture around 400 000 cycles.

The displacement of the beam is measured with a sensor-type Linear Variable Differential Transducer (LVDT) with a range of ± 1 mm. Material response and phase angle are measured during the test.

4 FOUR POINT BENDING FATIGUE TESTS AND RESULTS

A significant number of fatigue tests at three different strain levels (150 μm/m, 135 μm/m, 115 μm/m) were performed on Non-Reinforced (NR) and reinforced (R) asphalt specimens in order to determine the fatigue curves of the materials.

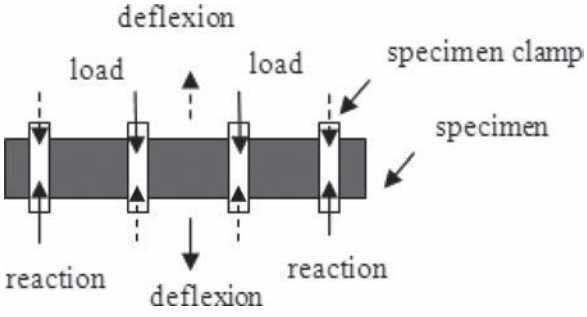

Figure 5. Principle of the fully reverse 4PB fatigue test [4].

The fatigue damage curves ($E/E_i - N$) at the strain level $\varepsilon = 135$ μm/m are presented in this paper (Fig. 6). Twelve 4PB fatigue tests were performed at 10°C with 25 Hz: 6 tests performed on NR asphalt specimens (1 NR .... 6 NR) and 6 tests performed on R asphalt specimens (1R .... 6R).

The 4PB fatigue test results presented in Table 1 show that the geogrid reinforces the asphalt mixture by the increase of the fatigue life. The average fatigue life for each group of specimens and the average fatigue life increase are calculated.

The indicator is the fatigue life, defined in [1],[2] as the number of cycles corresponding to a 50% decrease of the initial elastic modulus. This is represented by an evolution of the ratio $E/E_i = 0.5$ which corresponds to a damage "D" equal to 0.5, determined as $D = 1 - E/E_i$.

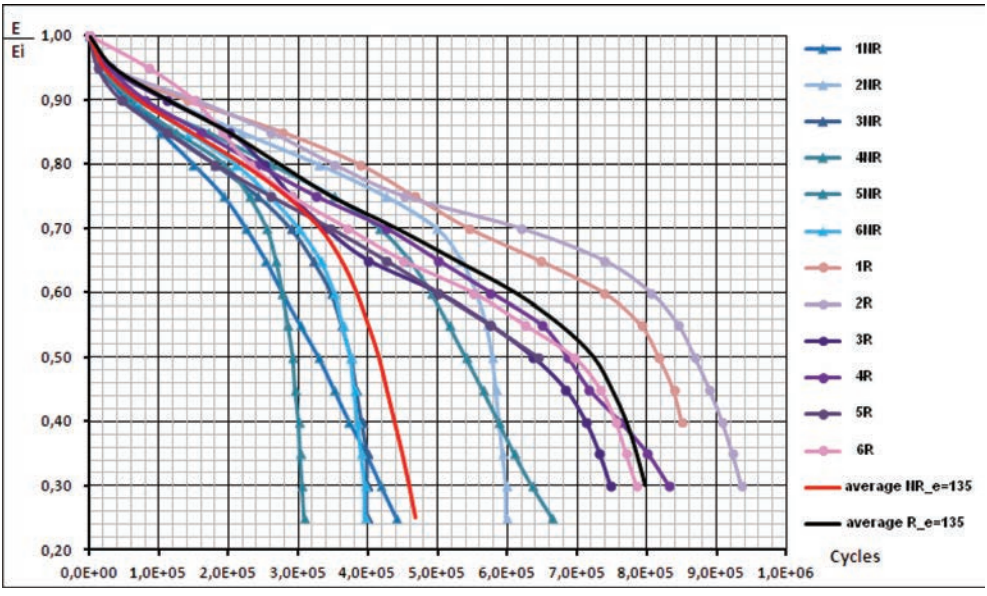

Figure 6. Fatigue damage curves ($E/E_i - N$) in the 4PB fatigue tests on *NR* and *R* specimens.

Table 1. Fatigue 4PB test results at $\varepsilon = 135$ μm/m, $T = 10$°C, $f = 25$ Hz.

Specimen name	Initial elastic modulus E_i	Fatigue elastic modulus E_f (50%)	Fatigue life $N_{f\,(50\%)}$
1 NR	13 976	6 988	328 210
2 NR	12 960	6 480	578 130
3 NR	13 728	6 864	374 550
4 NR	13 736	6 868	540 050 ($N_{f\,max}$)
5 NR	13 962	6 981	291 800 ($N_{f\,min}$)
6 NR	14 870	7 435	375 770
Average NR	13 872	6 936	414 752
1 R	13 470	6 735	817 200
2 R	12 692	6 346	868 210 ($N_{f\,max}$)
3 R	12 042	6 021	636 640 ($N_{f\,min}$)
4 R	12 222	6 111	685 650
5 R	11 864	5 932	643 584
6 R	12 000	6 000	695 210
Average R	12 382	6 191	724 416
Fatigue life increase			309 664 (74.66%)

Significance of the following terms:

NR—non reinforced asphalt beams,
R—reinforced asphalt beams,
E—elastic modulus in MPa,
E_i—initial elastic modulus, after 100 loading cycles,
$E_{f\ (50\%)}$—fatigue elastic modulus, $E_f = E_i/2$,
$N_{f(50\%)}$—fatigue life, number of cycles corresponding to E_f,
$N_{f,max}$—the maximum fatigue life in a group of specimens (NR and R),
$N_{f,min}$—the minimum fatigue life in a group of specimens (NR and R).

Observations on the 4PB fatigue tests results:

- The initial elastic modulus seems to be smaller for the R specimens in comparison with the NR specimens.
- Nevertheless, the fatigue life is considerably improved at the R specimens in comparison with the NR specimens. For the tested strain level $\varepsilon = 135$ μm/m, the average fatigue life increase due to the geogrid is 309 664 cycles, representing 74.66% of the average fatigue life of NR specimens.

5 ESTIMATION OF THE NUMBER OF CYCLES AT FAILURE WITH THE CASTRO-SANCHEZ DAMAGE MODEL

The disadvantage of the fatigue curve is the fact that it doesn't allow to estimate the number of loading cycles corresponding to failure (when damage $D = 1$).

The application of Castro-Sanchez analytical damage model [9] allows estimating the number of cycles at failure for the materials.

The fatigue curves have the general form [1]:

$$\ln N_{f(50\%)} = A_0 + A_1 \ln \varepsilon \tag{1}$$

where: $N_{f(50\%)}$ is the fatigue life, ε is the strain level, A_0, A_1 are material parameters identified from the fatigue tests results.

The Castro-Sanchez damage model is written as follow:

$$N = a\varepsilon^b D^c \tag{2}$$

where: N is the number of loading cycles, ε is the strain level, D is the damage, a, b, c are material parameters identified from the fatigue tests results.

For $D = 0.5$ the Eq. (3) becomes:

$$\ln N_{f(50\%)} = \left(\ln a + c \ln 0.5\right) + b \ln \varepsilon \tag{3}$$

From the association of the Eq. (1) with the Eq. (3) it results the parameter b as $b = A_1$ and the relation between parameters a and c:

$$\left(\ln a + c \ln 0.5\right) = A_0 \tag{4}$$

We firstly determine parameter c from Castro-Sanchez model and then parameter a results from the Eq. (4). For $D = 0.5$ it results the equation:

$$N_{f(50\%)} = a\varepsilon_0^b (0.5)^c \tag{5}$$

From the ratio $N/N_{f(50\%)} = (2D)^c$ it results:

$$c = \frac{\ln\left(\frac{N}{N_{f(50\%)}}\right)}{\ln(2D)} \tag{6}$$

The Eq. (6) is written at every strain level tested for the next values of D, respectively: 0.05; 0.1; 0.15; 0.20; 0.25; 0.30; 0.35; 0.40; 0.45; 0.55; 0.60; 0.65; 0.70; 0.75. The numbers of loading cycles corresponding to each D value are taken from the average fatigue damage curves ($E/E_i - N$). The parameter c is calculated as the average of the values obtained for each strain level (150 μm/m, 135 μm/m, 115 μm/m).

The parameters a, b and c are identified on the fatigue tests results and presented in Table 2.

The Eqs. (7, 8) are used to simulate the damage evolution presented in Figure 7 and Figure 8.

– Non reinforced asphalt concrete:

$$\ln N = 39.253 - 5.293 \ln \varepsilon + 0.47 \ln D \tag{7}$$

– Reinforced asphalt concrete:

$$\ln N = 43.008 - 5.905 \ln \varepsilon + 0.84 \ln D \tag{8}$$

Table 2. Parameters of the Castro-Sanchez damage model.

Parameters for the Castro-Sanchez damage model	Non reinforced asphalt mixture (specimens NR)	Reinforced asphalt mixture (specimens R)
a	39.253	43.008
b	5.293	5.905
c	0.470	0.840

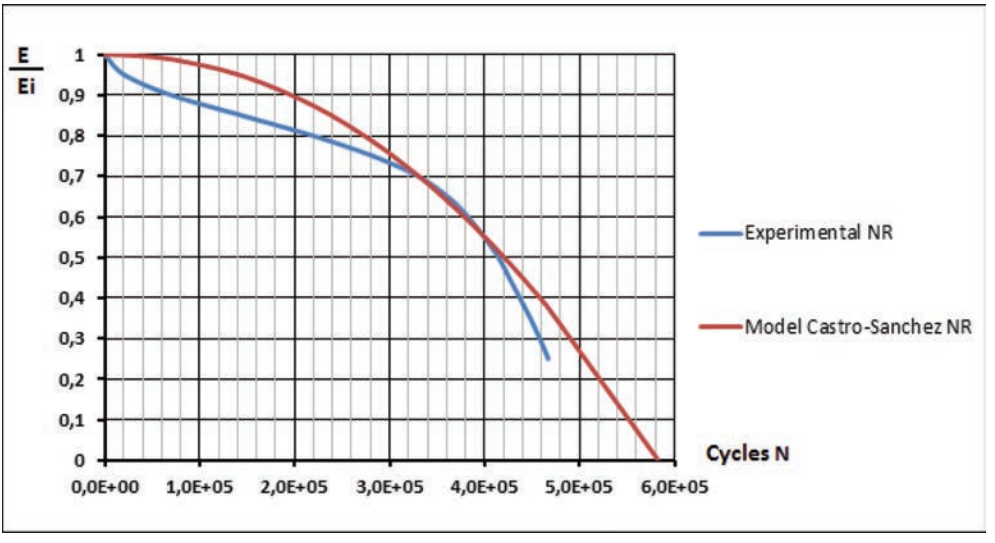

Figure 7. Experimental fatigue damage curve (average) versus simulated fatigue damage curve with Castro-Sanchez model, NR asphalt specimens at $\varepsilon = 135$ μm/m.

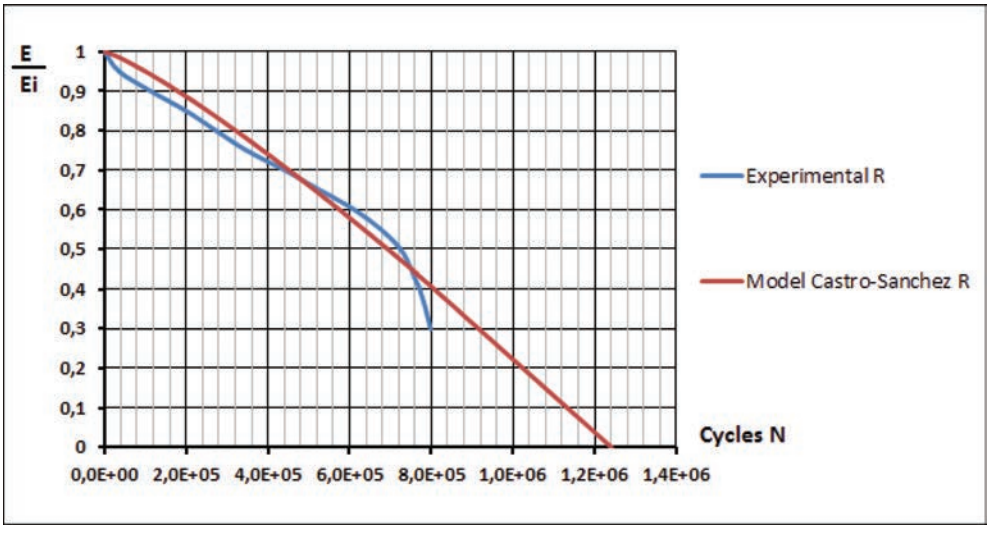

Figure 8. Experimental fatigue damage curve (average) versus simulated fatigue damage curve with Castro-Sanchez model, R asphalt specimens at $\varepsilon = 135$ μm/m.

Table 3. Estimation of the number of cycles at failure with Castro-Sanchez model.

Strain ε (μm/m)	Non reinforced asphalt mixture NR			Reinforced asphalt mixture R		
	$N_{f(50\%)}$	N_r	$N_{f(50\%)}/N_r$	$N_{f(50\%)}$	N_r	$N_{f(50\%)}/N_r$
135	414 752	590 887	0.702	724 416	1 254 631	0.577

At failure, damage $D = 1$, and the Eqs. (7, 8) become:

– Non reinforced asphalt concrete:

$$\ln N_r = 39.253 - 5.293 \ln \varepsilon \tag{9}$$

– Reinforced asphalt concrete:

$$\ln N_r = 43.008 - 5.905 \ln \varepsilon \tag{10}$$

where N_r is the number of loading cycles at failure.

Table 3 presents the number of cycles at failure, calculated with the Eqs. (9, 10). The comparison of the ratios $N_{f(50\%)}/ N_r$ between the non-reinforced asphalt concrete and the reinforced asphalt concrete shows that the glass fiber grid has a reinforcement role even after 50% stiffness loss (0.702 versus 0.577).

The simulated fatigue damage curves (D–N) at $\varepsilon = 135$ μm/m are presented versus the average (over 6 test results) experimental fatigue damage curves (D–N) in Figures 7 and 8. One can observe that the model fails to capture the trend of bituminous mixtures fatigue damage evolution. However, the simulated and experimental fatigue damage curves overlap for D in the range (0.3, 0.5) for NR specimens and D in the range (0.3, 0.55) for R specimens.

6 CONCLUSIONS

This paper presents a part of a laboratory study where an evaluation was done of the increase in fatigue life of asphalt by using the glass fiber grid. This was done using fully reverse Four

Point Bending tests (4PB), performed on Non-Reinforced (NR) and Reinforced (R) asphalt specimens.

The fatigue tests results were obtained at the strain level $\varepsilon = 135$ μm/m, at $T = 10$°C and $f = 25$ Hz, as recommended by the European fatigue standard. At this strain level, the average value (over 6 test results) of the fatigue life increase is 74.66% of the non-reinforced asphalt average fatigue life (over 6 test results). More 4PB fatigue tests must be performed in order to confirm this value.

Castro-Sanchez model was used to estimate the number of cycles at failure for both materials (NR and R). The ratios between the fatigue life and the number of cycles at failure show that the geogrid behavior is to reinforce the asphalt mixture even after the 50% decrease of its elastic modulus. Even if the model fails to capture the trend of bituminous mixtures fatigue damage evolution, the simulated and experimental fatigue damage curves overlap for D in the range (0.3, 0.5) for NR specimens and D in the range (0.3, 0.55) for R specimens. This is interesting because the simplicity of the model, which is easily applied and gives an idea of damage evolution.

An investigation into dynamic modulus of Western Australia Hot Mix Asphalt

Sarayoot Kumlai, Peerapong Jitsangiam & Hamid Nikraz
Department of Civil Engineering, Curtin University, WA, Australia

ABSTRACT: Most road networks in Western Australia (WA) are made of flexible pavement with a relatively thin asphalt wearing course and Dense Graded Asphalt (DGA), a commonly used asphalt mix with a continuous size distribution and a low design air-void of around 3% to 7%. Currently, the input parameters for asphalt material for pavement design in Australia still rely entirely on the resilient modulus which cannot incorporate the visco-elastic behaviour of such material into pavement analysis and design. Unlike resilient modulus, dynamic modulus can describe the stress-strain relationship of viscoelastic material across a wide range of temperatures and frequencies in the form of the Master Curve. The Master Curve is constructed through a sigmoidal function and the Time-Temperature Superposition principle (TTS) with a second-order polynomial shift factor function, according to AASHTO PP62-09. This study aims to investigate the dynamic modulus of Western Australian asphalt mixes, considering three different mixes with varying maximum aggregate sizes of 7 mm, 10 mm, and 14 mm. For this study, all test specimens were controlled to reach a 5% air-void with a Survopac gyratory compactor. Specimens were then tested with an Asphalt Mixture Performance Tester (AMPT) with a testing range of four temperatures: 4°C, 21°C, 37°C and 54°C, and six frequencies; 0.1 Hz, 0.5 Hz, 1 Hz, 5 Hz, 10 Hz, and 25 Hz, according to AASHTO TP62-07. Moreover, the dynamic modulus predictive equation proposed by NCHRP 1-37A MEPDG was modified and introduced to suit WA asphalt mixes.

Keywords: Asphalt concrete, dynamic modulus, master curve, AMPT, predictive equation

1 INTRODUCTION

Western Australia (WA) is the largest state in Australia, with an area of 2,529,875 square kilometres; one-third of the entire continent. Thus, road networks are crucial to such vast land areas in terms of connecting and maintaining communities and transporting goods. Consequently, the improvement of road network infrastructures, particularly pavement structures, is a fundamental responsibility for the WA government and road authorities. The first step to improving road infrastructures is to understand how pavement material behaves under real environmental and traffic conditions.

Most pavement structures in WA are made of flexible pavement with relatively thin asphalt wearing courses. Dense Graded Asphalt (DGA) is commonly used as a typical asphalt mix in which aggregate particle sizes are distributed evenly from coarse to fine, and the design air-void is relatively low, generally 3% to 7% [1]. This type of mix is suitable for wearing course applications as it has an enormous capacity for carrying traffic loads.

Currently, Australian pavement design approaches use the resilient modulus as an input parameter for performance criteria and structural analysis. This type of modulus can only represent the stiffness properties of asphalt concrete at a single temperature and frequency. It does not reflect real conditions and cannot incorporate the visco-elastic behaviour of asphalt concrete material into pavement analysis and design. Thus, the dynamic modulus was recently introduced as it has the ability to explain the stiffness and visco-elastic properties of asphalt

concrete across a wide range of temperatures and frequencies. It is therefore now possible for pavement engineers to effectively consider a wide range of environmental and traffic conditions that are as close to real conditions as possible.

2 MATERIAL CHARACTERIZATION

The stiffness of a material is always significant with regard to engineering purposes, as stiffness is an effective indicator of material strength. This information allows engineers to make decisions with regard to choosing suitable materials for particular applications. In the study undertaken here, asphalt concrete is characterised according to the dynamic modulus Master Curve with varying temperatures and frequencies.

2.1 *Shifting techniques*

The properties and the performance of asphalt concrete depend upon temperature and frequency (time), as illustrated by the multiple lines of the dynamic modulus in the frequency domains shown in Figure 1. However, there are also advantages in characterising the strength of asphalt concrete with a single smooth line, rather than multiple lines, in association with the Time-Temperature Superposition principle (TTS) [2–9]. This principle applies shift factors, $a(T)$, multiplied by frequencies, Eq.(1), to align multiple lines from different temperatures into one temperature reference line, the so-called the Master Curve. According to AASHTO PP62-09 [10], there are two recommended shift factor functions. They are the MEPDG shift factor and the Second-order polynomial function. Both functions rely on a reference temperature, but the first employs the viscosity of an asphalt binder, investigated with additional tests. Consequently, this study aims to investigate only the Second-order polynomial function, Eq.(2), due to its more practical purpose.

$$\log f_r = \log f + \log [a(T)] \tag{1}$$

$$\log[a(T)] = a_1 (T_R - T) + a_2 (T_R - T)^2 \tag{2}$$

where f_r is reduced frequency (Hz)
f is frequency (Hz)
$a(T)$ is shift factor

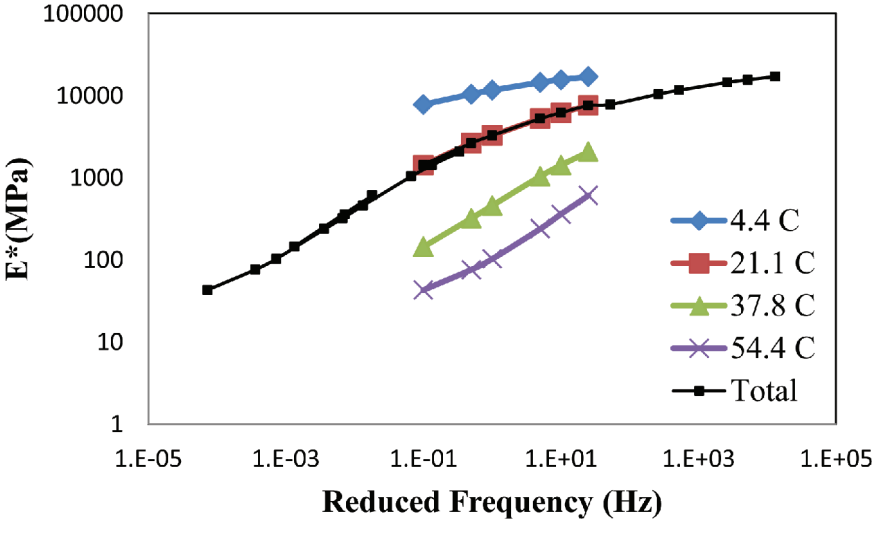

Figure 1. Dynamic modulus master curve.

T_R is reference temperature (°C)
T is temperature (°C)
a_1, a_2 is fitting coefficient

2.2 *Sigmoidal fitting function*

A single smooth line, known as the Master Curve, represents the dynamic modulus values over an observed range of temperatures. As a result, a single polynomial fitting function cannot be used to fit this curve. This is due to the fact that the polynomial swing at low and high temperatures causes irrational predictions of moduli for extrapolation outside a range of test data. Therefore, a sigmoidal function [2], Eq.(3), is usually applied to obtain greater accuracy in the model, and an optimisation technique is used to acquire each coefficient value in this function.

$$\log(|E^*|) = \delta + \frac{\alpha}{1 + e^{\beta - \gamma \log f_r}} \tag{3}$$

where $|E^*|$ is dynamic modulus (MPa)
$\delta, \alpha, \beta, \gamma$ is fitting coefficient

3 DYNAMIC MODULUS PREDICTIVE MODEL

To obtain the complex test data for constructing the Master Curve, a series of asphalt tests were performed, using a sophisticated testing machine, the Asphalt Mixture Performance Tester (AMPT). The Tester is generally unavailable in common asphalt and pavement engineering laboratories, leading to limitations of access to test results. Therefore, NCHRP 1-37A MEPDG [11] introduced a predictive equation which obtains the dynamic modulus of asphalt concrete over a range of temperatures, rates of loading, and ageing conditions. In this equation, Eq.(4), volumetric data of asphalt concrete mixture and bitumen viscosity are the main input parameters.

$$\log|E^*| = 3.750063 + 0.02932\rho_{200} - 0.001767(\rho_{200})^2 - 0.002841\rho_4 - 0.058097V_a - 0.802208\left[\frac{V_{beff}}{V_{beff} + V_a}\right] + \frac{3.871977 - 0.0021\rho_4 + 0.003958\rho_{38} - 0.000017(\rho_{38})^2 - 0.005470\rho_{34}}{1 + e^{(-0.603313 - 0.313351\log(f) - 0.393532\log(\eta))}} \tag{4}$$

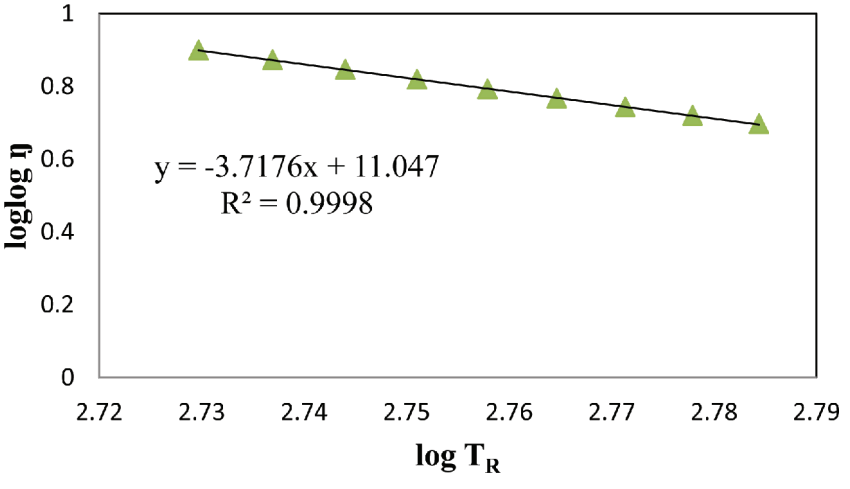

Figure 2. Bitumen binder properties.

where η is bitumen viscosity, 10^6 Poise
f is loading frequency (Hz)
V_a is air void content (%)
V_{beff} is effective bitumen content by volume (%)
ρ_{34} is cumulative % retained on the 3/4 in sieve
ρ_{38} is cumulative % retained on the 3/8 in sieve
ρ_4 is cumulative % retained on the No.4 sieve
ρ_{200} is % passing the No.200 sieve

Moreover, the bitumen binder viscosity, at the particular temperature of interest, is an important parameter which can be determined from the ASTM viscosity temperature relationship [12–13], Eq.(5)

$$\log \log \eta = A + VTS \log T_R \tag{5}$$

where η is bitumen viscosity (cP)
T_R is temperature (Rankine)
A is regression interception
VTS is regression slope of viscosity temperature susceptibility

4 EXPERIMENTAL WORK

4.1 *Materials*

This study used Dense Graded Asphalt (DGA) with three maximum sizes of 7 mm, 10 mm, and 14 mm, and the bitumen binder of class C170 [14] was selected, as it is a commonly used material in Western Australian hot mix asphalt mixes. The gradation details are shown in Table 1, and the bitumen viscosity can be estimated through Eq.(5) with values of A and VTS of 11.047 and –3.7176 respectively.

4.2 *Sample preparation*

According to AASHTO TP62-07 [15], a 150 mm diameter mould was selected for the sample preparation and a Survopac gyratory compactor [16] was utilised to compact samples until they reached a 5 ± 0.5% target air-void at 150 ± 5°C, in accordance with AS 2891.2.2-1995 [17].

Table 1. Gradation for this study.

	Percent passing (%)		
Size sieve (mm)	7 mm	10 mm	14 mm
26.5	100.0	100.0	100.0
19.0	100.0	100.0	100.0
13.2	100.0	100.0	98.0
9.5	100.0	97.9	83.8
6.7	98.3	81.0	68.2
4.75	83.1	65.5	52.8
2.36	57.6	44.2	35.7
1.18	41.9	30.6	25.1
0.6	31.4	20.9	17.4
0.3	18.4	13.4	11.5
0.15	8.6	8.0	7.2
0.075	4.8	5.2	5.1

Table 2. Recommended stress level, equilibrium time and number of cycles.

Temperature (°C)	Stress level (kPa)	Equilibrium time (hour)	Frequency (Hz)	Number of cycles
			25	200
			10	200
4	700–1400	4 hrs or overnight	5	100
21	350–700	3	1	20
37	140–250	2	0.5	15
54	35–70	1	0.1	15

Following this, sample-coring and top—bottom cutting was conducted to obtain a final diameter of 100 mm and a height of 150 mm.

4.3 *Testing procedures*

The Asphalt Mixture Performance Tester (AMPT), consisting of the testing machine, an environmental chamber, and a measuring system, was utilised for dynamic modulus testing. This study considered only four temperatures; 4°C, 21°C, 37°C, and 54°C, and six loading frequencies; 0.1 Hz, 0.5 Hz, 1 Hz, 5 Hz, 10 Hz, and 25 Hz, in accordance with AASHTO TP62-07 [15]. Stress levels, equilibrium time and the number of cycles were also recommended by this standard, as can be seen in Table 2.

5 TESTING RESULT AND MASTER CURVE

Two important parameters were obtained from the experimental work; the dynamic modulus ($|E^*|$), and phase angle (δ), but only the dynamic modulus values were applied to the Master Curve. As mentioned in section 2, the second-order polynomial and sigmoidal function were chosen for fitting shift factors and constructing the Master Curve by following the non-linear least square method. Optimised computer programs, for example the Solver function in MS EXCEL, and SPSS, were used to estimate the fitting coefficient; the details of each mix are shown in Table 3. The Master Curve can then be conducted by applying shift factors to generate reduced frequencies, as can be seen in Figure 3.

Some observations from the different asphalt mixes used in this study are presented below:

- Asphalt concrete material is temperature and frequency dependent; it was therefore stiffer at low temperatures and high frequencies and less stiff at high temperatures and low frequencies.
- Maximum size affects the stiffness properties of asphalt concrete at high frequencies (low temperature), as the 14 mm dynamic modulus Master Curve is above the others and this can be seen in Figure 3(a) and 3(b), with the fitting coefficient α, span of modulus value of the 14 mm mix, being the highest. This result is consistent with the recommendation of Australian standard [18] which states that the 14 mm mix is suitable for heavy-duty applications.
- The phase angle, representing the visco-elastic properties of asphalt concrete, gradually increases from low temperatures (4°C) to intermediate temperatures (37°C), but it starts decreasing at high temperatures (54°C), possibly due to aggregate interlocking effects.
- Maximum size does not affect the phase angle of asphalt concrete and the shift factor, which can be seen in Figure 3(c) and 3(d). There was a small difference among phase angle and shift factor values.

Table 3. Master curve fitting coefficients.

Parameter	Initial value	Estimated value		
		7 mm	10 mm	14 mm
δ	0.5	–0.25286	–0.2965	–0.29847
α	3	3.740696	3.842805	3.870229
β	–1	–1.31576	–1.42346	–1.36451
γ	–0.5	–0.55419	–0.51654	–0.54018
a_1	0.1	0.073573	0.073165	0.070497
a_2	0.0001	0.000353	0.000283	0.000257

6 MODIFIED PREDICTIVE MODEL

NCHRP 1-37A MEPDG [11] introduced the predictive model for estimating the dynamic modulus in level 2 and level 3 analyses. All the data in this model, as shown in Table 4, was substituted to predict the dynamic modulus at the same temperature and frequency as conducted in the experimental work. As a result, it is obvious that the predictive model results over-estimated the dynamic modulus prediction, particularly at high temperatures. All predicted Master Curves of the dynamic moduli are lined above the experimental curve, shown in Figure 4(a), 4(b), and 4(c). The graph in Figure 4(d) shows that almost all of the data points are higher than the line of equality related to predictive $|E^*|$ and experimental $|E^*|$.

Table 4. Input parameters of NCHRP 1-37A predictive model.

Maximum size	Input parameters					
	ρ_{34}	ρ_{38}	ρ_{4}	ρ_{200}	Vb_{eff}	V_a
7 mm	0.0	0.0	16.9	4.8	11.558	4.957
10 mm	0.0	2.1	34.5	5.2	11.513	4.927
14 mm	0.0	16.2	47.2	5.1	11.446	4.825

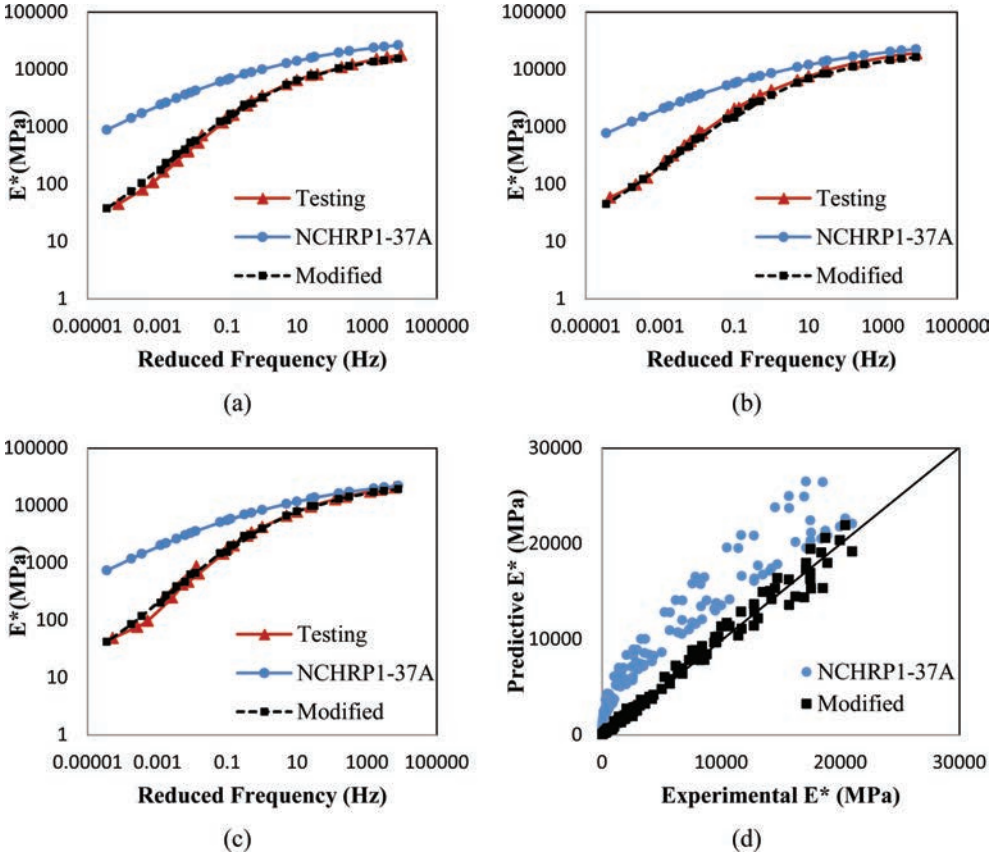

Figure 4. Master curve of $|E^*|$ from experiment and predictive model; (a) 7 mm, (b) 10 mm, (c) 14 mm, and (d) Comparison between NCHRP 1-37A and modified model.

$$\log|E^*| = 1157.579 + 80.63314\rho_{200} - 7.72723(\rho_{200})^2 - 0.15864\rho_4 - 66.7672V_a - 1471.54\left[\frac{V_{beff}}{V_{beff}+V_a}\right] + \frac{-110.51 + 6.756108\rho_4 - 62.2534\rho_{38} + 3.058393(\rho_{38})^2 - 0.005470\rho_{34}}{1+e^{(0.431204-0.5603\log(f)-0.65874\log(\eta))}} \quad (6)$$

In order to suit Western Australian HMA mixes, the NCHRP 1-37A MEPDG predictive model required modification. Within this model modification, the non-linear least square method and the optimisation computer program were employed to recalculate the model coefficient with the same function and the same parameters. A new modified predictive model is presented in Eq.(6). It can be seen that the predicted modulus results derived from this

modified model are very close to those of the testing modulus for all mixes, as the comparison between both moduli from the prediction and the tests is made as shown in Figure 4(a), 4(b), and 4(c). Moreover, the plotting between the predictive $|E^*|$ and the experimental $|E^*|$ illustrates that most of the data converges to the line of equality, shown in Figure 4(d). Consequently, it can be concluded that the modified predictive model from this study can be used to estimate the dynamic modulus value for typical WA mixes more effectively than the originally introduced model of NCHRP 1-37A MEPDG.

7 CONCLUSION

The Master Curve derived from the dynamic moduli and phase angles can be effectively used to characterise the stiffness and the visco-elastic properties of an asphalt concrete material across a wide range of temperature and frequencies. Dense Graded Asphalt (DGA) with three maximum aggregate sizes of 7 mm, 10 mm, and 14 mm is a typical mix for WA. The dynamic modulus results for all mixes in this study show that they are related to the aggregate size of mixtures at high frequencies (low temperature). Moreover, the traditional predictive model of the dynamic modulus, introduced by NCHRP 1-37A, does not suit predictions with regard to the WA mixes in this study due to trends of over-estimation. Thus, the predictive model modification was made to achieve a more appropriate prediction for WA hot mix asphalt mixes in particular. The modified predictive model for WA hot mix asphalt mixes was introduced, as in Eq.(6), to properly evaluate the WA dynamic moduli.

This study concentrated on only one typical hot mix asphalt mix. In fact, there are several asphalt mixes in use in Australia, for instance, Dense Graded Asphalt (DGA), Open Graded Asphalt (OGA), Stone Mastic Asphalt (SMA), and Fine-Gap Graded Asphalt (FGGA). Furthermore, only one original binder type was considered in this study, not including other types of binders such as modified binders. Therefore, investigation of the dynamic modulus for Australian mixes should take all these factors into account in future studies.

ACKNOWLEDGEMENT

The authors would like to thanks Western Australian Mainroads via Western Australian Asset Research Centre (WAPARC) for the financial support of this project, and the AARB Group Ltd for the supply of some relevant information. Moreover, the Australian Research Council (ARC) Linkage (LP110100634) is also gratefully acknowledged for its financial contribution to this work.

Composite stress analysis of fibre-reinforced Hot-Mix Asphalt mixtures

Pyeong Jun Yoo, Yeon-Bok Kim & Sang-Min Ham
KICT, Ilsan, Goyang, Republic of Korea

ABSTRACT: This study presented an experimental and analytic approach to predict the direct tensile bond strength of recycled plastic fibre-reinforced Hot-Mix Asphalt (HMA) mixtures. The toughening effects of recycled plastic fibre-reinforced HMA mixtures were characterized using the direct tensile loading test developed in this study. The direct tensile loading approach was based on a law of mixture that can separate the composite stress of the mixture into a matrix part and a fibre stress part. The approach showed good correlation among stresses within a limited range of experimental data. The interfacial bond strength could be predicted using this approach in view of the failure of the composite mixture partially due to fibre and matrix interfacial bond failure.

Keywords: Direct tensile loading, fibre-reinforced HMA, flexural strength, interfacial bond strength

1 INTRODUCTION

In recent years, increasing attention has been given to the possibility of improving the mechanical properties of Hot-Mix Asphalt (HMA) by incorporating fibrous reinforcement [1–3].

HMA mixtures with some types of plastic fibres, such as polyester, polypropylene, or nylon, have been reported to be superior to plain HMA in terms of toughness, indirect tensile strength, shear strength, and fracture energy. The improved toughness and fracture energy, which may increase the fatigue life of HMA, were the representative effects in the use of fibres with HMA [4–7].

In addition to HMA, steel fibres, polyesters, or nylon fibres in a short, discontinuous dimension were utilized to implement the enhanced toughness and fracture energy to concrete material by the fibre-bridging effect [8–10].

The toughening effects of the fibre composite are typically characterized using direct tensile tests associated with force-displacement curves or tension-softening curves; however, the fibre's random distribution and orientation require the use of assumptions regarding the probability density functions and randomly oriented effective fibres to calculate the effective composite stresses along the failure plane by accounting for the fibre's bridging forces [11].

The mechanical behaviour of the fibre reinforced composite typically depends on the fibre geometry, fibre contents, the relative stiffness of the matrix and fibre, and the fibre-matrix interfacial bond strength. However, the probabilistic approach to calculate the composite stress considers the bonding effect through an indirect parameter, such as the snubbing coefficient, that depends on the fibre geometry instead of through the interfacial shear stress or strength term [11, 12].

Not all fibres mixed in the composite are equally effective in their toughening with such randomness; however, if sufficient strength improvement can be obtained, the practical advantages of fibres in HMA will be confirmed. A promising cause of toughening may be that the fibres in HMA enhance the shear strength at the interface between the HMA matrix

and fibres, and the enhanced property can delay the initiation and propagation of damages [11, 12].

This study addresses the three-dimensional reinforcement of a HMA mixture using recycled plastic fibres to enhance the interfacial bond strength and proposed a method to calculate the effective fibre volume fraction along the failure plane. The effective fibre volume fraction estimated the interfacial bond strength along the failure plane.

The reinforcing effect by the fibres may occur through the fibre and matrix interfacial shear strength, and a law of mixture considering the matrix and fibre's contributions to enhancing the composite strength separately was adopted, and the interfacial bond strength, which depends on the various fibre contents, was also obtained using direct loading tests.

2 PLASTIC FIBRE-REINFORCED HMA

Plastic fibre-reinforced HMA is comprised of a fibre phase and HMA matrix phase. In addition to the HMA matrix, the fibre phase is also supposed to enhance the tensile strength of the composite. Plastic fibres that are randomly oriented in the matrix were used in this study; the fibres were manufactured through an extrusion process and have embossments on the surface of the fibre and a unique shape and dimensions depending on the rectangular or circular shape of extrusion nozzle.

To make the fibres, the recycled PET chips were first reproduced out of discarded PET bottles. A local recycling manufacturer provided the recycled PET chips. PET fibres having a unique dimension were produced through an extrusion process with a rectangular or circular nozzle. The dimensions of the recycled PET fibres for a coarse aggregate mixture are shown in Figure 1a and are 30 mm (length) × 1–1.5 mm (width) × 0.3–0.5 mm (thickness).

Figure 1a is the 30 mm PET fibres for an asphalt treated-base layer, which has the maximum aggregate size smaller than 19 mm. Figure 1a shows the embossments on the surface of rectangular fibre with a width of 1.5 mm. The colourless fibre, shown in Figure 1b, has one longitudinal groove for the additional separation of the fibre during dry mixing with the aggregate in a plant. The nozzle in this case has a sharp tip inside the rectangular extrusion nozzle to make the groove. The circular fibres, Figure 1c, are used in this study for the coarse aggregate gradation with the maximum aggregate size smaller than 19 mm; the circular nozzle can produce these fibres in the dimension of 0.5 mm wide and 30 mm.

This study only used PET fibres, shown in Figure 1c, to investigate the effect of the fibre content on the HMA toughness. For easiness of the mixing fibres with aggregates during the dry mixing process, the cylindrical fibre-packs as shown in Figure 1d were manufactured and the polypropylene cover-film of the pack was melted down during the dry-mixing process with aggregate because of its relatively lower melting temperature in the range of 150–160°C than the dry mixing temperature above 180°C in a plant.

The mechanical properties of the recycled PET fibres are as follows: the specific gravity of the recycled PET fibre is approximately 1.32, the tensile strength is 300–305 MPa, the elastic modulus at room temperature is approximately 13 GPa, and the elongation is 7.5%. All of the mechanical properties of a recycled PET fibre are equivalent to the typical values of a new PET fibre.

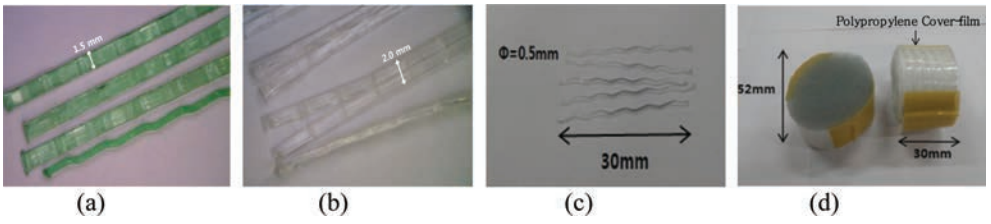

Figure 1. (a) Embossed PET fibres, (b) Grooved PET fibres, (c) Circular PET fibres, and (d) Cylindrical fibre packs.

The asphalt binders for all of the mixtures used in this study were the Superpave PG 64-22 grade with a penetration of 65 and a softening point of 49°C. The characteristics of the HMA mixtures are provided in Table 1, and the aggregate gradation of the mixtures is provided in Table 2. All HMA mixtures, both with and without fibres, were mixed with the optimum asphalt content according to the Marshall-Mix design process with a course aggregate gradation.

This study attempted to avoid the binder content's dependency on the mixture's behaviour, aiming to observe only variations due to the fibre contents. The fibre contents for the coarse aggregate gradation varied with values of 0.2, 0.4, 0.6, 0.8 and 1.0% to the specimen's weight. The aggregate gradation for the maximum aggregate size of 19 mm was in coarse gradation, as shown in Table 2. The lower G_{mm} of the fibre-reinforced mixes may due to the additional fibre volume and mass in the HMA.

Table 1. Mixture characteristics.

	Mix design data			
Mix type	Binder type	Design AC (%)	Air void (%)	G_{mm}
Control	PG 64-22	5.0 ± 0.02	4.5–5.0	2.521

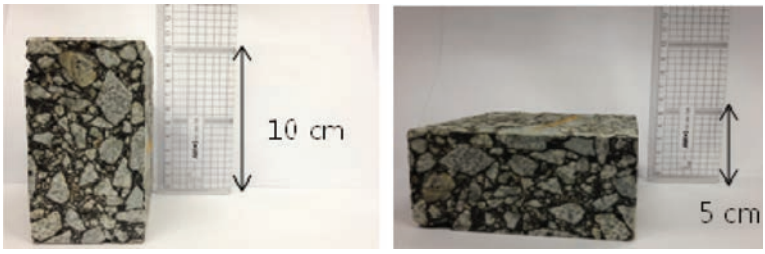

Figure 2. Direct loading test specimens.

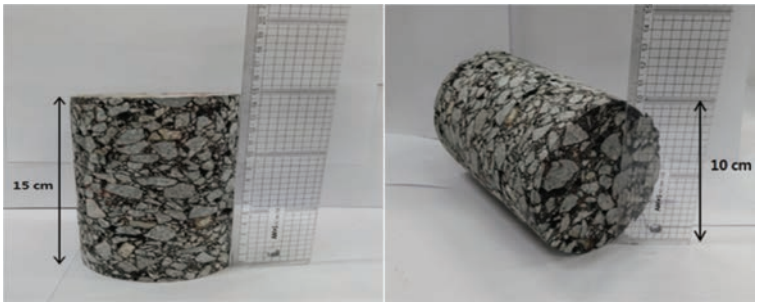

Figure 3. Dynamic modulus test specimens.

Without any balling of the fibres in the mixture, all of the specimens were compacted in a 150-mm-diameter mold at approximately 160°C using a gyratory compacter, with 100–120 gyrations applied to each specimen until the target height for each specimen (i.e., 120 mm) was achieved. The relatively higher air void content of the fibre-reinforced mixture required additional gyrations. The mass of each specimen was calculated as a function of the target air void content, such as 5%, the volume of the gyratory mold, and the theoretical specific gravity, G_{mm}. Two specimens with dimensions of approximately 100 mm (height) × 100 mm (width) × 50 or 70 mm (thickness), shown in Figure 2, were cut from each compacted specimen for direct tensile testing, as described in the following section. Figure 3 shows the specimens for the dynamic modulus tests with dimensions of 150 mm (height) × 100 mm (diameter).

3 LABORATORY TESTS

3.1 *Dynamic modulus tests*

The dynamic responses of PET fibre-reinforced HMA were investigated including 0.0, 0.2, 0.4, 0.6, 0.8, and 1.0% fibre contents by the total weight of asphalt mixture.

Asphalt mixture was well known as a viscoelastic material, which depends on loading time and temperature. For a linear viscoelastic material, the stress-strain relationship under a continuous sinusoidal loading can be explained in terms of the complex dynamic modulus (E*).

The dynamic modulus of asphalt mixtures was measured at five different temperatures and at six frequencies.

Figure 4 shows the test results of dynamic modulus at reference temperature of 10°C for specimens with or without fibres. The master curve describes the loading frequency and temperature dependent properties under linear viscoelastic condition.

It is indicated that the dynamic modulus increases with the increase of the frequencies, Figure 4. The dynamic modulus of fibre reinforced specimens in low temperature or high frequency are smaller than those of the plain HMA. This means that the stiffness of fibre reinforced HMA at low temperature can be reduced by the addition of fibres. Improved toughness due to the slightly greater value of phase angle by the decrease of dynamic modulus compared with the plain HMA can improve the resistance to fatigue damage after numerous cyclic loading at low temperature.

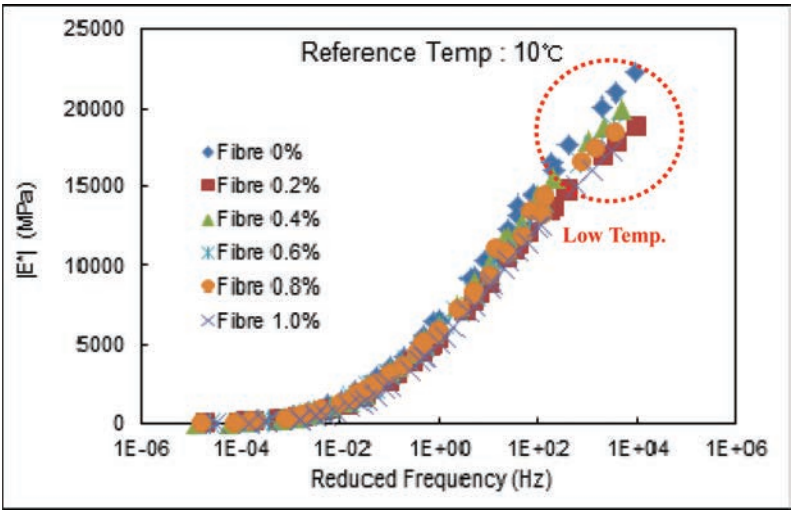

Figure 4. Dynamic modulus master curve in the semi-log scale.

In addition, the phase angles of the fibre reinforced specimens (5.7–45.6°) are greater than those of the plain HMA (5.1–39.5°). This may cause that the air voids in the fibrous HMA (5.0–6.3%) are higher than the values of the plain HMA (4.5–5.0%).

On the other hand, the fatigue parameters such as $|E^*|\sin\delta$ for the fibre reinforced specimens at the low and intermediate temperatures, such as −5, 5, and 10°C are smaller than the values for the plain HMA as shown in Figure 5. The loss modulus ($|E^*|\sin\delta$) could be a parameter to characterize the potential of fatigue cracking of asphalt mixture at low temperature.

The smaller fatigue parameters at the low and intermediate temperatures may indicate that the resistance to fatigue damage of fibre reinforced mixtures can be enhanced; this is due to the fibres can distract the stresses produced during cyclic loading.

In addition, the dynamic modulus data could be used to convert from dynamic frequency data to Prony series data, which is the linear viscoelasticity model to use in most finite element package for a future research purpose.

3.2 *Direct tensile loading test*

A new fixture with two clamping grips for a direct tensile test on HMA was presented. The new fixture makes it possible to use a rectangular specimen by imposing uniform tensile loading at the central area of the specimen. Using the new direct tensile test fixture, it was possible to determine the tensile force versus displacement curves of the various fibre contents.

The toughening effect of PET fibre-reinforced HMA is characterized by considering specimens subjected to uniaxial tension. Figures 6a–c illustrate the direct tensile loading test set-up, including the specimen mounting device, the plates that hold the test specimens, and the upper and lower loading jigs with two clamping grips. The specimen mounting device, shown in Figure 6a, holds the rectangular specimens and ensures identical test dimensions, such as the 1-mm gap between the plates and central point of the specimen, as shown in Figure 6b. The end of the mounted specimen is glued, whereas the middle of the specimen is not glued, as shown in Figure 6b; this schematic is used to induce a uniform uniaxial tension and a failure plane in the middle of the specimen. The glued portion of the specimen should not slip during the direct tensile loading test if a realistic force-displacement curve is to be obtained.

In addition to the specimen being glued to the plates, a uniform torque is applied at the end of a specimen to ensure that the plates do not slip and to obtain a uniform distribution of the tensile load in the middle of the specimen. A composite force-displacement curve was recorded

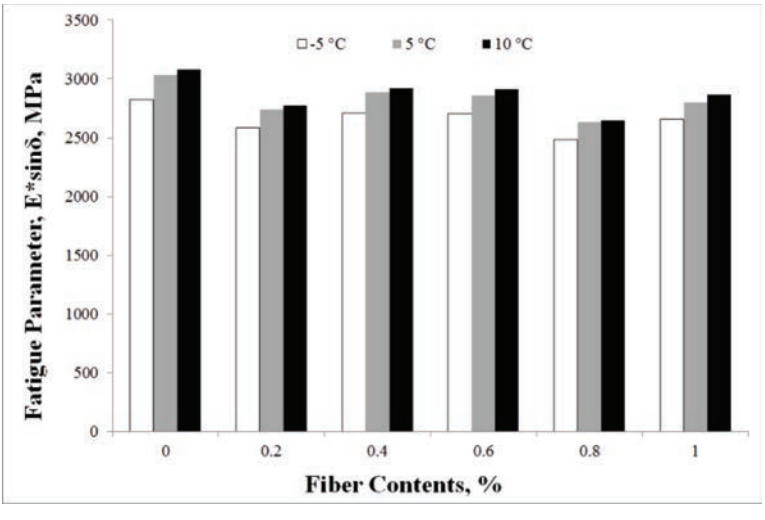

Figure 5. Maximum fatigue parameters.

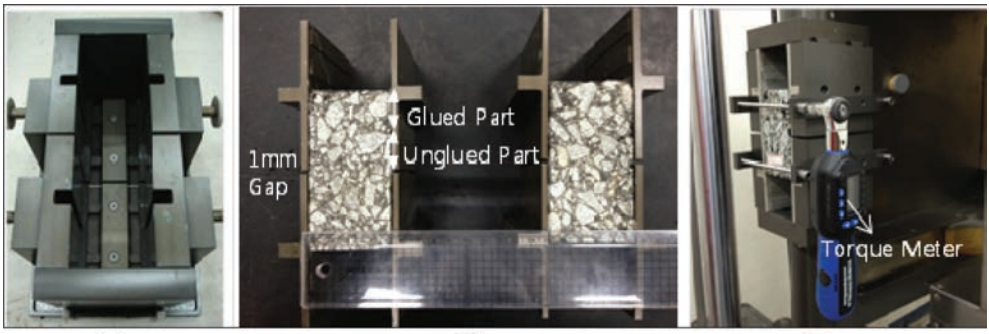

Figure 6. (a) Specimen mounting device, (b) Flanged test specimens, and (c) Test fixture with two clamping grips.

for each displacement-controlled test conducted at a rate of 0.02 mm/s at 20°C, which is a rather high loading rate compared to the rate of approximately 0.01 mm/s in the SHRP-A-641.

However, due to the maximum aggregate size of 19 mm and the coarse aggregate gradation in this study, the loading rate was arbitrarily increased without any mechanical consideration. The displacement at the center of each specimen's failure plane was monitored using a Linear Variable Differential Transducer (LVDT) in the Material Testing System (MTS), as shown in Figure 6c [13–15].

Failure occurred most often on the free part of the specimen, where the specimen was not glued to the inserts. In addition to the direct loading test set-up, analytic approaches were presented as practical applications of the use of short, discontinuous fibres; the fibres were randomly oriented and uniformly distributed without any balling of fibres in the matrix, although not all fibres were equally effective in strengthening. The approaches were based on a law of mixture in which the composite stress of the mixture is correlated with the tensile stress in the HMA matrix and the stress in the fibres, as described in the following section.

4 COMPOSITE STRESS ANALYSIS

This study presents a law of mixture that separates the composite stress into matrix and fibre components to calculate the tensile stress of fibre-reinforced HMA comprised of randomly oriented plastic fibres in a ductile HMA matrix with a lower tensile strength than the fibres.

Through regression analyses, the composite stress-displacement (σ–δ) curves were observed to make correlations among the composite stress (σ_c), the stress in the HMA matrix without fibres (σ_m), and the stress in the fibres (σ_f). The interfacial bond strength (τ) between the matrix and fibres was also determined. The interfacial bond strength resulted in additional tensile strengthening of the mixture whereby tensile load was transferred from the matrix to the fibres. As the tensile loading was transferred from the matrix to the fibres, the interfacial bond stress also began to increase until the composite failed when the fibre-matrix bond was broken. The critical fibre length, L_c, and the average interfacial bond strength of a fibre is given by Eq. (1) [9]:

$$L_c = \sigma_{fu} \frac{w}{2\tau} \tag{1}$$

where σ_{fu} is the ultimate tensile strength of HMA (2–5 MPa); w is the fibre width (1.0–2.0 mm); and τ is the average interfacial bond strength (0.1–0.5 MPa). For a fibre width of 1.5 mm and an average assumed interfacial bond strength of 0.1 MPa, as in this study, a fibre length of $L_f = L_c$ resulted in a length ranging from 1.5 to 3.75 cm [16, 17]. This study arbitrarily decided to use a fibre length of 3 cm.

The toughening of a fibre in Figure 7a, which bridges the matrix failure plane, depends on the centroid distance z from the matrix, the embedded length l, and the orientation angle φ. The orientation angle φ of the embedded fibre may result in a random value on the hemisphere, as shown in Figure 7b. If a fibre located along the failure plane is perpendicular to the loading axis ($\varphi = 90°$), no toughening effect is expected. Because of the randomness in φ, the probability density function $p(\varphi)$ is used, as illustrated in Figure 7c.

The immeasurable nature of the fibre's centroid distance of z in the matrix requires the use of the uniform random distribution function, $p(z)$, as follows [11]:

$$p(z) = \frac{1}{B - A}, \quad \text{for} \quad A = 0 \le z \le B = \frac{L_f}{2} \tag{2}$$

$$p(z) = \frac{2}{L_f} \tag{3}$$

The effective fibres enhancing the toughness along the failure plane have an equal probability of being located at any point on the semicircle that is one side of the failure plane in a three-dimensional view, as shown in Figure 7b. According to Figure 7c, the probability density function of the inclination angle to the matrix failure plane, $p(\varphi)$, is as follows [11, 13]:

$$p(\varphi) = \sin\varphi, \quad \text{for} \quad 0 \le \varphi \le \pi/2 \tag{4}$$

N_t is the total number of fibres in the failure plane of the volume in $A_c L_f$, which may include some fibres bridging the matrix failure plane in the middle of the direct loading specimen, and can be calculated as follows:

$$N_t = \frac{\text{Total fibre volume in failure plane}}{\text{Volume per fibre}} = \frac{A_c L_f \times V_f}{A_f L_f} = \frac{A_c V_f}{A_f} \tag{5}$$

where A_c is the cross-sectional area of the failure surface, A_f is the cross-sectional area of a fibre, and V_f is the volume fraction of the fibres in the HMA.

dN_e is the effective number of fibres along the failure plane, which increases the average bond strength. dN_e includes the randomness in the fibre's centroid distance and the fibre's orientation in terms of the uniform random distribution functions, such as $p(z)$ and $p(\varphi)$. The random number of fibres may be calculated using the orientation angle, from φ to $\varphi + d\varphi$, and the centroid distance, from z to $z + dz$, across the failure plane in the middle of the direct loading specimen as follows:

$$dN_e = N_t p(\varphi) d\varphi p(z) dz, \quad \text{for } 0 \le \varphi \le \frac{\pi}{2} \text{ and } 0 \le z \le \frac{L_f}{2} \tag{6}$$

Integrating Eq. (6) yields

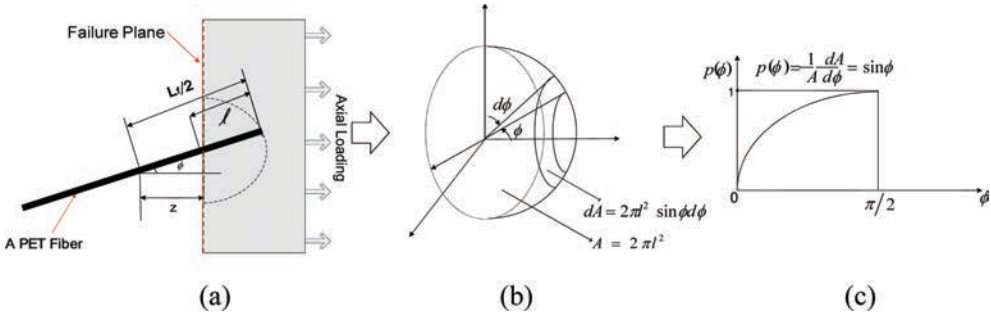

Figure 7. (a) Centroid distance of z, (b) Randomly oriented fibres, and (c) The probability density function of the fibre orientation [11].

$$N_e = \frac{A_c V_f}{A_f} \int_{z=0}^{\frac{L_f}{2}\cos\varphi} \frac{2}{L_f} \int_{\varphi=0}^{\pi/2} \sin\varphi d\varphi dz = \frac{1}{2}\frac{A_c V_f}{A_f} = \frac{1}{2} \times N_t \tag{7}$$

$$V_{fe} = \frac{1}{2} \times V_f \tag{8}$$

The effective number of fibres, N_e, describes the tensile stress along the failure plane. Substituting the effective number of fibres yields an expression for the tensile strength of the randomly oriented composite reinforced fibres. The tensile stress of the composite (σ_c), including the fibres (σ_f) in the matrix (σ_m), can be described by the law of mixtures as follows:

$$\sigma_c = \sigma_m\left(1 - V_{fe}\right) + \sigma_f \times V_{fe} = \sigma_m\left(1 - V_{fe}\right) + 2\tau\left(\frac{L_f}{w}\right) \times V_{fe} \tag{9}$$

$$\frac{\sigma_c}{V_{fe} \times L_f / w} = \frac{\sigma_m\left(1 - V_{fe}\right)}{V_{fe} \times L_f / w} + 2 \times \tau \tag{10}$$

where σ_m represents the stress in the unreinforced HMA matrix and σ_f is the stress in the fibre. A_c = 70 mm × 90 mm, A_f = 1.5 mm × 0.7 mm, L_f = 30 mm, and V_f = 0.0–1.0% are the cross-sectional areas of the matrix, the cross-sectional area of the fibre, the length of the fibre, and the volume fraction of the fibres, respectively.

The direct loading test of the fibre-reinforced HMA with the new fixture developed in this study yields distinguishable composite stress-displacement (σ_c–δ) curves that depend on various fibre volume fractions, as shown in Figure 8a. Eq. (10) can be used to predict both the tensile strength of the composite (σ_c) and the average bond strength of the composite (τ).

The total interfacial bond stress transmitted across the matrix failure plane could be regressed by Eq. (10) using the direct loading test results. Thus, Eq. (10) represents a combined strengthening composite relationship for the tensile failure of the fibre-reinforced HMA.

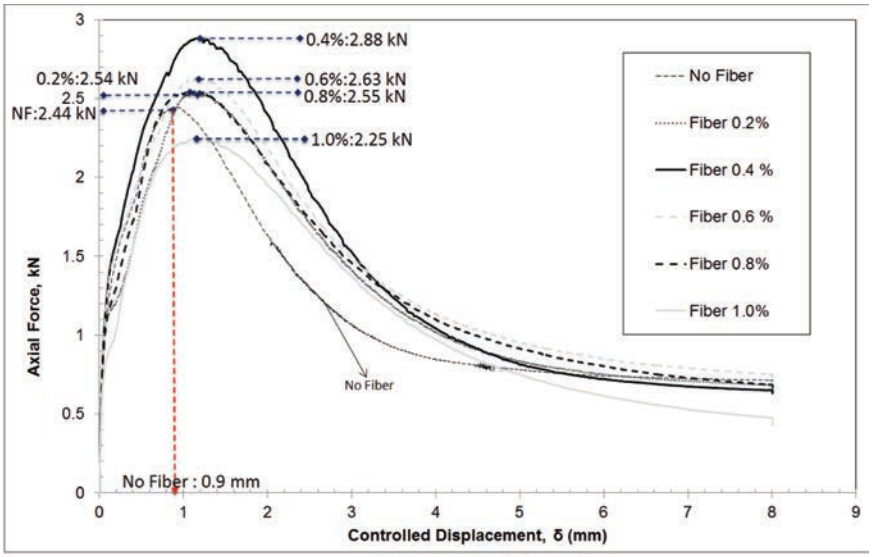
We defined the correlation among the experimental values of $\sigma_{cu}/(V_{fe} \times L_f/w)$, $(\sigma_m(1 - V_{fe}))/(V_{fe} \times L_f/w)$, and the average interfacial bond strength of τ for the composite reinforced with PET fibres, shown in Figure 8b, using the ultimate composite stresses (σ_{cu}) in each σ_c–δ curve, as shown in Figure 8a.

The composite stress model, Eq. (10), assumes that the frictional bond between the fibre surface and the matrix accounts for the interfacial shear force and neglects any effect of an elastic bond between them. The frictional resistance due to the fibres depends on the amount of slip on the interface between the matrix and fibre. The ultimate composite stress (σ_{cu}) exists before the slipping of the fibre in the matrix. During either the slipping or pulling-out process, the short embedded ends of the effective fibres at the matrix failure plane of the direct loading specimen are completely pulled out, whereas the longer embedded ends of the effective fibres may have had some slippage but are not fully pulled out.

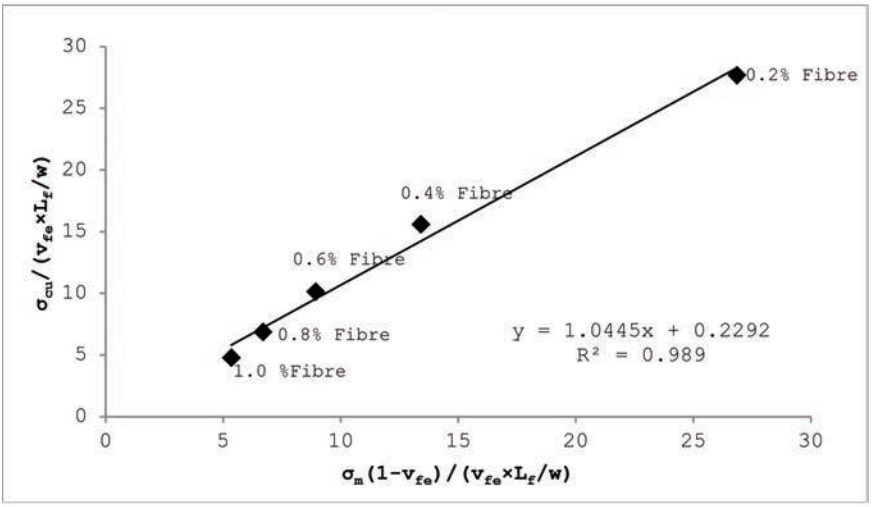
Figure 8a shows the direct loading versus displacement curves. The P–δ curves are experimentally determined and depend on the various fibre contents, such as μ = 0.0, 0.2, 0.4, 0.6, 0.8, and 1.0%, relative to the specimen's weight. The 0.4% Fibre mixture resulted in the highest peak force (2.88 kN) and the displacements at the peak force for fibre mixtures were also extended more compared with the 0.9 mm for the unreinforced mixture as shown in Figure 8a. The 0.4% of fibre content for the coarse aggregate gradation in this study could be set as the optimum and the enhanced toughness compared with the plain HMA, such as the area under the P–δ curve, can extend the performance of fibre reinforced mixture.

The direct tension tests yield the following relationship from a regression analysis, as shown in Figure 8b:

$$\frac{\sigma_c}{V_f \times L_f / w} = 1.04 \times \frac{\sigma_m\left(1 - V_f\right)}{V_f \times L_f / w} + 0.23 \tag{11}$$



(a)



(b)

Figure 8. (a) Composite load-displacement curves and (b) Regression of the law of mixtures.

Eq. (11) shows a composite stress and strength relationship for the tensile failure of the fibre-reinforced HMA with randomly oriented fibres. The slope of the regression line is 1.04, which is close to unity, verifying that the matrix reaches its ultimate tensile strength at failure. Comparing Eqs. (10, 11) yields the average interfacial strength, $\tau = 0.12$ N/mm^2, compared to the maximum tensile stress at the peak, 0.47 N/mm^2 (0.4% Fibre), as shown in Figure 8a. The fibre's contribution to resisting the failure is approximately 25.5%, and the remaining portion of the resistance is due to the bond strength of the HMA matrix. The some fibres lying perpendicular to the axial loading axis along the failure plane led to the lower rate of the shear resistance.

Given the PET fibre material's axial strength, which ranged from 300 to 350 MPa, it was assumed that no fibre rupture occurred during the tests because of the maximum tensile stress in the specimens was approximately 470 KPa at the failure plane.

The regression in Figure 8b indicates that the strengthening effect of the fibres is below average if the fibre contents are greater than 0.6% or less than 0.4%. The fibre contents in both of these cases are below to the regression line, indicating that the optimum fibre content with the coarse aggregate gradation in this study is 0.4–0.6% of the specimen's weight. The test results around the optimum fibre contents are concentrated slightly above the regression line, indicating that a higher value of the average interfacial strength could be possible.

5 CONCLUSION

This study presented a law of mixtures that separates the composite stress into matrix and fibre components to estimate the tensile shear stress of fibre-reinforced HMA comprised of randomly oriented plastic fibres in a softer, ductile HMA matrix. Because not all fibres enhance the toughness along the failure plane, this study proposed a method to calculate the effective fibre volume fraction along the failure plane to estimate the composite stress and interfacial bond strength along the failure plane.

The approach found a correlation among stresses, such as the composite stresses, the stresses in the HMA matrix without fibres, and the stresses in the fibre, using direct tensile loading tests. The interfacial bond strength representing the intercept of the regression equation was predicted because of the composite mixture failure due to the failure of the fibre and matrix interfacial bond. The average interfacial bond strength was $\tau = 0.12$ N/mm^2, indicating that the fibre's contribution in resisting failure is approximately 25.5% of the maximum tensile stress at a peak of 0.47 N/mm^2, and the remaining portion of the resistance is due to the bond strength of the HMA matrix. This result indicates that the fatigue life of the fibre reinforced mixture could be enhanced by the interfacial bond strengthening effect of the fibres along the failure plane.

The regression exhibits an acceptable correlation; however, fibre contents greater than 0.6% or less than 0.4% fall below the regression line, indicating that the optimum fibre content with the coarse aggregate gradation is 0.4–0.6% above the regression line.

Evaluation of Recycled Tire Rubber (RTR) modified binders to typical polymer modified binders for performance specifications

John A. D'Angelo
D'Angelo Consulting, LLC, Virginia, VA, USA

Gaylon Baumgardner
Paragon Technical Services, Jackson, MS, USA

ABSTRACT: The use of Recycled Tire Rubber (RTR) to produce PG modified binders has seen a tremendous increase in interest. Under the current economic conditions it is quite cost effective to produce RTR modified binders that will meet typical extended PG grades and Multi-Stress Creep and Recovery (MSCR) grades. One major question is, are RTR modified binders equivalent to typical polymer modified binders currently being used. To evaluate the binder properties new tools, such as the cup and bob Searle system, have been developed. This testing system is used to evaluate the binder properties of RTR modified binders under the AASHTO M 320 and MP 19 specifications.

This study evaluates binders modified with multiple RTR sizes and percentages to typical SBS modified binders. Sizes such as 60, 30 and 20 mesh RTR are blended with neat binders at zero, 5, 10, 15 and 20 percent to produce modified binders. The properties of the blends are being evaluated using both parallel plate and cup and bob geometries and M 320 and MP19 specifications against typical SBS modified binders. These blends will see further testing in asphalt mixtures to look at performance properties and make comparisons of these properties.

Keywords: Asphalt binders, recycled tire rubber, PG grading, MSCR, cup and bob

1 INTRODUCTION

With the introduction of Superpave and performance related asphalt binder specifications the use of binder modification has grown tremendously [1]. In some states in the US, such as Nevada, polymer modified binder is used almost exclusively. Styrene Butadiene Styrene (SBS) is the most commonly used polymer for modification because of its ease of use, relative stability and overall long term performance on the roadway [2]. Many tests and procedures have been developed to assure the SBS is in the asphalt binder; these are typically called SHRP + tests. Highway agencies in order to assure the polymer they want is in the binder have added these plus tests to the standard AASHTO M320 binder specification [3]. These developments have led to restrictive specifications that don't allow for innovation in the industry when it comes to performance enhancements to asphalt binders.

In the late 2000's the price of asphalt binder rose significantly. Highway agencies were use to prices of $150 to $200 dollars a ton in the 1990's, but today's prices are now in the range of $500 dollars per ton. There have been corresponding increases in the price of polymer also significantly increasing the final price of modified asphalt binder. In addition to the price increase there have also been shortages of polymer over the past few years. This increased cost and shortages of material has sparked an interest in looking for alternate materials to replace the polymer additives and reduce costs.

Recycled Tire Rubber (RTR) has been used as an asphalt binder additive for many years [4, 5]. Historically RTR had been blended with the asphalt binder at the mix plant and

directly pumped into the mixes or mixed dry with the hot aggregate in the plant. Over the past several years technologies and process have been developed that allow for blending of the RTR in a terminal facility and then shipping the modified asphalt binder to the mix plant similar to typical polymer modified asphalt binders. Additionally the cost of RTR in relationship to the cost of asphalt binder has reduced significantly. With increase in cost of SBS polymer and asphalt binder and the improvements in processing of RTR modified asphalt binder there has been a renewed interest in using RTR in paving projects.

This paper covers the evaluation of RTR modified asphalt binder to SBS modified asphalt binder using both the AASHTO M 320 specification tests and the AASHTO MP 19 specifications and tests. Multiple RTR sizes and percentages where use in the modification process to evaluate how the rubber modified binder compares to the typical SBS modified asphalt binder.

2 EXPERIMENTAL PLAN

In this study a Gulf Coast PG 64-22 asphalt binder was blended with various RTR size material and percentages. Table 1 shows the RTR size and blend percentages combinations. The 80 mesh RTR was only blended at 11 percent to produce a PG 76-22 material for comparison to the other blends. The properties of these various blends of RTR were then compared to typical SBS modified binder commercially blended to meet a PG 76-22 under the AASHTO M 320 specification. The SBS modified, PMBs 1 & 2, PG 76-22's were produced commercially with approximately 2.5 to 2.8 percent SBS polymer and approximately 0.25 to 0.4 percent Polyphosphoric Acid (PPA). A hybrid binder 76 AR HB was made with 7 percent 30 mesh rubber and approximately 1.5 to 2 percent SBS was also included in the study. Separation characteristics of the RTR binders were not evaluated.

The performance properties for each of the modified asphalt blends were tested using both the AASHTO M320 specification tests and the AASHTO MP 19 specifications tests. It has been shown that the M 320 tests and specifications do not accurately identify the performance characteristics of modified binders [6, 7, 8, 9]. The Multi-Stress Creep and Recovery (MSCR) test used in MP 19 has demonstrated a much better relationship to actual field rutting than $G^*/\sin\delta$ from the M 320 specification [10, 11]. In this study the results of the both specifications are compared.

Size and concentration of RTR in the asphalt blend will affect the final binder properties [12]. This is why several mesh sizes were used to account for the size and concentration affect. The gradations for the different mesh sizes are shown in Figure 1. Using several percentages of RTR for each mesh size allows for the evaluation of both the percent concentration and particle size on the binder properties. Each of the different mesh sizes have very different gradations clearly seen by looking at the 150 µm and 300 µm sieve sizes in Figure 1.

Standard test procedures for the DSR were adjusted to accommodate the addition of the RTR. For the 80, 60 and 30 mesh rubber the gap size was increased to 2 mm. The 20 mesh rubber was tested using the new cub & bob geometry [13]. The geometry uses a stationary cub with a rotational bob allowing a 6.5 mm gap. The cup & bob can be used in the typical oscillatory mode to measure G^* and δ and in creep and recovery to measure J_{nr} and % Recovery.

3 RESULTS

The results from the binder grading, for both M 320 and MP 19 specifications, of the RTR blends is shown in Table 2. As the amount of RTR increased the PG grading in both specifications increased. The M 320 high temperature grade increases from a PG 70 for the 5% blends to a PG 88 for the 20% blends. The MP 19 grading varied from a 64H-22 to a 70E-22. The interesting item with the MP 19 grading is that in any temperature there are four individual grades which are achieved by reducing the creep compliance requirement at any specific temperature, 4.0 for S grades, 2.0 H grades, 1.0 V grades and 0.5 for E grades. This system indicates going from a 64H to a 70E is actually 7 grade changes while the M 320 only has 3 grade changes.

3.1 *High temperature properties*

To compare the RTR modified rubber blends to the SBS binders and hybrid the high, intermediate and low temperature binder properties were compared for both the M 320 and MP 19 test results. Figure 2 compares the $G^*/\sin\delta$ @ 76°C to J_{nr} 3.2 kPa^{-1} @ 64°C for the RTR blends and 2 SBS 76-22, PMB 1 & 2 and hybrid 76–22, RTR and SBS. Only the materials that would meet the M 320 PG 76-22 are compared here to make the performance comparison. The 10 and 15% RTR 80, 60 and 30 mesh blends all met the PG 76-22 grade. As the percentage of RTR increases and the mesh size becomes finer the $G^*/\sin\delta$ increases and the J_{nr} 3.2 kPa^{-1} decreases as expected. Where the differences become significant is between the two grading systems. While the $G^*/\sin\delta$ results show all the material to be a PG 76 the J_{nr} results indicated that results vary over three grades from a 64V to and 64E+ grade.

As previously noted it has been demonstrated that the MP 19 J_{nr} results more accurately differentiate between the rutting potential of binders. The PMB and Hybrid binders all have $G^*/\sin\delta$ values close to the top of the PG 76 range. This is due to the SHRP+ requirements imposed by the highway agencies. For the 15% 30 and 60 mesh RTR the $G^*/\sin\delta$ are basically the same as the SBS PMB 2 and the 76 AR HB binders. However, the J_{nr} values indicate that there is a significant difference in results for these binders. The J_{nr} values go from about 0.15 for the PMB and hybrid binders to a 0.3 for the 15% RTR blends. This is actually a doubling

Table 2. M 320 and MP 19 grading for each of the RTR blends.

RTR mesh size	80	60	30	20

5		PG 70-22 PG64H-22	PG 70-22 PG64H-22	PG 70-22 PG64V-22
10	PG 76-22 PG 64E-22	PG 76-22 PG 64V-22	PG 76-22 PG 64V-22	PG 76-22 PG 64V-22
15		PG 76-22 PG 64E-22	PG 76-22 PG 64E-22	PG 82-22 PG 70E-22
20		PG 88-22 PG 70E-22	PG 88-22 PG 70E-22	

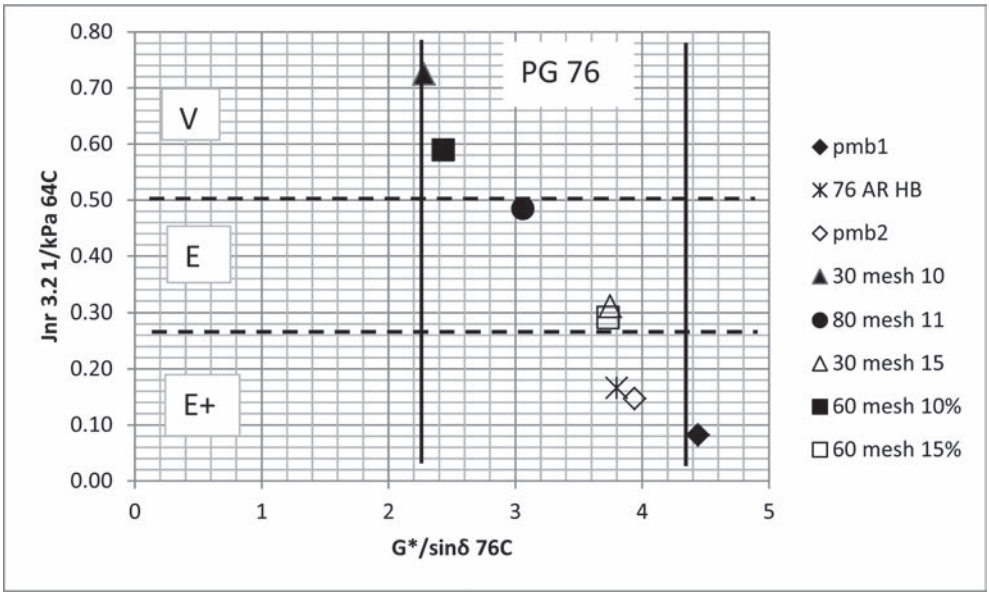

Figure 2. Comparison of M 320 $G^*/\sin\delta$ @ 76°C compared to the MP 19 J_{nr} 3.2kPa^{-1} @64°C.

of the J_{nr} value which indicates a full grade change even though the $G^*/\sin\delta$ value is the same. A similar difference in properties is seen for the 10% 30 and 60 mesh RTR. The $G^*/\sin\delta$ for the two blends are almost the same, but the J_{nr} properties are starting to show some differences from 0.72 to 0.59. This again demonstrates the difference in properties comparing M 320 and MP 19 requirements.

The evaluation of the change in properties with RTR mesh size and percentage clearly shows changes in the various blends. Figure 3 shows the J_{nr} 3.2 kPa^{-1} results for the various mesh sizes and blend percentages at 64°C. A reduction in the J_{nr} compliance is seen with the increase in percentage of RTR. The control PG 64-22 has a J_{nr} of 1.9 which decreases to 0.1 for the 20% RTR blends. In each of the RTR percentage there are also differences in properties based on mesh size. For the 5 and 10% RTR the 60 mesh material provides a lower compliance value than the 30 mesh material. Comparing the 80 mesh 11% RTR to both 10% RTR blends show that the finer 80 mesh material again reduces the compliance. At 15 and 20% RTR little difference can be seen between the 30 and 60 mesh materials. This is likely due to the overall high percentage of rubber in the blend and extremely low compliance values overwhelming the mesh size effect.

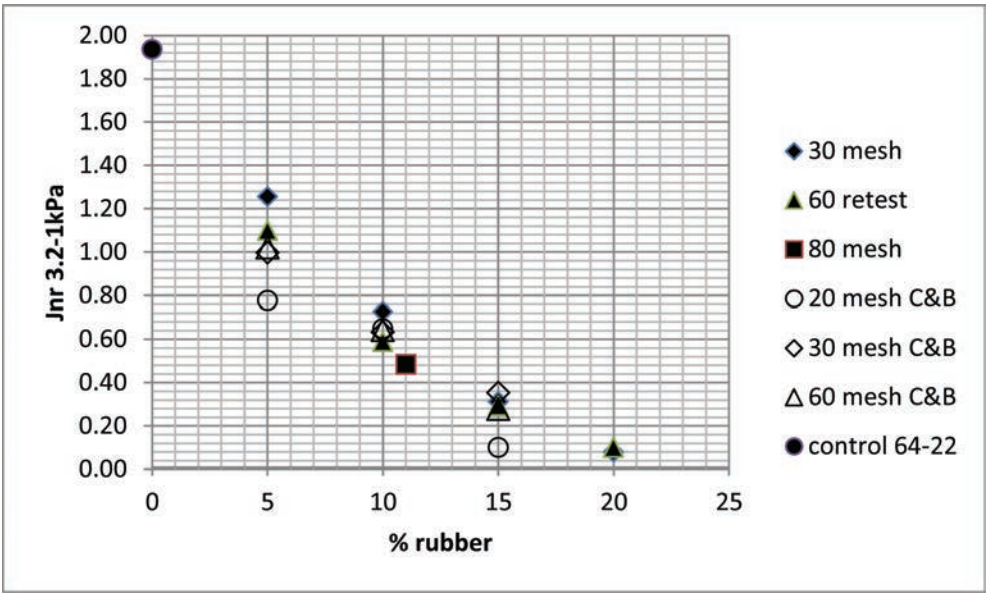

Figure 3. J_{nr} 3.2 kPa^{-1} results for the various RTR mesh sizes and percentages measured at 64°C.

Comparison of the cup and bob to parallel plate results for J_{nr} indicate that there are no significant differences. At 10 and 15% RTR the results fall right on top of each other. At 5% RTR the cup and bob results are slightly below the parallel plate results but well within the typical within lab differences. The cup and bob for the 20% RTR were not completed in time for this paper. There are no parallel plate results for the 20 mesh RTR because the large particle size would require the gap to be at least 6 mm. This is far greater than is practical for running parallel plate geometry in a dynamic shear rheometer at high grade temperatures. The cup and bob results for the 20 mesh RTR indicate that this material has a lower compliance value than the 30 or 60 mesh RTR. This is in contrast to the 30, 60 and 80 mesh samples which indicate that the finer mesh material produces lower compliance results. Further testing will have to be done to verify the results.

The second aspect of the MP 19 specification is the % Recovery measured during the MSCR test. Non-recoverable creep compliance J_{nr} is a measure of stiffness related to permanent deformation. The % Recovery from the test is a measure of the delayed elastic response of the material. The % Recovery for the various RTR blends is shown in Figure 4. The data mirrored what was seen with the compliance value J_{nr}. As the percent RTR in the mix increased the delayed elastic response increased from about 11% for 5% RTR to 65% for 20% RTR. At 5 and 10% RTR the finer mesh blends had higher % Recoveries than the courser mesh RTR. At 15 and 20% RTR the mesh size was either the same or the courser mesh had higher % Recovery. Again this is likely due to the high percentage of RTR overwhelming the size effect. While the parallel plate and C&B results were the same for the compliance results the % Recovery data indicated a difference. For each mesh size and percentage of RTR the C&B provided higher % Recovery than the parallel plate results. For the J_{nr} value to be the same for both geometries, but have the % Recovery to be higher the creep and recovery must be different. The unrecovered strain is the same, but the peak strain during the creep portion of the curve must be higher which would increase the recovery portion if the preeminent strain remains the same.

The cause for this difference is still under investigation, but one possible reason is the geometry. In the C&B the gap size between the bob and inside surface of the cup is 6.5 mm. The bob is also 25 mm high so with the applied stress the full gap for the height and circumference of the bob is moved. In the parallel plate geometry it is only the very outside edge of the plates that

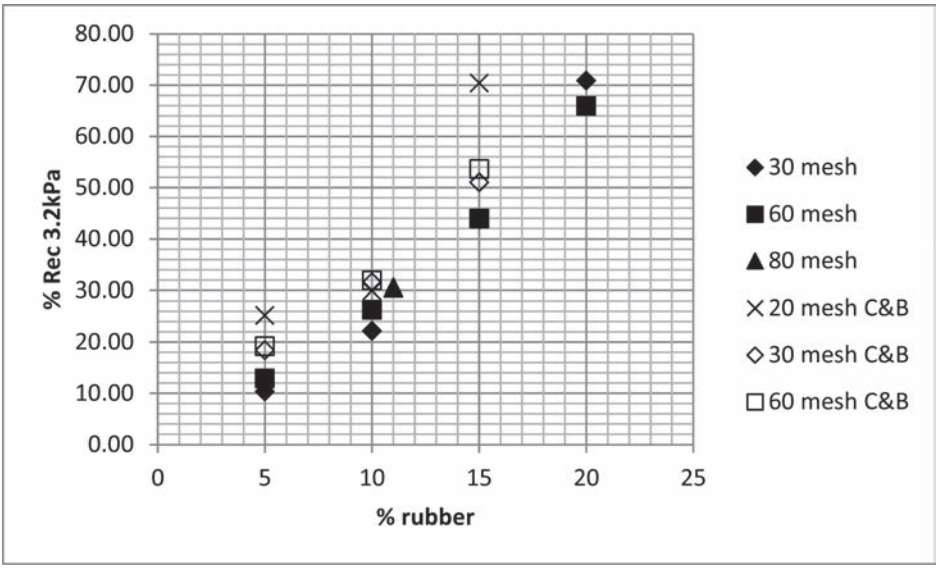

Figure 4. % Recovery results @ 3.2kPa^{-1} for the various RTR mesh sizes and percentages measured at 64°C.

sees any significant movement. The differences in geometry are shown in Figure 5. The effect of moving significantly more material in the sample, for the C&B geometry over the parallel plate, is likely causing the difference. This increase in volume of material moved in the C&B geometry will likely cause greater particle interaction than in the parallel plate geometry. Which geometry is more accurately measuring the properties on the material is still under investigation.

One approach to evaluate modified asphalt binders in the MP 19 specifications is to evaluate the J_{nr} 3.2 kPa^{-1} and the % Recovery together graphically. The % Recovery results were plotted against the J_{nr} results for each sample in the study. This data is shown in Figure 6. Samples with low J_{nr} values and high % Recovery plot to the upper left corner of the graph while samples with higher J_{nr} values and low % Recovery plot to the lower left corner of the graph. The SBS polymer modified binders are in the upper left hand corner of Figure 6. The control asphalt binder plots in the lower right hand corner of the mix. This plot again shows as the % RTR increases the J_{nr} reduces and the % Recovery increases. On the graph is also drawn a solid line labelled elastic response. This line was developed based on testing of polymer modified asphalt binders where binder with compatible polymers well blended and cross-linked would always plot above this elastic response line. The 15% RTR blends all easily meet the 64E grade, J_{nr} less than 0.5 and % Recovery greater than 35%. These results are very typical for commercial SBS modified asphalt binders. Though the specific pmb's used in this study were on the very stiff range for normal materials many would fall in the same range as the 15% RTR blends.

3.2 *Intermediate temperature properties*

The aged properties of the asphalt binder are evaluated by testing in the DRS at intermediate pavement temperatures. The Pressure Aging Vessel (PAV) conditioned binder blends were tested in the DSR to determine $G^*\sin\delta$ values. Aged binders become brittle and are prone to cracking at temperatures in the 15 to 25°C temperature range. Currently the cup and bob geometry cannot be used for intermediate temperature testing in the DSR. The large sample size and surface area of the bob cause significant machine compliance issues with the DSR. To address the RTR particle size the gap for the 8 mm parallel plate was increased from 2 mm to 4 mm. At the intermediate temperatures between 16 and 25°C the binder sample can maintain its shape in the DSR with the 4 mm gap without losing its edge integrity. The intermediate

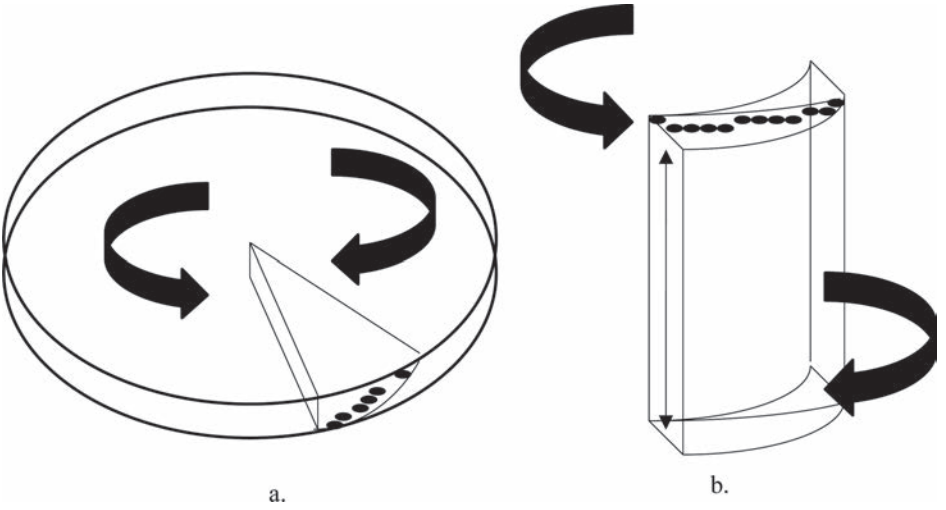

Figure 5. a) Parallel plate geometry with only significant movement at the outside edge of the plates, b) Cup & Bob geometry demonstrating the significant increase in volume of asphalt binder moved in the test.

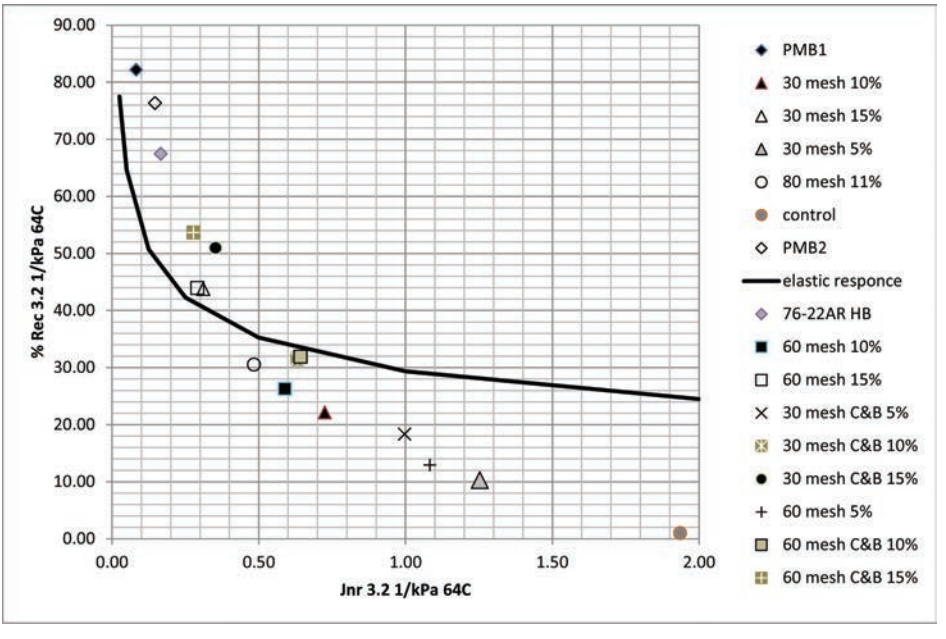

Figure 6. MSCR J_{nr} verses % Recovery comparison for the various RTR mesh sizes and percentages compared to the SBS PMB and hybrid binders.

DSR data at 22°C using the 4 mm gap is shown in Figure 7. Compared to the PG 64-22 control the finer mesh RTR blends 30, 60 and 80 mesh binders reduced the $G^*\sin\delta$ values. For the intermediate DRS properties the 20 mesh shows no effect on the control base binder.

The reduction in the $G^*\sin\delta$ for the 20, 30, 60 and 80 RTR is significant. At 5% rubber there is a 25% reduction the intermediate DSR value. At 20% RTR there is over a 50% reduction in the intermediate DSR value. This is likely due to the processing oils in the RTR defusing into the asphalt binder. Tire rubber typically will have approximately 17% process oils. While the

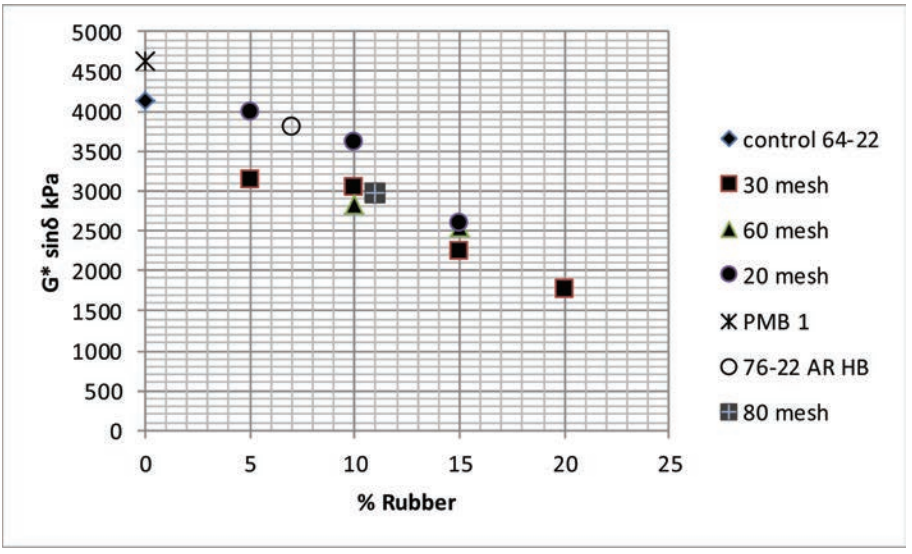

Figure 7. Intermediate PAV aged DSR test results for the various mesh sizes and percent RTR blends compared to the control PG 64-22.

RTR will absorb some of the maltene fraction of the asphalt binder the light processing oils will come out of the RTR defusing into the base asphalt lowers the intermediate properties. With typical SBS modified asphalt binders the intermediate DSR values of the base asphalt increase with the addition of the polymer. This is seen in Figure 7. This requires addition of other additives or a softer base asphalt to prevent the intermediate DSR value becoming too high and not meeting grade requirements. The softening effect of these RTR processing oils on the high temperature properties of the binder are likely overwhelmed by the particle interaction of the RTR particles.

3.3 *Low temperature properties*

Due to space limitations, details of the low temperature properties of the various blends will not be discussed in detail. The low temperature grades of the various blends were shown in Table 2. The Bending Beam Rheometer S values were slightly lower for the RTR blends and the m value had a slight increase. The property changes were not enough to actually change the low temperature grade of the base asphalt binder. The change that did occur is also, likely due the light processing oils in the rubber defusing into the base asphalt binder.

4 CONCLUSIONS

This study evaluated binder modified with multiple RTR sizes and percentages. Sizes such as 60, 30 and 20 mesh RTR are blended with neat binders at 5, 10, 15 and 20 percent to produce modified binders. The properties of the blends were evaluated using both parallel plate and cup and bob geometries and M 320 and MP 19 specifications against typical SBS modified binders.

- In cases where the M 320 high temperature RTFOT DSR indicated that the binders should have the same properties the MSCR J_{nr} properties indicated that the binders are not the same. The M 320 criteria indicate that all the 10 and 15 percent RTR blends would be graded as a PG 76-22. In the MP 19 MSCR the same blends indicated multiple grades

from a 64V to a 64E+ grade and that blends with the same $G^*/\sin\delta$ values would have different J_{nr} values. This indicates that the MP 19 specification is more discriminating than the M 320 specification.

- The RTR mesh size and blend percentage each had an effect on the blended binder properties. As the percentage of rubber increased and the mesh size decreased the binder high temperature properties would increase.
- The % Recovery from the MSCR testing indicates that the RTR does increase the delayed elastic response of the binder blends. An increase in RTR percentage or a reduction in mesh size both increased the % Recovery. The RTR blends could not reach the same magnitude of % Recovery as the SBS modified binders. Percent Recovery is not a performance indicator only an indicator of delayed elastic response. New criteria may have to be developed to evaluate the extent of response needed to evaluate RTR.
- The Cup & Bob geometry provide equivalent J_{nr} results to parallel plate testing for the 30 and 60 mesh size RTR. The % Recovery for the Cup & Bob was slightly greater than for parallel plate testing. This increase % Recovery is likely due to the increased rubber particle interaction in the larger Cup & Bob sample and the geometry effects of the movement of the bob to the outer wall of the cup as opposed to the movement at the outside edge of the parallel plate geometry.
- Processing oils from the RTR defuse into the asphalt binder reducing the intermediate and low temperature properties of the binder blend.
- Blends of RTR modified asphalt binder can be produced to provide equivalent properties to SBS modified binders.

Investigating the evolution of emulsified binder nanorheology using Atomic Force Microscopy

Pooyan Kabir, Maryam S. Sakhaeifar & Dallas N. Little
Department of Civil Engineering, Texas A&M University, College Station, TX, USA

ABSTRACT: This study involves evaluating the evolution of rheological and nanorheological properties of asphalt emulsion residue and its control binder through the application of two different test methods, Dynamic Shear Rheometer (DSR) and Atomic Force Microscopy (AFM). This study also involves evaluating chemical properties by application of Fourier Transform Infrared Spectroscopy (FTIR). The adopted methods use the same evaporative techniques to recover the residue but involve different consecutive curing periods (procedure A: 24 hours at 25°C and 24 hours at 60°C and procedure B: 6 hours at 60°C in a forced draft oven based on ASTM specifications). The evolutions of rheological properties have been investigated as the emulsion transitions through various degrees or stages of aging. Furthermore, the impact of aging in terms of its thermal history on the bitumen microstructure is reported. It was observed that certain asphalt chemical parameters have a consistent and measurable effect, as determined by the AFM, on bitumen microstructure. This study focuses on evaluating whether the full recommended curing periods are required and identifying the causes of different behaviors relative to base binders. Results indicate that oxidative aging contributes different to the change in rheology and nanorheology with various times of curing, compared with unaged base binder.

Keywords: emulsified binder; recovered residue; nanorheological properties; Chemical composition; atomic force microscopy

1 INTRODUCTION

An increase in the use of emulsion-based surface treatments has generated the motivation and need to better characterize and understand properties of emulsions that impact their constructability and in-service performance (1). A number of researchers from around the world (2, 3) have reported microstructural properties of neat and modified asphalt binders based on the results of Atomic Force Microscopy (AFM). Some of the microstructural studies have investigated the impact of oxidative aging (2). One of the challenges in characterizing the emulsion is to establish a widely acceptable residue recovery method. There are concerns expressed about the applicability of procedures regarding their length and the possibility for reducing the time required. The recovery by distillation, as defined in ASTM D244 has been reported by a number of researchers to be inadequate due to high recovery temperatures and extended recovery time (4). A recovery method using temperatures more consistent with those experienced in the field is needed to provide a residue representative of the as-built material and maintain the integrity of binder systems. Recently developed residue recovery methods involve recovery of a thin film of emulsion in a forced-draft oven to address the needs of both recovery at more appropriate temperatures, and the ability to produce adequate emulsion for testing (4). The evaluations of the ASTM method conducted by Hanz et al. (1) and by Kadrmas involved evaluation of emulsion residue rheological properties and comparison with the unaged base binders (5, 6). A similar study was conducted by Hanz et al. (1), which focused on evaluating rheological properties at various times during the recovery procedure, for unmodified and modified

emulsions, commonly used for chip seals. The results show that the properties of emulsion residue do not reflect those of the unaged base binder, and the evaporative recovery method preserves the effects of modification (5). Residues produced by the method under development by the New Zealand Transport Agency were using its standard test methods of penetration, softening point, and torsional recovery on unmodified and polymer-modified emulsions. Results of both methods of characterization indicate that the residue produced has properties significantly different from those of the unaged base binder (7).

An important component of asphalt durability is defined as the resistance of asphalt to the detrimental effects of oxidative age hardening on its performance properties. In asphalt pavements, oxidative age hardening contributes significantly to pavement embrittlement, eventually resulting in excessive pavement cracking. Oxidative hardening is attributed primarily to the introduction of polar, oxygen-containing chemical functionalities on asphalt molecules causing increased molecular interactions. These changes in chemical composition would be expected to increase asphalt hardening (8). The four fractions produced by the Corbett separation scheme in the order of their increasing molecular polarity are saturates, naphthene aromatics, polar aromatics, and asphaltenes. The saturates fraction is generally a light straw-colored oil, primarily hydrocarbon in nature, with little aromaticity and a low heteroatom content except for sulfur. Corbett (9) described the effects on physical properties of the four generic fractions separated by his procedure as follows: the asphaltenes function as thickeners; fluidity is imparted by the *saturates* and naphthene aromatics fractions which plasticize the polar aromatics and asphaltenes fractions; the polar aromatics fraction imparts ductility to the asphalts, and the *saturates* and naphthene aromatics in combination with the asphaltenes produce complex flow properties in the asphalt. A proper balance in the amounts of the different chemical components is necessary to produce asphalt that is durable and resistant to detrimental physical property changes on oxidative aging (8). Jemison (10) showed the advantages of using FTIR-ATR method for asphalt analysis with respect to ease of analysis and repeatability.

In this study, the impact of aging in terms of its thermal history on the bitumen microstructure is reported. The goal was to further understand the link between asphalt chemistry and macroscopic performance by investigating the findings obtained from AFM, DSR, and FTIR testing. Therefore, it was focused to evaluate and compare the need for the 48-hrs versus 6-hrs recovery time specified in ASTM D7497 to identify the cause of different behaviors relative to base binders. Evaluation was conducted at high and intermediate temperatures on emulsion residues and base binders subjected to different aging conditions. It was revealed that certain asphalt chemical parameters have a consistent and measurable effect, as determined by the AFM, on bitumen microstructure. The initial rheological evaluation of emulsion residue indicates that residue properties from two different recovery procedures are different and they exceed those of the unaged base binder. This research provides new and supporting evidence concerning the influence of aging on properties that ultimately govern macroscopic behavior.

2 MATERIALS AND EXPERIMENTAL PLAN

Three different types of binders; control binder, residue recovered based on procedure A at 25ºC for 24 hours followed by recovery at 60ºC for 24 hours and residue recovered through procedure B at 60ºC for 6 hours. The three different samples were prepared and evaluated at three different aging conditions; original, short term aged (Rolling Thin Film Oven; RTFO) and long-term aged (Pressure Aging Vessel: PAV). These binders were selected to compare the difference of evaporative techniques at different aging conditions. The selected emulsion is a CSS-1H which represents a cationic slow set emulsion and the base (control) binder is PG64-22. The volumetric percentage of cationic emulsifier is approximately 3.

2.1 *Sample preparation*

The asphalt binders were aged for short term aging based on the AASHTO T 240 for Rolling Thin-Film Oven (RTFO) test and for long term aging based on AASHTO R28 using the

pressure aging vessel. The residues from emulsified binder were obtained using the ASHTO PP 72-11 including both procedure A (48 hours recovery) and procedure B (6 hours recovery), based on the recovery procedure from AASHTO M140 and AASHTO M208 respectively. The microscope slides were cleaned by methanol before preparing the samples for AFM testing. The slide was heated by 160 °C and then was cooled down by 30°C intervals and then was kept in ambient temperature to prevent aging and dust absorption. The amount of 0.2–0.3 grams of binders were spread on 0.5×3 (cm^2) area to prepare the samples.

2.2 *Equipment*

The Bruker Dimension Icon AFM and the data processing unit were used to measure mechanical properties at the room temperature (25 °C). All of the images were obtained by using Peak Force Quantitative Nano-Mechanics (PF-QNM) and MPP-12100-10 silicon cantilevers manufactured by Bruker. The calibrated cantilevers used for this study have an average resonant frequency of 150 kHz, and a tip radius of 8 nm and an average tip angle of 18°. The spring constant of the cantilever used for the experiment was calculated by Thermal Tune in Icon AFM (4.9 N/m).

A Tensor 27 Bruker™ Fourier Transform Infrared (FTIR) spectrometer was used to measure the infrared spectra. The Attenuated Total Reflectance (ATR) method was utilized to collect the spectrum as described by Jemison et al. (10).

2.3 *Test methods*

The test for characterization of rheological properties of binders at different aging and different evaporative techniques were conducted by using the DSR at intermediate and high temperatures. The Multiple Stress Creep and Recovery (MSCR) was selected to evaluate the permanent deformation criteria and the effects of different aging conditions. The test was performed based on the ASTM D7405. The test was conducted by a 25 mm plate and 1 mm gap setting. The sample was loaded for 1 second followed by 9 seconds of rest period. Ten creep and recovery cycles were conducted at 100 (Pa) creep stress level and ten creep and recovery cycles conducted at 3200 (Pa) creep stress level. The non-recoverable creep compliance (J_{nr}) and percent strain recovery were used to evaluate the binder modification properties. The fatigue resistance of the binders was evaluated by running a sweep strain test at an intermediate temperature (25°C) by varying the percentage of strain applied to the samples. The test comprises of evaluating the effects of increasing the strain on asphalt binder stiffness, $|G^*|$, at a constant frequency and temperature. This test was done by 8 mm parallel plate and gap setting of 2 (mm). The sweep strain tests were conducted at the frequency of 10 rad/s.

2.3.1 *Multiple Stress Creep and Recovery (MSCR) and sweep strain results*

The standard suggests use of nonrecoverable compliance (J_{nr}) and percent strain recovery to evaluate test results. Polymer modification allows the binder to accumulate less permanent deformation due to delayed elasticity so a portion of the deformation is recovered after unloading (12). Use of the J_{nr} quantifies this behavior and allows for evaluation of the impact of modification on performance. Furthermore, percent strain recovery provides a means to detect the presence of a polymer network and evaluate its development as a function of curing time. These behaviors cannot be captured using the current $|G^*|$ and delta testing protocols, therefore the MSCR test has been adopted and used for polymer-modified binders.

The permanent deformation of binders was evaluated using the MSCR test conducted at 60°C considering two sample replicates. The non-recoverable creep compliance of each samples were calculated based on ASTM D7405 and the averaged values of two replicates were used for further evaluation. The results presented in Figure 1 demonstrate the non-recoverable creep compliance (J_{nr}) of two residues using different recovery procedures and base binder at two different stress levels of 100 Pa and 3,200 Pa. It was found that the J_{nr} for the PAV aged material are identical regardless of the binder type and the adopted recovery

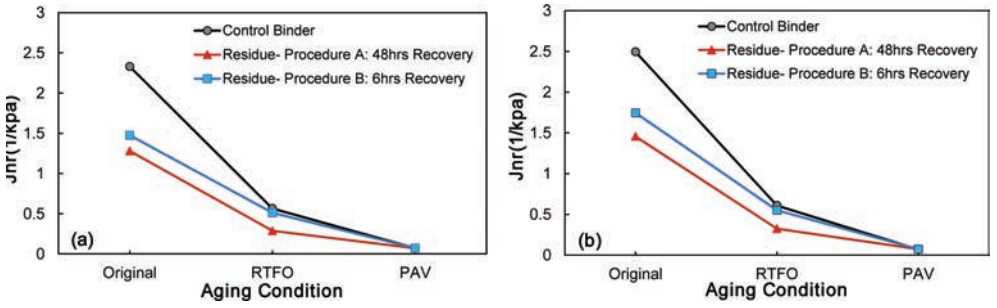

Figure 1. J_{nr} at different aging conditions for MSCR testing at 60°C testing temperature for (a) 100 Pa and (b) 3,200 Pa stress levels.

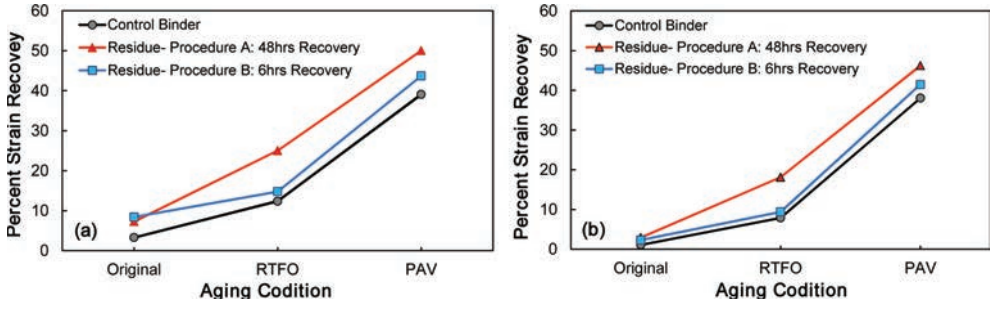

Figure 2. Average percent recovery at different aging conditions for MSCR at 60°C testing temperature for (a) 100 Pa and (b) 3,200 Pa stress levels.

procedure. The J_{nr} of control binder and recovered residue using procedure B are close and they both are different from the residue acquired using procedure A at short-term aging condition. The values of J_{nr} are different for both recovered residues and control binder at unaged condition (original). These results indicate that the recovery of the modified emulsion residues produces an aged material with rheological properties that approach those of the base binder subjected to the PAV aging. The benefit of modified emulsion is also noted by the significant increase in resistance to permanent deformation (lower J_{nr}) for emulsion relative to that of base binder at unaged and short-term aging conditions.

The average percent strain recovery was used to quantify development of the polymer network at various aging conditions in the emulsion residues and to compare results to the properties of the base materials. Percent strain recovery is defined as the difference in strain at the end of the creep and recovery cycles. In ASTM D7405, the average percent strain recovery over the 10 cycles of the test at a given stress level is reported (5). Figure 2 provides results of percent strain recovery evaluation at a 60 °C testing temperature at stress levels of 100 Pa and 3,200 Pa. The results demonstrate significant differences in the effect of recovery procedures and modification versus the base binder. At these testing conditions, both the control binder and two residues exhibited negligible percent recovery strain recovery. Both recovered residues show higher percent strain recovery that increases with aging time.

The failure properties of the control binder and two residues are presented in Figure 3. The results presented in this figure exhibit differing sensitivities to recovery procedures against the control binder. The procedure A exhibits significantly less strain tolerance after 48 hours curing by approximately 8% decrease in failure strain while procedure B leads to 4% decrease in failure strain comparing to control binder in original condition. The failure strain of the RTFO-aged binders are very close for both recovery procedures and base binder and is well below that of original condition which indicates the RTFO material demonstrate less strain tolerance. The PAV-aged residues demonstrate more strain tolerance comparing to the

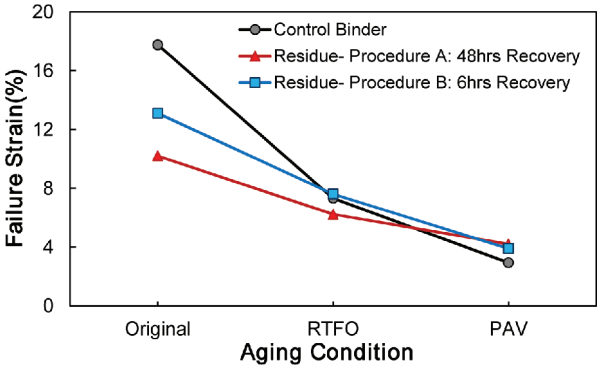

Figure 3. Failure strain as function of aging for sweep strain at 25°C.

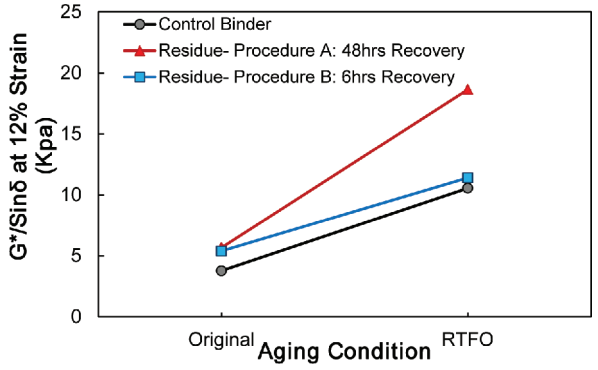

Figure 4. Resistance to permanent deformation criteria as function of aging.

control binder at the same condition. The deviation of behavior of residues from the control binder at different aging conditions indicate that in regard to strain tolerance, factors other than oxidative aging are affecting the performance of the emulsion residue.

Figure 4 provides the $|G^*|/\sin\delta$ values at different aging conditions. The results for the oven recovered emulsified binder for 48 hours indicate that the curing conditions produces levels of oxidative aging that are different from the other recovered binder for 6 hours and control binder. The largest increase in $|G^*|/\sin\delta$ was realized in RTFO aging condition for the residue recovered for 48 hours. From these results, the properties of the emulsion residues subjected to the ASTM recovery method reflect the effect of latex modification and aging.

2.3.2 *Atomic force microscopy results*

Asphalt chemical parameters have a measurable effect on the asphalt microstructure that can be observed with AFM to reveal the microstructure. Interesting findings can be derived through the interaction of the tip with the microstructure of the asphalt sample using the pull-off force curve (13). The atomic force microscopy was used in this study to image the surface and identify different phases and microstructures on the specimen surface. This was achieved in non-contact mode as the primary imaging mode. In addition, AFM was also used in Spectroscopy Mode (SM) to measure the nano-scale response of asphalt binders aged at different conditions. Therefore, a combination of these two techniques (AFM and SM) was used to map the microstructure of the asphalt binder and estimate microstructure mechanical properties as illustrated in Figure 5 and Figure 6 respectively. Different phases in an asphalt specimen were identified and a force measurement in each of the phases was performed at different aging conditions for control binder and emulsion residues. The tests consisted of

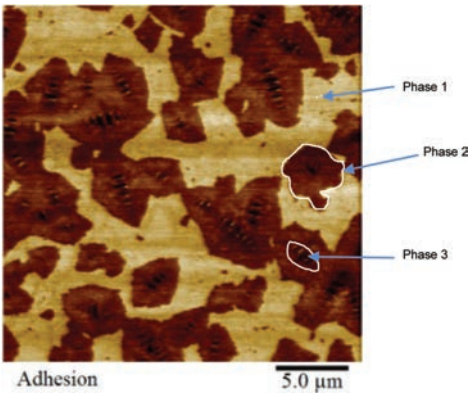

Figure 5. Adhesion image of control binder (color scale shows relative differences in phases based on tip adhesion during scanning).

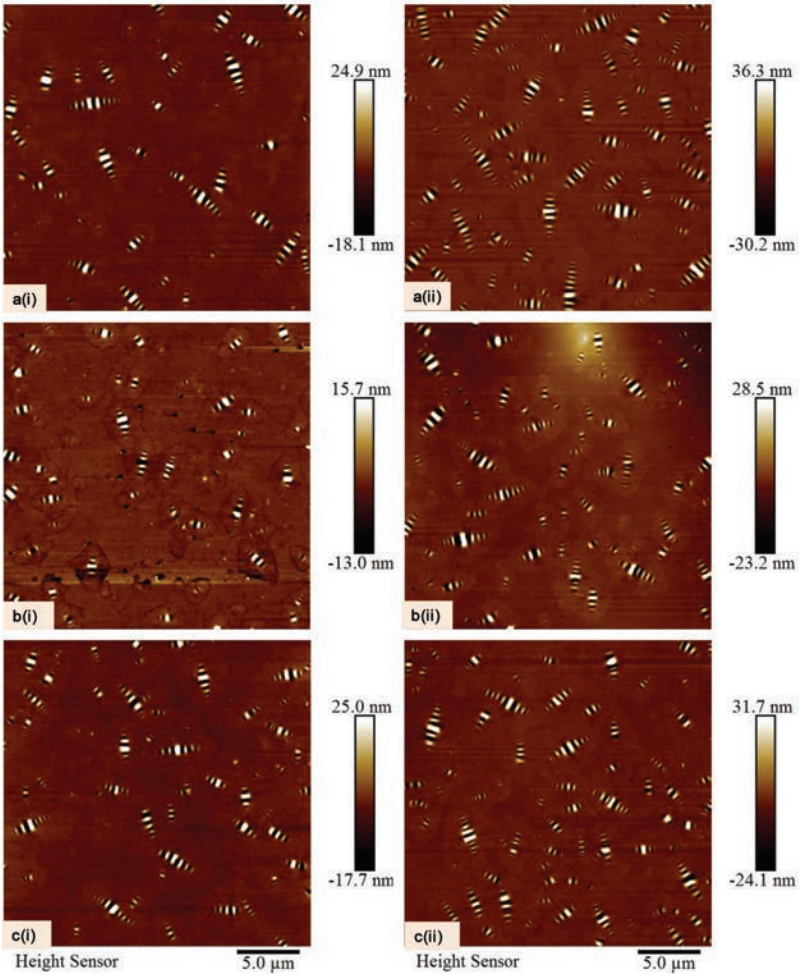

Figure 6. Topography images (25 µm × 25 µm) of control binder at a(i) Original, a(ii) PAV, residue using procedure A (after 48 hrs recovery: 24 hrs @ 25ºC and 24 hrs @ 60ºC) at b(i) Original, b(ii) PAV, and residue using procedure B (after 6 hrs recovery @ 60ºC) at c(i) Original and c(ii) PAV aging conditions.

three force measurements taken in each phase. An illustration of different asphalt phases and locations of each measurement is shown in Figure 5. A 25 μm × 25 μm topography image is presented for each asphalt binder, including identification of individual phases and a profile extraction of the corresponding phase topography.

Furthermore, evaluation of emulsification on asphalt calculated by conducting force distance curves and it has been shown in Figure 7 and mechanical properties were summarized in Table 1. From the results, it can be concluded that differences are mostly attributed to

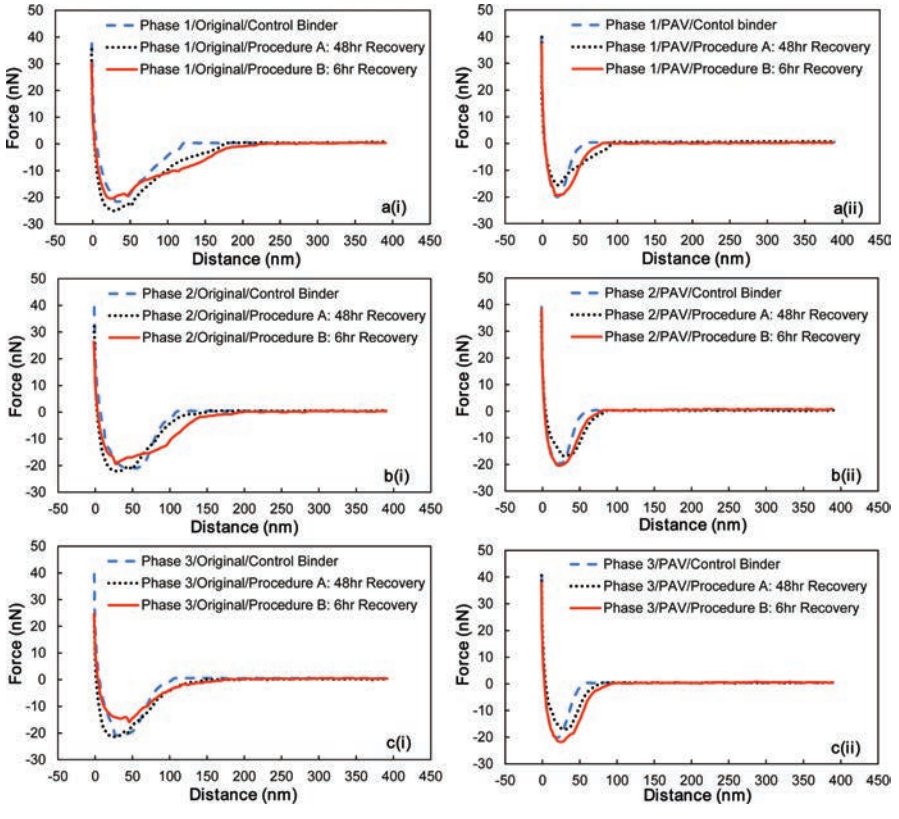

Figure 7. Results of force-distance curves from AFM testing.

	Phase 3	250	775	1110	1010

physical changes in the asphalt binder and emulsification process. Also hypothesized was that additional source of these differences are potentially oxidation, sample reheating, and residual water. The foaming of the residues during reheating might be another reason. Foaming during reheating indicates the possibility that a thin film was created over the emulsion residue during recovery. In the literature (14), this is referred to as *skinning*, a similar effect was noted by Takamura in development of the evaporative recovery method when recovery was attempted at high temperatures. This film has a significantly higher stiffness than conventional asphalts do; thus, the presence of the film with the remaining, partially cured, emulsion residue has the potential to increase DSR results.

The chemistry and microrheology of these microstructures within the asphalt binder influence its macroscopic properties, such as stiffness, viscoelasticity, adhesion, fracture and healing. Because the state of component dispersion (component compatibility) of an asphalt has a significant effect on asphalt oxidative hardening rate, the possibility is suggested by Peterson (8) that some of the antioxidants may have also reduced oxidative hardening by acting as a dispersant for the asphaltene-like components in the asphalt that leads to the improvement of component compatibility. Indeed, it has been reported by Dybalski (15) that *cationic asphalt additives*, commonly used as asphalt emulsifiers, augment the peptization of the asphaltenes constituent and thus reduces the asphalt hardening rate. According to their findings, of 82 asphalts tested, 81% were benefited by the additives, with a minimum of 15% and a maximum of 65% reduction in hardening rate during the rolling thin-film oven test (ASTM D2872-77). In another study (16), the hardening rate of a recycled pavement mixture during laboratory aging was reduced several fold by a high float emulsifying agent used to emulsify the recycling agent before recycling the pavement mixture in the laboratory.

In this study the Young's modulus and energy dissipation of different phases were calculated for the control binder and emulsion residues aged at different conditions. The findings have been summarized in Table 1. The young's modulus was calculated based on the Sneddon indentation theory by using the spring constant, tip radius, tip half angle and the sample Poisson's ratio. This parameter was used to compare the stiffness of different phases although the response was not purely elastic in this set of tests. The dissipated energy was also calculated based on the area under the force distance curves. As it is expected the dissipated energy decreases in more brittle materials like the control binder and recovered residues in PAV aging conditions compared to the unaged (or original) conditions. The interesting finding is that the dissipated energy was higher for recovered residues compared to the control binder at each aging conditions which indicates the dominant effect of emulsifying process in the residues obtained based on two adopted evaporative recovery procedures.

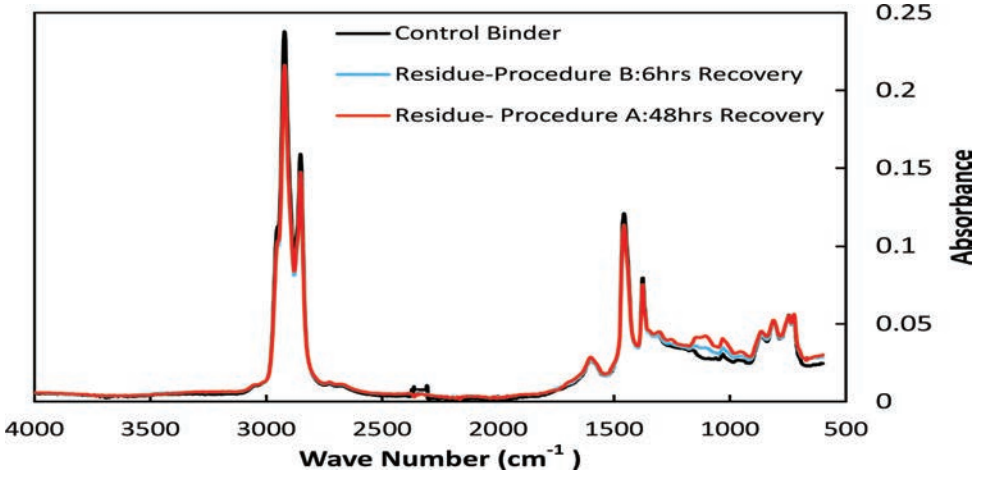

Figure 8. FTIR spectra for different recovery methods.

2.3.2 *Fourier transform infrared results*

Asphalt chemical parameters have a measurable effect on the aging of asphalt that can be observed with FTIR to reveal the chemical difference. Lau et al. (17) have showed that the carbonyl area would be a good measure of oxidation and the area under the peak between 1650 and 1820 wavenumber (cm^{-1}) was measured to determine if the asphalt was oxidizing during the curing processes. The Carbonyl areas were 0.69, 0.79, and 0.81 for control binder, 6 hours recovery, and 48 hours recovery respectively. The carbonyl area can be used as an indication of aging in binders. FTIR spectrum showed that longer process ages the binder more than shorter recovery method. The water was not observed in the specimens since there is no major peak around 3347 cm^{-1} wave number which can be related to the presence of water (18). The IR spectrum is shown in Figure 8 and the difference in spectrum should be related to recovery process and the emulsification process of binders.

3 CONCLUSIONS AND RECOMMENDATIONS

The objective of this study was to semi quantitatively characterize the micro-rheology and rheology of a control binder and emulsion residues obtained through different evaporative recovery procedures by using AFM, DSR, and FTIR testing. Based on the results obtained from the study the effects of long-term aging impact not only the material behavior of these microstructures, but also the distribution of each asphalt microstructure. The long-term aging clearly induces microstructural change in asphalt. The form and extent of these changes, however, were different for control asphalt versus emulsion residues. It is hypothesized that the remaining differences in rheological response as revealed through the evaluations of strain tolerance and percent strain recovery can be related to effects of emulsifier chemistry or different recovery methods. The strain sweep and MSCR produce results that are able to discriminate between recovery procedures and quantify the change in critical properties, as a function of aging time. It was observed that the properties of the emulsion residue do not correspond to those of the unaged base binder. Results support that residue be considered as rolling thin-film oven-aged or partially-aged material rather than unaged material. The theme of this research effort was to determine if these differences are due to oxidative aging, remaining moisture, chemistry of the emulsifier, or a combination of these factors. The findings of this study help the concerns that have been expressed about the length of long evaporative recovery procedure and the possibility for reducing the time required.

Further research is needed to understand the level of aging that occurs in the field relative to the aged state of the residue produced by the recovery method, to quantify the differences in performance between various emulsions and to correlate laboratory performance with actual field performance. The apparent relationships between component ratios and property changes on oxidative aging, as determined by the relationships of the generic fractions, are recommended to be acquired to enhance the results of this study to provide valuable insight into the chemical and physicochemical aspects of asphalt oxidative hardening.

Estimating the tensile strain at the bottom of the HMA layer using TSD deflection slope measurements

Samer Katicha, James Bryce & Gerardo Flintsch
Virginia Tech Transportation Institute, Blacksburg, VA, USA

ABSTRACT: In this paper, we use Traffic Speed Deflectometer (TSD) deflection slope measurements to estimate the tensile strain at the bottom of the HMA layer. The procedure we follow is essentially the one proposed by Thyagarajan et al. [1], which can be used to calculate the tensile strain at the bottom of the HMA layer using Falling Weight Deflectometer (FWD) measurements, modified to apply to the TSD deflection slope measurements. The TSD calculated tensile strains are compared to FWD calculated tensile strains. The results show that although the procedure was initially developed and tested for loading conditions corresponding to the FWD, when applied to TSD deflection slope measurements, the procedure gives similar results to those obtained from the FWD which suggest it is also applicable to the TSD. This shows that continuous deflection devices in general, and the TSD in particular, are viable devices that give reasonable results for at least network-level pavement management applications.

Keywords: Continuous deflection devices, Traffic Speed Deflectometer, tensile strain, HMA

1 INTRODUCTION

Measurement of the existing structural capacity of a pavement is a critical input for (1) structural analysis of in service pavements, (2) identification of sections with structural capacity deficiencies at the network level, and (3) design of pavement renewal or rehabilitation treatments at the project level. State Departments Of Transportation (DOT's) routinely use deflection measurements at the project level, using mainly the Falling Weight Deflectometer (FWD), and some are starting to use them also at the network level [2], [3]. Although the FWD provides a very useful tool to assess the pavement structural or bearing capacity of a pavement, and can be used to determine the moduli of the component layers, this technology has the limitation of only allowing stationary measurements at discrete points along the pavement sections. The need to stand on the road for a short period of time disturbs traffic and requires traffic control. This limits the productivity and the density of points at which data are collected and increases survey cost.

The use of continuous deflection measuring devices—that in some cases operate at traffic speed—allows a better spatial coverage with less negative impact on mobility compared to the FWD and potentially lower survey cost per unit length. Although the currently available "continuous" devices do not provide the same detailed information, accuracy, and repeatability as the FWD, they are becoming increasingly popular as a practical alternative, especially for network-level structural monitoring. These devices were evaluated in a recent Strategic Highway Research Program 2 (SHRP2) R06(F) project. The project surveyed user needs for a continuous deflection device, evaluated current technologies implemented in different types of continuous deflection measuring devices, identified the most promising devices for effectively supporting pavement management decisions, evaluated the capabilities of these devices, and identified and illustrated potential applications to support network-level pavement management [3].

As part of the SHRP2 R06(F) project, the Traffic Speed Deflectometer (TSD) was selected for further evaluation. Part of this evaluation included comparison of the TSD with the FWD. The Surface Curvature Index (SCI) and Base Damage Index (BDI) were two of the chosen parameters used in the comparison. The SCI and BDI were chosen because they can be calculated from measurements obtained from either the FWD or the TSD and because the two parameters have been shown to be good predictors of the tensile strain at the bottom of the HMA layer [1]. In this paper, we compare the calculated tensile strain at the bottom of the asphalt layer obtained from FWD deflection measurements and TSD deflection slope measurements.

2 OBJECTIVE

The objective of this paper is to compare the TSD and FWD calculated tensile strain at the bottom of the asphalt layer. TSD and FWD measurements were first converted to the SCI from which the tensile strain was calculated. Before we present the methodology followed and the results, a brief overview of the FWD and TSD are given.

3 EQUIPMENT DESCRIPTION

3.1 *Falling Weight Deflectometer (FWD)*

The FWD applies a load pulse that simulates the load of a rolling vehicle wheel to the pavement. The load is produced by dropping a weight onto a circular plate (generally of 300 mm diameter) placed on the pavement surface. The applied load and vertical pavement deflection at various radial distances (e.g. 0 mm, 200 mm, 300 mm, 450 mm, 600 mm, 900 mm, 1200 mm, and 1500 mm) from the center of the load are measured and recorded. The collected data obtained from FWD testing is used to determine the structural condition of the pavement.

3.2 *Traffic Speed Deflectometer (TSD)*

The TSD (Fig. 1) is mounted on an articulated truck with a rear axle load of 100 kN (22 kips) which, in the model evaluated, utilizes four Doppler lasers mounted on a servo-hydraulic

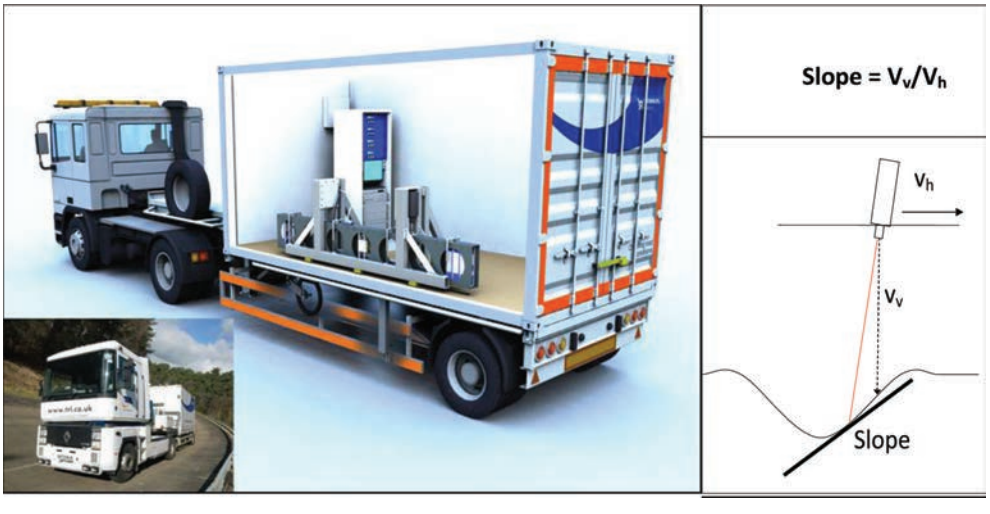

Figure 1. Computer render of the TSD, with the TSD in operation (inset).

beam to record the vertical deflection velocity of a loaded pavement under one of the dual wheel assemblies. Three Doppler lasers are positioned such that they measure deflection velocity at a range of distances in front of the rear axle. The fourth sensor is positioned 3.6 m in front of the rear axle largely outside the deflection bowl, acting as a reference laser. The beam on which the lasers are mounted moves up and down in opposition to the movement of the trailer in order to keep the lasers at a constant height from the pavement surface. To prevent thermal distortion of the steel measurement beam, a climate control system maintains the trailer temperature at a constant 20 °C. Two prototypes had been developed at the time of the evaluation by the manufacturer Greenwood Engineering A/S of Denmark. One is owned and operated by the Danish Road Institute (DRI) and the other is owned by the UK Highways Agency (HA) and operated on their behalf by the UK Transport Research Laboratory. Newer production devices have incorporated more Doppler laser sensors [3].

The lasers are mounted at a small angle to measure the horizontal vehicle velocity, the vertical and horizontal vehicle suspension velocity, and the vertical pavement deflection velocity. Due to its location, mid-way between the loaded trailer axle and the rear axle of the tractor unit, the reference laser is expected to measure very little vertical pavement deflection velocity, and its response can therefore be used to remove the unwanted signals from the three measurement lasers. When accurately calibrated, the TSD produces measurements of deflection velocity that depend on driving speed. To remove this dependence, the deflection velocity is divided by the instantaneous survey speed to give a measurement of deflection slope, as illustrated in the figure. Deflection velocity is measured in mm/s whilst survey speed is measured in m/s; therefore, deflection slope measurements are output in units of mm/m [4].

4 METHODOLOGY

The methodology followed in this paper is to first calculate the SCI from TSD and FWD measurements and then use the SCI to calculate the tensile strain at the bottom of the asphalt layer. For the measurements, the applied load for both the TSD and FWD was 40 kN and FWD deflection measurements were temperature corrected to the temperature at which the TSD tests were performed.

4.1 *Calculating the SCI and BDI*

The calculated SCI is SCI300 which is defined as d_0–d_{300}, while BDI is defined as d_{300}–d_{600}, where d_0, d_{300} and d_{600} are the deflections at 0 mm, 300 mm, and 600 mm from the applied load, respectively. For the FWD, d_0, d_{300}, and d_{600}, are directly measured and calculation of the SCI and BDI is straightforward. In the following section, we present the methodology used to calculate the SCI and BDI from TSD slope measurements.

The TSD measures the slope of the deflection bowl. Therefore, the deflection can in principle be obtained from the TSD slope by integration if a sufficiently detailed representation of the full deflection slope bowl is available. Integration is however only specified up to a constant value and therefore we cannot recover the deflection without a reference deflection measurement. We can however obtain the difference between two deflection readings (the constant cancels out) which gives the SCI or BDI. The relationship between slope, deflections and SCI and BDI is presented in Eq. (1).

$$\int_a^b s(x)dx = d(b) - d(a) = \text{SCI} \tag{1}$$

where, $s(x)$ is the slope at location x and $d(x)$ = deflection at location x. To calculate the SCI from TSD measurements, the TSD slope was integrated numerically. To calculate SCI, the integration interval is [0 mm; 300 mm] while for the BDI the integration interval is [300 mm; 600 mm]. TSD slope measurements were obtained at 100, 300 and 756 mm from the applied wheel load and the deflection slope at 0 mm was assumed to be equal to zero. This assumption

is valid if the load is uniformly (or approximately uniformly) applied over a specific area rather than being a point load, which is the case for a wheel load, and if viscoelastic effects are neglected. Note that viscoelastic effects will cause the response to the applied load to be slightly delayed so that the slope will actually be zero at a location slightly behind the applied wheel load. However, the calculation of SCI is not significantly affected by the location where the deflection slope is set to zero (see Fig. 3-41 and Fig. 3-42 in [3]).

4.2 *Calculating the tensile strain at the bottom of the asphalt layer*

Thyagarajan et al. [1] developed an equation to relate the tensile strain at the bottom of the asphalt layer with SCI and BDI using FWD deflection measurements. The relationships developed for determining the strain for aggregate base pavements are presented in Eq. (2), respectively:

$$Log(\varepsilon_{AC}) = 0.5492Log(SCI) + 0.3850Log(BDI) + 0.7812Log(H_{AC}) - 0.0017H_{AC} + 1.7353 \qquad R^2 = 0.994 \tag{2}$$

where:
ε_{AC} = strain at the bottom of the asphalt layer
H_{AC} = thickness (mm) of the asphalt layer
SCI = Surface Curvature Index (mm)
BDI = Base Distress Index (mm).

It is noted that these equations were developed for use with FWD measurements so may not be entirely appropriate when using deflections measured using a rolling-wheel load moving at traffic speed as with the TSD.

5 RESULTS

To demonstrate the applicability of the methods described earlier, the strain at the bottom of the asphalt layer was estimated for a tested pavement section approximately 2.2 km long. Figure 2 shows the TSD deflection slope measured 100 mm from the applied wheel load and the FWD d_0 both at 20 m intervals. Although the measurements from each device have

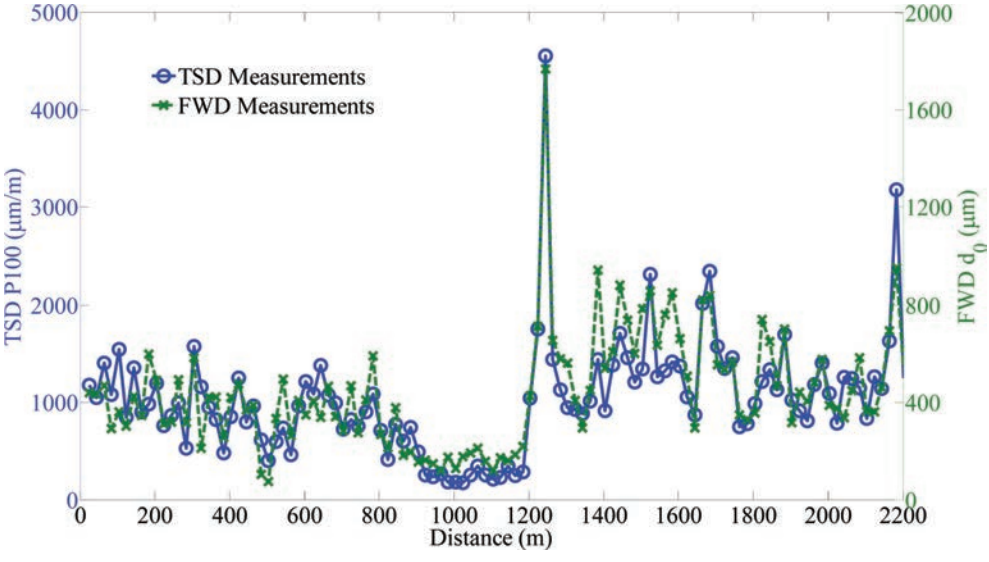

Figure 2. Comparison of TSD and FWD measurements.

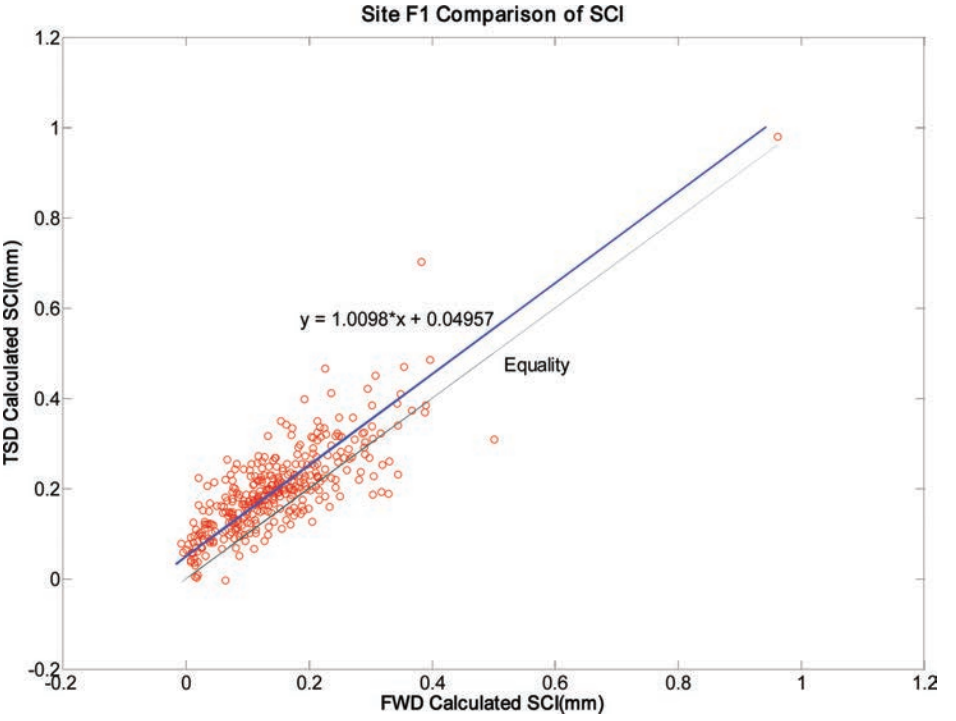

Figure 3. TSD calculated SCI versus FWD calculated SCI.

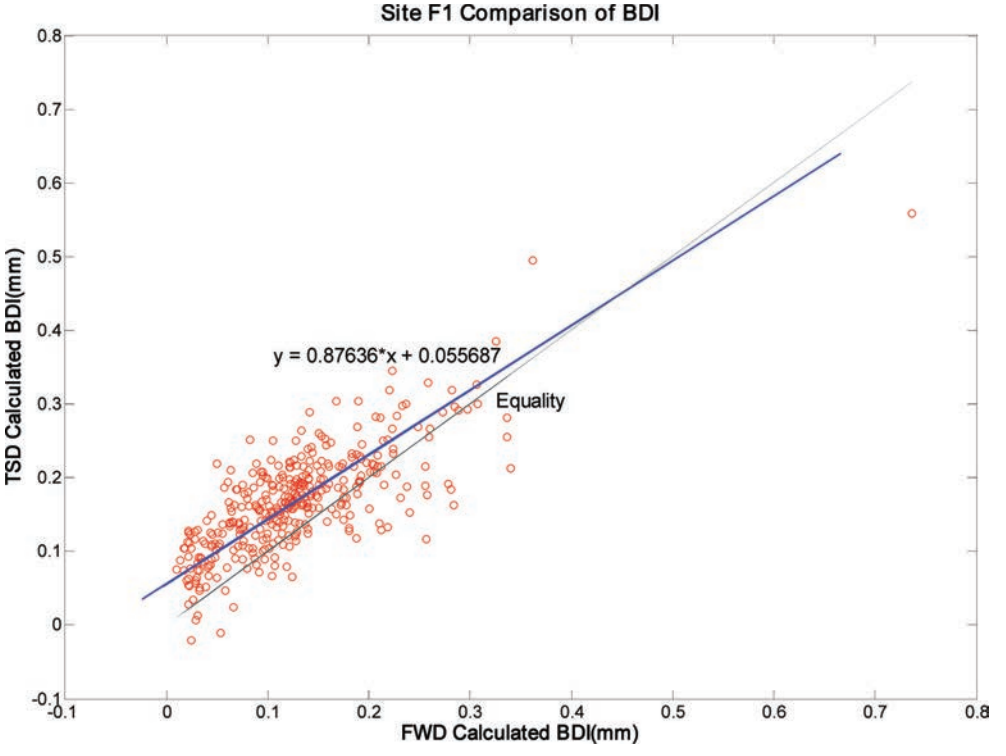

Figure 4. TSD calculated BDI versus FWD calculated BDI.

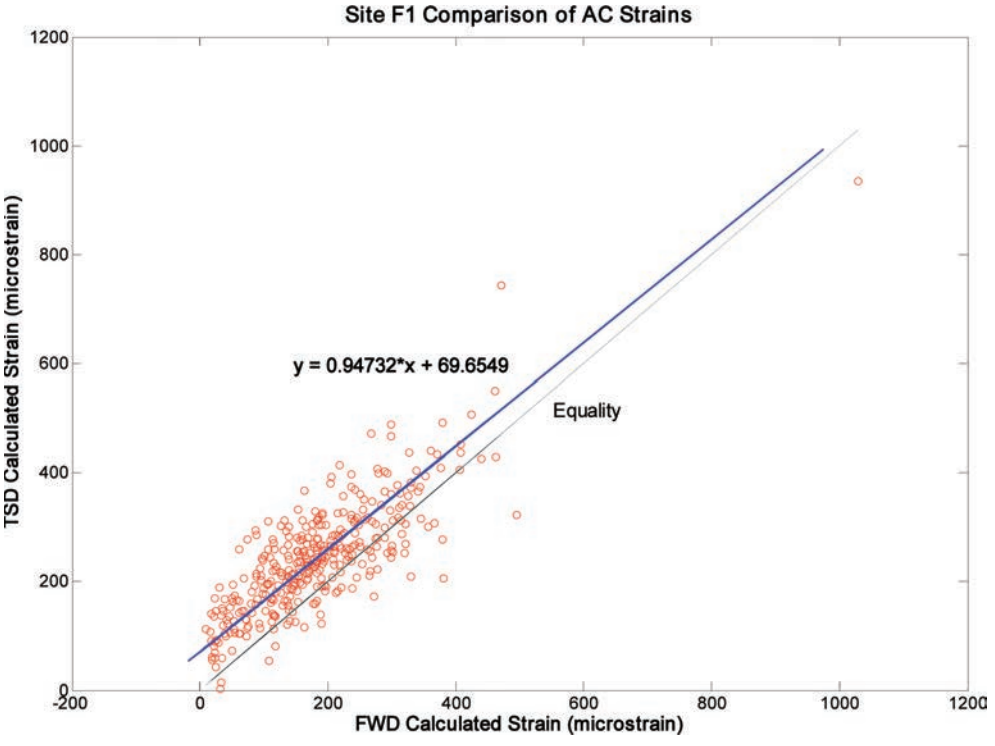

Figure 5. Strain at the bottom of the asphalt layer estimated by TSD and FWD.

different units, they both follow the same trends. The figure shows that like the FWD, the TSD was able to capture the structural variation in the pavement sections.

The comparison of the SCI calculated from data gathered by the TSD and FWD are presented in Figure 3, and the BDI calculated from data from each device are compared in Figure 4. The relationship shown in each case was determined using orthogonal regression, since both estimates contain measurement errors. For the SCI, the slope of the regression is close to 1 and the TSD calculated SCI is, on average, about 0.05 mm higher than the FWD calculated SCI. For the BDI, the two devices follow the same trends however the slope of the regression in this case is about 0.88 which suggests that the relationship between the TSD BDI and the FWD BDI while still good, is not quiet as good as the relationship in the case of the SCI. Similar to the case of the SCI, in general, the TSD calculated BDI values were larger than the FWD calcualted ones.

Using the SCI, BDI, and thickness of the pavement, the strain at the bottom of the asphalt layer was estimated along the site for each measuring device. The comparison of the strain at the bottom of the asphalt layer from the two devices is presented in Figure 5. The strains calculated from each device follow the same trends which shows the potential of using the TSD for network level applications; however, the TSD calculated strain was on average larger by about 65 microstrain than the FWD calculated strain and the variability around the trend line is still considerable compared to the accuracy required for detailed analysis such as is done at the project level. For example, the results presented in Figure 5 shows that there could be as much as 200 microstrain difference between the TSD and FWD calculated strain.

5 CONCLUSION

This paper compared the TSD and FWD estimated strain at the bottom of the asphalt layer. The results show that, in general, the calculated strain from either device follow the same

trends with TSD calculated tensile strain on average larger by about 65 microstrain than FWD calculated tensile strain. Furthermore, there is a significant variability in the relationship between the tensile strain obtained from each device. This variability could result in differences of as much as 200 microstrain.

The results here suggest that further investigation of the causes that lead to the TSD measuring higher strain levels is needed. Although the applied load was of the same magnitude (40 kN), the dynamics of how the load is applied in each case are much different. In the case of the FWD, the load is dropped onto the pavement whereas for the TSD the load is applied by a moving wheel.

Modeling the effects of constituent properties on the mechanical behavior of asphalt mixtures

Francisco Thiago Sacramento Aragão
Department of Civil Engineering, Universidade Federal do Rio de Janeiro-COPPE, Rio de Janeiro, RJ, Brazil

Yong-Rak Kim
Department of Civil Engineering, University of Nebraska-Lincoln, Lincoln, NE, USA

ABSTRACT: This study evaluates the influence of constituent properties on the mechanical behavior of asphalt mixtures. A computational microstructure model is used to simulate the overall behavior of the mixtures based on individual constituent properties. The heterogeneous mixtures are composed of linear elastic coarse aggregate particles that are embedded into a viscoelastic fine-aggregate asphalt matrix phase. To properly model the mechanical behavior of the composite, other complex mixture characteristics, such as geometrical properties of the aggregate particles and rate-dependent fracture characteristics of the fine aggregate asphalt matrix are taken into account in the model. Simulations are performed to demonstrate the ability of the model to identify the influence of mix constituents and design factors such as stiffness, volume fraction, and fracture characteristics on the overall mechanical behavior of the mixtures. Even if extra work is required to refine the model, the results demonstrate that carefully-developed computational microstructure models, such as the one presented herein, represent a promising strategy to model the complex behavior of asphalt mixtures in a scientifically-sound and efficient manner.

Keywords: Asphalt mixtures, mechanical behavior, mixture constituents, microstructural modeling, finite element method

1 INTRODUCTION

Asphalt concrete mixtures are particulate composites in which a rigid skeleton of aggregate particles is held together by a softer phase of Fine Aggregate Matrix (FAM) mixture that is composed of asphalt binder, air voids, and fine aggregates. To predict the mechanical behavior of these heterogeneous and viscoelastic composites that experience damage at different length scales, several researchers have proposed various computational predictive models based on the discrete and the finite element methods [1–10]. These computational microstructure models have stronger scientific basis than empirical methodologies that are based on statistical analyses of regional and case-specific databases. In comparison to other computational approaches, the computational microstructure models are also advantageous because they account for diverse complexities (*e.g.*, material inelasticity, heterogeneity, anisotropy, multiple damage forms). Computational microstructure models can also greatly reduce the costs associated with laboratory experiments because they generally only require individual mixture constituent properties as model inputs. Another advantage of the computational microstructure modeling approach is that it allows a comprehensive examination of the microstructural, inelastic material behavior so that stresses and strains within the microstructure can be analyzed more realistically.

In an attempt to characterize the microstructural fracture damage behavior of asphalt mixtures, Aragão [11] has recently proposed a computational microstructure model based on the finite element method that is incorporated with material viscoelasticity and rate-dependent Cohesive Zone (CZ) fracture. In 2010, Aragão *et al.* [8] successfully employed an earlier version of that model in numerical simulations of the dynamic modulus of asphalt mixtures and demonstrated the potential of the microstructural modeling approach to simulate the undamaged mechanical behavior of the material based on component properties.

Kim and Aragão [10] used the computational model proposed by Aragão [11] in fracture simulations of real microstructures of asphalt mixtures. In their work, Kim and Aragão [10] used component properties obtained from simplified testing programs [12] to simulate the individual component behavior within the microstructure of the mixtures and the corresponding overall mechanical responses of the composite. Kim and Aragão [10] observed that the rate-dependent fracture model generated considerably more accurate predictions than its rate-independent version, which clearly demonstrates the need for the consideration of this behavior in microstructure modeling of asphalt mixtures.

As demonstrated by Aragão *et al.* [8] and Kim and Aragão [10], the accuracy of microstructural models greatly depends on the level of understanding of the physics of the real problem and on how well the computational models simulate those physical characteristics. These characteristics include the heterogeneity and random distribution of aggregate particles, the inelasticity of the Fine Aggregate Matrix (FAM), the large size of the plastic zones around the crack tips of the damaged mixtures, and the rate-dependent characteristics of those fracture zones, among others.

In that sense, this paper presents the computational microstructure model proposed by Aragão [11] to simulate the effects of constituent properties on the mechanical behavior of asphalt mixtures. Parametric analyses are conducted in this paper to demonstrate the ability of the model to directly account for component characteristics, such as stiffness, volume fraction, and rate-dependent fracture on the overall mechanical behavior of the mixtures. The results presented in this paper demonstrate that carefully-developed models based on the computational microstructure approach have a great potential to become powerful design and analysis tools for asphalt mixtures and pavements. For that, only component properties and representative boundary conditions of the real problems are required to simulate the mechanical responses of the mixtures subjected to different loading conditions.

2 DYNAMIC MODULUS SIMULATIONS

As previously mentioned, Aragão *et al.* [8] have demonstrated the ability of the computational microstructure modeling approach to predict the dynamic modulus of asphalt mixtures. The predictive capabilities of different modeling methodologies typically used in the literature were compared and indicated the great potential of the numerical approach. In that study, the researchers also demonstrated that the computational microstructure methodology can directly account for the effects of constituent properties on the dynamic modulus of the mixtures. Figure 1a shows the virtual testing set-up (*i.e.*, mixture microstructure, boundary conditions and virtually-generated deformation sensors) used by Aragão *et al.* [8] to simulate the dynamic modulus of real mixture microstructures. Figures 1b and 1c show the results of the parametric analysis conducted by the researchers to evaluate the change in the overall mixture stiffness given changes in the asphalt content and aggregate stiffness, which are two important component properties that significantly affect the overall mixture stiffness. From the results shown in Figure 1b, it is clear that the computational model successfully captured the effect resulting from the addition of more asphalt binder in the mixture microstructure. The use of the matrix properties with a higher binder content resulted in lower dynamic modulus values, as expected. On the other hand, the stiffening effect resulting from the use of stiffer aggregate particles has also been successfully characterized, as shown in Figure 1c.

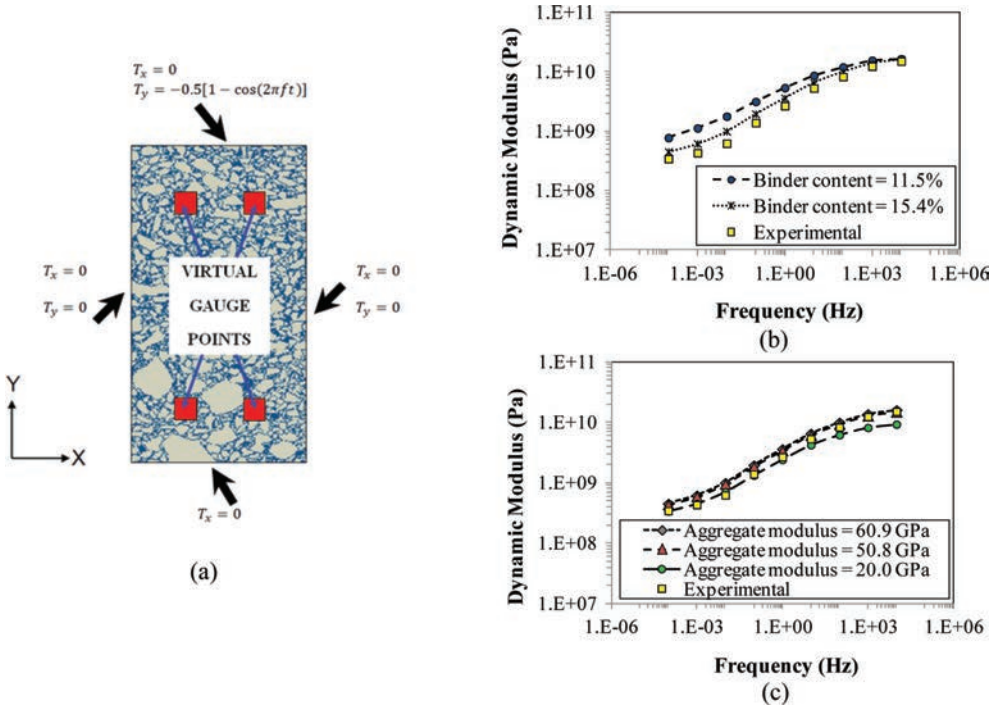

Figure 1. (a) Virtual testing set-up and parametric analyses on the effects of (b) binder content and (c) aggregate stiffness on the dynamic modulus of asphalt mixtures (Aragão *et al.*, 2010).

3 FRACTURE SIMULATIONS

Other important variables that affect the mechanical behavior of the mixtures include the volume fraction of aggregate particles, as well as the fracture characteristics of the FAM phase. Thus, this section presents a sensitivity analysis to illustrate the ability of the computational model to account for the effects of such important constituent properties on the overall fracture damage behavior of the mixtures. For that, virtually-generated mixture microstructures composed of linear elastic aggregate particles and viscoelastic FAM are simulated. Fracture is assumed to occur within the matrix phase and is modelled using the bilinear Cohesive Zone (CZ) fracture concept.

The bilinear CZ model was selected among several others due to its simplicity and interesting features, such as the ability to reduce the artificial compliance effect through the adjustment of the effective displacement, δ_t. As illustrated in Figure 2, the bilinear model postulates that there is a fully-recoverable, linear elastic behavior until the traction on the cohesive surface reaches the peak value, or cohesive strength, T_{max}, in the traction-separation curve. To the cohesive strength corresponds an effective displacement, δ_t, above which damage starts to take place and the ability of the CZ elements to sustain traction is gradually reduced until it reaches a critical displacement, δ_c. At that point, the complete dissipative and irreversible failure of the CZ element is reached, and the process is repeated for the next cohesive elements that are still active in the mesh.

The rate-dependence of the fracture properties is defined via Eqs. (1) and (2). Eq. (1) represents a simplification of the rate- and temperature-dependent expression for cohesive strength proposed by Espinosa and Zavattieri [13] because the consideration of thermal effects on the fracture properties is out of the scope of this study. A similar rate-dependent expression is assumed for the other CZ property, *i.e.*, the cohesive fracture energy, G_c.

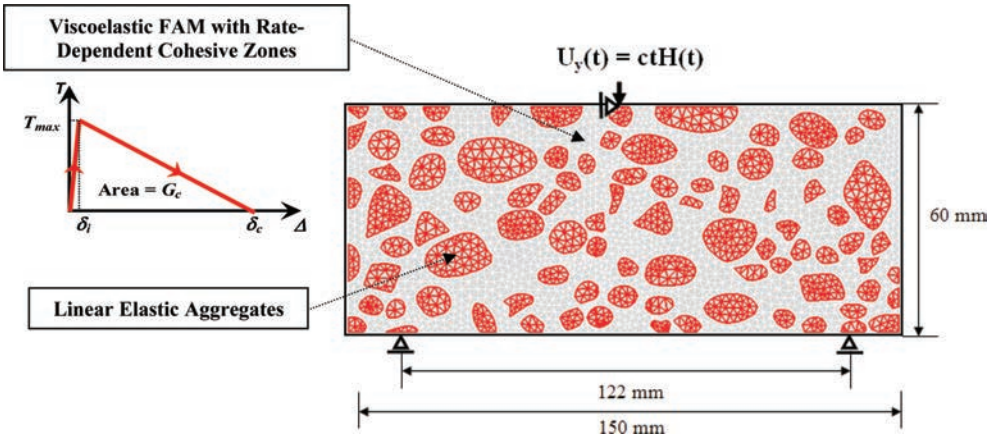

Figure 2. Bilinear CZ model and example of a virtual asphalt mixture microstructure used in the fracture simulations.

$$T_{max} = T_{max}^{ref}\left\{1+\beta_T \ln\left(\frac{\dot{\delta}_e}{\dot{\delta}_e^{ref}}\right)\right\} \tag{1}$$

$$G_c = G_c^{ref}\left\{1+\beta_G \ln\left(\frac{\dot{\delta}_e}{\dot{\delta}_e^{ref}}\right)\right\} \tag{2}$$

where $\dot{\delta}_e^{ref}$, T_{max}^{ref}, G_c^{ref}, and β_T and β_G = reference displacement jump rate, cohesive strength at $\dot{\delta}_e^{ref}$, cohesive fracture energy at $\dot{\delta}_e^{ref}$, and model parameters determined with the aid of experimental test results. δ_e represents the evolving effective displacement jump in each cohesive element and is calculated from the values of the normal and tangential displacement jumps, δ_n and δ_t, respectively, as shown in Eq. (3).

$$\delta_e = \sqrt{\delta_n^2 + \delta_t^2} \tag{3}$$

3.1 *Effects of aggregate volume fraction*

Two two-dimensional microstructures were generated to evaluate the effect of volumetric characteristics of aggregate particles on the fracture behavior of asphalt mixtures. The microstructures differed only on volume fraction of aggregate particles. For the analysis herein, two different values of aggregate volume fraction (qualitatively named as low and high volume fractions) were used to generate the two microstructures.

To simulate the complex geometry of the microstructures, finite-element meshes were generated with triangular elements measuring approximately 1 mm within the central region of the virtual beams and 2 mm outside that region. The objective of the higher refinement level at the central region was to maintain the geometric characteristics (*e.g.*, angularity) of the particles. Additionally, it is important to have a higher refinement level in the regions with higher potential for crack initiation and propagation because the possible crack paths are limited by the topology of the finite-element mesh. This mesh-dependence problem can be alleviated with the use of more refined meshes close to the evolving crack tips. However, the use of excessively refined meshes may result in very expensive computational cost and may also intensify the problem of artificial compliance that is inherent to intrinsic cohesive models.

The two finite-element meshes generated for the parametric analysis are shown in Figures 3a and 3b. To avoid the effects of the artificial compliance due to the use of an intrinsic

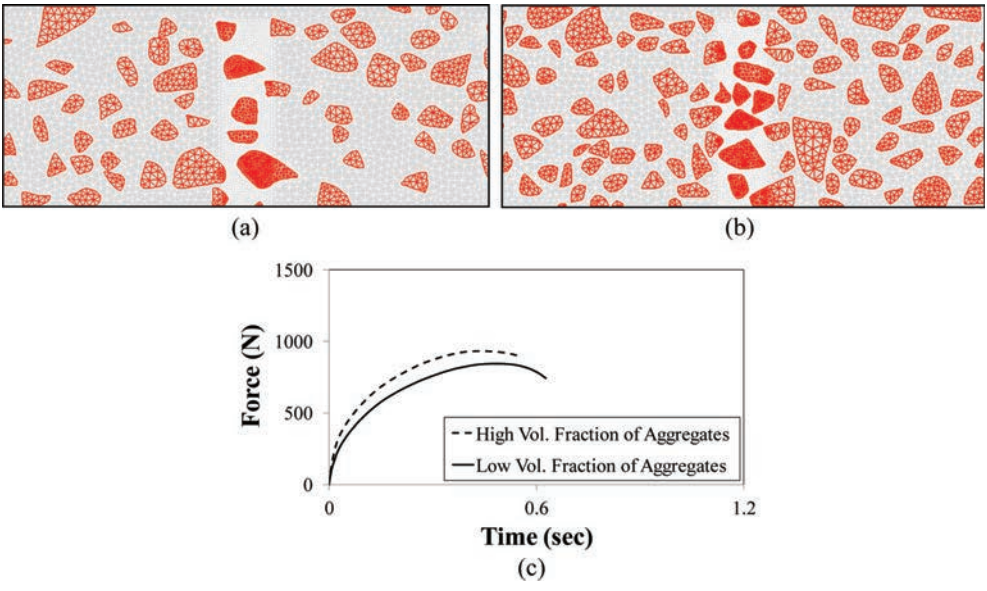

Figure 3. FEM mesh and microstructure of virtual HMA beam samples: (a) low and (b) high volume fraction of aggregates; and (c) simulation results.

CZ model, similar numbers of cohesive elements (2414 and 2170, respectively) were assigned to the meshes. Three-point bending tests were conducted and a monotonically-increasing displacement of 50 mm/min. was applied downwards to the node located at the middle of the top edge of the virtual specimens. Figure 3c presents the sensitivity of the force-time curve to the volume fraction of aggregate particles. From Figure 3c, it is clear that both initial stiffness and strength of the mixture increased as the volume fraction of aggregates increased.

Figure 4 shows snapshots of the virtual beams at a simulation time of 0.54 seconds and illustrates the different levels of microstructural damage experienced by the beams. Figure 4 also shows contour plots of the stress tensor horizontal component s_{11}. The contours reveal a higher concentration of stresses at rigid aggregate particles and around the crack tips, as expected. Such type of detailed information of the stress (and strain) distributions within the microstructures of the virtual specimens can be very useful during the asphalt mixture design process because components with appropriate characteristics may be selected based on the microstructural analysis.

3.2 *Rate-dependent fracture characteristics*

The two cohesive fracture parameters that mostly influence the overall mixture responses are the CZ strength and fracture energy. Therefore, this section presents sensitivity analysis results for the parameters T_{max}^{ref} and G_c^{ref} that define the functions relating cohesive strength and fracture energy to the rate of displacement jumps (Eqs. (1) and (2)) experienced by each cohesive element. For this parametric analysis, the beam shown in Figure 2 was used and the simulations were conducted at a rate of 50 mm/min.

Figure 5 presents the sensitivity of the force-time curve to the two rate-dependent parameters investigated. From the analysis of Figure 5a, it is clear that as T_{max}^{ref} increased, the peak load also increased. This was expected because damage initiation is retarded when larger strength values are specified to the cohesive elements. On the other hand, the analysis of Figure 5b reveals that as G_c^{ref} increased, the fracture resistance of the mixture also improved, which was demonstrated by the larger area under the force-time curve. This analysis clearly demonstrates that the rate-dependent fracture model developed herein successfully identified the influence of component fracture properties to the overall mixture damage behavior.

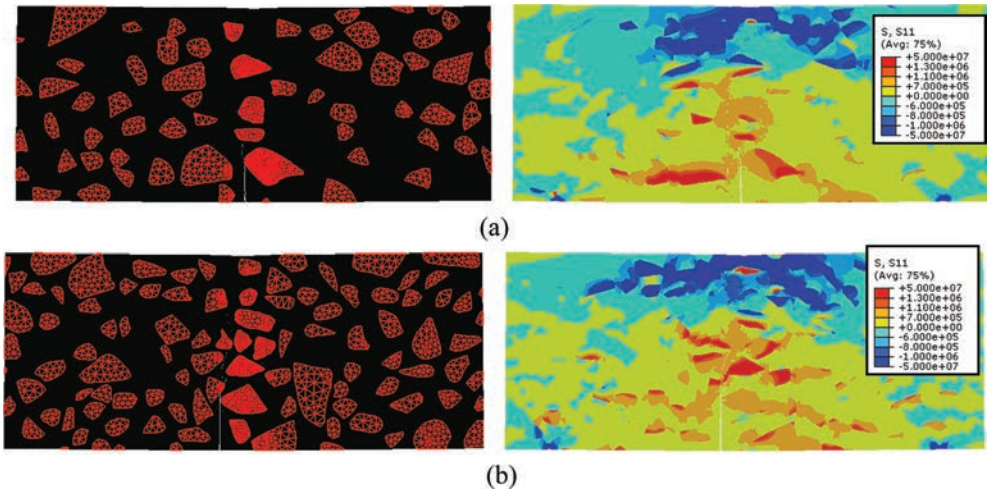

Figure 4. Microstructural damage and stress contour plots at for samples with (a) low and (b) high volume fraction of aggregates.

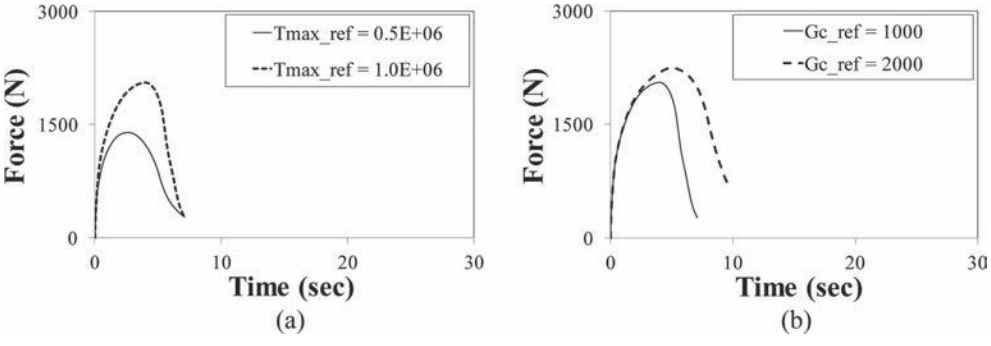

Figure 5. Parametric analysis for: (a) T_{max}^{ref} and (b) G_c^{ref}.

To further illustrate the effects of the rate-dependent fracture parameters on the fracture behavior of the mixtures, an additional analysis comparing progressive fracture damage levels experienced by the beam at different stages of the simulations was also conducted. Figure 6 shows comparisons for two different T_{max}^{ref}, *i.e.*, 0.5 MPa and 1.0 MPa. As expected, the analysis of Figures 6a and 6c reveals that the beam experienced premature damage initiation for a lower T_{max}^{ref} (0.5 MPa). Damage also propagated faster in the beam when a lower T_{max}^{ref} was assigned, as demonstrated in Figures 6b and 6d. Finally, Figure 7 shows comparisons for two different G_c^{ref}, 1000 J/m^2 and 2000 J/m^2. Damage initiated at similar simulation stages for both cases, as demonstrated in Figures 7a and 7c. However, as shown in Figures 7b and 7d, after the initiation of damage, crack propagation was much faster for the case with smaller G_c^{ref}, as less energy was required to fully separate the two faces of each CZ element in the mesh.

As previously mentioned, one interesting feature of the computational microstructure modeling approach is that it allows a more comprehensive examination of the microstructural, inelastic material behavior so that stresses and strains within the microstructure can be analyzed more realistically. To illustrate that capability, Figures 8b to 8e show progressive microstructural fracture and stress (s_{11}) contour plots at simulation times ranging between 4 and 14 seconds for the applied displacement rate of 25 mm/min. The corresponding force-time

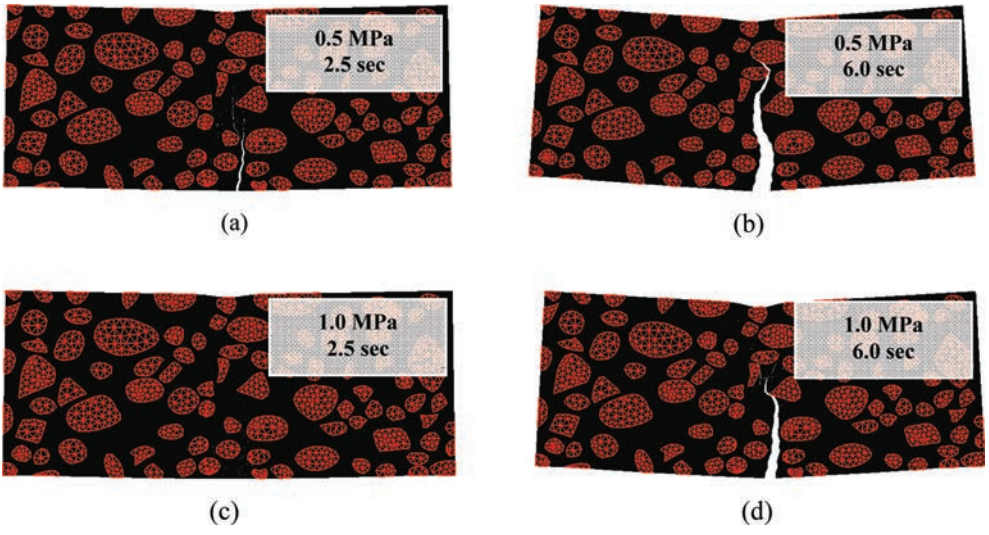

Figure 6. Progressive microstructural fracture at two simulation times, *i.e.*, 2.5 and 6.0 seconds, for two different T_{max}^{ref}: (a) and (b) 0.5 MPa; (c) and (d) 1.0 MPa.

Figure 7. Progressive microstructural fracture at two simulation times, *i.e.*, 2.5 and 6.0 seconds, for two different G_c^{ref}: (a) and (b) 1000 J/m^2; (c) and (d) 2000 J/m^2.

plot is shown in Figure 8a. The contour plots reveal that there is a higher concentration of stresses on the stiff aggregate particles. High stress levels were also observed around the tip of the crack. Stress levels were drastically reduced at the bottom of the beam after the formation and propagation of the macro-crack within the sample microstructure.

Another interesting observation can be made from the comparison between Figures 8c and 8d: in Figure 8c, two major cracks were initially formed, but only one has finally propagated, as shown in Figure 8d. Such behavior is typically observed in fracture tests conducted with real samples in the laboratory. Multiple cracks tend to coalesce from micro-cracks formed in the damaged sample, but the path that requires less energy to create new surfaces within the specimen microstructure is naturally chosen for the macrocrack propagation.

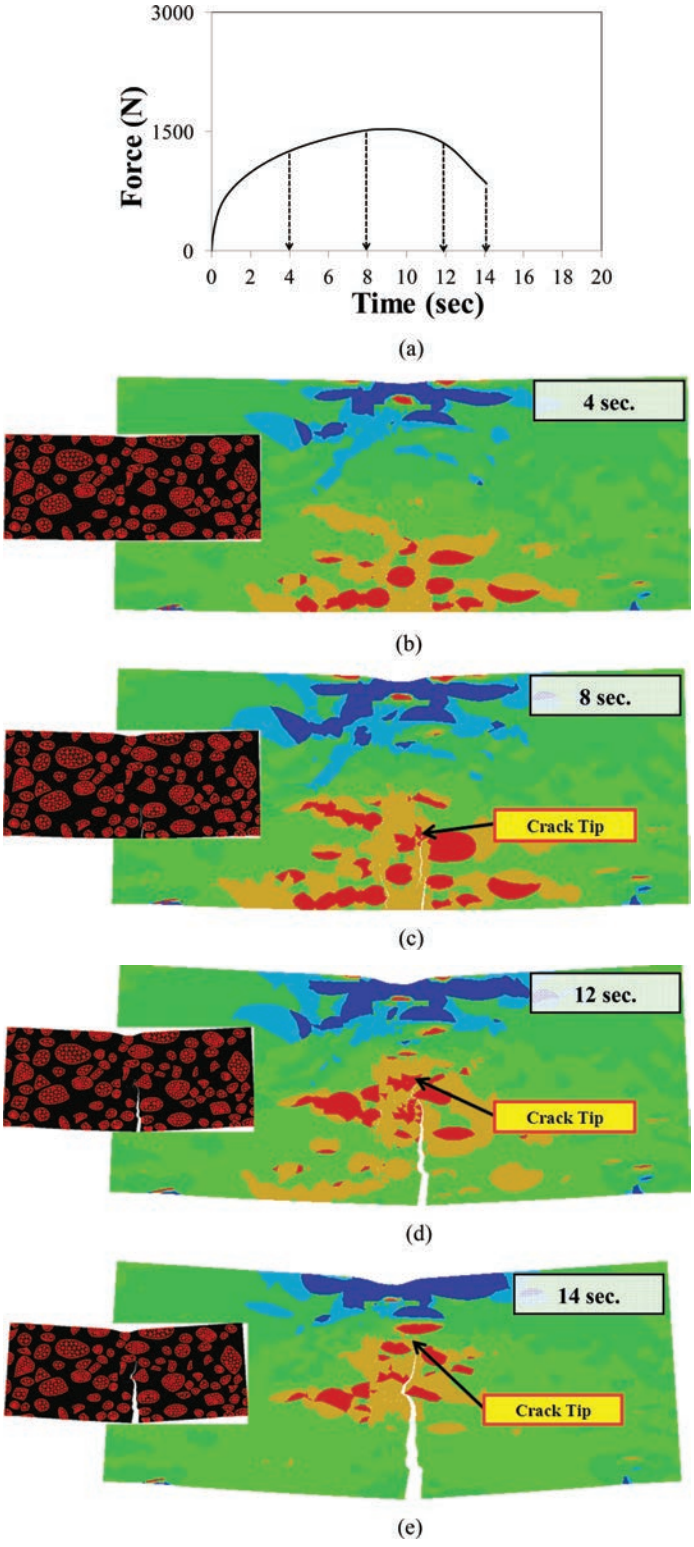

Figure 8. (a) Simulation results and progressive microstructural fracture and stress (s_{11}) contour plots at: (b) 4 sec.; (c) 8 sec.; (d) 12 sec.; and (e) 14 sec.

Such type of analysis can provide meaningful information that can be used during the mixture design phase and guide the process of material selection. Additionally, as demonstrated in this paper, carefully-developed computational microstructure models, such as the one presented herein, have a great potential to become efficient and comprehensive analysis tools that can be incorporated into the next generation of pavement design programs. The interesting features of the microstructural approach can also contribute to enhance the performance prediction capabilities of such design methodologies, which may result in significant savings on maintenance and rehabilitation of existing pavement structures.

4 CONCLUSIONS

Computational microstructure models have been regarded by the pavement mechanics community as a promising approach to model the mechanical behavior of asphalt mixtures. To demonstrate the potential of a well-designed microstructure model recently proposed by the authors of this study, numerical simulations were performed on virtual samples and several interesting results are presented in this paper. Based on the results and analysis, the following conclusions can be made:

- The computational microstructure modeling approach can directly account for the effects of diverse constituent properties on the overall mechanical behavior of asphalt mixtures;
- With the microstructural approach, detailed information about the stress and strain distributions within the mixture microstructure can be obtained from simulations and used for the selection of better engineered materials to compose the mixtures, as well as for further analysis of mixture performance;
- The microstructural methodology is also able to model the damage-dependent behavior of the heterogeneous mixtures in a realistic manner. As was exemplified in this study, an analysis of microstructural damage evolution demonstrated that the model could successfully capture the formation of multiple cracks within the microstructure and the choice for one path for the propagation of a macrocrack until complete failure of the virtual sample.

Viscoelastic behavior of mastic phase of Asphalt Concrete

Mohammad Hossain
Department of Civil Engineering and Construction, Bradley University, Peoria, IL, USA

Hasan Faisal & Rafiqul Tarefder
Department of Civil Engineering, The University of New Mexico, Albuquerque, NM, USA

ABSTRACT: Asphalt Concrete (AC) is a well-known viscoelastic material. In AC, asphalt binder is mainly responsible for the viscoelastic behavior, as it consists of coarse aggregate, asphalt binder and fines. The asphalt binder creates an asphalt film around the coarse aggregate and fines. Indeed, fines are trapped inside the binder film, which is also known as mastic. As mastic governs most of the mechanical properties of AC, a nano mechanical characterization of mastic of AC is done using nanoindentation tests. Nanoindentation tests created the opportunity to indent on the thin sample as integral part of AC system. Fifty nanoindentation tests were conducted on the mastic phase of AC. In, nanoindentation tests an extended creep hold is used to obtain the creep data of mastic phase. A Burgers viscoelastic model is developed using the laboratory nanoindentation data. In addition, the viscoelastic model is used in the Finite Element Model (FEM) framework ABAQUS to simulate nanoindentation test. The force-depth curve acquired from FEM framework showed good agreement with laboratory test data.

Keywords: Viscoelastic, nanoindentation, mastic, creep, Finite Element Method

1 INTRODUCTION

Several laboratory testing protocols are available to evaluate and characterize Asphalt Concrete (AC) mix. Laboratory tests are performed on both compacted and loose AC mix. In recent years, many researchers are conducting tests by nanoindentation on asphalt mixture components such as asphalt binder and aggregates to understand materials behavior at micron scale [1–3]. In a nanoindentation test, an indenter is used to indent a sample surface and the movement of the indenter is measured with an increasing load or deformation [4]. It is a very powerful technique to measure hardness and Young's modulus of a material. Very few studies have been done on the AC mix such as on mastic and matrix materials using nanoindentation techniques [5]. Though extensive research have been done in materials science and composite materials using this novel approach [6–9]. In addition, biomedical engineers used this test to measure mechanical properties of organ and components of human body such as strength of bones and muscles [10,11]. In this study, nanoindentation test is done on mastic phase of AC.

Mastic materials or asphalt mastic is defined as mixture of asphalt binder with fines passing through # 200 sieve (0.075 mm) [12,13]. On the other hand, matrix materials are mixture of asphalt binder with fine aggregate passing through a # 4 sieve and retained on a # 200 sieve. When aggregates are heated and mixed with hot asphalt binder to produce AC, coarse aggregates are coated with mastic materials and surrounded by matrix materials. It is challenging to do nanoindentation tests on the asphalt binder since the binder attach at the tip of indenter at the ambient temperature. Despite this challenge, successful indentation tests have been performed on the aged asphalt binder [14,15]. This study is done to

understand the viscoelastic behavior of mastic materials at the ambient temperature using nanoindentation tests.

2 OBJECTIVES

The objectives of this study are:

1. Perform nanoindentation tests on mastic materials at the ambient temperature and understand the viscoelastic behavior.
2. Develop a viscoelastic mechanical model from the nanoindentation creep data.
3. Validate the viscoelastic mechanical model using Finite Element Method (FEM) modeling.

3 METHODOLOGY

Two fulfill the objectives; AC samples are made by mixing fine aggregates and fines with asphalt binder. Laboratory nanoindentation tests are performed only on the mastic phase of AC. To understand the viscoelastic behavior, a creep indentation is applied following loading and before unloading an indenter from the mastic materials. A viscoelastic mechanical model is developed from the laboratory creep indentation data. Finally, a FEM model is developed in ABAQUS and the viscoelastic mechanical model is used to define the material properties of mastic and the force-depth relationship is compared and validated with the laboratory indentation tests. The limitations of this study are: mastic materials are mix of fines with binder and under nanoindentation indenter hit either fines or binder, but in this study, it is assuming that despite the indenter hit either component, it is the mastic phase of AC; another limitation is to select only one mechanical viscoelastic model and not several models are compared; finally, a two dimensional axisymmetric FEM model is developed where as a three dimensional model would provide better results.

4 BACKGROUND

Both load control and displacement control indentation tests can be performed on the materials. Figure 1 shows schematics of conventional nanoindentation test. Figure 1(a) shows the depths measure during loading and unloading of the indenter and Figure 1(b) shows the typical load-displacement curve. A sitting load is typically applied initially to facilitate contact between the tip and sample surface. Next, the load is increased gradually from point A to B. The tip is unloaded at the maximum load point B. The unloading path is assumed to be elastic for most of the elastoplastic material. The unloading curve does not come back to point A due to plastic deformation in the elastoplastic materials. The slope of the unloading curve at point B is usually equal to the slope of the loading curve at point A. The surface profile as shown in Figure 1(a) is a function of the penetration depth during loading and unloading. It should be noted that mastic materials is a visco-elastic-plastic material. To overcome the viscous effect into the unloading part, a creep load is applied at the maximum load after point B.

As it mentioned earlier, nanoindentation is mostly applied to measure Young's modulus and Hardness of materials. The Oliver-Pharr method is the most widely used method for determining stiffness and hardness values from load-displacement data. The following Eqs. (1, 2) are used to measure the reduced elastic modulus and hardness respectively.

$$\frac{1}{E^*} = \frac{1-\nu^2}{E} + \frac{1-\nu_i^2}{E_i} \tag{1}$$

where E is Young's modulus of the material, ν is Poisson's ratio of the material, E_i is Young's modulus of the indenter and ν_i is Poisson's ration of the indenter, E^* is the reduced modulus.

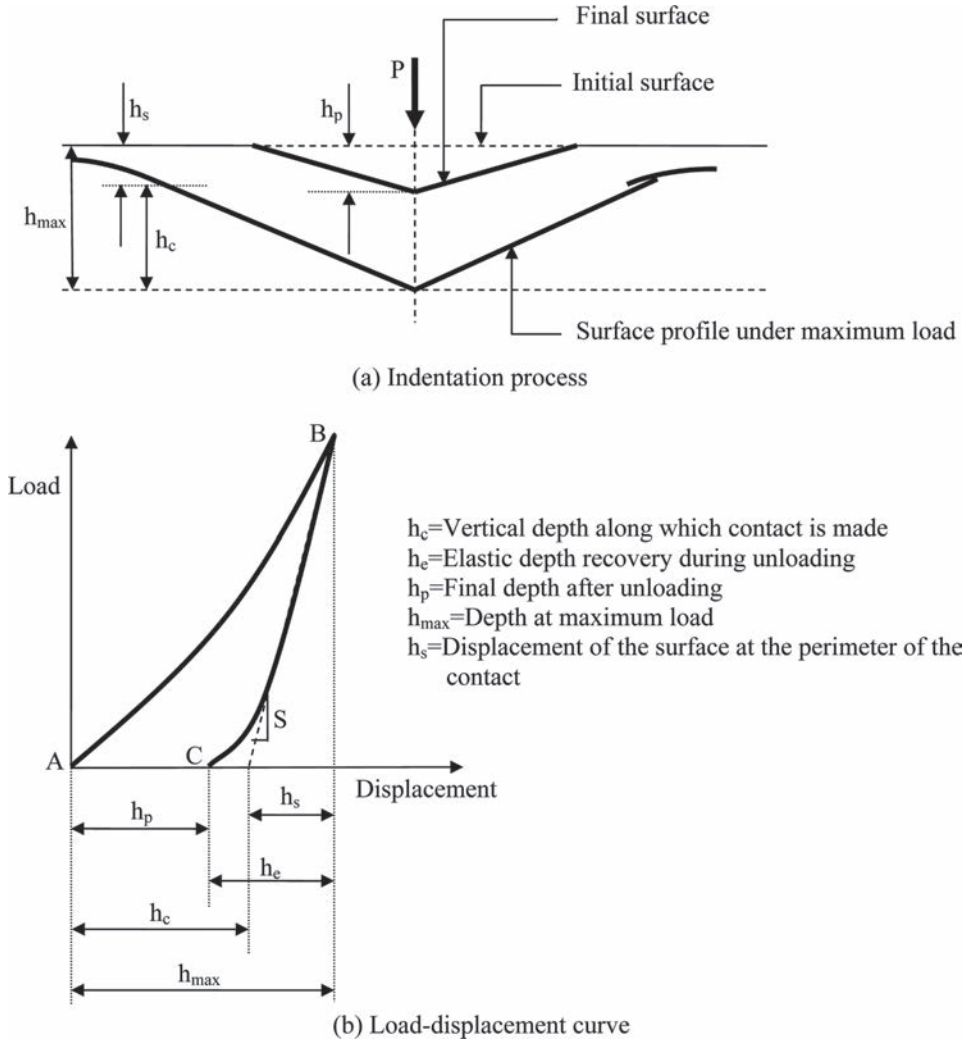

Figure 1. Schematic diagrams of indentation test.

$$H = \frac{P_{max}}{A} \tag{2}$$

where P_{max} is peak load and A is projected area of contact at peak load.

Young's modulus and hardness of mastic materials are already measured using nanoindentation [5]. Nanoindentation is performed on AC and claimed that Young's modulus of mastic materials are less than 3.0 GPa and for aggregate this value is greater than 12.0 GPa. They focused only on the loading and unloading part of the test data. In this study the test is done with loading and then creep and unloading and emphasis are given mostly on the creep indentation part to develop the viscoelastic mechanical model and later on loading, creep and unloading relationship is validated by the FEM modeling.

Nanoindentation on mastic materials has some challenges. The challenge arises due to use of fine aggregates in the AC mix. Fine aggregates are mixed to facilitate the compaction of AC to make thin samples for nanoindentation tests by cutting AC samples using laboratory saw. Schematics of nanoindentation tests are shown in Figure 2. Figure 2(a) shows the AC sample with fines, binder, micro voids, and fine aggregates; during indentation, indenter

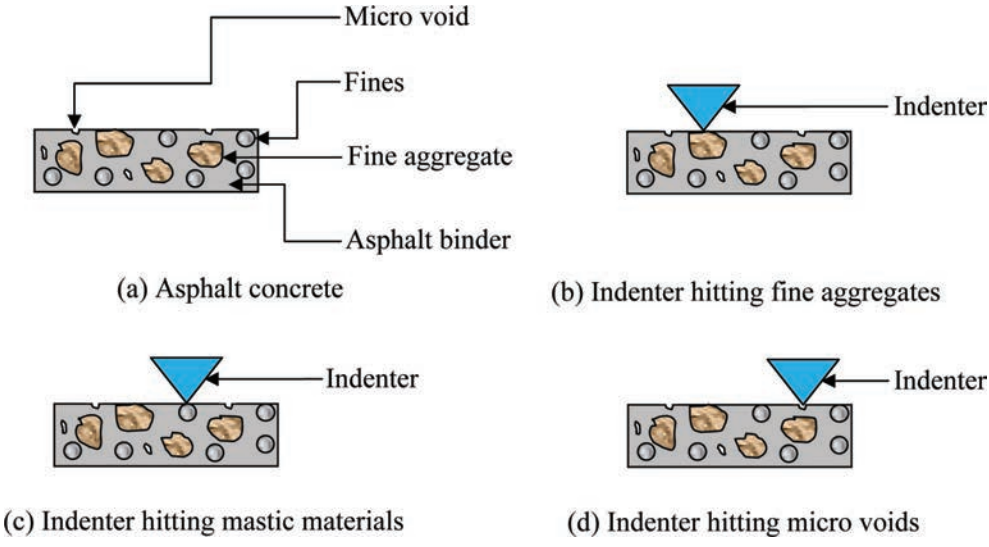

Figure 2. Schematic diagrams of nanoindentation on mastic materials.

might hit on the fine aggregates, which is shown in Figure 2(b); Figure 2(c) shows indentation on mastic materials and Figure 2(d) shows another limitation of this test that is indenter might hit on micro void. In this study, nanoindentation tests are done on such location that is free from fine aggregates and the test data is carefully analyzed to remove data that shows indentation on micro voids.

5 LABORATORY TEST

5.1 *Sample preparation*

Superpave mixes used with PG 70-22 and fine aggregates were collected from plant. Mixture was compacted into 150 mm (6 in) diameter cylinders by a Superpave Gyratory compactor using 600 KPa (87.02 psi) vertical pressure. The sample was prepared at a target low air voids of 4% to reduce voids in the sample. Using a fine laboratory saw, 6 mm (0.25 in) thick square shape of size 25 mm × 25 mm (1 in × 1 in) slices were prepared for the test. The slice that has minimum fine aggregates on the top of the sample was selected for the test. Many slices are discarded due to large voids, broken aggregates and parts and fracture face due to cutting by saw. Smooth surface of the cube is very important for nanoindentation experiment. Because the contact area is measured indirectly form the depth of penetration, a rough surface may cause errors in the determination of the area of contact between the indenter and the specimen. Therefore, the square samples were polished by a grinding machine rotating a angular speed of 150 rpm with sequence of SiC paper of decreasing abrasiveness (100, 200, 400, 800, 1000, 1200, and 1400 grit). Only one surface was polished. Finally the specimens were washed in a water bath to remove any remaining dusts. Figure 3 shows a sample on stud and substrate. Sample was fixed on substrate and stud with glue. The red box is shown to locate the location of indentation test, which is free from fine aggregates. It should be noted that the indentation on micro voids cannot be avoided during the test.

5.2 *Nanoindentation tests*

The nanoindenter device at the UNM nano test laboratory was used for indentation. More details on the nanoindentation testing equipment are given in this reference [14]. For this study, Berkovich indenter tip was used since some previous study shows than spherical

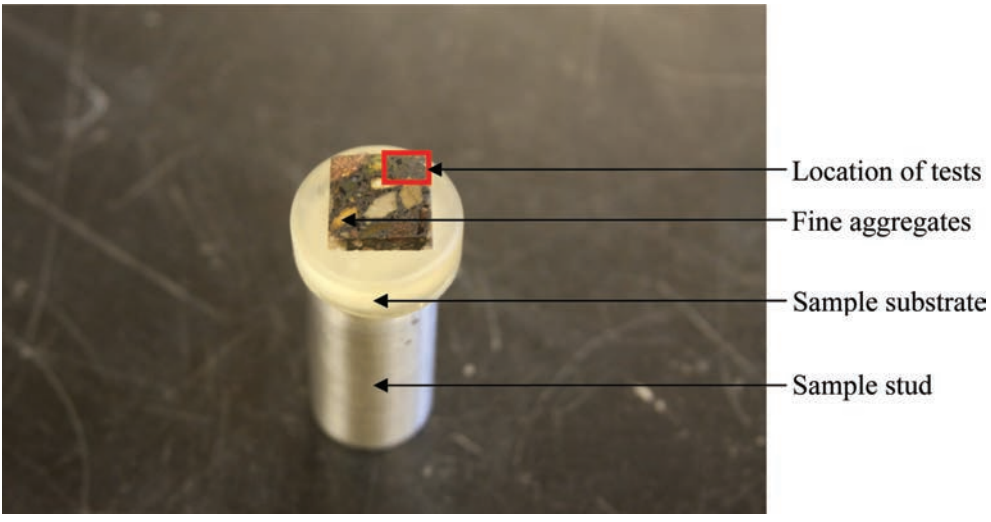

Figure 3. Laboratory sample for nanoindentation tests.

indenter glued with the unaged binder [5]. As a result, system compliance can be lost during indentation on asphalt. A Berkovich tip consists of three-sided pyramidal Berkovich tip with a semi angle of 65.27°. It has sharp and well-defined (pyramid defined by face angle 65.3°) tip geometry. In this study, a maximum load of 0.51 mN was applied with a loading and an unloading rate of 0.02 mN/sec. A sitting load of 0.01 mN was used for all the indentations. A creep time of 200 seconds was applied after reaching the maximum load. This creep time is also known as dwell time [16,17]. The viscous effects of the test results are reduced by using a fast unloading rate and applying an extended dwell time. Tarefder and Faisal have shown that a dwell time of 100–200 seconds can minimize the viscous effect of asphalt [14]. Mastic phase of the AC sample was indented at 50 locations to deal with the variability of nanoindentation results, considering the limitations as mentioned earlier, and due to material heterogeneity in the asphalt mastic.

6 RESULTS AND DISCUSSIONS ON LABORATORY TESTS

6.1 *Force-depth relationship*

Figure 4 shows the force-depth curves obtained from the nanoindentation tests on mastic materials. Forth indentations are plotted from the fifty indentation test results. Ten indentations are discarded due to fact that the indenter might hit on the micro voids. The force-depth curves are discontinuous or showing negative indentation depth for those discarded tests. It is observed that the force-depth curves widely ranges with indentation depth from 52.96 nm to 6392.30 nm for same load of 0.51 mN. This wide variation is due to the heterogeneous behavior of mastic materials. Also, as mentioned earlier, indenter might hit either fines or the asphalt binder. Though, all the indentations showed plastic depth after unloading. In addition, no negative slope is observed at the unloading curve, this means 200 sec holding time is appropriate to overcome the viscous effects of mastic materials. Due to this wide range of deformation, it would be practical to get an average value of the indentation depths.

6.2 *Creep behavior*

Figure 5 shows the creep behavior of mastic materials. The hold time was 200 sec for all indentations. Fourth creep indentations are plotted in Figure 5(a) and the average of the

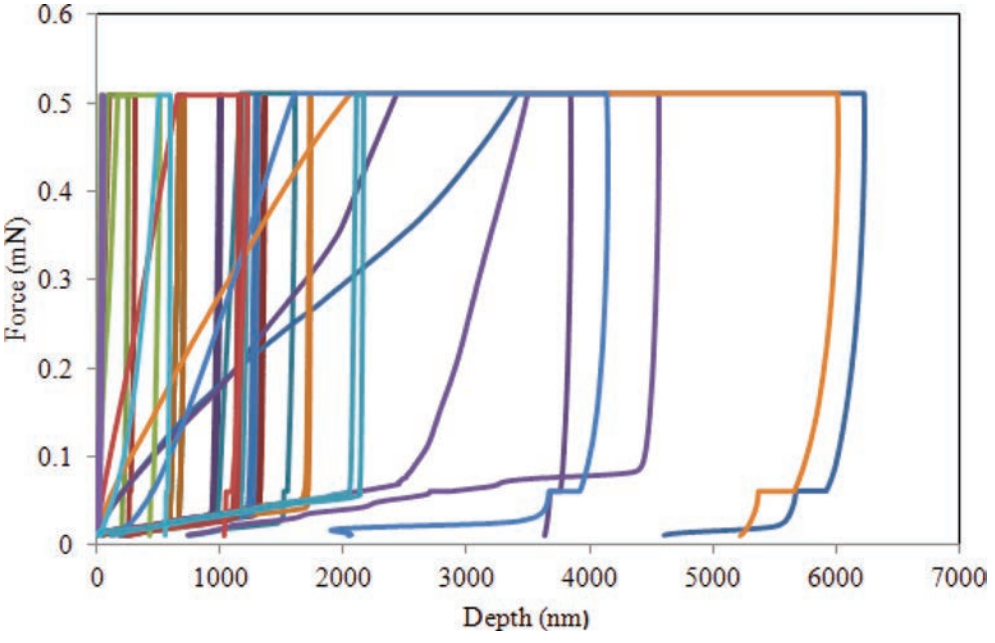

Figure 4. Force-depth relationships derived from nanoindentation test.

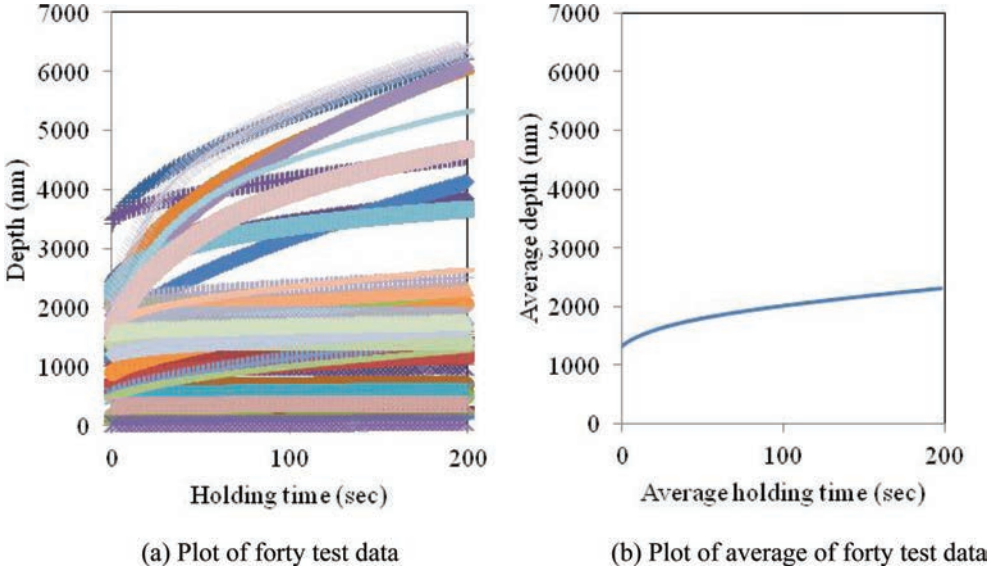

Figure 5. Creep behaviors of mastic materials under nanoindentation tests.

forty indentations are plotted in Figure 5(b). Creep data shows both linear and nonlinear indentation depth that increase with time. Again, the linear depth increase might be due to the fact that, indenter hits on the fines and the nonlinear depth increase caused by when indenter hits on the binder. Fines are elastic in nature, so indentation shows linear increasing lines; on the other hand, asphalt binder is viscoelastic and shows nonlinear increasing lines. Since fines mixed with binder and while indenter hits fine and pressed downward, underneath

the fines there are both binder and more fines and when indenter hits binder, underneath the binder there are fines or binder. So for mastic materials we have to consider combine effects of binder and fines. For this reason, to keep both linear and nonlinear creep behavior, the average depth is plotted in Figure 5(b). This average plot is further analyzed to develop viscoelastic mechanical model.

6.3 *Viscoelastic mechanical model*

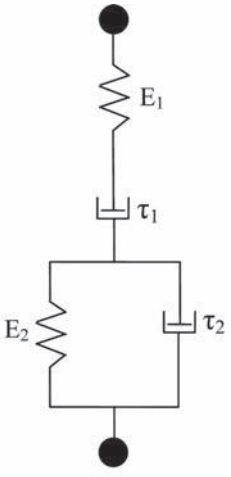
Viscoelastic model can be expressed using several mechanical modes such as Maxwell, Kelvin, Burgers model, and generalized model. Figure 6 shows representations of Burgers model, which is a combination of Maxwell and Kelvin models. Burgers model best represents the viscoelastic materials [18]. The mechanical Burgers model for the nanoindentation tests can be represented by the following Eq. (3).

$$h^2(t) = \frac{\pi}{2} P_0 \cot\alpha \left[\frac{1}{E_1} + \frac{1}{E_2}\left(1 - e^{-\frac{t}{\tau_2}}\right) + \frac{t}{E_1 \tau_1} \right] \tag{3}$$

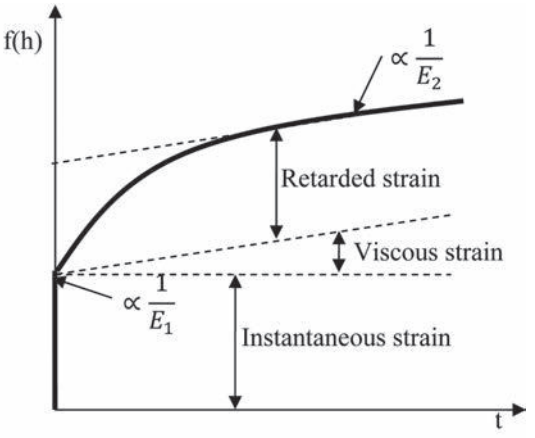
where h is the displacement due to applied load on a material, P_0 is the indentation load, α includes half angle of Berkovich indenter, E is the elastic modulus, t is time, and τ is retardation time. The total strain of the materials has three components, an instantaneous elastic strain, a viscous strain, and a retarded strain as shown in Figure 6(b). For the known value of h, P_0 and t, from the indentation test, the values of E_1, E_2, τ_1, and τ_2 can be obtained from the simplified Eq. (4).

$$h^2(t) = A_1 + A_2\left(1 - e^{-\frac{t}{\tau_2}}\right) + A_3 t \tag{4}$$

where $A_1 = \frac{\pi}{2} P_0 \cot\alpha \frac{1}{E_1}$, $A_2 = \frac{\pi}{2} P_0 \cot\alpha \frac{1}{E_2}$ and $A_3 = \frac{\pi}{2} P_0 \cot\alpha \frac{1}{E_1 \tau_1}$.



(a) Four elements Burgers spring and dashpot representation of viscoelastic material



(b) Displacement response for steep increase in load for Burgers model

Figure 6. Mechanical model of viscoelastic materials.

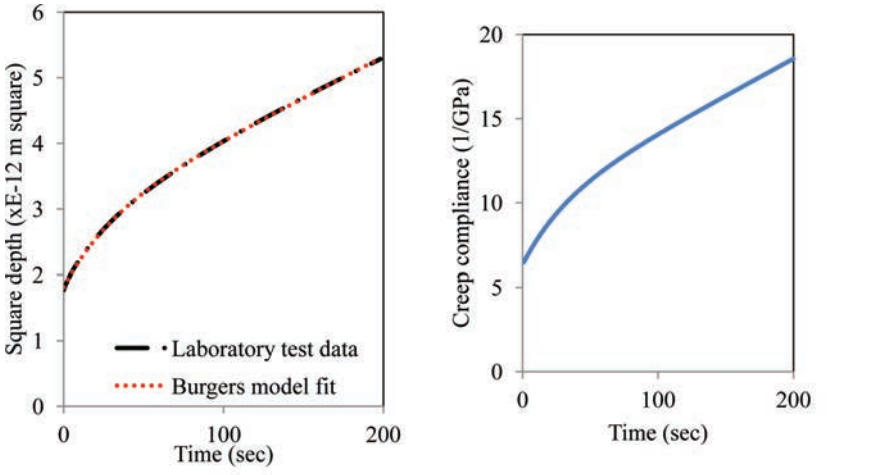


Figure 7. Mechanical model of mastic materials.

In this study, Eq. (4) is fitted with the Figure 5(b) to find A_1, A_2, and A_3. A nonlinear curve fitting algorithm is used in MATLAB to optimize those parameters.

Figure 7(a) shows the optimized Burgers model with the laboratory test results. The optimized values are: E_1 = 0.1580 GPa, E_2 = 0.2860 GPa, τ_1 = 144.85 sec, and τ_2 = 30.86 sec. Figure 7(a) shows very good fitting with laboratory average test data with R-square value 0.999. Using the Burgers model parameters, Creep compliance, $J(t)$ of the mastic materials is determined from the following Eq. (5):

$$J(t) = \frac{1}{E_1} + \frac{1}{E_2}\left(1 - e^{-\frac{t}{\tau_2}}\right) + \frac{t}{E_1 \tau_1} \tag{5}$$

The Creep compliance plot is shown in Figure 7(b). This is also known as contact creep compliance.

7 FEM MODEL DEVELOPMENT

Two dimensional axisymmetric FEM model is developed with ABAQUS/CAE 6.9-EF. The FEM model is shown in Figure 8. The rectangular block is 5.0 mm wide and 5.1 mm depth with 0.1 mm mastic materials on top of the 5.0 mm thick fine aggregate. The Burgers model is converted into Proney series parameters using the equations mentioned in the literatures [19]. The Poisson's ratio of mastic materials is considered as 0.40. The fine aggregate is considered as elastic materials with Young's modulus 48,264 MPa and Poisson's ratio 0.20 [20]. The indenter is considered as analytic rigid, the bottom of the model is hinged connected, the left side of the model is roller, and the right side is free. The elements are eight noded quadratic plane stress elements. The aspect ratio of the smallest element, under the indenter, is 1.63 and the aspect ratio of the largest element, at the bottom-corner of the model is 1.0. The loading is done similar to the laboratory tests, 25 sec loading, 200 sec hold time, 25 sec unloading. A 0.51 mN concentrated load is applied at the top of indenter tip.

One of the challenges in nanoindentation FEM simulation is to set contact between the indenter and the top of elements. Careful interaction modeling is performed to overcome this challenge. Interaction modeling required assigning master and slave surface and in this model, the indenter is assigned as master surface and top of mastic materials are assigned as slave surface.

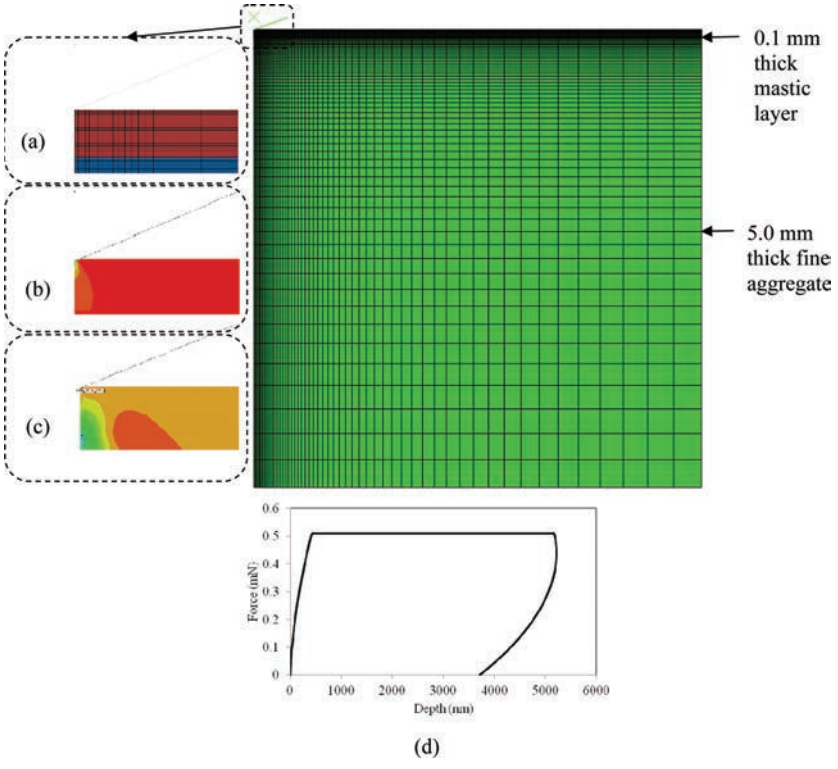

Figure 8. FEM model with (a) zoomed in section on mastic materials, (b) vertical strain distribution in mastic materials, (c) vertical stress distribution in mastic materials (d) force-depth relationship of mastic materials.

Only tangential behavior between master and slave surface is assigned. Contact control and contact initialization is also performed in the FEM simulation. Automatic over closure tolerance is assigned and the initial over closure is treated as interface fits. It should be noted that, deformation control nanoindentation automatically considered all the above mentioned contact properties.

Figure 8(a) shows a zoomed in view of the mastic materials with the indenter, Figure 8(b) shows the vertical strain (*E22*) distribution in mastic materials, and Figure 8(c) shows the vertical stress (*S22*) distribution in mastic materials. The stress and strain distributions are showed only for illustration purpose. Figure 8(d) shows the force-depth relationship of mastic materials measured at the element just under the indenter. The maximum depth measured is 5216.03 nm, which is measured at the end of holding time and before unloading. The maximum depth measured in the forty laboratory indentations is 6392.30 nm and that is 22.55% higher than the simulation results. So the maximum depth measured in the FEM simulation is in between the lowest and highest indentation measured in the laboratory. This validates the Burgers model developed in the previous sections. It should be noted that, Bercovich indenter is conical shape and the FEM model is axi-symmetric and the indenter is assumed as axi-symmetric as well and this assumption might cause some errors in the simulation results. In addition, only one Burgers model is assumed but in reality the mechanical model is a series of Burgers models or a generalized model might gives better results.

8 CONCLUSIONS

Nanoindentation tests are done to understand the contact creep behaviors of mastic materials and with the creep indentation data a Burgers model is developed. In addition, A FEM

model is simulated to validate the Burgers model. It has been observed that, the Force-depth curve acquired from FEM framework showed good agreement with laboratory indentation data. Nanoindentation is a novel approach to test materials and researchers are conducting these tests protocols for decades but this is new to pavement engineering. Though a limited study is done and more studies are required in this emerging field.

Uniaxial fatigue testing of diverse asphalt concrete mixtures

Waleed A. Zeiada, B. Shane Underwood & Kamil E. Kaloush
Department of Civil, Environmental and Sustainable Engineering, Arizona State University, Tempe, AZ, USA

ABSTRACT: The uniaxial fatigue test is a useful method for developing constitutive models to describe the fatigue behaviour of asphalt concrete mixture owing to the uniform states of stress across the specimen section. As part of the NCHRP 944-A project, a proposed uniaxial fatigue test protocol and software were developed to assess fatigue damage and healing. In this study, the protocol was used to evaluate a wide range of conventional and modified asphalt mixtures sampled from national and international projects as well as laboratory prepared mixtures with different volumetric properties. The study mixtures included those modified with rubber, polymer, fiber, warm mix additives, and combined rubber and warm mix. The fatigue analysis was performed using the simplified viscoelastic continuum damage (S-VECD) approach where the damage characteristic (C-S) curves were established for each mixture, and then used to obtain the fatigue relationships through simulated predictions. Overall, the proposed uniaxial fatigue test protocol was successfully used with respect to the S-VECD formulation to capture fatigue behaviour of all tested mixtures.

Keywords: Uniaxial, asphalt mixture, fatigue, viscoelastic, continuum damage

1 INTRODUCTION

Fatigue cracking, associated with repetitive traffic loading over time, is considered to be one of the most significant distress modes in flexible pavements besides thermal cracking and rutting. Fatigue cracking is a progressive distress and can be divided into three different stages. An early stage of fatigue cracking consists of intermittent longitudinal wheel path cracks. An intermediate stage of fatigue cracking called alligator cracking because the cracking pattern resembles an alligator's skin. A final stage of fatigue cracking is disintegration when potholes form.

The fatigue life of an asphalt pavement depends directly on the properties of the materials in the mix plus the complicated microstructure of asphalt concrete mixture, which is related to the aggregate size and gradation [1,2], binder grade [3], air voids and binder content [4,5], temperature [6,7], rest period [8,9,10,11], aging [12,13,14], and additives [15,16,17,18,19,20]. As a result, the fatigue properties of asphalt mixtures are very complicated and sometimes difficult to predict.

There are two main approaches that can be utilized to characterize the fatigue behavior of asphalt concrete mixtures: phenomenological and mechanistic. Mechanistic approach is inherently more complex than the Phenomenological one but it is more widely accepted because it uses material properties based on stress-strain relationships [21]. The mechanistic approach can be implemented through three main methods; dissipated energy [22,23,24], fracture mechanics [25,26,27], and continuum damage mechanics [28,29,30,31,32,33,34].

Different test methodologies have been developed over the past few decades for measuring the fatigue behavior of asphalt concrete mixtures such as the beam fatigue test [35,36], cantilever rotating beam test [37], trapezoidal cantilever beam test [38], supported flexure test [39], uniaxial direct-tension test [40,41,42,43], uniaxial tension-compression test [40,44,45], indirect diametrical test [46,47], triaxial test [48,49], and wheel track test [38].

As part of the NCHRP 9-44 A project, a uniaxial fatigue test protocol was developed to evaluate the fatigue damage and healing of asphalt concrete mixtures. The development test protocol includes several studies to identify appropriate sample fabrication procedures, gluing materials and procedures, alignment, machine compliance impacts, strain wave shape, and strain-controlled method [50]. The main objective of this study was to evaluate the fatigue behavior of diverse conventional and modified asphalt concrete mixtures tested by a developed uniaxial fatigue test method using the simplified-viscoelastic continuum damage (S-VECD) analysis. This analysis enables the prediction of the fatigue life relationships under both stain and stress controlled mode of loading with fewer experiments.

2 MIXTURES AND SPECIMENS PREPARATIONS

2.1 *Description of projects and mixtures*

In this study, the fatigue behavior of a diverse set of asphalt concrete mixtures from four main projects was evaluated by performing both dynamic modulus $|E^*|$ test and uniaxial fatigue tests. All the tested specimens were compacted in the laboratory using the Superpave gyratory compactor. Project 1 included the testing of four 19-mm conventional dense graded mixtures at combinations of two levels of air voids (4.5 and 9.5%) and two levels asphalt content (4.2 and 5.2%). The main objective of the first project was to investigate the effect of changing the volumetric properties on the fatigue behavior of asphalt concrete mixtures. Project two included the testing of three 19-mm gap graded Asphalt concrete mixtures. The first mixture was a control while the second and the third were polymer-modified and rubber-modified asphalt concrete mixtures respectively. The main objective of this project was to study the effect of polymer and rubber additives on the fatigue performance of asphalt concrete mixtures. Project three included the testing of two 9.5-mm dense graded mixtures. The first mixture was a standard dense graded mixture while the second mixture was the same mixture, but modified with 19-mm long fibers. The objective of project three was to evaluate the effect of adding fiber on the fatigue performance of asphalt mixtures. Project four included the testing of two asphalt mixtures. The first mixture was a regular 9.5-mm dense graded Warm Mix Asphalt (WMA) mixture using Evotherm additive while the second mixture was a newly used 12.5-mm gap graded rubber-modified WMA mixture. The main objective of this project was to compare the fatigue performance of both mixtures in order to investigate the replacement of the first mixture with the second newly used mixture. The asphalt mixtures of project one were mixed and short term aged in the laboratory while asphalt mixtures for the remaining projects were sampled from actual field projects and then compacted in the laboratory. Table 1 presents the aggregate gradation while Table 2 shows the design volumetric properties of the different mixtures.

Two different specimen geometries were manufactured for each test. For the $|E^*|$ test, gyratory plugs were compacted into 150 mm diameter and 170 mm tall specimens. Then, one 100 mm diameter sample was cored from each gyratory plug. The sample ends were sawn to arrive at typical test specimens of 150 mm in height. For uniaxial tension-compression fatigue test, the compaction height was increased to 180 mm and the final specimen dimensions were 150 mm height and 75 mm in diameter. The main reason to increase the compaction height was to allow for larger end cuts to produce a more homogeneous air void distribution which increases the chances to have a middle failure in the uniaxial fatigue test.

3 TEST METHODS

3.1 *Dynamic modulus test*

The $|E^*|$ tests, per AASHTO T342 were performed in the laboratory at five temperatures –10, 4.4, 21.1, 37.8, 54.4 °C and six load frequencies: 25, 10, 5, 1, 0.5 and 0.1 Hz. The stress levels were varied with the frequency to keep the specimen response within a linear viscoelastic limit

(recoverable microstrain below 150 microstrain). The test parameter values; dynamic modulus and phase angle, were measured at different temperatures and frequencies. The average dynamic modulus and phase angle values were summarized based on three replicates for each mixture. Figure 1 shows a typical instrumented test specimens and the applied wave shape.

3.2 *Uniaxial tension-compression test*

The first step prior to running the test included gluing end plates to the specimen using the jig shown in Figure 2. The applied glue was Devcon plastic steel 5 minutes epoxy putty. The test specimen was then instrumented with three LVDTs to monitor material response. The uniaxial tension-compression fatigue test was conducted to evaluate the fatigue damage of the

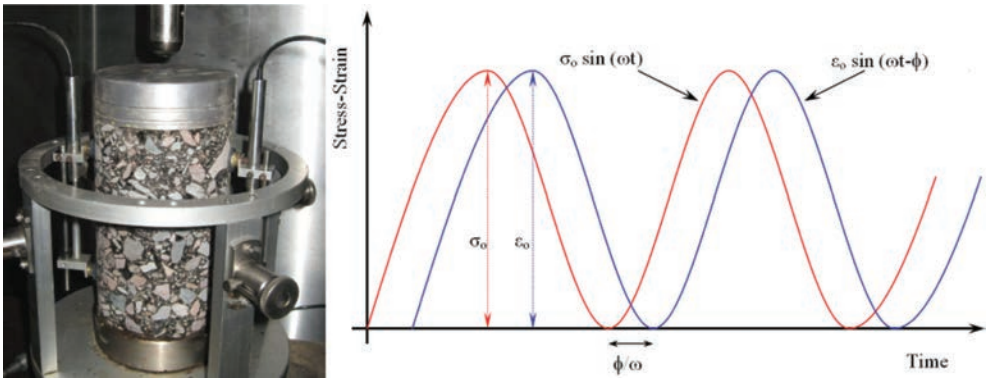

Figure 1. |*E**| Test setup and applied wave shape.

Figure 2. Specimen gluing jig and test setup with failed specimen.

tested mixtures using the viscoelastic and continuum damage model. A servo hydraulic testing machine was used to load the specimens under an on-specimen strain-control mode of loading (Fig. 2). A sinusoidal strain (continuous wave) was applied. The test software was capable of achieving and maintaining the target on-specimen strain based on the outputs from the three LVDTs by dynamically changing the actuator strain level to solve the machine compliance issue. New software was developed for Arizona State University by IPC (Industrial Process Control) company and is designated as UST032-v1.01b S-VECD fatigue test [50]. The uniaxial tension-compression fatigue tests were conducted using two or more specimens for each mixture at 21.1 °C. At each loading cycle, the software calculated the dynamic modulus and the phase angle plus the stress and the strain values from the actuator and the three LVDTs. The uniaxial tension-compression fatigue test was run until a sudden decrease in phase angle is reached as possible.

4 TEST RESULTS

4.1 *Dynamic modulus test results*

The |*E**| master curves were constructed for the tested mixtures from the four projects as shown in Figure 3. It can be observed from Figure 3(a) that the |*E**| values were more significantly

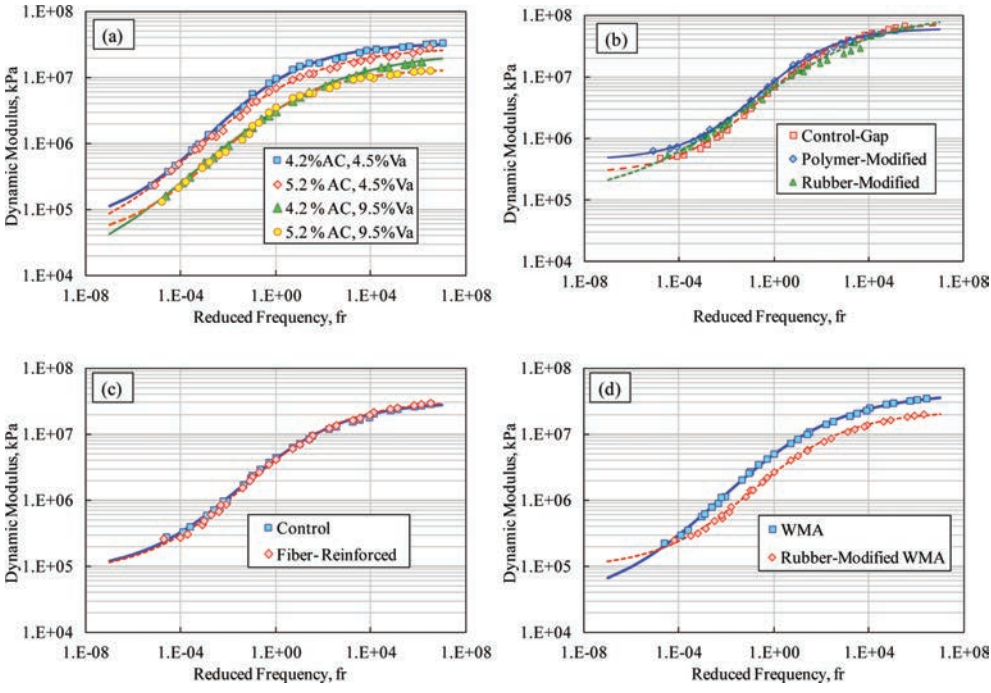

Figure 3. Dynamic modulus master curves of tested mixtures (a) Project 2; (b) Project 2; (c) Project 3; and (d) Project 4.

affected by varying the air voids from 4.5 to 9.5% than by varying the asphalt content from 4.2 to 5.2%. Figure 3(b) shows that at high test temperatures, the polymer-modified mixture expressed the highest stiffness followed by the reference and rubber-modified mixtures. In comparison, at low temperatures, the rubber-modified mixture had the highest stiffness followed by reference and polymer-modified. The rubber-modified mixture exhibited the lowest stiffness compared to the other two mixtures at 21 °C which is the test temperature used for the uniaxial tension-compression test. Figure 3(c) indicates that for the particular mixtures studied, the addition of fiber had almost no effect on the $|E^*|$ values. It can be observed from Figure 3(d) that at lower and intermediate temperatures the rubber-modified WMA mixture exhibits a lower $|E^*|$ values compared to the WMA mixture. However, at high temperatures, the $|E^*|$ values of both mixtures are closer. This unique behavior of rubber-modified mixtures would indicate an enhancement of their performance with respect to thermal and fatigue cracking at lower and intermediate temperatures with a sensible rutting resistance at high temperatures.

4.2 *Uniaxial fatigue test results*

Table 3 includes a summary of the uniaxial tension-compression fatigue tests. It is observed from this table that tensile strain levels were varied within the same project where it was expected that the tested mixture would give totally different fatigue behavior. That judgment was typically based on the relative difference in the dynamic modulus master curves. For only project three, both control and fiber-reinforced mixtures were tested on the same strain level as both exhibit similar dynamic modulus values. This issue does not affect the ability to make comparisons between mixtures as measured data can be interpolated and/or slightly extrapolated to the same conditions. The fingerprint data confirmed the findings from the dynamic modulus tests, which can be seen by observing the $|E^*|_{FP}$ column in Table 3. By comparing results of tests conducted at close strain levels, it can be observed

[a]Test did not show reduction in phase angle and test was stopped.
[b]450 με was stopped at approximately 130,000 cycles and then strain levels were increased repeatidly until failure.

that the fatigue response asphalt concrete mixtures in project one was not strongly affected by air void content (at a fixed strain level), but did exhibit observable asphalt content effects. In project two, the polymer-modified and rubber modified mixtures showed comparable fatigue performance and were better compared to the control mixture. The results of project three showed the fiber-reinforced mixture exhibits a superior fatigue resistance compared to the control mixture, however the dynamic modulus values for both mixtures were similar. For project four, the new rubber-modified WMA as expected showed an improved fatigue performance compared to the regular WMA mixture. It was also noticed that the rubber-modified WMA mixture tolerated the highest tensile strain levels among all the test mixtures with immense fatigue cycles.

5 DAMAGE CHARACTERISTIC (C-S) CURVE

The construction of C-S curves in this paper followed the most updated procedure to calculate damage parameter, *S* [33]. For each mixture, the C-S curves were established from each test sample. Then a single power model was fitted through the collapsed curves to represent the model C-S curve for the mixture. A more favorable damage characteristic curve is the one that has the greatest damage level for a given pseudo stiffness as it means that the rate of damage growth for a given pseudo energy input will be less and thus the incremental loss in pseudo stiffness will also be less. However, one cannot, or should not, use this curve alone to judge the fatigue resistance of the three mixtures. Figure 4 shows the C-S curves of the mixtures for four projects together. It can be observed from Figure 4(a) that, like the modulus response, the damage characteristic relationship is more strongly affected by the 5% change in air void content than it is by the 1% change in asphalt content. It can be also observed that mixtures with lower air voids and higher binder contents produce favorable damage characteristic curve. Figure 4(b) shows that the most favorably positioned damage characteristic curves are obtained from the reference-gap and polymer-modified mixtures.

It is interesting to observe in Figure 4(c) that both the control and the fiber-reinforced C-S curves are very similar; however, the pseudo stiffness at failure, $C_{failure}$, value for the control is higher compared to the fiber-reinforced mixture. This may imply that the addition of fibers does not appreciably change the internal structure of the mixture compared to other additives as polymer and rubber. What may support this argue is the fact that the fiber has almost no effect on the modulus obtained from either the dynamic modulus test or the uniaxial fatigue test. So, the fiber role is to hold the microcracks which consequently delay the formation of the macrocracks or the fatigue failure. For this particular mixture, microdamage that is affected by the fibers might occur relatively late in the fatigue process, e.g., after a *C* value of approximately 0.4 has been achieved. Figure 4(d) showed as anticipated that the rubber-modified WMA mixture showed a favorable C-S curve compared to WMA mixture.

6 FATIGUE PERFORMANCE SIMULATION

Damage curves alone are not sufficient to judge the fatigue resistance of an asphalt concrete mixture since they only indicate the resistance to damage. Under a given external condition (i.e., load level or deformation magnitude, temperature, frequency of loading, and load shape) the amount of pseudo strain energy created will vary by mixture. Therefore, one must consider the damage curves and the $|E^*|$ of a mixture in order to evaluate its fatigue resistance. The implication of this situation is simply that in order to gain useful information on fatigue performance, one must perform simulated predictions of the fatigue life at specific conditions of interest. In this paper, the Simplified-Viscoelastic Continuum Damage (S-VECD) theory is used to derive formulas for predicting the material response to fully reversed constant stress and constant strain loadings [33]. There formulas were verified using independent laboratory experiments and showed good prediction of fatigue life [51].

In this paper, only the simulation results for the controlled strain condition at 21 °C and 10 Hz frequency are presented as shown in Figure 5. In Figure 5(a), it is seen that there is little overall effect from the 5% air void content change, but a noticeable effect from the 1% change in asphalt binder content. Since the conditions simulated for these figures are very similar to the experiments, this finding is not surprising. It is observed from Figure 5(b) that overall the asphalt rubber mixture is expected to yield a longer laboratory fatigue life. Figure 5(c) showed a superior fatigue resistance for the fiber-reinforced mixture compared to the control mixture however both showed similar modulus values and C-S curve. Figure 5(d) showed that the addition of the rubber to the WMA mixture enhance the fatigue behavior.

7 DISCUSSIONS AND CONCLUSIONS

This paper presented research performed to compare properties and fatigue performance characteristics of diverse asphalt mixtures from laboratory studies and field projects.

The data were used to compare the performance of the mixtures within each project using the Simplified-Viscoelastic Continuum Damage (S-VECD) approach.

Results from project one showed as expected that increases in asphalt content and air voids reduced the modulus of the material. A 5% change in air void content was found to more strongly affect the modulus of the study mixture than a 1% change in asphalt content. Controlled on-specimen strain fatigue tests were also showed that the fatigue performance of the study mixture was more strongly affected by the 1% change in asphalt content than the 5% change in air void. The simulated fatigue behavior predicted in accordance with the viscoelastic continuum damage theory supported the experimental findings for controlled strain loading.

For project two, dynamic modulus test results indicate that, at high test temperatures, the polymer-modified mixture expressed the highest stiffness followed by the reference and rubber-modified mixtures. In comparison, at low temperatures, the rubber-modified mixture had the highest stiffness followed by reference and polymer-modified. The S-VECD analysis clearly showed the benefits of the rubber modified mixture in terms of laboratory fatigue resistance.

It was interesting in project three that both fiber-reinforced and control mixture showed similar modulus and C-S curve, however the fatigue life of the fiber-reinforced mixture was higher compared to the control mixture. That was mainly due to the elongated C-S curve of the fiber-reinforced mixture compared to a shorter damage curve for the control mixture.

For the tested mixture in project four, the rubber-modified WMA mixture showed a tendency to resist cracking and rutting more than the regular WMA by showing lower dynamic modulus at low and intermediate temperature and meantime similar modulus to the WMA mixture at high temperature. Both the uniaxial test result and the S-VECD analysis showed that the rubber-modified WMA expressed much better fatigue resistance compared to the WMA mixture. Overall, the results showed that the rubber-modified WMA mixture is by far the best fatigue resistance mixture followed by the fiber-reinforced mixture.

In conclusion, the S-VECD analysis represents a more powerful tool to evaluate fatigue resistance than the traditional method of examining only the number of cycles necessary to reach a certain stiffness reduction. Such approaches inherently smear the effects of modulus and damage into the analytical result. The rationality of the model with regards to air void content and asphalt content changes as well as the effect of using different additives has been examined in this paper. In addition, these results showed that the developed uniaxial fatigue test method was successfully able to capture the true fatigue behavior of the assorted tested mixtures.

ABSTRACT: It is commonly assumed that the two-phase morphology of bituminous materials at the micrometer length scale is the origin for the material's mechanical response at larger length scales. Usually this morphology, or microstructure, is observed by using Atomic Force Microscopy (AFM), providing height and phase maps of the material's surface. The aim of this work is to quantify the nanomechanical properties of the phases that constitute the microstructure of bitumen, using Peak-Force Tapping mode AFM. The mechanical properties, i.e. modulus, probe-sample adhesion force, dissipated energy and deformation are measured for four well defined bitumen grades from the SHRP library. It is found that the measured mechanical property maps possess similar morphological characteristics as the height and phase images from traditional AFM, i.e. they overlap. For all phases of the four bitumen the averaged mechanical properties could be obtained. After proper averaging, these properties could be compared between the four bitumen grades and with their documented macroscale properties. Such correlations were found to exits, but also anomalies have been found. These anomalies may originate from a different viscoelastic response of the material phases at the experimental loading rate of 2 kHz, while traditional mechanical tests are performed at much lower frequencies. Thus, a systematic study of the nanomechanical properties is presented, with promising results that shall enable a better understanding of the link between micro and macro-scale properties of bituminous materials.

Keywords: bitumen, nanomechanical properties, Peak Force AFM, Derjaguin–Muller–Toporov model

1 INTRODUCTION

Bituminous materials are known to be composed of a large range of dissimilar organic molecules. Upon solidification of the material from the melt, these molecules tend to locally order, or phase separate, giving rise to the material's microstructure. This microstructure has been characterized by Atomic Force Microscopy (AFM) [1–4]. The microstructural details are found to depend on the origin of the raw material and its thermodynamic history. Most bituminous binders are found to exhibit a two phase microstructural morphology, where domains of different sizes are dispersed throughout a matrix phase [2, 3, 5].

Phase images originating from one of the dynamic AFM imaging modes, tapping mode AFM, provide only qualitative evidence of the difference of mechanical properties between the domains and the continuous phase [2–5]. The mechanical property contrast observed in a

phase image is the cumulative contribution of all different mechanical responses like modulus, adhesion, deformation and energy dissipation. Therefore, it is very difficult to obtain micro scale mechanical properties from AFM phase images alone.

Usually the nanoindentation technique is used to characterize the viscoelastic properties of time dependent materials like bitumen at the nano to micro scale [6–8]. For example, the mechanical response of bitumen at the microstructural level was first studied using the grid indentation technique by Jaeger et al. [9]. However, this technique had several disadvantages such as its relatively poor spatial resolution (order of 5 μm). At this resolution it is impossible to obtain the separate mechanical properties of the various phases that have been identified by AFM, as these phases are typically found to be in the range of 1–10 μm.

With AFM, a spatial resolution of several nanometers is easily obtained. Employing a recently invented imaging mode of AFM (Peak Force QNM), quantitative mechanical property mapping of bituminous binders with nanoscale spatial resolution has become possible, e.g. Fischer et al. [10].

In the present work we focus on the identification of nanomechanical properties by utilizing the Peak Force AFM mode on four Strategic Highway Research Program (SHRP) bitumen: AAC, AAA, AAG and AAK. These four bitumen grades are known to possess rather distinct microstructure morphologies [3]. Meanwhile their macroscopic mechanical properties as well as chemical composition [11] are rather different. This suggests that the macroscopic mechanical properties of bitumen originate from the microstructural length scale. In order to establish the link between the microstructure of a bitumen and its macro-mechanical behaviour and performance, the first step is to quantify the mechanical properties of the various material phases observed. As mentioned before, some authors already reported some nanomechanical data for bitumen, though issues like repeatability, consistency and robustness of these data are yet not firmly established. Then these nanomechanical data are correlated with the well-established properties of these binders. If a correlation between these sets of data exists, it would allow for appraising the properties of bituminous binders by modification of its microstructure. This can be achieved by tailored processing conditions, application of additives etc.

2 MATERIALS AND METHODS

2.1 *Materials*

Four different bituminous binders were selected from the Materials Reference Library of the Strategic Highway Research Program (SHRP): AAC-1, AAA-1, AAG-1 and AAK-1. The binders were imaged and mechanically mapped using the Peak Force QNM mode of AFM. The materials were selected on the basis of their compositional and mechanical differences, which would ease the identification of possible correlations with nanomechanical properties. The characteristics of the selected bitumen are presented in Table 1.

2.2 *Sample preparation*

The samples were prepared by applying 20 mg of bitumen sample to the AFM sample substrate (steel sample disks with a diameter of 12 mm) with a spatula. And the specimens were

Table 1. Properties of SHRP bitumen [11].

Sample	Penetration in 1/10 mm units (25°C, 100 g, 5s)	Softening point (R & B) (°C)	Viscosity (at 60°C) (Pa·s)	Asphaltene (%)	Wax (%)
AAC-1	133	42.8	41.9	10.1	5.06
AAA-1	160	44.4	86.4	16.2	1.62
AAG-1	53	48.9	186.2	5.0	1.13
AAK-1	70	49.4	325.6	20.1	1.17

subsequently heated on a hot plate of 100°C for 30 seconds in order to create a thin flat film with thickness of 200–300 μm. Then the specimens were thermally conditioned inside an oven at 100°C for 60 minutes followed by cooling under ambient conditions. The specimens were later kept inside petri dishes to avoid any ambient particle pick-up, and stored at room temperature before AFM imaging.

2.3 *Peak-force QNM mode of AFM*

Peak Force QNM uses the Peak Force Tapping mode as principle of operation. In this scanning mode the probe is indirectly modulated by driving the AFM cantilever through a piezo-element in a sinusoidal waveform of 2 kHz and at an amplitude of 150 nm. This motion generates instantaneous force-distance curves each time the cantilever taps on the sample. The peak interaction force value of the force-distance curves is used as the imaging feedback parameter. The tip trajectory over time during a tapping cycle is portrayed in Figure 1. In Figure 1(a), the path 1-2-3 represents the approach part and 3-4-5 is the retract part of a single tapping cycle. At position 1, the tip is far from the sample surface. The probe then approaches the sample and experiences attractive forces until the contact point at 2 has been reached, and then slightly deforms the sample at 3. While going through the retract part, the probe is pulled off while the sample holds the probe momentarily with an adhesion force (at 4). Later the probe recovers back to its original position [12–15].

The force versus time curve is shown in Figure 1(b) which illustrates the Peak Force Tapping operation and the tip trajectory (note that the tip trajectory is in time versus tip location). By using the calibrated scanner settings, the system converts the force-time curve, Figure 1(b), into the force-distance curve as shown in Figure 1(c). These force-distance curves are comparable to the load versus penetration curves that are common in the context of nanoindentation studies. The analysis of the recorded data is done simultaneously by fitting with models from contact mechanics, resulting in a map of mechanical properties like elastic modulus, tip-sample adhesion, energy dissipation, and maximum deformation of the material.

2.4 *Instrumental settings and measuring environment*

The Dimension Icon Atomic Force Microscope from Bruker was used for Peak Force QNM imaging of the selected bitumen samples. RFESPA silicon AFM cantilevers (Bruker) were

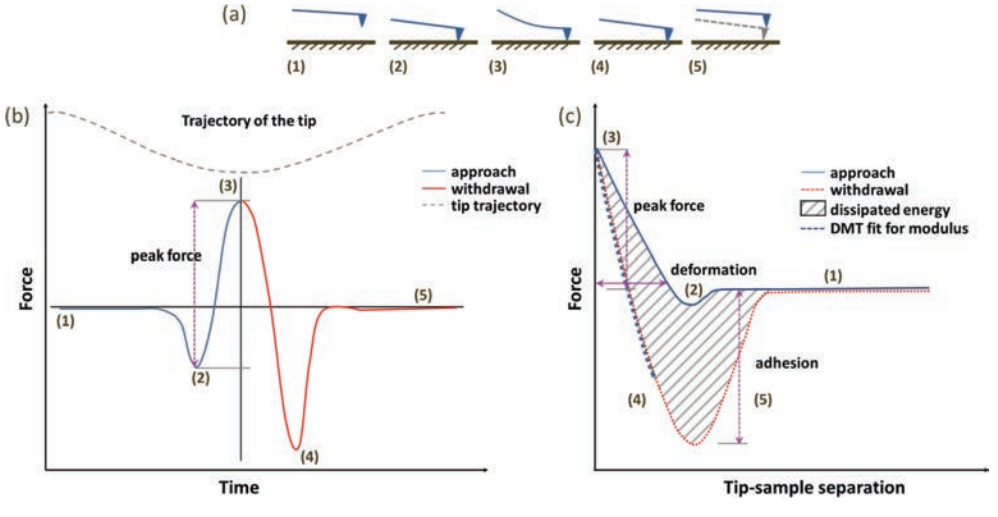

Figure 1. (a) Approach and withdrawal of the AFM-tip in a single tapping cycle (b) principle of Peak Force Tapping operation with the tip trajectory (c) schematic of force-distance curve obtained at each tapping cycle with the peak force as controlling parameter.

used as probe. These probes have a nominal resonance frequency of 75 kHz and a nominal spring constant of 3 N/m. The tip heights of these probes are in the range of 15–20 μm and have a nominal tip radius of 8 nm. The linear scanning rate was set to 1 Hz (1 line/s) and the mechanical mapping of the material was carried out at 30×15 μm^2 scan size with a pixel resolution of 512×256. The applied peak force was kept to 8 nN, leading to minimal and almost elastic deformation of the sample, which was iteratively found to be the best setting for optimal mechanical property mapping. The cantilever material is antimony (n) doped silicon which has a 40 ± 10 nm aluminium reflective coating on its backside. The nominal cantilever dimensions were $225 \times 35 \times 3$ μm. All the measurements were performed using the Peak Force QNM mode in air at ambient temperature (22°C).

The system was calibrated following the relative calibration method. The probe was selected and calibrated before every measurement series. The deflection sensitivity of the cantilever was measured by acquiring a force curve on a silicon wafer substrate. The spring constant was measured 2.8 N/m, using the 'thermal-tune' method. A reference sample of known modulus was used to measure the tip radius. The reference sample was imaged in Peak Force QNM mode and the tip radius was obtained by fitting with contact mechanics models until the known modulus value of the reference sample was obtained. This tip radius was later used in further fitting cycles.

As the applied force on the sample was very small (8 nN), the tip-sample contact geometry can be approximated by a hard sphere in contact with an elastic plane. Thus, the Derjaguin-Muller-Toporov (DMT) model from contact mechanics was used for real-time curve fitting to obtain the local value of the elastic modulus of the bitumen [12, 15, 16], Figure 1(c). Another mechanical property attained in the mapping is the adhesion force, illustrated by the minimum force in Figure 1(c). The origin of this force can be any attractive force between the tip and the sample. As the measurements were performed in air, Van der Waals forces, electrostatic forces, and forces resulting from a capillary meniscus between sample and AFM-tip, contribute to the adhesion force. The maximum deformation is defined as the penetration of the tip into the surface at the peak force. This property is calculated from the difference in separation from the point where the force is zero and the peak force point along the approach curve, Figure 1(c), and 70% of this value is recorded in the real-time mapping. The finally, the dissipated energy per tapping cycle is obtained by integrating the area between the approach and retract curves.

For the offline analysis of the AFM images the software package Gwyddion [17] was used. Offline analysis of the data was performed to obtain the statistical and spatial distribution of the measured mechanical properties at different regions of the imaged bitumen surface.

3 EXPERIMENTAL RESULTS AND DISCUSSION

The microstructural morphology along with the mechanical properties of thin film bituminous binders was obtained by Peak Force QNM mode AFM for specimens prepared according to the procedures described before. The mechanical properties of the bituminous binder's surface are obtained by analyzing the force curves in real-time. In the context of this research five different mechanical properties have been measured simultaneously: a) topography, which reveals the surface topography (height) of the bitumen sample, b) DMT modulus, which provides the local elastic modulus value of the material as derived from fitting with the DMT model, c) deformation, the maximum deformation occurring from the penetration of the tip into the surface at peak force, d) adhesion and e) the dissipated energy per cycle, obtained from the area enclosed by the loading and unloading curves.

In the following, first the complete set of measured local mechanical properties of a single binder, AAC, is presented and its qualitative features are discussed. Subsequently, the properties of the other binders are presented in a comparative setting. Finally, it is shown how overall consistent mechanical properties can be derived from the data, and how these relate to other microstructural and macro-mechanical properties.

3.1 *Morphology and mechanical properties of SHRP bitumen AAC*

The microstructure of the binder AAC, as presented in the height or topography image in Figure 2(a), displays the typical two phase features as observed by many other authors [2, 3, 9]. The microstructure is characterized by the presence of phase consisting of elongated, almost elliptical, domains. The size of these domains range from 3 to 8 μm along the long axes, along which also the typical undulating or wrinkling pattern is observed [2, 3, 5]. The domains are found to be dispersed in a continuous or matrix phase.

From the DMT modulus data channel, Figure 2(b), it is observed that the local modulus values vary over the scanned area, and these variations do show a similar pattern as observed in the height image, though not very pronounced in the case of AAC. Comparing Figures 2(a) and 2(b) one finds that the domains possess higher local modulus values than the surrounding matrix phase. This is consistent with the deformation results, Figure 2(c). The domains, possessing lower moduli, are expected to deform less than the matrix phase, which is also observed. One should note here that (elastic) modulus is a material property, while stiffness is defined as the resistance to deformation of a structure. As in the present experiment *local* mechanical properties, each pixel represents a 50×50 nm area, are probed, there is essentially no difference between stiffness and modulus. The local stiffness varies from 300 MPa to 800 MPa. At the centre of the domains the modulus is highest, and then gradually decreases towards the continuous phase. From the modulus point of view interfaces between the two phases are rather diffuse.

The adhesion and dissipated energy maps are shown in Figures 2(d) and 2(e). Here the interfaces are much sharper. For both, adhesion and dissipated energy, the domains display lower values than the matrix. The dissipated energy and adhesion data show similar trends. Therefore, for the other samples only the adhesion data will be presented.

3.2 *Morphology and mechanical properties of SHRP bitumen AAA, AAG, AAK*

Two phase morphology is also observed for the binders AAA and AAK, Figures 3(a) and 3(c). The size of the domains in AAA range from 0.3 to 3 μm and their shapes tend towards cir-

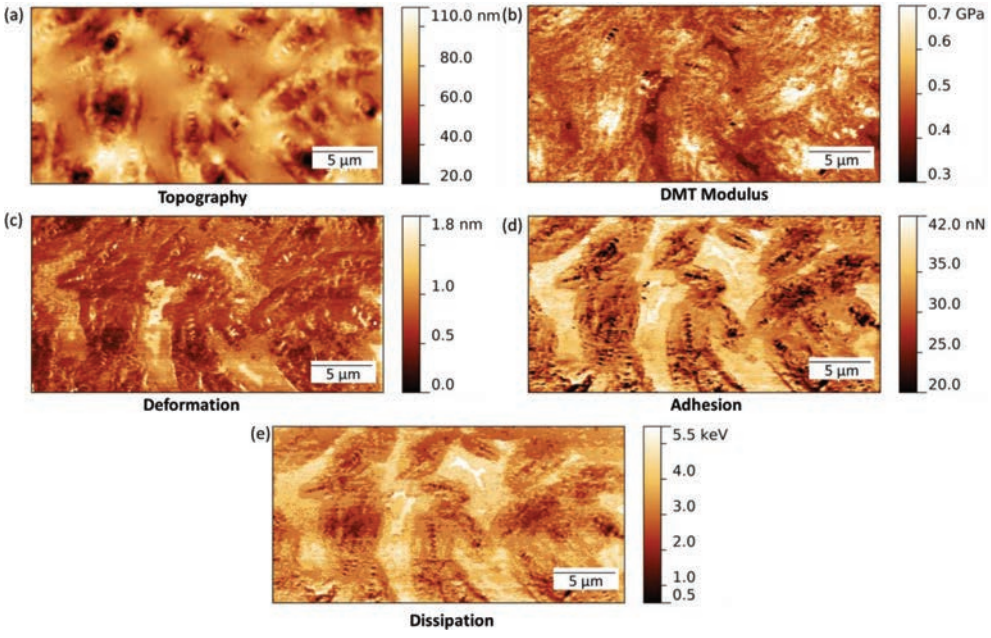

Figure 2. Quantitative nanomechanical property maps of SHRP bitumen AAC. 30×15 μm^2 Map of (a) Topography, (b) DMT modulus, i.e. the stiffness, (c) Deformation, (d) Adhesion and (e) Dissipation.

cular. The local mechanical properties of AAA, Figure 3(aii–iv), show that here the domains possess the lower modulus (~130 MPa and ~170 MPa), and that the material is overall softer than AAC. The domains are also found to be somewhat protruded from the matrix. Comparing this with the findings from AAC, suggests that the protruded phase is always the softer or lower modulus material. Surprisingly, the deformation of the softer domains is found to be lower than the deformation of the continuous phase. This may be explained by differences

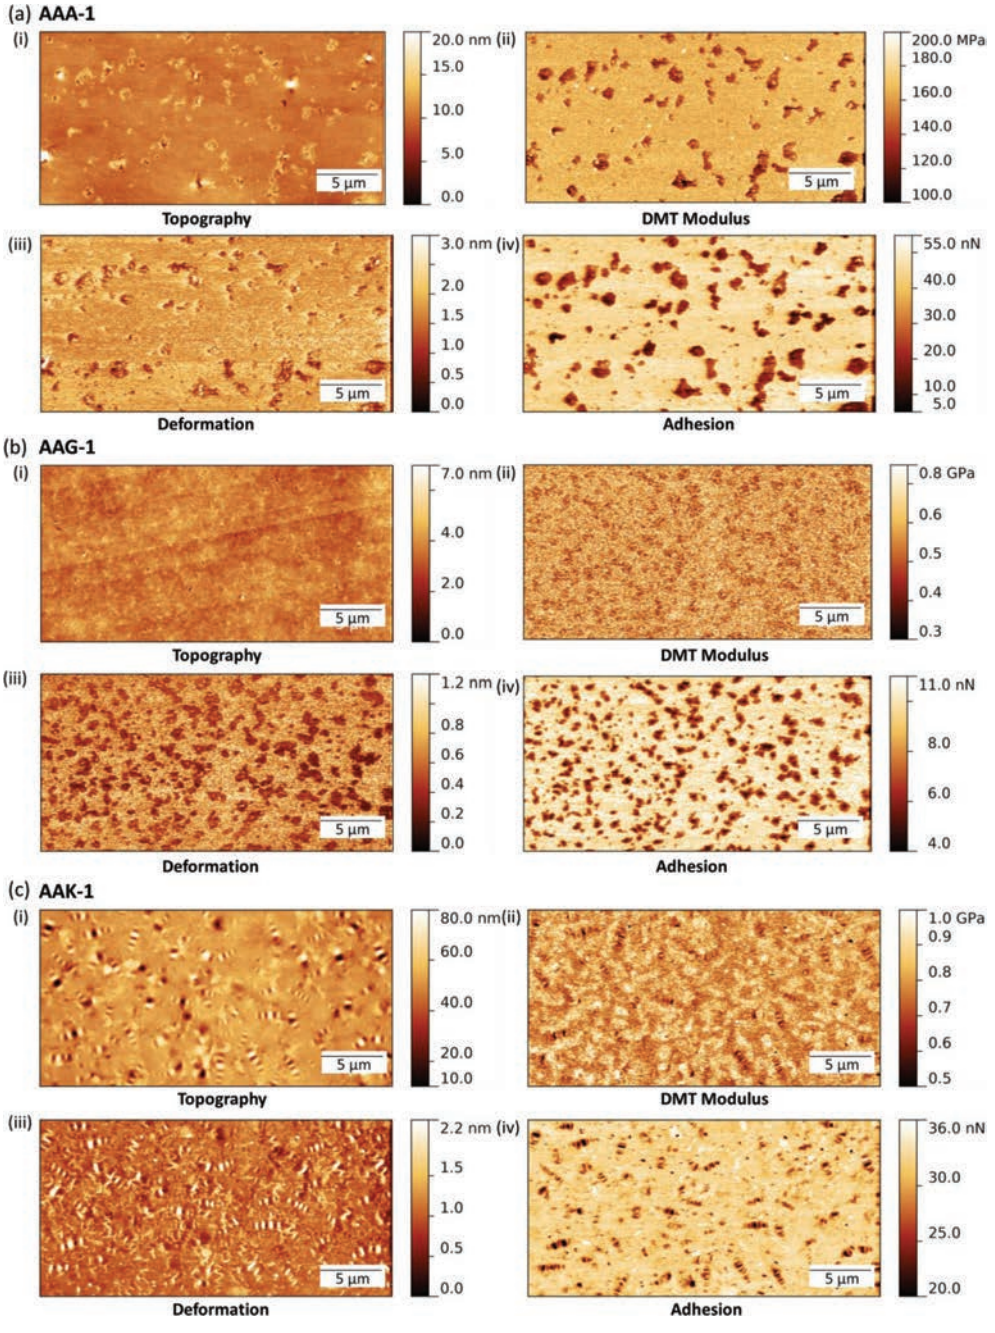

Figure 3. Quantitative nanomechanical property maps of (a) AAA-1, (b) AAG-1 and (c) AAK-1. 30×15 µm^2 maps of (i) Topography, (ii) DMT modulus, (iii) Deformation and (iv) Adhesion.

in viscoelastic properties of both phases. The QNM technique loads the material locally at a rate of 2 kHz, while viscoelastic response is known to be strongly frequency dependent. Finally, for AAA the domains are found to be the regions of lowest adhesion.

The topography image of the binder AAG, Figure 3(b), shows that the surface of this binder is extremely flat, with a z-range up to only 7 nm. From the height image alone, biphasic morphology is not apparent. Though, the mechanical property data presented in Figure 3(b) to 3 (e), the existence of two phases is obvious. The modulus data show structuring of regions with lower modulus (~500 MPa), sized from 0.2 to 1 µm. The modulus of the matrix phase is found to higher (~620 MPa). The 2-phase character is most apparent from the adhesion and deformation images. Both properties are found to be lowest for the domains. The contrast between phases in the latter images is much sharper than for the topography and modulus images.

The last bitumen selected for this study, AAK, is characterized by a dominant occurrence of the closely packed domains, which cover almost 90% of the scanned surface, Figure 3c. The domains are elliptical in shape with a wrinkling pattern along the long axis, leading to the well-known bee-like appearance of the domains. The size of the domains varies from 0.7 to 3 µm. The mechanical property data show that the (only slightly visible) matrix has the lowest modulus of about 780 MPa. The domains show a modulus minimum in the area that is wrinkled, surrounded by a region of highest modulus (~850 MPa). Future investigations with an ultra-sharp AFM cantilever tip should reveal whether the lower modulus in the domain centres is an imaging artefact caused by the wrinkling or represents the true local mechanical property. Lastly, the deformation and adhesion data reveal that the domains have lower values than the surrounding material.

3.3 *Translation of mechanical property maps to material characteristic values*

The mechanical maps as presented in the previous paragraphs provide an overview of properties over the scanned surface. In order to relate these maps to other properties of the studied binders, a proper averaging procedure has to be adopted. Firstly, the average value is taken over a square area that is completely within one phase, inset of Figure 4(a). In order to assure the statistical validity of the averaging procedure, the same procedure was followed at the same location of the sample surface but with averaging squares that were stepwise increased from 5×5 pixels to 30×30 pixels. For each of these square averaged properties also the standard deviation was calculated. It should be noted that each single pixel represents an independent measurement of a full force-distance curve, from which the presented properties are derived by analysis of these curves. In Figure 4(a) the result of this averaging procedure is demonstrated for the matrix phase of bitumen AAA. The averaged mean modulus appears to be independent of the averaging area, though the standard deviation initially decreases and flattens out at an averaging square of 30×30 pixels. Thus, to obtain a reasonable estimate of

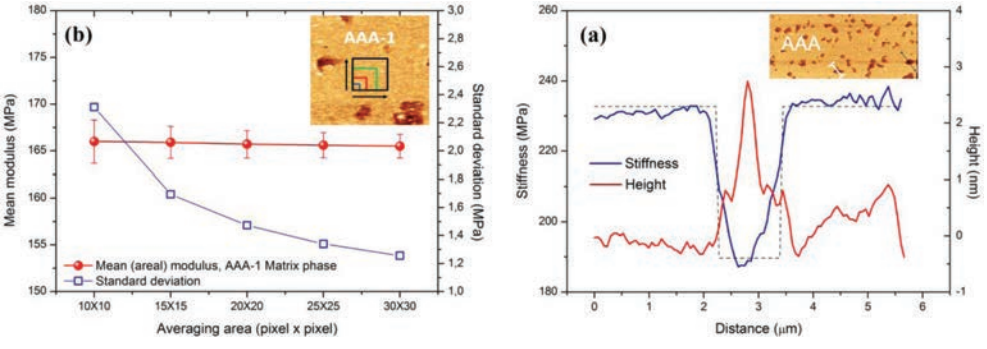

Figure 4. (a) Averaging procedure, and (b) correlation of height to modulus along a path (inset) for AAA.

the areal averaged mechanical properties from AFM images, averaging over a small square area is sufficient. Though, to obtain an idea of the precision, one has to find in an iterative way the averaging area where the standard deviation starts flattening out. It was also found that the averages are independent of the precise location of the averaging square within the phase.

Finally, in Figure 4(b) it is demonstrated how height variations of the sample surface correlate with variations in mechanical properties. In Figure 4(b) the height and modulus of AAA along the path is depicted in the inset. Here it appears that the softer phase is slightly elevated (4 nm) relative to the stiffer phase. As mentioned in the discussion of the individual material maps, this relation between phase stiffness and height is found consistently for all the materials examined in this study.

The results of the mean mechanical properties for both phases of the four bitumen grades have been summarized in Table 2. The areal averaging procedure as described earlier was followed throughout. Also some morphological features of the microstructure have been added. To facilitate comparison, for each material the phase with maximal modulus and deformation have been shaded (green).

From Table 2 one can conclude that AAA has phases with the lowest modulus: linear averaging using the phase fraction gives an average stiffness of 160 MPa at 22°C. This is in agreement with the information in Table 1. According to this latter table AAG should possess the highest modulus. However, for AAG one finds a modulus of 580 MPa, which is smaller than the same for AAK, 840 MPa. Further, for both AAC and AAK the domains constitute the phase with highest modulus, whereas for both AAA and AAG the matrix phase has the highest modulus. It should be noted that the assignment of phases (domains, i.e. 'bees' and matrix) was based on the universal appearance of an isolated, convex phase (the bees) embedded in a matrix that surrounds them. This distinction should possibly be adjusted, given the mechanical properties of these phases.

Another finding, that might explain the anomalies just mentioned, is that for AAC and AAK the stiffest phase experiences the lowest deformation at peak force. While for AAA and AAG the stiffest phase, surprisingly, shows also the largest deformation at peak force. Before it has been proposed that this might be due to very different viscoelastic properties of the two phases, which might lead to a switch in apparent modulus at the experimental frequency of 2 kHz, the loading rate. Applying the same linear approximation based on phase fractions for the adhesion data, AAA appears the stickiest bitumen, while AAG is the least sticky. These findings apparently correlate with the penetration and asphaltene fractions as given in Table 1.

Table 2. Averaged mechanical properties of bitumen phases at 22°C (per material the highest values are shaded green).

Materials/ phase	Modulus (MPa)	Deformation (nm)	Adhesion (nN)	Dissipation (keV)	Domain size (μm)	Phase fraction (%)

4 CONCLUSION

A novel AFM mode, Peak Force QNM, has been utilized to map simultaneously the topographical and mechanical properties of four bitumen from the SHRP materials library. This mode allows acquiring and analysing the individual force curves from each cantilever tap during the imaging process. These force curves are fitted in real time to obtain the local mechanical properties—modulus, adhesion, deformation and dissipated energy—of the bitumen sample. In this way the phase images of traditional tapping mode AFM are unravelled into the individual effects contributing to the phase signal.

It is shown that topographical features of the sample surface are reflected by the mechanical properties; the softest phase is always found to be 2–5 nm elevated relative to the higher modulus phase. Moreover, it is shown that phases as occur in topography images are observed as areas of constant mechanical properties in the mechanical maps. A method has been demonstrated that allows breaking down the mechanical property maps into averaged properties with standard deviation for each phase.

From this it is found that for two materials (AAC and AAK) the domains, or bee's, constitute the phase with higher modulus, while the opposite has been found for AAA and AAG. Moreover, an anomaly has been observed between the modulus and deformation for AAA and AAG. For these materials the stiffer phase displays at the same time the highest deformation. It is proposed that this may originate from viscoelastic effects that may be prominent at loading rates of 2 kHz.

By assuming a simple linear relation between the phase fractions and their mechanical properties, per bitumen (phase) averaged mechanical properties are obtained. Then, these phase averaged properties are compared with known properties of the binders as obtained by different means. Some properties like penetration (as a measure for 'stiffness') showed reasonable correlation with the nanomechanical results. Though a better understanding of the systems studied is required to formulate more sophisticated methods that allow for prediction of traditional bitumen properties from phase morphological and nanomechanical properties.

In conclusion, for the first time nanomechanical properties of distinct bitumen grades have been studied systematically. Phase morphology and nanomechanical maps appear to be congruent. Hence, the microstructure of bitumen can be safely identified as the property defining length scale. On-going and future research efforts are directed to explanations of the anomalies observed in this work. Thus it will contribute to a better understanding of bituminous materials from a more fundamental point of view, which should serve in the end the industrial, engineering and professional pavement communities.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Troy Pauli from the Western Research Institute (Laramie, USA) for providing the bitumen. Financial support from the Dutch national IOP Self-Healing Materials program (AgentschapNL, The Netherlands) under grant no. SHM01056 is gratefully acknowledged.

ABSTRACT: High surface temperatures increase the risks of rutting and top-down cracking in Hot Mix Asphalt (HMA) pavements. Reducing temperature extremes in asphalt pavements is a step towards building sustainable pavements. The objective of the research reported in this study was to evaluate the concept of using Geosynthetic Reinforced Chip Seal (GRCS) as an effective method to reduce temperatures in HMA pavements under different types of solar radiation conditions. Equipment was developed for simulating different levels of solar radiations, for different time periods, and determining temperatures at multiple depths of four pavement samples simultaneously. Temperature data at uniform depths of different types of HMA samples under a wide range of solar radiation conditions were collected. An instrumented test section was set up at the University of California Pavement Research Center site in Davis, CA. Temperature data from the GRCS and an adjacent Open Graded Friction Course (OGFC) section were compared. The major conclusion is that a GRCS reduces the temperature of HMA pavement, and the reduction in temperature at the different depths can be as high as 10C, which can result in an extension of pavement life substantially. The use of a GRCS is recommended for application in high temperature areas to reduce temperature and extend lives of asphalt pavements. Further study of reduction in temperature with higher albedo aggregates, double chip seals and concrete pavements is recommended.

Keywords: sustainable, temperature, geosynthetic, chip seal, solar

1 INTRODUCTION

High temperature related permanent deformation (rutting) is a major type of distress in HMA pavements. A rise in temperature leads to a reduction in stiffness and permanent deformation resistance under shear and compressive stresses in HMA and a consequent increase in potential of rutting [1, 2]. Also, higher temperatures lead to faster aging of asphalt binders, and hence accelerated deterioration of asphalt pavements due to low-temperature cracking, ravelling and top-down cracking [3]. One way to prevent high temperature related rutting is to modify the properties of asphalt pavement materials through the addition of stiffeners or modifiers, such as polymers, that make the asphalt binder stiffness less susceptible to a rise in temperature. Such an approach works well and has been commonly used; however there are two drawbacks, the use of polymers leads to an increase in cost, and the industrial supply of modifiers could be inconsistent. Furthermore, the use of polymer modified asphalt also necessitates the use of a higher temperature during production of HMA, which leads to greater energy consumption and higher amount of fumes and emissions.

An alternative approach could be to control the pavement temperatures through designing the pavement structure with specific layers such that the temperature of HMA could maintain a lower level (compared to conventional HMA pavements) at high ambient temperatures. This paper presents the results of a study that was carried out with that specific objective.

2 OBJECTIVE

The objective of this study was to evaluate a system of keeping the temperature of pavements at a lower level during high ambient temperature conditions through the use of GRCS with moderately high albedo aggregates.

3 THEORY

Temperatures in HMA pavements rise quickly and remain elevated in the summer season because of high absorption of solar radiation (less reflection, more absorption due to the low albedo of the asphalt) [4]. The temperature of the HMA layers becomes progressively hotter during hot spells, and typically the 7-day maximum temperature is considered for selecting the appropriate asphalt binder grade for prevention of rutting. Such temperatures can rise as high as 70–90 °C, depending on the location, and temperatures in the range of 60–70 °C are common in many parts of the US. Generally, if the span of temperature (high to low) is too large (>90 °C) a polymer modified asphalt is specified.

The hypothesis that is evaluated here is the following. If the amount of heat that reaches the HMA layer could be reduced, then the increase in temperature in the HMA layer could be lowered. This could be achieved by a two step process. First, a layer of geotextile, made of polypropylene, could be laid down on top of the HMA. Generally such layers are placed after the application of a thick layer of asphalt binder, such that the geotextile layer is "saturated". Since both polypropylene geotextile (0.1–0.22 W/mK) and asphalt binder (0.15–0.17 W/mK) have lower thermal conductivities compared to aggregates (2–7 W/mK) and HMA (0.8–1.5 W/mK) [5], the rate of heat transfer will be slowed down through the introduction of thermal insulation of the geotextile layer between the surface and the HMA layer. Secondly, a chip seal could be placed on top of the geotextile (resulting in a GRCS), in which the special aggregates have a high albedo (reflectivity) such that less of the solar radiation is absorbed by the pavement. The hypothesis is that the higher reflection at the chip seal surface and the lower conduction at the geotextile layer will jointly reduce the-temperature of the HMA layer though both solar reflection cooling and thermal insulation cooling [6]. It should be noted that asphalt mix layer has been recently evaluated as an insulating layer for concrete pavements by Khazanovich et al [7].

4 EXPERIMENTAL WORK

The experimental work consisted of two parts: laboratory and field. For the laboratory part, four pavement core samples (obtained from the field) consisting of four different types of HMA were instrumented, subjected to radiation, and tested for rise in temperature at different depths; GRCS was then applied on the top of each of the four samples, and they were retested for temperature under the same conditions of radiation. The temperature data from the samples with and without the GRCS were then compared. For the field part, temperature data from full scale test sections were obtained, as discussed in Section 4.3.

4.1 *Description of HMA samples*

The four samples (Table 1) have been characterized for their thermal properties earlier by the authors, and effective thermal conductivity and heat capacities have been reported in

Table 1. Description of samples.

Pavements	Sample/description	Layer composition	Bulk specific gravity
Highway-HMA layers over PMRAP base	S (9.5 mm over 12.5 mm NMAS over PMRAP base); PMRAP-RAP with 3.5% emulsion and 1.3% cement; 9.5 and 12.5 mm mixes	63 mm of HMA over 75 mm of Plant Mixed Reclaimed Asphalt Pavement (PMRAP)	Top layer + Middle layer 2.377 Bottom layer: 2.084
Highway-HMA layers over foamed asphalt base	M (9.5 mm over 9.5 mm over foamed asphalt base); foamed asphalt contained 3.1% binder and 1.4% cement; 9.5 mm mix	55 mm of HMA over 135 mm of foamed asphalt	Top layer + Middle layer 2.284 Bottom layer 2.067 1.975
Highway-HMA layers over cement treated base	R (9.5 mm over 12.5 mm over cement treated base); full depth reclaimed base with 4% cement; 9.5 and 12.5 mm mixes	70 mm of HMA over 165 mm of cement treated base	Top layer: 2.386 Middle layer: 2.209 Bottom layer: 2.033
Airport-HMA layers of different types two lifts	(FR) Fuel Resistant ½ inch NMAS mix over ¾ inch NMAS polymer modified (PM) binder mix over existing HMA or Macadam; FR—12.5 mm maximum size mix with 7% PG 88-22 binder PM—19 mm maximum size mix with 6% PG 82-22 PM binder	40 mm of FR and 53 mm of PM over 59 mm of existing P401 mix	Top layer: 2.549 Middle layer: 2.557 Bottom layer: 2.467

Chen et al [8]. Samples S, M and R are from highway pavements, while sample FR is from an airport pavement. The thermal properties, which were determined through a combined experiment, finite element analyses, and back calculation procedure, ranged from 1.3–1.8 W/mK for thermal conductivity, and 1,200–1,800 J/kgK for the heat capacity. For each sample, the temperature sensors [9] (thermistors, with an accuracy of ± 0.1C), were placed at 6 locations, as follows: 25 mm above the surface, on the surface, and 25, 50, 75 and 100 mm below the surface. The GRCS layers were created with PG 64–22 asphalt binder as tack coat, a non-woven fabric as the geotextile, and a locally available aggregate, with albedo of 0.24, with MS-2 emulsion as the chip seal. The gradation of the aggregates conformed to South Dakota Chip Seal Type 1A (100%, 40–70%, 0–15%, 0–5% and 0–1% passing the 12.5 mm, 9.5 mm, 4.75 mm, 2.36 mm and 0.075 mm sieves, respectively).

4.2 *Description of the solar radiation simulation equipment*

To test the samples under uniform conditions, a specialized piece of equipment called the "Solar Simulator" was developed. The frame of the Solar Simulator is essentially a wooden chamber; two of the sides are plywood secured with screws and wood glue, while the front and back are transparent polymer sheets, held in place with clamps (Fig. 1). One of the plywood sides has a port to which a chilled-air vent can be connected (for cooling, if required). The top of the chamber contains four round ports that serve to secure in place four halogen lamps (for heating). Beneath the lamps, the base of the cube is formed by insulation 'jackets' sitting atop plywood. Each jacket is a cube with a cylindrical opening; 4″ or 6″ × (up to) 8″ (100 or 150 × 200 mm) cylindrical asphalt mix samples sit inside the jackets, so that only the top surface is exposed. These asphalt mix samples contain sensors, in order to measure the temperature at the surface, as well as at varying heights throughout the sample. The halogen lamps (and chilled-air blower, when used) can be connected by computer and used to simulate a variety of real-world temperature profiles. The main components of the equipment consist of a microcontroller, a servo, a dimmer, and four halogen lamps. An algorithm (programmed with PuTTY software) in the microcontroller regulates the dimmer through the servo, to provide time dependent radiation from each of the four halogen lamps, allowing the simultaneous testing of four samples. The angle of rotation of the dimmer was calibrated

Figure 1. Four samples (with GRCS) being tested simultaneously (photo taken with side boards removed) in the solar simulator.

Figure 2. GRCS section at the UC Davis pavement research facility.

against radiation (kW/m^2) through test data acquired with a pyranometer (Brand: CMP3, Kipp and Zonen).

Essentially, once the user inputs the radiation as a function of time the dimmer setting versus radiation calibration curve is utilized to set a dimmer setting versus time function for the servo to control the dimmer. The microcontroller also collects data from the temperature sensors and provides them to the user as .csv files.

4.3 *Description of test section*

An approximately 4 m by 4 m section of GRCS was constructed over an existing HMA section (100 mm HMA + 150 mm Aggregate Base) at the University of California Pavement Center (UCPRC) test facilities in Davis, California in September 2013 (Fig. 2). The section was instrumented with a weather station and thermocouples, to obtain wind, solar radiation, air temperature and temperature at different depths of the pavements. Details of the existing sections are available in reference [10]. A PG 64-16 asphalt binder was applied on the existing surface at a rate of 1.3 liters per square meter. A non-woven geotextile layer was then rolled over the tack coat, first with a light (90 kg) hand roller and then with a side-walk roller (after application of sand). Next, a polymer modified cationic rapid set emulsion was applied at a rate of 2.7 liters per square meter, and then the chip seal aggregates were applied, which were rolled with a light hand roller first, and then using a pickup truck. The same aggregate/gradation that was used for the laboratory studies was used. Note that the temperature data for one day (from 4 pm, 9/18/13 to 5 pm, 9/19/13) from this section and an adjacent Open Graded Friction Course (OGFC) permeable pavement (100 mm OGFC + 300 mm Granular Base) with surface albedo of 0.08 [11] and permeability of 0.11 cm/s [12] were compared for this paper.

5 RESULTS AND ANALYSIS

The radiation intensity in the solar simulator was matched with solar radiation data that had been obtained earlier on a late spring/early summer day (outside the Civil Engineering department building, WPI, Worcester, MA, 42.2 N, 71.8 W) with a pyranometer, increasing from 0 to approximately 0.8 KW/m^2 in the first four hours, and then decreasing to 0 in the next four hours. The curve can be represented by the equation Radiation (kw/m^2) = -0.05(time, hour)^2 + 0.4(time, hour). The temperature data were collected for a

total time period of 16 hours, of which the simulated solar radiation was on for the first 8 hours and off for the next 8 hours. Figures comparing the temperature data at the different depths, between HMA and the GRCS sample are presented in Figures 3 through 6. In general, the temperatures were observed to be lower for the GRCS samples. The temperature is higher for GRCS in two cases—for 25 mm above surface in S sample, and for 25 mm above surface and the surface for the R sample. The higher temperature at the

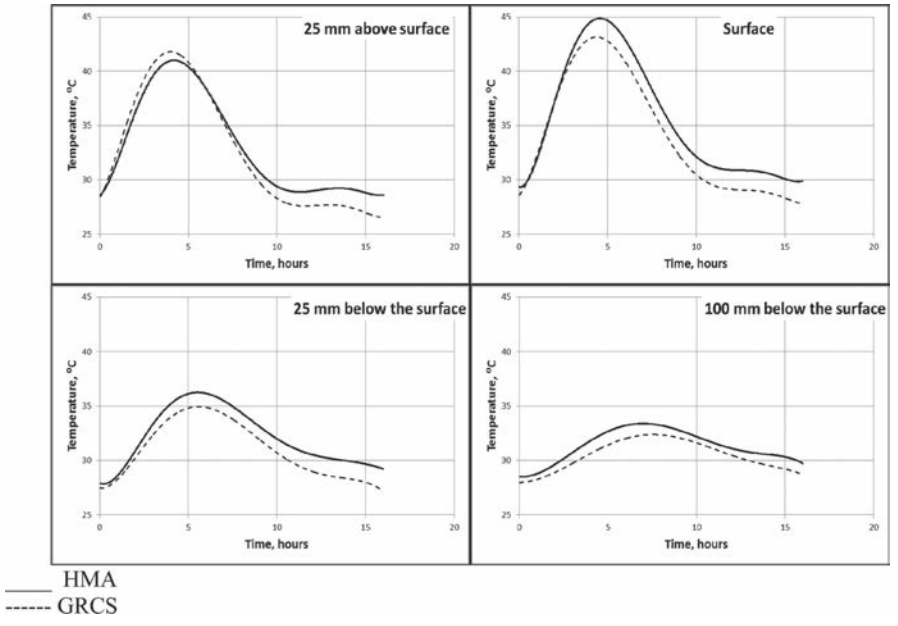

Figure 3. Temperature at different depths, S sample.

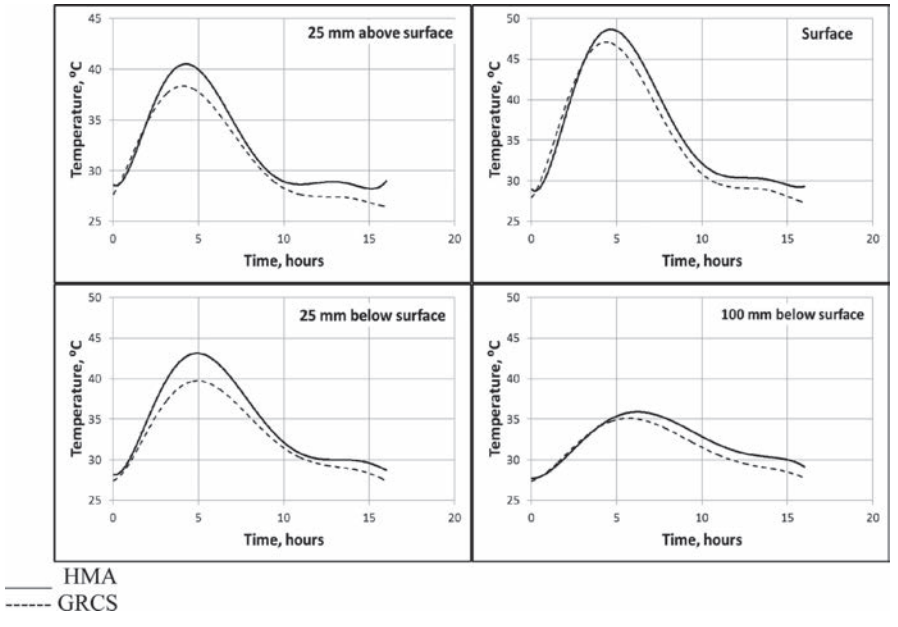

Figure 4. Temperature at different depths, M sample.

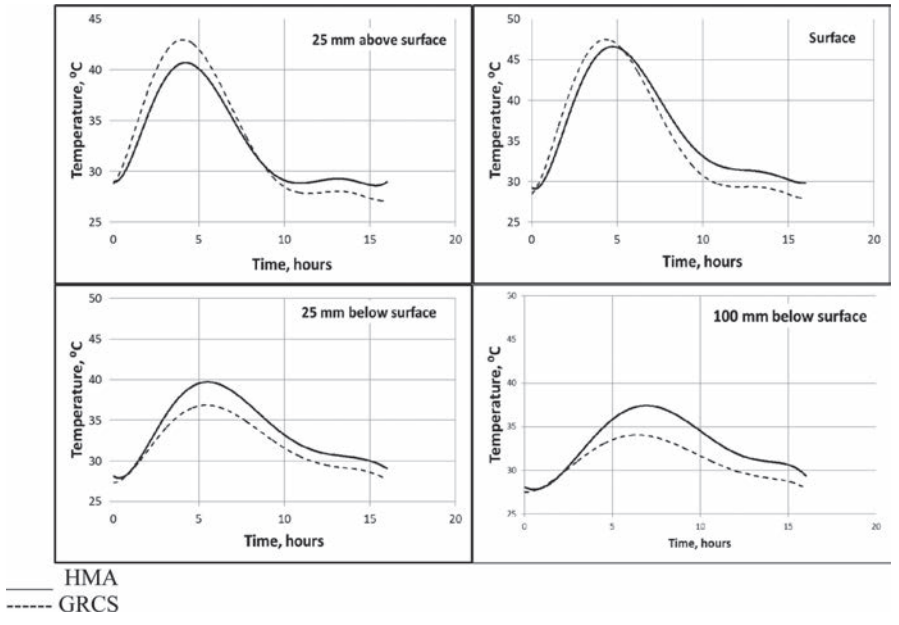

Figure 5. Temperature at different depths, R sample.

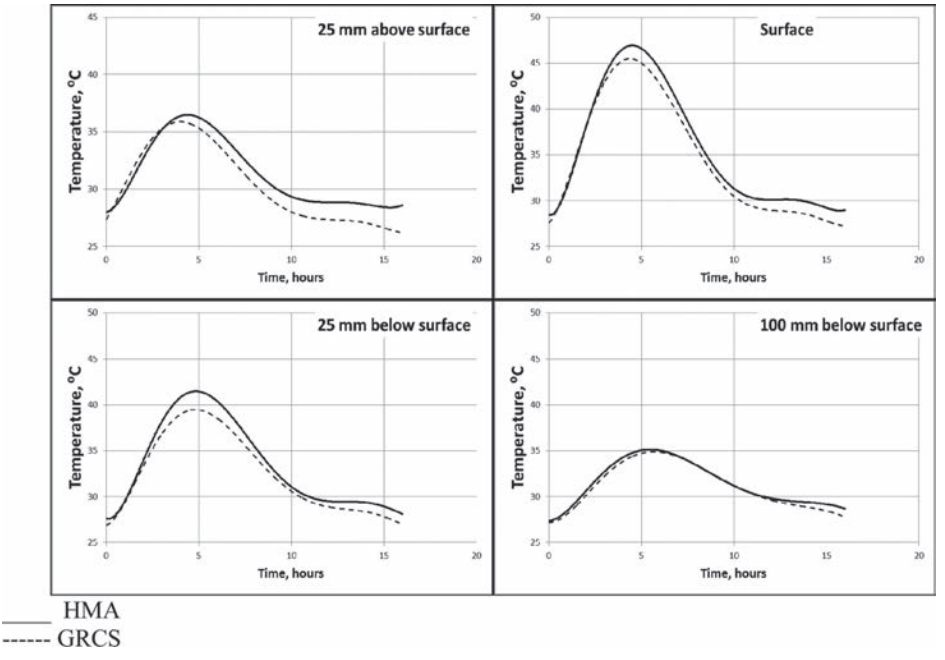

Figure 6. Temperature at different depths, FR sample.

surface of the chip seal (at the aggregate) should not be of concern regarding permanent deformation potential.

The temperatures throughout the depth of the samples are consistently lower for the GRCS samples, compared to the HMA sample. For the temperatures at a height of 25 mm above the surface, the difference at the end of the test (8 hours after the radiation is turned off)

is important. For all of the cases, a negative difference of 2 °C or higher is noted. In terms of percentage reduction in temperature at the end of the 16 hour period, throughout the various depths, the reduction in temperature with the use of GRCS ranges from 3.5–9%. The greatest reduction being noted near the surface of the samples, most of the reductions were between 5 and 7% (Fig. 7). This indicates that after sunset, the near surface temperature of the GRCS pavements would most likely be cooler than similar HMA pavements, and therefore will have a reduced effect on the environment/air quality, especially on warm days [13]. This also means that the cumulative effect of the high temperature would be much less in the case of the GRCS samples, and hence the average maximum 7-day temperature (at any depth) should also be much lower in the case of the GRCS samples. That is, throughout a large part of the HMA cross section, the overall rise in temperature, and the duration of rise in temperature will be much lower in the case of the GRCS samples. It is therefore expected that both (temperature related) aging and permanent deformation potential of HMA layers could be lowered by the use of GRCS. For example, analysis with the Mechanistic Empirical Pavement Design Guide/software has shown that a lowering of temperature of HMA layers from 70 °C to 60 °C can extend the rutting life of a pavement by more than 10 years [14].

If an aggregate with a higher albedo could be used then the benefits will be definitely greater. A reduction of temperature of 10 °C at a depth of 25 mm was confirmed with test of a HMA sample under a higher/longer (actual) solar radiation levels (Fig. 8); the tests have shown that the beneficial effects are enhanced at higher radiation levels/longer radiation periods (warmer days/summer time).

The temperature at the different depths for the GRCS test section and the adjacent OGFC test section at UC Davis (Fig. 9) show that the presence of the GRCS seems to be effective in signifcant lowering of temperature. The reductions range from 2 °C at 50 mm above the surface to 9 °C at a depth of 12.5 mm, as summarized in Figure 10. As Figure 9 shows, the temperaure fluctuations seem to be moderated by the presence of GRCS. Figure 11 shows the temperatures along the depths for the two sections for the entire time period of data collection. Note that the spread in temeprature is larger in the case of the OGFC section; for example, the temperature at 25 mm below the surface for the GRCS section ranges from 17 to 42 °C, wheras that for the OGFC section ranges from 15 to 51 °C; a reduction in high pavement temperature can extend the rutting service life, especially at the early part of its life. Also, for the GRCS section there is a greater reduction in temperature between the surface

and the lower layers. Figure 12 shows field data obtained from September–October: note the >10 °C reduction in temperature at the surface of the pavement.

6 CONCLUSIONS AND RECOMMENDATIONS

The following conclusions can be made on the basis of the laboratory and the field study that have been reported in this paper.

1. The use of geosynthetic reinforced chip seal can reduce the temperature of HMA pavements at different levels to different degrees.
2. The reduction of temperature depends on the intensity/duration of solar radiation.
3. Temperature reductions in the range of 10 °C are possible.
4. Daily fluctuations of temperature in pavements can be moderated through the use of GRCS.

The scope of further research with full-scale test pavement includes the use of the following: 1. Aggregates with higher albedo for chip seal; 2. Geotextile layer with different thicknesses; 3. Placement of double chip seals; 4. Use of GRCS on top of concrete pavements for lowering the temperature differential; 5. Durability of the GRCS to make it an effective and feasible treatment option for lowering pavement temperature, in both high and low traffic volume pavements.

Evaluation of SMA containing RAP and RAS

Stacey Diefenderfer
Virginia Center for Transportation Innovation and Research, Charlottesville, VA, USA

ABSTRACT: The use of Recycled Asphalt Shingles (RAS) is generating interest among agencies and industry as a means of encouraging environmentally friendly practices and potentially reducing material costs. The Virginia Department of Transportation (VDOT) has allowed the use of manufacturing waste shingles since 2008 and tear-off shingles since 2010; however, use is restricted to dense-graded asphalt mixtures. In 2012, an asphalt producer asked to be allowed to use RAS in Stone-Matrix Asphalt (SMA), which had not been previously permitted by VDOT. This paper examines the impact of RAS on SMA mixture properties and performance.

The mixture evaluated was a 12.5 mm nominal maximum aggregate size SMA produced with a PG 76-22 binder. The control mixture included 15% Reclaimed Asphalt Pavement (RAP). The RAS mixture design incorporated 10% RAP and 5% RAS, resulting in a binder replacement of approximately 29%. Testing performed included volumetric analysis, dynamic modulus, flow number, rut, and fatigue testing of the mixtures.

Test results indicated that for the SMA mixtures evaluated in this study, the inclusion of RAS appears to improve high temperature/low frequency modulus values and rutting resistance. The inclusion of RAS had mixed effects on the mixture performance in laboratory fatigue testing. Additional testing is required to determine if in-service cracking or fatigue performance is significantly or practically affected. In general, additional evaluation is recommended to allow a better understanding of the impact of RAS use.

Keywords: Recycled Asphalt Shingles (RAS), Reclaimed Asphalt Pavement (RAP), Stone-Matrix Asphalt (SMA), performance testing

1 INTRODUCTION

Highway agencies have been using increasing amounts of reclaimed and recycled materials over the past number of years, as asphalt prices have continued to rise. The primary reclaimed and recycled materials used in asphalt materials are Reclaimed Asphalt Pavement (RAP) and Recycled Asphalt Shingles (RAS).

RAP has commonly been used in asphalt mixtures since the late 1970s. The use of RAS is more recent, having been introduced in the late 1980s and early 1990s [1–3]. However, with the introduction of Superpave in the 1990s, recycling became less prevalent as agencies learned to deal with a new design framework that was not particularly optimized for recycled materials. However, with increasing material prices and a greater emphasis on environmental stewardship, the interest in using increased amounts of these materials has grown rapidly. Recently, a large number of studies have investigated the increasing quantities of recycled and reclaimed material in asphalt mixtures, specifically RAP [4, 5] and RAS [6].

The Virginia Department of Transportation (VDOT) specifications for asphalt paving mixtures allow the use of up to 30% RAP in dense-graded surface mixtures. The percentage of RAP allowed in Stone-Matrix Asphalt (SMA) mixtures is dependent upon the binder type specified for the mixture: up to 20% when PG 70-22 binder is used; and up to 15% when PG 76-22 binder is used. In addition, the specifications allow up to 5% by weight of mixture of either post-consumer waste RAS or manufacturing waste RAS in dense-graded asphalt

mixtures. The percentage of binder contributed by the RAP or RAS or combination thereof must not exceed 30% of the total binder content of the mixture. Currently, the specifications do not allow the use of RAS in SMA mixtures; however, the effect of such use is being investigated through the mixtures evaluated in this study and other projects.

2 PURPOSE AND SCOPE

This study was initiated to evaluate the laboratory performance of two plant-produced SMA mixtures that incorporated 10% RAP and 5% RAS into the mixture. Testing included volumetric analysis, dynamic modulus, and flow number testing; rutting analysis using the Asphalt Pavement Analyzer (APA); and fatigue analysis. The results of the testing of these mixtures were compared with those for a plant-produced control SMA mixture that included 15% RAP. All mixtures were sampled at the plant during production, and all test specimens were produced in the laboratory.

3 MATERIALS AND METHODS

All mixtures were produced by the same contractor using the same source materials; however, mixture RAS A was produced in a different drum plant than mixtures RAS B and RAP Control. Mixture designs are shown in Table 1. Loose mixture samples were collected at the plant during production to provide materials for this study.

3.1 *Volumetrics*

Volumetric analyses were performed to determine fundamental mixture properties. Data collected included asphalt content and gradation; bulk and Rice specific gravities (G_{mb} and G_{mm});

Table 1. Mixture designs.

3.2 *Dynamic modulus*

Dynamic modulus tests were performed with a Universal Testing Machine (UTM 100) (Industrial Process Controls, Inc. [IPC]) with a 25 to 100 kN loading capacity in accordance with AASHTO T 342 [9]. Tests were performed on 100-mm-diameter by 150-mm-tall specimens. Specimen air void levels of 7 ± 0.5% were obtained for each test specimen with the exception of one mixture, which averaged 8.0% air voids. Five testing temperatures ranging from –10.0ºC to 54.4ºC and six testing frequencies ranging from 0.1 to 25 Hz were used. Tests were conducted starting from the coldest temperatures to the warmest temperatures. In addition, at each test temperature, the tests were performed starting from the highest to the lowest frequency. Load levels were selected in such a way that at each temperature-frequency combination, the applied strain was in the range of 75 to 125 microstrain. All tests were conducted in the uniaxial mode without confinement. Stress versus strain values were captured continuously and used to calculate dynamic modulus. Dynamic modulus was computed automatically using IPC |E*| software. Results at each temperature-frequency combination for each mixture type are reported for three replicate specimens.

3.3 *Flow number*

The flow number test is used as a laboratory test to evaluate the rutting resistance of asphalt mixes. It is generally accepted that the higher the flow number, the lower the rutting susceptibility.

An IPC Universal Testing Machine (UTM 100) with a 25 to 100 kN loading capacity was used to conduct the flow number tests. Testing was performed on 100-mm-diameter by 150-mm-tall specimens having air void levels of 7 ± 0.5% with the exception of one mixture, which averaged 8.0% air voids. Tests were conducted at 54°C, which is based on LTPPBind software that represents the 50% reliability maximum high pavement temperature at locations in central Virginia. A repeated haversine axial compressive load pulse of 0.1 s every 1.0 s was applied to the specimens. The tests were performed in the unconfined mode using a deviator stress of 600 kPa and for two sets of specimens, 206 kPa. The tests were continued for 10,000 cycles or a permanent strain of 5%, whichever came first. During the test, permanent strain (εp) versus the number of loading cycles was recorded automatically, and the results were used to estimate the flow number. The flow number was determined numerically as the cycle number at which the strain rate is at a minimum based on the Francken model. All flow number testing at 600 kPa deviator stress was conducted on specimens previously tested for dynamic modulus. Testing using 206 kPa deviator stress was conducted on additional specimens.

3.4 *Asphalt pavement analyzer rutting analysis*

Rut testing was conducted using the APA and APA-Jr. (Pavement Technologies, Inc.) in accordance with Virginia Test Method 110 [8]. The APA was used to test a set of three replicate beams, and the APA-Jr. was used to test a pair of replicate beams. Other than the number of replicates, there were no differences in the manner in which the testing was performed in the two devices. Beams 75 mm thick by 125 mm wide by 300 mm long were tested at a test temperature of 49°C. Sets of beams were tested simultaneously. A vertical load of 120 lbf was applied through a rubber hose filled with compressed air at a pressure of 120 psi. The loading wheel speed was 2 ft/sec, and a total of about 135 min was required to complete 8,000 cycles of load applications. Total deformation after 8,000 cycles of load applications is considered the total rut depth. The reported test result is the average rut depth for the duplicate beams of each mixture type tested simultaneously.

3.5 *Fatigue analysis*

Four-point flexural beam fatigue tests were performed in accordance with AASHTO T 321 [9] using at least three replicate specimens at three strain levels (minimum total of nine beams) for each mixture type. IPC beam fatigue test equipment was used. All tests were conducted at a single temperature of 20ºC. The tests were conducted in the strain-controlled mode. Applied tensile strain levels ranging from 300 to 600 microstrain were used so that fatigue curves of strain versus number of cycles to failure could be developed. During the test, repeated application of the specified strain was continued until failure occurred in the test specimen. Specimen failure was defined as the number of cycles at which beam stiffness degraded to 50% of the initial flexural stiffness.

4 RESULTS AND DISCUSSION

Volumetric results for all mixtures are shown in Table 2. Most properties were fairly consistent among the mixtures. Mixtures RAS B and RAP Control had slightly low VMA and VTM for the compacted volumetric specimens. Volumetric values compared well with VDOT monitor data (not shown) except for the VMA results, in which case all monitor specimens passed the specification requirements.

G_{mm} = maximum theoretical specific density; VTM = voids in total mix; VMA = voids in mineral aggregate; VFA = voids filled with asphalt; VCA_{mix} = voids in coarse aggregate of mix; FA ratio = fines to asphalt ratio; RAP = reclaimed asphalt pavement; RAS = recycled asphalt shingles.

4.1 *Dynamic modulus*

Dynamic modulus results for all mixtures are shown in Figure 1. It can be seen that at reduced frequencies above approximately 0.1, the mixtures show good agreement in moduli values. At reduced frequencies below approximately 0.1, the RAP Control mixture is less stiff than the RAS mixtures. Despite being produced at different plants, the two RAS mixtures have good agreement in moduli values.

Direct comparisons of the dynamic moduli for the RAS and control mixtures are shown in Figure 2, where the light dashed lines indicate a 20% difference from the line of equality. At moduli values below about 15000 MPa, the RAS mixtures are considerably stiffer than the

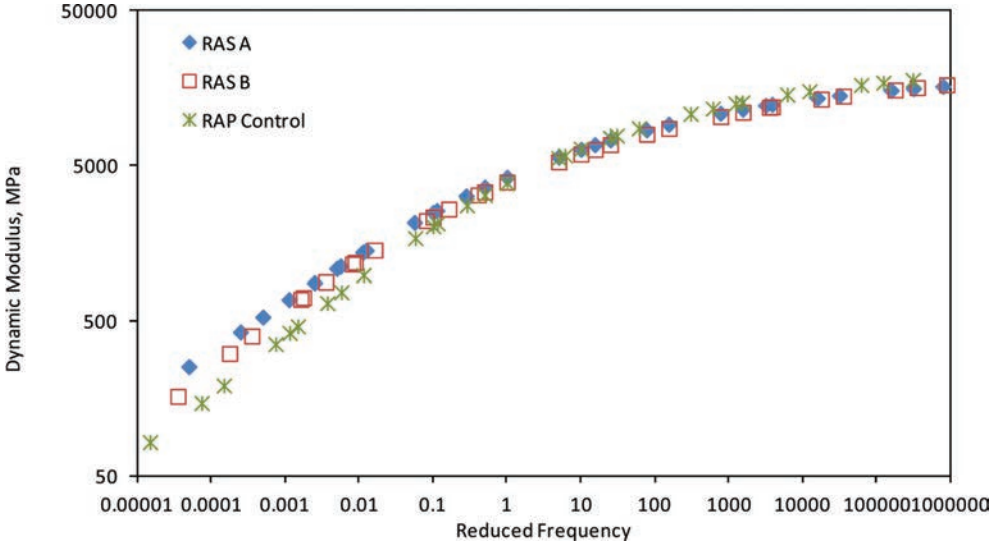

Figure 1. Dynamic modulus versus frequency for all mixtures.

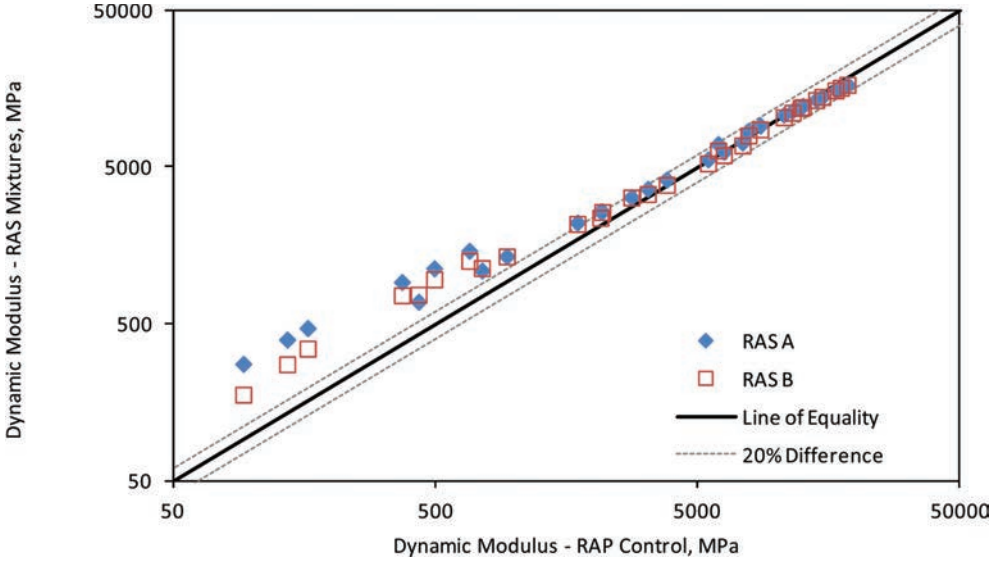

Figure 2. Comparison of modulus values for RAS mixtures versus RAP control mixture.

RAP Control mixture. These values correspond to tests performed at 54.4ºC at all frequencies and the 0.1, 0.5, and 1.0 Hz tests performed at 37.8ºC.

4.2 *Flow number*

Figure 3 presents the flow number values and air void contents for each specimen tested. The percentages at the base of each bar indicate the specimen air void content, and I-bars indicate one standard deviation about the average flow number. All mixtures were tested with a deviator stress of 600 kPa; however, material limitations prevented the testing of mixture 12-1006 at 206 kPa deviator stress. For the 600 kPa testing, the air voids for all specimens were consistent and were well within the acceptable test tolerance of 7.0 ± 0.5% air voids. Both RAS mixtures performed significantly better than the RAP Control mixture in the 600 kPa flow number test. In the 206 kPa deviator stress test, the RAS B mixture still performed better than the RAP Control mixture; however, the difference between the two (as well as the difference between the 600 kPa and 206 kPa tests) was also likely influenced by the difference in air voids, as it can be seen that the RAS B air voids were at the low end of the acceptable range whereas the RAP Control air voids were at the high end (with one specimen exceeding the acceptable tolerance).

4.3 *APA rutting analysis*

Rut testing was performed only on mixtures RAS A and RAS B because of a lack of material for the RAP Control mixture. The rut testing results are summarized in Table 3. Both mixtures rutted significantly less than the maximum VDOT criterion of 4.0 mm for SMA mixtures, despite the fact that the air void contents of all but one specimen were outside the specification requirement of 8.0 ± 0.5%. The rutting performance trend, with the RAS B mixture having a greater rut depth than the RAS A mixture, follows that shown by the flow number and indicates that RAS A mixture should be more rut resistant than the RAS B mixture.

4.4 *Fatigue analysis*

Fatigue testing was performed only on mixtures RAS B and RAP Control because of a lack of material for mixture RAS A. Figure 4 presents the fatigue curves and their regressed k-N

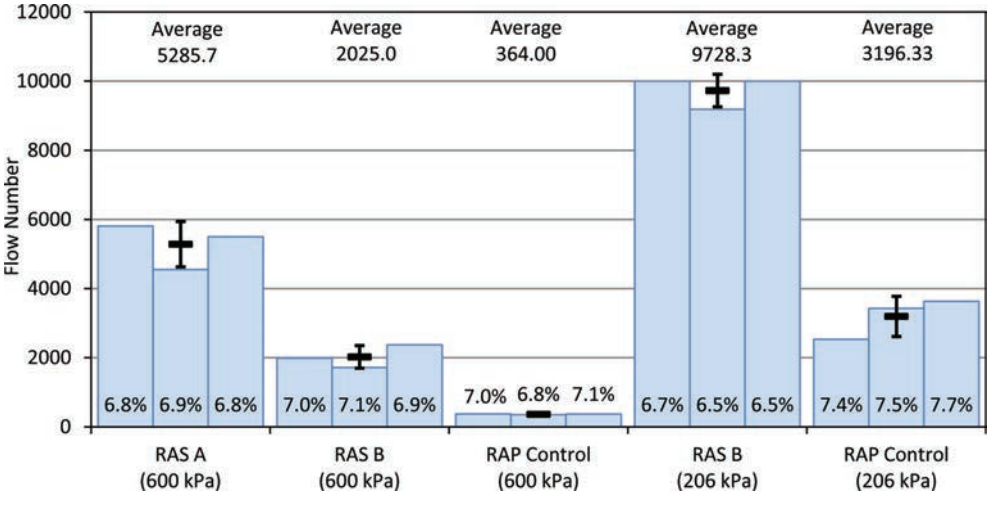

Figure 3. Flow number test results for all specimens. Black bars show average values, and I-bars indicate standard deviation. Specimen air void contents are shown near the base of each column.

Table 3. APA rut data.

	RAS A		RAS B	
Replicate	Air voids, %	Measured rutting, mm	Air voids, %	Measured rutting, mm
1	9.4	0.86	8.5	1.69
2	9.8	1.18	5.2	1.41
3	9.8	0.89	–	–
Average	9.7	0.98	6.9	1.55

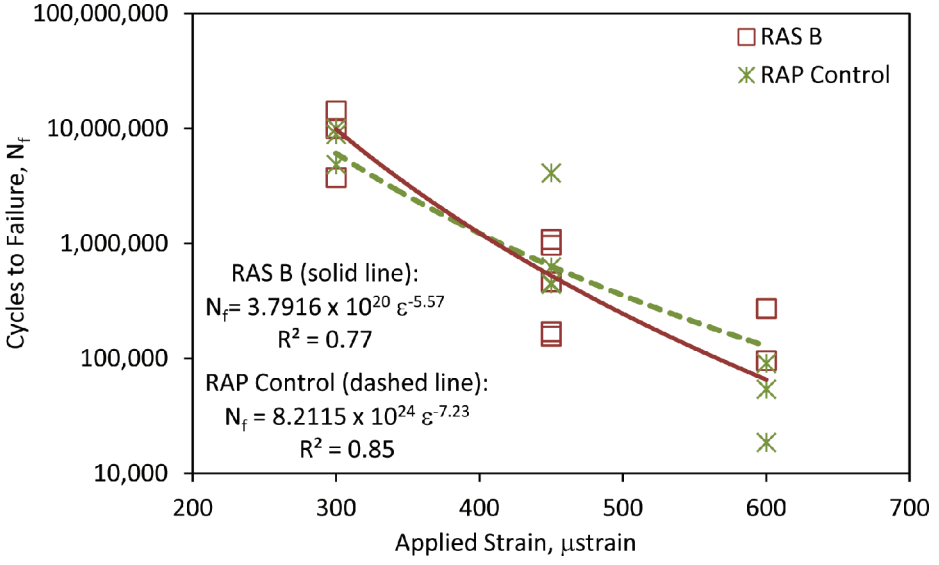

Figure 4. Fatigue curves.

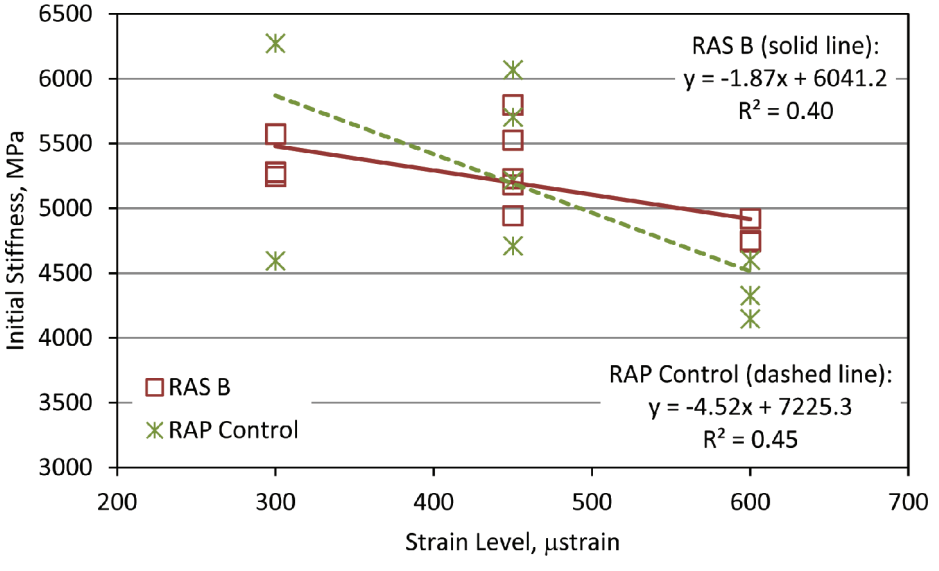

Figure 5. Applied strain versus initial stiffness for all fatigue specimens.

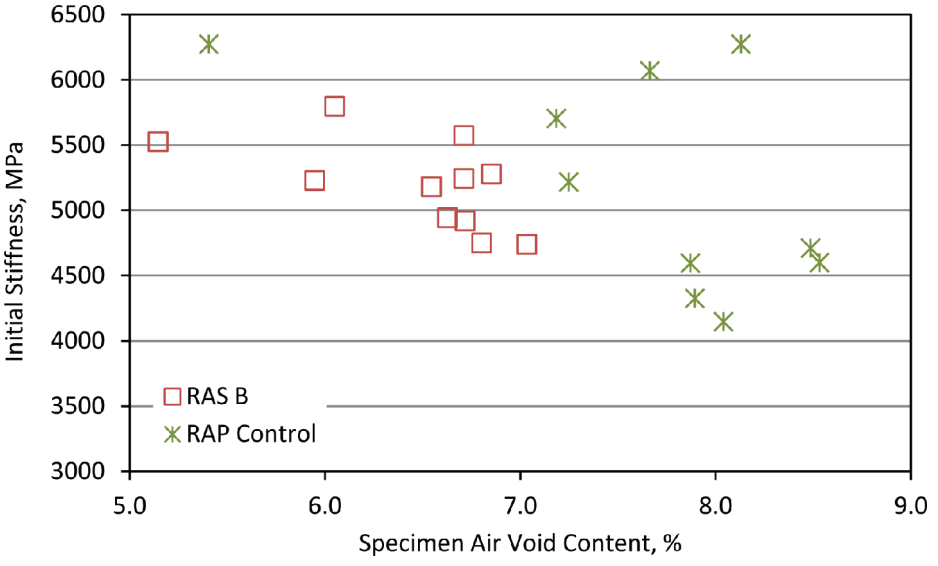

Figure 6. Specimen air void content versus initial stiffness for all fatigue specimens.

equations. The slope of the RAS B curve is greater than that of the RAP Control curve, indicating that at applied strains above approximately 400 microstrain, the RAS B mixture is expected to fail in fatigue sooner than the control mixture. Using the regressed k-N equations for each mixture and assuming a fatigue life of 50 million cycles, the fatigue endurance limit can be calculated to be 262 microstrain and 244 microstrain for the RAS B and RAP Control mixtures, respectively, indicating that under low applied strain loading, the RAS B mixture will outperform the RAP Control mixture.

In addition to the regression analysis of the fatigue data, the test results were investigated to determine if the initial stiffness of each mixture was particularly sensitive to applied strain level or specimen air void content. These results are shown in Figures 5 and 6. Figure 5 indicates a slight relationship between the applied strain and initial stiffness, although with R^2 values of only 0.40 and 0.44 for the RAS B and RAP Control mixtures, respectively, these relationships are not substantial. Figure 6 shows very little correlation in this study between the specimen air void contents and initial stiffness, with both data sets having R^2 values less than 0.35.

5 FINDINGS AND CONCLUSIONS

Based on the results of this study, the following findings are offered:

- RAS can successfully be incorporated into the design and production of SMA mixtures.
- The inclusion of RAS increased the stiffness and modulus of SMA mixtures at higher test temperatures and lower test frequencies. Very little effect on modulus was seen at temperatures below 37.8ºC.
- The inclusion of RAS significantly increased the rutting resistance of SMA mixtures as measured by the flow number test. The APA rut test indicated the same trend of rut resistance between the two RAS mixtures seen in the flow number results.
- The inclusion of RAS may adversely affect the fatigue resistance of SMA mixtures depending on the applied strains. However, this finding is based on laboratory testing of only two mixtures and additional mixtures should be evaluated both in the laboratory and in service to determine the extent to which this may affect in-service mixtures.

In conclusion, for the SMA mixtures evaluated in this study, the inclusion of RAS appears to improve high temperature/low frequency modulus values and rutting resistance as meas-

ured by the flow number test. This is likely to result in improved mixture performance and durability under conditions of heavy slow loading, such as with rest areas and truck climbing lanes, although in-service monitoring is recommended to verify this conclusion. The inclusion of RAS adversely affected the mixture performance in laboratory fatigue testing. Additional testing is required to determine if the in-service cracking or fatigue performance is significantly affected. In general, additional evaluation of RAS-containing SMA mixtures is recommended to allow a better understanding of the impact of RAS use.

ABSTRACT: Induction heating of asphalt concrete is accomplished by adding electrically conductive particles to the asphalt mixture, and heating them with an induction heating device. When the temperature of the asphalt concrete is higher than 30–70 °C, cracks may start closing. In this article, the healing properties of 25 different mixtures, with the same aggregates distribution and amount of bitumen, but with 2 different lengths, 4 different quantities, and 4 different diameters of steel wool fibers have been considered. It has been found that the asphalt concrete studied can be healed up to 60% and that healing happens when the temperature is higher than 50 °C. Additionally, asphalt healing versus the increase of temperature has been fitted through an equation based on the capillary theory, showing that capillary flow is the main parameter affecting asphalt healing at high temperature.

Keywords: Healing asphalt concrete, induction heating, capillary flow

1 INTRODUCTION

Bitumen starts behaving like a Newtonian fluid at temperatures ranging from 30 °C to 70 °C, depending on the type of bitumen [1–4] (T_{newt}). Above these temperatures, bitumen may start flowing through any possible crack open in the pavement, in a sort of capillary flow [5]. This may happen naturally when the temperature is high enough, for example during summer, although it can be also promoted artificially by induction heating [6–9] or by microwave heating [10].

Induction heating of asphalt concrete is a technique that consists in heating electrically conductive particles, for example, steel wool fibers, previously mixed into the asphalt concrete mixture [7, 8]. Then, with the help of an induction heating device, it is possible to heat the particles locally and, through heat diffusion, heat the binder and heal the cracks.

The objective of this research is to find out the inductive healing properties of dense asphalt concrete. Asphalt healing via induction heating has been demonstrated for asphalt mastic and for porous asphalt concrete, although the influencing factors have not yet been quantified [5]. Moreover, until now, it is not clear how induction heating will affect the healing properties of dense asphalt concrete. With this purpose, 25 different asphalt concrete

mixtures, with the same aggregate distribution and amount of bitumen, but with 2 different average lengths of fibers, 4 different fiber contents, and 4 different diameters of steel wool have been prepared and their healing properties have been analysed. Moreover, a model has been explained and the healing properties of asphalt concrete explained.

2 EXPERIMENTAL METHOD

2.1 *Materials*

A dense asphalt concrete mixture was used in this research. The mixture composition is shown in ref. [11]. The aggregates consisted of crushed basaltic material (size between 0.063 mm and 11 mm) and limestone filler (size < 0.063 mm). Virgin bitumen 70/100 pen was used.

Additionally, steel wool fibers were added to the mixture. These fibers had 4 different diameters, 0.02855 mm, 0.03642 mm, 0.08389 mm and 0.15498 mm and an average length after mixing and compacting of approximately 1.5 mm. Finally, 4 different amounts of fibers were used: 0%, 2%, 4% and 6%, by total volume of bitumen in the mixture.

2.2 *Test specimens preparation*

The amount of material in each mixture was approximately 16 kg. 16 kg materials were first heated to 160 °C and then mixed in a laboratory planetary mixer, at a mixing speed of 312 rpm, during approximately 5 minutes. After the mixing, the mixtures were conditioned for 12 hours in an oven at 160 °C. This was done to simulate extreme bitumen ageing conditions.

The 16 kg batch was used to prepare specimens of 12 cm × 5 cm × 5 cm. Additionally, a 3 mm wide and 8 mm deep notch was created in the middle of the test samples. These test specimens had air void content between 4% and 10%.

2.3 *Temperature and induction heating measurements*

The temperature change in the asphalt concrete test samples was measured with a 640 × 480 pixels, infrared camera. The induction heating experiments were performed with a 30 kW induction heating generator at a maximum frequency of 78 kHz. The air temperature during the process was 20 °C.

In this research the total temperature of the 12 cm × 5 cm × 5 cm specimens has been calculated as an average between the temperature at the bottom of the test sample and the temperature at the top surface, after 1 minute heating. Moreover, the Newtonian cooling constants (ξ) of the 25 cm × 25 cm × 5 cm test specimens were calculated by observing their cooling rates during 20 minutes. The average value of the Newtonian cooling constants for all the mixtures was 0.0055 $(m^2 \cdot s)^{-1}$ and their standard deviation was 0.0012 $(m^2 \cdot s)^{-1}$.

2.4 *Bitumen rheology*

The asphalt binder of the mixtures was recovered by rotary evaporator in order to determine the temperature when Newtonian behaviour occurs. With this objective, the dynamic shear properties of bitumen were measured with a dynamic shear rheometer in a configuration with 25 mm diameter parallel plates, with a 1 mm gap. Oscillatory frequency sweeps were carried out over a range of 0.001 Hz to 0.1 Hz at temperatures from 30 °C to 70 °C under a constant strain of 0.1% within the linear viscoelastic region. The complex viscosity (η^*) as a function of frequency (ω) at different temperatures was recorded automatically during the tests.

2.5 *Healing measurements*

Induction healing of the asphalt concrete prismatic specimens was done as follows: first the tests specimens were numbered; then, they were randomly selected for heating during 0.5 minutes, 1 minute, 1.5 minutes, 2 minutes and 2.5 minutes, respectively. Later, they

were tested under three-point bending configuration at –20 °C at a deformation rate of 0.5 mm/min, stopping the tests when the force in the discharge curve of the beams reached 20 N. This load was enough to produce a crack of approximately 200 μm width crossing the specimen from the tip of the notch to the load application point. In this research, it was found that the average 3-point bending strength of the beams was 6.61 kN and the standard deviation 0.75 kN.

Once cracks were created, the test specimens were let to rest during 2 hours at 20 °C and heated during the time selected. Finally, the test samples were tested again under three-point bending. The healing level ($S(\tau)$) of asphalt mastic was defined as the relationship between the ultimate force of the test specimens during a three point bending test, F_0, and the ultimate force measured in the beams after the healing process $F_b(\tau)$, where τ is a parameter that gives an idea of the amount of energy in the asphalt concrete test sample during the healing process:

$$S(\tau) = \frac{F_b(\tau)}{F_0} \tag{1}$$

3 THEORETICAL BACKGROUND

3.1 *Temperature evolution of the test samples*

Healing does not happen only during the time induction heating, but also during the cooling time, as long as the temperature of asphalt concrete is above T_{newt} (see coloured area in Fig. 1). With this in mind, the cooling of a hot body can be described by the Newton's law of cooling [14]:

$$\frac{dQ}{dt} = \alpha A\left(T_{air} - T\right) \tag{2}$$

where Q is the thermal energy, α is a heat transfer coefficient, taken constant as a simplification, A is the surface area across which the heat is being transferred, T is the temperature of the asphalt surface and T_{air} is the temperature of the environment.

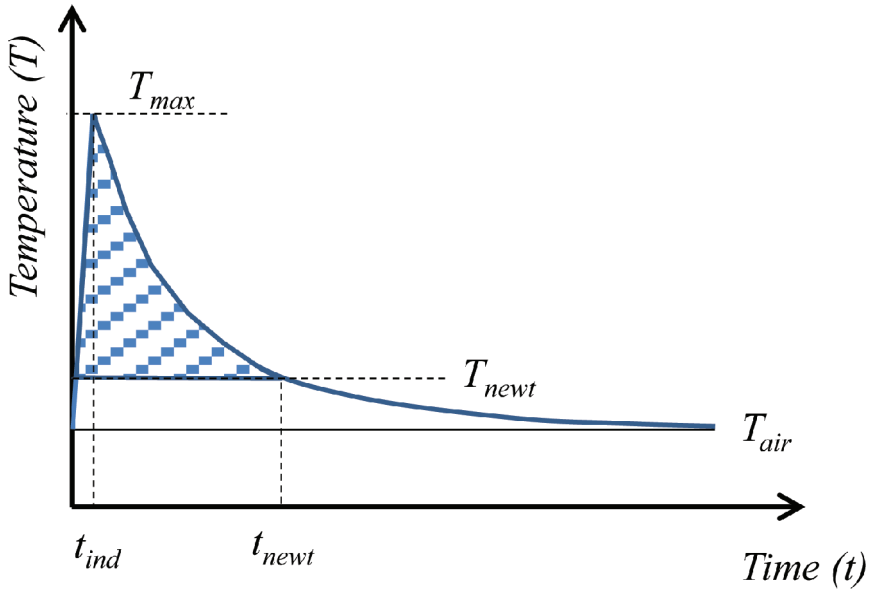

Figure 1. Temperature changes in dense asphalt concrete due to induction heating [12].

If the temperature T of the asphalt concrete surface is higher than the environmental temperature T_{air}, asphalt concrete will lose an amount of heat dQ in a time interval between t and $t + dt$, reducing its temperature T by dT.

$$dQ = -mcdT \tag{3}$$

where m is the mass of asphalt concrete and c is its specific heat.

The equation that shows the change in temperature as a function of time is

$$-mc\frac{dT}{dt} = \alpha A\left(T_{air} - T\right) \tag{4}$$

Integrating this equation, knowing that at time $t = 0$ s, the temperature of asphalt concrete will be T_{max} and introducing ξ to α/mc (m^{-2} s^{-1}), one obtains

$$\int_{T_{\max}}^{T} \frac{dT}{T_{air} - T} = -\xi A\int_{0}^{t} dt \tag{5}$$

and therefore

$$\ln\left(T - T_{air}\right) = -\xi A\cdot t + \ln\left(T_{\max} - T_{air}\right) \tag{6}$$

Hence, the time (T_{newt}) until the temperature of the test sample equals T_{newt}, i.e. when healing will be stopped is

$$t_{newt} = \frac{\ln\left(T_{\max} - T_{air}\right) - \ln\left(T_{newt} - T_{air}\right)}{\xi A} \tag{7}$$

With this in mind, the total time when the temperature of the test sample is above the environment temperature reads

$$t = t_{ind} + t_{newt} \tag{8}$$

where t_{ind} is the time of induction heating and t_{newt} is the time until the test sample comes back to the original temperature.

As the time of induction heating is very small (less than 2.5 minutes) compared to the total time when the temperature of the sample is above T_{newt} (can be more than 500 minutes), it can be eliminated from the equation, and the time healing can be approximated with Eq. (7) alone.

Finally, by solving T in Eq. (6),

$$T = T_{air} + \left(T_{\max} - T_{air}\right)e^{\left(-\xi A\, t\right)} \tag{9}$$

the area below the cooling curve (coloured area in Fig. 1), between $t = 0$ and $t = t_{newt}$, can be calculated:

$$\tau = \frac{T_{air}\xi A t_{newt} - \left(T_{\max} - T_{air}\right)\left(e^{\left(-\xi A t_{newt}\right)}\right)}{\xi A} - T_{newt}t_{newt} \tag{10}$$

This parameter will be called tau (τ) from now, its units are K · s and gives an impression of the total amount of heat in asphalt concrete during the healing process.

3.2 *Asphalt self-healing theory*

The capillary phenomena can be studied through a modification of the Lucas-Washburn equation [13] (see Fig. 2). As a simplification, in this research the crack has been assumed circular and vertical. The main forces that act in the crack are due to the surface tension (F_t),

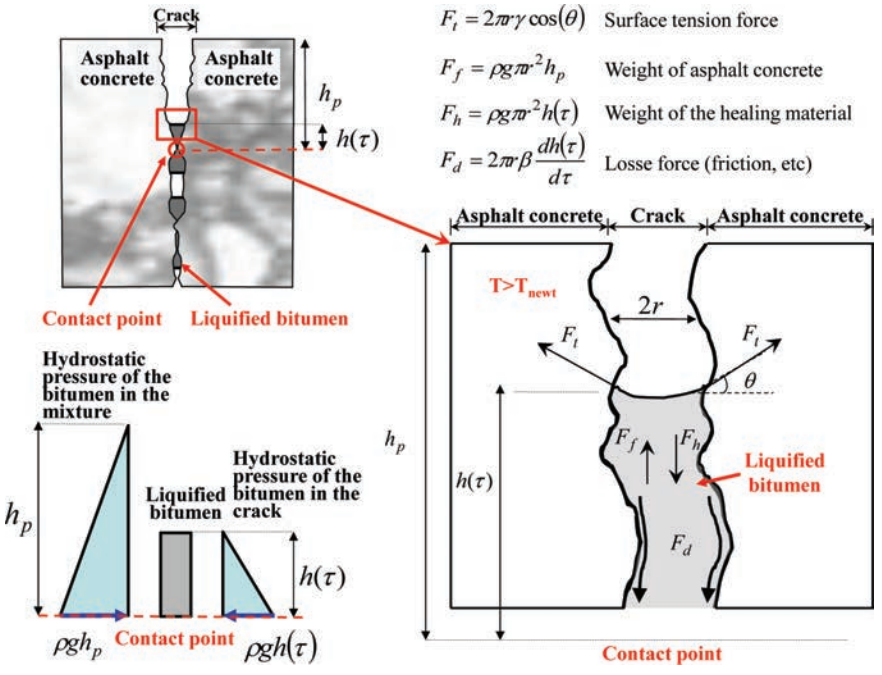

Figure 2. Scheme of the forces acting in an asphalt concrete crack during the healing process [12].

$$F_t = 2\pi r\gamma\cos(\theta) \tag{11}$$

where r is the capillary radius or half the crack width in this case; γ is the surface tension of the liquid and θ the contact angle in the wetting front. The contact angle is not constant, but will vary with the healing rate and with the different materials in the composite. To simplify the model, the contact angle has been assumed constant, and $\cos(\theta)$ equal to 1 in the calculations. Additionally, the force exerted by gravity (F_g) is considered in this model as the hydrostatic force in the zone where the binder is flowing into the crack (F_f) minus the force exerted by the weight of the healing material in the crack (F_h):

$$F_g = F_f - F_h = \rho g\pi r^2\left(h_p - h(\tau)\right) \tag{12}$$

where $\rho g\pi r^2 h_p$ is the positive hydrostatic force in the crack, being ρ the density of the binder, g the gravity and h_p the distance from the beam surface to the bottom of the healed zone being considered and $\rho g\pi r^2 h(\tau)$ the weight of the healed zone, which depends on the τ parameter. In this case, h_p is an artificial reference point which represents the distance of the crack to the surface. It is variable in time for each healed zone, but constant and equal to the height of the specimen (H) (see Fig. 2) when the whole length of the crack is being considered.

Moreover, a dissipation parameter β can be introduced in order to take into account possible sources of energy dissipation during healing, for example the force of friction by the movement bitumen against the crack faces (F_d):

$$F_d = 2\pi r\beta\frac{dh(\tau)}{d\tau} \tag{13}$$

With this in mind, the equation obtained by balancing the surface tension force, the gravity force and the energy dissipation force is:

$$2\pi r\left(\gamma - \beta\frac{dh(\tau)}{d\tau}\right) = \rho g\pi r^2\left(h(\tau) - h_p\right) \tag{14}$$

And the analytical solution for Eq. (14) is given by

$$h(\tau)=\left(h_p+\frac{2\gamma}{\rho gr}\right)\left(1-e^{-\frac{\rho gr\tau}{2\beta}}\right) \tag{15}$$

As the speed at which this process will happen will be constant in all directions, the effective area ($A_E(\tau)$) in the broken beam after some time heating, assuming a certain number of contact points (n) from where the healing process may happen, will be:

$$A_E(\tau)=\int_0^{\tau}2\pi nh(\tau)dh(\tau)=\frac{\rho grn}{2\beta}\left(h_p+\frac{2\gamma}{\rho gr}\right)^2\int_0^{\tau}\left(1-e^{-\frac{\rho gr\tau}{2\beta}}\right)e^{-\frac{\rho gr\tau}{2\beta}}d\tau \tag{16}$$

Solving the equation

$$A_E(\tau)=C\cdot e^{-D\tau}\left(-1+e^{\frac{D\tau}{2}}\right)^2, \tag{17}$$

where

$$C=\pi n\left(h_p+\frac{2\gamma}{\rho gr}\right)^2 \tag{18}$$

and

$$D=\frac{\rho gr}{\beta} \tag{19}$$

3.3 *Mechanical resistance estimation*

At the beginning of the healing, even when both faces of the crack are very close to each other, they are not completely in contact, only in certain points, randomly distributed through the crack. This means that for a complete recovery, the binder has to flow through these empty spaces and that healing will extend from the contact points through the crack.

After some time of healing (τ), during the three points bending tests, the maximum momentum ($M_F(\tau)$) in the middle of the beam is:

$$M_F(\tau)=\frac{F_b(\tau)\cdot L}{4} \tag{20}$$

where $F_b(\tau)$ is the force carried by the beam after some time heating and L is its span.

In addition, the maximum tension in the sample (σ_u), before breaking after some time of heating is given by:

$$\sigma_u=\frac{M_F(\tau)\cdot H}{2\cdot I(\tau)} \tag{21}$$

In this equation, σ_u is the maximum resistance capacity of the material, H is the height of the specimen, assuming that asphalt concrete cracks heal uniformly. Moreover, $I(\tau)$ is the moment of inertia for the area $A_E(\tau)$ given by (16):

$$I(\tau)=Ce^{-D\tau}\left(-1+e^{\frac{D\tau}{2}}\right)^2 \tag{22}$$

In addition, the force the beam resists after some specific time heating can be obtained by inserting Eq. (22) and Eq. (20) in Eq. (21),

$$F_b(\tau) = C_1 \cdot e^{-D\tau}\left(-1 + e^{\frac{D\tau}{2}}\right)^2, \tag{23}$$

where C_1 is

$$C_1 = 8\frac{\sigma_u \cdot C}{L \cdot H}, \tag{24}$$

Finally, substituting Eq. (23) in Eq. (1) leads to the following equation representing the healing level:

$$S(\tau) = \frac{C_1}{F_0} \cdot e^{-D\tau}\left(-1 + e^{\frac{D\tau}{2}}\right)^2. \tag{25}$$

4 RESULTS AND DISCUSSION

4.1 *Rheological properties of the bitumen extracted from dense asphalt concrete*

Figure 3 (a) shows the effect of frequency on the complex viscosity (η^*) of the extracted bitumen at different temperatures. To analyse the deviation of the bitumen behaviour from Newtonian, the rheological data were fitted through the following power law relationship [15]:

$$\eta^* = m \cdot |\omega|^{n-1}. \tag{26}$$

where ω is the frequency and η^* is the complex viscosity, with m and n denoting the fitting parameters. $n = 1$ corresponds to a Newtonian fluid and $n < 1$ reflects a higher degree of pseudoplastic properties of the fluid. In this study the bitumen properties were considered Newtonian when the flow behaviour index was higher than 0.9. This transition from $0.9 \leq n < 1$ is also known as near-Newtonian behaviour [16].

In Figure 3 (a), it can be seen that at the higher testing temperatures this bitumen presents a near-Newtonian behaviour, where the complex viscosity is relativity independent of the applied shear frequency. In contrast, at lower temperatures, the complex viscosity decreases with increasing frequency, exhibiting shear-thinning behaviour (pseudoplasticity).

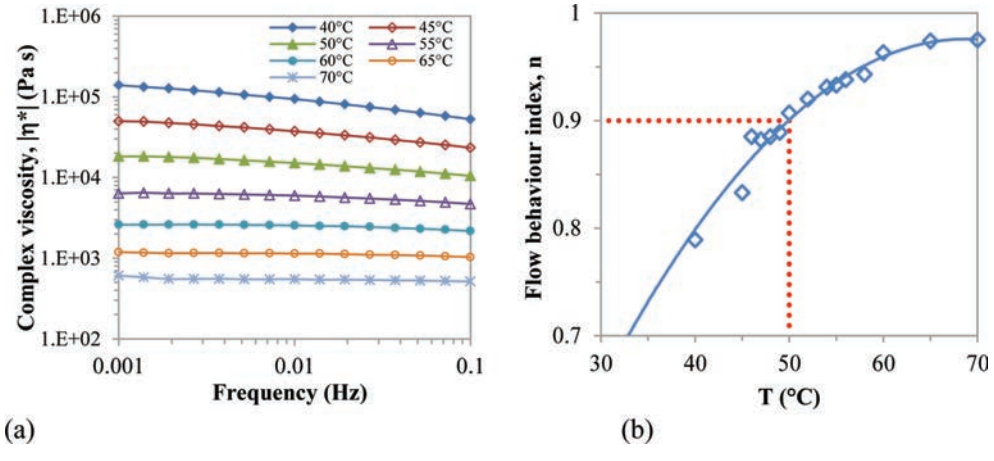

Figure 3. (a) Complex viscosity (η^*) as a function of shear frequency at temperatures from 40 °C to 70 °C and (b) flow behavior index (n) at different temperatures [12].

Moreover, the flow behaviour indexes (n) obtained at different temperatures are plotted in Figure 3 (b). It can be observed that the flow behaviour index increased with increasing temperature, getting close to 1 (ideal Newtonian behaviour). Hence, it can be concluded that the tested bitumen behaves like a near-Newtonian fluid at temperatures above 50 °C. This transition temperature is associated to the type of bitumen and ageing level, varying for other bitumens and ageing states.

4.2 *Asphalt healing results*

In Figure 4, the healing level of asphalt concrete versus the average temperature of the test samples is shown. All results obtained from different test samples, with different percentages and diameters of steel wool are shown. One of the most remarkable points is that all results for the different materials align in a single curve. In Figure 4, it can be observed that the healing, so as the point dispersion, starts at approximately 50 °C, when bitumen has a near-Newtonian behaviour. From this point, the healing levels increase with the temperature in the test samples until approximately 0.6, which happened at around 100 °C.

Since the test samples were heated without a mould, their shape changed constantly with temperatures above 50 °C. Therefore, the healing levels could not be 1, as in reference [5], where the test samples were contained in the same moulds where they had been made. Besides, these results are lower than those in reference [17] for porous asphalt concrete, where the highest healing levels reached approximately 0.8. A higher healing level was not reached because the geometry of these test samples was different. Additionally, to improve the understanding of the data, the healing results have been filtered by using a moving average filter (see solid points in Fig. 4).

Moreover, in Figure 1, the healing levels versus the τ parameter and the fitting corresponding to Eq. (25) are shown. For the fitting, only data at a temperature higher than near-viscoelastic threshold have been considered. The fitting by the model is relatively good, with an R^2 coefficient of 0.949, a maximum error of 0.1167 and an average error of 0.037. From the fitting of the equation, the maximum healing level possible with this material is approximately 0.60. This value is lower than others reported in previous researches [5] and may be caused by the different test samples geometries during healing. For future work it

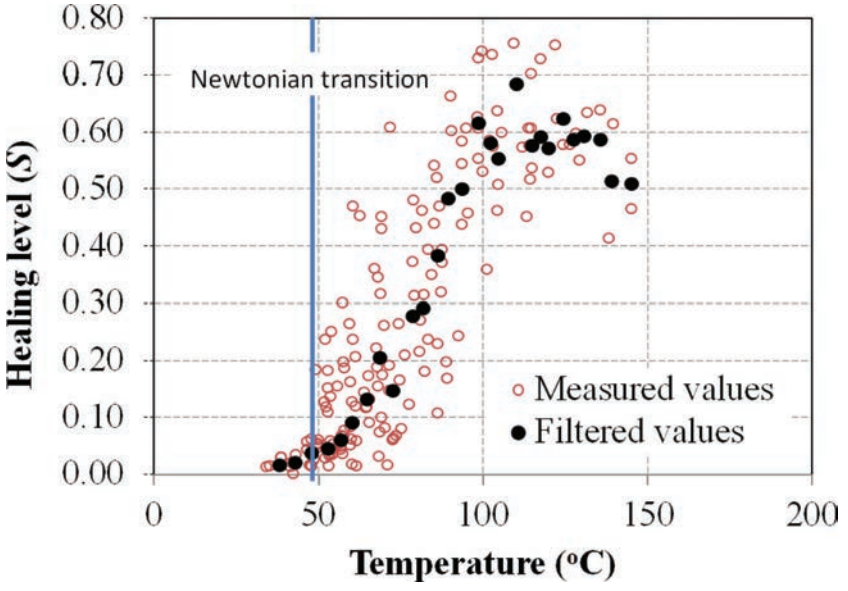

Figure 4. Healing data versus average temperature in the test samples [12].

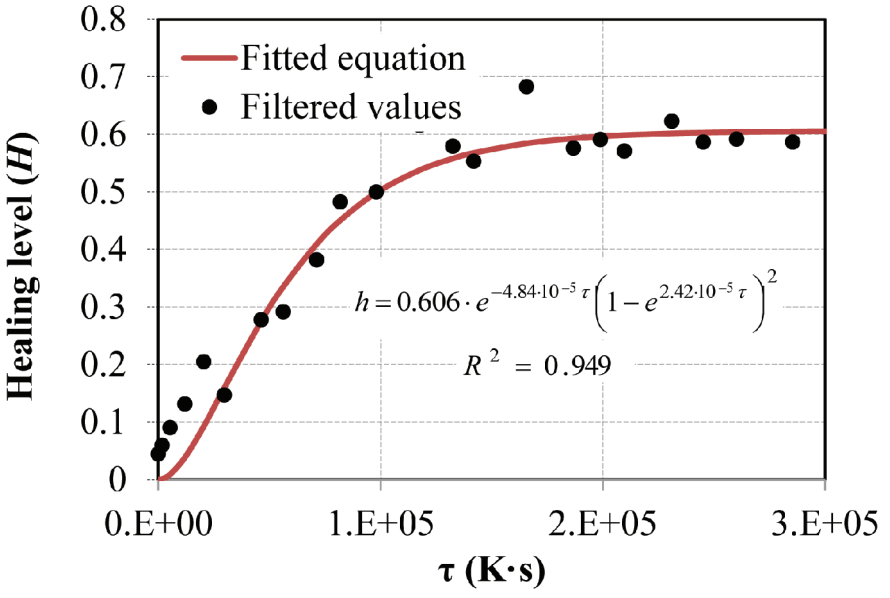

Figure 5. Healing level versus τ parameter and fitted equation [12].

will be very important to standardize a method for measuring the healing levels of asphalt concrete.

From these data, and after comparing them with those presented in reference [5] it can be concluded that the most appropriate way for healing asphalt concrete is to increase and maintain the temperature above the Newtonian transition (see Fig. 4) for a certain amount of time. If the temperature is very high during a long time, healing levels can be reduced [5], and if the temperature is too low, healing will not occur. For this reason, an optimum asphalt concrete material for self-healing applications should have a thermal conductivity as low as possible, such that the energy is not easily dissipated in the environment. With this, healing may happen at lower temperatures and the global efficiency of the system will be increased.

5 CONCLUSIONS

This article showed the effect of induction heating on the healing of damaged test samples of dense asphalt concrete. It has been found that the healing rates of dense asphalt concrete increase with increasing temperature.

Besides, the mechanical resistance of the test samples could be recovered up to 60% at around 100 °C. To reach a certain healing level, it is necessary to heat the samples above a certain temperature. If the heating time is less, damage will not be fully recovered.

Moreover, the healing recovery of dense asphalt concrete depends on the capillary flow of bitumen through the crack. This occurs above a certain temperature, in this case 50 °C, which corresponds to the near-Newtonian behaviour temperature. From the model deducted from the Lucas-Washburn equation and from the experimental results, it can be concluded that for the same bitumen and aggregates in a crack with constant width, healing recovery will depend only on the average temperature reached in the asphalt concrete specimen.

For this reason, the most appropriate way for healing asphalt concrete is to increase the temperature above the Newtonian transition and maintain it for a certain amount of time. Hence, asphalt concrete material should have a very low thermal conductivity, so that the energy is not easily dissipated in the environment.

A limitation of the model explained in the article is that it does not consider the cases where the total amount of energy introduced in the asphalt concrete is too high, i.e. at a level where the structure of asphalt concrete can be destroyed. Moreover, it is still unclear which is the exact amount of heat necessary for healing a crack in asphalt concrete, as with the induction heating method, the whole asphalt concrete volume, including the undamaged volumes are being heated.

ABSTRACT: Cement Asphalt Emulsion Composites (CAEC) are mixtures of bitumen emulsion, cement, water and aggregates that harden at ambient temperature. They are mixed at ambient temperature and harden due to breaking of the emulsion, water evaporation and cement hydration. Potential advantages of CAEC are lower temperature susceptibility than asphalt concrete and higher flexibility than cement concrete. To quantify the effects of cement hydration on the mechanical properties of CAEC, two different emulsions (cationic and anionic) mixed with either 0%, 3% and 6% Ordinary Portland Cement (OPC) by mass of dry aggregates were studied by isothermal calorimetry and Marshall tests. By monitoring the mass of the specimens and estimating the amount of water bound by the cement, the water content was calculated. This study shows that bitumen emulsion has no significant effect on the degree of cement hydration. Cement hydration, however, significantly contributes to the hardening of CAEC. Moreover, a higher amount of cement added to the mixture results in a higher amount of bound, adsorbed and capillary water in the CAEC.

Keywords: CAEC, bitumen emulsion, Portland cement, isothermal calorimetry

1 INTRODUCTION

Cold mix asphalt consists of bitumen emulsion, water, unheated aggregates and filler. This material has low environmental impact and is cost-effective [1–3]. However, it has rarely been used as structural layer for heavy-duty pavements [2,3], mainly because of the long time (several weeks) required to reach its full strength [4], resulting in inadequate performance (inferior early strength and high porosity) compared with conventional Hot Mix Asphalt (HMA) [3,5,6].

In order to improve the early performance of cold mix asphalt, cement can be added to the mixture. The addition of 1% to 2% wt. of Ordinary Portland Cement (OPC) to cold mix asphalt may improve its early-life mechanical properties [7] and the fully cured material acquires comparable mechanical properties to an equivalent HMA [3,8,9]. Research on these

composite materials, often called CAEC (Cement-Asphalt Emulsion Composite) [10,11], started in the 1970s. CAEC shares characteristics of both cement and asphalt concrete [12]. In particular, compared with HMA, CAEC has higher deformation resistance, lower temperature susceptibility [10], and better resistance to water damage [11]. Additionally, the introduction of cement in cold mix asphalt accelerates emulsion breaking [5], because cement hydration consumes water in the emulsion and meanwhile it increases its alkalinity. This has a special impact when a cationic bitumen emulsion is used [13]. However, because of the long time required to reach its full strength and an inadequate understanding of this material, CAEC has rarely been used in pavements.

This research aims at obtaining a general perspective of CAEC. It focuses on OPC hydration and on water evaporation and their contribution to the mechanical properties of CAEC. With this purpose, two emulsions, one cationic and one anionic, have been mixed with Ordinary Portland Cement (OPC) in various amounts (0%, 3% and 6% by total mass of aggregates) and with aggregates to prepare CAEC. The evolution of the mechanical properties of the mixture with time was characterized with Marshall Stability tests. The effect of emulsion on the cement hydration has been investigated by means of Isothermal Calorimetry tests. Finally, the evolution of water content in CAEC has been quantified to characterize the hardening of the mixture.

2 MATERIALS AND METHODS

2.1 *Materials*

A dense CAEC mixture (0/8) was used in this research [14]. The aggregates used to make CAEC were quarry material (size between 2 and 8 mm and density 2770 kg/m^3), crushed sand (size between 0.063 and 2 mm and density 2688 kg/m^3), and filler (size < 0.063 mm and density 2638 kg/m^3). The total amount of filler in the mixture was 6% by mass of dry materials (aggregates + filler). Two types of commercially-available unmodified bitumen emulsion, with 60% of residual bitumen content, were used in this paper. The first one was a rapid-setting cationic emulsion, while the second one was a solvent-free, slow-setting anionic emulsion (Table 1). Additionally, to facilitate the mixture preparation, 2.52% wt. (by dry aggregates) tap water was added to the mixture. Ordinary Portland Cement (OPC) CEM I 42.5 N (chemical analysis and phase composition shown in Table 2) was added to the mixture, by replacing 0%, 3% and 6% (all filler replaced) of filler. Table 3 shows the mix compositions. In this paper, OPC designates ordinary Portland cement; 3 and 6 represent 3% and 6% cement by mass of dry aggregates, and A and C denote anionic and cationic bitumen emulsion, respectively. An example is OPC3C-7d, a cationic bitumen emulsion with 3% OPC by mass of dry aggregates 7 days after compaction.

2.2 *Test specimens preparation*

The raw materials were added to the bowl in this order: first the coarse aggregates, then water and emulsion, then the sand and finally the filler and cement. The materials were mixed during 1 minute. The temperature during the mixing process was 20 ± 1°C. One mix was used to make 9 cylindrical Marshall specimens with 101.6 mm diameter, approximately 7 cm height and 1190 g of mass. Immediately after placing the specimens in the mould, they were compacted with 100 blows of the Marshall hammer, 50 for each side of the specimens.

			0	5.04	6

[a]Percentage of cement by mass of dry aggregate.

The specimens, still in the moulds, were left in a humidity-controlled room (relative humidity 90 ± 3% and temperature 20 ± 1°C) for one day. After this, the test samples were demoulded and the lateral and bottom surfaces were sealed with aluminum foil. Then, the specimens were left in the humidity-controlled room during the required curing time: 1, 3, 7, 14, 21 and 28 days. During the curing period, water in the specimens could evaporate from the specimens' upper side only. Additionally, 3 hot mix asphalt specimens (made by residual bitumen from both anionic and cationic emulsion) were prepared for comparison purposes.

2.3 *Isothermal calorimetry*

Isothermal calorimetry tests were conducted at 20°C with a Thermometric TAM Air instrument calibrated at 600 mW. The rate of heat release was measured on mixtures containing the three types of cement and the two types of bitumen emulsion, with duplicate specimens for each mixture. The water-to-cement ratio (w/c) of the CAEC mixtures was 3.14 for mixtures with 3% cement and 1.57, for mixtures with 6% cement, including both the water in the emulsions and the extra water added for workability. In addition to the CAEC mixtures, cement paste with w/c 1.0 and cold mix asphalt mixtures without cement were measured for comparison purposes. Cement paste with w/c 1.0 was used in order to avoid settlement of cement paste in the case of high w/c. Furthermore, it has been confirmed in reference [15] that the increase of w/c has no significant influence on cumulative heat released in the case when w/c is beyond 0.42. 20 g of freshly-mixed CAEC or 6 g of cement paste were inserted into glass vials of internal diameter 22.5 mm, sealed with a tight lid and placed in the measuring cell. The rate of heat release was then measured during 72 hours and integrated to obtain the cumulative heat release.

2.4 *Moisture losses and amount of trapped water*

The moisture loss of the Marshall specimens during curing was monitored by weighing them regularly during 28 days. Simultaneously, the Marshall specimens without cement were cured in a humidity-controlled room (relative humidity 90 ± 3% and temperature 20 ± 1°C) for 4 months until mass loss due to evaporation stopped. Then they were crushed and oven-dried at 105°C to obtain the trapped water content. The trapped water was defined as the water adsorbed on the surfaces of aggregate and filler as well as the water trapped in the closed pores within the bitumen and that cannot evaporate. In this study, the amount of trapped water was determined from the average of 20 duplicate samples.

Because the cationic emulsion broke immediately when fine aggregates were added to the mixture, a considerable amount of water was lost during the compaction process. For this reason, it was possible to quantify the water-content evolution only for the mixtures with anionic emulsion.

2.5 *Marshall tests*

The Marshall stability of cold mix asphalt samples was measured at 1, 3, 7, 14, 21 and 28 days. The tests were carried out immediately after the specimens had left the humidity-controlled room and were finished in approximately 10 min. The testing room temperature

was strictly controlled at 20 ± 1°C. Marshall tests were conducted in room temperature other than 60°C treatment in water bath. The reason is that the water bath will increase the cement hydration. Furthermore, the water bath will raise the water content in the samples which and thus decrease the strength of samples [9]. Every Marshall stability value was obtained from the average results of 3 specimens.

3 RESULTS AND DISCUSSION

3.1 *Isothermal calorimetry*

Mixtures without cement did not show any heat liberation, confirming that all the heat liberated from the CAEC mixture came from cement hydration. In addition to the CAEC, also the rate of heat liberation and the cumulative heat for the cement pastes are shown in Figure 1.

Compared with the cement paste, the main hydration peak of mixtures with anionic emulsion was wider and occurred significantly later, which reveals a retardation of the OPC hydration. However, the main hydration peak of OPC in the presence of cationic emulsion occurred slightly earlier than for the OPC paste. The cumulative heat release of OPC in the presence of anionic emulsion was initially lower than for cement paste, but increased steadily and eventually surpassed the heat released by the cationic mixture and by the cement paste. From Figure 1 it can be observed that cement with anionic emulsion samples showed a longer dormant period than cement with cationic emulsion samples, while there is no significant difference between cationic emulsion samples and the cement pastes. Similar conclusion has been made in reference [13]. In that paper, the author indicated that the addition of small percentage of cationic to cement paste didn't influence the rate of heat liberation or the cumulative heat released. However, the addition of anionic bitumen emulsion slightly increased the dormant period of cement hydration [13]. The initial retardation or acceleration observed in Figure 1 may be due to the pH of the bitumen emulsions [13], while no significant effect of the emulsion or of the bitumen could be observed on the later development of hydration. Similar conclusion has been made in reference [16] that emulsifier has no significant influence on cumulative heat released of cement hydration.

The degree of hydration reached by the cement was obtained as described in [17]:

$$\alpha(t_i) = \frac{H_{t_i}}{H_{cem}} \tag{1}$$

where $\alpha(t_i)$ is the degree of hydration at time t_i; H_{t_i} is the cumulative heat measured at time t_i (J/g of cement) and H_{cem} is the potential heat of OPC hydration which is 433.6 J/g of cement [18].

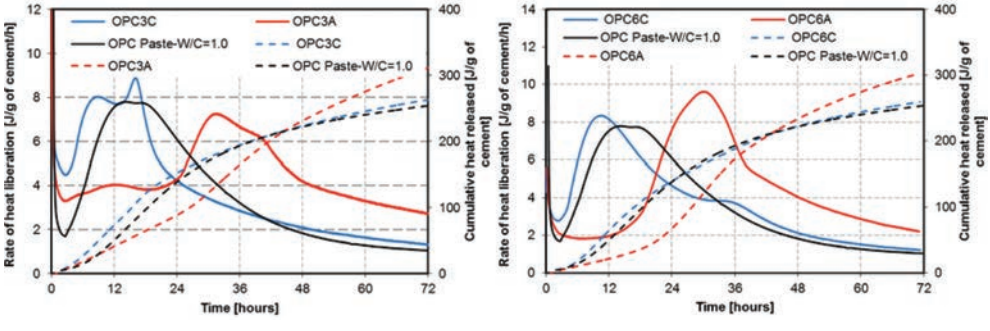

Figure 1. Isothermal calorimetry of OPC: 3% cement (left) and 6% cement (right) with cationic emulsion (blue) and anionic emulsion (red), cement paste (black—w/c = 1.0). Rate of heat liberation as continuous lines; cumulative heat as dashed lines.

Table 4. Degrees of OPC hydration at 24 h, 72 h and 28 d.

Mixtures	OPC3C	OPC6C	OPC3A	OPC6A	Cement paste
W/C	3.14	1.57	3.14	1.57	1.0
24 h [%]	35.1	32.2	20.3	15.4	32.0
72 h [%]	60.7	60.3	71.8	70.3	58.6
28 days [%]	60.7	60.3	71.8	70.3	58.6

The degrees of hydration of OPC at 24 h and at 72 h, obtained from Eq. 1 are shown in Table 4. Additionally, the influence of different types of bitumen emulsion on the hydration degree of mixtures with 3% and 6% OPC hydration are shown in Figure 1.

As the initial w/c in the CAEC is rather high (3.14 for 3% cement and 1.57 for 6% cement), it is assumed in this study that the loss of water due to evaporation in the Marshall specimens has little impact on cement hydration in the first few days. Thus, the degree of hydration reached in the first three days is assumed to be equal to that of the mixtures hydrating in sealed condition in the isothermal calorimeter (considering the moisture loss by evaporation for the OPC mixtures after 3 days the w/c of the Marshall specimens is approximately between 0.9 and 1.7).

After 3 days, the degree of hydration was considered to remain constant up to 28 days. Of course this approach will lead to an underestimation of the amount of bound water, which in reality will continuously grow, albeit at a low rate. However, since the degree of hydration at 3 days is already rather high, and considering the unknown effect of evaporation on the rate of hydration in the CAEC, this approach is considered to yield less uncertainties than a possible estimation of the degree of hydration at 28 days based on the rate of hydration in the first three days.

3.2 *Quantification of water content evolution*

The water in the mixture comes mainly from the bitumen emulsion and partly from the extra water used to wet the coarse aggregates. In reference [9] it has been shown that the water content has a significant effect on the mechanical properties of CAEC. Thus in this section, the amount of water evaporated, the amount of water trapped and the amount of water bound by the cement is quantified. The water in the specimens can be classified in three categories: *i)* residual water consisting of residual evaporable water at time t_i and of trapped water, *ii)* physically bound water on the surface of the cement hydration products and *iii)* chemically bound water within the hydration products [19]. Evaporable water refers to the capillary water within the capillary pores that are present in the hydration products of the cement and in the pores between the aggregates and the filler. The evaporated water is the water evaporated through the upper face of the specimens and is monitored by regular weighing. The driving force for water evaporation is the difference in the water potential between the interior of the CAEC specimens and the air in the climate chamber, which progressively decreases (due to evaporation and binding by cement hydration products) until an equilibrium with the ambient relative humidity is eventually reached.

In this paper, the bound water (both chemically bound and physically bound, see categories *ii)* and *iii)* above) was determined according to Powers model [19]. In particular, 1 g of OPC that has fully reacted binds a total amount of 0.42 g of water [19].

The mass loss from all the mixtures with anionic emulsion as a function of time, corresponding to the amount of evaporated water, was measured by regular weighting. The results revealed that the evaporated water increased rapidly during the first week after compacting and very small increase was observed afterward until 28 days. It is very clear that samples showed higher evaporated water content in the absence of cement. This is result from the consequences that cement hydration bound water and reduced the amount of evaporable water. The amount of trapped water was 1.21%; in this paper, it is assumed that the amount of trapped water is the same for all mixtures, independent of the amount of cement.

The residual evaporable water in specimens used for the Marshall tests was calculated by subtracting the water that had already evaporated at time t_i, the water bound by the cement and the trapped water from the initial water present in the samples. Thus the residual evaporable water content was quantified as:

$$p_{ev,res}(t_i) = p_{tot} - p_{bou}(t_i) - p_{trap} - p_{ev}(t_i) \quad (2)$$

where p_{tot} is the total initial water content in the mixtures. It was the same for every type of material with anionic emulsion and was obtained from the water in the emulsion plus the extra water used to wet the aggregates. Its value was 7.90%: 2.52% (tap water) + 13.45% (amount of emulsion) × 40% (water from the emulsion), see Table 3. $p_{ev}(t_i)$ is the percentage of water by initial mass of mixture that has evaporated at time t_i, $p_{bou}(t_i)$ is the percentage of water bound by the cement and p_{trap} is the water trapped in the mixture (1.21%). The residual evaporable water was quantified by Eq. 2 other than by oven drying is due to the reasons that the heating will accelerate cement hydration and the loss of volatile components of bitumen. Furthermore, $p_{bou}(t_i)$, the water bound by cement hydration, was quantified as:

$$p_{bou} = \lambda \cdot C \cdot \alpha(t_i) \quad (3)$$

where λ is the amount of water bound by 1 g of cement, which is 0.42 g/g; C is the percentage of cement in the mixture, 2.52% and 5.04% for mixtures with 3% and 6% of cement, respectively (see Table 3) and $\alpha(t_i)$ is the degree of hydration at curing time, t_i (Table 4).

According to this equation, the residual evaporable water left in the specimens, the water bound by cement and the water evaporated at after 1 day, 7 days and 28 days were quantified and are shown in Figure 2. In this Figure, it can be observed that OPC6A bound more water than OPC3A. But at the same time, OPC6C contained more residual evaporable water. This result partly explained why the modulus of CAEC steadily increases even after several months [4,12]. It should be noted that on one hand, a higher amount of cement in the CAEC mixture will definitely bind more water. On the other hand, the amount of water held by capillary forces may be higher in the mixtures with more cement. This will result in the decrease of the evaporation rate and also in a higher content of residual evaporable water at equilibrium. Although this is just a hypothesis and it is pending of further research.

3.3 *Marshall stability results*

In the case of the reference HMA, the Marshall stabilities of samples, made with the residual bitumen obtained from the anionic and cationic emulsions, were 25.9 kN and 36.5 kN, respectively.

The evolution of the Marshall stability with 0%, 3% and 6% of OPC is shown in Figure 4. A linear growth of the stability can be observed in the case of test samples made with cationic

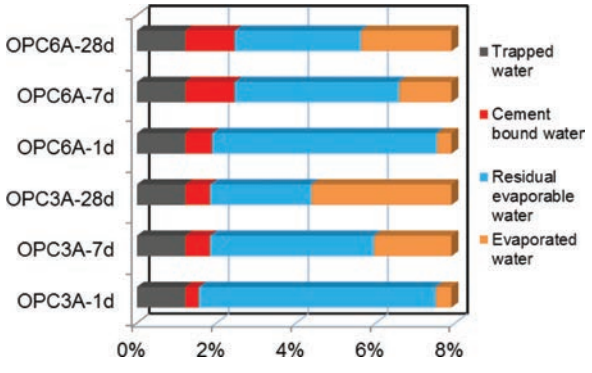

Figure 2. The water content evolution of Marshall specimens with anionic emulsion.

bitumen emulsion, without cement (OPC0C). However, in the case of anionic emulsion without cement (C0A), the bitumen emulsion broke too slowly to provide enough strength. The dimension changed during curing because of gravity. For this reason, the measured stability was presented here as a reference. The Marshall stability of mixtures with both cationic and anionic emulsions increased significantly with the addition of cement. The stability increased steadily during the 28 days curing period except for OPC3C, which remained almost constant after 7 days curing. The stability of OPC6C at 28 days was lower than that of the corresponding reference HMA, while the stability of test samples made with anionic emulsion (OPC3A and OPC6A) was similar to that of the reference HMA.

3.4 *The contribution of cement to CAEC*

In the case of mixtures without cement, only bitumen acts as a binder. The Marshall stabilities of mixtures with cationic emulsion are lower than the stabilities of those containing cement and, in the case of slow setting anionic emulsion, the test samples collapsed after demoulding.

When a small amount of cement was added to CAEC, it had an immediate effect on the mechanical properties of the cold mixed asphalt: the stability of mixtures containing 3% OPC and cationic emulsion was higher than for mixtures without cement 1 day after mixing (see Fig. 3a). However, in the case of mixtures with OPC and anionic emulsion, there was no significant difference in the Marshall stability after 1 day curing when compared to the test samples without OPC (see Fig. 3b). In Figure 1, it can be observed that in the presence of cationic emulsion, the main hydration peak of OPC occurred before 24 hours curing, while in the case of mixtures with anionic emulsion the main hydration peak took place after 24 hours curing. Besides, as the contribution of the emulsion to the Marshall stability

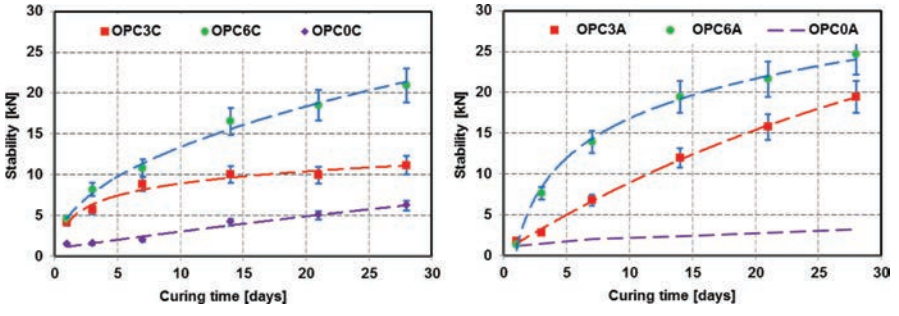

Figure 3. Evolution of the Marshall stability with curing time (a. OPC-C, b. OPC-A).

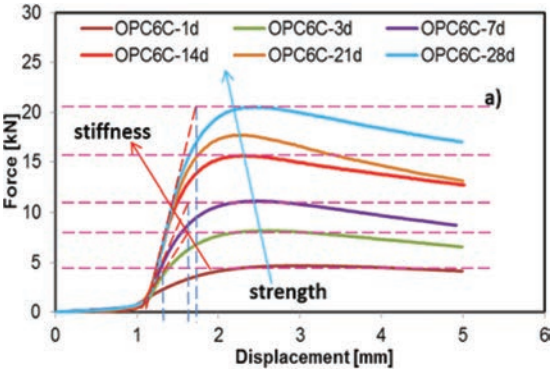

Figure 4. Marshall force-displacement curve of OPC6C (left) as a function of curing time.

Table 5. Degree of hydration VS Marshall stability of mixtures at 24 h.

Mixtures	OPC3C	OPC6C	OPC3A	OPC6A
Degree of hydration [%]	35.1	32.2	20.3	15.4
Marshall stability [kN]	4.1	4.6	1.8	1.4

is very limited (see OPC6C in Fig. 4), the increase of strength could be mainly attributed to cement hydration. Table 5 shows the degree of cement hydration versus the Marshall stability of anionic emulsion mixtures and cationic emulsion mixtures after 24 h curing. It indicated clearly that mixtures with higher degree of hydration clearly show higher Marshall stability. This can be confirmed by reference [6] and [20], in which rapid hardening cement was used to accelerate the hardening of CAEC.

3.5 *The contribution of bitumen emulsion to CAEC*

The most important contribution of bitumen emulsion to the mixture is to supply the bituminous binder for increasing the flexibility of CAEC and to provide water for the cement hydration. In this article it has been concluded that bitumen emulsion has no significant effect on the ultimate degree of cement hydration. On one hand, bitumen emulsion provides water for the cement hydration and on the other hand, cement particles consume the water and trigger the flocculation of bitumen droplets. By quantifying the moisture losses in the mixtures, it was found that the residual evaporable water content in the mixtures is relatively high after 28 days curing (from 2.5% to 3.5% by initial mass of mixtures). Thus, the increase of strength in these mixtures may be caused by the hardening of bitumen. The contribution of bitumen emulsion to the asphalt concrete mixture has however not been fully understood and needs to be characterized in detail in the future.

4 CONCLUSIONS

In this article, the cement hydration in the CAEC mixtures was characterized by isothermal calorimetry and the results indicated that bitumen emulsion may slightly retard or accelerate cement hydration, but has no significant effect on the ultimate degree of hydration of cement.

Cement hydration products act as a binder by forming bridges between aggregates and thus increasing the Marshall stability of cold mixed asphalt. Meanwhile, cement hydration products act as a stiffener of the binder substrate and consequently increase the stiffness of cold mixed asphalt. Bitumen emulsion provides water for cement hydration and some flexibility for the mixture.

The quantification of water content indicates that although cement hydration consumed a part of water, a relatively high amount of water still existed in CAEC mixtures after 28 days. This is the main reason for later development of strength and stiffness.

It can be concluded that CAEC has comparable mechanical properties to hot mix asphalt when cement is well distributed in the mixtures. The early strength of cold mixed asphalt can be substantially improved by adding a certain amount of cement. Although bitumen emulsion has no significant effect on the cement hydration process, the individual contributions of cement and bitumen emulsions to the mechanical properties of cold mix asphalt are still unclear.

ACKNOWLEDGEMENTS

The authors thank Hans Kienast, Walter Trindler, Axel Schöler and Dr. Mateusz Wyrzykowski for help with the experiments and CTW Strassenbaustoffe AG for providing bitumen emulsion. The first author was financed by a scholarship from the China Scholarship Council.

ABSTRACT: In order to provide an indicator of the performance of SMA surface course, the Scottish Inspection Panel (SIP) was established in 2006. This paper describes the work undertaken by the SIP, including the development of a visual assessment procedure that has its roots in a system established in the 1950s. The SIP team comprises a group of widely experienced asphalt experts who represent a cross-section of the asphalt industry. The survey team record any features that appear to affect the service life of the surface course to establish initial causes and typical modes of failure. Sites of special interest are also inspected to assess the performance of new materials and to identify longer term deterioration trends. Based on the observations and results of SIP surveys, several recommendations have been made to improve material design, construction and aftercare. Examples of improvements include closing up the surface texture to improve durability, without compromising safety; improved joint construction techniques, advice on treatment selection; and promoting the importance of maintaining drainage systems. Recent SIP results (2012) have shown that year-on-year improvements are being made and the process has been successful in improving the performance of surface courses laid on the Scottish trunk road network.

Keywords: SMA, durability, defects, visual inspection, performance

1 INTRODUCTION

In order to provide an indicator of the performance of asphalt surface course, Transport Scotland established an annual monitoring procedure in 2006. Each year the Scottish Inspection Panel (SIP) is responsible for assessing the visual condition of a selection of surface courses (Fig. 1).

Sites are selected to provide an indication of early-life performance and estimates of service life. Prominent faults are recorded to establish initial causes and modes of failure. The SIP team comprises road experts representing Transport Scotland and the road industry.

This paper describes the development of the method used and how results have been used to steer research, document performance and promote and develop best practice.

2 VISUAL INSPECTIONS

Visual inspections have been used for many years to assess and record the general condition of a road surfacing, and compare new materials or techniques with existing ones. The original approach [1] was developed over many years by the Road Research Laboratory

Figure 1. Scottish inspection panel.

in the 1950s to inspect full-scale road experiments. Some properties such as resistance to deformation or skidding could be measured by suitable apparatus, but other features such as excess binder, disintegration and uniformity of appearance could only be determined by visual examination. A basic marking regime using a 6-point scale was applied by a panel of experienced road engineers.

2.1 *Present method*

The 1990s saw an influx of new materials and material types from mainland Europe. It was necessary to revise the assessment procedure so that it could encompass all the types of materials likely to be used. The present method involves a panel of experts following a laid down methodology that has been used since 1993. A basic mark is allocated from a 7-point scale with fault suffixes, if appropriate, and the mean of individual results is calculated by the panel Convener. The system has been fully utilised by Transport Scotland and the Highways Agency in England to assess the durability of asphalt surfacing over the last decade.

2.1.1 *Marking*

The panel members attribute marks to each surfacing site on the basis of its current serviceability irrespective of the elapsed time since it was laid. In considering the serviceability of the surfacing, the aspects given in Table 1 are considered. If any of the aspects are evident to a significant degree on the site, the relevant suffix from Table 1 is applied to the basic marking.

Once any appropriate fault suffixes have been assigned, the basic mark is allocated from the 7-point scale shown in Table 2. Only the panel mark is reported and this is based on an average consensus of the panel. When considering the markings, any sections that warrant a suffix cannot receive the basic mark of G or better. The exception to this rule is the use of joint open (j_o) or joint fretted (j_f) suffix, e.g. if given a G_{J_o} or G_{j_f} this reflects that the mat is fault free but there has been a problem in constructing the joint.

2.2 *Site selection*

Transport Scotland's integrated pavement management system is used to provide information on materials laid on the network. Schemes are chosen to represent a range of sites in terms of climate, terrain, geographical location, traffic and surfacing type. For the purposes of retaining supplier anonymity, sites inspected are allocated specific acronyms throughout reports. In certain instances sites are subdivided into separate parts. This is typically done when the

Table 1. Defects and associated suffixes.

Suffix	Description	Notes
v	Variable	Random variations from point to point within the section only, not "traffic laning" or of obvious variations from load to load
t	Variability with traffic intensity	Marked transverse differences caused by variations in traffic intensity between lanes
+	Fatting up	Macadam, surface dressing
–	Loss of chippings	Hot rolled asphalt
	Loss of aggregate	Porous asphalt, macadam, thin surfacings, slurry surfacing
	Loose chippings	Surface dressing
	Wearing causing substrate to "grin" through	High-friction surfacing
j_o/j_f	Joint issue	j_o = open joint/j_f = fretting at joint
f	Fretting of mortar	Hot rolled asphalt
g	Growth of vegetation	Porous asphalt
p	Ponding	Porous asphalt
d	Delamination from substrate	Porous asphalt, thin surfacings, surface dressing, high-friction surfacings, slurry surfacing
s	Stripping	All except high-friction surfacings
c	Cracking	Hot rolled asphalt, macadam, thin surfacing, high-friction surfacings

Table 2. Basic seven-point scale.

Mark	Description	
E ("Excellent")	No discernible defect	
G ("Good")	No significant defect	Termed serviceable
M ("Moderate")	Some defects but insufficient for serious problem	
A ("Acceptable")	Several defects but would usually be just acceptable	
S ("Suspect")	Seriously defective but still serviceable in the short term	
P ("Poor")	Requires remedial treatment	Termed unserviceable
B ("Bad")	Requires immediate remedial treatment	

site contains areas that are subject to different levels of traffic stress, e.g. bends, junctions, or display distinct differences in surfacing condition.

2.2.1 *Early-life performance*

A review of surfacing performance in 2006 looked at sites in both good and poor condition to establish the reasons behind their relative performance. This led to an annual review to assess the early-life performance of surface courses that have been in service for approximately two years. Due to the surfacing season typically running from September to March each year, the actual age of the schemes inspected varies between 18 and 30 months. The nominal period of two years is selected as it is generally accepted that the condition of a surfacing after two years is a good indicator of its potential to achieve its predicted design life. After two years the surfacing has carried a reasonable amount of traffic and has been subjected to the cyclic environmental effects of seasonal change. Importantly, the supplier also remains the guarantor for a period of two years. As a guide, it is generally acknowledged that a surfacing should be assessed as either Excellent or Good after two years in service, with little or no significant defects.

2.2.2 *Estimates of service life*

In addition to inspecting two year old sites, older sites are inspected to assess the long term durability of surface courses and provide further estimates of service life.

2.3 *Reporting*

An example of the visual assessment results for inspections undertaken in 2006 is summarised in Figure 2. In most instances, the panel mark represents the average of six individual assessments and the mean visual condition marks are plotted using the following transformation:

E = 6; G = 5; M = 4; A = 3; S = 2; P = 1; and B = 0.

Research carried out for the Highways Agency [2] estimated that the average typical service-life of a surface course was between 13 and 14 years. This service-life relates to surfacing that has been manufactured and installed correctly in accordance with the appropriate specification. The limit of serviceability for the surface course was defined as when the visual condition drops to below *Acceptable*. The line drawn on Figure 2 represents an idealised linear deterioration with time. A recommended requirement to ensure a reasonable design life is that the condition of the surfacing should be assessed as Good or better after two years.

The two circles superimposed onto Figure 2 highlight sites that were assessed to have particularly poor visual condition for their age in 2006. The circle on the left of the graph represents a cluster of sites that are less than two years old.

2.3.1 *Observations*

The SIP team also record features that affect service life. Survey results consistently show that aggregate loss is the most commonly occurring defect. The fault is described as either latent or severe. The former is associated with materials that have an open texture owing to a lack of fine aggregate or mortar (Fig. 3) and, although assessed to be serviceable at the time of the inspection, are predicted to have poor long-term durability. The second type of aggregate loss is commonly described as fretting. This is where both coarse and fine aggregate are seen to be lost from the mix under the action of trafficking.

2.3.2 *Quality of construction*

A visual inspection, in itself, cannot always attribute the cause of poor quality, but it can assess the quality of workmanship associated with parts of the installation process. A common SIP observation was that the construction of joints could be improved. All asphalt surfacing

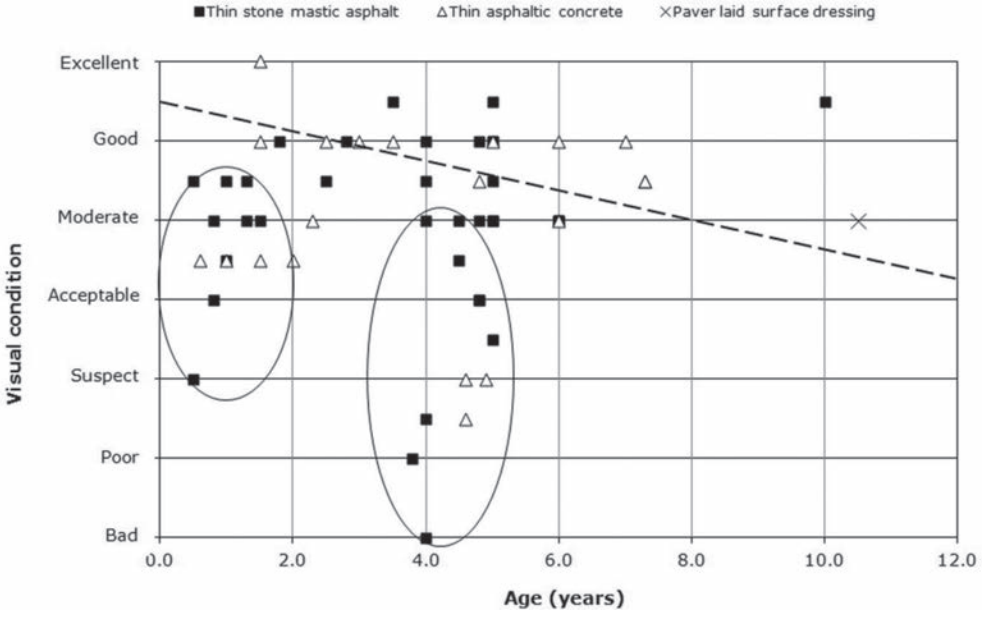

Figure 2. Average visual condition marks (2006).

Figure 3. Open texture.

joints are potential areas of weakness because they are likely to be less well compacted and can allow increased access to water penetration. It was evident from older sites that joints were often the first place to show the signs of deterioration which then start to migrate across the pavement. SIP surveys have recommended that steps should be taken to ensure that joints are well constructed and sealed to prevent water infiltrating and adversely affecting the lower pavement layers.

3 USE OF RESULTS

Examples of how SIP results have been used to steer research, document performance and promote and develop best practice are given below.

3.1 *Driver for new research*

The results of the SIP surveys carried out between 2006 and 2008 were a major driver in Transport Scotland commissioning a programme of research to adjust Scotland's domestic Specification to improve material durability, quality control and safety. The SIP surveys provided evidence that many existing surface courses were not providing good value for money. The open nature of the surface course and poor joint construction were highlighted to be of particular concern. The research led to the introduction of a new national specification in 2010 [3] that requires denser modified mixes using smaller stone sizes. It is expected that the dissemination of the research findings [4] and the new specification will improve the durability of new surface courses, extend service life and the value for money spent on road construction. It also addresses the Government's aim of reducing disruption to road users caused by road construction and maintenance.

3.2 *Benchmarking*

As an overseeing organisation, Transport Scotland strives to improve the performance of trunk road pavements. The SIP surveys play an important role in monitoring and tracking the technical performance of road surfacing. A comparison of the breakdown of average survey markings for SIP surveys 2008 to 2012 is shown in Figure 4. It can be seen that the surface courses examined in 2012 received the highest percentage of E and G markings. There was a marked improvement on 2011, and the results were better than earlier surveys.

The proportion of sites exhibiting defects over this period is presented in Figure 5. Compared to previous surveys, the 2012 survey recorded the lowest number of visual defects. Seventy per cent of the 2012 sites were assessed as being defect free.

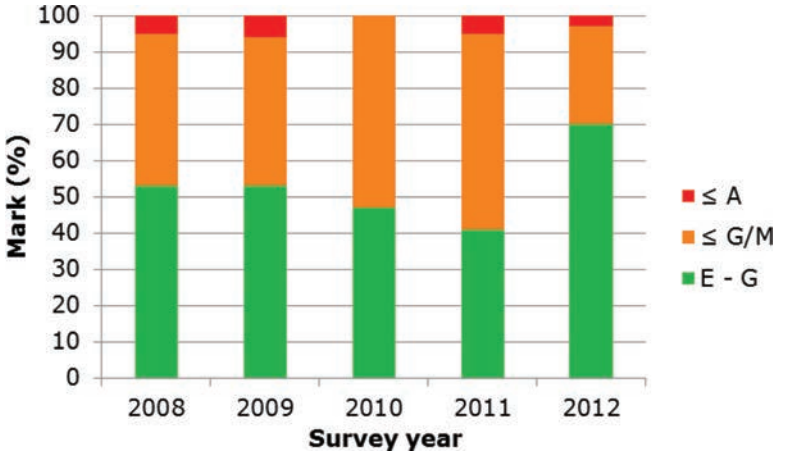

Figure 4. Comparison of average markings for SIP 2008–2012.

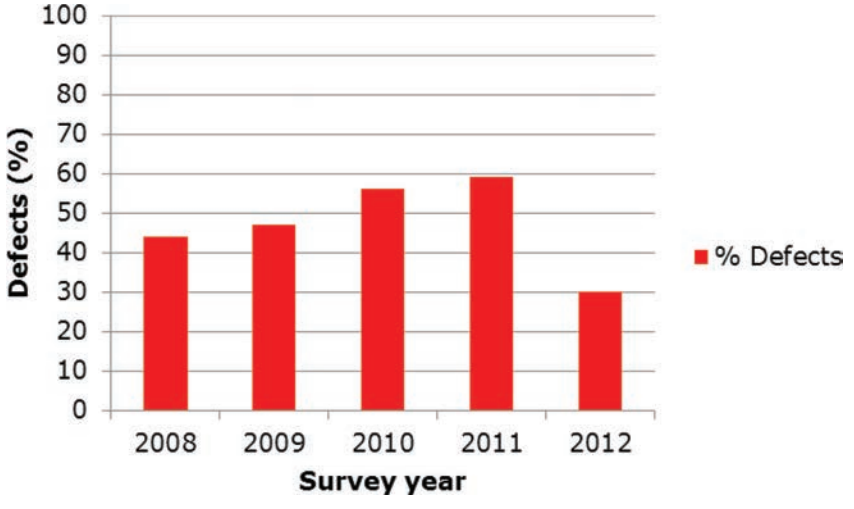

Figure 5. Comparison of recorded defects for SIP surveys.

Figure 6 shows a breakdown of the type of defect as a proportion of all the defects recorded for each SIP survey between 2008 and 2012.

Miscellaneous defects (coded red) include faults such as material variability, variability with traffic intensity, delamination and cracking. In 2010 it was decided to introduce a fault suffix for joint defects such as an open or fretted joint. Information on the specific condition of the joint was not recorded prior to 2011.

The improved results for 2012 are believed to be as a direct result of the implementation of recommendations from previous inspections. It is planned that future visual inspections will be continued on an annual basis to assist the process of further improving the performance of road surfacing.

3.3 *Developing best practice*

3.3.1 *Material selection*

Based on the poor performance of 0/14 mm surface course at highly stressed sites, such as roundabouts and busy junctions, it was recommended that the nominal aggregate size be

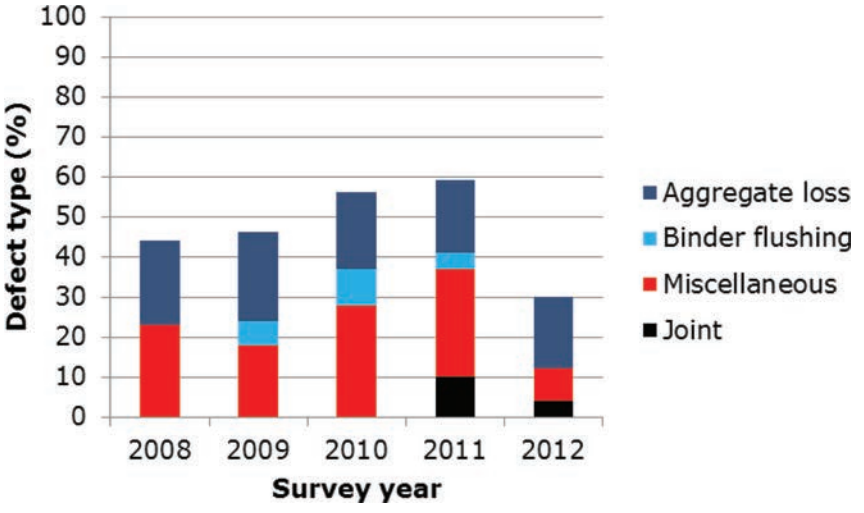

Figure 6. Type of defect recorded on SIP surveys.

Table 3. Extract from guidance on the selection of TS2010 SMA mixtures [3].

Mixture Description	Site Category/Description					
	Non-event	Medium Risk of Skidding	High Risk of Skidding	Noise Sensitive Area		High Stress
				High speed	Low speed	e.g. roundabouts
SMA 14						
SMA 10						
SMA 8 (Developmental)						
SMA 6						

reduced for high stress sites and new guidance was produced on selecting the correct material to suit the location (Table 3). Since 2011, the stress level of SIP sites has been assessed and designated as high, medium and low, e.g. junctions and roundabouts (High); crawler lanes and bends (Medium); and straight-run sections (Low).

3.3.2 *Joints*

In an attempt to elevate the importance of joints additional suffixes were introduced in 2010 as part of the visual assessment process. This raised the question of how joints were being constructed and how they could be improved in the future. On recent new build schemes echelon paving has been employed to remove joints altogether. For maintenance schemes a new approach to constructing longitudinal joints has been trialled with excellent results. The technique involves using a special cutting wheel that creates a chamfered joint (Fig. 7). The method appears to have several benefits that include reduced wastage of material, ease of coating joints and a better quality, well-sealed joint.

3.3.3 *Drainage*

SIP observations regularly highlight examples of poor or inadequate drainage and it has been highlighted that there is a continuing need to promote and generate dialogue on the importance of maintaining drainage systems. This has led to Transport Scotland funding

Figure 7. Chamfered joint.

new research to collect quantitative data on the impact that drainage has on the life of a road pavement.

4 SUMMARY

After the initial review of surfacing performance in 2006, Transport Scotland introduced an annual monitoring procedure to assess the visual condition of surface courses laid on the strategic network. The approach has been refined and has been successful in steering new research, documenting performance and promoting and developing best practice. The results from the annual surveys have demonstrated that the implementation of recommendations from previous inspections have made valuable improvements. Future visual inspections are planned to assist the process of continuing to improve the performance of Scotland's roads.

The residual life of thin surfaced pavements

David Alabaster
NZ Transport Agency, Christchurch, New Zealand

Theunis Henning & Douglas Wilson
The University of Auckland, Auckland, New Zealand

ABSTRACT: The practice of applying thin wearing course layers of asphaltic concrete over unbound granular pavement layers is wide-spread in New Zealand. Determining the as-built life of new thin surfaced unbound granular pavements is becoming increasingly important for two reasons. The first is the increasing use of "design and construct" type contracts where the client is required to make some judgement of the length of life of the finished pavement at the end of the defects liability period. The second is the continual constraints on maintenance budgets making it imperative that all designs are as efficient and effective as possible.

Previous attempts to develop a residual life determination for thin surfaced pavements have used transient surface deflections. Equipment such as the Falling Weight Deflectometer (FWD) provide key inputs to the Mechanistic—Empirical pavement design models that estimate life. More advanced models have combined laboratory testing and deflection measurements effectively attempting to eliminate the more conservative empirical aspects of the modelling process. Both approaches have their limitations which will be discussed and illustrated with data from the Canterbury Accelerated Pavement Testing Indoor Facility (CAPTIF).

The aim of this paper is to report the issues surrounding existing residual pavement life models used in New Zealand and propose a methodology of research into addressing the gaps in knowledge and/or practice.

Keywords: Accelerated pavement testing, long term pavement performance, residual life, CAPTIF

1 INTRODUCTION

New Zealand's sealed roading network consists primarily of chipsealed or thin wearing course layers of asphaltic concrete over unbound granular pavement layers. Traditionally pavements have been designed by consultants and built by contractors, resulting in conservative designs and the average pavement life on the State Highway network is approximately 40 years. Routine maintenance is carried out promptly and periodic resurfacing is the only major treatment requirement. There is an increasing use of "design and construct" type contracts where the client is required to make some judgement of the length of life of the finished pavement at the end of the defects liability period and New Zealand Transport Agency is about to undertake its first Public Private Partnership with similar requirements. There has also been a strong drive to keep maintenance budgets at current levels making it imperative that all designs are as efficient and effective as possible. Thus determining the as-built life of new pavements is becoming increasingly important.

Three residual life models based on Mechanistic—Empirical pavement design and FWD measurements have been trialled in previous research [1]. The best model was "*plus or minus 500%. This means if the FWD predicts the pavement life of two million ESAs then the actual life could range from 400,000 ESAs to 10 million ESAs. The range of life predicted makes it*

difficult to use in compliance and if penalties are imposed then the 'greater' life of 10 million is taken as the achieved life."

2 EXISTING RESIDUAL LIFE DETERMINATIONS FOR UNBOUND GRANULAR MATERIALS

Mechanistic—Empirical pavement design based residual life determinations for unbound granular materials have been tested by New Zealand researchers [1]. The research reviewed the accuracy of the residual life predictions from three common methods to analyse FWD data. The methods were tested against New Zealand pavements where the life was known or could be estimated from rutting or roughness data.

The first method reviewed was a prediction based on the central deflection of the FWD. This method is used in the Austroads Guide to Pavement Technology [2] to infer the load carrying capacity of pavements that are being rehabilitated. The research found that this method was the most inaccurate and recommended that it not be used in the future.

The Austroads mechanistic pavement design method was used as the basis of the second method. The pavement life was estimated from the vertical compressive strain in the subgrade, back calculated from the FWD deflections. This method generally underestimated the life by 10 to 100 times. But the method was also capable of overestimating the life where the pavement failed in the granular layers.

In the third method tested, the Austroads mechanistic pavement design method was calibrated. Again, the pavement life was estimated from the vertical compressive strain in the subgrade back calculated from the FWD. But the subgrade strain criteria that links the elastic strain to life had been 'broadly' calibrated to the soil types. Calibrating the model resulted in the predictions ranging from 0.1 times the life to 10 times the life, but typically between 0.2 and 5 times the life.

Additional methods were investigated in the project, CAPTIF data [3] was reviewed in detail to determine whether a soil specific subgrade strain criteria could be developed. It was found that the variables of; assumed end of life rutting conditions, the timing of the FWD test (before trafficking or after an initial period) and the depth of the pavement, played a significant role in the determined subgrade strain criteria. Figure 1 below illustrates the effect of pavement depth on the subgrade strain criteria on the same Tod Clay subgrade

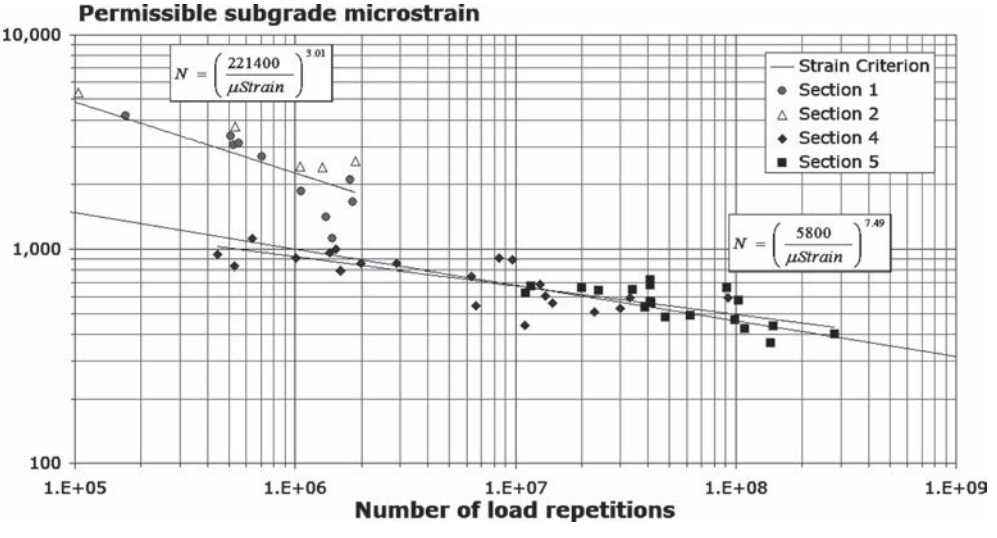

Figure 1. CAPTIF load cycles vs subgrade strain for 15 mm VSD for the mature pavement.

material constructed at different moisture contents, with State Highway Standard TNZ M/4 basecourses. Sections 1 and 2 were 150 mm deep basecourses on a subgrade CBR of 7 and 9 respectively, while sections 4 and 5 were 300 mm deep basecourses on a subgrade CBR of 3 and 8 respectively. The Figure suggests that thinner pavements built on stronger subgrades will perform better than softer subgrades with thicker pavements where the elastic strains are equal at the top of the subgrade. Reviewing the data, it is arguable that section 5 could be included in the thinner data set without difficulty and that in fact it was the weaker subgrade in section 4 that is creating the diverging result.

Supplementary checks were suggested to consider the performance of the basecourse but not considered in detail. They included a curvature check for near surface deformation similar to that used by Austroads for asphaltic concrete surfaces, a CBR check on near surface deformation by inferring CBR from modulus, a check on near-surface deformation by applying a strain criterion at the mid-height of granular layers and finally a check on the modular ratio of adjacent pavement layers.

Three key observations and recommendations were made:

- That a single project could have individual point reading with predicted lives ranging from 0.01 million ESA to 100 million ESA. The research recommended that the 10th percentile prediction of life be used as it is generally accepted that a pavement requires rehabilitation once 10% of a pavement needs repair.
- Analysis could follow the Austroads subgrade strain approach, generally with considering the basecourse layers and only need broad calibration based on past project experience.
- Contractor payment reductions should only be applied where the predicted life is 1/5th of the design life.

Clearly the existing techniques are not accurate enough to use in a contractual arrangement.

3 PAVEMENT PERFORMANCE CONSIDERATIONS

In developing a new model a review of parameters effecting pavement performance prediction is required. These can be broadly separated in Traffic Loading, Pavement Materials, Environment and Maintenance regime, Analysis Methods and finally the Definition of Failure.

3.1 *Traffic loading*

Despite the obvious need, accurate loading data is difficult to establish in most situations. The New Zealand Transport Agency (NZTA) has six Weigh in Motion (WIM) sites to develop loading parameters for 94,000 kilometres of road network. All of the 114 nationally managed traffic monitoring sites are on the 11,000 kilometres of State Highway network throughout New Zealand that are continuously counted. These sites classify the traffic composition by length by the use of dual inductive loops. The sites are then supplemented with 1500 count sites that are part of regional state highway traffic monitoring contracts. These include 127 continuously counted and 466 non-continuously dual inductive loops. Furthermore, 141 are continuously counted and 655 are non-continuous single inductive loops that provide counts only. 113 Pneumatic tubes that provide classification by axle and a further 328 "virtual" sites are used to assist in coverage of the full road network [4]. The NZTA's design guidance, contained in the 2007 New Zealand Supplement to the Austroads Pavement Design Guide, averages the number of Standard Axle Repetitions per heavy commercial vehicle axle across the WIM data. The supplement also provides the average number of heavy vehicle axles per heavy vehicle from the WIM data. Design loadings for pavement design are calculated from the Annual Average Daily Traffic and its growth, the percentage of heavy commercial vehicles calculated at the site or estimated from adjacent sites and the average WIM parameters for Standard Axle Repetitions. Directional and lane usage factors are applied where required [5].

Research in to network deterioration modelling has suggested that quality of traffic loading data is poor for model development. The research recommended installing telemetry sites

on the Long Term Pavement Performance (LTPP) sites with temporary "Weigh in Motion" loading samples to also be obtained [6].

Australia has some 200 Weigh in Motion sites and the data for each site is summarised in the Austroads Guide to Pavement Technology [7]. The guide lists the average number of heavy vehicle axles per heavy vehicle at each site and the number of standard axle repetitions per heavy commercial axle. Thus the number of standard axle repetitions per heavy commercial vehicle can be determined by multiplying the two together. Finding the highest and lowest values of the two parameters does not necessarily find the range of standard axle repetitions per heavy commercial vehicle. However, it certainly suggests it can range from 1 to 7 confirming, at least in part, that traffic loading data in New Zealand could be a major source of error in any subsequent residual life determination.

3.2 *Pavement materials*

Current residual life systems assume that elastic strain (deflection) can be related to plastic strain (rutting) with one relationship for all materials. While this may be approximately true for basecourse materials made and laid to highway standard specifications, such as the NZTA M/4 Basecourse Specification and TNZ B/2 Construction Specification, there are still other compliant materials such as Dacite where the current CAPTIF test suggests this doesn't appear to apply.

A constant relationship between elastic strain and plastic strain is less likely to be true for subbase materials that have wider specifications [8] and it is definitely untrue for subgrades such as volcanic ashes which appear to be very tolerant of high deflections [3, 9].

3.3 *The environment and maintenance regimes*

The Environment and Maintenance regimes play a significant role in the life of unbound granular pavements. HDM-4 provides two forms of rutting progression models. One for cracked sections and the other for uncracked sections, with default model coefficients provided for both chipseal and asphalt surfaced pavements. Attempts to calibrate the models using the New Zealand LTPP sites failed and a two phase model was then proposed. The first phase modelled stable rut progression and the second phase an accelerated progression defined as twice the average expected stable progression [6]. The rate of rut progression in the stable phase was able to be modelled from CAPTIF data as a function of the pavement thickness and the modified structural number and was validated on the Gisborne and Hawkes's Bay State Highway networks. CAPTIF data was also used to develop a logistic model to estimate the probability of accelerated rut progression; the model was a function of equivalent standard axle repetitions, modified structural number and pavement thickness. The research considered the mechanism was generally only seen on over loaded low strength pavements.

3.4 *Mechanistic analysis system*

Mechanistic—Empirical pavement design models are in themselves relatively simple approximations of reality. They are generally conservative (which serves their purpose) but they are not an adequate model for residual life predictions in a contractual environment. These systems involve the iterative mechanistic calculation of stresses and strains to fit the measured deflections. This generates a best fit model of the elastic performance of the pavement layers. The pavement life is then estimated by comparing the calculated elastic strains or stresses with empirical performance relationships at critical points in the pavement, such as the vertical strain at the top of the subgrade.

The existing models all analyse static loads using the theory of elasticity which is a gross but practical simplification of the real situation [10]. In fact the loads are dynamic, the materials are granular not solid and the behaviour at the stress levels we are considering contains some element of plastic movement. Better models exist; Finite Element Models provide the flexibility to consider non-linear material models, dynamic loads and material yielding.

Analysis at CAPTIF shows Finite Element Models certainly provide closer approximations to measured elastic strains. Distinct Element Methods provide a granular model however they too are simplifications with approximations required for at the least environmental conditions and the computational needs generally mean not all load cycles are modelled. However, there are no models that provide an exact replication of reality.

Current life prediction systems for unbound materials assume a constant or an increasing resilient strain within the pavement [1]. Results from CAPTIF have shown a third option with some pavements showing decreasing strain and deflection values, whilst plastic strains still gradually increase. This adds to the inaccuracy of current residual life predictions when the deflections are not measured at construction.

3.5 *Failure mechanisms*

A key part of any model predicting failure is to clearly define what failure is. In the New Zealand context, pavements are often noted to be rehabilitated due to excessive maintenance costs rather than having met some terminal fatigue condition.

Attempts have been made to create data driven models of the rehabilitation decision making process. Most recently an attempt was made to develop a model for maintenance costs and then develop criteria to define the "end of life" of State Highway pavements [11].

RAMM data was collect from the West Wanganui, Southland, Gisborne and Hawke's Bay networks to develop the models and the Nelson network was used to validate the results. The variables for the models included, Roughness, Shoving, Rutting, Potholes, Alligator cracking, Edge break, Scabbing, Pavement Maintenance Costs, Surfacing Maintenance Costs, Shoulder Maintenance Costs, Total Maintenance Costs (a summation of the previous three), Traffic Levels (AADT), Pavement Age (since construction or last rehabilitation) and Urban or Rural Environment.

A Total Maintenance cost model (Pavement, Surfacing, Shoulder costs) found the most significant variable to be roughness, which is intuitively sensible, followed by shoving, alligator cracking, traffic, rutting, age and potholes in prioritised order.

A Pavement Maintenance cost model also listed roughness as the most significant variable, which again is intuitively sensible, followed by shoving, traffic, rutting, alligator cracking, age and potholes in prioritised order.

A Pavement and Surfacing Maintenance cost model was also developed and not surprisingly roughness was again shown to be the most significant variable and intuitively sensible, followed by traffic rutting, shoving, alligator cracking, age and potholes.

While the parameters in all of the models where almost all statistically significant the overall low r-squared values (<0.25) suggested that that models would have difficulty accurately predicting maintenance costs at individual sites. The researcher suggested that there must be a substantial random element to maintenance costs, or an alternative view is that there are additional influences on the maintenance costs not considered in the data, be that other parameters (such as material type), sampling errors (cracking and potholes are a 10% sample) or simply sampling once a year is not fast enough to detect some modes of distress adequately (ie shoving, cracking and potholes).

Despite the setback of not finding a robust maintenance cost model the research went on to try and predict rehabilitation decisions with a logit model developed from the RAMM data available. A logit model allows the modeller to set a "threshold probability" above which rehabilitation is predicted to occur and below which it won't. Again the four networks were combined to produce a single network, but this time the networks were also separately modelled as well.

The model for all four networks and the total maintenance cost as the only cost parameter suggested that total maintenance was the most significant parameter in rehabilitation decisions with the traffic level and whether it was Urban or Rural also being highly ranked.

By setting the threshold at 11% the model has a 72% probability of correctly predicting rehabilitation and equally a 72% probability of correctly predicting no rehabilitation when the site does not need it.

Using the Pavement and Surfacing Maintenance costs as separate variables resulted in traffic being the most significant variable. Surfacing costs being more significant than pavement costs, that was also ranked below roughness and the urban/rural split. Rutting was not considered to be a significant parameter in the model.

The total maintenance cost model had a better log likelihood value and thus was likely to provide a better model to predict maintenance decisions.

The research also investigated individual models for the separate networks which were much simpler, suggesting some significant regional variance in either performance or the decision to rehabilitate.

The models with no traffic parameter imply that all that is required for rehabilitation is for the maintenance costs to rise over a predetermined value—irrespective of traffic volume. To a certain extent this is true as the State Highway decision making procedure for Rehabilitation is purely based on the Net Present Value (Present Worth of Costs) of the ongoing Maintenance cost vs the Net Present Cost of the Rehabilitation. The inclusion of the traffic parameter in the models is presumably a risk or priority adjustment made at the regional level—higher volume roads are more important and likely to deteriorate faster, thus earlier intervention may be needed. What is interesting is that keeping all others factors equal—the models suggest that Hawkes Bay would seem to need four times the maintenance cost that Southland intervenes at.

The Nelson network was used to validate the combined four network maintenance cost or rehabilitation models. The Nelson network had 408 treatment lengths, 14 of which had been rehabilitated.

The maintenance cost model had a poor fit to the actual data, which is not surprising as the R squared values of the model were low.

The research concluded that:

- A two tier model may have been better, the first tier triggering on condition such as rutting or roughness with the 2nd tier triggering rehabilitation on maintenance cost. But a two stage model was not investigated.
- Maintenance costs could not be accurately predicted from the data considered
- Maintenance costs did not appear to rise dramatically with time
- Maintenance costs, Traffic and Roughness, in that order, were the main drivers of rehabilitation.

The research demonstrates that defining the end of life of pavements is difficult and the end of a pavements life appears to be a function of the funding rules for rehabilitation and the local regions interpretation of those rules. Across all regions total maintenance costs, roughness and traffic volumes appear to be the key drivers of rehabilitation decisions.

Total maintenance costs, while difficult to model accurately with the available data, are a function of Roughness, Shoving, Alligator cracking, Traffic, Rutting, Pavement Age and Potholes. While Pavement Maintenance cost are subtlety different and are driven in order of importance by Roughness, Shoving, Traffic, Rutting, Alligator cracking, Pavement Age and Potholes.

4 PROPOSED METHODOLOGY

It is proposed that data from previous CAPTIF pavement tests could be used to develop a practical residual life determination. Previous CAPTIF projects contain data sets that would be ideal for this research work.

This methodological step would add a new and novel approach to the traditional analysis to encompass the fundamental limitations of the existing approach. The aim of the extra step is to provide a "site calibration of the model" to the analysis that would possibly be a combination of laboratory testing, QA data and early life performance data (during the defects liability period). The objective of the calibration would be to reduce the uncertainly in loading data, moisture conditions and elastic-plastic performance data and measures of construction quality. Figure 2 indicates how the process could enhance the determination of residual life.

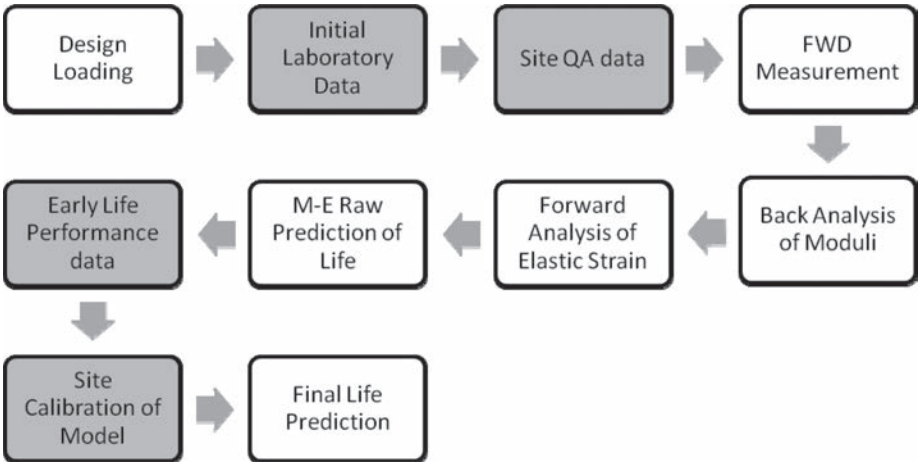

Figure 2. Proposed residual life determination process (non traditional steps grey shaded).

CAPTIF provides a data set that demonstrates why traditional approaches are inaccurate on State Highway strength pavements [12]. Two test sections with nearly identical FWD readings provide significantly different performance. The same project has pavements using the same basecourse materials but at different thicknesses which provides a measure of the sensitivity required in the model.

The current CAPTIF project "The relationship between vehicle axle loadings and pavement wear on local roads" will add a number of ideal data sets to test the model at local road strengths. With these data sets it will be possible to investigate the influence of traffic loading, pavement materials, analysis methods and the definition of failure.

The model would be validated against suitable LTPP sites to check that it works in the field; this will also confirm whether the environment and maintenance regimes need further consideration. This will ensure the quality and validity of this project, which will have significant impacts on future NZTA business processes.

5 CONCLUSIONS

An improved calibrated residual pavement life model that can be used at the project level to assess the remaining life in newly constructed pavements is needed. If a suitably flexible model can be developed it could also be used to determine the remaining life of all pavements. In that case it could be used to prioritise network level models that have identified pavements that are nearing the end of their lives.

A calibrated residual life determination has the following benefits:

- Accurate judgement of the likely life of "Design and Construct" pavements.
- It will provide a way to review all constructed pavements to ensure they are efficient and effective.
- Improved forward programme predictions.
- Improved asset valuations.
- Improved understanding of when to transfer to more expensive but low risk/low maintenance bound pavements.

More complex models that combine laboratory testing and deflection measurements with Finite Element Models will not alone produce good models—a number of practical limitations need to be addressed:

1. The real life loading situation is almost always unknown. For example New Zealand reports data from six weigh in motion sites for 94,000 km of road network.

2. Pavement material response to load becomes increasing complex with depth. Elastic strain to performance relationships need to be calibrated at each site.
3. The environment and maintenance regimes affect pavement performance. The quantity, quality and effect of future maintenance needs to be assumed, as does the future environment that pavement the will operate in.
4. All Mechanistic—Empirical design models are approximations to reality and need calibration.
5. Assumed failure conditions and real life decisions on rehabilitation need to be aligned.

It is clear that the proposed methodology to predict the life of new (and existing) pavements is needed.

Comparison of rutting performance between the PURWheel and the NCAT test track

Yu Tian, Ali Hekmatfar & John E. Haddock
School of Civil Engineering, Purdue University, West Lafayette, IN, USA

ABSTRACT: Continuously increasing traffic volumes, vehicle loads and tire pressures require asphalt mixtures to be designed to achieve better performance. This increased performance can be more easily obtained if asphalt mixture designs can be more closely tied to in-service performance. One way of doing so is with the use of laboratory tests tied directly to in-service asphalt pavements.

The Indiana Department of Transportation took the opportunity to establish rutting performance relationships between laboratory wheel tracking tests and the in-service pavement represented by the National Center for Asphalt Technology test track. Laboratory wheel tracking tests are performed in a relatively short time period. Conversely, pavements on the test track are typically trafficked over a period of years and thus subjected to seasonal and daily climate cycles in addition to traffic loads. Direct correlation between the two tests without considering the effects of temperature and aging is unrealistic.

In this research, applying temperature-aging modifications to the asphalt mixtures made comparisons between the laboratory wheel tracking and the full-scale test track more realistic. The findings show a good correlation between the two can be achieved by properly accounting for environmental factors.

Keywords: Test track, PURWheel, rutting, temperature, aging

1 INTRODUCTION

Over the past decades in-service pavements have seen increased traffic volume, vehicle loads and tire pressures. As a result, pavements often deteriorate more quickly than anticipated during the design phase, thus posing significant challenges to the design profession. Such challenges highlight the need for pavement design methods and materials selection that can link laboratory-scale testing with in-service pavement performance. Such methods could help to provide extended service life of asphalt pavements.

Design models must be calibrated and validated using actual traffic. The most desired way is utilizing in-service traffic loads and monitoring the pavement performance throughout the pavement service life. However, to do so is unrealistic in that it would take 10–20 years before enough data were collected. In order to represent the potential long-term performance within a relative short period of time, extensive efforts have been made to develop accelerated pavement testing techniques. In such tests, either full-or partial-scale traffic loads are applied in such a manner that the accumulation of damage is accelerated into a compressed time period. There are three levels of accelerated pavement tests: 1) Full-scale test track; 2) full-scale accelerated loading devices; and 3) laboratory wheel tracking devices. Full-scale test track and laboratory wheel tracking testing are discussed in this paper.

Full-scale test tracks apply controlled traffic loads to test sections, usually built for specific purposes. Such testing can duplicate real-world traffic loads, usually in an accelerated manner and is most representative of in-service pavements. However, accelerating the traffic load of a pavement test track also means the test sections are not exposed to the same amount of

varying seasonal temperatures. In late 1990s, the National Center for Asphalt Technology (NCAT), with the cooperation of several state departments of transportation, constructed a full-scale pavement test track in Alabama. The Indiana Department of Transportation (INDOT) took this opportunity to establish rutting performance relationships between the Purdue laboratory wheel tracking system (PURWheel) and the in-service pavement represented by the NCAT track.

The primary objective of the work described herein is to establish useful rutting relationships between in-service pavements, as represented by NCAT track and the PURWheel, Such relationships can help facilitate the development of pavement rutting performance predictions based on laboratory test results.

2 EXPERIMENTAL DESIGN

In order to validate the Superpave mixture design method and establish the desired relationships between the NCAT track and PURWheel, the experimental design shown in Table 1 was developed. Three factors were considered in the design, binder type, binder content and aggregate gradation); each factor had two different levels as shown in Table 1.

NCAT track sections N3 and N4 were sponsored by INDOT, sections N5-N8 by the Alabama Department of Transportation (ALDOT), sections N9 and N10 by the Federal Highway Administration (FHWA), and sections N1 and N2 by the track project. Specimens cut from track sections N1-N8 were transported to Indiana and tested in the PURWheel. While additional data is always better when making conclusions, in this particular experiment, the cost of producing and transporting samples made it difficult to increase the number of samples placed in the PURWheel device. Specimens tested in PURWheel were directly sampled from test track and hence represent as-constructed field conditions. The sample disturbance was minimized when taking samples and hence the reliability of testing results was increased.

Aggregates used in the mixtures were an Alabama limestone and a blast furnace slag. Gradations of the fine-graded mixtures plot above the Primary Control Sieve (PCS) while the coarse-graded mixture gradations plot below the PCS. The asphalt binders used in this study were an unmodified (neat) PG 67-22, a Styrene Butadiene Styrene (SBS) modified PG 76–22, and a Styrene Butadiene Rubber 63 (SBR) modified PG 76-22 binder. The HMA mixture designs were completed according to the Superpave volumetric mixture design method. Specimens for the design procedure were compacted with 100 gyrations of the SGC. The optimum binder content was chosen at 4 percent air voids. Detailed mixture design and test track construction information can be found in [1, 2, 3].

2.1 *NCAT test track*

The NCAT test track, as shown in Figure 1, is 2,743 m long and consists of 1,829 m tangents and 914 m curve sections. The original track construction was finished in the summer of

Table 1. Experimental design.

Binder	Binder content (%)	NCAT track section	
		Fine-graded	Coarse-graded
67-22 Unmodified	Optimum	N4	N6
	Optimum + 0.5	N3	N5
76-22 SBS	Optimum	N1	N9
	Optimum + 0.5	N2	N10
76-22 SBR	Optimum	–	N8
	Optimum + 0.5	–	N7

Figure 1. NCAT test track [3].

Figure 2. PURWheel testing device [1].

2000, and traffic application was started in the fall of that year. The test track includes 26 test sections on the tangents, 13 on the North (N) and 13 on the South (S), and 20 test sections in the curves, 10 West (W) and 10 East (E). The Alabama Department of Transportation (ALDOT), the Federal Highway Administration (FHWA), and the INDOT jointly sponsored sections N1 through N10. The ten mixtures shown in Table 1 were produced and placed on the track and subjected to 10 million Equivalent Single Axle Loads (ESAL) in approximately two years. Trafficking was accomplished using four tractor-trailer combinations operating at 72 km per hour. The individual single axles were loaded so that one truck pass applied approximately 10 ESAL [1]. Due to constraints at the time, and for the results reported in this paper, only the rutting data recorded from 18 September 2000 to 10 May 2002 were used. The number of ESAL applied in this time period was 7,102,106.

2.2 *PURWheel*

The PURWheel is a laboratory wheel-tracking device developed in the 1990's at Purdue University and has been implemented by Indiana DOT and Mississippi State University to simulate performance associated with rutting and stripping. As shown in Figure 2, the

PURWheel is in a self-contained temperature chamber where the desired test temperature can be maintained and wheel load and wheel speed can be controlled and rut depth measured. PURWheel specimens are 305 mm long, 286 mm wide and 50 mm thick. In this research, specimens were cut from the inside lane of NCAT track and trimmed to fit into the PURWheel., two replicates were tested for each NCAT track section. Two specimens were tested simultaneously at temperature of 50C. The PURWheel pneumatic tires were inflated to 690 kPa and loaded to 1.5 kN. One wheel pass consists of a forward and backward movement of the wheel with velocity of 33 cm/s. Tests were terminated after 20,000 passes or a 20 mm (0.8 in) rut was observed, whichever occurred first. Rut depth was measured over the entire length of a specimen using moving Linear Variable Differential Transducers (LVDT) [4, 5]. Sivasubramaniam [1] discovered a linear relationship between the logarithm of rut depth and the logarithm of number of PURWheel.

3 DIRECT CORRELATION

The first attempt at a relationship between the PURWheel and NCAT track rutting performance was direct correlation. This was done by comparing the total rut depths from the PURWheel at 20,000 passes to those of the NCAT track at approximately 7 million ESAL. As shown in Figure 3, overall there is a fair correlation; the coefficient of determination is 0.69. However, when the modified binder and unmodified mixture data are separated, the correlations are poor. The coefficient of determination for modified mixtures is 0.1; the coefficient of determination for the unmodified mixtures is 0.3. Perhaps even more disturbing

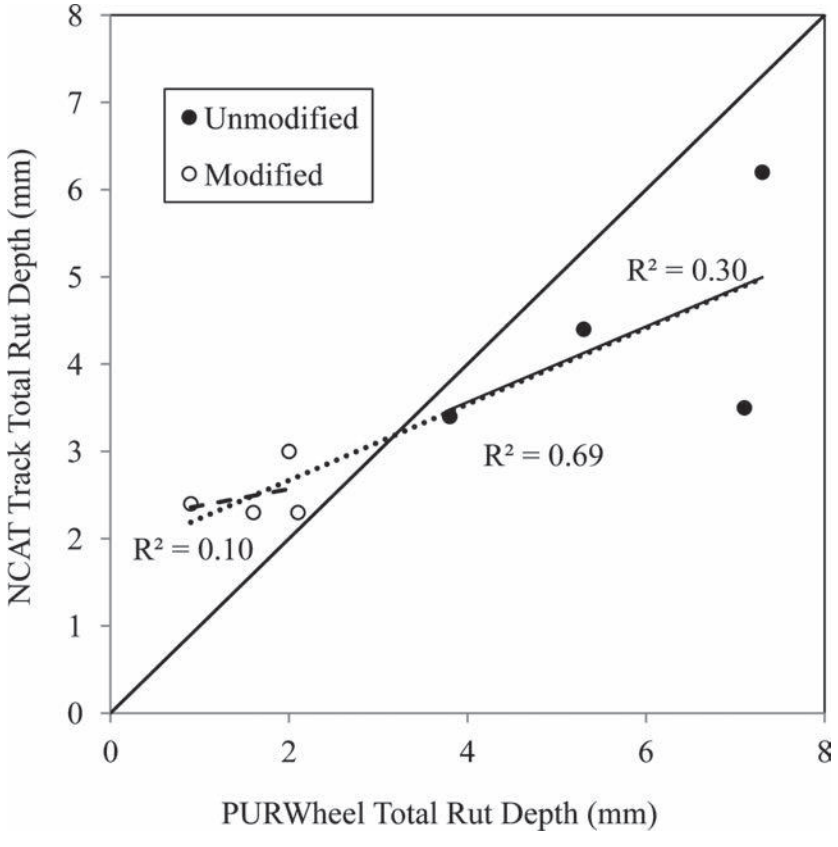

Figure 3. PURWheel and NCAT rut depth correlation [1].

than the poor correlations is the fact that for the modified asphalt mixtures the relationship between the NCAT track and the PURWheel might be negatively correlated, suggesting that as rut depths increase in the PURWheel, they decrease on the track. The relationship seems unlikely, at best.

The correlations displayed in Figure 3 are not entirely unexpected given that fundamental differences exist between the two tests [4]. More importantly, the NCAT track traffic was applied during two full calendar years. The mixtures were thus exposed to the environment, for two years, including the natural temperature cycling between day and night, as well as seasonal changes. Traffic applied during higher temperature days can result in more rutting than would occur with the same amount traffic applied during cooler temperatures. To the contrary, the PURWheel trafficking was conducted under a constant temperature of 50C.

Asphalt mixture aging can also make it difficult to compare the rutting performance between full-scale test tracks and laboratory wheel tracking devices. When asphalt mixtures are placed and trafficked on a full-scale test track, they are exposed to the environment and thus some aging of the asphalt binder occurs, even if the traffic loading is accelerated. The result can significantly alter the rutting performance of a mixture during the loading period; a load applied early in the traffic cycle can generate more damage to a test section as compared to an equivalent load applied late in the traffic cycle. This aging does not occur in laboratory wheel tracking tests as they are generally completed in only a few days.

The two factors, variations in rutting due to temperature cycles and variations in rutting due to asphalt binder aging, must be properly accounted for when comparing full-scale test track and laboratory wheel tracking results. If this is done, the results from the two methods should be more comparable.

3.1 *Temperature influence*

The NCAT track rutting data are shown in Figure 4. The basic idea of temperature influence is based on the fact that full-scale test track sections respond to same traffic loads differently depending on temperature of the asphalt mixture. In the case of the NCAT track, the ESAL applied to the pavement should be weighted differently, depending on the pavement temperature at which they were applied. This can be accomplished using a "load-temperature spectra" approach [3].

Since the asphalt pavement test section is softer at higher temperature and hence less resistant to rutting damage, it is expected that the stiffness of the asphalt mixture in the test section

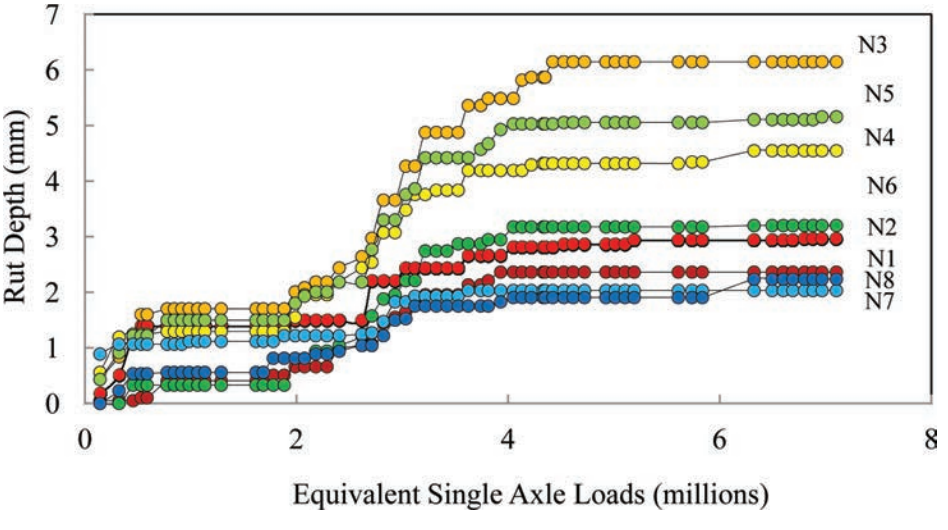

Figure 4. NCAT track rutting data.

can be used to generate a temperature modification factor. A statistical correlation between mixture temperature and mixture stiffness was developed based on data collected from the 2003 NCAT track trial. The mixture stiffness can be expressed as a function of temperature as shown in Equation (1), where T is the pavement surface temperature in Celsius [6]. Such a correlation provides an approach to modify the rutting results with consideration of the temperature effect; the stiffness serves as a temperature dependent indication of the mixture's rutting performance.

$$\text{Stiffness}_T = \frac{1}{\text{Compliance}_T} = \frac{2{,}793{,}344}{e^{0.05976T}} \tag{1}$$

The first step in applying the load-temperature spectra approach is to divide the NCAT track temperature data from the testing period into several temperature ranges. Temperature ranges were chosen based on the Performance-Graded (PG) asphalt binder grading system. Little rutting was observed on the NCAT track when the traffic was applied at pavement surface temperatures lower than 34C [1,6]. Therefore, the first range was chosen as 34–40C, with 37C being the range midpoint. This midpoint was selected as the standard point to develop the temperature modification factors, hereafter referred to as temperature factors. The temperature factors for each temperature range were then constructed using Equation (2), where T again is the pavement surface temperature in Celsius [6]. The temperature factors for all the PG temperature ranges were thus derived and are shown in Table 2. Since 37C is the standard point, the temperature factor for this temperature range is one.

$$\text{TemperatureFactor} = \frac{\text{Compliance}_T}{\text{Compliance}_{37C}} \tag{2}$$

Multiplying the number of ESAL applied by the proper temperature factor yields the modified number of ESAL applied. This "modified ESAL" number accounts for the pavement surface temperature when the original ESAL were applied; the traffic applied at higher pavement temperatures is weighted with a larger temperature factor. To accomplish this the plot of ESAL applied to the NCAT track as a function of time was examined and broken into increments based on the accumulated ESAL applied to the track at the time rut depth was measured. For each traffic increment, the average pavement surface temperature was calculated and the temperature factor corresponding to the temperature range was multiplied by the ESAL increment. After applying this process over the entire two-year period of traffic at the NCAT track, a sum of 16 million modified ESAL was the result. This is over twice the number of ESAL physically applied to the track and is the result of accounting for the temperature effects on rutting. The modified NCAT test track results are plotted in Figure 5.

For the PURWheel data the temperature modification is more straightforward. Since all testing was conducted at 50C, which corresponds to a temperature factor of 2.049 as shown in Table 2. This factor was applied to all PURWheel data, as shown Figure 6.

Table 2. Temperature factor.

Temperature range (C)	Midpoint of temperature range (C)	Temperature factor
<34	Not applicable	0
34–40	37	1.000
40–46	43	1.431
46–52	49	2.049
52–58	55	2.932
58–64	61	4.196

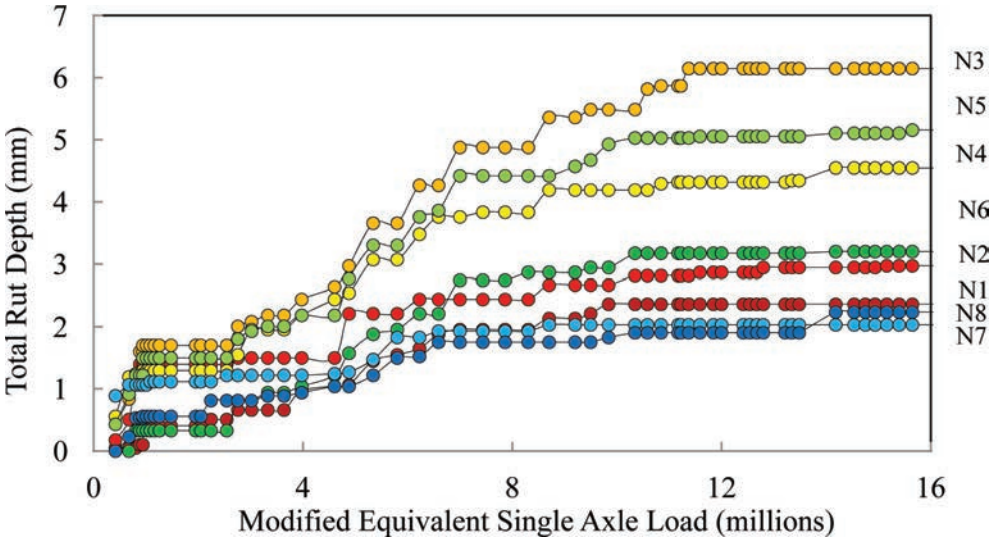

Figure 5. Temperature modified NCAT track rutting data.

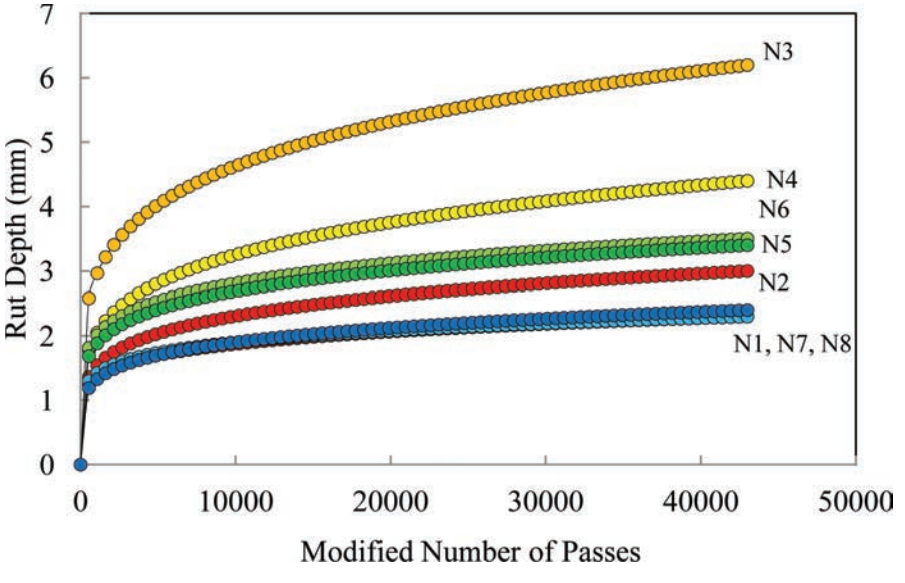

Figure 6. Temperature modified PURWheel rutting data.

3.2 *Aging influence*

Asphalt binder aging can make a direct comparison between the NCAT track and PURWheel more difficult. When an asphalt pavement is exposed to the environment, the asphalt binder in the mixture begins to age, making the binder and the pavement stiffer. Due to this aging, or stiffening of the asphalt pavement, the rate of rutting tends to decrease with pavement age; thus asphalt pavement performance can change between a pavement's early and later life. While the PURWheel is a laboratory test that can be completed in only a few days, testing on the NCAT track took approximately two years to complete. To account for potential rutting differences due to asphalt binder aging, a methodology was applied to both the NCAT track and PURWheel data.

Similar to accounting for temperature effect, the concept of aging modification is to convert rut depths measured at different pavement ages into rut depths at some standard time. To do so an aging factor is applied to the rutting data. The aging factor is defined as the ratio of the rutting rate at a given pavement age to the rutting rate at a standard time; the factor is larger than one before the standard time and smaller after. Dividing the rutting data by the aging factor thus makes the early age rut measurements smaller and the late age rut measurements larger. Powell suggested the standard time be chosen in the middle of the testing period for NCAT track, 301 days, to provide the best correlation between laboratory and field performance. A regression model was derived to calculate the aging factor as shown in Equation (3) [3].

$$\text{Aging factor} = 90.622 \times \text{days}^{-0.7397} \tag{3}$$

Since the field experiments in this research were also conducted at the NCAT track, Powell's aging factor was adopted. These aging modifications were applied to the already temperature modified NCAT track rutting data and are shown in Figure 7.

The aging modification method was also applied to PURWheel rutting data. As with the NCAT track data, it was decided the middle point of the testing period (9750 passes) should be chosen as the standard time. A regression model similar to the track model was developed and is shown in Equation (4). This aging modification was applied to temperature modified PURWheel data and is shown plotted in Figure 8.

$$\text{Aging factor} = 9074.4 \times \text{passes}^{-0.992} \tag{4}$$

3.3 *Modified data comparisons*

The correlation between the NCAT track and PURWheel data, when both sets of data have been temperature and aging modified is plotted in Figure 9. As shown in the figure, the correlations between NCAT track and PURWheel data have been significantly improved. The coefficients of determination for the overall, modified, and unmodified mixtures are improved from 0.69 to 0.84, 0.1 to 0.87, and 0.3 to 0.61 respectively.

Figure 9 also shows a fairly consistent bias in the data. The NCAT track consistently shows about 2 mm more rutting depth than does the PURWheel. This bias may be due to geometry, tires pressures, or mechanical reasons. Additional work will be needed to investigate reasons

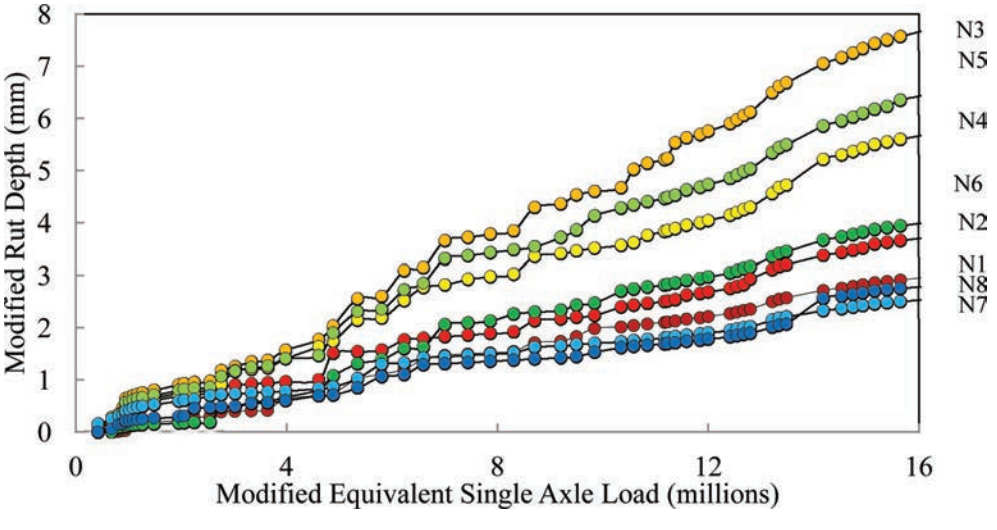

Figure 7. Temperature/aging modified NCAT rutting data.

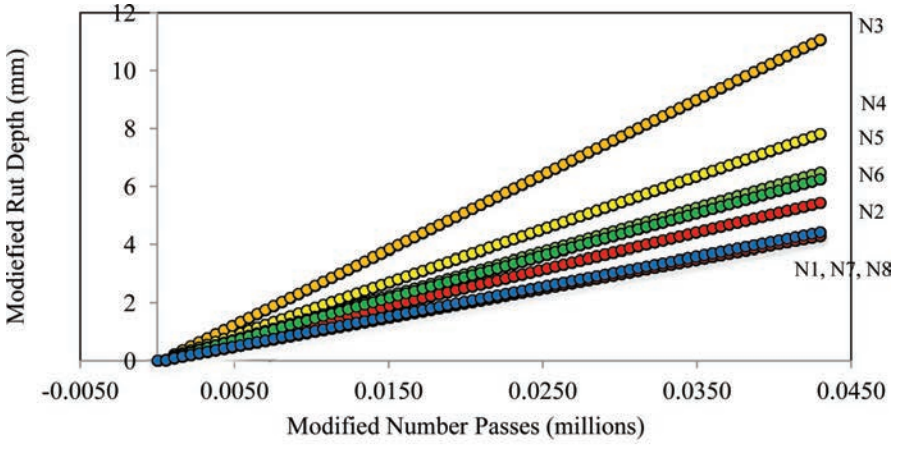

FIGURE 8 Temperature/aging modified PURWheel rutting data

Figure 8. Temperature/aging modified PURWheel rutting data.

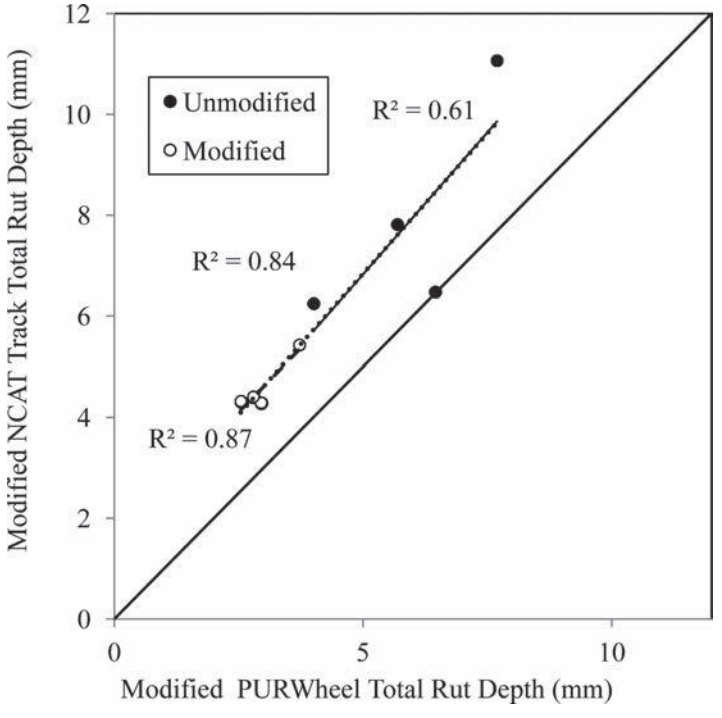

Figure 9. Correlation between modified NCAT track data and PURWheel data.

for the bias. However, although currently unexplained, the consistency of the bias can be dealt with by simply shifting the data.

4 CONCLUSIONS

Laboratory-scale wheel tracking tests have been used for years in the asphalt industry. However, in order to make them more useful they need to be more closely comparable to

in-service results. The work reported in this paper has sought to make the laboratory wheel tracking results from the PURWheel comparable to the in-service pavement of the NCAT track. Based on the data and analyses reported herein, it appears that comparisons between the NCAT track and the PURWheel are more valid when adjustments are made to account for the effects temperature and aging can have on asphalt mixtures.

Alternative methodologies to evaluate storage stability of rubberised bitumens

Davide Lo Presti, Naeem Memon, James R.A. Grenfell & Gordon Airey
Nottingham Transportation Engineering Centre, Pavement Research Building, University of Nottingham, Nottingham, UK

ABSTRACT: Tyre Rubber Modified Binders (TR-MBs), produced through the McDonald wet process and used worldwide (e.g. asphalt rubber), have demonstrated various benefits to pavements and, moreover, they represent a good opportunity for recycling tyre rubber. However this technology is still struggling to be fully adopted in Europe. One of the reasons is their poor stability during high temperature storage, which leads to high initial costs due to usage of specialised equipment. No-agitation (storage-stable) TR-MBs is proving to be a great alternative and its development could also be the key to increase the use of tyre rubber in paving applications in Europe. This paper presents the results of a study which focuses on investigating conventional and alternative methodologies to evaluate the storage stability of TR-MBs. Results have shown that an accurate binder design is fundamental to improve compatibility of TR-MBs. Furthermore, the study highlights that Dynamic Mechanical Analysis (DMA) and X-Ray CT scans are very suitable techniques to control the compatibility of tyre-rubber bitumen blends leading to the development of storage-stable TR-MBs.

Keywords: Tyre rubber, modified bitumen, storage stability, DMA, X-Ray CT

1 INTRODUCTION

Polymer modification of bitumens is not a new phenomenon, but interest of this technique has increased considerably during the past decade due to the increased performance-related requirements on asphalt pavements. One of the prime roles of a bitumen modifier is to increase the resistance of the asphalt to permanent deformation at high road temperatures without adversely affecting the properties of the bitumen or asphalt at other temperatures. As a matter of fact, processing compatible polymer-bitumen blends allows to greatly increase the high temperature end of paving grade, leaving the low temperature slightly better [1]. Another common practice in the more recent years consists in manufacturing modified bitumens by using recycled polymers. One of the most common is recycled Tyre Rubber (TR) and the relative method of modifying bitumen is referred to be as the "wet process". The major restriction encountered in polymer modifications of bitumen remains the incompatibility of the modifying polymer and the bitumen matrix. Tyre Rubber—bitumen blends are usually not compatible system and these forces contractors to adopt specialized expensive equipment to avoid phase separation during storage or transportation. For this reason most of the research in this field is focusing on developing technologies and methodologies to produce compatible tyre rubber—bitumen blends. The optimisations of these technologies pass also through the development of the assessment techniques and a better understanding of the phase separation during binder storage. This paper aims to enrich this field of research by providing techniques and results toward a better assessment of storage stability of tyre rubber modified bitumens.

2 BACKGROUND

2.1 *Compatibility (Stability) of polymer-bitumen blends*

In general, incorporating a polymer in a bitumen matrix results in a multiphase material with a great tendency to phase separate [2], (Fig. 1). If, without taking any special precautions, a road bitumen and a given thermoplastic polymer are mixed hot, one of the following three results may occur:

- *The mix is heterogeneous*: this is the most likely result (i.e., where the polymer and the bitumen prove to be incompatible). In this case, the constituents in the mix separate and the mix has none of the characteristics of a road binder.
- *The mix is totally homogeneous*, including at the molecular level: this is the infrequent case of perfect compatibility. In this case, the oils in the bitumen solvate the polymer perfectly and destroy any intermacromolecular interactions. The binder is extremely stable, but the modification of service qualities with respect to those of the initial bitumen is very slight. Only its viscosity increases. This is, therefore, not the desired result.
- *The mix is microheterogeneous* and is made up of two distinct finely interlocked phases. This is the compatibility sought and gives the bitumen genuinely modified properties. In such a system, the compatible polymer "swells" by absorbing some of the oily fractions of the bitumen to form a polymer phase distinct from the residual bitumen phase comprising the heavy fractions of the binder (the rest of the oils, plus the resins and asphaltenes).

A desirable system, therefore, has to be a blend of bitumen with a partially miscible polymer that is homogeneous as judged by eyesight but heterogeneous under the microscope [3]. As a consequence, even for compatible systems, the equilibrium situation is a macroscopic phase separation of the two-phases: the Asphaltene Rich Phase (ARP) being the denser phase and on the other hand the Polymer Rich Phase (PRP).

Since these binders consist of two distinct phases, they are subject to the same physical principles as those governing the separation or sedimentation of bitumen emulsions (Stokes' law). In other words, the velocity of displacement of dispersed particles (polymer phase in the case of a bitumen matrix and bitumen phase in the case of a polymer matrix) increases as:

- The particle size increases,
- The difference in density between the two phases increases, and
- The viscosity of the continuous phase decreases.

Thus the larger the density difference and the larger the particle size, the faster the separation rate. Polymer/bitumen compatibility is indeed a dynamic concept and compatible systems are

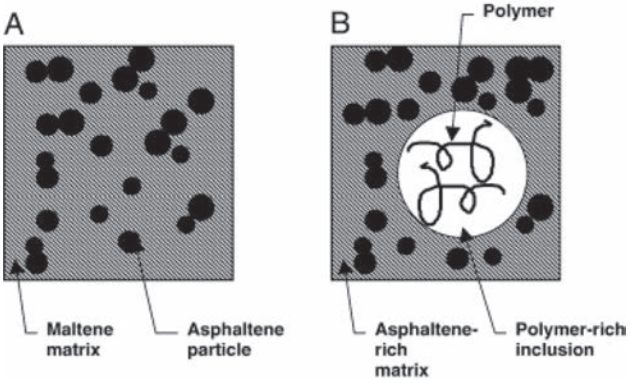

Figure 1. Effect of polymer-modification on the colloidal structure of a bitumen: original bitumen (A) and the corresponding PMB with increased asphaltenes content in the matrix (B) (adapted from Lesuer, 2009).

those with slow separation rate [1]. Usually this equilibrium is reached with a medium-high percentage of polymer, around 5–6% by weight, which creates a three-dimensional polymer network that radically changes the properties of bitumen; with lower percentages (<3–4%) a continuous bitumen phase with a dispersed polymer is obtained, with higher amounts (6–7%) instead it is the bitumen that is dispersed in a continuous polymer phase [1]. Tyre rubber—bitumen blends, are micro-heterogeneous mixes that in order to provide the desired level of modification need a very high amount of polymer (between 10–25%).

2.2 *Tyre rubber—bitumen blends*

Depending on the adopted processing conditions and on the selected materials, the wet process leads to different technologies. Caltrans [4], makes an important distinction between the various blends related to the rotational viscosity of the resulting Tyre Rubber Modified Bitumens (TR-MBs) at high temperature. Based on this distinction, it is possible to divide the wet process into two families: the "wet process–high viscosity" and the "wet process–no agitation". The High Viscosity—wet process is the original wet process, invented by Charles McDonald [5], and leads to a product with a series of benefits which are basically all linked to the binder's increase in elasticity and viscosity at high temperatures that allow greater film thickness in paving mixes without excessive drain down or bleeding [6]. Despite the fact that these types of technologies (e.g. asphalt rubber), have been demonstrated to provide various benefits to pavements, it is still struggling to be fully adopted in Europe, mainly because of their poor stability during high temperatures storage, which leads to high initial costs in modifying existing asphalt plants. In the wet process-no agitation, the characteristic swelling process of the wet process-high viscosity is replaced by the depolymerisation/devulcanisation and the optimised dispersion of the TR into the bitumen by using a high processing temperature (200–260°C) and high shear stress during the mixing (up to 8000 rpm), resulting in a smooth, homogeneous product. In this process, no modifications to the asphalt plant are required. In fact, these blends are manufactured with very fine TR particles that can be digested (broken down and melted in) relatively quickly and/or can be kept dispersed by normal circulation within the storage tank rather than with agitation by special augers or paddles. Although such binders may develop a considerable level of modification, rotational viscosity values rarely approach the minimum threshold of 1,500 cPs (1.5 Pa.s) at 177°C, that is necessary to significantly increase binder contents above those of conventional asphalt mixes without excessive drain down [4]. Hence, depending on the chosen materials and processing variables, the modification of bitumen with TR can provide different products and improving one aspect (e.g. storage stability) could compromise another (e.g. rheological properties).

3 EXPERIMENTAL PROGRAMME

The experimental programme consists of the application of different storage stability analysis techniques on some TR—bitumen blends. Conventional analysis is based on the sole estimation of the softening point of top and bottom sections of a "tube" sample of modified binder after hot storage. The proposed techniques make use of Dynamic Shear Rheometers (DSR) and X-Ray CT analysis with image processing to provide a better understanding of the phase separation process. This section will show details of the methodologies and the next will provide the reader with results and discussions.

3.1 *Materials*

Several Tyre Rubber Modified Bitumens (TR-MBs) were produced and then subjected to conventional storage stability analysis (EN 13399) together with two innovative methodologies involving a rheological investigation by means of Dynamic Shear Rheometer (DSR) and X-Ray CT together with image analysis techniques. The first two analyses were performed on TR-MBs made of a 50/70 pen bitumen and 18% by weight of 30# TR. These components have been blended for 120 minutes in high shear at two different processing

temperatures: 180°C and 210°C. This was performed to have a better understanding of the effect of the processing temperature on storage stability. The X-Ray CT analysis was performed on another TR-MB made with a 70/100 pen bitumen and 15% by weight of 40# TR. These components were blended in high shear at 180°C and for 180 minutes.

3.2 *Conventional softening point storage stability analysis*

Storage stability testing was undertaken based on European Standard EN 13399, but modified with several storage times in order to have a better understanding of the phase separation process. Aluminium toothpaste tubes were filled with TR-MB straight after production at 180°C. The tubes were then sealed and placed n a vertical orientation and holding them in an oven at 180°C (Fig. 2).

After different storage periods the tubes were taken from the oven and cooled down to ambient temperature, before placing into a freezer at –20°C. Once frozen the samples were cut into thirds and the top and bottom sections were subjected to Softening Point tests (EN 1427). In order to define a bituminous binders is stable under hot storage, EN 13399 prescribes a maximum ΔSP of 5ºC between the two sections.

3.3 *Storage stability analysis by means of DSR*

In order to obtain a complete rheological characterisation, a Dynamic Mechanical Analisys (DMA) of the top and bottom section of the blends was performed by making frequency sweep tests over a wide range of temperatures with an Antoon Paar Physica MCR 101 Dynamic Shear Rheometer (DSR). The tests were performed under the following conditions and making at least three repetitions:

- Loading Mode: controlled-strain
- Temperatures: 0ºC to 80ºC with 5ºC intervals (neat bitumen) 30ºC to 80ºC with 5 or 10ºC intervals (TR-MB)
- Frequencies: 0.10, 0.16, 0.25, 0.40, 0.63, 1, 1.6, 2.5, 4, 6.3 and 10 Hz
- Plate geometries: 8 mm ϕ and 2 mm gap (0–50ºC) (only neat bitumen) 25 mm ϕ and 1 and 2 mm gap (30–80ºC)
- Strain amplitude: 0.5% with 8 mm plates (within LVE dependent on G^*) 0.5% and 2%–12%@80°C with 25 mm plates (within LVE response dependent on G^*)

Figure 2. Toothpaste tubes in a rack prior to placing in the oven.

For each test, samples were prepared by means of a hot pour method, based on Alternative 1 of the AASHTO TP5 Standard (AASHTO, 1998). The gap between the upper and lower plates of the DSR was chosen such that the rheological properties taken at wider gap widths (2 mm for 25 mm) were independent of the gap. The rheological properties of the binders were measured in terms of their complex (shear) modulus, G^*; and phase angle, δ. Black diagrams, were used as the basis of all the rheological analyses in this paper. Furthermore, TR-MBs have been tested only at the higher temperature range, 30ºC to 80ºC, because high temperatures provide a major evidence of polymer networks within a bitumen matrix.

3.4 *Storage stability analysis by means X-Ray CT and image processing*

3.4.1 *X-Ray CT scans*

X-Ray CT imaging is a non-destructive method that allows the internal structure of a material to be imaged. This means that internal slices can be made near to the top and the bottom of the samples without damaging the internal structure of the TR-MB. The specimen is scanned by X-Rays at the desired location, which results in a series of linear attenuation coefficients, which are then reconstructed to form a cross-sectional image of the specimen. A CT image is called a slice and represents what an object would look like if it were sliced open along a plane. The grey levels in a CT slice correspond to the molecular weight of what is being imaged and is due to X-Ray attenuation. The X-Rays are scattered or absorbed as they pass through each volume element. The higher the molecular weight of the element the lighter it appears in the obtained image. In order to achieve the best possible image, a set of parameters are needed. These are based on current, voltage, exposure time and the use of filters. For this work the following parameters were selected; voltage 310 kV, current 2.1 mA, exposure time 90 ms, a 2 mm copper source filter and a 25 mm aluminium back filter.

3.4.2 *Image processing*

For the Image Processing, a minimum of two slices were taken through each section (top and bottom) and these were obtained as 16 bit digital images. The ImageJ programme was then used to separate the bitumen and crumb rubber phases in the captured image based on the densities of the materials. The Image J programme was then used to carry out also the thresholding of the CT image. In this technique, specific ranges of pixel greyscales were isolated for analysis. The images used are 16 bit images, meaning that they have 65536 (2^{16}) shades of grey. Each shade of grey represents a different density due to the specific attenuation properties. Different densities relate to different materials, which can therefore be isolated and quantified. Figure 3 shows the X-Ray CT image before and after thresholding.

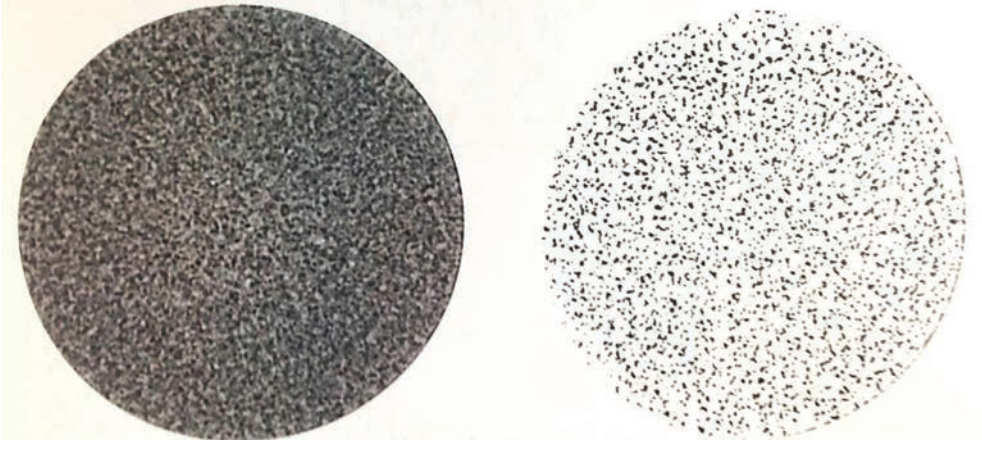

Figure 3. CT image of TR-MB (left), thresholded image of TR particles (right).

The right image shows a black and white TR-MB, where the bitumen is the white phase (higher density), while the left images shows only the isolation of TR particles (black).

4 RESULTS AND DISCUSSION

This section will show a comparison between the SP storage stability methodology and a Dynamic Mechanical Analysis (DMA) first. These results will be enriched by the outcome of another investigation aiming at understanding the mechanism of phase separation through X-Ray CT analysis coupled with image processing techniques.

4.1 *Dynamic mechanical analysis*

The first part of the investigation was focused on assessing the effect of the processing temperature on the stability of the blends. TR-MBs were produced and then subjected to a more conventional SP storage stability analysis together with DMA. SP analysis (Table 1) shows that rubber phase separation starts to be relevant after a few hours. The results do not show a clear trend, since TR-MB produced at 210ºC seems to have a higher separation rate after 4 hours, while after 24 hours of hot storage it is the TR-MB HS180 which shows the higher difference between the top and bottom sections. For this reason, all the binders were also characterised through rheological tests.

DMA was performed by frequency sweep tests at high service temperatures (30–80ºC) with conditions shown in section 2. The results of these analyses are shown in terms of Black diagrams and clearly highlight the differences between the two TR-MBs. After 1 hour (Fig. 4)

Table 1. Softening points of TR-MBs HS before and after hot storage.

Softening point (UNI EN 1427)	TR-MB HS 180 (°C)		TR-MB HS 210 (°C)		ΔSP (°C)	
	Top	Bottom	Top	Bottom		
Before hot storage	62.0		55.0			
After 1 h of hot storage	61.0	63.0	54.0	55.0	2.0	1.0
After 4 h of hot storage	59.0	61.5	55.0	59.0	2.5	4.0
After 24 h of hot storage	50.0	63.0	50.0	59.0	13.0	9.0

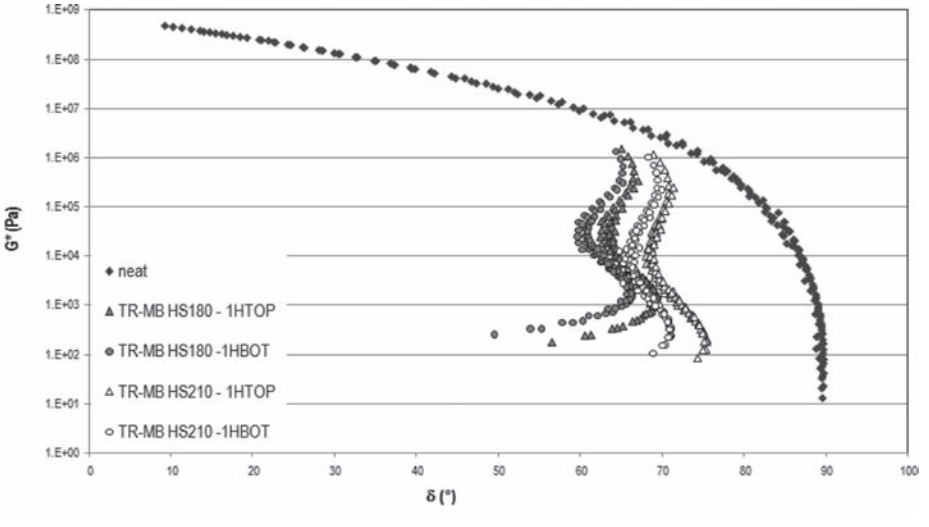

Figure 4. Black diagrams of top and bottom parts of the TR-MBs after 1 h of hot storage.

both TR-MBs show almost no separation, but already after four hours (Fig. 5) TR-MB HS 210 demonstrates a large difference in performance between the top and bottom sections. The majority of the rubber tends to settle towards the bottom and the Black diagram of the top part tends to have the properties of the base bitumen (neat). After 24 hours, (Fig. 6) TR-MB HS180 also shows a big gap between the upper and lower sections, but it is not comparable with the loss in properties of TR-MB HS210, which shows the rheology of the top section being extremely close to that of the neat bitumen.

Comparing these results with those of the conventional tests, shown in Table 1, it is possible to notice that from the SP test the TR-MB HS180 seemed to be the less stable while, on the contrary, the DMA results (Figs. 4–6) show that the TR-MB produced at 210ºC has a higher separation rate than the TR-MB produced at 180ºC. In fact, the results clearly show

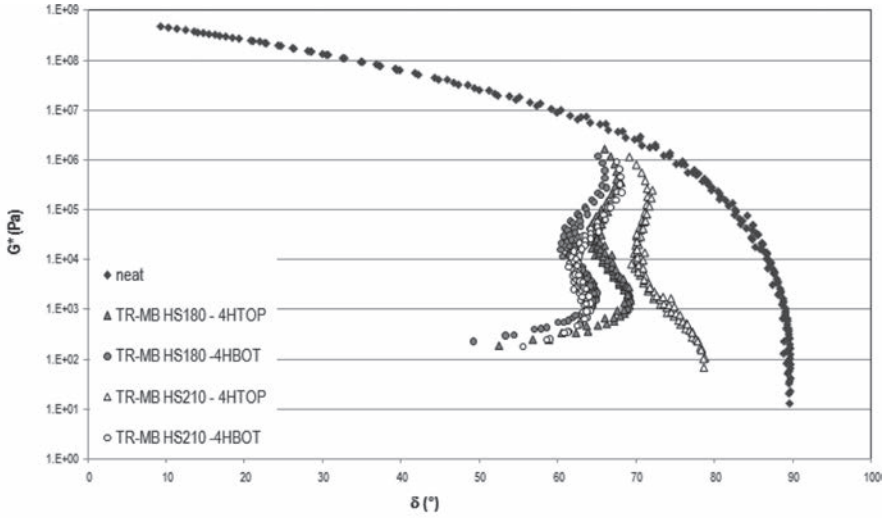

Figure 5. Black diagrams of top and bottom parts of the TR-MBs after 4 h of hot storage.

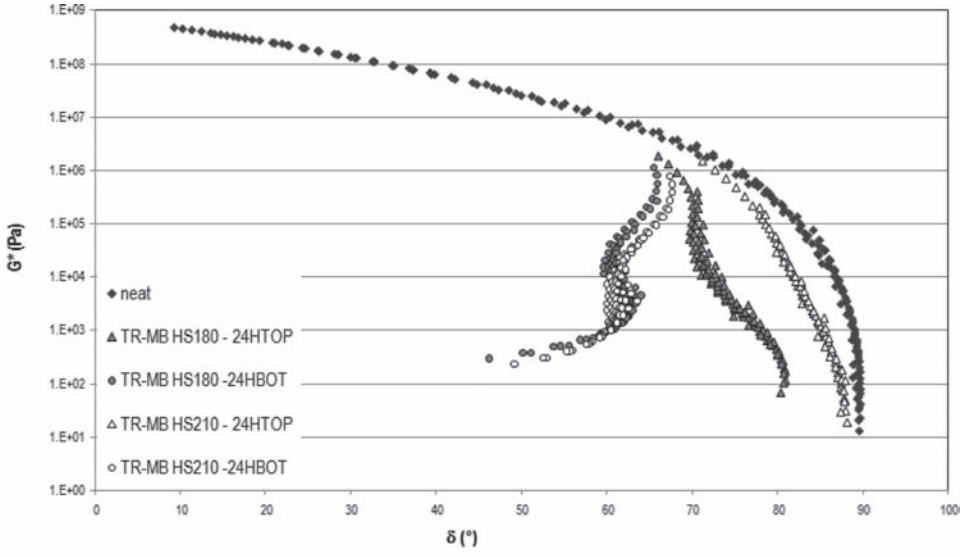

Figure 6. Black diagrams of top and bottom parts of TR-MBs after 24 h of hot storage.

that the difference in terms of Black curves between the top and bottom sections of the TR-MB HS210 is much higher than the difference measured for the TR-MB HS180.

4.2 *X-Ray analysis*

X-Ray CT images of TR-MB 70/100 blends with 15% of TR (40 mesh) are presented before and after storage in Figure 7. These images are representative sections at 100× magnification so that the clear distribution of the TR particles in the different sections before and after hot storage can be seen. So that the storage stability could be assessed, the amount of TR particles in both the top and the bottom of the samples were investigated separately. The particle area measurement was performed using X-Ray images at 50 times magnification using the Image J software.

Figure 1 shows the dispersion of the TR particles within the bitumen matrix after production and the top and bottom sections after 24 hours of the storage stability investigation.

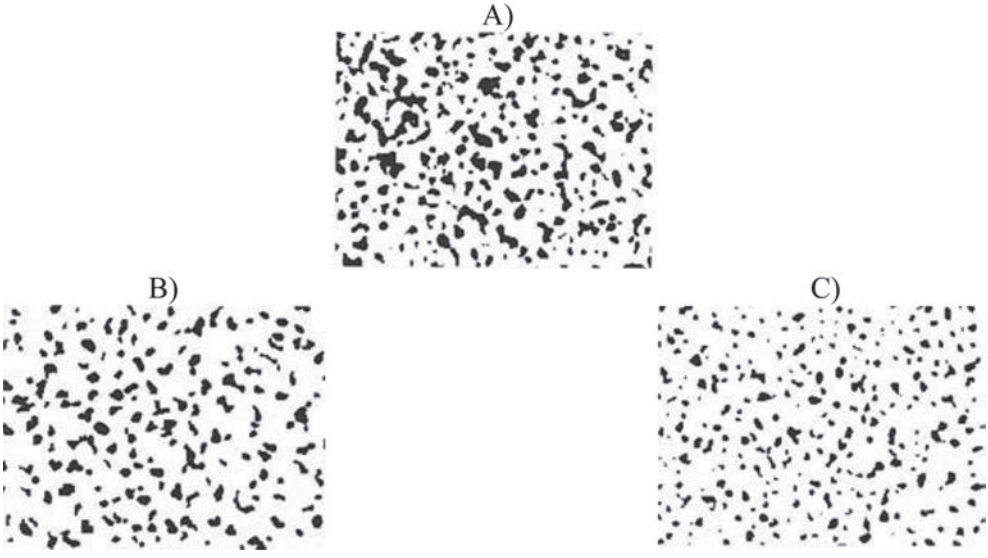

Figure 7. X-Ray CT images of A) TR-MB before storage, B) top after storage and C) bottom after storage at 200 × magnification.

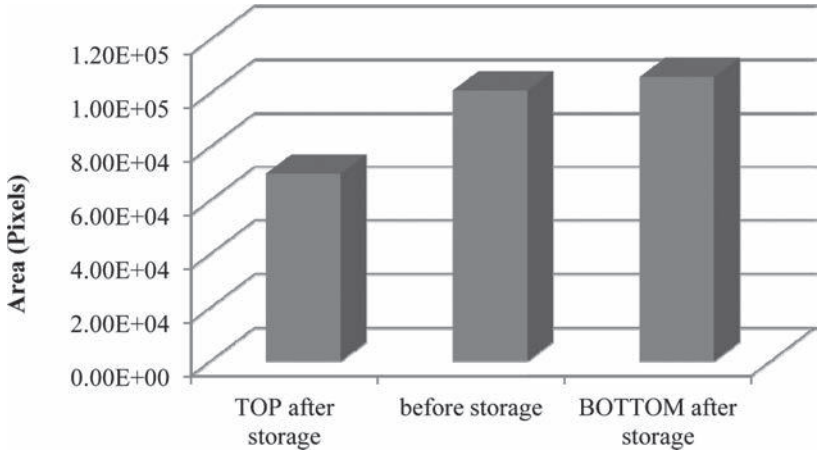

Figure 8. Area of TR particles in different sections of the storage tube before and after storage.

The X-Ray CT images indicate that the TR phase is evenly distributed after the production phase (Fig. 7a). However, a significant separation has occurred after prolonged hot storage. In general, the TR with a higher density than the bitumen (fine particles) has settled to the bottom third of the tube (Fig. 7c), whereas the lower density TR particles (coarse particles) have migrated to the top (Fig. 7b). The TR concentration in the blend has also affected the migration of the TR particles during the storage period.

Following these visual observations, the areas of the TR particles were also calculated in these sections taken from the storage tubes. This was done to confirm the observations quantitatively. These measurements, shown in Figure 8, demonstrate the between the values calculated before and after the hot storage, but also the clear difference between the amounts of TR particles in the top and bottom sections after hot storage. In fact, the bottom section has more TR compared to the top section, which now has less TR than after initial mixing. Also it can be seen that it is the smaller particles that in the bottom section that have led to this increase (Fig. 8).

5 CONCLUSION

This study presents two alternative methodologies for the assessment of a very complex phenomenon related to polymer modification of bitumen: the storage stability under high temperatures. In fact conventional tests such as the ring and ball test have not been designed for such complex materials as rubberised binders. A proof of this statement is provided by the fact that performing the test with such heterogeneous material is almost never problem-free, compared to the testing of neat bitumen. This may result in significant errors as shown by this study. On the other hand, Dynamic Mechanical Analysis proved to be a more effective tool and the authors believe that assessing the storage stability of modified binders through rheological characterisation gives a better understanding of the separation process. Furthermore, X-Ray CT and image analysis proved to be very useful to clarify a complex phenomenon, which had not yet been fully characterized, such as the behavior of modified binders under hot storage. This part of the investigation led to the clarification of the phase separation process of the rubberised binders after a long period of hot storage. As a result, the finer TR particles (higher density) tend to sink in the bottom section, also due to agglomeration, while the larger TR particles (lower density) tend to float the top. In addition, image analysis clarified that the sinking phenomenon is more relevant than floating, and this justifies the better rheological properties of the bottom section recorded through the dynamic mechanical analysis.

ACKNOWLEDGEMENTS

The authors wish to acknowledge the University of Palermo (IT) for the significant contribution to the experimental programme.

Investigation of the effect of temperature on asphalt binder fatigue

Farinaz Safaei & Cassie Hintz
Department of Civil, Construction, and Environmental Engineering, North Carolina State University, Raleigh, NC, USA

ABSTRACT: Fatigue resistance of asphalt pavements is known to be a temperature dependent phenomenon. The temperature dependence of pavements is driven by its constituent asphalt binder. This study evaluates the effect of temperature on asphalt binder fatigue resistance using the Dynamic Shear Rheometer (DSR). Results were analyzed using a Simplified Viscoelastic Continuum Damage (VECD) analysis framework. Results demonstrate that damage during DSR testing only manifests as fatigue cracking below a certain critical temperature above which flow rather than fracture dominates failure. Similarly, at sufficiently low temperature, adhesive failure between the DSR plates and asphalt specimen is found to confound results. Over the range of temperatures where cohesive fatigue cracking is found to occur in the DSR, time-temperature superposition using linear viscoelastic time-temperature shift factors can be applied to VECD results, allowing for efficient fatigue characterization at multiple temperatures. Trends in fatigue life with varying temperature appear to be binder dependent.

Keywords: asphalt binder, fatigue, time-temperature superposition, viscoelastic continuum damage modeling

1 INTRODUCTION

Fatigue cracking in asphalt pavements results from the accumulation of damage under repeated traffic loading. It is generally assumed that fatigue damage in asphalt pavements is most critical at intermediate temperatures corresponding to springtime when layers underlying the asphalt concrete become saturated due to thawing of snow and ice and/or rain [1]. However, pavements are subjected to a variety of temperatures associated with seasonal and daily fluctuations in temperature and thus, fatigue damage does not accumulate not at a specific temperature but rather over a critical range of temperatures. Therefore, understanding and modeling temperature effects on fatigue is an area of great interest. At sufficiently high temperatures, fatigue damage is not expected to be of concern as the soft nature of the asphalt binder will lead to failure by plastic flow rather than cracking and also promote self-healing of existing microcracks. Similarly, at sufficiently low temperatures, asphalt binder becomes very stiff and brittle, which will lead to dominance of thermal cracking as opposed to fatigue.

Asphalt binder is weakest asphalt concrete constituent and is responsible for the temperature sensitivity of asphalt concrete. Thus, this study aims to investigate the effect of temperature on asphalt binder fatigue measured using the Dynamic Shear Rheometer (DSR). The effect of temperature on the failure mechanism of the asphalt binder (i.e., fracture versus plastic flow) is investigated. Additionally, application of Time-Temperature Superposition (TTS) to fatigue damage growth, quantified using simplified ViscoElastic Continuum Damage (VECD) framework is used to aid in interpretation of results and offers an efficient means to predict fatigue damage growth under varying climatic conditions.

2 BACKGROUND

2.1 *Binder fatigue testing*

In the current Superpave, Performance Grading (PG) specification for asphalt binders, the parameter $|G^*| \cdot \sin \delta$ measured within the linear viscoelastic regime at a single temperature is used to evaluate fatigue performance under the assumption that a softer and more elastic binder will be more fatigue resistant [2]. Recent research has shown that this parameter is not a good indicator of the damage resistance, particularly in the case of modified asphalts, since it is only a single point at a small strain level and does not take the traffic loading in to account [3]. Therefore, Bahia et al. introduced a new test method, called the time sweep, which consists of repeated cyclic loading in the DSR at constant loading amplitude as an alternative to the current specification [4]. One can change the amplitude of loading during the test to simulate differing pavement structures and calculate a fatigue life based on monitoring the changes in loading resistance with respect to number of loading cycles. The procedure has been shown to capture binder contribution to asphalt mixture fatigue resistance based on laboratory comparison of time sweep results and asphalt concrete fatigue test results [4].

However, the temperature at which the time sweep test is applicable and how to account for fluctuations in temperature in fatigue modeling has not been rigorously studied. Hintz and Bahia [5] studied the mechanism of fatigue failure of asphalt binders in the time sweep test. Their work demonstrated that fatigue failure in the DSR manifests as "edge cracks," which are circumferential cracks that initiate from the periphery of the specimen and propagate towards the specimen center as the number of loading cycles increases, effectively causing the reduction of sample radius and consistent with other materials fatigued under cyclic torsional loading. However, their study was only done over limited temperature range and others account in the literature have noted confounding effects of edge flow during time sweep testing in the DSR. Anderson et al [6] observed two mechanisms of failure in the time sweep test, depending on the test temperature. At low temperatures, the formation of cracks was noted as the failure mechanism but plastic flow at the periphery of the sample was found to occur when tests were conducted at relatively high temperatures. Soenen and Eckmann also reported as the stiffness of binder decreases as a result of testing temperature increase, edge flow occurs but as long as the modulus was sufficiently large fatigue cracks developed toward the center of the sample [7,8].

This study investigates the effect of binder temperature (and thus, $|G^*|$) on the failure mechanism of asphalt binder based on image analysis of specimens following testing.

2.2 *S-VECD model*

Fatigue test results were interpreted using a Simplified Viscoelastic Continuum Damage (S-VECD) model. VECD-based frameworks have been used extensively to characterize the complex behavior of asphalt mixtures [9,10] and more recently have been applied to binders [11]. Details on the S-VECD model development are provided elsewhere [12]. However, a brief overview is provided in the interest of the reader. Viscoelastic continuum damage modeling of asphalt materials is based on Schapery's work potential theory which utilizes an internal state variable, S, to quantify damage as a result of microstructural changes which lead to a reduction in effective stiffness. This internal state variable representing damage is derived from the following damage evolution law:

$$\frac{ds}{dt} = \left(-\frac{\partial W^R}{\partial s} \right)^{\alpha} \tag{1}$$

where W^R is the pseudostrain energy density defined in Eq. (1) and α is a material dependent constant. For the work herein, α is defined as $1/m$ where m is the steady-state slope of the dynamic shear modulus master curve in log space [11].

$$W^R = \frac{1}{2} C(S)\left(\gamma^R\right)^2 \tag{2}$$

where γ^R is pseudostrain and $C(S)$ is the pseudostiffness of the materials.

Effectively, pseudostrain is equivalent to the linear viscoelastic stress response to loading history of interest divided by an arbitrary reference modulus, often selected to be one as is the case here. In the case of cyclic loading applied in the DSR, peak pseudostrain can be calculated as:

$$\gamma_{pp}{}^{R}{}_{cycle\,i} = \frac{1}{G_R} \cdot \left(\gamma_{pp_{cycle\,i}} \cdot |G^*|_{LVE}\right) \tag{3}$$

where G_R is an arbitrary modulus, selected to be one, $\gamma_{pp_{cycle\,i}}$ is the peak pseudostrain in a given cycle I and $|G^*|_{LVE}$ is the linear viscoelastic $|G^*|$ at the fatigue testing temperature (i.e., reduced frequency).

The pseudostiffness is defined in Eq. (4). The value of $C(S)$ with no damage is one and $C(S)$ decreases as material integrity is lost. The Dynamic Modulus Ratio (DMR) is a parameter used to account for specimen to specimen variability equal to $|G^*|_{Initial}/|G^*|_{LVE}$. For each time sweep test the DMR value is generally between 0.9 and 1, indicating good repeatability.

$$C^*(S) = \frac{\tau_{pp}}{\gamma_{pp}{}^{R} \cdot DMR} \tag{4}$$

where τ_{pp} is the peak shear stress in cycle of interest. Damage, S, is derived through numerically solving Eq. (1) with input of Eq. (2) to arrive at:

$$S = \sum_{i=1}^{N} \left[\frac{DMR}{2} \left(\gamma_{pp}{}^{R}\right)^2 \left(C^*{}_{i-1} - C^*{}_{i}\right) \right]^{\frac{\alpha}{1+\alpha}} \cdot [t_i - t_{i-1}]^{\frac{1}{1+\alpha}} \tag{5}$$

where t is time, and i refers to the cycle number. The primary benefit of the S-VECD model is that it is found that the relationship between $C(S)$ is the same regardless of loading history. This is illustrated in Figure 1 for a binder tested in the DSR using initial strain amplitudes of 3% and 4%.

2.2.1 *Incorporation of temperature effects in the S-VECD model*

Temperature effects have been incorporated into the S-VECD model for asphalt mixtures through use of time-temperature superposition. It has been generally accepted that asphalt is a thermo-rheologically simple material [14]. Furthermore, it has been demonstrated that

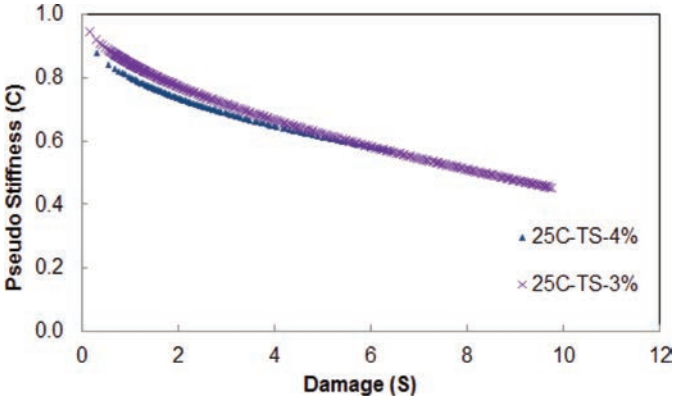

Figure 1. Damage characteristic curve for 370903 at 3 and 4% strain level.

thermorheological simplicity extends to the damage regime for asphalt mixtures. In 2001 Chehab et al [9] conducted uniaxial monotonic tests on mixture specimens at varying temperatures and loading rates and demonstrated that the time-temperature superposition can be used to collapse resultant VECD damage curves. Daniel and Kim [15] performed cyclic direct tension tests on mixtures at various cyclic crosshead displacement amplitudes, frequencies, and temperatures to investigate if predictions can be made from one temperature to another. These studies incorporated temperature effects into VECD models through replacing actual time with reduced time determined using linear viscoelastic time-temperature shift factors [9, 15].

In the case of the S-VECD framework for binders presented, time temperature is incorporated through the concept of reduced time by replacing t with reduced time, ξ (Eq. (6) and (7)). Reduced time is used in the damage calculation in order to shift to the reference temperature using time-temperature shift factors determined from linear viscoelastic characterization.

$$\xi = \frac{T}{a_T} \tag{6}$$

$$S = \sum_{i=1}^{N} \left[\frac{DMR}{2} \left(\gamma_{pp}{}^{R} \right)^2 \left(C^*_{i-1} - C^*_{i} \right) \right]^{\frac{\alpha}{1+\alpha}} \cdot \left[\xi_i - \xi_{i-1} \right]^{\frac{1}{1+\alpha}} \tag{7}$$

Similarly, pseudostrain and consequently pseudostiffness are calculated using reduced frequency.

2.2.2 *Fatigue life prediction from S-VECD model*

The VECD model can be extended to allow for fatigue life predictions. To do this, a power law model is fit to the unique $C(S)$ versus S curve:

$$C = 1 - C_1 \left(S \right)^{C_2} \tag{8}$$

where C_1 and C_2 are experimentally determined coefficients. Then, the following solution for fatigue life (N_f) can be derived:

$$N_f = \frac{\left(f_R \right) \left(2^{\alpha} \right) S_f^{\alpha - \alpha C_2 + 1}}{\left(\alpha - \alpha C_2 + 1 \right) \left(C_1 C_2 DMR \right)^{\alpha} \left(\gamma^R \right)^{2\alpha}} \tag{9}$$

where S_f = damage accumulation at failure, f_R = reduced loading frequency (Hz). Any pseudostrain amplitude of interest can be input into Eq. (9), allowing for prediction of results at any loading amplitude from results of a single test.

3 OBJECTIVES

The primary objectives of this research are to:

1. Evaluate the effect of temperature on the failure mechanism of asphalt binders tested under fatigue loading in the DSR
2. Evaluate applicability of time-temperature superposition to fatigue damage growth in the DSR.

4 EXPERIMENTAL PLAN

All tests were conducted in a TA ARG2 DSR using the 8 mm parallel plate-plate set-up. The tests were in the strain control mode. The binders tested are listed in Table 1. Two of

Table 1. Tested binders.

ID	Binder PG
30-0903	64-22
37-0903	70-22
C35	70-34

the binders were from the Long-Term Pavement Performance (LTPP) program, 30-0903 and 37-0903, which are from New Jersey and Oregon, respectively. Binder C35 is a polymer modified asphalt used in Minnesota. Thus, binders used in varying climates were selected which were anticipated to have very different behavior. All binders were aged in the Rolling Thin Film Oven (RTFO) prior to testing.

Frequency sweep tests were conducted to determine the linear viscoelastic properties of asphalt binders. In these tests, a constant load amplitude of 1% strain is applied to avoid damaging the specimen and the frequency changed between 0.1 to 30 Hz. Tests were performed at 50, 35, 20 and 5°C for all binders. Asphalt binder dynamic shear modulus and phase angle master curves were constructed from frequency sweep results and the Williams–Landel–Ferry (WLF) equation (Eq. (10)) was fit to the data to allow for prediction of the time-temperature shift factor at any temperature [2]:

$$\log \frac{a_T(T)}{a_T(T_o)} = -\frac{c_1(T - T_o)}{c_2 + (T - T_o)} \tag{10}$$

a_T = the shift factor at temperature T and, C_1, C_2 = experimentally determined coefficients.

Time sweep tests were conducted to study effects of temperature on fatigue resistance of asphalt binders. Tests were conducted at 5, 10, 15, 20, 25, and 35°C for all binders. Time sweep tests were all conducted in displacement controlled model at 10 Hz loading frequency and 3% initial strain amplitude.

5 RESULTS

5.1 *Linear viscoelastic master curves*

Dynamic shear modulus master curves for the three binders tested are presented in Figure 2. Moduli values for the fatigue testing conditions, 10 Hz frequencies with varying temperature are superimposed on the master curves, which show a wide range of $|G^*|$ values was covered by the temperatures considered.

5.2 *Analysis of failure mechanism and relation to binder $|G^*|$*

A depiction of samples following fatigue testing in the DSR at all test temperatures for binder 300903 is shown in Figure 3. The top pictures were obtained by freezing specimens following testing and then detaching the spindle using procedure proposed by Hintz and Bahia [4]. The bottom row of pictures is of the specimens in the DSR after testing before spindle detachment. It can be seen that as temperature increases, the failure mechanism translates from being fracture to flow. The radial lines emanating from specimen edge indicate the failed area and the smooth center of the specimens indicates the portion of the sample that remained intact. Similar observations were made for other binders and were made to judge failure mechanism. At 5°C it can be seen that the sample appears macroscopically flat. In this case, the binder had detached from the spindle rather than failing by cohesive fracture. For all binders, at 5°C adhesion loss between the DSR plates and the binder specimen occurred

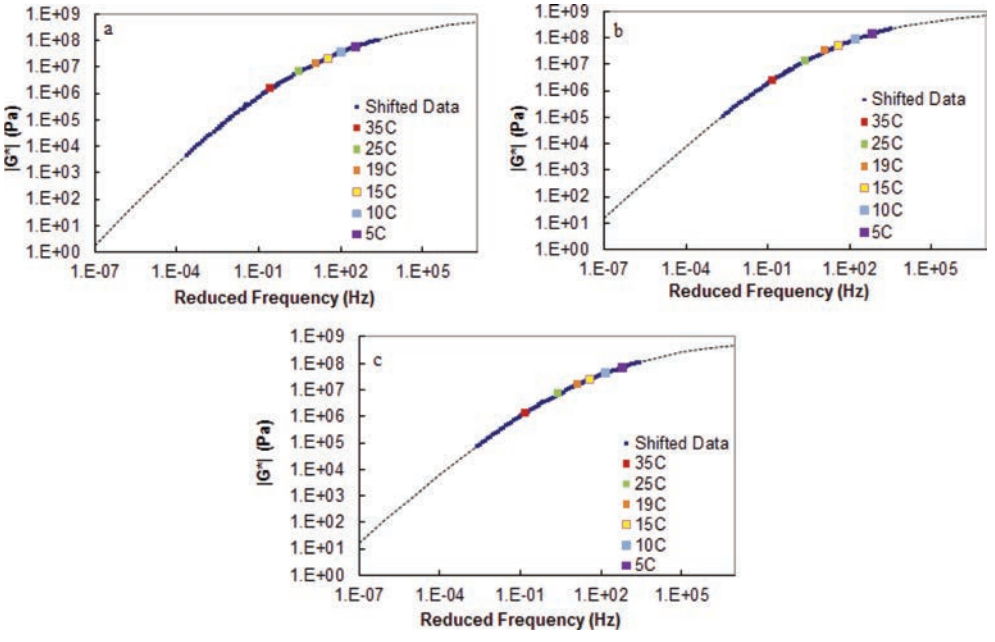

Figure 2. Master curves containing selected temperatures for a) 300903 b) 370903 c) C35.

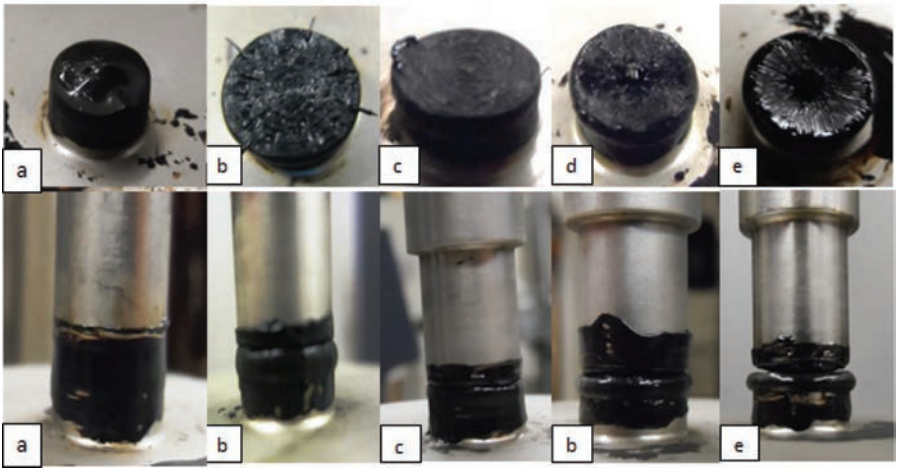

Figure 3. Specimen 300903 after testing at a) 5°C, b) 10°C, c) 15°C, d) 25°C, and e) 35°C.

rather than cohesive fracture of the specimen, determined based on a sudden drop in loading resistance during testing and visual observation of debonding following testing. The linear viscoelastic $|G^*|$ and phase angles determined from the master curves presented in Figure 2 at 10 Hz frequency and each testing temperature are provided in Table 2 with color coding to indicate the dominant failure mechanism. While only based on testing of three binders, these results suggest that cohesive fatigue fracture will occur during the time sweep test when the $|G^*|$ at the testing temperature and frequency is between 10 MPa and 50 MPa. It can be seen that above $|G^*|$ values of approximately 50 MPa, adhesive failure becomes a concern and that below values of 10 MPa, flow becomes evident with dominant flow rather than fracture at values below roughly 6 MPa.

Table 2. Complex modulus (|G^*|) and phase angle (δ) values for tested binders at tested temperatures.

Temperature (°C)	300903		370903		C35	
	|G^*| (MPa)	Phase angle (°)	|G^*| (MPa)	Phase angle (°)	|G^*| (MPa)	Phase angle (°)
35	1.49	58.51	2.44	34.73	1.38	35.90
25	6.50	48.16	13.15	48.15	6.70	46.34
19	13.90	45.68	30.99	42.81	15.21	42.57
15	21.95	46.96	51.07	36.80	24.87	38.00
10	36.83	51.18	88.23	31.22	43.26	33.81
5	58.33	56.63	140.36	27.37	70.45	30.88

= cohesive fracture, = cohesive fracture with moderate flow, = adhesive failure, = predominately flow failure.

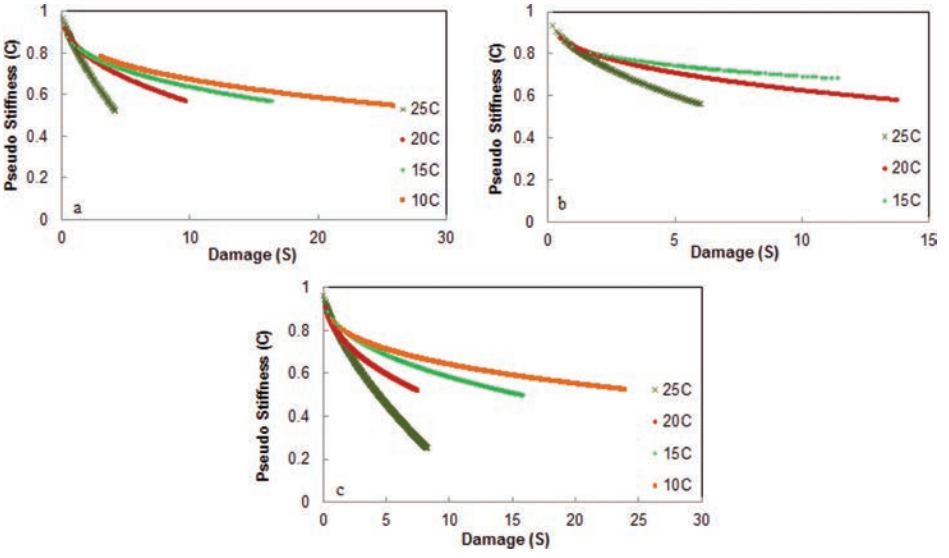

Figure 4. Time sweep damage curves for a) 300903 b) 370903 c) C35.

5.3 *Application of time-temperature superposition to S-VECD damage curves*

Based on the above presented results, S-VECD analysis was conducted for tests where cohesive fracture was found to be the dominant failure mechanism. S-VECD damage curves before and after application of time-temperature superposition are shown in Figures 4 and 5. Note that for Figure 5, a reference temperature of 20°C was used and linear viscoelastic time-temperature shift factors determined from frequency sweep testing were used. Trend is consistent with previous mixture findings.

Results demonstrate that by shifting the data to a reference temperature of 20°C, C vs. S curves collapse to a single curve, indicating time-temperature superposition is applicable in the range of temperatures where cohesive fracture is the dominant failure mechanism, indicating the S-VECD model can be used to efficiently characterize fatigue damage over the dominant range of temperatures where fatigue occurs.

5.4 *Fatigue life trends with temperature*

In defining a point for fatigue failure, besides the damage characteristic curves, the material integrity (i.e., C value) at failure is also important. Here, the peak in CxN (where N is number

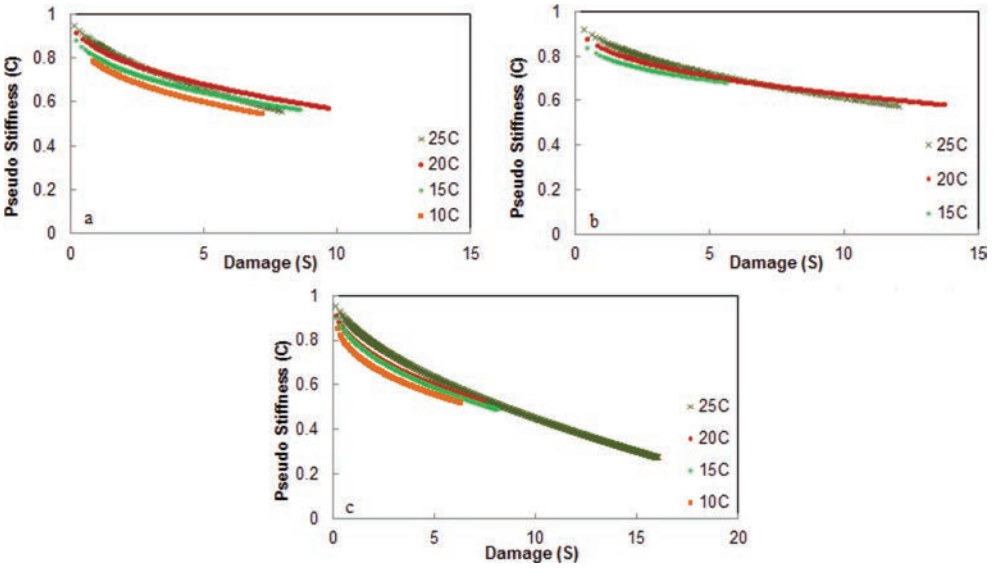

Figure 5. Shifted time sweep damage Curves for a) 300903 b) 370903 c) C35.

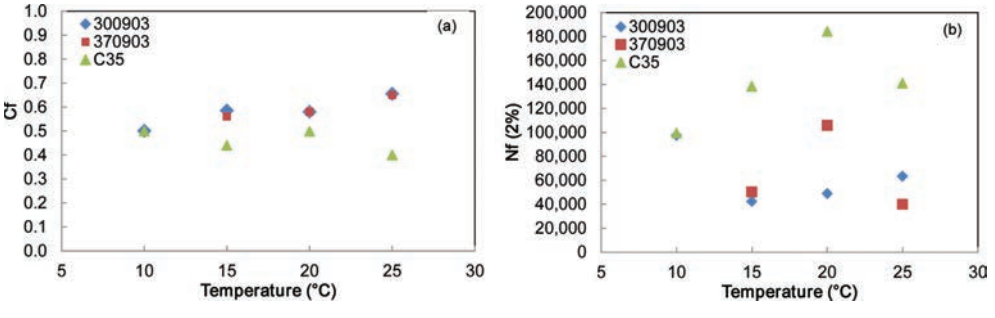

Figure 6. (a) PseudoStiffness at failure versus temperature and (b) fatigue life versus temperature.

of loading cycles) versus N is used to define failure, which is similar to the stiffness times N approach proposed by Rowe and Bouldin [16]. The peak in C times N corresponds to a marked change in the rate of loss in material integrity, as shown in, and is therefore considered a logical failure definition.

Trends in C_f with temperature for the three asphalt binders tested are shown in Figure 6(a). Note that data where flow or adhesion loss were found to be significant were excluded from analyses. Results show C_f is more or less stable with temperature. To determine the number of cycles to failure from the predicted results using the SVECD model, the C value at the failure cycle (C_f) is used as the failure criterion to determined S_f in Eq. (9). Results of fatigue life prediction at 2% strain amplitude are shown in Figure 6(b). Results show that binder C35 shows superior fatigue performance compared to other binders regardless of temperature, which is somewhat expected as this is a highly polymer modified asphalt. In addition, it can be seen that both binders 370903 and C35 show a peak in fatigue life at 20°C whereas binder 300903 shows a consistently increasing trend in fatigue life with increasing temperature. These results demonstrate that fatigue life is temperature dependent and the dependency of fatigue resistance on binder is also related to binder type.

6 CONCLUSIONS

- The time sweep appears to be applicable within the range of $|G^*|$ values of 10 to 50 MPa. Above this limit, adhesion loss becomes problematic. Below this limit, flow rather than cohesive fatigue fracture dominates failure.
- It can be seen that time temperature superposition applies to the time sweep results within the S-VECD framework in the range of temperature which cohesive fracture is the dominant fatigue failure mechanism.
- Results demonstrate no clear trend in fatigue life with temperature within the regime where cohesive fracture is observed. Thus, the effect of temperature on cohesive fatigue fracture in binders merits further study.

Effective temperature for permanent deformation testing of asphalt mixtures

Alaeddin Mohseni
Pavement Systems Inc., Bethesda, MD, USA

Haleh Azari
AASHTO Materials Reference Laboratory (AMRL), National Institute of Standards and Technology, Gaithersburg, MD, USA

ABSTRACT: Effective temperature for rutting (T_{eff}) is defined in the literature as a single testing temperature for asphalt mixtures to simulate rutting in the field. This temperature is essential in reducing the testing and analysis of asphalt mixture performance. Current procedures are developed during SHRP A-407 and NCHRP 9-22 projects which calculate T_{eff} from Mean Annual Air Temperature (MAAT). The objective of this study is to review the existing T_{eff} approaches for testing asphalt mixtures and to explore the possibility of developing a more robust and simplified T_{eff} procedure.

Comparison of the SHRP and NCHRP procedures with the calculated rutting determined that the test temperatures provided by these procedures were too low to cause rutting damage. Furthermore, the comparison of Degree-Days parameter, which correlated well with rutting, and MAAT revealed that MAAT is over-predicting T_{eff} in coastal areas due to mild winters while under-predicting it in desert areas due to colder nights. An enhanced T_{eff} approach was developed based on the incremental rutting damage concept that was used for the LTPP Bind high-temperature model. The proposed procedure is more accurate since it is calibrated to the field and experts' opinion, yet it is simpler and easier to use than the current approaches.

Keywords: Effective temperature, asphalt mixture performance, permanent deformation, degree-days, rutting

1 BACKGROUND

The determination of a single testing temperature for asphalt mixtures to simulate permanent deformation (rutting) is essential in reducing the testing and analysis of AC mixture performance. The presence of a single temperature at which AC mixtures can be evaluated has been termed the "Effective Temperature—T_{eff}" in the literature.

T_{eff} is defined by SHRP A-407 (1) as "a single test temperature at which an amount of permanent deformation would occur equivalent to that measured by considering each season separately throughout the year." T_{eff} is defined by SHRP A-415 (2) as "that temperature at which loading damage accumulates at the same average rate in service as in the laboratory. Thus, when testing at the effective temperature, there is a one-to-one correspondence between laboratory and in-service loading cycles."

1.1 *Existing effective pavement temperature models*

The SHRP effective pavement temperature was developed during SHRP A-407 (1) and is based on mean annual air temperature and critical depth as follows:

$$T_{eff} = 30.8 - 0.12\,(z) + 0.92\,(MAAT_{design})$$
$$MAAT_{\text{design}} = MAAT_{\text{Average}} + K_{\alpha}\sigma_{\text{MAAT}} \quad (1)$$

where:
T_{eff} = Effective pavement temperature for rutting, °C
z = critical depth down from pavement surface, mm
$MAAT_{\text{design}}$ = mean annual air temperature, °C
K_{α} = K at appropriate reliability level of 95% (1.645)
σ_{MAAT} = standard deviation of distribution of MAAT for site location.

Sotil and Witczak (3) proposed an extended equation that included loading frequency. This model is identical to SHRP A-407 model for the depth of 1.0 in. and frequency of 1 Hz. The model was utilized in NCHRP 9-30A (4), however, it was attributed to SHRP A-415. NCHRP 9-22 (5) introduced another T_{eff} model that introduced seasonal variability and three new climatic parameters into the model as follows:

$$T_{eff} = 14.62 - 3.36\,\text{Ln}(Freq) - 10.94\,z + 1.121\,MAAT - 1.7178\,\sigma_{\text{MAAT}} - 0.431\,Wind + 0.333\,Sun + 0.08\,Rain \quad (2)$$

where:
T_{eff} = modified Witczak effective temperature for rutting, °F
$Freq$ = effective loading frequency, Hz
z = desired pavement depth, inches
$MAAT$ = mean annual air temperature, °F
σ_{MAAT} = standard deviation of the mean monthly air temperature
$Wind$ = mean annual wind speed, mph
Sun = mean annual sunshine percentage, %
$Rain$ = cumulative annual rainfall depth, inches.

Note that σ_{MAAT} for SHRP and NCHRP equations are not the same. In the SHRP model, σ_{MAAT} is the yearly MAAT variation, however, in NCHRP it is the monthly variation of Mean Monthly Temperature (MMT) which indicates seasonal variation. Both models have a depth term which is linear with depth and results in about 3ºC (SHRP) and 6ºC (NCHRP) reduction in T_{eff} for every inch depth into the pavement. The NCHRP model is also used in NCHRP 9-33A (6) for specification criteria for Simple Performance Tests (SPT).

1.2 *SHRP temperature models*

In order to calculate the design temperatures for SUPERPAVE, equations were developed relating design air temperature to design pavement temperature for both high and low design air temperatures. During SHRP-A-637 (7) project, pavement surface temperature during the hottest 7-day period of the year was calculated for five sites in Maryland, New York, Virginia, Arizona and Saskatchewan using Integrated Climatic Model (ICM) software. Solar absorption, radiation transmission through air, atmospheric radiation, and wind speed data was used to estimate pavement temperatures at different depths within AC layer. SHRP-A-648A (8) used these calculations to determine high design pavement temperature with depths below the pavement surface. The model was utilized for the SHRP high temperature Performance Grade selection. Equation 3 includes the SHRP model for estimating pavement temperature at the depth of 20 mm below the pavement surface ($\boldsymbol{T_{20}}$) from air temperature ($\boldsymbol{T_{air}}$) and latitude (***lat***):

$$T_{20\text{mm}} = (T_{air} - 0.00618lat^2 + 0.2289lat + 42.2)\,(0.9545) - 17.78 \quad (3)$$

1.3 *LTPP Seasonal AC Pavement Temperature (SAPT) model*

FHWA initiated a project to utilize LTPP Seasonal Monitoring Program (SMP) data to validate and/or enhance the SHRP equations. The SMP data was measured from within the

pavement layer for 25 locations for up to 3 years which was significantly more data that SHRP had access to at the time. During this project, Mohseni (9, 10) developed new temperatures models from SMP data which were included in the LTPPBind V2.1 software. Following is the high temperature model:

$$T_d = 54.32 + 0.78\ T_{air} - 0.0025\ Lat^2 - 15.14\ log_{10}\ (d + 25) \quad (4)$$

where:
T_d = High AC pavement temperature below surface, °C
T_{air} = Air temperature during the hottest 7-day period of the year, °C
d = Depth to surface, mm.

1.4 *LTPPBind version 3.1 pavement temperature model*

SUPERPAVE binder Expert Task Group (ETG) initiated a project to address the concern from the Southern U.S. states that the SHRP high temperature grades did not correspond to their climate. During this project, Mohseni (11) determined that the SHRP high temperature determination (mean 7-day high pavement temperature) is short-sighted and does not consider the longevity of the high temperatures. Mohseni introduced a new parameter, the degree-days, to replace the SHRP high mean 7-day parameter. An incremental rutting damage model based on NCHRP 1-37A stiffness and permanent deformation models (12–14) was developed based on hourly calculation of temperatures and damage within pavement layer. The incremental rutting damage for different binder grades, aggregate gradations, and traffic levels were accumulated on hourly basis for 20 years for about 280 locations within the U.S. The calculated rutting correlated very well with pavement degree days at depth of 20 mm. A transfer function was developed to convert the pavement temperature to air degree days for easier implementation (Equation 5). Equation 5 was implemented in LTPPBind version 3.1.

$$T_{20} = 22.8 + 14\ DD - 0.96\ DD^2 \quad (5)$$

where:
T_{20} = Design high pavement temperature at 20-mm depth
DD = Annual Air Degree-Days > 10°C (×1000°C)
Accumulated Daily Air Temperature in Excess of 10°C for Entire Year
Statistics: R^2 = 90%, N = 1307, SEE = 2.5°C.

1.5 *Pavement temperature with depth*

Determination of the pavement temperature and heat exposure within the pavement layer is a critical part of effective pavement temperature model. Significant temperature gradient exist in the pavement, especially during afternoon hours when air temperatures peaks. Pavement surface temperature rises accordingly and the temperatures within the pavement also increase with time, but with some delay. During night, however, the process is reversed when surface temperature quickly drops but pavement temperatures are still high. Before the sunrise next day, however, the temperatures within the pavement layer stabilize. Different procedures have been developed to estimate the high pavement temperature with depth. SHRP (8) developed Equation 6 to estimate high mean 7-day pavement temperature from surface temperature.

$$T_d = T_s\ (1 - 0.063\ d + 0.007\ d^2 - 0.0004\ d^3) \quad (6)$$

where:
T_d = maximum pavement temperature (°F) at depth "d"
T_s = maximum pavement surface temperature (°F)
d = depth of critical location to surface, in.

Mohseni (9) developed a pavement temperature model (Equation 4) from LTPP using empirical climatic data from Seasonal Monitoring Program which was used in LTPPBind software for binder grade selection. Equation 7 is the depth term of Equation 4 previously mentioned:

$$T_d = T_s - (15.14\ log_{10}(d + 25) - 21.16) \quad (7)$$

where:
T_d = high AC pavement temperature below surface, °C
T_s = high pavement surface temperature, °C
d = depth of critical location to surface, mm

Figure 1 shows the estimated high pavement temperature gradient through a pavement using the LTPPBind depth term (dash line). The points in Figure 1 are annual pavement Degree-Days within asphalt layer estimated using ICM and hourly weather data (air temperature, wind speed, and sunshine) for four Arizona sites. It should be noted that the LTPPBind depth model, based on measured SMP data, and the calculated pavement temperatures for Tucson agree well. The LTPPBind depth term also agrees with other weather station locations shown in the figure since the depth term adjust itself with surface temperatures (the line shifts up and down).

1.6 *Objectives*

The objective of this study is to 1) review existing effective temperature approaches and 2) develop an enhanced approach for calculating the effective temperature (T_{eff}) for testing asphalt mixtures as part of prediction of in situ rutting performance. Specifically, the objective of this research study is to explore the possibility of developing a more accurate and simplified procedure for calculating effective temperature for asphalt mixture rutting performance prediction for any location in the U.S.

2 REVIEW OF THE CURRENT METHODOLOGIES

2.1 *White paper on effective pavement temperature for rutting*

Mohseni (15) reviewed existing effective temperature models in 2005 and proposed a simplified approach for FHWA. Mohseni employed the incremental hourly damage concept and

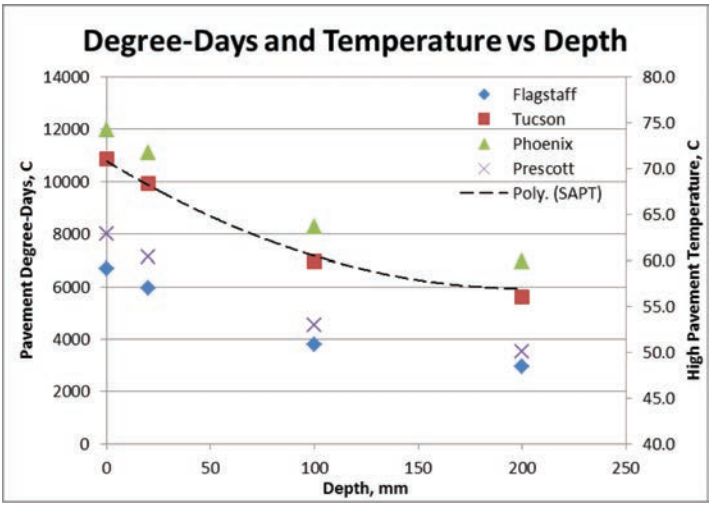

Figure 1. High pavement temperature versus depth from LTPPBind study.

the Degree-Day parameter to develop an effective temperature for Flow Number testing. The analysis showed that the effective temperature equation recommended by SHRP and NCHRP (based on Mean Annual Air Temperature) provided significantly lower temperatures than the incremental hourly damage approach. Subsequently, FHWA adopted 50% high temperature PG from LTPPBind version 3.1 (equation 5 above) as the test temperature for flow number testing.

2.2 *Test temperatures of asphalt ETG flow number study*

The FHWA Asphalt Expert Task Group (ETG) initiated a study in 2010 to examine different rutting tests in order to nominate the most promising for Asphalt Mixture Performance Tester (AMPT). Three different test temperatures were used in this study by several competing approaches. The details of the study are included in Reference 16. Most test temperatures were based on 50% high temperature PG from LTPPBind V3.1.

Test method 1 (from NCHRP 9-30), test methods 4 through 6 (proposed by MTE construction) and test method 7 (iRLPD method) all used 50% LTPPBind high temperature PG grade as the test temperature. Method 2 (by NCAT) used 50% PG minus 6°C and method 3 (from NCHRP 9-30A) used the effective pavement temperature algorithm developed by SHRP (1). Figure 2 shows the test temperatures versus Degree-Days from LTPPBind for the nine mixtures included in the study. As indicated from the figure, NCHRP 9-30A test temperatures were more than 20°C lower than the test temperatures for most other test methods.

Some adjustments were made to the LTPPBind-based temperatures and a lower temperature than 50% reliability PG was actually used. The final test temperatures were about 2°C lower than 50% reliability high-temperature PG from LTPPBind V3.1. This adjustment was done since the ETG study participants believed that 50% PG was a little too high for testing the mixtures. Furthermore, analysis of preliminary test data showed that the lowered test temperature agreed better with the mixture performance in the field. There were also confusion in using LTPPBind high-temperature model. Therefore, it was decided that a separate model was needed for calculating the effective temperatures instead of using LTPPBind 50% reliability PG.

2.3 *Review of the existing T_{eff} rutting equations*

Equation 1 was used by SHRP to estimate T_{eff} rutting using Mean Annual Air Temperature (MAAT) and critical depth. Since rutting occurs under pavement loadings at high

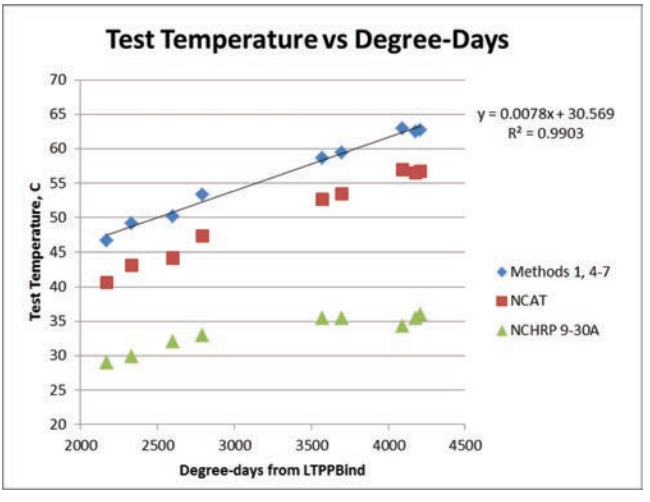

Figure 2. Test temperature versus degree-days for nine mixtures from ETG flow study.

temperatures, the analysis for rutting should also concentrate on the hot days of the year when the predominant rutting takes place. Mean Annual Air Temperature (MAAT), however, is an annual statistic and includes the temperatures of the cold winter days as well hot summer days. As a result, locations with hot summers days and cold winters days may have similar MAAT with areas with mild summer and mild winter. Conversely, in the desert environment MAAT is lowered by the lower temperatures of the nights. For this reason, MAAT did not seem to be a proper climatic parameter for estimating rutting damage at a site.

Equation 2, developed by NCHRP 9-22, tried to address this problem by incorporating the seasonal variations (σ_{MAAT}) and three additional climatic variables into the model. Apart from its complexity, the resulting T_{eff} of this model still has the above mentioned problems.

Furthermore, the depth term in the SHRP and NCHRP models is linear. Past research indicates that the control temperature that relates to rutting reduces with depth in a non-linear fashion and therefore the temperature change is reduced with depth. For this reason, Equation 1 (SHRP) may be underestimating and Equation 2 (NCHRP) may be overestimating the temperature at lower depths.

The 50% reliability high-temperature from LTPPBind seems to provide a reasonable test temperature for asphalt mixture testing. However, it may be fine tuned and better defined for wider use.

3 COMPARING DIFFERENT METHODS

3.1 *Comparing Mean Annual Air Temperature (MAAT) versus Degree-Days (DD)*

Mean Annual Air Temperature (MAAT) is utilized by several SHRP and later NCHRP projects as the temperature parameter for determining effective temperature for rutting. MAAT parameter was used in NCHRP 9-22 and 9-30A for determining the effective temperature. Degree-Days parameter has been used by LTPPBind for binder grade selection. The two climatic parameters (MAAT and Degree-days) are compared here to determine the differences. Figure 3 shows MAAT versus Degree-Days (DD) for 20 selected cities in the U.S. Figure 3 shows a relatively good agreement between the two parameters for most

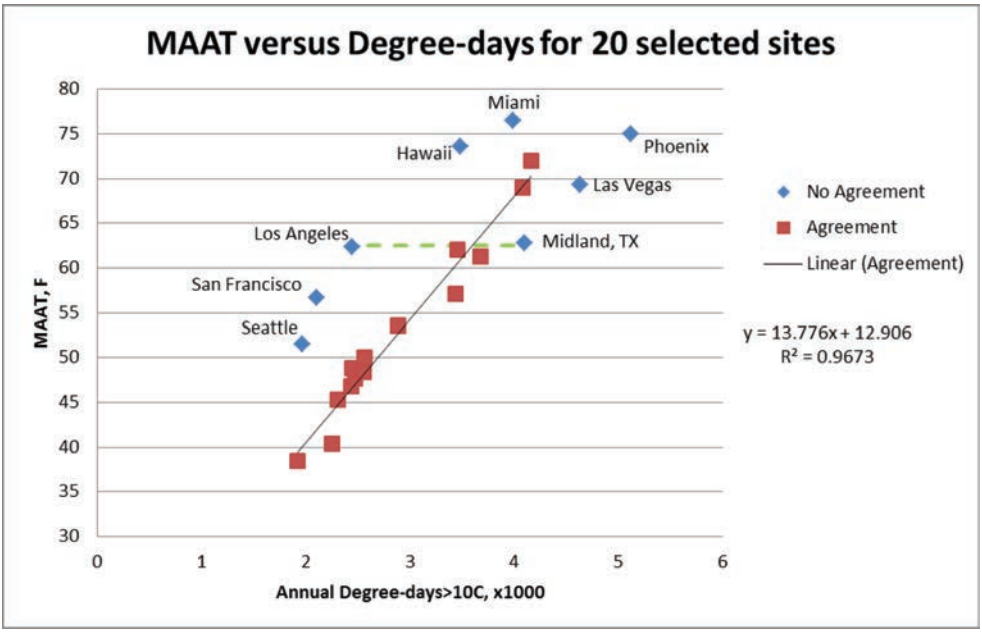

Figure 3. Mean Annual Air Temperature (MAAT) versus degree-days for selected cities.

locations within U.S. (points shown as red squares). However, for some sites (shown in blue diamond) the two parameters are significantly different. Figure 3 shows three locations (Los Angeles, Tulsa, and Midland) on a green dash line that have the same MAAT (about 62.5°F) but significantly different Degree-Days (2.5, 3.7 and 4.1 × 1000°C respectively). It appears that MAAT overestimates heat exposure in coastal areas by about 7°C and underestimates heat exposure in desert environments (Phoenix, Midland, Las Vegas) by at least the same amount.

The reason for the discrepancy of the two metrics for some locations was investigated. The points above the line in Figure 3 are locations that MAAT over-estimates the temperature compared to DD. These locations are all close to ocean and since coastal regions have milder winters than further inland, this fact has caused the increase in MAAT. Furthermore, the points below the line belong to desert locations where temperature drops drastically at night. MAAT is an average of temperatures for days and nights (high and low) and over seasons and as a result:

- MAAT is higher for coastal areas because of the milder nights and milder winters
- MAAT is lower for desert areas because of the colder nights

Therefore, including low temperatures in the temperature parameter is not feasible. Degree-days, which is based on the accumulation of higher temperatures than 10°C, does not include temperature at cold nights and cold winter months, therefore, it does not suffer from the shortcomings of MAAT.

3.2 *Comparing pavement temperature with depth algorithms*

Figure 4 shows the depth term for four procedures mentioned previously. The SHRP A-407 T_{eff} algorithm is a function of pavement surface temperature and for this purpose 55ºC was assumed. Figure 4 shows that the SHRP A-648 procedure and LTPPBind agreed up to the depth of 125 mm, however, SHRP temperature drops at higher rate than LTPPBind model at lower depths. SHRP A-407 and NCHRP 9-22 T_{eff} procedures are linear with depth and does not level out at lower depths. NCHRP 9-22 procedure provides much higher estimates of temperature drop with depth than SHRP A-648 and LTPPBind and is significantly

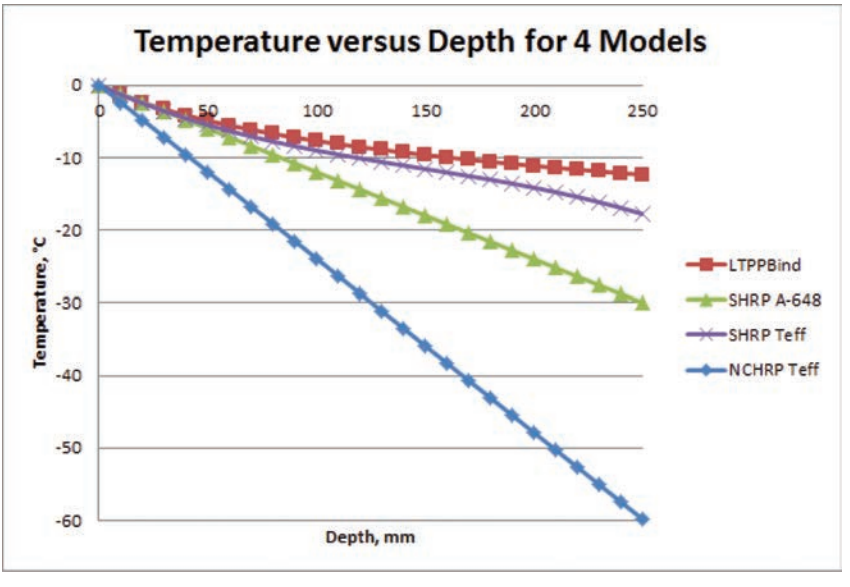

Figure 4. Depth term for different pavement temperature algorithms.

over-estimating the effect of depth on reduction of pavement temperature. The LTPPBind model has the best functional form and provides better estimate of maximum temperature with depth of AC layer.

4 DEVELOPMENT OF A SIMPLIFIED EQUATION FOR T_{eff}

A Mechanistic-Empirical approach similar to the approach used for the development of enhanced high temperature PG binder selection procedure (LTPPBind) (11) was utilized in this study to develop T_{eff} for asphalt mixtures based on rutting damage. Hourly pavement temperature frequencies at the critical depth of 20 mm which was developed under LTPPBind project was used in this study for a typical pavement structure and for 270 locations in the U.S. These data were developed using Integrated Climatic Model V 2.6 (ICM) and hourly climatic data for a 20-year period. Using NCHRP 1-37a (12–14) calibrated stiffness model, AC stiffness was estimated for every temperature and subsequently the rutting damage was calculated using NCHRP 1-37a final permanent deformation model. Several assumptions had to be made regarding pavement structure, traffic loadings and allowable rut depth.

A typical pavement structure (6 inch conventional Asphalt Concrete (AC) over 12 inch base course) with standard loading of 3 million standard axles and loading frequency of 10 Hz (for highway speed) and a limiting rut depth of 12.7 mm was considered. The binder parameter used in the NCHRP 1-37A AC stiffness model was consistent with the LTPPBind PG selection at 98% reliability. Rutting damage for all temperatures in a 20-year analysis period was accumulated on hourly basis to calculate the total rutting damage for every location. Effective Pavement Temperature was then calculated as the temperature that produces similar rate of rutting damage in laboratory as in the field (with climatic variations) under similar loading conditions.

4.1 *Develop proposed T_{eff} using degree-days*

As a result of the correlation analysis it was found that degree-days correlate best with T_{eff}. The derived model is shown in Equation 8.

$$T_{eff} = 33 + 7 * DD + \varepsilon \tag{8}$$

where:
T_{eff} = effective pavement temperature for rutting, ºC
DD = average yearly air degree-days over 10ºC, ×1000, °C
Accumulated Daily Air Temperature in Excess of 10°C for Entire Year
Statistics: $R^2 = 88\%$, $SEE = 1.43$, $N = 216$.

Equation 7 has a depth term $15.14\ log_{10}(d + 25)$ which is currently used in LTPPBind version 3.1 to determine temperature drop within the pavement. This term at depth of 20 mm ($d = 20$) was used to determine the temperature drop within the pavement layer for T_{eff}. Equation 9 includes the proposed procedures for calculating effective temperature for rutting with depth.

$$T_{eff} = 58 + 7.0 * DD - 15\ log_{10}(z + 45) \tag{9}$$

where:
z = depth of layer, mm (depth of layer to pavement surface)

4.2 *Comparing different effective temperature approaches*

Four different approaches for effective temperature that were discussed in this paper, is compared to show the differences. Figure 5 shows LTPPBind 50% reliability PG (Equation 5),

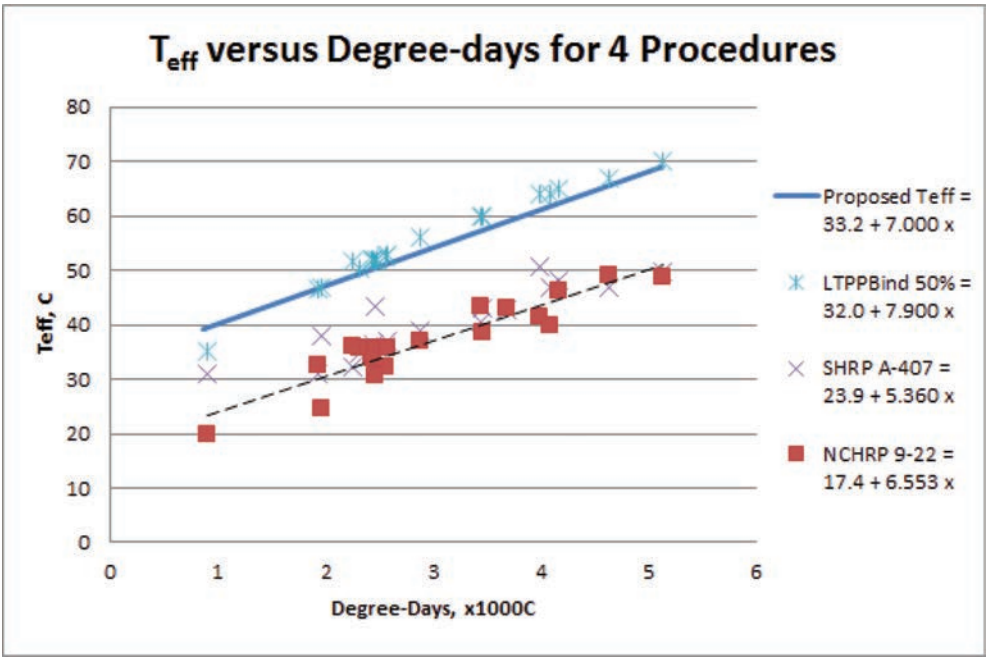

Figure 5. SHRP, NCHRP, 50% PG and new effective temperatures versus degree-days.

the proposed T_{eff} model (Equation 9), SHRP model (Equation 1), and NCHRP model (Equation 2) versus Degree-Days from LTPPBind. The proposed parameter is slightly lower than LTPPBind 50% PG which is currently used by several agencies. SHRP and NCHRP T_{eff} at the depth of 1 inch are similar except for four points, which are locations that are close to the ocean. On average, the proposed T_{eff} is about 20°C higher than SHRP and NCHRP T_{eff}.

Although effective temperatures similar to the proposed T_{eff} was used in the ETG flow number study as test temperature successfully, the main application of model was as the test temperature for the newly developed incremental Repeated Load Permanent Deformation test procedure introduced by Azari and Mohseni (17). The results of iRLPD tests performed on nine ETG specimens from eight different states (various design traffic and binder type) were used to estimate rutting (17) and it was found that the rutting damage parameter from iRLPD test using proposed T_{eff} and deviator stress of 600 kPa (to simulate standard axle loading) provided reasonable estimate of rutting and correlated well with the expected performance of the mixture in the field. However, the tests performed using the SHRP T_{eff} temperature (method 3 using NCHRP 9-30A) did not exhibit any noticeable damage mainly due to the low effective temperature. The proposed T_{eff} was judged for reasonableness by the experts and was also field calibrated to provide feasible rutting damage results.

5 FINDINGS AND RECOMMENDATIONS

Existing effective temperature models for rutting were reviewed and a simplified equation was developed in this study. A rational approach was developed for calculating the effective temperatures (T_{eff}) for rutting for asphalt mixture design. Although this procedure was utilized to establish the test temperatures for the incremental Repeated Load Permanent Deformation (iRLPD) tests, it can also be used for flow number tests. The result of this analysis was a simple procedure that estimates effective pavement temperature for rutting for any location in the U.S. as a function of a readily available climatic parameter (degree-days) and depth of asphalt layer.

The followings findings were made from this study:

1. Comparison of the SHRP and NCHRP procedures with the calculated rutting data and judgement of experts determined that the test temperatures provided by these procedures were too low to cause rutting damage at standard loading.
2. Mean Annual Air Temperature (MAAT), the climatic parameter used in SHRP and NCHRP models, is over-predicting T_{eff} in coastal areas with mild winters while under-predicting it in desert areas with colder nights.
3. Degree-Days, correlated with rutting damage, is significantly better than MAAT, which was used in the SHRP and NCHRP equations.
4. The linear depth term in SHRP and NCHRP models is different from actual pavement temperature profiles with depth which shows significant non-linearity.
5. The NCHRP depth term is significantly over-estimating the effective temperature with depth while SHRP A-648 and the proposed depth term is closer to the actual pavement temperatures with depth.
6. The proposed procedure is more accurate, calibrated to the field and experts' opinion, yet simpler and easier to use than the currently available approaches.

The following recommendations are given for the future studies:

1. SHRP and NCHRP T_{eff} concept should be revisited as these procedures may not provide reasonable temperatures for laboratory testing of AC specimens.
2. The proposed effective temperature seems to provide significantly better temperatures for high-temperature testing of asphalt specimens and is highly recommended for test temperature of iRLPD and flow number tests.
3. The depth term from LTPPBind high temperature model was used for effective temperature; however, this term is not validated below 100 mm (about 4 inch) depth. An improved depth term should be developed for T_{eff} using the Degree-Day concept using more data.

ABSTRACT: AsButon is natural rock asphalt and it has been used as granular material for macadam base course in actual pavement works in Indonesia. However, AsButon was expected to utilize as the alternative asphalt materials, because there are huge amount of AsButon deposit and it is estimated at 163 million tons. Institute of Road Engineering (IRE, Indonesia) and Public Works Research Institute (PWRI, Japan) has been conducting the cooperation researches to seek for better utilisation of AsButon since 2011. In this research, the physical properties and chemical properties of AsButon were analysed, and the AsButon can be expected to be more durable than straight asphalt at high temperatures. The tendencies of the compositions of AsButon were close to the tendency of the composition of Trinidad Lake Asphalt (TLA). Therefore the asphalt mixture tests for guss asphalt using AsButon were conducted. As the results, the guss asphalt mixture using AsButon ratio of 20% was met the Japanese standards of guss asphalt mixture for fluidity, dynamic stability and flexural strain. AsButon is regarded to be possible alternative for TLA as guss asphalt material for steel bridge deck pavement.

Keywords: AsButon, natural rock asphalt, alternative asphalt, guss asphalt, steel bridge deck pavement

1 INTRODUCTION

In Japan, the rising price and decreasing production of petroleum asphalt has become a problem in recent years, and so a technology for using natural asphalt as well as petroleum asphalt needs to be developed. A natural asphalt called AsButon is produced around Butung in Indonesia. AsButon can be mined directly from the surface of the earth and is converted into granular material by primary processing. This granular material contains 70–80% minerals. In Indonesia, AsButon is mainly used by being blended with subgrade material in the macadam construction method and petroleum asphalt. AsButon reserves have been estimated at 163 million tons, and so its use as a surface asphalt mixture would be advantageous in view of its abundance. Indonesia intends to study the complete extraction of asphalt from AsButon. Thus, the Institute of Road Engineering (IRE) in Indonesia and the Public Works Research Institute (PWRI) in Japan have been conducting joint research since 2011 on effective ways to use AsButon. Using AsButon from Kabungka and Lawele, where there are large reserves, the joint research clarified its chemical and physical properties [1]. The results indicated that as physical properties, AsButon was hard at ordinary temperatures and thick at high temperatures compared with straight asphalt, and was also more promising in fluidity resistance than straight asphalt. Especially, AsButon from Kabungka was much harder but more brittle than straight asphalt at low temperatures. Regarding chemical properties, AsButon was composed

of fewer aromatic series and more resin and asphaltene than straight asphalt. This is heavy asphalt, and is similar in composition to TLA, which is a type of natural asphalt.

In Japan, the guss asphalt mixture is used for the base of steel plate deck pavement, and TLA is employed as a binder of this guss asphalt mixture. As of 2012, there are 680,728 bridges over 2 m long in Japan [2]. Of these, 158,897 bridges are over 15 m long, of which 60,432 (38%) with a total length of 4,722 km are steel bridges. Therefore, a large quantity of AsButon could be used if it can be employed for the guss asphalt mixture.

In this research, mixture properties were studied in order to clarify the potential use of AsButon as a material of the guss asphalt mixture, and the results are reported here.

2 APPROACH

2.1 *Test materials*

AsButon used for the test is natural asphalt produced around Butung in Indonesia, and would be an inexpensive source of asphalt for pavement because it can be mined directly from the surface of the earth. AsButon is natural rock asphalt containing 70–80% minerals, is granular and is sold packed in bags for sandbags. Therefore, AsButon would eliminate the need to break up solid lumps, as required with TLA, resulting in improved workability.

In this research, AsButon from Kabugka and Lawele, where there are large reserves, was tested using TLA as a comparison sample. Table 1 shows the combined gradation of the mixtures used for the study. In Japan, it is common practice to use mastic asphalt mixtures composed of 75% of straight asphalt 20/40 and 25% of TLA. In this study, therefore, comparison was made between mixtures made by using 15, 20 or 25% of AsButon in place of TLA and mixtures made by using 25% of TLA.

2.2 *Test items*

The five items shown in Table 3, which are provided in the bridge deck pavement standard for Honshu–Shikoku bridge (proposal, hereinafter referred to as "HSBE standard"), the waterproofing handbook for highway bridges, pavement investigation and a testing methodology handbook, were tested. Evaluation was conducted to determine if the mixture using AsButon satisfies the standard values shown in Table 3.

2.2.1 *Study on workability*

The guss asphalt mixture must create a dense impermeable asphalt layer by spreading without rolling, differently from ordinary asphalt mixtures. The Luer fluidity test was conducted in order to evaluate the difficulty (workability) of spreading. After pouring the guss asphalt

Table 1. Combined gradation.

Sieve opening	Combined gradation	Gradation envelop

Table 3. Test items and criteria.

Item	Test method	Test temperature	Standard-specified value	Compliance criterion
Workability	Luel fluidity test	240°C	20s or less	HSBE
Dynamic stability	Wheel tracking test	60°C	300 times/mm or more	
Flexibility at low temperature	Bending test (breaking strain)	–10°C	8.0×10^{-3} or more	
	Bending test (brittleness, small specimen)	–5, 0, 5, 10, 15, 20, 25°C	–	Source [3]
Adhesiveness	Tensile adhesive strength test (steel deck, mixture)	23°C	0.6 N/mm^2 or more	Source [4]
		–10°C	1.2 N/mm^2 or more	
Waterproof property	Permeability test by pressurized water	Temperature correction	No leakage	Source [5]

mixture at 240°C into a container of a certain depth and placing a 995 g heavy bob on the mixture, the time for the bob to penetrate 5 cm by its own weight was measured.

2.2.2 *Study on fluidity resistance*

To evaluate fluidity resistance, the dynamic stability (times/mm) was obtained by a wheel tracking test at a test temperature of 60°C. The test specimen was 300 mm long, 300 mm wide and 50 mm thick, and was created by pouring guss asphalt into the mold since compaction was not required.

2.2.3 *Study on deflection at low temperatures*

To evaluate the deflection at low temperatures, the fracture strain was measured by a bending test at a test temperature of –10°C and loading rate of 50 mm/min. The test specimen was 300 mm long, 100 mm wide and 50 mm thick. Moreover, to confirm the tendency of brittleness temperature, bending test using small specimen were conducted. This test specimen was 120 mm long, 10 mm wide and 10 mm thick. The loading speed of bending test was 20 mm/minutes, and test temperature was –5, 0, 5, 10, 15, 20, 25°C.

2.2.4 *Study on adhesiveness*

Not only the steel plate deck and the guss asphalt mixture layer but also the guss asphalt mixture layer and the surface course must adhere to and unite with each other. Therefore, the adhesive tensile test was conducted between a steel plate that imitated the steel plate deck and the guss asphalt mixture, and between the guss asphalt mixture and the mixture for surfaces. In this test, two kinds of primers were used in order to bond a steel plate and the guss asphalt mixture. Both were solvent adhesives: one was the conventional type (solvent type), and the other greatly shortened the drying time at low temperatures. For bonding between

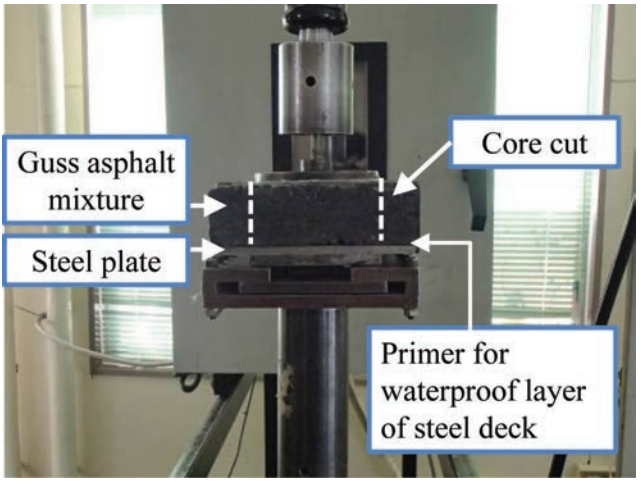

Figure 1. Method of adhesive tensile test.

the guss asphalt mixture and surface course, the emulsified rubberized asphalt was used as tack coat. The test specimen was created by pouring the guss asphalt mixture into a mold for a wheel tracking test with a 5-mm-thick steel plate placed on the bottom. In the adhesive tensile test, the tensile strength was measured using a universal tester with the φ10 cm core cut as shown in Figure 1.

2.2.5 *Study on waterproofing property*

The guss asphalt mixture is used as a waterproofing membrane in a steel plate deck. Therefore, waterproofness is one of the most important performance requirements, and was estimated by a permeability test by pressurized water. During the test, the permeability for 10 min was measured after pressurization at 1.5 MPa for 24 h.

3 TEST RESULTS

3.1 *AsButon ratio and fluidity*

Figure 2 shows the relationship between the AsButon ratio and fluidity. As the AsButon ratio increased, Luel fluidity showed a tendency to increase. All AsButons meet the standard specification (20 s or less) if the AsButon ratio is 20% or less, indicating that fluidity comparable to or higher than that obtainable at the TLA ratio of 25% can be obtained under the same conditions.

3.2 *AsButon ratio and dynamic stability*

Figure 3 shows the relationship between the Asbuton ratio and dynamic stability. As the Asbuton ratio increased, dynamic stability showed a tendency to increase. All Asbutons meet the standard specification (300 times/mm) if the Asbuton ratio is 20% or more. If the Asbuton ratio is 25%, dynamic stability of AsButon can be obtained higher than that obtainable at the TLA ratio of 25%.

3.3 *AsButon ratio and flexural strain*

Figure 4 shows the relationship between the Asbuton ratio and flexural strain. Flexural strain does not show any tendency to change significantly depending on the Asbuton ratio. The standard-specified requirement is met if the Asbuton ratio is in the 15–25% range.

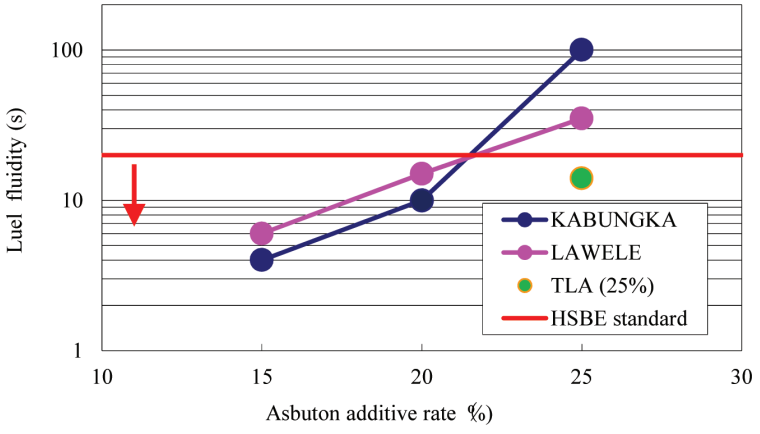

Figure 2. Relationship between the AsButon ratio and luel fluidity.

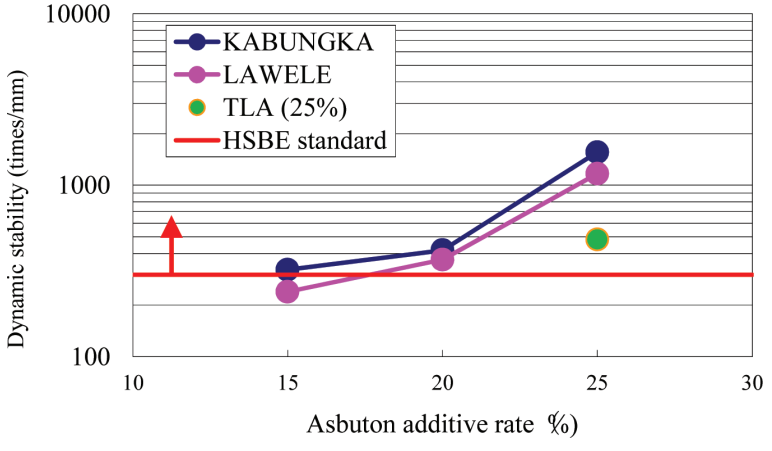

Figure 3. Relationship between the AsButon ratio and dynamic stability.

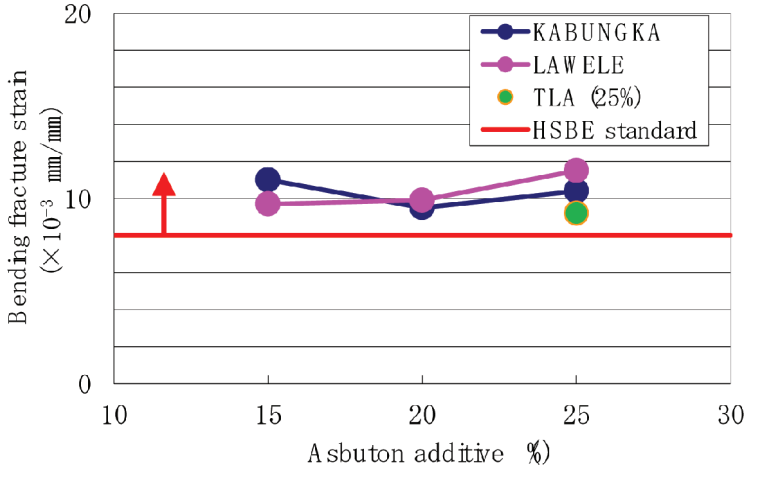

Figure 4. Relationship between the AsButon ratio and flexural strain.

Figure 5 shows the bending test results using small specimen of each mixture which indicate tendency of brittleness temperature. The inflection temperatures of bending strength of all AsButon were higher or same as that of TLA, therefore the AsButon have good flexibility at lower temperature than TLA.

3.4 *Results of adhesive tensile test*

The results of the adhesive tensile test between the steel plate deck and the guss asphalt mixture using primer-1 and primer-2 are shown in Figure 6. AsButon from Kabugka (20%) and Lawele (25%) met the target values in the waterproofing handbook for

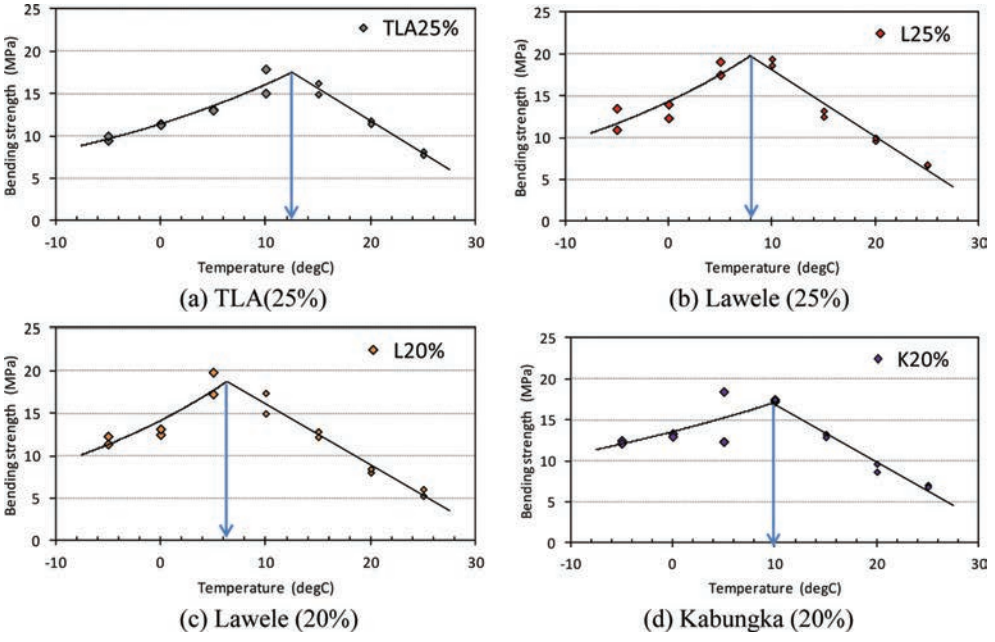

Figure 5. Bending test results using small specimen of each mixture.

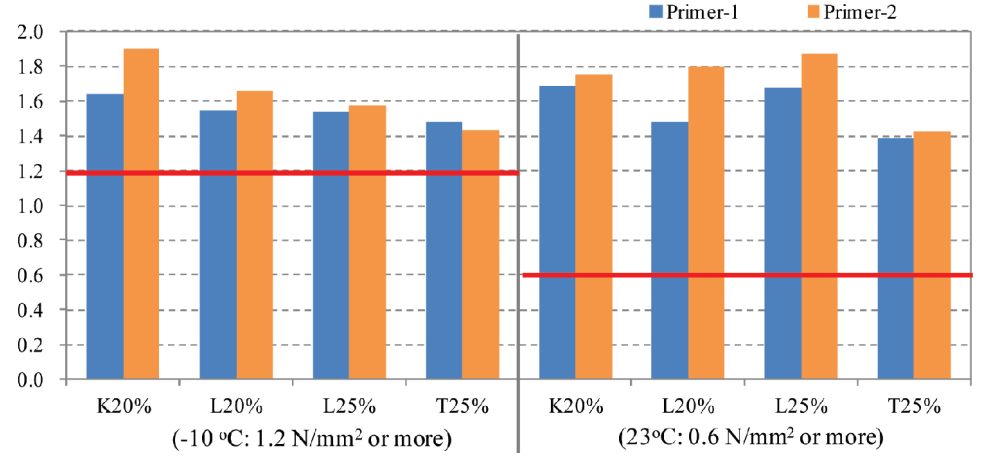

Figure 6. Results of adhesive tensile test between steel plate deck and guss asphalt mixture.

highway bridges under all measurement temperatures. Therefore, adhesion between the steel plate deck and the guss asphalt mixture using AsButon is considered to be quite good.

The results of the adhesive tensile test between the guss asphalt mixture and the mixture for surfaces using emulsified rubberized asphalt are shown in Figure 7. AsButon from Kabugka (20%) and Lawele (25%) met the target values in the waterproofing handbook for highway bridges under all measurement temperatures. Therefore, adhesion between the mixture for surfaces and the guss asphalt mixture using AsButon is considered to be quite good.

3.5 *Results of permeability test by pressurized water*

The results of the permeability test by pressurized water are shown in Table 4. Impermeability was confirmed because the amount of permeability for 10 min after pressurization for 24 h was 0 cm^3 under all conditions.

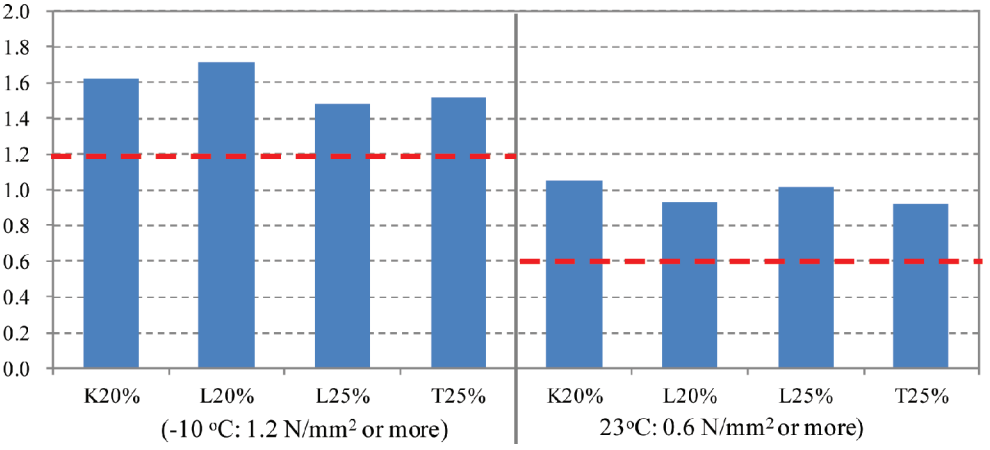

Figure 7. Results of adhesive tensile test between guss asphalt mixture and surfaces course mixture.

Table 4. Results of permeability test by pressurized water.

Test case	Natural asphalt	No.	Pressure	Pressurization time	Measuring time	Amount of permeable water	Result
1	*AsButon*						
	KABUNGKA (20%)	1	1.5 MPa	24 hours	10 minutes after 24 hours	0 cm^3	Impermeable
		2				0 cm^3	
		3				0 cm^3	
2	LAWELE (20%)	1				0 cm^3	Impermeable
		2				0 cm^3	
		3				0 cm^3	
3	LAWELE (25%)	1				0 cm^3	Impermeable
		2				0 cm^3	
		3				0 cm^3	
4	TLA (25%)	1				0 cm^3	Impermeable
		2				0 cm^3	
		3				0 cm^3	

4 CONCLUSION

It has been verified that all five requirements as a standard of the guss asphalt mixture in Japan, including the workability (Luel fluidity), fluidity resistance (dynamic stability), deflection at low temperatures (fracture strain), adhesiveness (adhesive tensile intensity), and waterproofness (for permeability test by pressurized water), are met by mixing the natural asphalt (AsButon, 20%) from Indonesia.

Therefore, AsButon can be used as a binder of the guss asphalt mixture. However, the optimal mixing ratio may vary somewhat with the location of production, mining site, etc., and thus it is necessary to consider quality control of AsButon in the future.

Tianjin Highway Engineering General Company, Tianjin, China

ABSTRACT: Moisture damage is one of the most common distresses of asphalt pavement. Silane Coupling Agent (SCA) has been used as an additive to prevent the moisture damage of asphalt pavement. This paper aims at investigating the effect of SCA on moisture sensitivity of asphalt mixture in the laboratory. The freeze-thaw cycle and the dynamic water flushing were applied to simulate the moisture damage conditions of asphalt mixtures. The effectiveness of SCA was confirmed by the hydrophilic coefficient test. The effects of SCA on moisture sensitivity of asphalt mixtures were evaluated by various methods, including indirect tensile strength (low-temperature and mid-temperature), high-temperature creep test and mid-temperature fatigue test. The results show that SCA can improve the moisture resistance of the granite filler obviously; SCA can effectively improve the moisture sensitivity of asphalt mixtures, and the significance is aggregate dependent. Freeze-thaw cycle and dynamic water flushing are two effective methods for simulating moisture damage.

Keywords: Asphalt mixture, moisture damage, silane coupling agent, freeze-thaw cycle, dynamic water flushing

1 INTRODUCTION

Moisture damage is a major failure mode in asphalt pavements. This failure can be defined as the loss of strength, stiffness and durability due to the presence of moisture leading to adhesive failure at the binder–aggregate interface and/or cohesive failure within the binder or binder–filler mastic [1,2]. The damage of water on asphalt mixture can be summarized into two forms, one is the freeze-thaw cycle, the other is dynamic water flushing under wheel loads. Recently, there are many researches about freeze-thaw cycle destruction, but little about dynamic water flushing under wheel loads. Shin-Che Huang et al. [3] indicated that the composition in the asphalt–aggregate interfacial region may change during repeated freeze–thaw cycling, and found that carboxylic acids play a major role in determining the moisture sensitivity of pavement mixtures. Raquel Moraes et al. [4] found that the bond strength of asphalt–aggregate systems was highly dependent on modification and moisture exposure time by using the Bitumen Bond Strength (BBS) test. E. Pasquini et al. [5] studied the fatigue property of open graded asphalt rubber mixtures in both dry and wet conditions with and without temperature cycles. They found that fatigue resistance of the studies materials was only little affected by water and temperature cycles and superior to traditional open graded mixtures produced with SBS modified bitumen only. And they validated and modeled the results by means of an elasticity-based damage model.

In fact, dynamic water flushing under wheel loads is one of the most important causes for moisture damage of asphalt pavement (Fig. 1). L.D. Poulikakos et al. [6] used an innovative test method to mechanically test 150 mm diameter cylindrical cores from eight materials in

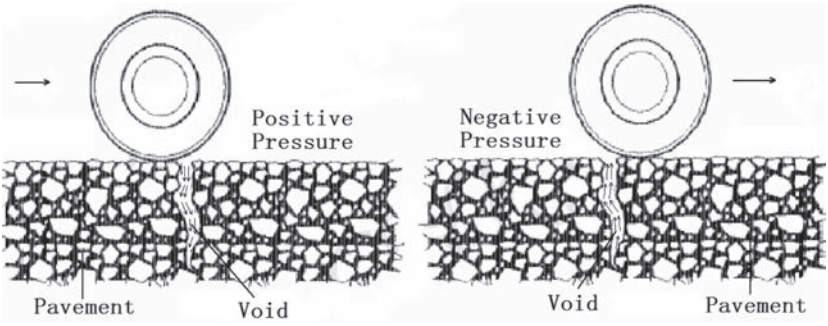

Figure 1. Dynamic water flushing induced by wheel loads.

dry state and while being submerged under water. They found that the application of Coaxial Shear Test (CAST) for a twin lay porous asphalt as well as conventional porous asphalt shows a reduction in complex modulus due to fatigue loading after each thermal cycle and due to detrimental effects of water submersion. Moisture susceptibility results using CAST reflected the field inspections of surface degradation.

Modifying materials or changing structure composition can improve the moisture sensitivity of asphalt pavement. Some studies have confirmed that the anti-stripping agent can improve the moisture damage resistance performance of asphalt mixture. F. Moghadas Nejad et al. [2] studied the effects of nanomaterial, namely Zycosoil, on the moisture damage of asphalt mixtures. They found that limestone has less moisture damage potential compared to granite. The ratio of wet/dry values of Indirect Tensile Strength Test (ITST) and Indirect Tensile Fatigue Test (ITFT) for mixes containing Zycosoil was higher than the control mix for two types of aggregate. Yong-Rak Kim [7] evaluated the effects anti-stripping additives on bituminous mixtures through multiple scale laboratory test results, they found that the mixes, where high-quality aggregates and polymer-modified binder are used, are fairly self-resistant to moisture damage without treating any anti-stripping additive and do not show any visible sensitivity between additives, whereas the effects of additives and their sensitivity are significant in the mixes that use the unmodified binder and low-quality aggregates. Jun Xie et al. [8] found that the asphalt mixture with Compound Fly Ash Modifier (CFAM) has excellent moisture sensitivity in terms of higher indirect tensile strength and tensile strength ratio during frost–thaw process. In addition, after specific moisture damage treatments, CFAM modified asphalt mixtures show better stiffness modulus, resistance to permanent deformation and fatigue life. Shu Wei Goh et al. [9] found that the addition of nanoclay and carbon microfiber would improve a mixture's moisture susceptibility performance or decrease the moisture damage potential in most cases. Xiao Qing-yi et al. [10] confirmed the silane coupling agent can form a coupling layer in surface of granite and basalt to by infrared spectroscopy. The cohesiveness between asphalt and granite or basalt can reach level 5 if asphalt is modified by SCA. In contrast, it can only reach level 2 or level 3 if the asphalt is not modified by the coupling agent. After being treated by silane coupling agent, Marshall stability can increase by 10%~20%, Marshall modulus can increase by 6%, and residual Marshall stability can increase by 18%~28%. TSR of asphalt mixtures after three freeze-thaw cycles can increase by 25%~33%. Wang Zhenjun et al. [11] found Si-O bond on the surface of aggregate modified by SCA, and Si-O-Si bond on the interface between asphalt mastics and aggregate modified by SCA by infrared spectrum. Saeed Ghaffarpour Jahromi [12] found that AC-20 have less moisture induced damages compared to AC-10 and dynamic modulus values for mixes with AC-20 were higher than the one with AC-10 for all the aggregate types. Addition of lime for river gravel samples showed significant difference between two types of bitumen but no major differences were found in crashed granite. Weibiao Wang et al. [13] investigated the use of strip-prone aggregates in hydraulic asphalt concrete, and they found that the significant detrimental effects of using strip-prone aggregates for open-grade porous asphalt, but that aggregate-bitumen adhesion

and tensile strength could be increased by adding amine or hydrated lime to the asphalt mix. Mohammad Zia Alavi et al. [14] demonstrated that the use of specific WMA additives has potential to improve the moisture resistance of the mixture by using Bitumen Bond Strength (BBS) and dynamic modulus ratio (ESR) tests. The above researches fully confirmed the potential of the anti-stripping agent in improving asphalt mixture moisture sensitivity, but the models simulating water behavior were too simple (only the freeze-thaw cycle), not considering the dynamic water flushing caused by wheel loads. The influence of water behavior (including freeze-thaw cycle and dynamic water flushing) on road performance (including high-temperature deformation resistance, low-temperature cracking resistance, and mid-temperature fatigue cracking resistance) is not clear.

2 MATERIALS

2.1 *Asphalt*

Asphalt binder with a penetration grade 90 was used in this study, whose basic properties are shown in Table 1.

2.2 *Aggregate and filler*

Aggregate used in this paper consists of basalt, andesite I, and andesite II.

As indicated by Roberts et al. [15], the mineral filler is used in HMA to: (i) meet aggregate gradation specifications, (ii) reduce the optimum asphalt content by filling voids in the granular skeleton, (iii) increase mixture stability and (iv) enhance "bond" of the aggregate–asphalt system. More recently, Prowell et al. [16,17] summarized that the addition of filler to HMA can be associated with the following main effects: (i) stiffen the asphalt, (ii) extend the asphalt–increase the asphalt volume in the HMA, or (iii) simultaneously extend and stiffen the asphalt.

Fillers used in this paper are divided into three categories, including limestone, andesite and granite, whose basic properties are shown in Table 2.

2.3 *Anti-stripping agent*

Anti-stripping agent used in this paper is Silane Coupling Agent, whose structure contained two kinds of functional groups, and one group can attract organic compounds of asphalt,

Table 1. Physical properties of asphalt.

Properties	Standard	Result
Penetration (100 g, 5 s, 25°C), 0.1 mm	ASTM D5-73	89
Softening point (°C)	ASTM D36-76	48
Ductility (15°C, 5 cm/min), cm	ASTM D113-79	>100
Ductility (5°C, 5 cm/min), cm	ASTM D113-79	16.4

Table 2. Physical properties of fillers.

Filler	Apparent relative density (g/cm^3)	Sieve passing percentage (%)		
		0.6 mm	0.15 mm	0.075 mm
Limestone	2.827	100	96.5	76.7
Andesite	2.864	100	98.7	76.7
Granite	2.614	100	85.7	74.2

the other group can react with compounds on the surface of inorganic materials. Coupling agent reaction process is as follows:

Firstly, some composition of the coupling agent experiences hydration reaction because of the water vapor existing in the air and stone surface pores, and the silicon alcohols is obtained. The chemical reaction is shown in function (1);

Secondly, condensation reaction happens between silicon alcohols and hydroxyl on stone surface, and a coupling layer (PDMS) is obtained. The coupling layer can reduce surface contact angle between asphalt and aggregate, improve the wetting and infiltration rate of asphalt in the stone surface. Therefore, silane coupling agent can effectively improve the interface bonding between asphalt and aggregate. The chemical reaction is shown in function (2);

Finally, a chemical bond or a chelate forms between R groups and organic material (asphalt), and physical bonding such as Van der Waals' force can also occur. So the coupling between two different chemically properties materials is completed. The chemical reaction is shown in function (3).

(2)

(3)

2.4 *Mixture design*

AC-16C mixture type was adopted according to China's specification. The grading curve for mixtures was shown in Figure 2. Marshall Tests were carried out to find the optimum asphalt binder content of mixtures, which was 4.6% by weight of aggregates.

Note:

1. The temperature heating asphalt can't be more than 160 °C, and the content of SCA is 0.3% of asphalt (mass ratio).
2. Asphalt mixtures need to be conditioned in 150 °C for 50 minutes before compaction.

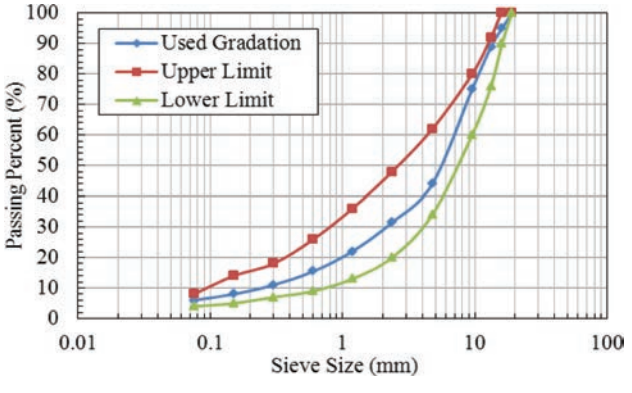

Figure 2. Aggregates gradation curves of asphalt mixtures.

Table 3. Test project.

Serial number	Aggregate	Filler	Treated by SCA
No. 1	Basalt	Limestone	No
No. 2	Basalt	Andesite	Yes
No. 3	Andesite I	Limestone	No
No. 4	Andesite I	Limestone	Yes
No. 5	Andesite I	Andesite	Yes
No. 6	Andesite I	Granite	Yes
No. 7	Andesite II	Limestone	No
No. 8	Andesite II	Andesite	Yes
No. 9	Andesite II	Granite	Yes

In order to study the improvement of SCA on road performance of asphalt mixtures, test project in this paper is shown in Table 3.

3 TEST METHODS

3.1 *Filler hydrophilic coefficient*

In order to study the improvement of SCA on asphalt mastics, hydrophilic coefficients of six kinds of fillers (including untreated limestone, untreated andesite, untreated granite, treated limestone, treated andesite and treated granite) were tested. The treat process is as follows: firstly, weigh the SCA (mass of SCA:mass of filler = 1.5:100), then disperse the SCA into water (mass of SCA:mass of water = 2:100); secondly, put the solution into filler, and stirring for 15 min; finally, remove moisture with the temperature 105 °C.

3.2 *Freeze-thaw cycle test*

3.2.1 *Freeze-thaw cycle procedure*

Compaction method of specimen is gyratory compacting, and the diameter of specimen is 100 mm, height is 63.5 mm ± 1.3 mm. The procedure of free-thaw cycle is as follows:

① The specimens were randomly divided into two groups. The first group of specimens were kept on the platform at room temperature; the second group of specimens were immersed in water with 97.3~98.7 kPa (730~740 mmHg) for 15 minutes, then open the valve, kept specimen in the water without pressure for 0.5 hours.
② The second group of specimens were removed into a plastic bag with 10 ml water, then maintain the condition temperature −18 °C ± 2 °C for 16 hours.
③ The specimens removed from the low-temperature case were immediately put in water tank with the temperature 60 °C ± 0.5 °C for 24 hours.

3.2.2 *Evaluation method*

3.2.2.1 Tensile Strength Ratio (TSR)

The specimens were kept in 15 °C ± 0.5 °C constant temperature water tank for 2 hours, then were removed and immediately applied splitting loading by MTS machine. The loading rate is 50 mm/min. The indirect tensile strength is calculated according to equation (4), and he TSR is calculated according to equation (5).

$$R_T = 0.006287 P_T / h \tag{4}$$

where:

R_T = Indirect tensile strength, MPa;
P_T = The maximum value of test load, N;
h = The specimen height, mm;

$$TSR = (R_{T_2} / R_{T_1}) \times 100 \tag{5}$$

where:

TSR = Tentile strength ratio,%;

R_{T_1} = Indirect tensile strength before freeze-thaw cycle, MPa;

R_{T_2} = Indirect tensile strength after freeze-thaw cycle, MPa;

3.2.2.2 High-temperature creep rate

High-temperature creep test was used to evaluate deformation resistance performance of asphalt mixture. Creep rate was selected as evaluation index. The lower creep rate should be, the better mixture high-temperature performance should be. Creep rate growth rate was selected as index evaluating the influence of freeze-thaw cycle on high-temperature of asphalt mixture. The lower creep rate growth rate should be, the better moisture sensitivity of mixture high-temperature performance should be.

(1) Creep indexes calculation method. Data in a stable deformation section was used to calculate the creep indexes. Creep rate was calculated according to function (6), and the creep rate growth rate was calculated according to function (7).

$$\varepsilon_s = \frac{\varepsilon_2 - \varepsilon_1}{(t_2 - t_1)/\sigma_0} \tag{6}$$

where:

σ_0 = Indirect tensile strength, MPa;

t_1 = The starting time of creep stability period, s;

t_2 = The ending time of creep stability period, s;

ε_1 = The creep strain corresponding to the starting time;

ε_2 = The creep strain corresponding to the ending time;

ε_s = The creep rate, 1/s/MPa.

$$\alpha = \frac{\varepsilon_{s_2} - \varepsilon_{s_1}}{\varepsilon_{s_1}} \times 100 \tag{7}$$

where:

α = Creep rate growth rate, %;

ε_{s_1} = Creep rate before freeze-thaw cycle, 1/s/MPa;

ε_{s_2} = Creep rate after freeze-thaw cycle, 1/s/MPa;

(2) Test condition. The forming method of specimens was Marshall compction test. The diameter of specimens is 101.6 mm, and height is 63.5 ± 1.3 mm. After compaction, half of specimens go through freeze-thaw treatment, the other half are as control samples. Before loading, all specimens need to be kept in 45 °C water tank for 1 hour, and then removed into 45 °C MTS environmental cabinet immediately. The constant loading is 0.04 MPa.

3.2.2.3 Low-temperature Indirect Tensile Strain (LITS)

This study evaluated the low-temperature anti-cracking performance by low-temperature indirect tensile test. The LITS was selected as the evaluation index of asphalt mixtures low-temperature performance. The bigger the LITS should be, the more excellent the low-temperature performance of asphalt mixtures should be. The LITS rate was selected as the evaluation index of moisture sensitivity of asphalt mixtures low-temperature performance. The bigger the LITS rate should be, the better the moisture sensitivity of asphalt mixtures low-temperature performance should be.

The forming method of specimens is Marshall compaction test, the diameter of specimens is 101.6 mm, and the height is 63.5 ± 1.3 mm. After compaction, half of the specimens need to go through the freeze-thaw cycle, the other half are selected as the control samples. The test temperature is –10 °C, and the loading rate is 1 mm/min.

3.2.2.4 Mid-temperature fatigue life

1. Evaluation Index. This research adopts the fatigue life to evaluate the fatigue performance of asphalt mixture. The higher the fatigue life should be, the better the anti-fatigue performance of asphalt mixtures should be. The fatigue life ratio was selected as evaluating the moisture sensitivity of fatigue performance of asphalt mixtures. The higher the fatigue life ratio should be, the better the moisture sensitivity of fatigue performance of asphalt mixtures should be.
2. Test conditions. The forming method of specimens is rotary compacting test. The diameter of specimens is 101.6 mm, and height is 63.5 ± 1.3 mm. The test temperature is 15 ± 1 °C. The loading frequency is 10 Hz. The load waveform is sine wave, and the minimum load is 2% of the maximum load. Before loading, 30 s preloading was applied on the specimens in order to make every part in good contact. The stress level is 30% of indirect tensile strength.

3.3 *Dynamic water flushing test*

In order to study the influence of dynamic water flushing on asphalt mixture, a device was developed to simulate the union impact of water, temperature and loading (Fig. 3).

The characteristics of the dynamic water flushing device are as follows:

1. It can provide excitation to simulate the dynamic water pressure caused by wheel loads;
2. It can control the pressure value and repeating frequency exactly;
3. The temperature of circulated water can be controlled exactly.

When the piston moves downward, the water in area A is pressed into specimen voids, some water can reach area B, which can simulate the case that water is pressed into the pavement under wheel loads. When the piston moves upward, the water in area B goes back into area A, which can simulate the pore water pumping action when the wheel loads go away. During the test, the piston does not contact the specimen. The test parameters are as follows:

Frequency: 10 Hz;
Water pressure: 0.4 MPa;
Water temperature: 45 °C;
Flushing time: 15 minutes;
The evaluation method is same as 3.2.2.

All the test values shown in this paper are averages of results from up to four individual experiments.

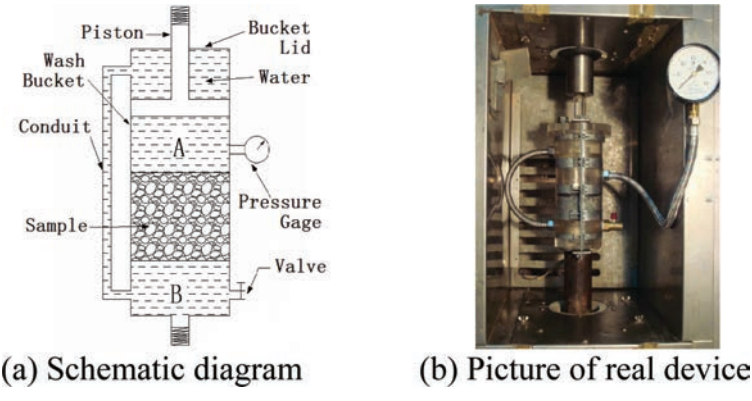

Figure 3. Dynamic water flushing device.

4 RESULTS AND DISCUSSION

4.1 *Hydrophilic coefficient test*

It can be seen from Figure 4 that the SCA effects little on limestone filler and andesite filler, but hydrophilic coefficient of granite filler treated by SCA decreases by 16%, that's because limestone and andesite are good at attracting oil, but granite is good at attracting water. It shows that SCA can improve the adhesion between acidic aggregate and asphalt.

4.2 *Freeze-thaw cycle test*

4.2.1 *TSR*

It can be seen from Figure 5 that, before freeze-thaw cycle, the strength of andesite aggregate I is highest, andesite aggregate II is minimum if the mixtures weren't treated by SCA. After adding SCA, the strength of andesite aggregate II is nearly the same with basalt aggregate, and the strength of andesite aggregate I increases by 13%. For andesite I aggregate and andesite II aggregate, modified andesite filler and modified granite filler show better performance than unmodified limestone. For basalt aggregate, the improvement of SCA on different fillers is not remarkable. Comparing No. 3 and No. 4, we can see that after freeze-thaw cycle, SCA can increase TSR of andesite I aggregate mixtures by more than 13%, which is corresponding to the hydrophilic coefficient test. TSR of modified andesite filler mixtures can catch up with the level of unmodified limestone filler mixtures. But SCA effects little on TSR of granite filler mixtures, which is different from the hydrophilic coefficient test. The reason is the effect of aggregate and the test scale dependence.

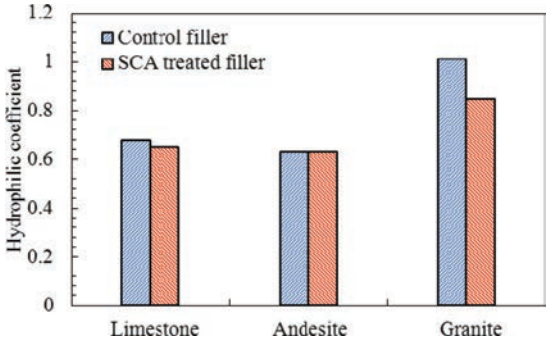

Figure 4. Hydrophilic coefficient of fillers.

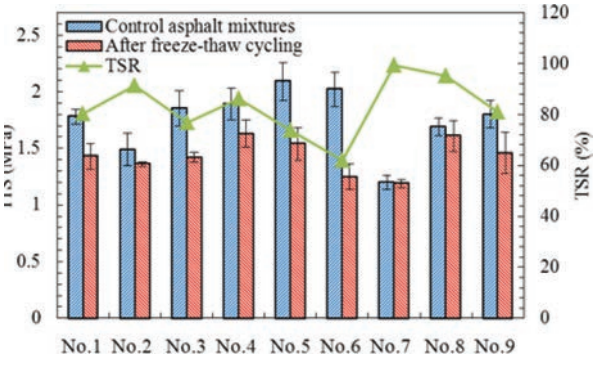

Figure 5. ITS and TSR results through freeze-thaw cycle.

4.2.2 *High-temperature creep test*

It can be seen from Figure 6 that, creep rate of andesite II aggregate is highest, and SCA can improve its high-temperature performance. SCA can decrease the creep rate growth rate of andesite I aggregate dramatically, but this phenomenon is not obvious for basalt aggregate and andesite II aggregate.

4.2.3 *Low-temperature indirect tensile strain*

It can be seen from Figure 7 that SCA effects little on LITS of all asphalt mixtures, which means SCA effects little on low-temperature of asphalt mixtures. After freeze-thaw cycle, SCA can increase the LITS rate of basalt aggregate and andesite II aggregate obviously, which means SCA can improve moisture sensibility of asphalt mixtures low-temperature performance.

4.2.4 *Mid-temperature fatigue life*

It can be seen from Figure 8 that SCA can increase fatigue life of basalt aggregate mixtures, but decrease fatigue life of andesite II aggregate mixtures. SCA effects little on fatigue life of andesite I aggregate mixtures. After freeze-thaw cycle, SCA can increase fatigue life of all asphalt mixtures. The above shows that SCA can improve moisture sensibility of asphalt mixtures mid-temperature fatigue performance.

4.3 *Dynamic water flushing test*

Dynamic water flushing can make the interface adhesive between asphalt and aggregate weaken, which can effects road performance of asphalt mixtures.

(a) Fracture surface of control sample (b) Fracture surface through dynamic water flushing

Figure 10. Inner morphology variation of asphalt mixtures through dynamic water flushing.

It can be seen from Figure 9 that dynamic water flushing can damage the low-temperature performance of all asphalt mixtures. SCA can decrease the indirect tensile strain ratio of asphalt mixtures after dynamic water flushing. And SCA has the biggest effect on granite filler mixtures, the minimal effect on limestone filler mixtures. Inner morphology variation of asphalt mixtures under dynamic water flushing is shown as Figure 10.

Figure 10 shows that dynamic water flushing can strip the asphalt from the aggregate, which means the pore water pressure caused by wheel loads is one of the most important reasons on moisture damage of asphalt pavement. Figure 10 can demonstrate the device developed in

this paper can simulate the dynamic water flushing well. We can study the influencing factors of moisture damage, evaluate the moisture sensitivity of asphalt pavement, and reveal the mechanism of the moisture damage of asphalt pavement by using the method.

5 CONCLUSIONS

Based on the testing and analysis presented herein, the conclusions of the study are summarized as follows:

1. The hydrophilic coefficient tests indicate that SCA can improve the moisture sensitivity of the granite filler obviously, but the influence of SCA on strong lipophilic powder is not significant.
2. The freeze-thaw splitting test indicates that SCA can improve the moisture sensitivity of the andesite aggregates and three kinds of fillers, and SCA is more effective for acid aggregate or acid filler.
3. High-temperature creep tests show that SCA can improve the high-temperature stability of andesite aggregate mixtures and its moisture sensitivity obviously, but effects little on basalt aggregate mixtures.
4. Low-temperature indirect tensile tests show that SCA effects little on low-temperature of asphalt mixtures, but it can improve moisture sensibility of asphalt mixtures low-temperature performance.
5. Fatigue tests indicate that the influence of SCA on the fatigue life of asphalt mixtures is aggregate dependent. SCA can improve moisture sensibility of asphalt mixtures mid-temperature fatigue performance.
6. Dynamic water flushing can make the interface adhesive between asphalt and aggregate weaken. SCA can improve the performance of asphalt mixtures resisting dynamic water flushing.

Above all, freeze-thaw cycle and dynamic water flushing are two effective methods for simulating moisture damage. SCA can effectively improve the moisture sensitivity of asphalt mixtures, and the significance is aggregate dependent. Further researches on SCA treated asphalt mixture are highly recommended to understand the correlation between the laboratory and practical applications.

ABSTRACT: Ground Tyre Rubber (GTR) bitumen pellets is a relatively new technology to deliver rubber modified binders to asphalt mixtures. The pellets are manufactured by producing a rubber modified binder by means of the wet process which is then pelletized by the aid of mineral filler. The resulting pellets are solid particles relatively hard produced in a range of individual sizes from 5 mm to 20 mm and consisting of a rubber-bitumen core coated with a thin layer of filler. These pellets can be incorporated directly into asphalt as a partial replacement of some of the bitumen to introduce a polymer (GTR) into the mixture, or as a rubber modified binder in hot mix recycling operations. In both applications, the total binder content of the asphalt mixture and the rubber content by weight of the total binder will depend on both the amount of pellets added and their composition. In this work, Thermogravimetric Analysis (TGA) has been used to estimate the amount of bitumen, rubber and filler in a pellet. TGA was carried out on the individual components of the pellets i.e. rubber, bitumen and filler and on the pellets before and after removal of the bitumen by means of solvent extraction. The pellets were then used to produce an asphalt mixture by replacing some of the bitumen. Binder content analysis of the mixtures was then carried out using standard techniques. It was found that the contribution from the pellet to the total binder content of the mixture reflected the composition of the pellet derived from TGA.

Keywords: Ground Tyre Rubber (GTR), rubber-bitumen pellet, Thermogravimetric Analysis (TGA), binder content

1 INTRODUCTION

The use of Polymer Modified Binders (PMBs) in asphalt has increased steadily during the last years. In Europe PMB consumption is estimated to be more than 10% of the total bitumen consumption [1]. This demand is also expected to grow during the coming years due to, among others, performance based specifications for asphalt. Elastomeric polymers such as SBS and SBR are, however, expensive and are not always readily available. As a result the use of more economical waste polymers particularly Ground Tyre Rubber (GTR) has gained considerable attention particularly in Europe.

Ground Tyre Rubber (GTR) has been used extensively in road pavement applications for more than 60 years. Two generic processes namely the 'wet process' and the 'dry process' have been developed for incorporating tyre rubber into asphalt mixtures. In the wet process the rubber particles are blended with bitumen at elevated temperatures to produce a rubber modified binder. In the dry process, on the other hand, the rubber particles are added directly into the aggregate blend before introducing the binder into the mixture.

The performance of bituminous mixtures containing tyre rubber has varied greatly. Mixtures produced with asphalt-rubber binders (wet process) have shown, in general, better over-

all performance than those produced by the dry process. Poor compaction, durability and resistance to permanent deformation have been generally associated with mixtures produced by the dry process [2]. Furthermore, most of the highways agencies in the USA recommend the use of the wet process.

In the US the term Asphalt Rubber as defined by ASTM D8 is used for rubberised binders produced by the wet process with at least 15% rubber by weight of total binder. Separation and settling of the rubber particles during storage and rubber degradation as a result of extended heating periods are however common problems associated to these types of binders. Alternatively, crumb rubber modified binder with lower concentration of rubber, between 5 to 15%, and therefore less prone to these issues are used by some agencies in the US.

Ground Tyre Rubber (GTR) bitumen pellets is a relatively new technology to deliver rubber-modified binders. The pellets are manufactured by producing an asphalt-rubber binder which is then pelletized using mineral filler. The resulting pellets are solid particles relatively hard of similar size as the aggregates consisting of a rubber-bitumen core coated with a thin layer of filler. These pellets can be incorporated directly into asphalt as a partial replacement of some of the bitumen to introduce a rubber polymer (GTR) into the mixture. The level of modification required can be easily adjusted by adding the correct amount of pellets and depends on the performance requirements for that specific mixture.

The level of polymer modification i.e. the amount of GTR by weight of total binder in the mixture is dependent on the amount of GTR and bitumen in the pellet thus in its overall composition. In order to estimate the composition of the pellets TGA analysis has been carried out on the individual components of the pellets i.e. rubber, bitumen and filler, and on the pellets before and after removal of the bitumen by means of solvent extraction. GTR bitumen pellets were then added to an asphalt mixture and the binder content of the mixture was determined using standard techniques.

2 GTR BITUMEN PELLETS

GTR bitumen paving pellets were manufactured by Billian UK Ltd. at their factory in Sheffield, UK. The manufacturing process consists of first producing a rubber-modified binder (asphalt-rubber binder) by blending fine GTR with bitumen and then pelletizing the modified binder with the aid of mineral filler. The base bitumen used to produced the rubber-modified binder was a 100/150 pen and the GTR had a maximum nominal size of 1.0 mm and was sourced from truck tyres.

A blending unit AR150M manufactured by Phoenix Industries was used to produce the rubber-modified binder. The unit consists of a bitumen heating tank, a mechanical mixer and a reaction tank. The heating tank is used to maintain the temperature of the bitumen at 175 °C before blending with the GTR using a mechanical high shear mixer. The bitumen and GTR are fed directly into the mixer at controlled rates to give 15–25% rubber by weight of total binder. Mixing continues until an homogenous blend is produced. The modified binder is then kept in a reaction tank for about 1 to 2 h. During this time bitumen components diffuse into the rubber causing it to swell [3]. Once produced, the rubber-modified binder is fed to a pelletizer through an insulated line. The pelletizer consists of a rotating disc where the filler is fed from a silo through a line at a controlled rate. The binder is applied by slow flowing line. As the binder makes contact with the filler on the rotating disc a small pellet is formed until it is large enough to be removed from the hood. After the pellets are formed they are transported to an air cooling unit by means of a vibrating conveyor belt. Once cooled, these are screened into different sizes typically 5 mm to 20 mm and stored in different size bags (10 kg, 25 kg and 1 tonne sacks). The mineral filler used to produce the pellets was Hydrated Lime (HL). The introduction of an adhesion promoter filler (HL) to the mixture via the pelletised binder is known to enhanced the durability of asphalt [4]. The effect of HL on mixture performance was, however, outside the scope of the paper.

The final pellets are solid particles relatively hard of similar size as the aggregate (typically around 10 mm maximum nominal size) consisting of a rubber-bitumen core coated

Figure 1. GTR bitumen paving pellets.

with a thin layer of filler (see Fig. 1). The pellets can be stored in bags without the need of heated storage tanks and can be incorporated directly in to the mixing box by conventional systems.

3 EXPERIMENTAL

3.1 *Thermogravimetric analysis of GTR bitumen pellets*

Thermogravimetric Analysis (TGA) is an experimental method widely used in composition analysis and it is particularly useful for multi-component materials [5]. In this method a sample is heated to extremely high temperatures of up to 2000 °C and its mass loss is monitored continuously as a function of temperature. As the temperature increases, various components of the sample are decomposed (volatilised) and the percentage mass loss of each component is measured. Results are plotted with temperature on the X-axis and mass loss on the Y-axis. Decomposition rates, i.e. first derivatives, are also plotted to determine decomposition temperature range of each component. The concentration of each component can then be determined from the mass loss and the temperature range of the decomposition of the component.

TGA of the pellets was carried out in two stages. The first stage was to analyse the individual components of the pellets i.e. GTR, bitumen and hydrated lime in order to determine the mass of the residue and find out at which temperature the decomposition of components take place. This was followed by TGA of the pellets as received. The second stage involved the removal of bitumen from the GTR bitumen pellets using solvent extraction. Carbon disulphide (CS_2) was used as a solvent as this solvent is specific to dissolving the bitumen without affecting the other components [6]. Portions of the GTR pellets were treated to dissolution in CS_2 by adding 20 cm^3 of the solvent onto approximately 0.8 g of solid. Three separate portions were treated with the solvent. The residues from the filtration were then dried in an oven at 75 °C for 24 hours before being analysed by TGA.

The GTR pellets and the rubber samples were ground using a SPEX Sample Prep Model 6850 Freezer/Mill. The bitumen sample was unsuitable for this preparation, and both the hydrated lime and the treated pellets after removal of the bitumen were deemed to not require any further grinding. The sample was placed into a polycarbonate vessel with a steel impactor and then lowered into a bath of freezing liquid nitrogen (about −196 °C). The frozen sample was then pulverised by the magnetically-driven impactor before retrieval and further analysis.

The TGA experiments were carried out using a Stanton Redcroft STA1500 apparatus. The mass of the samples was approximately 30 mg. Samples were placed in 70 µl platinum crucible. Heating rate applied was 10 °C/min and an atmosphere of air at a flow rate of 50 cm^3/min was employed.

Table 1. Composition of mixtures.

	Composition (%)	
Component	Control mixture	GTR pellet mixture
4/10 mm	39.6	39.6
2/6.3 mm	11.3	11.3
0/4 mm	39.5	39.3
Limestone filler	4.0	3.8
Binder (100/150)	5.6	4.6
GTR pellets	–	1.4
Total	100	100

3.2 *Compositional analysis of asphalt mixtures*

Two asphalt mixtures with and without the GTR bitumen pellets were prepared in the laboratory and used for compositional analysis. The control mixture was produced with a 100/150 pen bitumen and the bitumen content was 5.6%. The GTR pellet mixture, on the other hand, contained 4.6% bitumen (100/150 pen) and 1.4% GTR bitumen pellets. Mixture components and proportions are presented in Table 1.

Aggregates and bitumen were heated in an oven at 170 °C and mixed in a mechanical mixer. GTR pellets were incorporated directly to the hot aggregates before the bitumen was added. The mixtures were produced in 5 kg batches. Un-compacted loose material was used for analysis. In total, 3 identical samples of the control mixture and 9 samples of the GTR pellet mixture were manufactured.

Compositional analysis was carried out following standard tests method. These included binder content by ignition [7] and soluble binder content [8]. In the ignition method a sample of 1500 g approximately was heated in a furnace at 480 °C for 50 minutes. The binder content was then determined from the total mass of the mixture before and after ignition. A correction factor of 0.21 for the aggregate blend used was applied to counteract for mineral loss of mass during ignition, in accordance with the test method, Three different laboratories (A, B, C) tested a sample of each mixture using this method.

The soluble binder content method, on the other hand, involved binder extraction by dissolving in a solvent (dicholromethane), separation of the mineral matter from the binder solution, determination of the quantity of binder by difference and by binder recovery (direct) and finally calculation of the soluble binder content. Separation of the mineral matter was carried using bottle rotation machine and pressure filter (binder by difference). Bucket centrifuge-Type 1 and volume calculation from an aliquot portion was employed for soluble binder content by recovery method. Three different laboratories (D, E, F) tested the GTR pellet mixture using both binder by difference and by recovery methods.

4 RESULTS AND DISCUSSIONS

4.1 *Composition of GTR bitumen pellets*

The results from the TGA experiments are presented in Figures 2–6. Figure 2 shows the TGA results for the GTR. It can be seen that there were a series of overlapping mass losses starting at around 200 °C and reached completion at around 550 °C. The total mass loss was 92.1% and the amount of residue after completion of the test was 7.9%. At temperatures below 300 °C mass loss is due to the volatilization of lubricants, stabilizers and other small molecules in the rubber with relatively low boiling points. Main polymeric compounds of the rubber like polyisoprene and styrene-butadiene rubber decompose at temperatures between 300 and 600 °C. At these temperatures, the polymer chains break down into a variety of smaller molecular fragments that will eventually vaporize. The remaining mass of

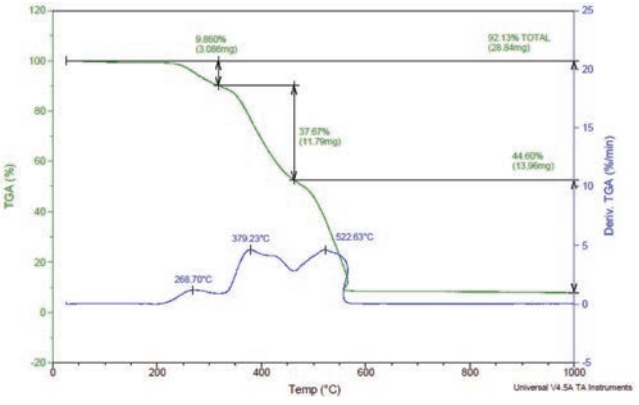

Figure 2. TGA of Ground Tyre Rubber (GTR).

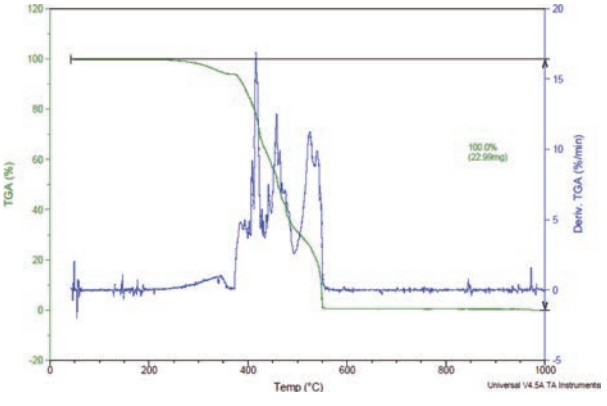

Figure 3. TGA of bitumen (100/150 pen).

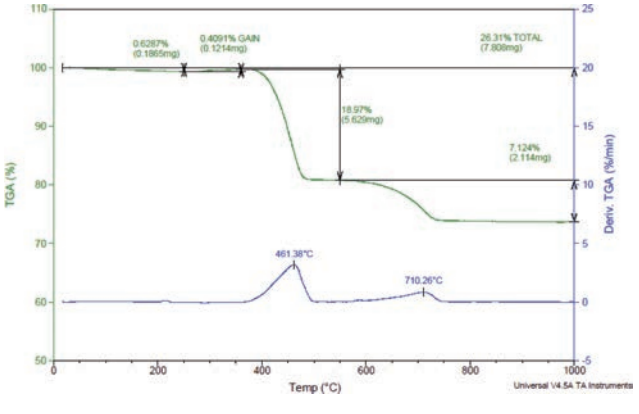

Figure 4. TGA of hydrated lime.

material at temperatures higher than 600 °C is carbon black and the remaining mineral ash residues. Similar thermal degradation curves for crumb rubber modifier have been reported elsewhere [9].

Figure 3 shows TGA results for the bitumen. The mass losses indicated decomposition of the different bitumen components from light molecular weight aromatics to high molecular

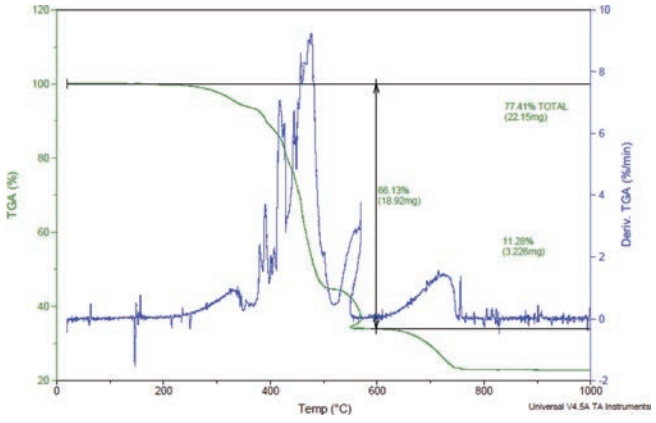

Figure 5. TGA of GTR bitumen pellets.

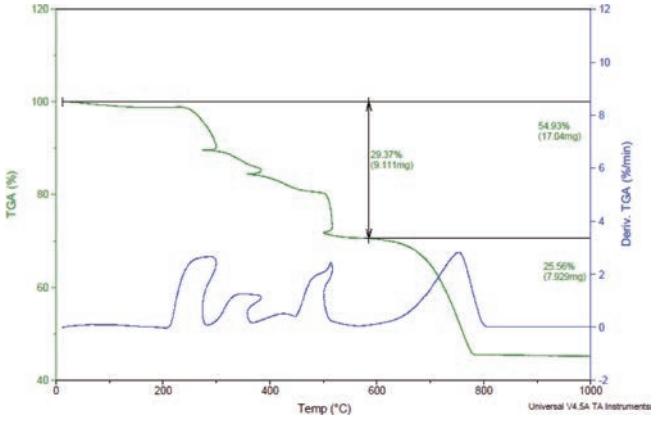

Figure 6. TGA of treated GTR bitumen pellets.

weight compounds. Furthermore, mass losses began soon after 200 °C and were completed in the region of 550 °C. A total mass loss of 100.0% was seen with no residue.

TGA results for the hydrated lime sample are shown in Figure 4. It can be seen that there were two main mass loss events with around 19.0% being lost by 500 °C followed by a smaller broad mass loss of 7.1% from around 550 °C to 750 °C. The residue was seen as a fine grey powder and amounted to 73.7%. The TGA profile for this material was not expected. The decomposition scheme for hydrated lime is $Ca(OH)_2 \rightarrow CaO + H_2O$ and as such would only expect a single mass loss step. The presence of the mass loss at around 400 °C overlaps with the bitumen and GTR mass losses.

TGA test results for the GTR bitumen pellets are presented in Figure 5. The GTR bitumen pellet showed a series of mass losses. The first section was the mass loss before 600 °C, while the second section was the mass losses occurring after 600 °C. It was assumed that the mass loss at temperatures higher than 600 °C were due solely to the decomposition of the hydrated lime. TGA tests were carried out in quadruplicate (see Table 2).

TGA test results of the residues from the samples treated with CS_2 are shown in Figure 6. It can be seen from the samples with the bitumen removed, that the oxidation of the remaining crumb rubber is very reactive under air, producing a large amount of heat. This sample generated heat increases the heating rate of the experiment distorting the TGA curve when plotted against temperature. However the triplicate determinations on the produced residue were all in good agreement as can be seen in Table 2.

Table 2. Mass losses of GTR bitumen pellets samples.

Material	Sample no.	Mass loss (%)			
		20–600 °C	600–1000 °C	Total	Residue
GTR bituminous pellets	1	66.5	11.1	77.6	22.4
	2	66.1	11.4	77.5	22.5
	3	66.0	11.3	77.3	22.7
	4	66.8	11.3	78.1	21.9
	Mean	66.4	11.3	77.6	22.4
	CoV	0.005	0.010	0.004	0.013
Treated GTR bituminous pellets	1	29.4	25.6	55.0	45.0
	2	26.7	26.3	53.0	47.0
	3	27.8	25.7	53.5	46.5
	Mean	28.0	25.9	53.8	46.2
	CoV	0.049	0.015	0.019	0.023

Due to the complexity of the hydrated lime mass loss profile and its overlapping with the GTR and bitumen decompositions, the estimation of the components of the GTR bitumen pellets is not straight forward. For the estimation of the composition of the pellets it was assumed that the mass loss from the heating above 600 °C was solely due to the hydrated lime.

The solvent treated GTR bitumen pellet samples showed an average mass loss of 28.0% between about 20 °C (ambient temperature) and 600 °C. Assuming that this mass loss was solely due to GTR and knowing the residual mass from the GTR was 7.9%, then the GTR content is: $28.0 \times (100/92.1)\% = 30.4\%$. The untreated GTR bitumen pellets showed an average mass loss of 66.4% between ambient temperature and 600 °C. Therefore, subtracting the mass loss occurring due to the GTR (28.0%) should yield the mass loss due to bitumen. In this case, the bitumen content is $(66.4 - 28.0)\% = 38.4\%$. Therefore, the level of hydrated lime present is, assuming that the composite consists of only three ingredients, 31.2%. Therefore the composition of the GTR bitumen pellet can be estimated at 38.4% bitumen, 30.4% GTR and 31.2% hydrated lime.

Typical or target pellet composition provided by the supplier of the pellets was 50% bitumen, 20% GTR and 30% hydrated lime. Results obtained from TGA showed lower bitumen content and higher rubber content that the target proportions. Estimated hydrated lime content, on the other hand, was close to the target value. The effect of such a change in composition was seen as an increase in the modification level i.e. rubber content while the binder content remained practically the same. Differences between the estimated and the target bitumen and rubber contents could be due to various causes. First, the TGA method used in this study provides just an estimation of the composition of the pellets as it is assumed that the mass loss at temperatures above 600 °C is solely the result of the decomposition of the hydrated lime. Also, the size of the samples used for the analysis is very small i.e. 30 mg approximately which could introduce some experimental error.

Higher rubber contents determined from TGA analysis might also suggest that during the manufactured of the rubber modified binder a higher amount of rubber than the target is blended with the bitumen. This could be monitored by adequate controls and calibration of the bitumen and rubber addition systems. Another possibility is that some rubber could have been deposited at the bottom of the reaction tank after a production run. This rubber could have then been blended with the freshly mixed rubber-bitumen binder increasing the overall rubber content of the binder. Nevertheless, quality control on the rubber—bitumen blends is carried out periodically at the plant and is primarily based on viscosity measurements. Viscosity values of the binders produced at the plant were determined using a digital viscometer (Haake VT-02) and were found to be between 20 to 60 dPa · s (2000–6000 cP) at 175 °C. It should be noted that viscosity values specified

for asphalt rubber in the US are 1500–5000 at 177 °C for binders containing a minimum of 15% rubber.

4.2 *Composition of asphalt with GTR bitumen pellets*

This section presents theoretical and experimental binder contents for the control and GTR pellet mixtures. As indicated before, the control asphalt mixture had 5.6% bitumen content whereas the GTR pellet mixture contained 4.6% bitumen and 1.4% GTR bitumen pellets by weight of the total mixture. The total binder content of the GTR pellet mixture can be calculated theoretically based on the composition of the GTR pellets and the percentage of pellets in the mixture. Table 3 shows the theoretical binder content and rubber content for two different GTR pellets composition, one based on the target GTR pellet composition (50% Bit, 20% GTR, 30% HL) and the other determined from TGA experiments (38.4% Bit, 30.4% GTR, 31.2% HL). It can be seen first that the total binder contents of the control and GTR pellets mixture were 5.6% and 5.5%, respectively. The percentage of GTR in the binder was, however, higher when the estimated GTR pellet composition from TGA were used.

Binder content determined by the ignition method and soluble binder content determined by different and by binder recovery (direct) methods are presented in Table 4. It can be seen that for the control mixture binder content by ignition was the same as the target value i.e. 5.6%. Binder content by ignition for the GTR pellet mixture was 5.3%, thus, lower than the target value for that particular GTR pellet composition. It should be noted that the binder content was determined by heating the samples in a furnace at 480 °C for 50 minutes. TGA of the GTR showed, however, that not all the components of the rubber decomposed below this temperature. It is believed that at this temperature some rubber compounds primarily synthetic rubber, carbon black and other ash mineral are still present in the sample. This can then introduce some errors in the calculation of the binder content determined from the total mass of the mixture before and after ignition. Larger variability was also found for the GTR pellets mixture. This could be the results of uneven distribution of the pellets within the mixture under laboratory conditions.

Soluble binder contents for the GTR pellet mixture determined by difference and by binder recovery (direct) methods showed lower binder content that the target value. It is known that vulcanised rubber as in tyre rubber does not completely dissolve in organic solvents. So, in the determination of the soluble binder content the bitumen dissolved in the solvent but not the GTR. The calculated soluble binder content was; therefore, lower than the actual total binder content which includes non-dissolve rubber compounds. If it

Table 3. Theoretical binder content of the GTR pellet mixture.

GTR pellets componets	GTR pellet composition (%)	GTR pellets by wt of total mixture (%)	Components in the mixture	Content by wt of total mixture (%)

		Mean	5.3

is assumed that the rubber particles do not dissolve, the soluble binder content is just the bitumen content of the mixture. For the GTR pellet mixture the theoretical bitumen content was 5.1% which is close to the experimental soluble binder content. (5.1%—direct method and 5.3%—by difference).

5 CONCLUSIONS

- TGA was found to be a useful tool to characterise the individual components of the GTR bitumen pellets and to estimate their overall composition.
- The composition of the GTR bitumen pellets determined by TGA was estimated at 38.4% bitumen, 30.4% GTR and 31.2% hydrated lime.
- Percentage of rubber-binder in the pellet determined by TGA (68.8%) was similar to the target binder content provided by the supplier of the pellets (70.0%). Rubber concentration determined by TGA (30.4%) was, however, larger than the value provided by the supplier (20.0%).
- Binder content for the GTR pellet mixture determined by the ignition method (5.3%) was lower that the control mixture and the target value (5.6%). This was attributed to non-combusted rubber compounds at during oven ignition. Furthermore, TGA of the rubber confirmed that some rubber compounds volatilised at temperatures above the ignition oven temperature.
- Soluble binder contents for the GTR pellet mixture (5.2% direct method and 5.3% by difference method) were also lower than the target value (5.6%). This could be attributed to non-dissolve rubber particles during binder extraction.
- The level of polymer (rubber) modification i.e. the amount of GTR by weight of total binder in the mixture is dependent among others on the overall composition of the pellets. Hence, robust quality control measures are required during the manufacture of the GTR bitumen pellets to ensure consistence in the product and its composition.

Towards modeling rutting for asphalt pavements in hot climates

Aaron D. Mwanza & Mundia Muya
Department of Civil and Environmental Engineering, School of Engineering, University of Zambia, Lusaka, Zambia

Peiwen Hao
Highway College, Chang'an University, Shaanxi Province, Xi'an, China

ABSTRACT: Rutting is a chronic disease in asphalt pavements despite several mitigation measures. Although many attempts have been made by both researchers and practitioners to develop rutting prediction models, each model, however, has certain inherent limitations due to assumptions and data used during the development of the model. Placement of an asphalt overlay is the most common method used in Zambia to rehabilitate existing asphalt pavements. The objective of this research is to go towards developing a national rutting prediction model for use in tropical hot climates based on default finite element creep and elasto-visco-plastic analysis tools in abaqus. Dynamic modulus and repeated load tests are conducted on overlay mixtures designed based on the pavement residual structural adequacy from deflection tests to provide material properties for the constitutive rutting model. Unified, three dimensional linear viscoelastic boundary value problems were formulated for six national representative pavement sections. In general, the FE creep and elasto-visco-plastic rutting evolutions were in agreement with the measured laboratory scaled one third mobile load simulator's. Performance ranking of the validated models revealed optimal pavement system combination suitable for calibration. The study recommends future directions for local adoption of the South African mechanistic-empirical design method currently being developed.

Keywords: Finite element, rutting, creep, elasto-visco-plastic, overlay

1 INTRODUCTION

The use of asphalt overlays is one of the most common methods used in Zambia to rehabilitate deteriorated existing asphalt pavement roads. The type of an overlay and its required thicknesses are principally governed by the residual structural adequacy and strength of the existing pavement (PVMNT), determined mostly from non-destructive deflection tests such as the Falling Weight Deflectometer (FWD). Once adequately constructed, the satisfactory performance of an asphalt overlay is influenced by various factors including the existing PVMNT conditions, traffic loading, and environmental conditions (temperature, etc.).

Permanent Deformation (PD) in asphalt overlays is most severe in hot climates particularly under heavy traffic loading [1]. Estimation and prediction of the maximum distresses likely to occur within the PVMNT layers after construction of an overlay is critical to optimize PVMNT design and management [2]. Constitutive modeling of the PD behavior of asphalt pavement structures enables PVMNT engineers to evaluate the PVMNT deterioration progress and develop regional specific performance based asphalt mix specifications.

In this study, Finite Element (FE) analysis tools in ABAQUS were used to simulate a PVMNT model to predict PD that leads to rutting estimation. To validate the ABAQUS models and the related FE analysis, Accelerated Pavement Testing (APT) with the third-scale Mobile Load Simulator (MLS3) was used to measure the PD on laboratory scaled constructed overlay test sections of similar PVMNT structure and materials as the ABAQUS models.

2 STUDY OBJECTIVES AND METHODOLOGY

Given the above background, the objectives of the work documented in this paper were three-fold, namely:

- To evaluate the PD models in ABAQUS platform for the suitability of predicting rutting in hot tropical climates like Zambia.
- To characterize the Zambian roads asphalt mixes for PD response and rutting performance.
- To determine the regional temperature correction factors that adequately accounts for the effect of prolonged heat and high temperatures on deflection measurements.

The study methodology incorporated Nondestructive Testing (NDT) with the FWD conducted on in-service roads for a period of 2 years in different seasons to generate regional temperature correction factors and the overlay mix design data. In-situ characteristics of PVMNT layers in combination with dynamic modulus and repeated load testing on asphalt mixes provided material input parameters for the PD and rutting models. FE analysis in ABAQUS was executed to compare and validate the rutting performance of various laboratory-scaled PVMNT structures under accelerated trafficking with the MLS3.

3 EXPERIMENTAL PROGRAM

As discussed in the subsequent text, the experimental design plan comprised of FWD testing, modulus back-calculation and computations, sensitivity analysis, asphalt mix design and laboratory testing, accelerated PVMNT testing with the MLS3 and ABAQUS FE modeling.

3.1 *Falling Weight Deflectometer (FWD) testing*

Deflection response of a PVMNT to any applied load is an important indicator of the structural capacity, material property characterization, and subsequent PVMNT performance [3]. A Dynatest FWD model 8000 was used to collect deflection data, with typical test parameters, namely: 40 kN impulse load at one drop per point in the wheel path, 30 cm diameter circular foot plate, and seven geophones radially located at 0, 203, 306, 457, 610, 914, and 1534 mm, interspacing. Deflection measurements were taken at minimum 100 m interspacing on alternate lanes in the wheel path of a 45 km two-lane road, with one lane in each direction.

In order to account for the effects of seasonal temperature variations on deflection measurements, FWD tests were conducted over a period of 2 years spread over the three significant seasons of Zambia, namely rainy, cold, and hot season. Five representative PVMNT sections were selected based on the normal variation in the PVMNT cross-section, layer thickness, material type and quality, subgrade support, riding quality, and surface distresses for FE analysis.

3.1.1 *Modulus calculation-back analysis*

Based on the 90th percentile, a representative deflection basin was established for each PVMNT section for analyzing the representative moduli values. Raw deflection measurements were normalized and calibrated for regional temperature correction through a protocol model that was developed by taking into account a two years' seasonal temperature variation effects on deflection measurements before processing the elastic moduli back-calculations.

Back-calculation involves iterative and regression techniques to minimize errors between measured and calculated deflection values. This was computed using the following Eq.(1).

$$MSE = f(E,h) = \frac{1}{n}\sum_{i=1}^{n} We_i \left\{ D_i^c(E,h) - D_i^m \right\}^2 \quad (1)$$

where:
$D_i^c(E,h)$ = Calculated deflection at location i based on E and h,
D_i^m = Measured deflection at location i,
n = Number of FWD sensors,
E = {E1, E2, E3, ….., Em} (unknown moduli of the layers),
H = {h1, h2, h3 …… hm-1} (known layer thickness), and
We_i = Weighing factor for sensor i (We_i = 1 if all sensors are given the same importance).
MSE = Mean Square error

3.1.2 *Sensitivity analysis of modulus values*

A temperature correction model that was developed in this study based on moduli obtained from back-calculation analysis of the Evaluation of Layer Moduli (ELMOD) software at different temperatures was used to compare the moduli values obtained on each PVMT section throughout the temperature regime and season that the FWD tests were conducted. The default model format for temperature correction is expressed in Eq.(2).

$$D_{25} = D_0 e^{0.279T} \tag{2}$$

where:
D_0 = Measured center deflection
T = Temperature at the bottom of the wearing surface (approximately 40 mm from the surface)

In order to compare the deflections between sections, the deflection temperature models for each PVMNT section were normalized to the average HMA temperature during the testing period of 25 °C. An example of a generalized model for some PVMNT sections after nonlinear regression is shown in Figure 1.

Temperature correction factors can be read off from the relevant graph and applied to deflection measurements before in-putting into the ELMOD back-calculation software [6].

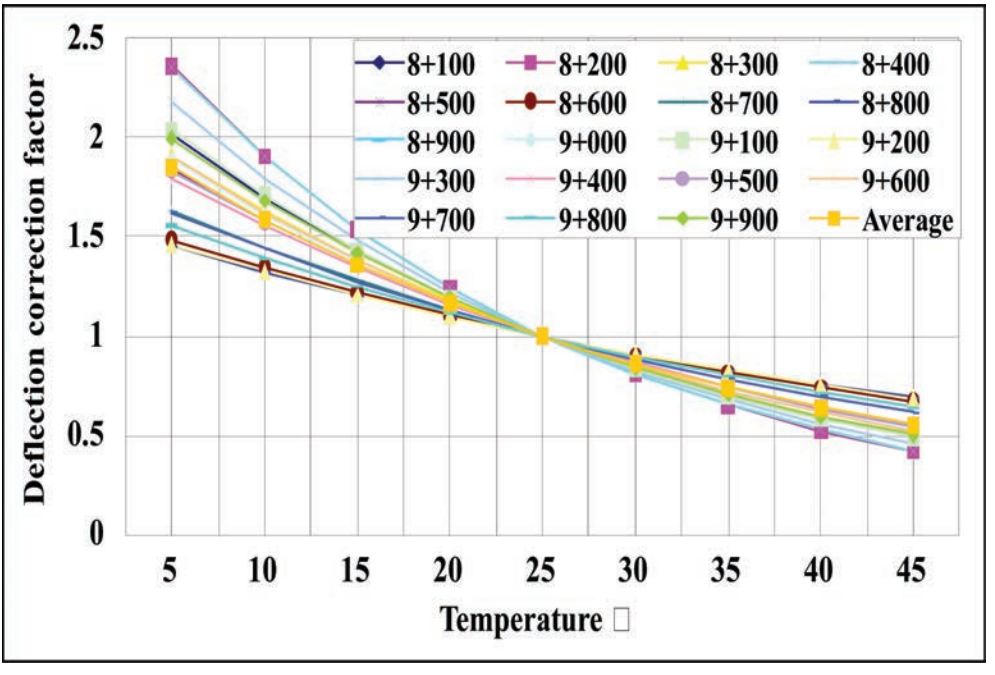

Figure 1. Temperature correction factors for deflection measurements.

Based on these adjustments, the corrected in-situ layer moduli were then utilized for development of PD and rutting prediction models. The residual life of each PVMNT section and the required overlay thickness were calculated based on the 1993 AASHTO PVMNT design guide. The 1993 AASHTO overlay thickness design method utilizes the effective thickness approach. The required thickness of the Asphalt Concrete (AC) overlay was determined and computed as a function of the structural capacity required to meet future traffic demands and the structural capacity of the existing pavement [7].

$$h_{oL} = \frac{SN_{OL}}{a_{OL}} = \frac{SN_f - SN_{eff}}{a_{OL}} \tag{3}$$

where:
h_{OL} = Required thickness of asphalt overlay,
SN_{OL} = Required structural number of asphalt overlay,
a_{OL} = Structural layer coefficient of asphalt overlay,
SN_f = Structural number required to carry future traffic; and
SN_{eff} = Total effective structural number of the existing pavement prior to overlay.

The design subgrade resilient Modulus (M_R value) was obtained from FWD measurements based on back-calculation analysis. The effective structural number (SN_{eff}) was obtained using the AASHTO residual life method [8].

3.2 *Asphalt mix design and laboratory testing*

The original and existing PVMNT structures were designed based on the South African standards and codes of practice [9]. Five asphalt mixes were prepared for use on each delineated PVMNT sections as seen in Table 1 and the SuperPave mix-design method was used to characterize the volumetric and engineering properties of the mixes. Laboratory tests on asphalt mixes that provided elastic- and viscoelastic-plastic properties included dynamic modulus (|E^*|) [10], repeated load testing, flow number (F_N), and static creep—flow time (F_t) [11]. Dynamic modulus test was performed on the overlay mixes to obtain the modulus parameters for the surfacing course material that was used in the analysis for the models. For the creep model, dynamic and static creep compliance tests were performed to obtain the flow number and flow time respectively for determining creep model parameters (*A, n,* and *m*).

Table 1. Basic material characteristics for the asphalt mixes.

PVMNT section	A	B	C	D & E
Chainages (km)	7.16–7.5	9.9–13.8	16.8–18.75	21.75–24.2

Nominal aggregates size (mm)	19.0	12.5	12.5	12.5
N_{design}	100	75	100	100
AS—constructed volumetric properties				
AC (%)	5.61	5.2	5.3	5.4
AV@N_{design} (%)	4.08	3.33	4.4	4.4
VMA	18.4	15.8	18.862	17.4
VFA	55.2	59.1	51.8	57.1
%G_{mm}@N_{ini}	88.2	88.8	85.4	85.5
%G_{mm}@N_{des}	96.1	95.6		
%G_{mm}@N_{max}	97.2	99.9	97.2	97.3
In-situ AV (%)	6.00 ± 0.5	6.75 ± 0.5	9.38 ± 0.5	7.00 ± 0.5

The Frequency sweep at constant height test was performed to obtain the dynamic shear moduli (*G*, G'* and *G''*) and bulk moduli (*K*, K', K'')* as input parameters for the viscoelastic model.

Dynamic modulus for each mix was determined by conducting the test at two temperatures, thus 20 °C and 35 °C each at 0.1, 0.5, 1.5, 10, and 25 Hz frequencies, respectively and then generating $|E^*|$ master-curves at 35 °C as a reference temperature that is representative of the Zambian summer high temperature regime when asphalt PD and rutting are more critical. The shift factors were determined using a sigmoidal function [12]. Equation 4 shows the sigmoid function (master curve—fit equation) that was used in this study.

$$\log|E^*| = \delta + \frac{\alpha}{1 + e^{\beta - \gamma(\log(f_r) + S_T)}} \tag{4}$$

where:
$|E^*|$ = Dynamic modulus,
δ = Minimum modulus value,
$\delta + \alpha$ = Maximum value of $|E^*|$
β and γ = Sigmoid function fitting parameters
f_r = Reduced frequency at the reference temperature
S_T = Shift factors

The reduced frequency was computed using the equation below;

$$\log f_r = \log f + \frac{\Delta E_a}{19.14714}\left(\frac{1}{T} - \frac{1}{T_r}\right) \tag{5}$$

where:
f_r = Reduced frequency at the reference temperature
f = Loading frequency at the test temperature;
T_r = Reference temperature in °K;
T = Test temperature in °K;
ΔE_a = Activation energy (treated as a fitting parameter)

The temperature shift factors are given by Eq.(7).

$$\log a(T) = \frac{\Delta E_a}{19.14714}\left(\frac{1}{T} - \frac{1}{T_r}\right) \tag{6}$$

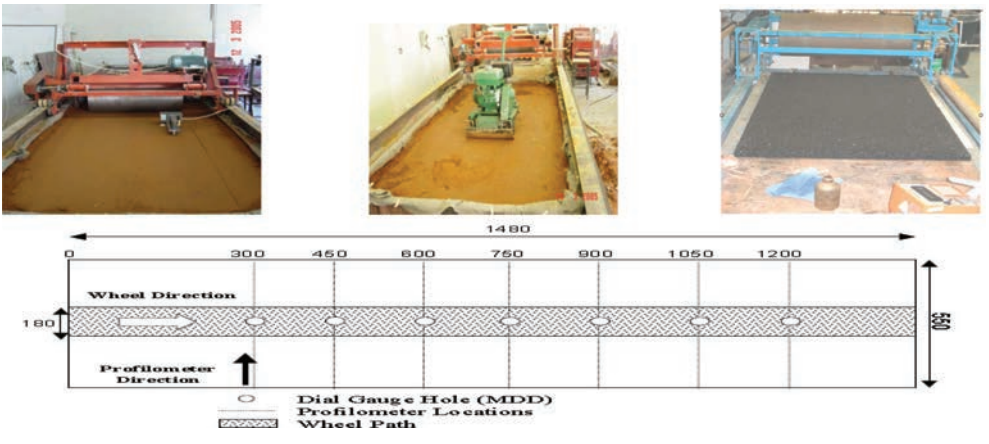

Figure 2. Schematic of PVMNT test preparation and profile marking.

where:
a(T) = Shift factor at temperature T,
T_r, T and ΔE_a = as defined in Equation 4 and 5

3.3 *Accelerated third-scale mobile load simulator (MLS3) testing*

A model mobile load simulator MLS3 (MMLS3) is a one-third scale of a full scale APT machine with the potential to test the effect of different environmental impacts to rutting such as temperature under wet and dry conditions [13]. It can be applied both in the laboratory and in the field. The MMLS3 consists of four axles, each with a 300 mm diameter inflated pneumatic wheel, circulating in a vertical closed loop. The nominal wheel speed is 2.5 m/s resulting in 7200 wheel loadings per hour. Slower speeds can be selected if desired. A series of accelerated load testing on laboratory scaled pavement sections were carried out and rut depth was recorded at profilemeter gauge positions of every 1000 incremental load applications under a one-third scaled value of the actual truck wheel. The tyre pressure was set at 750 kPa at a wheel load of 2.9 kN and temperature of 25 °C in conformity with the average HMA test temperature during the period of conducting the deflection tests on in service pavements.

3.3.1 *Test protocol*

The test method includes pre-conditioning of the laboratory scaled pavement test sections at the predetermined test temperature and measuring a set of cross section profiles before the MMLS3 is moved into position. Trafficking is applied to the pavement while maintaining the test temperature. At predetermined intervals the loading is stopped and cross-section profiles measured. After a predetermined number of repetitions the loading is terminated and a total depth of rutting is reported.

4 FINITE ELEMENT (FE) PROBLEM FORMULATION

Three models in ABAQUS Version 6.10 were selected; namely, creep, elasto-visco-plastic, and viscoelastic. The model selection criteria were based on the ability to conduct material characterization tests for the required input data. The PVMT configuration and boundary conditions adapted are shown in Figure 3. Representative PVMNT sections and material parameter models used in each FE analysis are shown in Table 2.

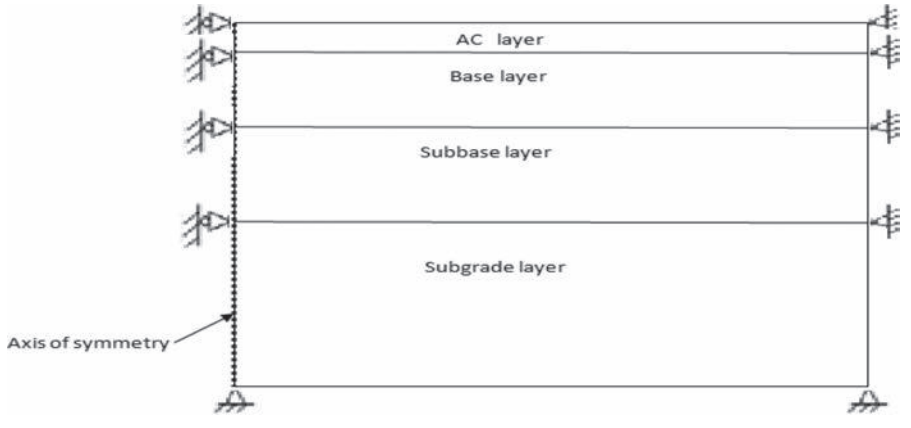

Figure 3. PVMNT configuration and boundary conditions for abaqus analysis.

5 RESULTS, ANALYSIS, AND DISCUSSIONS

PD prediction models implementation in ABAQUS showed that the viscoelastic model could not capture the PD response characteristics. The displacements measured were too small (2*E-11 mm) in magnitude, which can be considered negligible. Two models, the creep and elasto-visco-plastic, were able to capture the PD response characteristics of

the asphalt (AC) mixes. A linear formulation was subsequently used to predict the evolution of PD in the asphalt mixes. Ranking of the models for each asphalt mix is shown in Table 3 including comparisons of the models to the MLS3 results.

It can be seen from Table 3 that the two model predictions are very close to each other due to the complementary creep compliance found in both PD models. The APT prediction from the MLS3 is also comparable to the analytical model PD predictions, albeit that its PD values are about 5% higher than the analytical PD values. Overall, the results from laboratory testing, field FWD testing, APT, and numerical modeling were plausible and substantiated the significance of local temperature normalization of the FWD deflection measurements.

6 CONCLUSIONS

In-situ material tests were conducted using NDT techniques (i.e., FWD) to design overlay mixes. Laboratory tests were performed on the overlay mixes to generate model input parameters needed for FE ABAQUS analysis. In order to validate the models, APT trafficking with the MLS3 were performed on the scaled laboratory constructed PVMNT sections to further compare the PD performance of the five Overlay (AC) mixes. From the results and study findings, the following conclusions were drawn:

- The two models, *creep and elasto-visco-plastic*, predicted a total PD that is close to the APT (MLS3) measured values; hence, the models are considered reliable with modifications as suggested in this paper.
- The FWD tests provided reliable information for the PVMNT layer moduli values that can be used for PD analysis in ABAQUS.
- It has been demonstrated that back-calculation techniques in ELMOD software need temperature correction factors that are project specific to achieve reliable and representative PD predictions.
- Asphalt mixes were ranked for their PD and rutting performance; therefore, calibration of the rutting models can be carried out based on APT in the field or lab as well as observation of rutting performance in service.

Evaluation of low temperature stability of bitumen and hot mix asphalt pavement

Bagdat Teltayev, Yevgenya Kaganovich & Yerick Amirbayev
JSC "Kazakhstan Highway Research Institute", Almaty, Kazakhstan

ABSTRACT: Evaluation of low temperature stability of bitumen and hot mix asphalt pavement is actual in conditions of sharp continental climate of Kazakhstan.

In this paper low temperature stability of bitumen of grades BND 60-90 (BND means an oil road bitumen) and BND 90-130 has been carried out by testing on Bending Beam Rheometer (BBR) under Superpave method. Low temperature stability of hot mix asphalt pavement has been carried out by method based on integral equation of theory of linear viscoelasticity and applying tensile strength of hot mix asphalt.

The results of testing on BBR have shown that bitumen of grades BND 60-90 and BND 90–130 meet the requirements of Superpave specifications up to –39°C and –42°C respectively, which does not correspond to reality. Low temperature cracks on hot mix asphalt pavement occur during first years of operation and in future the distances between them reduce. In 3–5 years the distances between low temperature cracks on hot mix asphalt pavement correspond to 10–70 m.

Evaluation of low temperature stability of hot mix asphalt pavement considering volumetric indices and viscoelastic properties of hot mix asphalt and conditions of temperature falling has shown that such characteristics as cooling start temperature and cooling rate influence greatly over cracking of pavement. Unfavorable one is complex of high cooling start temperature and high cooling rate. Depending on cooling start temperature and cooling rate the first low temperature cracks can occur at the temperature of –1 to –24°C, which is close to reality.

Keywords: Bitumen, superpave, hot mix asphalt, low temperature cracking

1 INTRODUCTION

Study of low temperature stability of bitumen in sharp continental climatic conditions of Kazakhstan is actual due to the provision of stability to low temperature cracking of hot mix asphalt pavement.

Analysis of climatic characteristics of northern part of the Republic has shown that practically every year in winter months air temperature falls below –40°C several times. There are considerable differences not only in values of minimum temperature in regions, but also in character of temperature falling during cold season and its vaiations. Thus, for Astana city duration of temperature falls in winter season for 65% of measurements corresponds to 12–18 hours, temperature falling rate in 20% of measurements is more than 1.0°C per hour with maximum in 1.9°C per hour. It is obvious that such climatic characteristics influence greatly over low temperature stability of bitumen and hot mix asphalt pavement.

In this paper low temperature stability of bitumen of grades BND 60-90 and BND 90-130 of Pavlodar plant, which often has been applied in northern part of the country, has been determined by testing on BBR under Superpave method.

Evaluation of hot mix asphalt pavement temperature cracking stability has been carried out by method, based on integral equation of theory of linear viscoelasticity and using hot mix asphalt tensile strength.

2 MATERIALS APPLIED

In this paper bitumens of grades BND 60-90 and BND 90-130 have been used, meeting the requirements of Kazakhstan standard ST RK 1773-2005. Basic standard indices of the bitumens have been shown in the Table 1. The bitumens have been produced by Pavlodar plant from crude oil of Western Siberia (Russia) by direct oxidation.

Porous hot mix asphalt of type B under standard of Kazakhstan ST RK 1225-2003 has been prepared with the use of aggregate of fractions 5–10 mm (20%), 10–15 mm (13%), 15–20 mm (10%) from Novo-Alekseevsk rock pit (Almaty Oblast), sand fraction 0–5 mm (50%) from the plant "Asphaltconcrete-1" (Almaty city) and mineral powder (7%) from Kordai rock pit (Zhambyl Oblast). Content of bitumen of grade BND 90-130 in hot mix asphalt is 4.8% by weight of dry mineral material. Basic standard indices of aggregate and hot mix asphalt have been shown in the Tables 2 and 3 respectively. The grading curve of mineral part of hot mix asphalt has been shown in Figure 1. In this figure, lower and upper permissible limits of the passing of particles are designated by bold lines. As it is seen, grain composition of the hot mix asphalt meets the requirements.

3 LOW TEMPERATURE STABILITY FOR BITUMEN

The indices for low temperature stability of bitumen–creep stiffness (S) and the indicator, characterizing stress relaxation rate (m-value) of bitumen have been determined by testing on BBR at temperatures –18, –24, –30 and –36°C under standard ASTM D 6648-08 after double aging of bitumen under standards ASTM D 2872-08 and ASTM D 6521-08. The device has been produced by the company ATS (Applied Test Systems Inc., USA).

Table 1. Basic standard indices of bitumen.

Indice	Measurement unit	Requirements of ST RK 1773-2005		Value	
		BND 60-90	BND 90-130	BND 60-90	BND 90-130

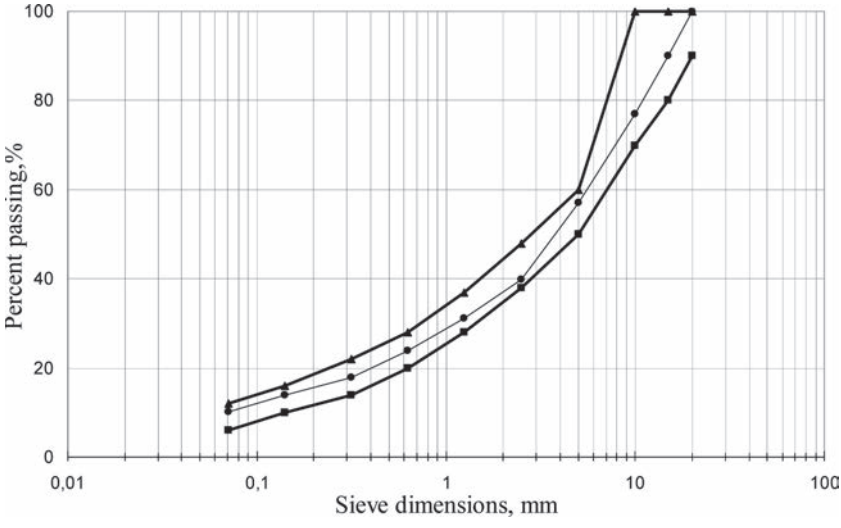

Figure 1. Asphalt mixture grading curve.

Sample of bitumen in the form of beam with dimensions 125 × 12.5 × 6.35 mm has been tested by applying load of 100 g (980 mN) to the center of the sample. Deflection of the center of the beam has been measured at 8, 15, 30, 60, 120 and 240 s. Stiffness has been calculated by Eq. (1):

$$S(t) = \frac{PL^3}{4bh^3\delta(t)'} \quad (1)$$

where, S(t)—stiffness at load time t;
P—applied load;
L—length of beam span;
b, h—width and height of beam;
δ(t)—deflection of center of beam span at time t.

The results of testing for bitumen have been represented in Figures 2 and 3. Superpave specifications require bitumen stiffness at load duration for 60 s not to exceed 300 MPa at

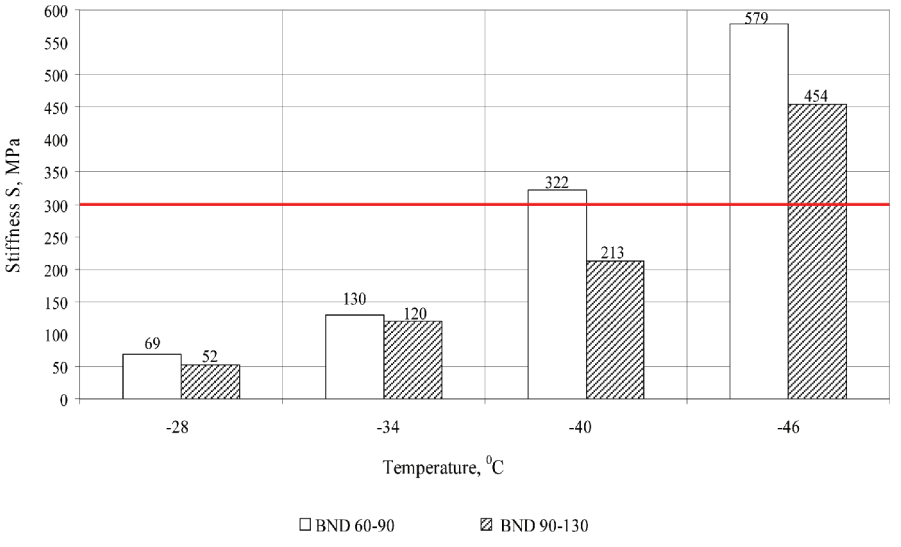

Figure 2. Bitumen stiffness at low temperatures.

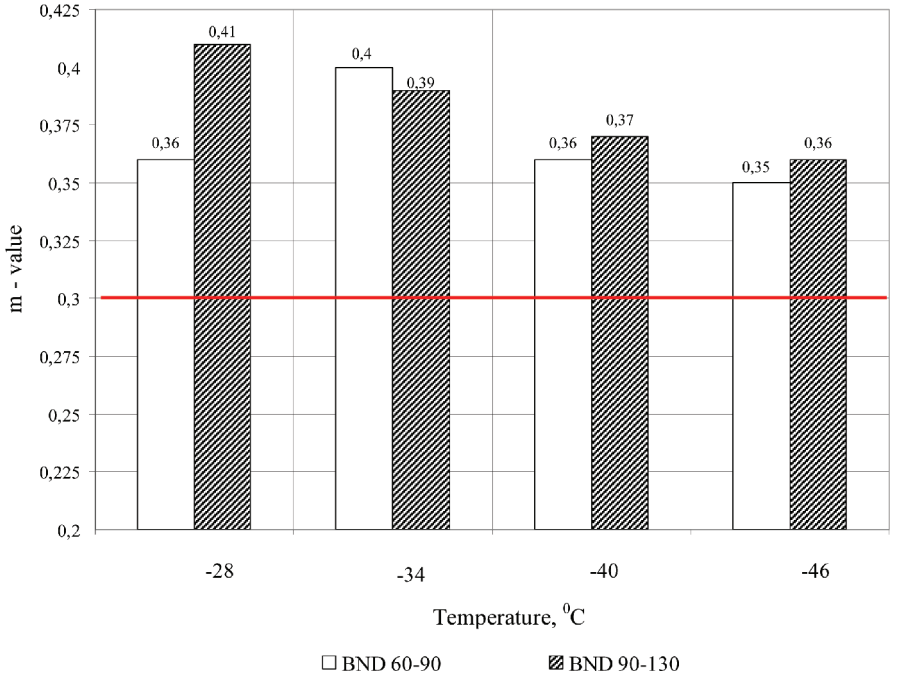

Figure 3. m-value for bitumen at low temperatures.

estimated minimum temperature, and m-value was not less than 0.3 [1]. We can note that except for bitumen of grade BND 60–90 at temperature –28°C, with temperature falling m-value decreases, but at all temperatures it exceeds minimum allowable value 0.3. As it could be expected, with temperature falling the bitumen stiffness increases. Bitumen of grade BND 60-90 meets the requirements of Superpave specifications up to –39°C inclusively, and BND 90-130—up to –42°C inclusively, which does not correspond to reality. Low temperature

cracks on hot mix asphalt pavement occur during first years of operation and in future the distances between them reduce. In 3–5 years the distances between low temperature cracks on hot mix asphalt pavement correspond to 10–70 m.

4 LOW TEMPERATURE CRACKING STABILITY OF HOT MIX ASPHALT PAVEMENT

4.1 *Calculation of temperature stress*

Road specialists believe that low temperature crack on hot mix asphalt pavement occur due to impossibility of free deformation of pavement in horizontal direction with temperature falling. Its neighboring sections hamper any section of continuous hot mix asphalt pavement to deform freely. Value of non-realized temperature deformation in hot mix asphalt pavement at time t one can determine under Eq. (2):

$$\varepsilon_T(t) = \alpha\left[T(t) - T_0\right], \tag{2}$$

where, α—linear temperature contraction coefficient of hot mix asphalt, 1/°C;
T_0—initial temperature, °C;
T(t)—temperature at time t.

Present paper considers hot mix asphalt pavement as infinite bar, lying on continuous homogeneous base, between which there is no friction. Temperature of hot mix asphalt pavement will be characterized by its value on the pavement surface, i.e. air temperature.

Temperature variation during time has been set by Eq. (3):

$$T(t) = T_0 - \frac{1}{3600} \cdot k \cdot t, \tag{3}$$

where, k—temperature falling (cooling) rate, °C/h;
t—time, s.

Hot mix asphalt is a typical viscoelastic material, mechanical properties of which depend on load duration and temperature [2–4]. Therefore temperature stress in hot mix asphalt pavement can be determined by the following integral equation of theory of linear viscoelasticity [5], i.e. Eq. (4):

$$\sigma_T(t) = \int_0^t E(t-\tau)d\varepsilon_T(\tau), \tag{4}$$

where, E(t)—hot mix asphalt relaxation function;
t—time, at which stress $\sigma_T(t)$ has been calculated;
τ—parameter of integration;
$\varepsilon_T(\tau)$—non-realized temperature contraction in hot mix asphalt pavement.

Hot mix asphalt relaxation function has been described by the correlation model of M.W. Witczak [6] and has been shown in Figure 4.

4.2 *Calculation of low temperature cracking stability of hot mix asphalt pavement*

Considering that air temperature falling in the area of Astana city often starts at the temperature of –8 to –12°C, temperature stress in hot mix asphalt pavement has been calculated at the cooling rate of 0.4, 0.8, 1.2, 1.6 и 2.0°C/h, starting from the cooling start temperature of $T_0 = -10$°C. The results obtained have been shown in Figure 5. As it is obvious, temperature falling under linear law causes the increase of temperature stress in hot mix asphalt pavement under non-linear law at all the considered cooling rates. Dependence of temperature stress at various cooling rates from low temperature has been shown in Figure 6. On diagrams of

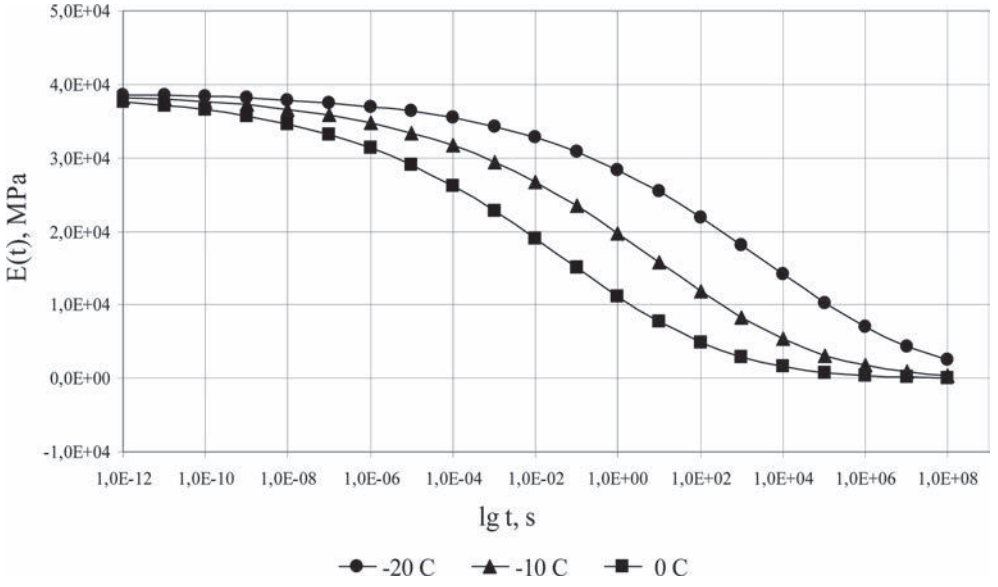

Figure 4. Hot mix asphalt relaxation function.

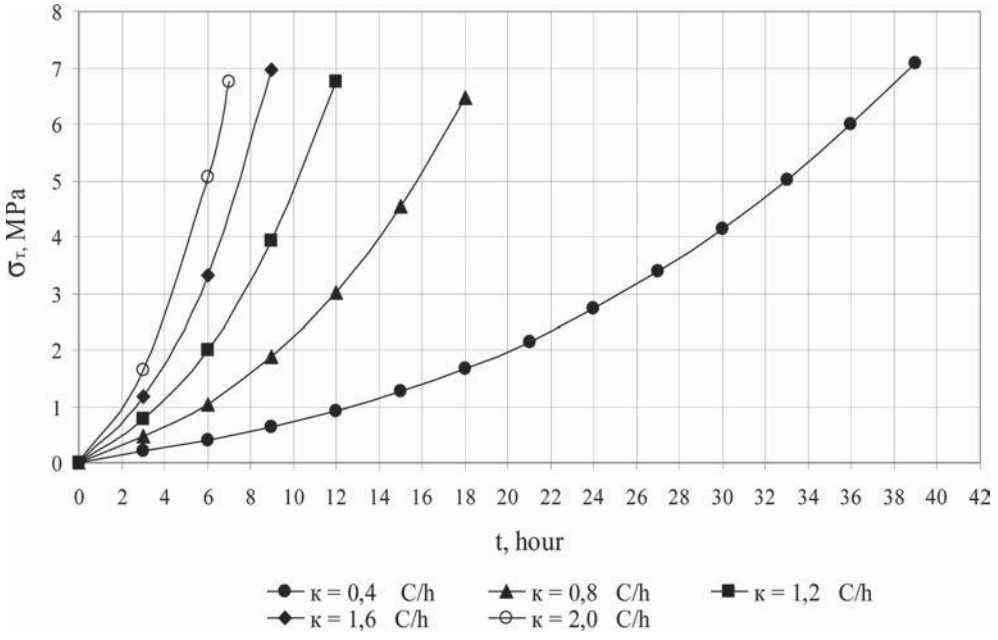

Figure 5. Temperature stress in hot mix asphalt pavement at cooling start temperature $T_0 = -10°C$.

this figure another diagram has been applied, showing the dependence of hot mix asphalt tensile strength on temperature R(T), which has been obtained by testing of samples in the form of beam with dimensions $40 \times 40 \times 160$ mm in special testing system TRAVIS under standard EN 12697-46. The device has been produced by the company InfraTest (Germany). Such combination of diagrams allows finding of important indices for cracking occurrence on hot mix asphalt pavement.

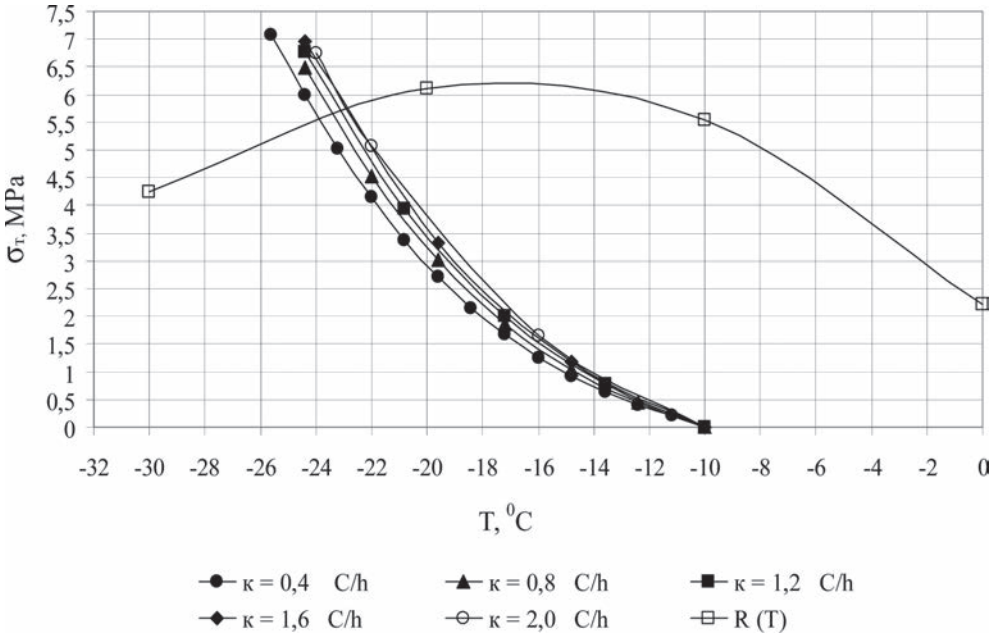

Figure 6. Combined diagrams of temperature stress in hot mix asphalt pavement at cooling start temperature $T_0 = -10$°C and tensile strength of hot mix asphalt.

Thus, dropping vertical line from cross point of diagrams, on horizontal axis one can find critical temperature T_{cr}, when low temperature cracks occur on pavement. Drawing horizontal line from cross point of diagrams, one can determine critical stress σ_{cr} on vertical axis, when low temperature cracks occur. Knowing values of critical stress, from diagram of Figure 5 one can determine values for critical time t_{cr} at various cooling rates. Critical time shows in what time since the commencement of low temperature crack occurs in pavement.

Obtained by the above methods the values of critical time, critical temperature and critical stress have been represented in the Table 4. Data of this Table show that critical time considerably depends on temperature falling rate. At low cooling rates occurrence of low temperature cracks on pavement has been expected after expiring of long time, and at high cooling rates the cracks can occur in relatively short time. Thus, at k = 0.4°C/h occurrence of low temperature crack can be expected approximately in 34 hours, and at k = 2.0°C/h—in 6 hours.

It has been found that critical temperature and critical stress at considered cooling start temperature and accepted hot mix asphalt do not practically depend on cooling rate: $T_{cr} = -23$ to −24°C, σ_{cr} = 5.5–5.8 MPa. In other words, regardless of rate and duration of cooling the first low temperature cracks on hot mix asphalt pavement can occur at temperature range of −23 to −24°C.

It has been found that in the considered climatic area at high rates of air cooling (for example at κ = 1.0°C/h) temperature falling starts from the temperature of $T_0 = -3$ to −10°C, and at low rates of cooling (for example at κ = 0.4°C/h)—from the startt temperature of $T_0 = +1$ to −20°C. Considering that further evaluations of low temperature cracking stability for hot mix asphalt pavement have been carried out at two cooling rates (κ = 0.4 and 1.0°C/h) and at three values of cooling start temperature ($T_0 = 0, -10, -20$°C). Specific values of critical time, critical temperature and critical stress obtained have been shown in Table 5. The results of analysis for the data of the Table have shown that cooling start temperature influences greatly over cracking stability of pavement. The increase of cooling start temperature provides the increase of critical time, critical stress and critical temperature. And reduce of cooling start temperature causes opposite phenomena: critical time and critical stress reduce, and critical

Table 4. Critical time, critical temperature and critical stress at cooling start temperature $T_0 = -10$°C.

Temperature falling rate κ,°C	Critical time t_{cr}, h	Critical temperature, T_{cr},°C	Critical stress, σ_{cr}, MPa
0.4	33.8	–24.0	5.5
0.8	16.5	–23.6	5.6
1.2	10.8	–23.4	5.7
1.6	7.2	–23.2	5.8
2.0	6.4	–23.0	5.8

Table 5. Critical time, critical temperature and critical stress at various cooling rates and cooling start temperatures.

Cooling rate κ,°C/h	Cooling start temperature T_0,°C	Critical time t_{cr}, h	Critical temperature T_{cr},°C	Critical stress σ_{cr}, MPa
0.4	0	52.0	–21.0	6.0
	–10	34.5	–24.0	5.6
	–20	19.5	–28.0	4.6
1.0	0	17.5	–17.5	6.2
	–10	13.0	–23.4	5.6

temperature falls. For example, in the case of increasing of cooling start temperature from –20°C to 0°C critical time increases 2.7 times, critical stress increases for 1.4 MPa, and critical temperature increases for 7°C. It has been found out that from the point of view for provision of temperature cracking stability for pavement, combination of high cooling start temperature and high cooling rate is unfavorable one. Thus, at cooling start temperature $T_0 = 0$°C and cooling rate $\kappa = 1.0$°C/h critical temperature is equal to –17°C.

5 CONCLUSIONS

The results of hot mix asphalt pavement low temperature stability evaluation obtained in this work allow making conclusions as follows:

1. Method, which uses integral equation of linear viscoelasticity theory and hot mix asphalt tensile strength, allows considering the hot mix asphalt properties, including bitumen properties, as well as conditions of cooling while evaluation of hot mix asphalt pavement low temperature cracking stability. With the help of this method one can determine important values of low temperature cracking stability of pavement—critical time, critical temperature and critical stress.
2. In those cases when cooling starts from similar initial temperature, equal to –10°C, without dependence on rate and duration of cooling, the first low temperature cracks on pavement can occur at the temperature range of –23 to –24°C.
3. Cooling start temperature influences greatly on temperature cracking stability of pavement. Its increase causes the increase of critical time and critical stress, as well as the increase of critical temperature.
4. From the point of view for provision of low temperature cracking stability of pavement combination of high cooling start temperature and high cooling rate is unfavorable one. Calculations show that in case of cooling from the temperature of 0°C and at cooling rate of 1.0°C/h the first low temperature cracks on pavement can occur at the temperature of –17°C.

Development of field-calibrated master curves for in-place modulus

Mary Robbins
National Center for Asphalt Technology at Auburn University, Auburn, AL, USA

David Timm
Auburn University, Auburn, AL, USA

ABSTRACT: This study developed a method for estimating in-place modulus of Asphalt Concrete (AC) by developing a master curve calibrated to strains measured at the National Center for Asphalt Technology Pavement Test Track. This innovative approach utilizes parameters that can be measured directly in the field, eliminating the need for a time-frequency conversion, a topic that has been heavily debated. Unlike dynamic modulus master curves that are reliant on testing frequencies and temperatures, the field-calibrated master curves developed in this study were constructed with vehicle speed and mid-depth pavement temperature, thereby more accurately representing field conditions of in-place AC modulus. Field-calibrated master curves were constructed for fourteen sections from the 2006 and 2009 research cycles utilizing strain measurements under heavy trucks. Although these trucks operate at a target speed of 45 mph (72.4 km/h), 95% of the speeds measured ranged from 42 to 52 mph (67.6–83.7 km/h). These master curves were found to accurately predict in-place modulus with coefficients of determination, R^2, ranging from 0.82 to 0.98. When applied to strains under much slower speeds (14–33 mph (22.5–53.1 km/h)), the field-calibrated master curve resulted in an R^2 of 0.97, indicating that this procedure is applicable at a wider range of vehicle speeds.

1 INTRODUCTION

Pavement design has progressed over the years into the more robust and adaptable Mechanistic-Empirical (M-E) design framework. Central to M-E design is dynamic modulus (|E*|) of Asphalt Concrete (AC) which enables the prediction of critical stresses and strains within the pavement that are used to predict specific distresses. |E*| captures the viscoelastic nature of AC through its dependency on both temperature and frequency (time) and is meant to characterize how a particular mixture is likely to respond to a moving load under varying pavement temperatures and vehicle speeds in the field. |E*| can be determined in the laboratory through the application of sinusoidal compressive stress pulses applied at varying frequencies and temperatures. Although |E*| is measured at a wide range of frequencies and temperatures, it is difficult to capture the entire range of pavement temperatures a pavement may experience in-service, therefore master curves are constructed to enable the prediction of |E*| at any frequency (speed) and temperature.

As states look to adopt recently developed M-E design frameworks such as the Mechanistic-Empirical Pavement Design Guide (MEPDG) and the associated AASHTOWare® Pavement ME Design software, it is important to understand how the prediction of critical distresses compares to field performance. Because tensile strain is dictated by |E*|, it is necessary to investigate how |E*| relates to field conditions. To translate |E*| to field conditions

requires loading, frequency, and temperature to be accurately defined in the field. With this several challenges arise; frequency is difficult to measure in the field and furthermore, the testing parameters (loading and induced strain) in the laboratory differ from field conditions. Loading frequency is challenging, if not impossible, to measure in the field. However, loading frequency is necessary to capture the viscoelastic effect of truck speed on AC modulus. As a result, researchers have relied on time-frequency relationships to provide frequency since loading time can be measured from stress or strain pulses under traffic loading. Although time can be measured from either strain gauge responses or pressure plates embedded in the pavement, there has been disagreement on the definition of loading time.

|E*| testing in the laboratory includes the application of the compressive load pulses in a continuous fashion for each frequency tested, however, load pulses are not continuous in the field due to axle configurations and vehicle spacing. Furthermore, |E*| testing is completed at a range of frequencies; however, in the field, load is applied at a range of vehicle speeds. To translate laboratory conditions to field conditions would require the time of loading be determined in the field and converted to loading frequency. The proposed time-frequency relationship utilized in the MEPDG is simply $t = 1/f$, where f is loading frequency and t is loading time [1]. Some researchers propose that the correct conversion is $1/(2\pi f)$ based on the field of rheology [2–4], while others suggest alternative relationships [5–8].

An alternative to |E*| testing to characterize the AC modulus is to backcalculate moduli from deflections measured with a Falling Weight Deflectometer (FWD). Although FWD testing is a relatively quick way to assess the in-situ material properties and condition of the pavement layers, it is similar to |E*| testing in that FWD testing does not accurately represent traffic loading. Rather than applying a dynamic load similar to a truck traveling at highway speeds, FWD testing is completed with an impact load. Research at the National Center for Asphalt Technology (NCAT) Test Track has shown that the impact load applied during FWD testing is more representative of a truck traveling at 120 mph (193.1 km/h) [9].

In a recent study [10], a master curve was constructed for in-situ AC modulus considering vehicle speed and temperature. This study utilized backcalculated moduli from FWD to adjust dynamic modulus for damage. Although vehicle speed was considered, it was done by developing loading frequency-vehicle speed relationships which incorporated the $t = 1/f$ relationship to convert measured load durations into frequency at various vehicle speeds [10]. A previous study at the NCAT Test Track found that when this time-frequency conversion was used, an underprediction of strain relative to field measured strain resulted [11]. Therefore, there is a need to develop a method that predicts AC modulus directly from field conditions to more closely match strains measured in the field.

2 OBJECTIVES AND SCOPE

The primary objective of this study was to develop a method to construct master curves for in-place composite AC modulus calibrated to field measured strain, using vehicle speed and pavement temperatures.

To meet this objective, strain measurements were made under heavy loading in fourteen instrumented test sections at the National Center for Asphalt Technology (NCAT) Test Track. Mid-depth pavement temperature and actual vehicle speed was recorded at the time of each strain measurement. Additionally, in-place volumetrics were determined based on as-built properties at the time of construction. A Layered Elastic Analysis (LEA) program, WESLEA, was utilized to determine the in-place composite AC modulus that corresponded to tensile strain measurements in each test section.

3 METHODOLOGY

To develop master curves for in-place AC modulus, AC moduli were determined based on measured tensile strain. Tensile strain was measured at the bottom of the AC in fourteen

instrumented pavements. Using field measured strain, the modulus of the entire AC layer (as a composite of the individual AC layers) was determined based on a layered elastic analysis unique to each section using WESLEA. Since it has been well-established that strain is influenced by vehicle speed and pavement temperature, the AC modulus required to achieve that strain should reflect the field conditions at which the strain was measured. To do so, an AC modulus master curve calibrated to field conditions and field-measured strain was created for each test section. This was done by applying a sigmoidal fit function, consistent with the form described in AASHTO PP 61-09 for creating dynamic modulus master curves using vehicle speed (mph) rather than testing frequency (Hz) and mid-depth pavement temperature, to the moduli required to achieve the strain measured in the field.

3.1 *Test sections*

A total of fourteen instrumented test sections from the 2006 and 2009 test cycles at the NCAT Test Track were used to complete this study. The NCAT Test Track is a 1.7 mile (2.7 km) oval track located in Opelika, Alabama. Live traffic is applied at a target vehicle speed of 45 mph (72.4 km/h). Heavy trucks are manually operated for 16-hours a day, 5 days a week, totalling approximately 10 million Equivalent Single Axle Loads (ESALs) in the 2-year traffic period. Each of the five trucks used in daily operations have approximately a 12-kip (53.4 kN) steer axle, 40-kip (178 kN) tandem axle, and 5 trailing 20-kip (89.0 kN) single axles.

Four of the fourteen sections were constructed in the 2006 test cycle and included N1, N2, N8 and N9. Sections N1 and N2 were designed to mirror one another with identical aggregate skeletons in the AC layers and both were constructed with approximately 7 inches (178 mm) of AC atop the same limerock aggregate base typically used by Florida Department of Transportation (FDOT) placed at approximately 10 inches (254 mm). These sections differed by the Performance Grade (PG) of the asphalt binder (PG 67-22 and PG 76-22) used in the top two AC lifts. Sections N8 and N9 also complemented one another as both used the compacted Track soil as base material atop a compacted soft subgrade material all over top the uncompacted Track soil. The soft subgrade material was imported from Seale, Alabama and closely replicates subgrade materials typically encountered by the Oklahoma DOT. Both sections were composed of the same four AC mixtures including a Stone Matrix Asphalt (SMA) surface lift and rich bottom layer, with the difference being the AC thickness. Section N9 was designed at 14 inches (357 mm) of AC, whereas section N8 was designed at 10 inches (254 mm) of AC.

For this investigation nine of the ten newly constructed sections in the 2009 test cycle were evaluated in addition to the N9 section left in place from the 2006 test cycle. The compacted subgrade used in all nine newly constructed sections has been well-documented as an AASHTO A-4(0) metamorphic quartzite soil found on-site [12]. The aggregate base was also consistent among the nine newly constructed sections in the 2009 cycle and was a crushed granite material often used by the Alabama DOT [12]. Two sections sponsored by Shell Oil Products, USA [13], N5 and N6, were constructed of sulfur-modified Warm-Mix Asphalt (WMA) in the binder and base courses and were designed at 9 and 7 inches (229 and 178 mm) of AC, respectively. Section N7, sponsored by Kraton Performance Polymers, Inc. [14], was the thinnest section at 5.75 inches (146 mm) and constructed entirely with high polymer (7.5% Styrene Butadiene Styrene (SBS)) modified asphalt. Two sections, N10 and N11, were part of a larger group experiment [15] and included 50% Reclaimed Asphalt Pavement (RAP) in each lift and were designed at 7 inches (178 mm) thick. Section N11 was produced as a WMA using the foaming technique, while section N10 was produced at typical production temperatures for hot-mix asphalt. Section S9 was the control section of the group experiment, designed at 7 inches (178 mm) thick and containing typical Superpave AC mixtures. Sections S10 and S11 in the group experiment were 7-inch (178 mm) sections and both were constructed with warm-mix technologies. AC mixtures in section S10 were produced with foaming technology and the AC mixtures in S11 contained additives to reduce the viscosity during production. The last section, S12, was designed at 7 inches (178 mm) and utilized pellets of naturally occurring asphalt produced by Trinidad Lake Asphalt (TLA) to replace 25% of the virgin binder (PG 67-28) in all lifts throughout the AC cross-section.

3.2 *Instrumentation*

Each section was instrumented with a strain gauge array at the bottom of the AC, earth pressure cells at the top of the granular base and subgrade as well as embedded temperature probes. The strain gauge array consisted of six longitudinal (measuring strain in the direction of traffic) and six transverse (measuring strain perpendicular to traffic) strain gauges. The gauges were installed in groups of three with the center gauge along the outside wheelpath with the remaining gauges offset two-foot on-center, to the right and left, to account for wheel wander. Temperature probes were embedded in the shoulder of each section to capture pavement temperature at the surface, mid-depth and bottom of the AC in addition to 3-inches (76 mm) into the granular base. Mid-depth pavement temperatures associated with measured tensile strains in this study varied from mid-30s (1.6°C) to upwards of 120°F (48.9°C). Detailed information regarding the embedded instrumentation has been documented elsewhere [16].

Data were collected on a weekly basis, including strain measurements under 3 passes of each truck to capture the best-hit and in-situ pavement temperatures at the time of collection. Consistent with previous studies at the track [17], it was found that strain in the longitudinal direction was larger than in the transverse direction, therefore this study considered only longitudinal tensile strain at the bottom of the AC under single axle loads. The best-hit approach consisted of obtaining data from each of the working longitudinal strain gauges on a given date and selecting the maximum peak strain measured from all the passes of a given axle type.

Traffic at the Test Track operates at a target vehicle speed of 45 mph (72.4 km/h), however due to the manual operation of these heavy triple-trailer trucks, the speed is somewhat variable. Actual vehicle speed was calculated using raw strain traces and known distances between instrumentation, as previously documented [18]. This was necessary to associate actual speed with measured strain values. Tensile strains were measured under vehicle speeds ranging between 33 and 63 mph (53.1 and 101.4 km/h), although more than 95% of the strains measured were at vehicle speeds between 42 and 52 mph (67.6 and 83.7 km/h).

3.3 *In-place AC modulus*

To construct a master curve for in-place AC modulus, the in-place modulus was first determined through modulus-strain relationships. Modulus-strain relationships for each of the fourteen sections included in this study were developed using an LEA program, WESLEA version 3.0, as previously documented [18]. By using the field-measured strain with the modulus-strain relationship, the in-place modulus required to achieve that strain was determined. The number of iterations that were required to model all of the different AC lifts in each cross-section was unmanageable and the LEA program utilized for this analysis was limited to a maximum of 3 AC layers. Therefore, the AC was considered as one layer, as documented elsewhere [18], and relationships were developed for a composite AC modulus. Using section-specific surveyed thicknesses measured during construction and average backcalculated moduli for the aggregate base and subgrade layers (also section-specific); each section was simulated under a single axle load, representative of the Test Track traffic. By varying the AC modulus over a wide range of values while holding the aggregate base and subgrade moduli constant at their respective backcalculated values, maximum horizontal tensile strain at the bottom of the AC was predicted. By varying the AC moduli, a wide range of vehicle speeds and mid-depth pavement temperatures were accounted for inherently. The ranges of AC moduli were selected to achieve predicted tensile strains that were within the range of the maximum and minimum peak strain measured in the field for each section. This enabled the development of modulus-strain relationships in which tensile strain measured in the field at the bottom of the AC could be applied to determine the in-place (composite) AC modulus required to achieve that strain value. By using this method, the master curves developed were calibrated to field-measured strain under varying speeds and pavement temperatures, and thus circumvented the short-falls associated with FWD testing and backcalculated AC moduli, as were discussed previously.

In following layered elastic theory, the strain used to determine the in-place AC modulus must be elastic. Therefore, several steps were taken to ensure that the strains used in this investigation were elastic in nature and were measured in an un-damaged pavement. These steps, although documented elsewhere [18], included the evaluation of strain as a function of time, and temperature; assessing the difference between 95th percentile strain and maximum strain; and assessing the root mean squared error associated with backcalculated AC moduli.

3.4 *Master curve construction*

Because AC is a linear viscoelastic material that is time and temperature dependent, the time-temperature superposition principle can be applied. The time-temperature superposition principle allows for data to be shifted using a reference temperature. |E*| master curves are developed by first measuring |E*| in the laboratory at a range of frequencies and temperatures, following either the AASHTO TP 79-09 (specific for the Asphalt Mixture Performance Tester (AMPT)) or the AASHTO TP 62-07 specification. According to AASHTO PP 61-09 the dynamic modulus master curve is a sigmoidal fit function of the form shown in Equation (1). It should be noted that this provisional procedure is intended for use with the AMPT and |E*| measurements made in accordance with AASHTO TP 79-09. This procedure utilizes a modified Hirsch equation to determine the limiting maximum modulus by fixing the dynamic shear modulus of the binder at 145,000 psi (1 GPa), thus transforming the "$3|G^*|_{binder}$" term into 435,000 psi (3 GPa) as shown in Equation (2). It should also be noted that Equation (2) is presented differently in AASHTO PP 61-09, such that the parameter P_c is shown to be applied to the entire equation. The authors used the form of the equation shown in Equation (2) by verifying the original form of the Hirsch model presented in [19] and confirming this is the form of the equation used in the MasterSolver Excel spreadsheet developed by Bonaquist under the NCHRP 09-29 project [20]. To shift the data to one reference temperature, the Arrehenius shift factor is used according to AASHTO PP 61-09 and is shown in Equation (3), below. Essentially, the frequency corresponding to the |E*| measurement is transformed to reflect the frequency required to achieve the same |E*| value at said reference temperature. This is completed by applying the shift factor determined in Equation (3) to the test frequency, as described by Equation (4).

$$\log(|E^*|) = \delta + \frac{(Max - \delta)}{1 + e^{\beta + \gamma(\log \omega_r)}} \tag{1}$$

where:
$|E_*|$ = dynamic modulus, ksi
δ = fitting parameter, represents logarithm of limiting minimum modulus
β, γ = fitting parameters
ω_r = reduced frequency, Hz
Max = logarithm of limiting maximum modulus (ksi), see Eq. (2)

$$|E^*|_{\max} = \frac{1}{1000}\left[P_c\left[4{,}200{,}000\left(1 - \frac{VMA}{100}\right) + 435{,}000\left(\frac{VMA \times VFA}{10{,}000}\right)\right] + \frac{1 - P_c}{\left[\frac{\left(1 - \frac{VMA}{100}\right)}{4{,}200{,}000} + \frac{VMA}{435{,}000(VFA)}\right]}\right] \tag{2}$$

where:
$|E^*|_{max}$ = limiting maximum modulus, ksi

$$P_c = \frac{\left(20 + \frac{435{,}000(VMA)}{VFA}\right)^{0.58}}{650 + \left(\frac{435{,}000(VMA)}{VFA}\right)^{0.58}}$$

VMA = Voids in mineral aggregate (%)
VFA = Voids filled with asphalt (%)

$$\log a(T) = \frac{\Delta E_a}{19.17142}\left(\frac{1}{T} - \frac{1}{T_r}\right) \tag{3}$$

where:
$a(T)$ = shift factor
ΔE_a = activation energy, treated as a fitting parameter
T = temperature, °K
T_r = reference temperature, °K

$$\log(\omega_r) = \log(\omega) + \log[a(T)] \tag{4}$$

where:
ω_r = reduced frequency (Hz)
ω = test frequency (Hz)

In developing a master curve for in-place composite AC modulus, it was elected to use the same form of the sigmoidal fit function used for dynamic modulus, shown in Equation (1). Due to the previously noted issues surrounding load duration in the field and conversion to frequency, rather than using loading rate (frequency in Hz) and temperatures as applied in dynamic modulus testing, it was elected to utilize loading rates and temperatures associated with the measured tensile strains (from which composite modulus was determined). Therefore, the actual vehicle speed and pavement temperatures relative to the tensile strain measured at the bottom of the AC were used for the construction of in-place composite AC modulus master curve. Based on previous studies at the Test Track [17] which found strong correlations between strain and temperatures at the mid-depth of the AC, mid-depth pavement temperatures measured from the embedded temperature probes at the time of strain measurements were utilized for use in the field-calibrated master curves.

The form of the master curve equation used for in-place composite AC modulus is shown in Equation (5). The same Arrehenius shift factor (Equation (3)) was used but was applied to the actual vehicle speed associated with the in-place composite AC modulus (field-measured strain) as described by Equation (6) and for a reference temperature of 22°C. As applied here, the activation energy represents the activation energy of the composite AC layer. Consistent with the |E*| master curve construction, ΔE_a, β_{comp}, γ_{comp}, and $log\ E_{comp,min}$ (shown in Equation (1) as δ) were treated as fitting parameters and determined for each of the field-calibrated master curves. The values of these regression terms were determined using non-linear optimization as is done in the MasterSolver spreadsheet and recommended in AASHTO PP 61-09 for |E*| master curve construction. The initial estimates utilized in the MasterSolver spreadsheet developed by Bonaquist [20] for the fitting parameters, δ, β, γ, and ΔE_a were also utilized for the initial estimates for field calibrated master curve as well and were as follows: 0.5, –1, –0.5, 200,000, respectively. The Generalized Reduced Gradient (GRG) non-linear method was used in Excel solver to complete the non-linear optimization with the solver options identical to those used in MasterSolver as it also relies on Excel Solver. During the non-linear optimization, rather than continuing to alter the fitting parameters to converge on a solution for each, the first set of solutions was utilized. This is consistent with MasterSolver and if allowed to continue through several iterations the predictions worsen, in some cases resulting in a negative coefficient of determination. The goal of the non-linear optimization was to minimize the Sum of the Squared Errors (SSE). For each field-calibrated master curve,

the coefficient of determination (Equation (7)) as well as the ratio of standard error of the predictions (S_e) (Equation (8)) to standard deviation of measured values (S_y) was computed in arithmetic scale for evaluating the goodness of fit. Equations 7 and 8 are consistent with fit statistics used by Dongré et al. in a 2005 evaluation of the Witczak and Hirsch predictive models for dynamic modulus [21].

The parameters utilized in developing the field-calibrated master curve for in-place composite AC modulus must also represent a composite AC layer. Therefore in determining the limiting maximum composite modulus for the field-calibrated master curve, the AASHTO PP 61 procedure for limiting maximum dynamic modulus shown in Equation (2) was used; however, the VMA and VFA used to calculate the limiting maximum composite modulus represent the VMA and VFA of the in-place composite AC layer rather than VMA and VFA for one AC mixture. In-place VMA and VFA values for each AC lift were computed for each section based on as-built properties recorded at the time of construction. These values were then combined using the same method used for determining blended G_{sb}, this procedure is documented elsewhere [18].

$$\log(E_{comp}) = \log E_{comp,min} + \frac{\log E_{comp,max} - \log E_{comp,min}}{1 + e^{\beta comp + \gamma comp(\log v_r)}} \tag{5}$$

where:
E_{comp} = composite modulus, ksi
$\log(E_{comp,min})$ = fitting parameter
β_{comp}, γ_{comp} = fitting parameters
$E_{comp,max}$ = limiting maximum composite modulus, ksi

$$\log(v_r) = \log(v) + \log[a(T)] \tag{6}$$

where:
v_r = reduced vehicle speed (mph)
v = vehicle speed (mph)

$$R^2 = 1 - \frac{(n-k)}{(n-1)}\left(\frac{S_e}{S_y}\right)^2 \tag{7}$$

where:
n = number of observations
k = number of fitting parameters (4)
S_y = standard deviation of the measured values

$$S_e = \sqrt{\frac{SSE}{n-k}} \tag{8}$$

where:
S_e = standard error of the prediction
SSE = sum of squared errors = $\sum_i^n (E_{mi} - E_{pi})^2$
E_{mi} = ith Measured E_{comp}, ksi
E_{pi} = ith Predicted E_{comp}, ksi

4 RESULTS AND DISCUSSION

Field calibrated master curves were developed for each of the fourteen sections included in this investigation. An example of a field-calibrated master curve is shown in Figure 1 for section N5, a 9-inch (229-mm) sulfur-modified WMA section. Table 1 summarizes the fitting

parameters and fit statistics (in arithmetic scale) for each curve. It should be noted that the values in Table 1 are based on U.S. customary units. Sections N8 and N9 from the 2006 test cycle have negative values for the log $E_{comp,max}$ term, indicating that the limiting minimum modulus for each of these sections is greater than zero and less than 1 ksi. Overall, the master curves fit the data very well. Only three of the fourteen sections had R^2 values less than 0.9. However, as shown in Table 1, the field-calibrated master curves for each of these three sections, N1 (Florida, 2006), N9 from 2009 (Oklahoma) and N10 (High RAP), maintained acceptable coefficients of determination, with the lowest accounting for more than 82% of the variability in the data. These same sections are the only sections to have S_e/S_y ratios less than 0.35, a common threshold for defining excellent fit.

A speed study completed for section S9 was used to validate the application of the field-calibrated master curves to speeds beyond the narrow range at which they were developed. The speed study was conducted on four different test dates throughout the course of the 2009 test cycle to capture tensile strains at a variety of mid-depth pavement temperatures and vehicle speeds. On each test date four speeds were tested: 15, 25, 35 and 45 mph (24.1, 40.2, 56.3 and 72.4 km/h). For this evaluation, however, only the first three target speeds were used, as the strains at 45 mph (72.4 km/h) were already incorporated into this study. Actual vehicle speeds ranged from 14 to 33 mph (22.5 to 53.1 km/h) and mid-depth pavement temperatures

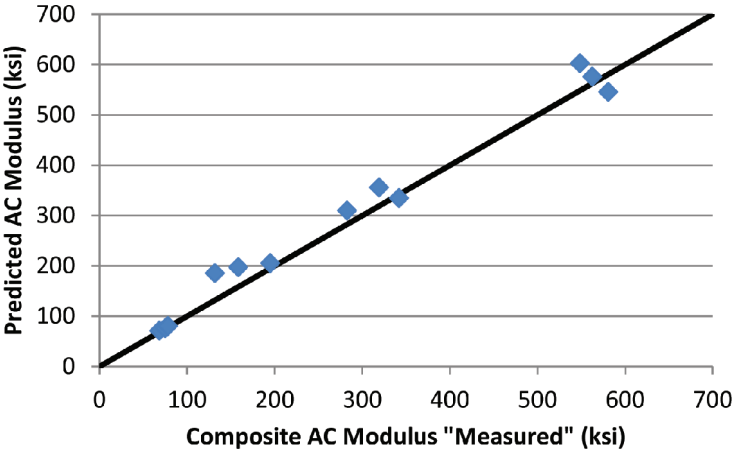

Figure 2. "Measured" vs. predict AC modulus for S9 Speed Study.

ranged from 48 to 113°F (8.9 to 45°C). The in-place AC moduli were predicted for S9 by applying the field-calibrated master curve for S9, with fitting parameters shown in Table 1, to the field conditions (vehicle speed and mid-depth pavement temperatures) at the time of the strain measurements. The tensile strains measured under varying speeds and temperatures were applied to the S9 modulus-strain relationship to determine "Measured" in-place composite AC moduli. Figure 2 plots the "Measured" in-place composite AC moduli against the AC moduli predicted by the field-calibrated master curve. Evident from this plot, as the data are approximately centered along the line of equality, the field-calibrated master curve is a very good predictor of in-place composite AC modulus at a range of vehicle speeds and pavement temperatures. This is reaffirmed by a very high coefficient of determination of 97%.

5 CONCLUSIONS AND RECOMMENDATIONS

This study aimed to develop a method for constructing master curves for in-place AC modulus using known field conditions such as vehicle speed and pavement temperature calibrated to field measured strain. Based on this study, the following conclusions can be drawn:

- Overall, the developed master curves fit the data very well, allowing for the estimate of in-place AC composite modulus specific to a test section, at a given mid-depth pavement temperature and vehicle speed. Therefore, it can be concluded that a master curve can be accurately calibrated to field measured strains to predict in-place AC modulus of the composite AC layer using known vehicle speed and mid-depth pavement temperature.
- This simple and straightforward method enables direct computation of modulus for undamaged pavement sections exhibiting elastic responses without relying on time-frequency conversions.
- Although master curves were constructed using a narrow range of vehicle speeds (42–52 mph (67.6–83.7 km/h)), based on the validation of the S9 speed study data, the master curves are applicable to speeds slower than 45 mph (72.4 km/h), down to 15 mph (24.1 km/h).
- Given the strong fit statistics reported for the field-calibrated master curves and the inability of FWD testing to capture the effect of real traffic speeds, this method for predicting in-place AC modulus has the capability of being an alternative to backcalculation of AC moduli through FWD testing for instrumented pavements.
- It is recommended that the field-calibrated master curves developed in this study be related to other known as-built properties of the pavement cross-section to create a model to predict in-place composite modulus for any cross-section, vehicle speed and mid-depth pavement temperature.

The development of pavement rehabilitation design guidelines for increasing the allowable axle load from 100 kN to 115 kN

Laszlo Petho
ARRB Group Ltd., Sustainable Infrastructure Management, Albion, QLD, Australia

Csaba Toth
Department of Highway and Railway Engineering, Budapest University of Technology and Economics, Budapest, Hungary

ABSTRACT: The road network in Hungary had to be improved and reconstructed due to the mutual EU agreement to increase the then allowable 100 kN axle load to 115 kN. This requirement was a challenge on an aged road network, where the pavement layers were designed and built to a lesser frequency and amplitude of vehicle loading.

The Instrument for Structural Policies for Pre-Accession (ISPA) was launched to assist the candidate countries with this issue. This paper provides a summary of the development of a series of guidelines for road pavement rehabilitation design in Hungary. The complex problem of the pavement structural design in a semi-empirical system is discussed; the EU does not provide harmonised standards for pavement design purposes. Also, the paper outlines how to incorporate existing asphalt layers prone to plastic deformation into the rehabilitated pavement structure, while maintaining a low risk of future distresses.

The guidelines were developed on a series of case studies of an overall length of 300 km. FWD tests and wheel tracking tests combined with visual inspections provided the basis for the work. Using this approach it was possible to develop a series of guidelines for cost-effective pavement rehabilitation design.

Keywords: pavement rehabilitation; semi-empirical; plastic deformation; design guidelines; cost-effective

1 INTRODUCTION

Due to the mutual agreement between the European Union (EU) and Hungary, (which joined the EU in May 2004), a significant section of the trunk road network had to be improved and reconstructed to a higher standard, which allowed increasing the then permitted 100 kN axle load to 115 kN. The Hungarian road network is 31 628 km in total (excluding local roads maintained by local Councils), of which 8297 km forms the trunk network [1]. The agreement for improvement applied to 7400 km in total. This requirement was a challenge on an aged road network, where the pavement layers were designed and built, mainly in the 80 s and 90 s, to a lesser frequency and amplitude of vehicle loading.

The Instrument for Structural Policies for Pre-Accession (ISPA) was launched by the EU to assist the candidate countries with this issue. This paper provides a summary of the development of a series of guidelines for road pavement rehabilitation design in Hungary as part of the ISPA II main framework. The ISPA program included a systematic road infrastructure upgrade, which involved road pavement rehabilitation and widening, upgrade of intersections, traffic calming measures, parallel bikeways and bridge rehabilitation or reconstruction works.

In order to address this issue, the Directorate for the Coordination of Road Transport Affairs–EU project division (the Client) commissioned the University of Technology,

Budapest, and the two largest commercial road material testing institutes, IMI and Bau-Teszt to develop specific Guidelines for the road rehabilitation program based on 115 kN axle loads. The ISPA II project included five sections of the trunk network, namely Main Roads no. 2 (38.8 km), no. 6 (121.9 km), no. 42 (55.1 km), no. 47 (29.3 km) and no 56 (54.6 km), a total length of 299.7 km. These road sections form part of the trans-European transport network (TEN-T) and the Transport Infrastructure Needs Assessment (TINA) network [2]. The Guidelines worked out for ISPA II was a pilot project and later formed the technical basis for tenders and technical investigations on the project level and other road rehabilitation projects under the 115 kN strengthening projects [3].

According to the scope of the preparation of the Guidelines the focus was on pavement rehabilitation and widening. It was necessary to include the following tasks:

- review of relevant function parameters
- review of the pavement design methodology, and harmonisation with the then current technical specifications
- development of a methodology for reconstruction, including, but not limited to the following main objectives:
  - incorporating existing asphalt layers prone to plastic deformation into the rehabilitated pavement structure, while maintaining a low risk of future distresses
  - minimising the amount of Recycled Asphalt Pavement (RAP) and developing options for re-use
  - developing a methodology for design of widening; focussed on avoiding longitudinal cracks and subsidence of the newly widened widening strip
  - as road sections within urban areas are often built with kerb and channel, this results in a major restriction on overlay treatments. The feasibility of the overlays and possible other options to address the structural capacity requirements had to be analysed.

The following documents and data were supplied by the Client:

- concept design documents, outlining alignment design and upgrade requirements
- existing pavement configurations from the road network database (OKA in Hungarian)
- traffic count data for each sub-section
- rut depth measured by the Road Surface Tester (RST)
- road surface condition, determined according to Roadmaster, a uniform methodology applied by Main Roads Hungary
- deflection results, measured by the KUAB Falling Weight Deflectometer (FWD)
- thickness of layers and wheel-tracking test results for each layer based on cores taken from the pavement at 1000 m frequency; in order to maintain cost-effectiveness, where the rut depth did not exceed 15 mm, sampling was not performed
- local treatments and rehabilitations of short sections, not yet transferred to the road network database.

2 ASPHALT OVERLAY DESIGN

2.1 *Pavement rehabilitation concept*

Hungary, as a member of the EU and the Comité Européen de Normalisation (CEN)—European Committee for Standardization—implement the EN standards on the national level. However, these standards apply for products and test methods, and the EU and CEN do not provide harmonised standards for pavement design purposes. The Hungarian approach in pavement structural design is semi-empirical (mechanistic-empirical) and the complex task, combined with technological considerations, had to be treated in the Guidelines.

In general, a pavement rehabilitation design seems to be a straightforward process today. The basic question is how to allocate the technically possible minimum and maximum asphalt overlay thickness in a particular situation (Fig. 1A); the minimum should be sufficient to be able to increase the bearing capacity of the existing pavement (say a minimum of 50 mm), but also should have a realistic maximum limit (which is around 200–250 mm).

The process is basically influenced by two major parameters, e.g. the number of traffic loading and the performance of the existing pavement. Low traffic volume combined with relatively good pavement condition would require a minimum overlay thickness, while heavy traffic combined with poor road condition requires significant overlay (Fig. 1B). This simplified approach is behind every pavement overlay design: empirical, semi–empirical or mechanistic; however, in order to avoid subjective decisions among the pavement engineers, the asset owner usually requires one of the above methods to provide consistency on the road network.

The refinement of the input parameters is vital. This is the driver of introducing innovative materials and technologies, and provides effective pavement configurations in the longer term. However, the effectiveness cannot be considered only from the structural capacity point of view, there are many other aspects, such as the increased axle loads and tyre contact pressure and consequently the plastic deformation of existing layers. Therefore, in the broader context it is necessary to analyse the cost-effectiveness by using a Pavement Management System (PMS). However, the thinking should not stop at the PMS level, it could be made even more complex considering the areas of energy balance, emissions and the impact on the natural and built environment (Fig. 1B).

The scope of the work outlined in this paper did not make it possible to consider the whole system and the boundaries of the work were identified at the advanced pavement rehabilitation design level (Fig. 1B).

2.2 *Asphalt overlay based on the deflection criteria*

A two layered system, transformed into an equivalent infinite layer was used for the overlay design [4–5]. The semi-empirical asphalt overlay design was developed on the basis of

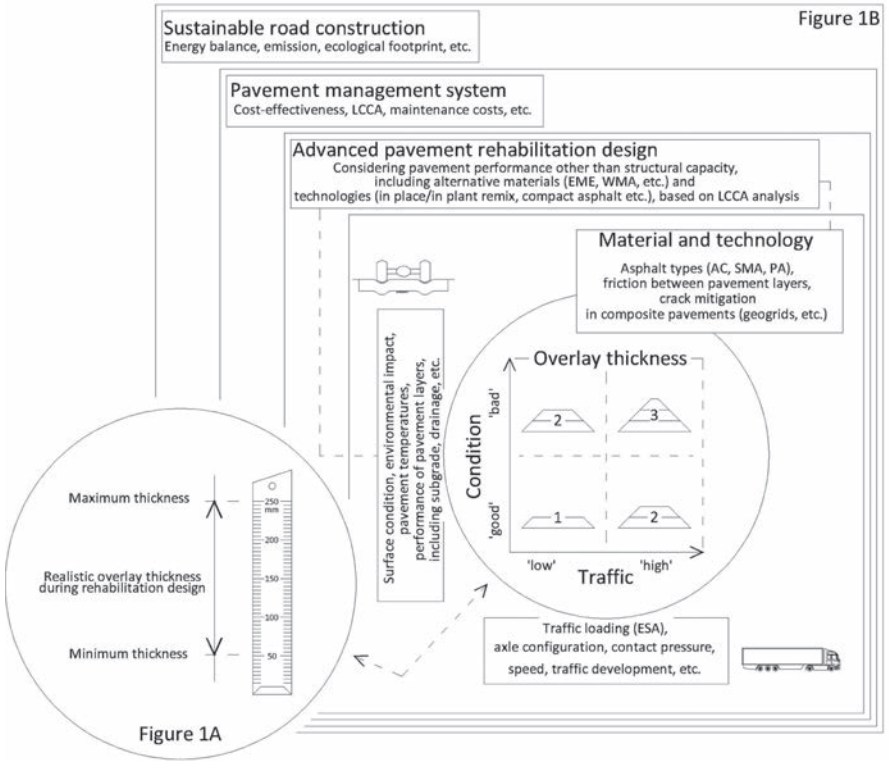

Figure 1. a) and b) Complex engineering assessment of the pavement design.

measured deflection of the existing pavement structure [5]. The overlay design was based on the deflection criteria; however the deflections in the pavement structure were calculated using the General Mechanistic Pavement (GMP) design approach. This method gives a unique tool in the overlay design. It has its constraints, but basically provides a rational tool for pavement engineers.

The characteristic value of the measured deflection ($s_{measured}$) should be compared to the allowable (tolerable) deflection ($s_{tolerable}$); the deflection of the overlaid pavement should not exceed the allowable deflection, which value depends on the traffic loading, expressed in Equivalent Standard Axle (ESA) repetitions. The performance of the existing pavement layers did not provide design input, and the layer properties were not back-calculated for further application; the pavement structures were be described by the characteristic deflection. The characteristic deflection was calculated from the D0 value derived from the FWD measurement, tested at 100 metres frequency per traffic lanes. The method provided a solution solely for the asphalt overlay design; unbound granular or concrete overlay was out of the scope for this method.

The design method can be summarised as follows: the representative deflection (*SM*) for a homogeneous section was determined by means of appropriate non-destructive testing [5]. The tolerable deflection (*SE*) was determined based on semi-empirical equations. Based on the two deflection values the required asphalt layer thickness (*HF*) was calculated as specified in Eq. (1).

$$SM \leq SE \tag{1}$$

The load in the pavement model was $F = 100$ kN axle load, which was distributed on single tyres. The assumption was that the load on each tyre was distributed on a circular area, and the contact pressure between the tyre and pavement had a value of $P = 0.65$ MN/m^2. The deflection of the two layered system (existing pavement structure and overlaying asphalt) was calculated according to Eq. (2), where *S* is the overall rebound deflection of the pavement structure after overlay (in mm), *SA* is the calculated deflection of the existing pavement (in mm) and *SF* is the calculated deflection of the overlaying asphalt (in mm).

$$S = SA + SF \tag{2}$$

The calculated deflection of the upper layer (*SF*) was computed using Eq. (3) [5], where *R* is the radius of the loading area (in mm), *P* is the contact stress between pavement and tyre (in MN/m^2), *EF* is the overlaying asphalt mix stiffness (in MPa), *MF* is the Poisson value of the overlaying asphalt and *ZF* is the corrected thickness of the upper layer, calculated according to Eq. (4) [5]. In the calculation of *ZF* in Eq. (4), *V* is the correction factor and *HF* is the thickness of the overlaying asphalt (in mm); *HF* is calculated in an iterative process. The calculations were performed using $EF = 7000$ MPa, $MF = 0.35$ and $V = 0.9$.

$$SF = \frac{P * R}{EF} * \left[\begin{array}{l} 2*(1-MF^2) - 2*(1-MF^2)*\left(1+\left(\frac{ZF}{R}\right)^2\right)^{\frac{1}{2}} \\ \quad + \dfrac{(1+MF)*\left(\frac{ZF}{R}\right)^2}{\left[1+\left(\frac{ZF}{R}\right)^2\right]^{\frac{1}{2}}} - \left(MF + 2MF^2 - 1*\left(\frac{ZF}{R}\right)\right) \end{array} \right] \tag{3}$$

$$ZF = V * HF \tag{4}$$

The calculated deflection of the lower layer (*SA*) was computed using Eq. (5) [5], where *EL* is the equivalent modulus of the existing pavement structure, calculated from the measured

deflection according to Eq. (6) [5] (in MN/m^2), ML is the Poisson value of the existing pavement structure (in this calculation 0.40), ZL is the corrected thickness of the lower layer, calculated according to Eq. (7) [5] (in mm), EL is the equivalent modulus of the existing pavement structure (in MPa) and SM is the representative deflection (in mm).

$$SA = \frac{P*R}{EL} * \left[\begin{array}{l} 2*(1-ML^2)*\left(1+\left(\frac{ZL}{R}\right)^2\right)^{\frac{1}{2}} + \left(ML+2ML^2-1\right)*\left(\frac{ZL}{R}\right) \\ -\left(1+ML\right)*\frac{\left(\frac{ZL}{R}\right)^2}{\left[1+\left(\frac{ZL}{R}\right)^2\right]^{\frac{1}{2}}} \end{array} \right] \tag{5}$$

The equivalent modulus of the existing pavement structure (EL) was calculated according to Eq. (6) and the corrected thickness of the lower layer ZL according to Eq. (7).

$$EL = 2*\left(1-ML^2\right)*\frac{P*R}{SM} \tag{6}$$

$$ZL = V*HF*\left(\frac{EF}{EL}*\frac{1-ML^2}{1-MF^2}\right)^{\frac{1}{3}} \tag{7}$$

The calculation of the overlay thickness (HF) is an iterative process, where the thickness of the overlaying asphalt is increased gradually by 5 mm increments until Eq. (1) is met. For the ISPA II project it was decided to continue using the above mentioned equivalent standard axle load and use a factor of 1.5 to account for the increased strains induced by the increased load magnitude. This decision was made by the executive group prior to commencing the works and it is not an outcome of the project in scope; however, this project fully utilised this methodology and it was considered a reasonable approach.

A key element of the design process was the correct calculation of the tolerable deflection. The original equation was based on the American Association of State Highway and Transportation Officials (AASHO) investigation, and it was used as an overall description of any type of pavement structure. However, in the 1970s Hungarian researcher proved [6] that the designer has to determine the actual pavement structure and accordingly a different equation should be applied during the pavement design as outlined in Eq. (8) [6–7] and in Table 1.

$$SE = a*(F100)^{\frac{-1}{b}} \tag{8}$$

The above calculation is summarised in nomographs [7]; also the authors of this paper developed a spreadsheet for the above procedure. The advantage of using a spreadsheet for such a procedure is that the input parameters of the new asphalt layer can be changed, and asphalt materials with higher performance, such as high modulus asphalt, can be readily implemented, resulting in cost-effective pavement design methods.

Table 1. Tolerable deflection calculation (F_{100} is the design axle load) [7].

Type of existing pavement	Constant a	Constant b
Fully-flexible pavement structure (unbound granular pavement)	25	4.00
Flexible pavement structure (full depth asphalt pavement)	14.5	4.55
Semi-flexible pavement structure (composite pavement)	9.0	5.00

2.3 *Homogeneous sub-sections*

The characteristic deflection (s_m), which is represented by the allowable deflections (*SE*) in the calculations, is expressed according to Eq. (9), where $\bar{b}$ is the mean value of the measured deflections within the homogeneous sub-section; homogenous sub-sections were determined using the cumulative sum method [8], s_b is the standard deviation within the homogeneous sub-section and μ is the factor for the level of risk.

$$s_m = \bar{b} + \mu \cdot s_b \tag{9}$$

The deficiency of this system is that the measured deflection, which relates to the full existing pavement, is a major input into the calculations and the method cannot consider the impact of removal of existing pavement layers by cold planing. If removal of existing layers is necessary, due to low resistance to plastic deformation, the method will result in overdesigned pavement structures, as the higher structural capacity of the back-filled layers will not be taken into consideration. Also, the deflection criteria may be misleading on composite pavements due to the higher structural capacity of the cement treated or concrete subbase layers.

3 ASPHALT TECHNOLOGY RELATED CONSIDERATIONS

3.1 *Risk of plastic deformation*

The increased axle load does not only have an influence on the pavement structural capacity, but also increases the risk of plastic deformation under the extremely high contact pressure generated by super single tyres. Many asphalt layers, built in the 70 s to 80 s consisted of river gravel and/or soft bitumen, and these asphalt layers could not withstand the shear forces of such a high contact pressure.

Realising this issue, the hot mix asphalt specification [9] had already required wheel tracking test for pavement rehabilitation, performed on cores extracted from the existing asphalt layers. Although the specification [9] provided threshold values, the action list of the specification was quite vague. As a result, in reality, layers prone to plastic deformation were always removed to avoid any risks. An outcome of the Guidelines was that it provided risk management for such a situation, returning cost-effective pavement structures, while maintaining a low risk of future distresses in terms of plastic deformation. A series of wheel tracking tests were performed for the above mentioned five road sections at a frequency of 1000 metres, where all asphalt layers were tested. The tests were performed according to EN 12697-22 [10] which was in prEN form at the time of preparation of the work.

In the road pavement the traffic load induces vertical (positive) stress and horizontal (negative) stress and the difference of these stresses results in the deviator stress. The plastic deformation is a result of a positive deviator stress, and the magnitude changes as a function of the depth. This theoretical consideration is in line with experience, i.e. the most vulnerable layers in terms of plastic deformation are the upper 100–120 mm of the pavement. Therefore, if the layer, which is prone to plastic deformation, is covered by suitable, rut resistant asphalt layers of more than 120 mm, the non-conforming layer may remain in the pavement structure without any major risks.

This consideration—supported by the project steering group—was based on experience; such a depth reduces the deviator stress and the temperatures so that plastic deformation cannot develop under traffic load. The temperature distributions in depth and its effect on the material properties are discussed elsewhere [11]. It should be noted that the above considerations are valid in the Central-European climate and other climatic regions may need thicker or thinner asphalt layers to overcome the risk of plastic deformation. If the risk of plastic deformation is eliminated, and the non-conforming layer remains in the pavement, additional benefits can be obtained. Layers, prone to plastic deformation, usually contain soft binders or have high binder content, which positively influences the fatigue properties of the pavement. It should be noted that in this study the term plastic deformation is not

exchangeable with post-compaction of the pavement layers, even though they sometimes show the same symptoms.

3.2 *Overlay design combined with plastic deformation problems*

Based on the above consideration, the following options can be applied, if the existing pavement contains asphalt layer(s) prone to plastic deformation:

a. Non-conforming subbase layer (3rd asphalt layer); if the total thickness of the conforming 2nd and 1st layer in the existing pavement are less than 130 mm, and there is no need for an overlay, the removal of the 3rd layer (including the 2nd and 1st layer) would be extremely costly. In this case, applying an overlay (even if it is not necessary from the structural point of view) may be more cost-effective.
b. Non-conforming intermediate layer (2nd asphalt layer); based on cost-effectiveness and risk acceptance, there are more options to consider:
   - applying a thick overlay, so that the existing intermediate layer will be overlaid by at least 130 mm of new asphalt. Such a solution can only be cost-effective, if there is already a need for structural strengthening and there are no height constraints. If the existing pavement does not require strengthening, this solution may not be cost-effective.
   - removal of the non-conforming 2nd layer (including the 1st layer) and back-filling with conforming asphalt layers.
   - removal of the 1st layer and apply Remix Add technology for the non-conforming 2nd layer—then back-filling the 1st layer.
c. Non-conforming wearing course (1st asphalt layer);
   - cold milling of the 1st layer and back-filling with suitable asphalt mix
   - apply Remix or Remix Plus technology for the 1st layer, if the existing asphalt layer is suitable for such a modification.
   - apply a thick overlay, so that the existing wearing course will be overlaid by at least 130 mm of new asphalt. Such a solution can only be cost-effective, if there is already a need for structural strengthening and there are no height constraints. If the existing pavement does not require strengthening, this solution may not be cost-effective.

It can be seen that the pavement designer has two major options, mill and replace, or significant overlay. In case there is a need for significant structural strengthening, the second option is very cost-effective. If there is a need for moderate strengthening (70 mm), the second option may still be cost-effective. Also, minimising the milling operation would not only result in less RAP, but would also shorten construction time, resulting in less impact on road users and overall costs. If it is more suitable to remove the layer prone to plastic deformation, it is paramount that the entire layer be removed from the pavement structure.

3.3 *Urban areas, height restrictions by kerb and channel*

Significant lengths of the five road sections, designed in the pilot project, were in urban areas, where height restrictions by existing kerb and channel had to be considered. Re-construction of existing kerb and channel alignment does not include only the removal and replacement of concrete kerbs and channels, but would also include adjustment of intersections, drainage, and verge and every driveway and road entry, which was out of scope. The cost implications were estimated to be enormous and therefore in urban areas it was considered not possible to apply overlay with significant thickness. If structural strengthening was not required, mill and replace was suggested (considering the options in Section 3.2) or a maximum thickness of 50 mm overlay was applied. The asset owner acknowledged that the design life was shorter than necessary (<15 years) on these sections. The Guidelines also discussed and included suggestions for the following topics:

- required asphalt types (wearing, intermediate and base course)
- allowable minimum and maximum layer thicknesses

- applied binder types
- allowable RAP content according to the asphalt type
- volumetric and performance related requirements for each asphalt type.

As a practical outcome, the pilot project provided detailed pavement design and technology considerations. For a better visualisation—including all input (see Section 1) and output data—longitudinal section were developed; an example is shown in Figure 2. Due to the limited available space only the methodology is provided in this paper. The background on data collection and analysis and verification of the methodology is discussed in details in the contract report provided to the Client [12].

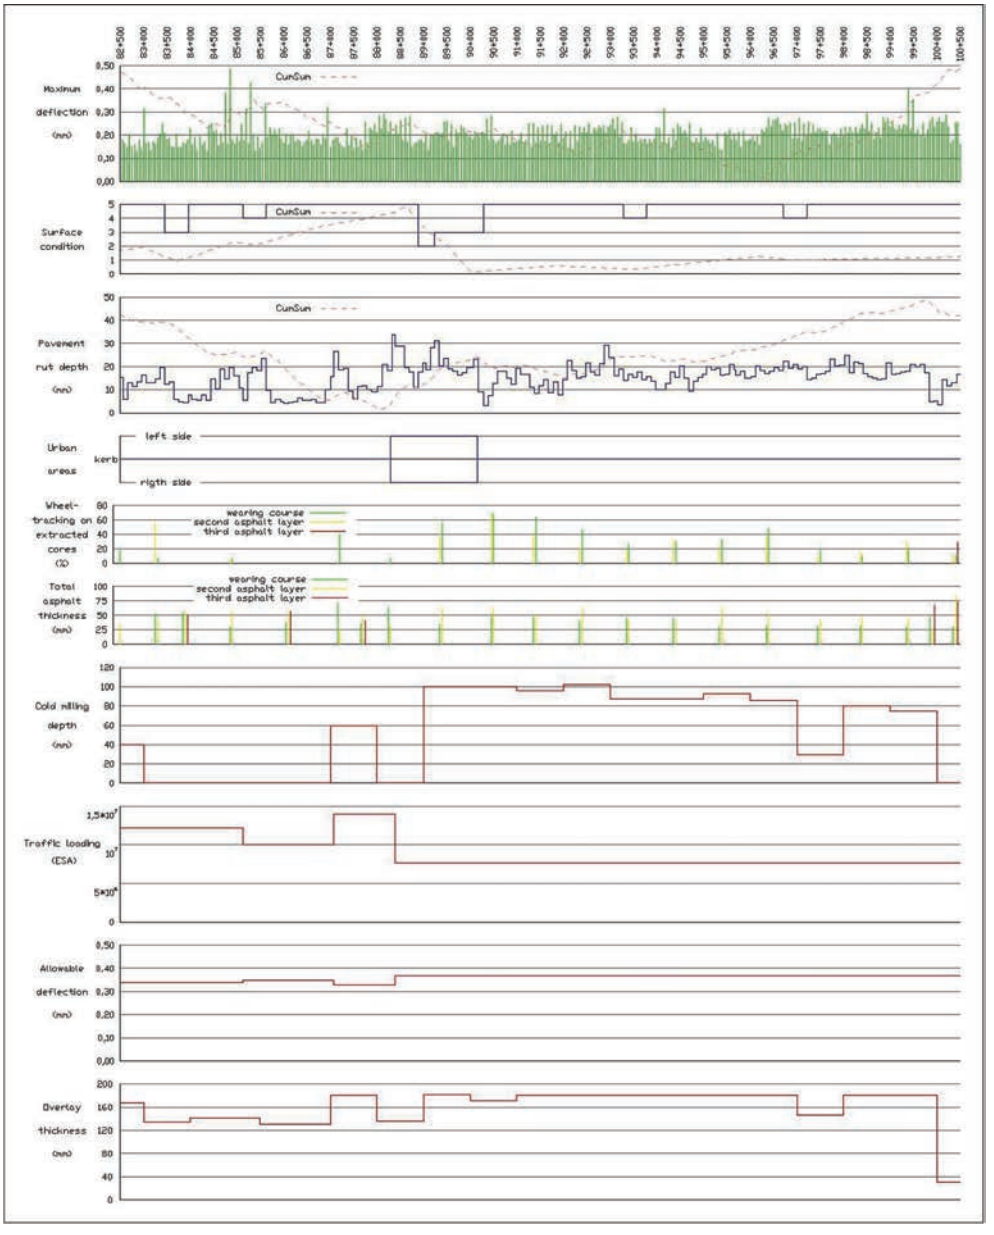

Figure 2. Longitudinal section of input and output data (example on road no. 6).

3.4 *Cost savings*

By using the above methodology which is based on semi-empirical pavement design, extensive FWD and wheel-tracking test, for the five road sections—a total length of 299.7 km -, 482 000 tonnes of asphalt were required; the estimated amount of RAP was 27 000 tonnes. These values were later refined in the detailed design phase; however, the authors were not involved in this phase of the works.

4 SUMMARY

A significant section of the Hungarian trunk road network had to be improved and reconstructed to a higher standard due to an agreement with the EU. Following reconstruction the allowable axle load was increased from 100 kN to 115 kN.

The Instrument for Structural Policies for Pre-Accession (ISPA) was launched to assist with this issue. This paper provides a summary of the development of a series of guidelines for road pavement rehabilitation design in Hungary as part of the ISPA II main framework. The ISPA program involved a systematic road infrastructure upgrade, including road pavement rehabilitation and widening, upgrade of intersections, traffic calming measures, parallel bikeways and bridge rehabilitation or reconstruction works.

The ISPA II project included five sections of the trunk network, a total length of 299.7 km. Development of the Guidelines for ISPA II was a pilot project and later formed the technical basis for tenders and technical investigations on the project level and other road rehabilitation projects under the 115 kN strengthening projects.

The complex problem of the pavement structural design in a semi-empirical system is discussed. Also, the paper outlines how to incorporate existing asphalt layers prone to plastic deformation into the rehabilitated pavement structure, while maintaining a low risk of future distresses. Using this approach it was possible to develop a series of guidelines for cost-effective pavement rehabilitation design.

As a practical outcome of the work presented here, detailed pavement designs and technology considerations, also visualised in longitudinal sections were developed, which provides practical help for considering all input parameters and understanding the complex nature of the road pavement rehabilitation design.

Asphalt Pavements – Kim (Ed)

The crack resistance potential of sand asphalts subjected to thermal loading

ABSTRACT: A test method which involves the use of thermal cycling rig was developed to evaluate crack resistance of three sand asphalt mixtures called Sand asphalts 1, 2, and 3. The specimens were three-layer beams. The bottom layer was 10 mm asphalt concrete with 10/20 penetration grade bitumen. The middle layer was the sand asphalt and the top (surface) layer was also made of 10 mm asphalt concrete, but 40/60 penetration grade bitumen was used in the mix. Also, the control specimen (without sand asphalt layer) was examined. The specimens were subjected to thermal loading by cyclic opening and closing of the crack at the centre of the specimen at a temperature of −3°C, increasing the magnitude of crack opening with each cycle, until it was deemed to have failed. It was found that the specimens with sand asphalt layer performed better than the one without the asphalt layer. Also, the tests showed that specimen with Sand asphalt 1 in the middle layer was more successful that either Sand asphalt 2 or Sand asphalt 3 and it allowed a crack opening approximately two times greater than the control case.

Keywords: Sand asphalt, cracks, thermal loading, overlay

1 INTRODUCTION

The rehabilitation of deteriorated pavement usually involves overlaying with a new surfacing material called overlays. The major problem with overlays is reflective cracking. Reflective cracking is simply the propagation of existing cracks in an old pavement through the underside of the overlay to the surface [1]. This allows water to infiltrate the pavement causing premature failure of the overlay. Researchers have identified that the two major causes of reflective cracking in overlays are the action of traffic loading and the daily/seasonal temperature variation resulting in thermal loading [2–7]. This study focuses on the thermal loading. The daily temperature variation causes a series of repeated temperature changes over a period with the temperature above the fracture temperature of the asphalt concrete, while the seasonal temperature variation causes a single drop in temperature below fracture temperature of the asphalt concrete.

Temperature variations induce stress in the overlay. The dissipation of the stress through the process called relaxation prevents the initiation of cracks. At high temperature, the stress is dissipated quickly because asphalt is visco-elastic. However, at low temperature, asphalt behaves more as elastic material and the stress induced are not fully dissipated, resulting in concentration of stress in the crack region. This causes initiation of cracks in the overlay.

A number of researchers have investigated the crack resistance potentials of different materials used with overlays to thermal loading. Cleveland et al [8] evaluated geosynthetics placed under or within a Hot Mix Asphalt (HMA) overlay to reduce the severity or delay the appearance of reflection cracks using Texas Transport Institute (TTI) overlay tester. The overlay tester evaluates the relative ability of a HMA beam ($3 \times 6 \times 20$-inch) with and without geosynthetics to resist thermal cracking. The geosynthetics used in the research were Bitutex composite, Pave-Dry 38, PetroGrid 4582, Ha Telit C40/17, Glass Grid 8501, and Star Grid G + PF. In the study, six beams were reinforced with geosynthetic materials, with the seventh unreinforced representing the "control" beam. The beams were tested to failure in the overlay tester. The results showed the best performance was recorded with grid and composites and the non-woven products performed better than the thin asphalt surface.

Also, Bhosale and Mandal [9] carried out laboratory study on Open Graded Asphalt Concrete (OGAC) as a crack relief layer using an asphalt concrete slab fatigue testing equipment. In the research, they investigated the conventional Dense Bitumen Macadam (DBM) and the OGAC overlay under simulated thermal and traffic loads with 5 mm differential deflection of zero load efficiency factor. They performed the experimental work in a strain-controlled environment with an average room temperature of 29°C. A gap of 5 mm was maintained between two pavement plates, representing the initial existing crack width in the old distressed pavement. Simulation of daily and seasonal thermal contraction and expansion cycle was achieved by cyclically opening and closing the initial existing crack by 1.83 mm at a strain rate of 4.547 mm/min. They also considered mixed mode of displacement. They found that the conventional overlay of DBM showed faster rate of decay with number of simulated thermal load cycle than OGAC overlay. They concluded that it did arrest the crack propagation.

Dempsey [10] developed and evaluated the use of ISAC to alleviate the problem of reflective cracking in asphalt pavements. The ISAC consisted of a low-stiffness geotextile as the bottom layer, a viscoelastic membrane layer as the core, and a very high stiffness geotextile for the upper layer. In his study, a laboratory pavement section with an AC overlay placed on a jointed Portland cement concrete slab was constructed and tested in an environmental section. The thermal strain was simulated using a mechanical device, opening and closing the joint at extremely low rate. The temperature of the chamber was maintained at –1.1°C. His results showed that the laboratory AC overlay section without ISAC (control) cracked and separated completely within seven cycles of joint movement. The AC overlay performed exceedingly well when it was treated with the ISAC system and tested under the same conditions as the control pavement, cracks appeared only when the slab movement had increased to 5.08 mm and over and the ISAC geotextile had been subjected to 158 cycles.

This study investigated the performance of three different sand asphalts used with a 10 mm asphalt concrete overlay subjected to thermal loading against reflective cracking.

2 MATERIALS AND METHODS

The materials used for this study, the characterization tests carried out on the materials and the methods adopted are presented in this section.

2.1 *Materials*

The materials used in this study are as follows:

10 mm asphaltic concrete with 40/60 and 10/20 penetration grade bitumen. The mix composition is as shown in Table 1 and the particle size distribution curve for the blend of aggregates is shown in Figure 1.

The Stress Absorbing Membrane Interlayers (SAMIs) mixtures used in this research were sand asphalts 1, 2 and 3. The mix compositions of the SAMIs are shown in Table 2. The Indirect Tensile Stiffness Moduli (ITSM) of the asphalt concrete mixtures and the sand asphalts were determined using the Nottingham Asphalt Tester (NAT) in accordance with (DD 213:1993) [11]. In the ITSM a load pulse was applied to the vertical diameter of a cylindrical

Table 1. Mix composition for 10 mm asphalt concrete.

Sample type	Percent by composition of aggregate
10 mm aggregate	37%
6 mm aggregate	26%
Dust	36%
Filler	1%
Binder type	10/20, 40/60 bitumen
Binder content	5.3% by mass of total mix
Target air void	5%

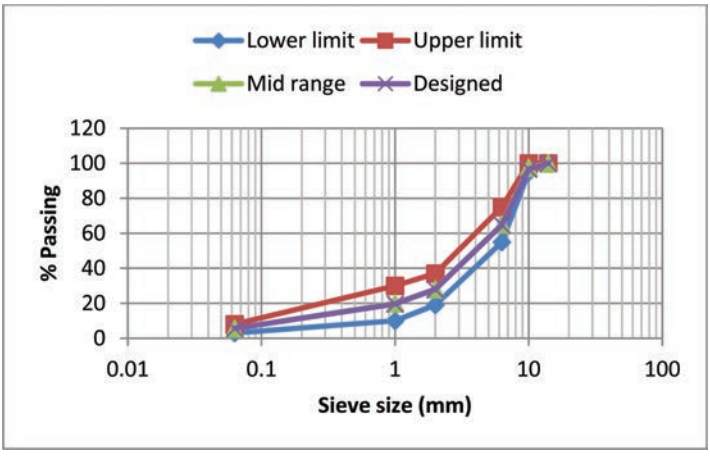

Figure 1. Particle size distribution curve for the blend of aggregates for 10 mm asphalt concrete.

Table 2. Mix compositions for sand asphalts 1, 2 and 3.

	% by composition of aggregate	% by composition of aggregate	% by composition of aggregate
Sample type	Sand asphalt 1	Sand asphalt 2	Sand asphalt 3
0/4 crushed rock fill	95%	74.5%	–
Fine sand	–	20%	84%
Filler	5%	5.5%	16%
Binder type	Polymer modified binder	Polymer modified binder	160/220 bitumen
Binder content	9% by mass of total mix	9.1% by mass of total mix	10.3% by mass of total mix
Target air void	2%	2%	5%

specimen (100 mm in diameter and 40 mm thick) positioned centrally between the upper and the lower platens and the resultant peak transient deformation along the horizontal diameter was measured. The ITSM results for the 10 mm asphalt concrete with 40/60 and 10/20 penetration grade bitumen and sand asphalts at 10°C, 20°C and 30°C are shown in Table 3.

2.2 *Methods*

The objective of this study was achieved using the thermal cracking simulation apparatus developed at the University of Nottingham. The thermal cracking testing device is shown

Table 3. Indirect tensile stiffness moduli.

Asphalt concrete (AC)/SAMIs	Stiffness (MPa)		
	Temperature		
	10°C	20°C	30°C
AC (40/60)	10035	3899	1098
AC (10/20)	15435	9591	5008
Sand asphalt 1	8548	2725	636
Sand asphalt 2	7564	2444	510
Sand asphalt 3	635	209	118

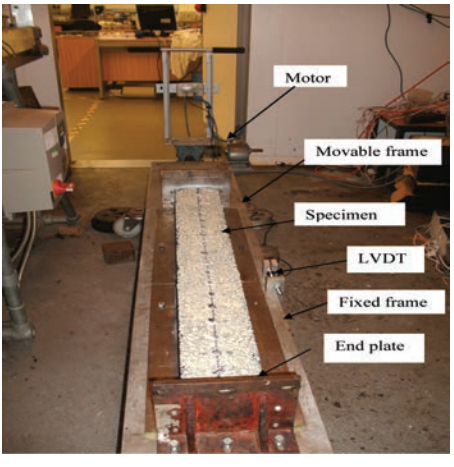

Figure 2. Thermal cycling device.

Figure 3. Thermal cycling device control unit.

in Figure 2. The mould and the control unit (see Fig. 3) were modified for the present study. The thermal cracking device is made up of a horizontal frame 2 m and 0.2 m in length and width, respectively. The horizontal frame is in two halves with one half fixed and the other half connected to a DC motor through a worm drive. This allows it to be opened and closed at a chosen rate.

It was modified such that the motor will provide selectable, variable extension and contraction rates between 1.0 mm in one hour and 1.0 mm in twenty four hours. To allow the motor to rest, the delay between individual operations varies between 5 and 95 seconds. The contraction/expansion rates were read from a Linear Variable Differential Transformer (LVDT). The indicator lights on the device control unit (see Fig. 3) were used to monitor the direction of movement of the movable plate, completion of selected operation and any fault encountered during the test.

2.2.1 *Specimen preparation and instrumentation*

The test specimens were made up of 3-layer beams of length 1000 mm and width 125 mm. The first (base) layer was a 40 mm thick 10 mm asphaltic concrete with 10/20 penetration grade bitumen, the middle layer (where present) was sand asphalt of 10 mm thickness. The top layer was a 30 mm thick 10 mm asphaltic concrete with 40/60 penetration grade bitumen. The control specimens were prepared in two layers without sand asphalt layer (the base and surface layers). In this case, the base and the surface layers were both 40 mm thick.

The beams for the first (base) layer were produced by manufacturing a slab of dimension 500 mm × 500 mm × 40 mm. The aggregates and binder were batched as shown in Table 1, mixed at 185°C and compacted in a mould 500 mm × 500 mm × 205 mm with a roller compactor at a temperature of 180°C just before compaction to a thickness of 40 mm. The slabs were cut into beams of 500 mm and 125 mm in length and width, respectively. Two steel and end plates were bolted on the frame; then the two beams were glued on the steel plates and the sides of the mould were bolted to the end plates as shown in Figure 2. The sand asphalts' materials were batched as shown in Table 2. The aggregates and binders for sand asphalt 3 were heated at 140°C and compacted at 130°C, while the aggregates and binder for sand asphalts 1 and 2 were batched and heated to a temperature of 180°C, and compacted on the bottom layer at a temperature of 150°°C. The compaction was done with a vibrating hammer (Kango). The surface layer aggregates were batched as shown in Table 1 and heated to 160°C and compacted to the required thickness at 150°C. All the mixtures were mixed in accordance with (BS EN 12697-35:2004) [12].

Demec pips were glued to the centre of the top layer 50.8 mm apart to measure the surface strain. Also, the expansion and contraction (opening and closing) of the frame was monitored using the LVDT readings. The top of the specimen was painted white to monitor the appearance of cracks.

3 TEST PROCEDURE

The thermal cycling testing device with the specimen in place was placed in a temperature controlled room at test temperature of −3°C for a minimum of five hours. The test was conducted by opening the movable part of the rig for a period of 6 hours and closing it for another 6 hours. This was achieved by setting the contraction (closing) or the expansion (opening) rate on the control box and the required travel distance. The appearance of a crack on the surface was monitored visually and the movement of the movable frame was read from the LVDT. The strain on the overlay (surface layer) was measured and recorded. The test was stopped when the sample was deemed to have failed completely. The criterion for failure was the appearance of a crack at the surface of the specimen.

4 TEST RESULTS

The surface strain was determined from the demec gauge readings. The results were presented as graphs of surface strain versus the distance from the centre of the specimen to the point the measurement was taken on the specimen.

4.1 *Control specimen (No SAMI)*

The specimen was tested by opening the movable frame for 6 hours and closing it for 6 hours at each prescribed travel distance. It failed after crack opening of 1 mm. The surface strains for 0.5 mm and 1 mm crack openings are shown in Figure 4. It shows that for 0.5 mm crack opening, the strains were almost uniformly distributed with peak strain developing at –50 mm (50 mm to the left of the beam's centre) and at the centre, no crack was seen on the specimen at this point. Also, at 1.0 mm crack opening, the strain concentration developed at the centre of the specimen directly above the centre of the split base and cracks appeared at the surface (centre) spanning the whole width of the specimen. The photographs of the specimen before and after the test are shown in Figure 5.

The reason for early appearance of a crack can be attributed to two major factors. The first is the bond between the surface layer (overlay) and the base layer, subjected to tensile loading. At low temperature, strong bond exists between the overlay and the base layer for the control specimen [1]. The strong bond provides restraint for the horizontal movement of the base layer, therefore resulting in tensile strain concentration at the base of the overlay. The second factor is the lack of any soft interlayer (sand asphalt) between the overlay and the base layer. The horizontal deformation of this layer allows dissipation of energy and the slip

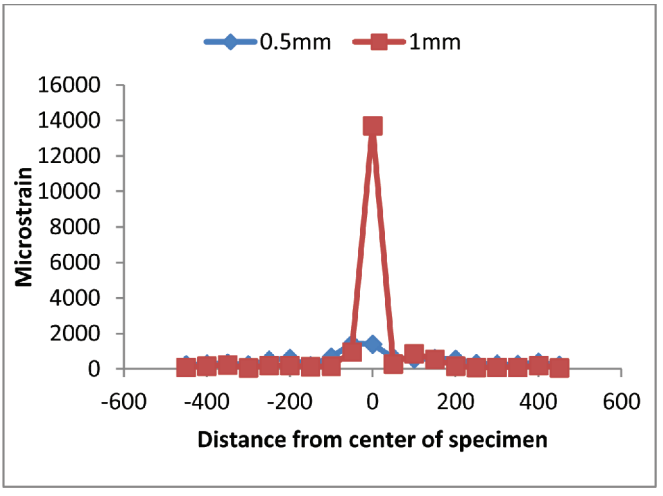

Figure 4. Strains at 0.5 and 1.0 mm opening.

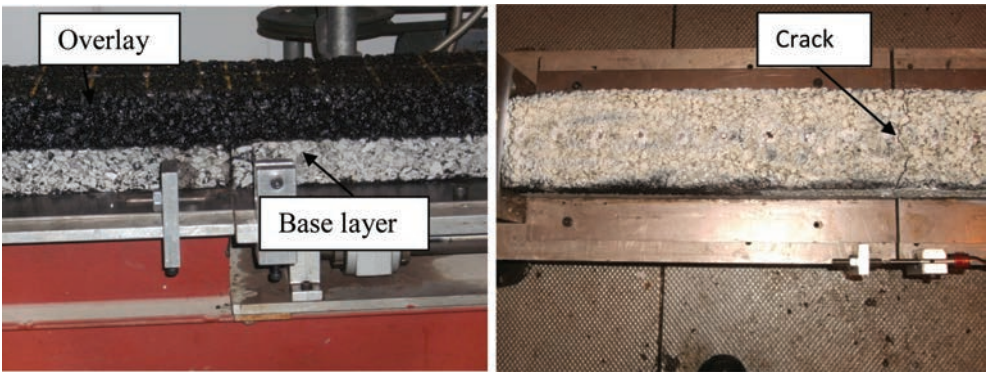

Figure 5. Photographs of the control specimen (a) before (b) after the test.

between the layer and the overlay isolates the overlay from the tensile strain concentration because of reduced restraint to the horizontal movement of the base layer, therefore reducing the tensile strains in the overlay. In the case of a control specimen with strong bond and no sand asphalt, high tensile strains developed in the overlay leading to rapid propagation of a crack when the fracture strength of the overlay is exceeded.

4.2 *Specimen with sand asphalt 1*

The specimen with sand asphalt 1 was subjected to thermal cycling and cracks appeared after 2.0 mm crack opening. The surface strain distribution in the specimen for crack openings of 0.5 mm, 1.0 mm, 1.5 mm and 2.0 mm are shown in Figure 6. The figure shows that the strain distribution was uniform at –150 mm to –400 mm while strain concentration developed at –100 mm to 450 mm. Cracks were seen after the device was opened by 1.5 mm at the part of the beam with high strain concentration, the test was stopped after crack opening of 2.0 mm when the specimen was deemed to have failed The photographs of the specimen before and after the test are shown in Figure 7. It can be seen from the figure that cracks developed in the area with high strain concentration, while no crack was seen in the area with uniform stress concentration.

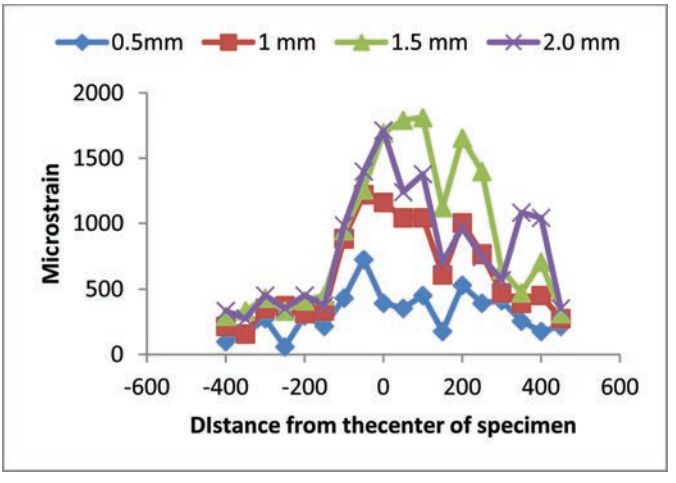

Figure 6. Strains at 0.5 mm and 1.0 mm, 1.5 mm and 2.0 mm opening.

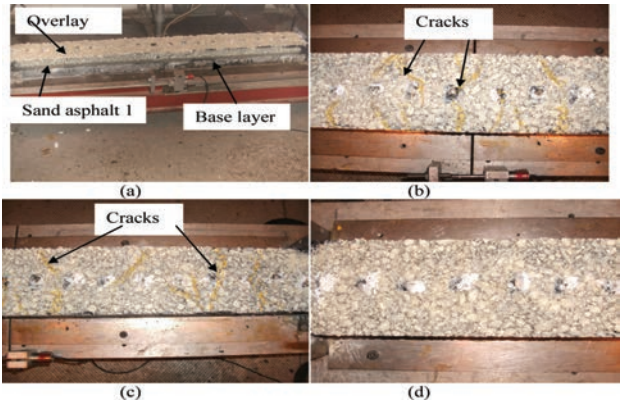

Figure 7. Photographs of the specimen incorporating sand asphalt 1 (a) before (b) after the test (center) (c) after the test (right) (d) after the test (left).

Also, as explained for the control specimen, two factors were responsible for the performance of sand asphalt 1. These are the bond between the overlay, the sand asphalt and the base layer and the crack resistance of the sand asphalt because of its stiffness. The sand asphalt 1 (SAMI layer) allows the dissipation of energy and in turn less tensile strain in the overlay. Cracks appeared after crack opening of 2.0 mm compared to 1.0 mm for the control specimen.

4.3 *Specimen with sand asphalt 2*

The same test procedure was carried out for the specimen with sand asphalt 2. The test was stopped after crack opening of 1.5 mm as cracked appeared at the surface. The surface strain distributions at 0.5 mm, 1.0 mm and 1.5 mm crack openings are shown in Figure 8. The figure shows that strain concentration developed at the centre of the specimen, while the strain distribution was uniform at the right and left of the specimen. Cracks appeared after opening the movable frame by 1.5 mm in the region of strain concentration. The photographs of the specimen before and after the test are shown in Figure 9.

Although the specimen failed at 1.5 mm crack opening, the strain distribution in the overlay was more uniform than that in specimen with sand asphalt 1. This is probably because sand asphalt 1 mixture is coarser, thus having greater stiffness and less flexibility than sand asphalt 2. Jung and Vinson [13] observed that mixture fracture strength depends on the aggregate type and sizes and the air voids of the mixture. It is clear like the specimen with sand asphalt 1 that the crack resistance is influenced by the presence of sand asphalt 2 with lower stiffness than the overlay and the base layer.

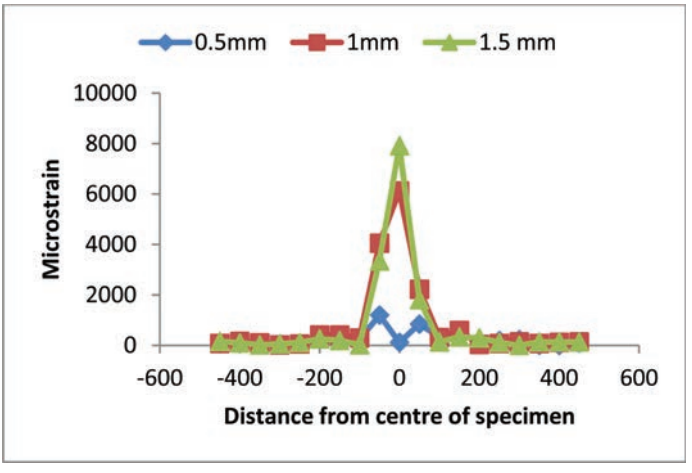

Figure 8. Strains at 0.5 mm and 1.0 mm, and 1.5 mm opening.

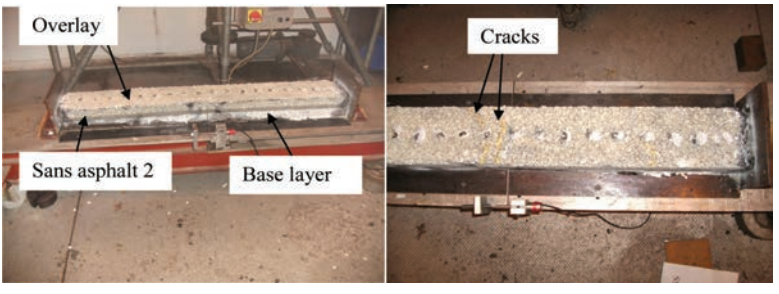

Figure 9. Photographs of the specimen incorporating sand asphalt 2 (a) before test (b) after test.

4.4 *Specimen with sand asphalt 3*

The test for the specimen with sand asphalt 3 was carried out like the other specimens. At 0.5 mm and 1 mm crack openings as shown in Figure 10, the strain distribution was uniform at the two ends with peak concentration developing around the centre of the specimen (crack region). Also, the figure shows that at 1.5 mm and 2.0 mm crack openings, the stress at this stage was concentrated at the centre and the test was stopped after 2.0 mm when a full width crack developed at the centre. Dave et al [14] found in their study that sections with highly modified sand asphalt placed under the overlay under thermo-mechanical loading cycle showed no crack, but that the bottom of the binder course (overlay-interlayer interface) was at the threshold of complete softening and separation. This shows the importance of the interface bond to the resistance of the SAMIs to crack developing at the surface of the overlay under thermal loading.

Also, in this case, the specimen benefits from the slip between the overlay and the sand asphalt 3 allowing relative movement of the base layer and isolating the overlay from stress concentration in the crack region. The photographs of the specimen before and after test are shown in Figure 11. However, the ineffectiveness of the sand asphalt against reflective cracking under traffic loading has to be taken into consideration [15]. This indicates that while the low stiffness of the interlayer aids retardation of cracks, their load carrying capacity must be considered before they are chosen for a particular purpose.

4.5 *Summary*

The summary of the surface strain results are presented in Figure 12. It shows the maximum measured strain at the surface of the specimen. These results are most revealing. Based on

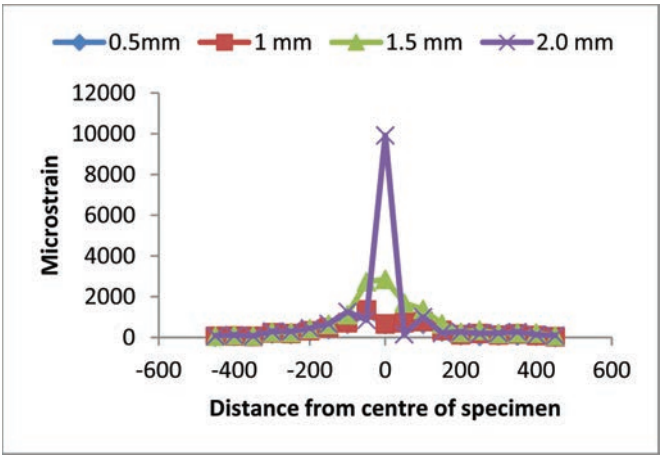

Figure 10. Strains at 0.5 mm and 1.0 mm, 1.5 mm and 2.0 mm opening.

Figure 11. Photographs of the specimen incorporating sand asphalt 3 (a) before test (b) after test.

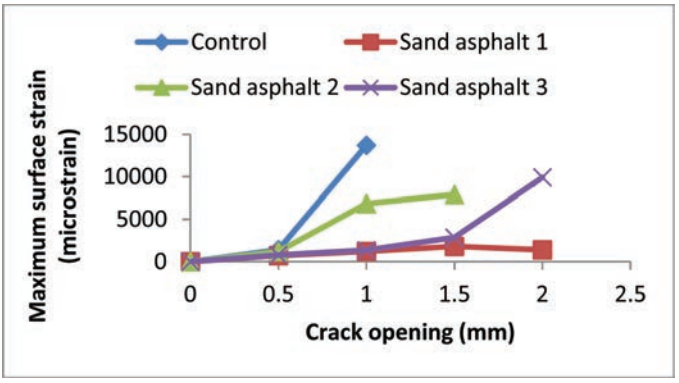

Figure 12. Summary of data from thermal cycling test.

experience from fatigue testing one would expect cracking to propagate rapidly once the strain level reached greater than about 2000–3000 microstrain and this does indeed appear to have been the case. Sand asphalt 1 has been the most successful and it is considered likely that the final point shown on the curve may be false, perhaps because the location of maximum strain was outside the strain measurement zone. Nevertheless sand asphalt 1 has clearly been more successful than either sand asphalt 2 or the sand asphalt 3 and it allowed a crack opening approximately two times greater than the control case.

5 CONCLUSION

This paper presents an evaluation method for performance of sand asphalt against reflective cracking under thermal loading. It can be seen from the tests that all the specimens with sand asphalt performed better than the control specimen with no SAMI. This indicates that having a soft interlayer like sand asphalt between the overlay and existing pavements retards/delays crack growth, thus increasing the life of the overlay. The strain distribution was more uniform in all the specimens with sand asphalt than the control specimen and they sustained greater crack opening than the control specimen. This established the importance of the slip between the overlay and SAMIs to the crack resistance of sand asphalts used as interlayer between overlay and existing pavement. The slip ensures that stress concentration around the crack region is not transferred to the overlay.

ABSTRACT: The Ministry of Transportation Ontario (MTO) is committed to maintaining the provincial transportation infrastructure in a sustainable manner. One way to achieve pavement sustainability is through the combined use of environmentally sound pavement preservation and in-situ pavement recycling strategies. Pavement preservation is the use of proactive, planned strategies that extend the life of the pavement, providing a cost effective solution for asset management. In-place pavement recycling is a pavement rehabilitation strategy that reuses 100% of the existing roadway materials, conserving non-renewable resources, eliminating disposal costs, and reducing environmental impacts.

This paper outlines the various pavement preservation and in-place recycling strategies utilized in Canada to achieve sustainability. Pavement sustainability is quantified by comparing the energy consumption and Greenhouse Gas (GHG) emissions generated by the various pavement rehabilitation strategies using the PaLATE software. The results indicate that pavement preservation and in-place recycling strategies are cost competitive and provide a significant reduction in energy use, aggregate consumption, and GHG emissions when compared to traditional rehabilitation treatments. Detailed discussion on these technologies and their environmental impacts are presented, as well as a 10 years historical perspective of the Ministry's pavement preservation and in-place recycling program.

Keywords: Pavement preservation, in-place pavement recycling, greenhouse gas emissions, sustainable pavements, PaLATE

1 INTRODUCTION

The Ministry of Transportation Ontario (MTO) believes that the protection of air, water and land resources is necessary to sustain current and future generations. The main benchmarks established for sustainable pavements are reducing the use of natural resources, reducing energy consumption and minimizing Greenhouse Gas (GHG) emissions [1]. One way to achieve pavement sustainability is through the combined use of environmentally sound pavement preservation and in-place pavement recycling strategies.

This paper outlines the various pavement preservation and in-place recycling strategies utilized in Canada to achieve sustainability. Also, detailed discussion on these technologies and their environmental impacts are presented, together with the 10 years historical perspective of the ministry's pavement preservation and in-place recycling program.

2 PAVEMENT SUSTAINABILITY TREATMENTS

Pavement sustainability can be achieved through the combined use of pavement preservation and in-place recycling strategies. The following subsections outline the various pavement preservation and in-place recycling strategies utilized by MTO.

2.1 *Flexible pavement preservation treatments*

Pavement preservation is a proactive, planned strategy applied in a timely manner to extend the life of the pavement without adding structural strength to the pavement. The timeframe to apply pavement preservation is early in the pavement's life before the pavement has deteriorated past a certain condition; thereafter a more costly, less sustainable rehabilitation treatment is required. The various pavement preservation treatments used by MTO are summarized as follows: [2].

2.1.1 *Crack sealing*

Crack sealing treatments are used to prevent water and debris from entering cracks in Hot Mix Asphalt (HMA) pavement. Limiting water infiltration protects the underlying pavement layers and reduces the detrimental effects of freeze thaw cycles. Typically, the Ministry expects crack sealing to extend the life of a pavement by 3 years and as such, crack sealing is a cost effective treatment to prolong the pavement life.

2.1.2 *Slurry seal*

Slurry seal is a thin cold slurry treatment applied to the entire HMA surface. Typically it is used to seal the pavement surface, fill minor surface irregularities, address ravelling and oxidation, and to improve friction. It consists of a mixture of well-graded aggregate and slow setting emulsion and has an expected pavement extension life of 3–5 years.

2.1.3 *Micro-surfacing*

Micro-surfacing is a premium, polymer-modified cold slurry paving system applied to the entire HMA surface. Typically it is used to address ravelling and oxidation, fill ruts and minor surface irregularities, and to improve friction and ride. It consists of a mixture of dense-graded aggregate, asphalt emulsion, water and mineral fillers that is typically placed 10–12 mm thick, with an expected pavement life extension of 7–9 years. Micro-surfacing is a good example of preventive maintenance and the Ministry considers this treatment to be one of the most cost effective preservation treatments.

2.1.4 *Chip seal*

Chip seal is a mechanized spray patching application of asphalt and single-sized aggregate chips rolled onto the existing pavement surface. Typically it is used to seal the pavement surface, enrich hardened or oxidized asphalt, and to improve surface friction. It can be applied on a small patch area (Dynapatch) or the entire HMA surface, with an expected pavement life extension of 4–6 years.

2.1.5 *Ultra-thin bonded friction course*

Ultra-thin bonded friction course, also known as Novachip®, is a thin HMA treatment that is applied to the entire pavement surface. Typically it is used to address surface distress, seal the surface and increase surface friction. It consists of gap-graded polymer-modified HMA placed about 10 to 20 mm thick on a heavy, polymer-modified emulsified asphalt tack coat. This treatment has a relatively high initial cost and, subsequently, has shown limited use by the Ministry.

2.1.6 *Fibre modified chip seal*

Fibre Modified Chip Seal (FMCS), also known as FiberMat®, is a mechanized spray patch thin treatment that is applied over the existing HMA surface. It is a similar process

to regular chip seal with the addition of fibre to help prevent reflective cracking. FMCS incorporates chopped fibreglass strands on the polymer-modified emulsion which has been sprayed onto the existing surface, applies a second spray of polymer-modified emulsion and covers this with an aggregate layer. Typically it is used either to seal the surface to prevent water ingress and control reflective cracking or as a Stress Absorbing Membrane Interlayer (SAMI) to mitigate reflection cracking of a new overlay. This is a relatively new treatment utilized by the Ministry, and the results and performance are being monitored.

2.1.7 *Hot in-place recycling*

Hot In-place Recycling (HIR) is used by the Ministry as both a pavement preservation and pavement rehabilitation strategy for pavements that are generally free of major structural distress. HIR is used to address surface distress, and improve surface friction and ride. For the HIR process, the existing surface is heated and scarified in-place to a depth of 40–50 mm, rejuvenated and reprofiled to a new grade. This operation is carried out with an HIR train in a continuous operation. HIR is considered a sustainable preservation treatment since it recycles 100% of the existing HMA surface in-place, which minimizes material hauling to and from site. This preservation treatment has an expected pavement life extension of 7 to 9 years, similar to a conventional one lift HMA overlay.

2.1.8 *Warm mix asphalt*

Warm Asphalt Mix (WMA) is an environmentally friendly alternative to HMA. WMA is produced at temperatures about 30 °C lower than conventional HMA. Producing WMA at lower temperature uses less energy and also significantly reduces the emissions generated. Some other potential WMA benefits: mix can be transported over longer haul, easier to achieve compaction density, shorter time required for opening to traffic, potential to improve construction of transverse and longitudinal joints and reduced workers' exposure to fumes during placement and compaction of the WMA.

2.2 *In-place flexible pavement recycling strategies*

For over two decades, in-place pavement recycling technologies have been developed which enable an existing pavement surface to be rejuvenated and reprofiled in-place. This eliminates the need for off-site hauling and processing, enhancing the environmental benefits. The Ministry has successfully implemented a number of in-place pavement recycling technologies in the past, and they are performing well. Following outlines the various in-place recycling rehabilitation strategies used by MTO [3].

2.2.1 *Full Depth Reclamation (FDR)*

FDR is a pavement reconstruction technique where the existing HMA pavement and a predetermined portion of the underlying granular base are pulverized in-place to produce a well graded, homogenous base material [4]. A new HMA binder and surface courses are placed after FDR to complete the pavement rehabilitation. FDR is performed on the roadway without the addition of heat, and the treatment depths are typically 100 to 300 mm.

2.2.2 *Cold In-place Recycling (CIR)*

Conventional CIR is an established pavement rehabilitation technique that processes in-place the existing HMA pavement for depths up to 125 mm, mixes in a small amount of emulsified asphalt cement (about 1–1.5%) and then reprofiles the mix as a binder course in one continuous operation. A new HMA surface course is placed after the emulsion has set and the moisture and compaction specification requirements have been met, typically after 14 days [5].

CIR is a cold process that saves energy and reduces emissions. It is well suited to address a wide range of moderate to severe pavement distresses, and it has been found to mitigate reflective cracking and extend pavement life [6].

2.2.3 *Hot In-place Recycling (HIR)*

HIR is a pavement rehabilitation technique that consists of heating and softening the existing HMA surface, scarifying the heated pavement surface, adding rejuvenator, fine aggregates and/or admixture as required, mixing, reprofiling and then compaction as a binder or surface course in one continuous operation. Typical treatment depth is about 40 to 50 mm, with some multi-stage trains claiming to treat up to 75 mm depth. HIR is also considered as a preservation treatment because, when properly designed, it can act as a standalone surfacing not requiring a separate overlay.

2.2.4 *Full depth reclamation with Expanded Asphalt Stabilization (EAS)*

FDR with EAS is a reconstruction process that includes in-place full depth reclamation of the HMA and underlying granular with the addition of expanded (foamed) asphalt cement. To expand or "foam" the asphalt, a small amount of cold water is injected into the hot asphalt cement in the expansion chamber of a reclaimer/stabilizer. As the cold water turns to steam, the asphalt cement 'foams', facilitating mixing with the cold, damp, reclaimed material from the FDR process. With a minimum of two-day curing period after the stabilized material is graded and compacted, the expanded asphalt stabilized base can be overlaid with HMA [7].

EAS is an in-place process that allows for 100% cold recycling of the roadway material, resulting in fuel savings and reducing emissions. The stabilizing process, which typically involves the top 150 mm of the FDR layer, strengthens the recycled base, thus, reducing the thickness requirements of the HMA overlay.

2.2.5 *Cold In-place Recycling with Expanded Asphalt Mix (CIREAM)*

CIREAM is a recent development in CIR technology that uses expanded asphalt rather than emulsified asphalt to bind the mix. It adopts the same concept of adding 1% cold water into the heated asphalt cement to expand (foam) the asphalt for more efficient coating of the reclaimed asphalt material. In addition, the curing time required prior to overlay with a HMA surface course is significantly reduced from the conventional CIR of 14-days to 2-days with CIREAM, since less moisture is added during the process [5].

2.3 *Quantities of sustainable pavement treatments*

Over the years, MTO has carried out many pavement preservation treatments and in-place recycling strategies to extend the pavement life. Table 1 below summarizes the quantities of pavement preservation and in-place recycling treatments that were carried out in the past 10 years.

Micro-surfacing accounts for the vast majority of the Ministry's preservation treatment quantities (72%). The performance of the micro-surfacing has been very good and

Table 1. Summary of MTO sustainable treatments quantities (2003–2012).

Treatment	Quantities (m^2)
Preservation	
Slurry seal	906,050
Micro-surfacing	7,309,677
Chip seal	849,178
Fibre modified chip seal	578,878
Ultra-thin bonded friction course	450,223
In-place processing	
Hot in-place recycling	324,124
Full depth reclamation	16,097,880
Cold in-place recycling	4,388,508
Expanded asphalt stabilization	2,929,914
Cold in-place with expanded asphalt mix	3,758,829
Total sustainable treatment quantities	**37,593,261**

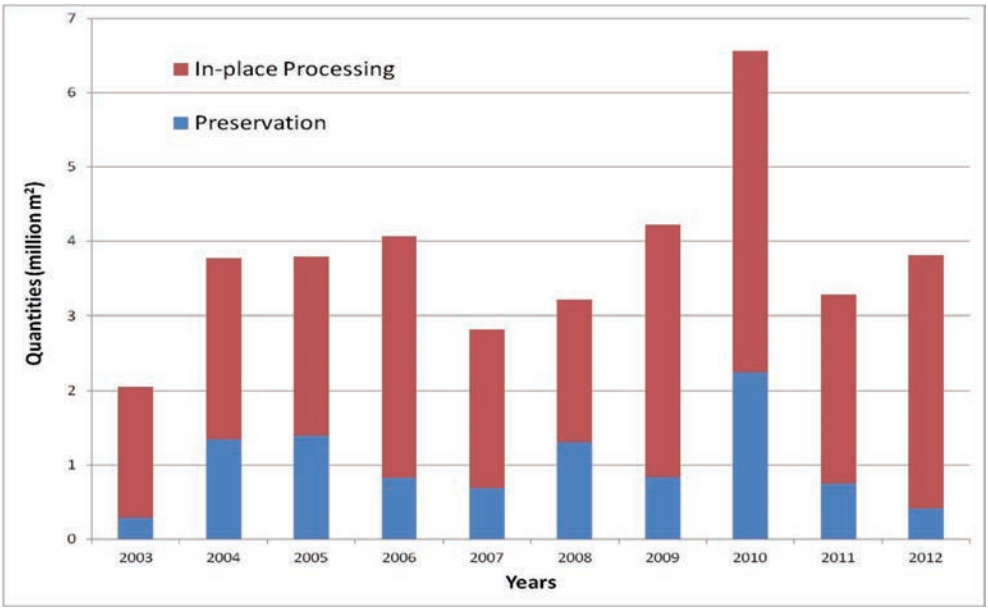

Figure 1. Historical perspective of MTO sustainable pavement quantities.

has demonstrated a relatively long service life, which makes it a cost effective preservation treatment. As an in-place processing strategy, FDR accounts for the vast majority of the Ministry's in-place recycling quantities (59%). However, in recent years the quantities of FDR has been decreasing as a result of the nature and focus of the Ministry's capital construction program and the use of other in-place recycling methods.

Figure 1 presented the 10 years (from 2003 to 2012) historical perspective of the Ministry's preservation and in-place recycling program.

As noted in Figure 1, the preservation treatment and in-place recycling rehabilitation quantities fluctuate year-to-year based on the focus and nature of the capital construction and preservation programs. It is important to note that MTO achieves its sustainable pavement goals by incorporating pavement preservation and in-place recycling strategies in its day-to-day program decision making process.

3 PAVEMENT SUSTAINABILITY METRICS

Recently, MTO has been using the PaLATE software to calculate GHG emissions produced by various road construction activities to assist decision-makers in evaluating the use of recycled materials in highway construction. PaLATE, which stands for Pavement Life-cycle Assessment for Environmental and Economic Effect, was developed at the University of California at Berkley [8]. Material quantities and haul distances are entered for specific treatments and the model calculates the emissions and energy consumption according to production, transportation and processing. Based on a typical 2-lane km highway pavement section, Table 2 below illustrates the environmental effects for the various pavement preservation and in-place recycling treatments estimated using PaLATE.

Table 2 is subdivided into preservation and in-place processing subsections. For the preservation treatment subsection, micro-surfacing appears to be the most environmentally friendly option with the least energy consumption and lowest CO_2 emissions. For the in-place processing subsection, CIR and CIREAM exhibit similar environmental benefits, and they appear to be the most sustainable of the in-place recycling options.

Table 2. Environmental metrics for various construction activities.

Treatment	Energy (MJ)	CO_2 (tonne)	Aggregate (t)
Preservation			
Micro-surfacing	105,993	6	140
50 mm hot in-place recycling	627,646	28	0
Mill 50 mm + pave 50 mm (WMA)	700,015	35	831
Mill 50 mm + pave 50 mm (HMA)	749,586	36	831
In-place processing			
180 mm FDR + 90 mm HMA	1,219,783	63	1,496
100 mm CIR + 50 mm HMA	851,409	45	831
150 mm EAS (180 mm FDR) + 50 mm HMA	1,264,264	68	831
100 mm CIREAM + 50 mm HMA	844,974	44	831
Mill 100 mm + 130 mm HMA	1,481,675	74	2,161

Table 3. Energy consumption and GHG emissions of various preservation treatments.

Treatment	Energy (MJ)	CO_2 (tonne)	NO_x (tonne)	SO_x (tonne)
Mill 50 pave 50 (HMA)	749,586	36	264	159
Mill 50 pave 50 (WMA)	700,015	35	236	148
50 mm HIR	627,646	28	202	127
Microsurfacing	105,993	6	37	25

3.1 *Case study: Preservation treatment*

This case study compares the environmental benefits in terms of energy and GHG emission reductions for selected pavement preservation techniques versus traditional mill and overlay (shave and pave) techniques.

3.1.1 *Quantifying environmental effects using PaLATE*

The following are the pavement preservation treatments selected in this case study for comparison with traditional mill 50 mm and overlay 50 mm HMA:

- Mill 50 mm and overlay 50 mm with Warm Mix Asphalt (WMA)
- 50 mm Hot In-place Recycling (HIR)
- Micro-surfacing

Based on a typical 2-lane km highway pavement section, Table 3 below illustrates the energy consumption and GHG emissions of the selected treatments generated by PaLATE and further verified with other references [9].

According to Table 3, the traditional mill and overlay treatment with conventional HMA generated the greatest energy consumption and GHG emissions compared to the other selected preservation treatments. Since the treatments have different expected service lives, the expected service life should be factored into the energy consumption and GHG emissions to normalize the data to allow for an appropriate comparison [9]. Therefore, all the above treatments were further broken down into the energy and emissions generated per year of service (Table 4). The annualized energy and GHG emissions were calculated by dividing the information from Table 3 by the expected service life of each treatment.

According to Table 4, micro-surfacing is the most sustainable pavement preservation technique among the four treatments. It emits the least GHG and consumes the least amount of energy. It is important to note that the other preservation treatment options are also more sustainable when compared to the traditional mill and overlay techniques.

With the data presented in Table 3 and 4, if MTO were to perform a traditional mill and overlay instead of micro-surfacing over the past 10 years, the figures below show the

Table 4. Annualized energy consumption and GHG emissions generated.

Treatments	Service life	Energy (MJ)	CO_2 (tonne)	NO_x (kg)	SO_x (kg)
Mill 50 pave 50 (HMA)	10	74,959	3.6	26.4	15.9
Mill 50 pave 50 (WMA)	10	70,002	3.5	23.6	14.8
50 mm HIR	9	69,738	3.1	22.4	14.1
Micro-surfacing	7	15,142	0.9	5.3	3.6

Table 5. Additional GHG emissions with mill and overlay only strategy.

	CO_2 (tonne)	NO_x (tonne)	SO_x (tonne)
Mill & overlay (A)	37,593	276	166
Micro-surfacing (B)	6,265	39	26
Additional emissions (A)-(B)	**31,327**	**237**	**140**

Table 6. Additional life cycle GHG emissions if using mill and overlay.

	CO_2 (tonne)	NO_x (tonne)	SO_x (tonne)
Mill & overlay (A)	37,593	276	166
Micro-surfacing (B)	8,951	55	37
Additional emissions (A)-(B)	**28,642**	**220**	**129**

Table 7. Annualized costs savings for micro-surfacing vs. mill and overlay.

Treatments	Unit cost (m^2)	Expected service life (yrs)	Annualized unit cost (m^2/year) (Unit cost/service life)
Mill and overlay	\$15.09	10	\$1.51
Micro-surfacing	\$7.00	7	\$1.00

associated additional GHG emissions (Table 5). This is calculated based on the 10 year micro-surfacing quantity (from Table 1: 7,309,677 m^2, which is equal to 1,044 2-lane km), and the GHG emissions from Table 4.

For a more appropriate comparison, the data should be annualized by factoring in the expected service life. Using the information from Table 4, the associated additional GHG emissions from Table 6 below are calculated to reflect the life cycle emissions. This is calculated based on the 10 year micro-surfacing quantity (from Table 1: 7,309,677 m^2, which is equal to 1,044 2-lane km), multiplied by the annualized GHG emissions from Table 5, and then by the life cycle of 10 years.

3.1.2 *Economic assessment*

As part of the definition of sustainability, it is also important to look at the economics of the various preservation treatments. Table 7 illustrates the approximate cost associated with the preferred preservation technique (micro-surfacing) versus the traditional mill and overlay technique.

According to Table 7, micro-surfacing has an initial 53% construction cost savings when compared to mill and overlay on a m^2 basis. After factoring in the expected service life of the treatment, the annualized unit cost for micro-surfacing has a 34% cost reduction compared to mill and overlay on a m^2 basis. Based on the information from Table 1 and 7, the initial and life cycle cost savings are presented in Table 8 below. This is calculated by multiplying the micro-surfacing

quantity (from Table 1: 7,309,677 m^2) to the associated costs presented in Table 7. Please note the dollar figures have been rounded off, which may cause some discrepancy.

3.1.3 *Aggregate conservation assessment*

As part of the definition of sustainability, it is also important to assess the savings of natural resources in preservation treatments. Table 9 below illustrates the approximate aggregate tonnages associated with the preferred preservation technique (micro-surfacing) versus the traditional mill and overlay technique for a 2-lane-km highway.

Based on the information from Table 1 and 9, the initial and life cycle aggregate consumption quantities are presented in Table 10 below. This is calculated by multiplying the micro-surfacing quantity (from Table 1: 7,309,677 m^2, which is equal to 1,044 2-lane km) to the associated aggregate consumption presented in Table 9. Please note the quantities have been rounded off, which may cause some discrepancy.

3.1.4 *Summary of the quantified sustainability of micro-surfacing*

This is to summarize the environmental and economic benefits of applying micro-surfacing verse mill and overlay as discussed previously. Table 11 below shows the life cycle savings of using micro-surfacing for the past 10 years (2003 to 2012).

Therefore, from a life cycle perspective, if MTO were to have performed a traditional mill and overlay instead of micro-surfacing over the past 10 years, there would have been 28,642 tonnes additional CO_2 emissions released, more than $37.2 million additional cost, and 658,915 tonnes of additional aggregate consumed.

Table 8. Cost savings for using micro-surfacing vs. mill and overlay.

	Initial construction cost ($)	10 years life cycle cost ($)
	(Unit cost × quantity)	(Annualized unit cost × quantity × 10 years)
Mill & overlay (A)	110,303,026	110,303,026
Micro-surfacing (B)	51,167,739	73,096,770
Cost savings (A)-(B)	**59,135,287**	**37,206,200**

Table 9. Annualized aggregate consumption for micro-surfacing vs. mill and overlay.

Treatments	Weight (t)	Expected service life (yrs)	Annualized weight (t/year) (Weight/service life)
Mill and overlay	831	10	83.1
Micro-surfacing	140	7	20

Table 10. Aggregate savings for using micro-surfacing vs. mill and overlay.

	Initial aggregate consumption (t)	10 years life cycle aggregate consumption (t)
	(Weight × quantity)	(Annualized weight × quantity × 10 years)
Mill & overlay (A)	867,763	867,763
Micro-surfacing (B)	146,194	208,848
Aggregate savings (A)-(B)	**721,570**	**658,915**

Table 11. Life cycle savings for micro-surfacing vs. mill and overlay.

	CO_2 (t)	Cost ($)	Aggregate (t)
Mill & overlay (A)	37,593	110,303,026	867,763
Micro-surfacing (B)	8,951	73,096,770	208,848
Savings (A)-(B)	**28,642**	**37,206,256**	**658,915**

For comparison purposes, this savings in CO_2 emissions is equivalent to making a town with a population of 6,952 households carbon-neutral for one year.

4 CONCLUSION

There is an increased focus on sustainable asset preservation, both at the federal, provincial and municipal levels. Pavement preservation and in-place recycling rehabilitation treatments applied at the right time can significantly extend the pavement life and result in improved network performance over time.

Pavement preservation and in-place recycling processes are less disruptive to the travelling public, produce less GHG emissions, consume less energy and conserve materials. With a coordinated pavement preservation/in-place recycling program, the value of our road network investments will increase. Implementation of sustainable asset management principles and performance measures are critical to addressing our infrastructure investment requirements and environmental stewardship obligations over the long-term.

ABSTRACT: Aging induced embrittlement of the asphalt mixtures makes them more susceptible to cracking. The oxidation and embrittlement rates are the most rapid at the surface of the pavement where the asphalt is exposed to the traffic and various environmental factors. It is envisioned that applying a surface treatment may isolate the asphalt from the environment to some extent, and thereby delay the oxidative aging processes. Asphalt Institute and Minnesota DOT launched a research study to quantify the effect of chip seal on preserving the asphalt pavements. Field cores were taken from a test track which was initially constructed in 1999 in Minnesota. A chip seal layer was applied on different sections of the test track at 1, 2, 3, and 4-year time intervals after the construction. The field core specimens were subjected to IDT creep/strength, and DC(t) tests to evaluate the effect of chip seal and its optimum application time on the low-temperature cracking of the pavement. The overall results revealed that the application of the chip seal significantly decreased the rate of embrittlement of the asphalt layer. Furthermore, the optimum time of sealing was found to be immediately after construction of the pavement, and the advantageous effect of chip sealing diminished as the time of application was postponed to 3 years or longer after construction.

Keywords: asphalt pavement preservation; chip seal; performance testing; thermal cracking

1 INTRODUCTION

Development of an effective pavement management program requires a broad understanding of the maintenance and rehabilitation techniques. In the current practice, the type and timing of maintenance operations are typically determined by projecting the current conditions of the pavement to a common period and into the future [1]. In this approach, the current pavement conditions are assessed in terms of the surface distresses, structural capacity, ride quality, and surface friction. The results of such assessments are then projected over a period of time in terms of Present Serviceability Index (PSI), Pavement Condition Index (PCI), International Roughness Index (IRI), or some specific pavement distresses. As conceptually illustrated in Figure 1, the projection of the pavement conditions without a treatment serves as a baseline to identify the critical points for intervention.

Several surface treatment methods are used in pavement management programs. The goals of such treatments are to arrest light deterioration as well as delay or prevent progressive failures due to either load-related or environmentally-induced damages [2]. The concept of such preventative maintenance methods implies that the treatments should be applied before any visible distress can be observed. Therefore, the optimal timing of such treatments cannot be predicted based on the exiting distresses in the pavement. Furthermore, the benefits of

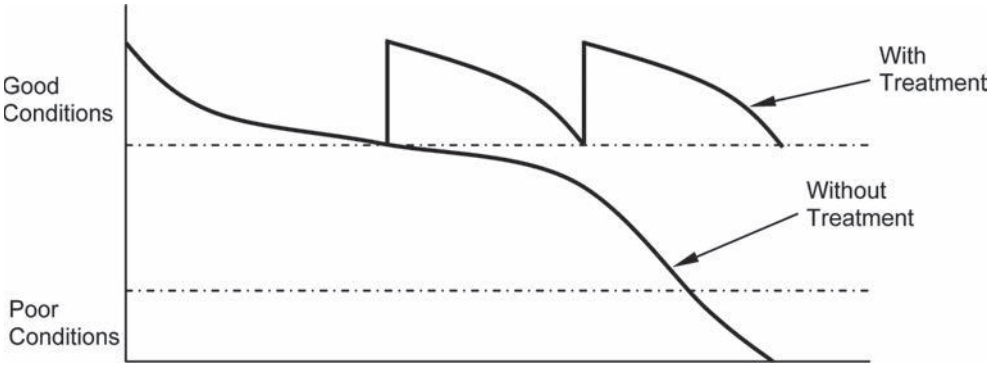

Figure 1. Conceptual approach for identifying proper timing of maintenance operations.

these surface treatments in preserving the performance properties of the pavements are not fully understood.

In cold climates, low-temperature cracking constitutes a major type of distress in asphalt pavements. These pavements become more susceptible to cracking as they age. Oxidation of the asphalt molecules, which gradually takes place over years, makes the asphalt material more brittle, and thus, more susceptible to cracking. At the pavement surface, where the asphalt is exposed to the traffic and environmental factors, the rate of aging is faster than in deeper layers. As a preventative maintenance practice, the surface of the asphalt pavement is coated with a thin layer of asphalt that can be mixed with some fine or coarse aggregate. It is believed that such a coating can reduce the rate of aging by restricting the supply of oxygen to the asphalt pavement, and reducing the permeability.

Chip seal is one of the most commonly used surface treatment techniques which is performed by spraying an asphalt coat on the pavement and covering the coat with aggregate (chips) followed by rolling and brooming [3]. The early uses of chip seal in 1920s predominantly involved making wearing courses on low-volume roads. Since then, chip seals have evolved into popular maintenance treatments due to their low initial costs when compared to thin asphalt overlays [4]. Most of the research studies on chip seals have focused on the durability of the seal coat, and its bond strength to the underneath layer [5–7]. However, the effect of chip seal coating on preserving the pavement performance is not fully known.

Asphalt Institute in cooperation with Minnesota Department of Transportation conducted a research study to gain a better insight into the benefits of chip seal coats on preserving the pavements in cold climates. The primary objective of the study was to optimize the application time of chip seal coating to maximize its preservative effects on the pavement. Furthermore, the effect of chip sealing on the thermal cracking performance of the studied pavement was quantified through laboratory testing. The results of this study could help highway agencies improve their pavement management systems. It is noteworthy to mention that in addition to reducing the aging rate, chip seal provides crack sealing as well as improves the surface friction of the asphalt pavement. This paper, however, only focuses on the performance of the asphalt layer beneath the seal coat.

2 MATERIALS AND EXPERIMENTAL PLAN

Highway 56 near Austin, Minnesota in the United States was used for the study. This is a 24-mile long rural highway with two lanes and an ADT of 2000. According to the LTPPBind database [8], the average high pavement temperature in the area is 52.1°C, and the average low pavement temperature is –23.2°C. The road was originally paved in 1999. Given the environmental and traffic conditions of the road, a PG 58-28 had been used in the mix design. To examine the effect of treatment time on the pavement performance, different sections of the

pavement were treated with a chip seal layer at 1, 2, 3, and 4-year intervals after the original construction. After applying the chip seal coat, a fog seal was applied to the pavement surface with CSS-1H emulsion which was diluted at 50:50 ratio with water, and spread at an application rate of 0.11 gal/yd^2. Furthermore, a section of the road was left without any treatment to be used as the control and comparison point for the other sections with chip seal treatment. In year 2011, several field cores were taken from the sections of the highway with various chip sealing time, and transported to the Asphalt Institute laboratory for testing. Table 1 presents the information about the cores used in the study as well as their treatment properties. As seen in this table, the notation used for each specimen group indicates the age of the pavement at which the chip seal treatment was applied. For instance, the T3 cores were taken from the section of the highway that was treated when the original pavement was three years old.

As a part of the study, some of the field cores were subjected to performance testing in order to assess the effect of chip sealing on the mechanical properties of the asphalt layer. To prepare the test specimens, the chip seal layer was cut from the top of the cores. The chip seal layer was distinguished from the main asphalt layer by visual examination of the side of the cores. The difference between the asphalt mixture and chip seal material creates a separation line between the two layers on the circumference of the core. After separating the chip seal layer, a disk shaped specimen was cut from the top of each core to be used for mechanical testing. This specimen was identified as the first 25-mm from the top as depicted in Figure 2. Next, another 25-mm thick specimen was cut from the top of the remaining part of the asphalt mixture cores. This specimen was labeled as second 25-mm from the top and represents the asphalt mixture materials below the surface layer (Fig. 2).

By cutting the cores into layers, the effect of aging could be studied as a function of depth as well as the treatment time. To examine the effect of chip sealing time on preventing the thermal cracking in the pavement, a laboratory test plan was developed which included three performance tests as follows: Disk-shaped Compact tension [DC(t)] fracture test, Indirect Tensile (IDT) creep compliance test, and Indirect Tensile (IDT) strength test. Moreover,

the three aforementioned tests were repeated for first 25-mm from the top specimens as well as the second 25-mm specimens to investigate the effect of aging at various depths of the asphalt layer. Before performance testing, the specimens were individually tested for bulk specific gravity to ensure that all of them have similar air void contents.

3 LABORATORY TESTING

3.1 *Disk-shaped compact tension fracture test*

Presence of cracks and flaws in an engineering material can substantially change its strength as well as cracking susceptibility. Disk-shaped Compact tension [DC(t)] test quantifies the resistance of an asphalt mixture to growing the existing cracks [9]. To make a DC(t) specimen, a notch is cut along a radius of a disk-shaped specimen. Additionally, two loading holes are cored at the two sides of the initial notch. The prepared specimen is then tested by applying a tensile load on the initial notch through the loading holes. The load is applied at a constant displacement rate, and the Crack Mouth Opening Displacement (CMOD) is recorded during the test. As the result of the tensile load, the initial notch grows into the specimen until the specimen fails. The fracture energy of the tested specimen is then determined by calculating the area under the load-CMOD displacement curve, and dividing it by the fractured area of the broken specimen. The DC(t) test method is standardized for asphalt mixtures under the ASTM D7313 [10].

In general, the mixtures with higher fracture energy would provide more cohesion and would have a better resistance to crack growth. Asphalt Institute utilized the DC(t) fracture test in a research study to evaluate the effect of environmentally-induced loads and aging on cracking of various asphalt pavements [11]. This research concluded that to prevent severe thermal cracking, a minimum fracture energy value of 350 J/m^2 is required for the mixture at 10°C warmer than its anticipated cracking temperature. This 350 J/m^2 value was employed as the minimum threshold requirement in this study to investigate the effect of chip seal on preserving the ductility of the pavement.

The DC(t) test was conducted on first and second 25-mm specimens from the top of the cores as depicted in Figure 2. After preparation, the specimens were conditioned at –24°C, which was 10°C higher than the lower temperature grade of the binder in this project, for at least three hours. The temperature of the specimens during the conditioning time was monitored using a dummy specimen with two thermocouples installed at its surface and its center. Figure 3 displays the fracture energy data for the field cores with various treatment times. Moreover, the fracture energy of the cores from the control section is depicted in Figure 3 with horizontal dashed lines.

Typically, the DC(t) test is conducted on 50-mm thick samples. In this study, however, the specimens were made at a thickness of 25 mm to account for the aging of asphalt at various depths. Testing 25-mm DC(t) specimens requires higher accuracy. That is, because the thickness of the specimen does not provide a plane-strain conditions, and the specimen fails at a much lower tensile load. Furthermore, reducing the specimen's thickness influences the obtained fracture energy. Wagoner and Buttlar [12] conducted a research to evaluate the effect of various specimen size parameters on the DC(t) fracture energy of asphalt concrete. The outcome showed that on average, the normalized fracture energy obtained with a 25-mm thick specimen is 41.3% lower as compared to a standard 50-mm specimen. Consequently, the 350 J/m^2 threshold for the fracture energy of 50-mm thick specimens may be reduced to 205 J/m^2 for 25-mm specimens. This adjusted threshold is shown by a solid black horizontal line in Figure 3.

For all sets of field cores, the average fracture energy of the first 25-mm from the top specimens was found to be lower than the second 25-mm specimens (Fig. 2). In other words, the field cores were more brittle at their surface. This finding agrees with the fact that the top part of the cores was more exposed to the environmental factors, which could accelerate the aging of asphalt. Figure 3 demonstrates a clear diminishing trend as the application of the chip seal was deferred to a much later time after the pavement construction. It should be noted that all the field cores were collected when the pavement was about 12 years old. At this age, the first 25-mm from the top specimens from the control section cores exhibited an average fracture

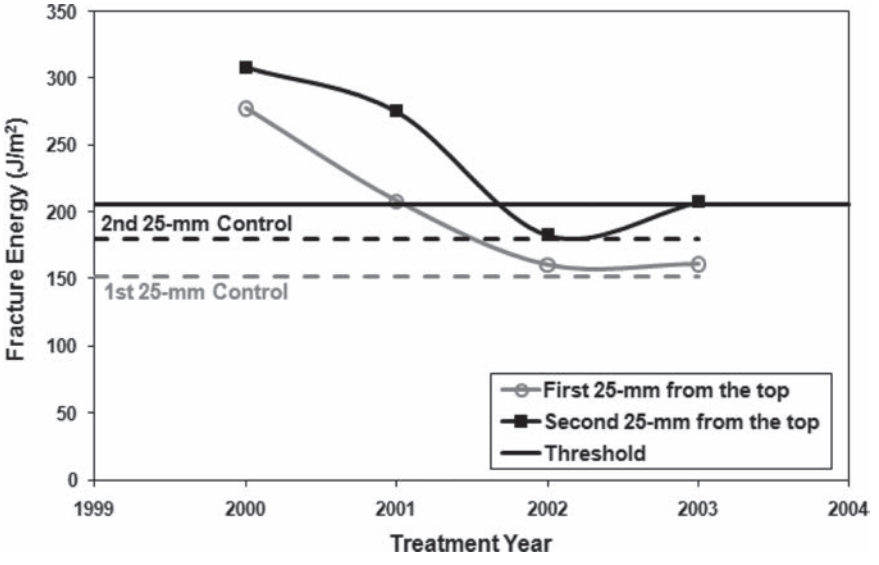

Figure 3. Average DC(t) Data at –24°C and comparison to the control section.

energy of 151 J/m^2. However, the samples from the sections that were covered by a chip seal layer one year after the pavement construction (T1 group in Table 1) had an average fracture energy of 277 J/m^2. As the chip sealing time was postponed to three years after pavement construction (T3 cores), the fracture energy of the field cores reduced to the same amount as the control section without any preventative protection (Fig. 3). In fact, in the first three years of pavement life, the oxidative aging and weathering had already embrittled the pavement to a degree that further protection would not help maintain its ductility.

Comparing the various fracture energy data in Figure 3 to the threshold line sheds more light on the effect of chip seal treatment on preserving the ductility of the pavement. The T1 and T2 cores, which were taken from the sections that were treated by a chip seal layer within 2 years of the original construction, proved to show higher facture energies than the minimum threshold (horizontal solid line in Fig. 3). Nonetheless, when the chip seal layer was applied three years or later after the construction time, the specimen's fracture energy was lower than the minimum threshold of 205 J/m^2. Thus, the chip seal application could have a protective benefit, which was large enough to prevent the excessive aging of the pavement.

A comparison of the DC(t) test load-vs-deformation data plots can better describe the difference between the responses of the samples with various treatment times. Figure 4 presents the fracture DC(t) data plot of one top 25-mm specimen from each treatment year. The DC(t) data plot for the specimen that was sealed in year 2000, one year after construction, exhibited a much higher peak load as compared to the control specimen with no sealing. This implies that the specimen had a much higher resistance to crack initiation. Furthermore, the horizontal stretch of the data plot indicates that the specimen had undergone a significantly lower embrittlement, and it provides a better cohesion as compared to the control specimen. The specimen which was sealed two years after construction (2001) still shows a high peak load; however, the horizontal stretch of its DC(t) data plot shows that it is more brittle than the specimen which was sealed one year earlier. Finally, the specimens that were treated in years 2002 and 2003 demonstrated very similar DC(t) data plots which were both close to the plot of the control specimen with no chip seal treatment.

3.2 *Indirect tensile creep and strength tests*

Asphalt is a viscoelastic material whose response to loading is a function of its temperature and the loading duration. At high temperatures, asphalt behaves similar to a viscous material

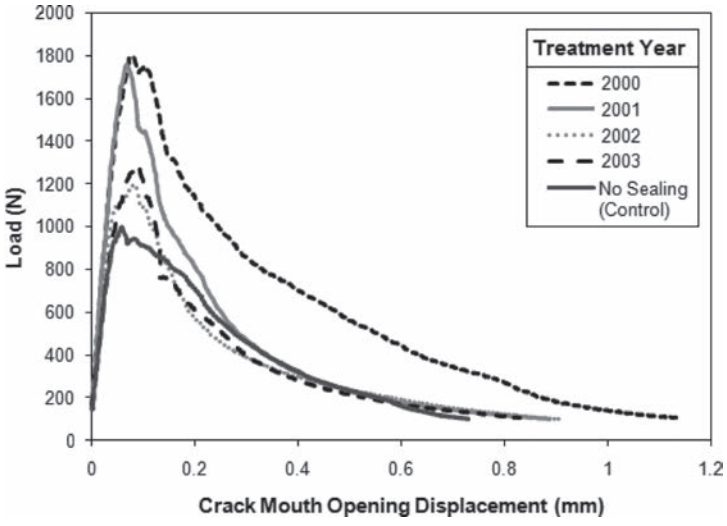

Figure 4. DC(t) data plots for the first 25-mm from the top specimens.

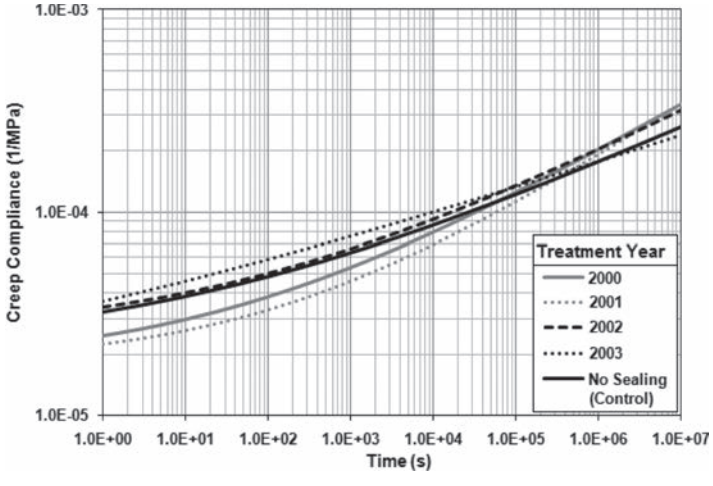

Figure 5. Creep compliance master curves of the first 25-mm from the top at –30°C.

with high stress relaxation properties. By lowering the temperature, asphalt becomes more brittle and its stress relaxation capability diminishes. It is vital for an asphalt pavement in a cold region to maintain its flexibility and stress relaxation property.

To examine whether or not the application of chip seal helped the asphalt pavement in this study preserve its flexibility, a set of IDT creep compliance test was conducted. In this type of test, a disk-shaped specimen in loaded compressively along a diameter. During the test, the deformation of the specimen is recorded using four extensometers, which are installed on the surface of the specimen in vertical and horizontal directions. Based upon the load and deformation data, the creep compliance of the specimen is then calculated along the test duration.

In this study, the creep compliance test was performed in accordance with the AASHTO T 322 standard method [13], and at three temperatures: –20°C, –30°C, and –40°C. At each temperature, triplicate specimens were tested for each sampling group. The creep compliance master curves were then developed by shifting the isotherm creep compliance curves and using the time-temperature superposition principle. Figures 5 and 6 present the final

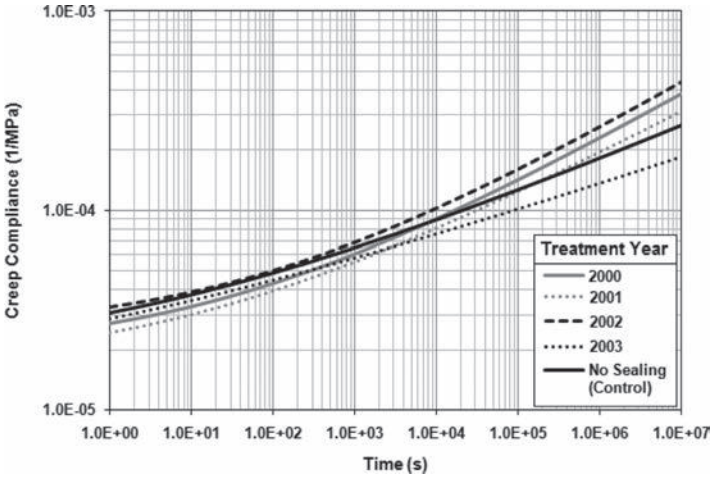

Figure 6. Creep compliance master curves of the second 25-mm from the top at –30°C.

Table 2. Slope of the stiffness curves at –24°C.

Specimen	Treatment year	Age at treatment time (years)	60-second loading		3600-second loading	
			Slope	Stiffness (MPa)	Slope	Stiffness (MPa)
First 25-mm from the top	2000	1	0.14	22247	0.18	11385
	2001	2	0.14	26710	0.19	13572
	2002	3	0.12	17277	0.15	9792
	2003	4	0.13	15817	0.15	8894
	No sealing (control)	N/A	0.11	18756	0.14	11118
Second 25-mm from the top	2000	1	0.15	18821	0.19	9449
	2001	2	0.15	20381	0.18	10414

	2003	4	0.11	19249	0.12	11940
	No sealing (control)	N/A	0.13	17684	0.14	10149

N/A = not applicable.

creep compliance master curves for the first 25-mm from the top and second 25-mm from the top specimens, respectively. In general, the stiffness of the mixture is inversely related to its compliance, and a higher creep compliance implies a more compliant mixture with lower stiffness. It was found that, the second 25-mm from top specimens showed a slightly higher compliance (lower stiffness) as compared to the first 25-mm specimens. This could be due to the faster oxidative aging of asphalt at the surface of the pavement.

The capability of a mixture in relaxing the rapid thermally induced stresses can be quantified by measuring the slope of its stiffness (or creep compliance) curve. Table 2 contains the slope of the creep compliance curves of different core groups at –24°C, which is 4°C above the lower temperature grade of the PG 58-28 asphalt binder. These slopes were calculated by fitting a polynomial function to the stiffness-time data at –24°C. All the fits had coefficient of determinations (R^2) higher than 0.9998. The stiffness curve slopes of the top specimens from the pavement sections that were sealed one or two years after construction, as seen in Table 2, were higher than the control section of the pavement. Thus, these sections are expected to have a better stress relaxation capability. However, by postponing the chip seal application to the third or fourth year after construction, the slope of the stiffness curve decreased very

slightly. In other words, delaying the chip seal application resulted in faster loss of relaxation capability of the pavement.

In addition to the creep compliance, the tensile strength of the field cores was measured by the indirect tensile strength test. As presented in Figure 7, deferring the application time of the chip seal had a deteriorating effect on the tensile strength of the field cores. On average, the tensile strength of the first and second 25-mm specimens from the top samples decreased by 0.25 and 0.21 MPa, respectively, with every one year delay in chip seal treatment of the pavement.

The tensile strength data can be used to estimate the critical cracking temperature of the pavement. Since the magnitude of the thermally-induced stresses depends on the rate of temperature drop, a similar cooling scenario was assumed for all the analyses. In this scenario, the cooling starts at 5°C and the pavement temperature continues to decrease at 2°C/hr. Additionally, a coefficient of linear expansion of 0.0002/°C was assumed for the calculation of the imposed stress in the pavement. In a stepwise process, the stress relaxation modulus for each core group was determined at each temperature and using the creep compliance data. The stress relaxation modulus was then utilized to calculate the accumulated tensile strain and the resulted tensile stress at each temperature step. Finally, the critical cracking temperature for each section of the pavement was calculated by comparing the thermally-induced stresses to the tensile strength of the pavement.

Figure 8 displays the effect of application time of chip seal on the critical cracking temperature of the pavement. The horizontal dashed lines represent the critical cracking temperature of the control section without the preventative chip seal layer. Except for the section that was sealed in 2003, the second 25-mm from top specimens from all the sections had lower critical cracking temperatures. This agrees with the data obtained from the fracture energy test and it implies that the deeper layers of the asphalt mixture experienced lower embrittlement and maintained a better flexibility. Furthermore, this analysis revealed that chip sealing had a positive effect on preserving the resistance of the mixtures to thermal cracking. As seen in Figure 8, a critical cracking temperature –27.2°C was obtained for the surface 25-mm layer that was covered with a chip sealed layer in 2000. Comparing this to the critical cracking temperature of the non-sealed control section (–19.9°C) indicates that the chip sealed layer helped preserve the performance of the pavement with respect to low-temperature cracking. In general, an increasing trend was observed in the critical cracking temperature as the sealing time was delayed after the original construction. In conclusion, if the purpose of chip

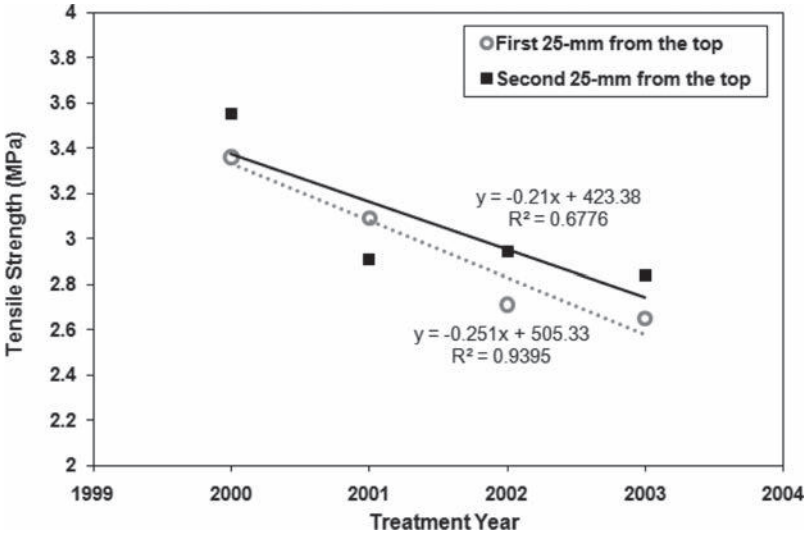

Figure 7. Average tensile strength of the cores with various chip sealing time.

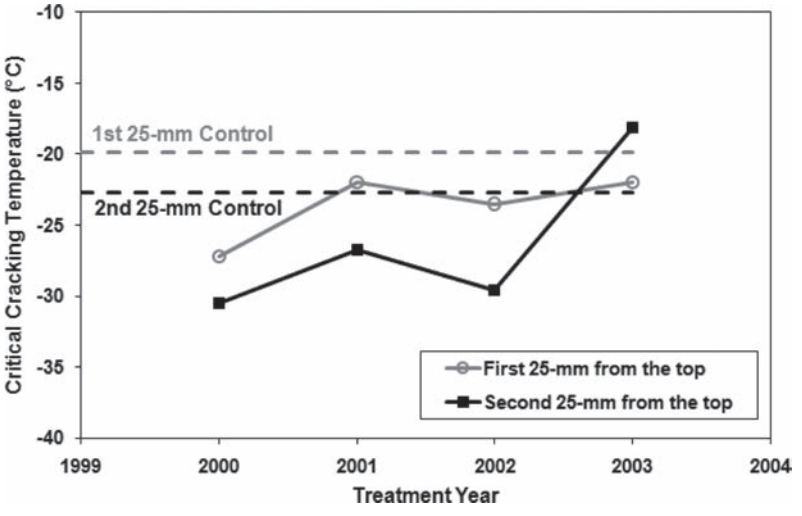

Figure 8. Critical cracking temperatures from IDT creep and strength tests.

sealing is to preserve the cracking performance of the pavement, it is better to be applied during the first year after the pavement construction.

4 SUMMARY AND CONCLUSIONS

An experimental study was conducted to evaluate the effect of chip sealing on preserving the low-temperature cracking performance of asphalt pavements. A pavement in the state of Minnesota, USA was used for the study, which was originally constructed in 1999. A chip seal layer was applied on 1-mile sections of the pavement at 1, 2, 3, and 4-year time intervals after the construction. In 2011, field cores were collected from all the sections with chip seal as well as the control section, which had no treatment. At the Asphalt Institute laboratory, the chip seal layer was separated from the top of the cores and two 25-mm thick disk-shaped specimens were cut from the top of each core. To investigate the low-temperature cracking performance of the pavement with various sealing times and at various depths, the fabricated specimens were subjected to DC(t) fracture energy test, IDT creep compliance test, and IDT tensile strength test.

The fracture energy test results indicated that application of the chip seal layer helped the pavement maintain its ductility and cohesion. The fracture energy data obtained from the first 25-mm from the top of the cores were consistently lower than the values obtained from the second 25-mm layer beneath the surface. Furthermore, the sections which were seal coated one year after the construction exhibited the highest fracture energy. As the chip seal treatment time was postponed, the fracture energy diminished, and after 3 years, it declined to the same level as the control section without any seal coats.

The IDT creep test was conducted at –20°C, –30°C, and –40°C, and the master creep compliance curves were developed for various sections of the pavement. The analysis on the slope of the creep compliance curves showed that the sections with earlier treatment had a better ability to relax the stresses imposed by sudden temperature drops. The field cores were also tested for tensile strength using the IDT test. The results showed that on average, the tensile strength of the first 25-mm specimens from the top of the pavement decreases by 0.25 MPa for every year of delay in applying the chip seal layer. Moreover, the critical cracking temperature of the various pavement sections was estimated by assuming a temperature cooling scenario. The general trend of the critical cracking temperature data agreed with the results from the DC(t) fracture energy test. Again, tensile strength findings indicate that

deferring the application of chip seal to three years or longer after pavement construction, would diminish the beneficial effects of chip seal. Based upon the findings of this research it could be concluded that if the goal of chip seal treatment is to preserve the low-temperature cracking performance of the pavement, its optimal time of application is during the first year after the construction.

ACKNOWLEDGEMENTS AND DISCLAIMER

The authors wish to thank Zack McKay at Asphalt Institute for his work in preparing samples for this study. No project can be started without the preparation of samples. This material is based upon work supported by Minnesota DOT as a part of the project TPF-5(153), "Optimal Timing of Preventive Maintenance for Addressing Environmental Aging in Hot-Mix Asphalt Pavements". Thanks to Tom Wood, Minnesota DOT, as Research Project Manager, and Mike Anderson, Director of Research and Laboratory Services at Asphalt Institute. Asphalt Pavements – Kim (Ed)

Final evaluation of LTPP SPS-3 flexible maintenance performance

Dennis Morian & Guangming Wang
Quality Engineering Solutions Inc., Conneaut Lake, PA, USA

Doug Frith
Quality Engineering Solutions Inc., Reno, NV, USA

ABSTRACT: The paper addresses the final performance of LTPP SPS-3 maintenance treatment test sections. The evaluation of SPS-3 monitoring data, with some sections having over 13 years of performance information, was undertaken to assess performance predictions made by the primary author in "Maintaining Flexible Pavements—The Long Term Pavement Performance Experiment SPS-3 5-Year Data Analysis," published in March 1998. A similar distressed based evaluation of the treatments, thin overlay, chip seal, slurry seal, and crack seal, and untreated control section has been used. However, since sections have continued to fall out of service over time, a survivor analysis approach has been used here. Results of the survivor analysis confirm the reasonableness of the original performance estimates.

The authors were able to successfully evaluate deflection data after many years of data collection to assess the effect of the treatments on preserving the stiffness of the pavement sections, as compared with the control sections. This could not be accomplished in the original 5 year analysis. Results indicate that the stiffness response associated with the treatments provided improvement when compared with the stiffness of the associated control section. This relative deflection reduction is believed to impact the overall performance of the test sections.

Keywords: chip seal, slurry seal, thin overlay, crack seal, survivor analysis, pavement performance

1 BACKGROUND

The importance of pavement preservation as a tool for maintaining pavements economically has been well recognized. A synthesis by Geoffroy [1] postulated that each dollar invested in preventive maintenance at the right time in the life of a pavement may save $3-$4 in future rehabilitation or reconstruction costs. However, the actual benefit of these treatments is not well documented. Further, when and what kind of surface maintenance treatments should be applied to the existing pavements presents challenges for highway agencies, which historically have relied heavily on past experience and engineering judgment. To advance the state of knowledge, the Strategic Highway Research Program (SHRP) initiated two projects with focus on flexible pavement maintenance. Project H-101, Pavement Maintenance Effectiveness, and an experiment constructed under the Specific Pavement Studies-3 (SPS-3) were designed under the SHRP program. The SPS-3 experiment was specifically intended to address performance of surface maintenance activities used on flexible pavements. A total of 81 test sites were constructed across the United States and Canada in 1990 to capture the effects of different climate zones, subgrade types, traffic levels, and pavement conditions. Four common surface treatments, thin overlay, slurry seal, crack seal, and chip seal, were applied at each test site, and their performance has been monitored along with that of the adjacent control section which remained untreated. Numerous assessments of portions of the SPS-3 test sites have been made.

Smith *et al*. [2] implemented a sigmoidal (S-shaped) model to perform pavement damage analysis. In general, each type of pavement distress can be expressed as a damage index between zero and one, where zero indicates no damage and one indicates full damage. This model set the base for remaining life analysis used in developing the AASHTO 1993 design guide.

Morian *et al.* [3] conducted a 5-year expert task group evaluation of SPS-3 performance and concluded that the thin overlay performed best after five years relative to other treatments. The chip seal treatment performed best in the wet-no freeze environment in the Southern region. The crack seal treatment appeared to be very cost effective, as compared with the chip seal, and performed well in wet-freeze environments. A year later in 1998, Morian *et al.* [4] used multiple regression analysis to develop performance prediction models for distress (cracking and rutting) using a distress index called Pavement Rating Score (PRS).

Eltahan *et al.* [5] performed survival analysis on the 8-year SPS-3 sites in the LTPP Southern region to determine the life expectancy of each treatment. The results showed that the probability of failure was two to four times higher for sections that were in poor condition at the time the treatment was applied than those sections that were in a better condition. Chen *et al.* [6] evaluated the effectiveness of preventative maintenance treatments using 14 SPS-3 sites in Texas. Their study revealed that the thin overlay is the most effective treatment to resist rutting, and that the chip seal performed well on a wide range of existing pavement conditions. They also found that crack seal provides the best alternative for low volume routes with a sound underlying pavement structure, when initial cost was considered. Shirazi *et al.* [7] conducted a statistical analysis to compare the effectiveness of each treatment in relation to the others and the control section. These researchers concluded that the thin overlay and chip seal treatments are effective options with respect to fatigue cracking for most design conditions. The difference in the performance of crack seal, slurry seal, and control section was not found to be statistically significant with respect to any distress type, or design factor.

Although numerous studies have been conducted to study the performance of the treatments in SPS-3 experiment, most of them have been limited geographically or by the length of monitoring period, such as five years. This paper considers the complete set of SPS-3 monitoring data, i.e., includes all regions and monitoring data since 1990. In addition, the effect of the preservation maintenance treatments through the life of the treatments was evaluated.

2 OBJECTIVE

The primary objective of this study is to evaluate the life expectancy and benefit to maintaining structural stiffness of the SPS-3 treatments. The following tasks were conducted:

- Conduct pavement condition analysis based on Pavement Rating Score (PRS).
- Perform Kaplan–Meier Survival Analysis to assess life expectancy of the treatments in the SPS-3 experiment.
- Evaluate FWD deflection data in the SPS-3 experiment.
- Perform Friedman Test to evaluate the structural contribution of the treatments in the SPS-3 experiment.

3 SCOPE

The research conducted in this study focused on evaluating treatment performance life in terms of the PRS distress index and structural benefit in terms of FWD deflection under the load. All data were obtained from the on-line LTPP database (http://www.ltpp-products.com/index.asp).

4 PERFORMANCE LIFE OF THE SPS-3 TREATMENTS

4.1 *Pavement condition analysis*

To determine the performance life of the SPS-3 treatments it was necessary to determine the condition of each test section. Pavement condition data dating back to 1990 was obtained from the LTPP database. All distress data such as cracking and patching were collected in a table and converted to the single distress index, Pavement Rating Score (PRS), as used in the original SPS-3 5-year Evaluation. The PRS approach was developed for the analysis of LTPP SPS-3 sections by Morian's team [4]. This method is based on a scale of 0 to 100 with deduct values assigned to individual distresses and severity levels. A pavement with no distresses present would have a PRS score of 100; the value decreases with increasing distress.

4.2 *SPS-3 treatment performance life tracking*

To determine the performance life of the SPS-3 treatments, a failure threshold PRS value of 50 was defined in the 1998 study and used in this work as well. However, one of the biggest problems with SPS-3 experimental data is that many of the test sections were not monitored until failure. These sections were removed from the experiment before they reached the failure condition for a variety of reason, making determination of the performance life of the treatments difficult. Therefore, the research team decided to identify the sections that were removed from the experiment, failed, or survived after some number of years. Incremental performance tracking was arbitrarily set at years 3, 5, 8, and 11. To better illustrate this concept, the thin overlay treatment is provided as an example, as shown in Figure 1. For instance, after three years in service, 50 of 81 sections survived (designated as SV), 5 sections failed (designated as FA), and 26 sections were out of the monitoring program (designated OM). After 11 years, only 2 sections survived, 18 sections failed and 61 sections were out of the monitoring program.

4.3 *Kaplan–Meier survival analysis*

As stated early, one of the biggest problems with the SPS-3 experiment is that not all sections were monitored until they reached failure. Obviously, for those sections not monitored until failure, their exact survival time cannot be determined. Such sections are treated as censored data from the perspective of survival analysis. Fortunately, the Kaplan-Meier sur-

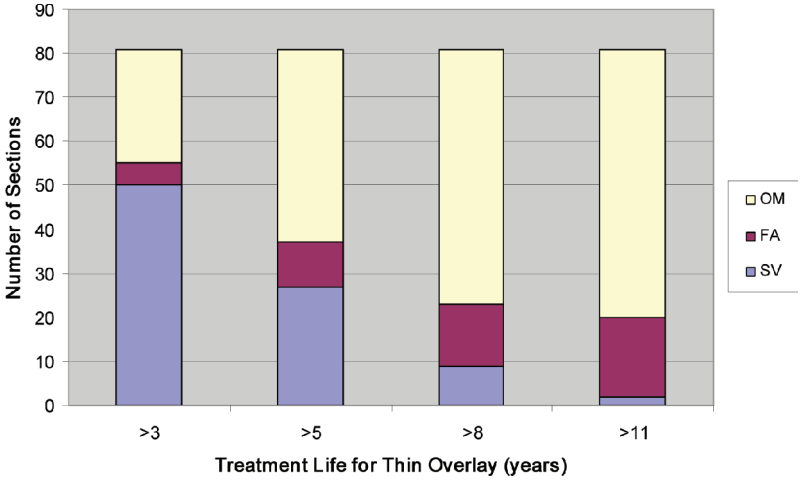

Figure 1. Performance life tracking for thin overlay.

vival analysis can take this kind of censored data into account, particularly right-censoring, which occurs if a section is withdrawn from a study, i.e., is lost from the sample before the final outcome is observed. This approach makes the life determination of the treatments possible. A brief introduction to Kaplan-Meier method is presented below, with details in the literature [8,9].

Let T be the random variable that measures the time of failure and let $F(t)$ be its cumulative distribution function. The survival function $S(t)$ can be expressed as:

$$S(t) = P[T > T] = 1 - P[T \leq t] = 1 - F(t) \tag{1}$$

where, $S(t)$ can be estimated through the Kaplan-Meier estimator:

$$\hat{S}(t) = \prod_{t_i \leq t} \frac{n_i - d_i}{n_i} \tag{2}$$

where, d_i is the number of death events. n_i is the number of survivors just prior to time t_i when there is no censoring. With censoring, n_i is the number of survivors less the number of losses (censored cases). It is only those surviving cases that are still being observed (have not yet been censored) that are "at risk" of an (observed) death.

Based on the above method, the estimated survival probabilities were plotted against the corresponding survival times. The survival curves developed from the SPS-3 experiment data are presented in Figures 2 through 5, with each figure representing a specific maintenance treatment. In each figure, a survival curve was developed based on each original pavement condition. As observed from the figures, the sections in good condition at the time of treatment placement always perform better than either fair or poor conditions for all treatments. However, it is not clear whether sections with a fair initial condition outperform the sections with poor initial condition due to lack of observed "death" events in either the fair or poor conditions. This affects modeling of fair pavement condition performance. Therefore, an average curve that combined all three original pavement conditions was developed for each treatment and is also shown in Figures 2 through 5.

To compare the life expectancy of different treatments, a polynomial curve fitting for each treatment based on the average survival curve was developed using the following format:

$$y = ax^2 + bx + 1 \tag{3}$$

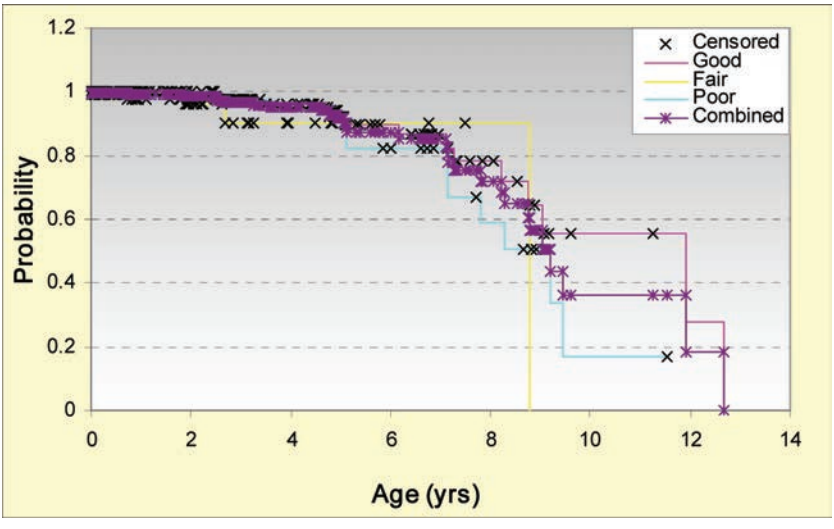

Figure 2. Survival curve for thin overlay.

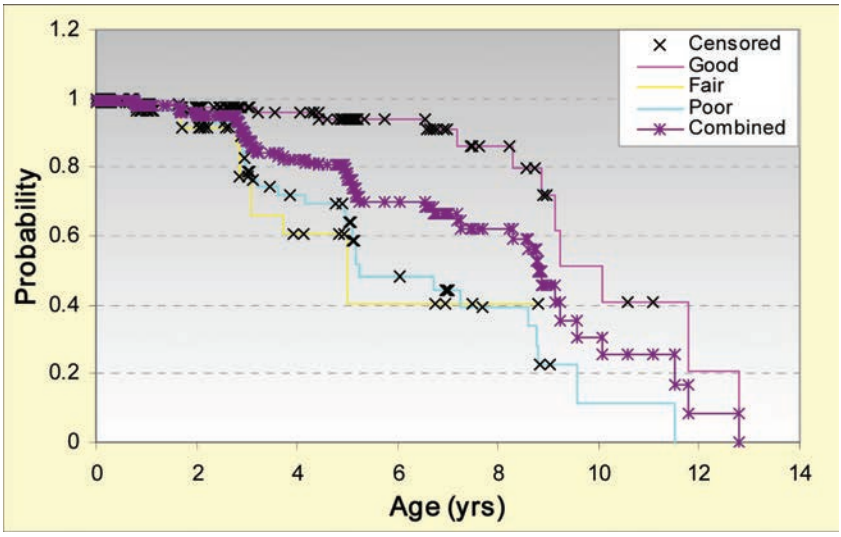

Figure 3. Survival curve for slurry seal.

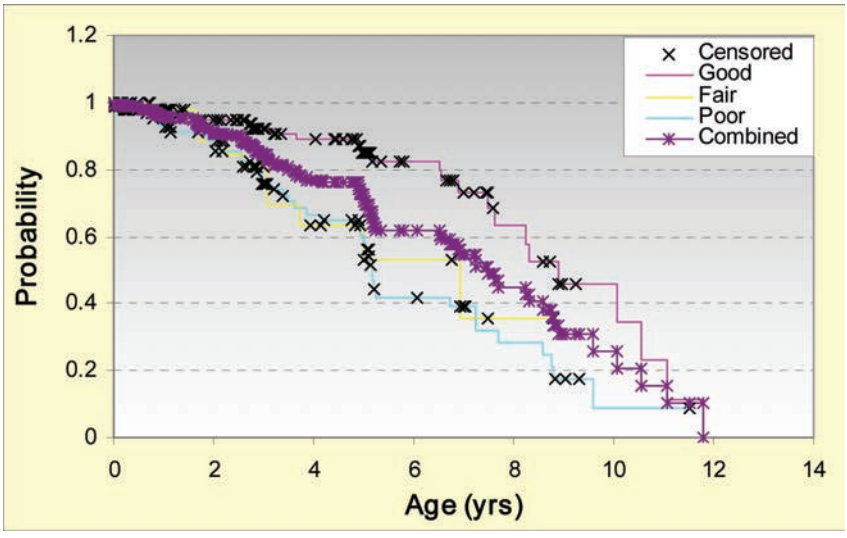

Figure 4. Survival curve for crack seal.

The coefficients, *a* and *b*, for each treatment, as well as their corresponding R squares are summarized in Table 1. Based on the curve developed for each treatment, the life expectancy at three levels of survival probability, namely 0.8, 0.6, and 0.5, was calculated and also summarized in Table 1.

From Figures 2 through 5 and Table 1, the following observations can be made:

- At a high probability of survival (>0.7), the thin overlay performs best, followed in order by chip seal, slurry seal, crack seal, and control section.
- At a low probability of survival (≤0.7), the chip seal performs best, followed in order by thin overlay, slurry seal, control section, and crack sealing.

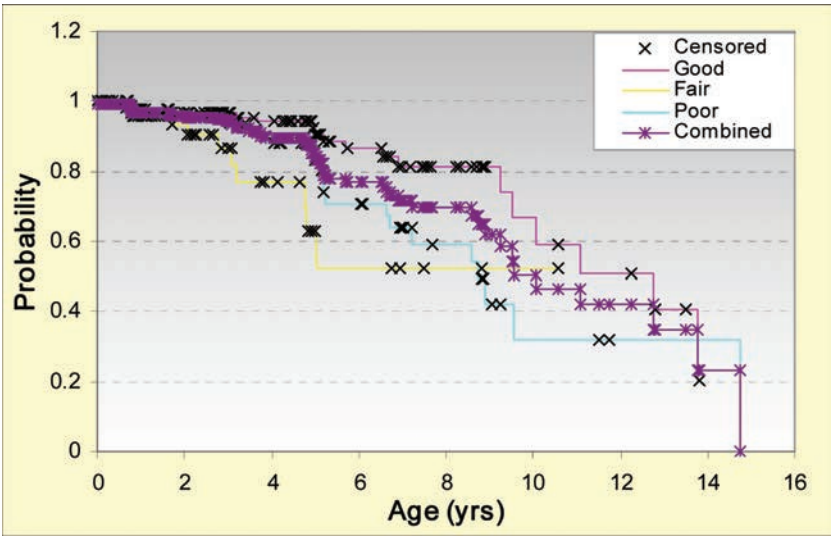

Figure 5. Survival curve for chip seal.

Table 1. Statistical results for survival analysis.

Treatment type	Treatment code	a	b	R^2	Survival probability	Estimated life (yrs)
Thin overlay	310	–0.0072	0.0216	0.9646	0.8	7.0
					0.6	9.1
					0.5	10.0
Slurry seal	320	–0.004	–0.0239	0.9803	0.8	4.7
					0.6	7.4
					0.5	8.6
Crack sealing	330	–0.0034	–0.0426	0.9927	0.8	3.6
					0.6	6.3
					0.5	7.4
Control section	340	–0.0009	–0.0601	0.9846	0.8	3.2
					0.6	6.1
					0.5	7.5
Chip seal	350	–0.0027	–0.0179	0.9795	0.8	5.9
					0.6	9.3
					0.5	10.7

- At 0.5 survival probability, the life expectancy for the thin overlay, slurry seal, crack sealing, control section, and chip seal were 10.0, 8.6, 7.4, 7.5, and 10.7 years, respectively, which agrees well with the ETG estimates from the SPS-3 5-year report [4].
- Compared with the control section, the life benefit for crack sealing is not significant, based on the PRS distress analysis. This is expected, since the distresses are quite similar for the two sections, by definition.

From a practical perspective, the above observations indicate that performance of the treatments can be related to the owner's level of risk associated with the roadway classification. For high profile roads where the objective is to minimize the risk of underachieving the expected performance, the high probability ranking is appropriate. For lower road classifications where higher risk of performance is acceptable, the lower probability ranking of performance is better suited.

5 STRUCTURAL CONTRIBUTION OF TREATMENTS

It has generally been believed that preservative maintenance treatments do not contribute significantly to the structural capacity of a pavement. Although this may be true for some treatments such as crack sealing, it might not be the case for other treatments like the thin overlay. The structural contribution of the treatments in SPS-3 experiment was evaluated on the basis of the complete set of monitoring data. A comparison of the change in deflection under load over time was used to assess the structural contribution of the treatments in SPS-3 experiment. The D_0 deflection values were adjusted for temperature at the time of testing, and the change in deflections over time compared for the several treatments.

5.1 *FWD data processing and temperature adjustment*

Since a large amount of FWD test data exists in the SPS-3 experiment database, the following steps were adopted to process the data:

- Normalize all FWD deflection data to a 40 kN load
- Average the deflection data across the 152 meter test section.

Deflections were normalized to a 40 kN load using the following equation:

$$\bar{D}_0 = \frac{40}{F} D_0 \tag{4}$$

where, F is the actual FWD testing load in kN.

Since the FWD data collection time varied throughout the year, deflection results were adjusted to account for the seasonal and temperature effects. Over the years, a number of methods have been developed to measure the asphalt temperature and to adjust the deflection results for the effects of temperature. Lukanen *et al.* [10] developed a method to calculate Temperature Adjustment Factors (TAF) for FWD tests based on data from the LTTP Seasonal Monitoring Program (SMP), which was adopted in this study. This method of calculating temperature adjustment factors accounts for the strength of the subgrade and for the different asphalt behavior that has been correlated with the site latitude. All the average deflection data were adjusted to a 20° C reference temperature using this method, and the following equations [10]:

$$\bar{D}_{0-ref.Temp.} = TAF \times \bar{D}_{0-Meas.Temp.} \tag{5}$$

$$TAF = \frac{D_{36} + \Delta_{36-ref.Temp.}}{D_{36} + \Delta_{36-Meas.Temp.}} \tag{6}$$

$$\begin{aligned} \log(\Delta_{36}) = {} & 3.05 - 1.13\log(H_{AC}) + 0.502\log(\theta)\log(D_{36}) \\ & - 0.00487T\log(\theta)\log(D_{36}) + 0.00677T\log(H_{AC})\log(\theta) \end{aligned} \tag{7}$$

where,
H_{AC} = Total thickness of the HMA, mm;
θ = Latitude of the pavement section;
Δ_{36} = Deflection (normalized to 9,000 lb or 40 kN) at 915 mm from the load center, μm;
T = Temperature at the mid-depth of the HMA, °C.

Figures 6 and 7 show a typical comparison of FWD deflections before and after the temperature adjustment. As observed, the deflection curves become smoother after this seasonal adjustment.

5.2 *Contribution to preservation of pavement structure*

To test whether the treatments in the SPS-3 experiment have any structural effect on the pavement, the Friedman Test [11,12] was utilized. The Friedman Test was adopted because

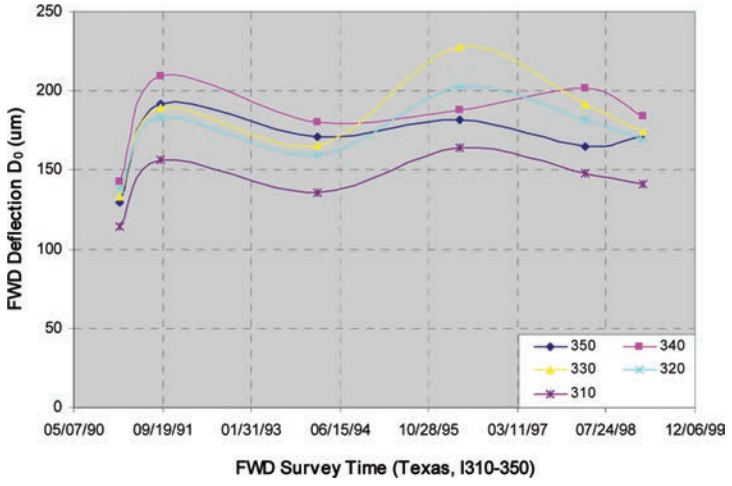

Figure 6. FWD deflections before temperature adjustment.

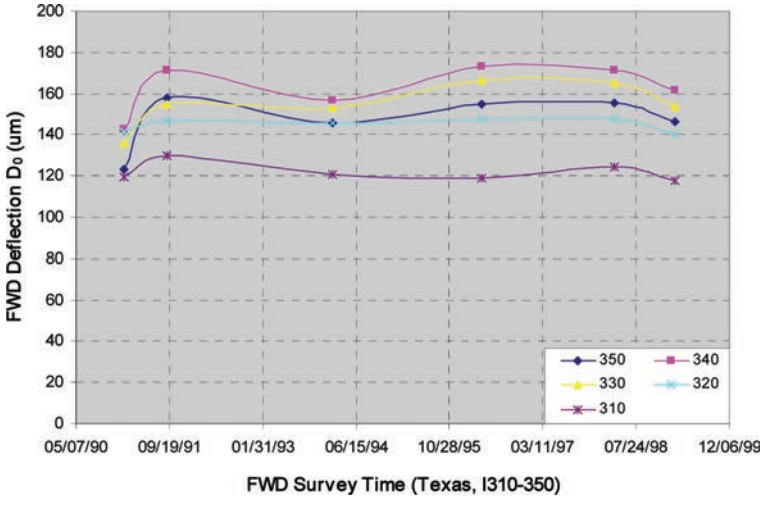

Figure 7. FWD deflections after temperature adjustment.

it is a non-parametric test and can be used for multiple comparisons. Unlike the parametric repeated measures ANOVA or paired t-test, the Friedman Test requires no assumptions about the distribution of the data. In addition, it not only detects the differences in treatments across multiple test sections, but also ranks the performance of the treatments, making it well suited for use in this study. The test statistic for the Friedman Test is a Chi-square (χ^2) with n-1 degrees of freedom, where n is the number of repeated measures.

The effect of the preventive maintenance treatments on the structural capacity of the pavement sections was compared with that of the control sections, as well as among the different treatment types. A total of nine test sites from different climate zones, each with five treatment sections, were randomly selected for the Friedman Test. This resulted in 45 different FWD measures, as reported in Table 2. As shown in Figures 6 and 7, the change in deflection magnitude is small. Therefore, this comparison is relative, and does not imply that the treatments provide significant structural enhancement to the pavement structure.

As shown, there is a statistically significant difference among treatments at the 95% confidence level. The thin overlay had the lowest sum of ranks, followed by slurry seal,

Table 2. Friedman test results of deflection D_0.

Compare pairs	n	Rank sum	Mean rank	Friedman's statistic	DF	p	Significant at 95% level?
Thin overlay	45	56	1.24	80.3	4	<0.0001	Y
Slurry seal	45	133	2.96				
Crack sealing	45	158	3.51				
Control section	45	181	4.02				
Chip seal	45	147	3.27				

Head to head Friedman test	Difference	Friedman's statistic	DF	p	Significant at 95% level?
Crack sealing vs. control section	7	1.09	1	0.2967	N
Chip seal vs. control section	19	8.02	1	0.0046	Y
Slurry seal vs. control section	23	11.76	1	0.0006	Y
Thin overlay vs. control section	43	41.09	1	<0.0001	Y

chip seal, crack sealing, and control section. Here, a lower sum of ranks indicates better contribution in preserving structural capacity, which means the thin overlay has the highest contribution and crack sealing has the lowest contribution when compared with the control section.

A direct comparison between each treatment section and the control was made using the Friedman Test, using deflection as the basis of comparison. The results indicate that all treatments, except for crack sealing, provide statistically significant benefit in the form of preserving pavement structural capacity as measured by the deflection magnitude. The difference between each treatment and the control section was expressed in terms of a rank sum difference. A comparison of the rank sum difference values provides a means of further quantifying the individual treatment benefit to maintaining pavement structural capacity. As shown in Table 2, thin overlay provides about six times the benefit to the pavement structural capacity of crack sealing, and about two times more than both slurry seal and chip seal. Compared to crack sealing, both slurry seal and chip seal could provide approximately three times more benefit to pavement structural capacity as expressed in terms of rank sum difference. Although there is no significant difference between crack sealing and the control section, crack sealing still provides benefit to pavement structural capacity as expressed by the lower rank sum. This can be explained by the mechanism by which crack sealing helps prevent water from entering the pavement, resulting in reduced loss of subgrade support.

From a practical perspective, the relative reduction in deflection as compared with the control section for the treatments are 9% for crack seal, 11% for chip seal, 17% for slurry seal, and 29% for thin overlay.

6 CONCLUSIONS

Based on a statistical analysis of performance life and structural benefit of the treatments in the SPS-3 experiment, the following can be concluded:

- Performance life tracking indicated that chip seal and thin overlay have similar performance life and outperform both crack seal and slurry seal as shown by more survival sections and fewer failure sections within each tracking period.
- Kaplan–Meier survival analysis indicated that test sections with good initial condition always perform better than either fair or poor conditions for all treatments. However, there is no clear distinction indicating whether fair condition sections outperform poor condition sections as a result of insufficient observed "death" events in these categories.

- At a high probability of treatment survival (>0.7), the thin overlay performs best, followed respectively by chip seal, slurry seal, crack sealing, and the control section. This is appropriate for higher roadway classifications. At a lower probability of treatment survival (≤0.7), the chip seal performs best, followed by thin overlay, slurry seal, control section, and crack sealing. This performance expectation is suitable for use on lower classification roadways.
- At 0.5 survival probability, the life expectancy for thin overlay, slurry seal, crack sealing, control section, and chip seal were found to be 10.0, 8.6, 7.4, 7.5 and 10.7 years, respectively. These results agree well with the ETG estimates from SPS-3 5-year report conducted by Morian's team [4].
- Compared with the control section, the life benefit of crack sealing is not significant as determined from the PRS distress data analysis.
- The analysis indicated statistically significant benefit in preserving pavement structural response from all the treatments except crack sealing. This differs from the perspective that the pavement preservation treatments do not enhance pavement structure, but rather demonstrates the effect of maintaining the structural response of the pavement section over time. From a practical perspective, the relative reduction in deflection as compared with the control section for the treatments are 9% for crack seal, 11% for chip seal, 17% for slurry seal, and 29% for thin overlay.

ACKNOWLEDGEMENT

The authors would like to express our thanks to Mr. William Bellinger for his assistance in providing us with a complete set of the monitoring data for the sections included in the SPS-3 Experiment.

RAVAN Construction Company, Tehran, Iran

ABSTRACT: Major distresses on the pavement of Ardebil-Khalkhal main road in North-East of Iran caused an immediate pavement rehabilitation process to be planned. Among the different rehabilitation methods, cold in-place recycling technique, using foam-bitumen and cement slurry, was selected to be applied on a 5 Km length of this route.

Using a cold in-place recycling machinery chain, the top layers of the pavement, including Hot Mix Asphalt (HMA) and part of unbound existing sub base layer, were milled and were mixed together applying foam-bitumen and cement slurry and hydrated lime powder. Finally, an HMA layer was laid over to form the final pavement surfacing.

A mix design analysis was carried out using Indirect Tensile Strength (ITS) and Marshall testing. ITS was performed on both dry and conditioned samples and tensile strength ratio parameter was determined. The results indicated that increased mechanical properties were achieved in foam-bitumen and cement recycled layer.

Quality control testing results shows that the applied mix design and cold recycling method was appropriate to rehabilitate this road.

Keywords: Cold in place recycling, stabilization, foam bitumen, Indirect Tensile Testing

1 INTRODUCTION

Ardebil province is located in a mountainous area in North-East of Iran (Fig. 1). The climate conditions are variable in this area. For example, Ardebil city has cold and wet winters and mild summers while Bilesavar and Parsabad cities have warm summers and mild winters.

Ardebil-Khalkhal road is the main route connecting two major cities of Ardebil Province. Sever climatic conditions of the region, poor pavement conditions; including insufficient bearing capacity, improper cross falls, existence of high portion of fine materials in the sub-base layer and shoulders and inadequate drainage system; resulted in sever distresses in the existing pavement. There for rehabilitation of this main road with length of 30 km and width of 7 m was planned. Different methods were proposed for rehabilitation of this route that are summarized as below:

A—Existing HMA patching and overlaying with new HMA layers,

B—Pavement renovation applying a new granular base course and new HMA layers,

C—Cold recycling of existing HMA layer using foam bitumen and cement slurry.

Among the above mentioned rehabilitation methods, cold in-place recycling technique, was chosen and applied along 5 Km length of this main road.

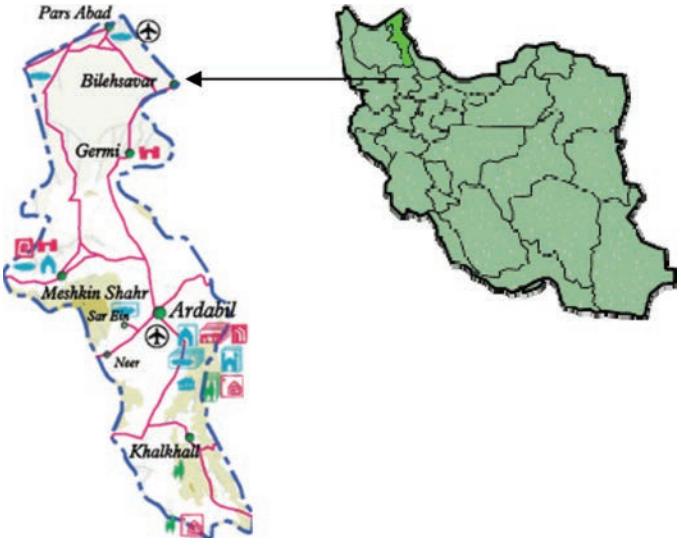

Figure 1. Road project location.

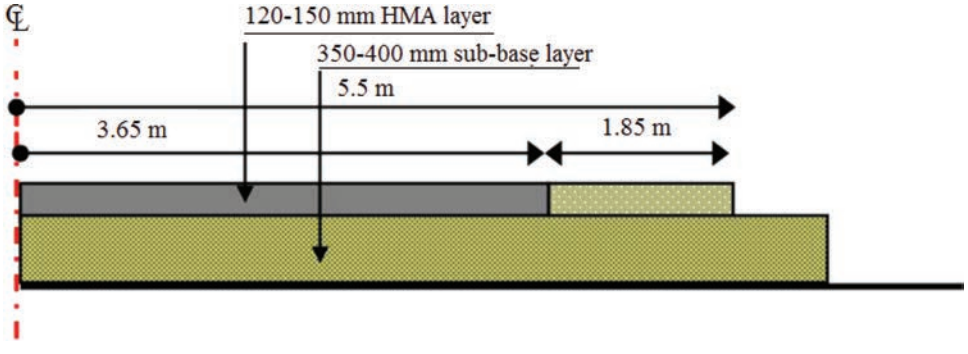

Figure 2. Existing pavement cross section.

2 EXISTING CONDITION

Typical cross section of Ardebil-Khalkhal main road before rehabilitation is shown in Figure 2. The major pavement distresses in this road could be summarized as it follows:

- Alligator cracking due to insufficient bearing capacity of the pavement,
- Non uniform longitudinal profile and rutting,
- Longitudinal and transverse cracking,
- Thermal and fatigue cracking developed due to low winter temperatures,
- Shoulder settlement in some sections and shoulder blow up in other areas.

3 REHABILITATION METHODS

3.1 *Method A: Asphalt patching and overlaying*

According to design requirements, rehabilitation method A included patching of the existing HMA layer and then, overlaying 160 mm of new HMA layer (in three layers) as shown in Figure 3. Due to unsuitable conditions of the sub-base layer such as existence of fine materi-

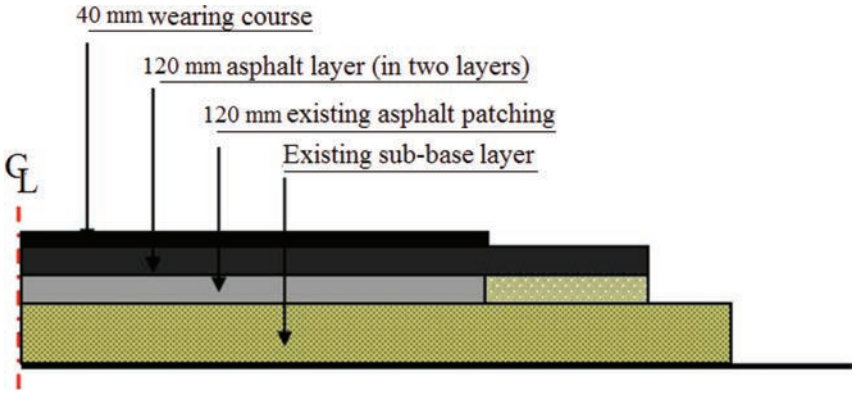

Figure 3. Repaired road cross section using method A.

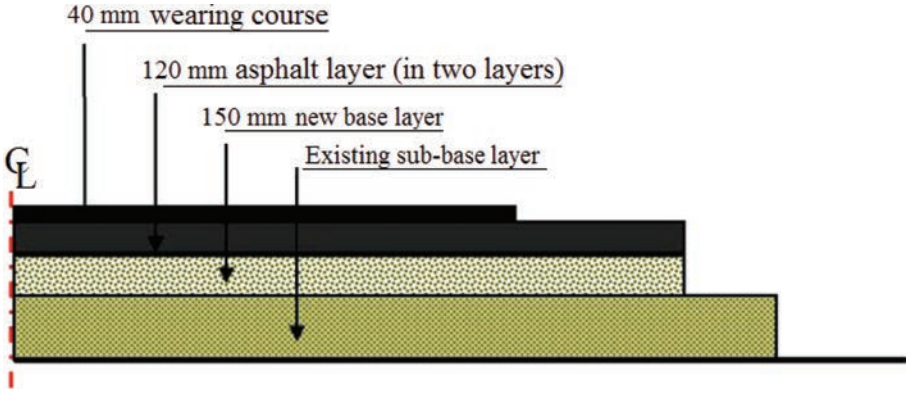

Figure 4. Repaired road cross section using method B.

als in the layer and insufficient layer compaction, and also large required patch working area (about 40% of the total area), the new pavement could not have sufficient strength.

The required HMA (for 30 km of the road) was calculated to be 160000 tons and the required time to construct this layer was estimated to be 18 working months. With regards to the region cold climate, this method needed 3 years to be completed.

3.2 *Method B: Pavement renovation*

Rehabilitation method B included milling 150 mm of the existing asphalt layer, levelling and compacting of the existing sub-base layer, performing 150 mm new base layer and overlaying 160 mm of HMA layer (in 3 layers). Compared with the previous method, the strength of this new pavement would be greater (Fig. 4).

The required time to accomplish this method was estimated to be almost 3 years with regards to limited seasonal working time.

3.3 *Method C: Cold recycling method*

With this method, using an in-situ cold recycling machine (WR 2500), the existing 150 mm HMA layer and 100 mm of existing sub base layer were milled and mixed with foam-bitumen and cement slurry in the machine rotational chamber. The stabilized layer was then protected, applying an HMA layer 60 mm thick (Fig. 5). This method required only 4 months to be completed.

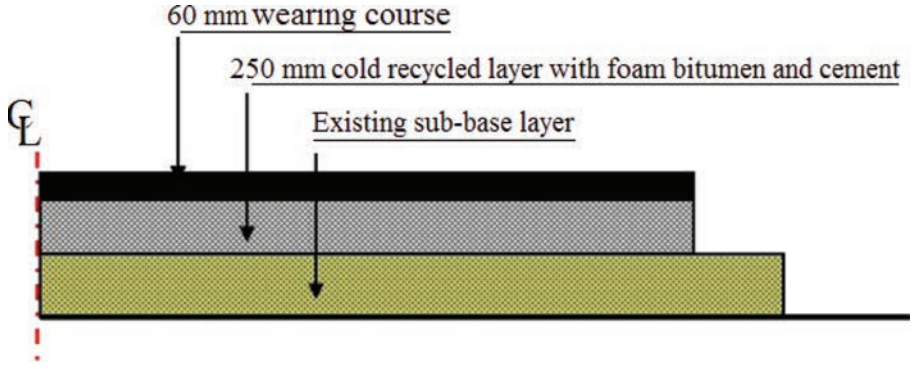

Figure 5. Repaired road cross section using method C.

This alternative design method was selected as the most appropriate method and resulted in the following advantages compared with the previous explained methods:

– 100 mm savings in total pavement thickness,
– No need to transport good quality materials from long distances,
– Greater pavement bearing capacities and structural strength,
– Minimized traffic disruption,
– Decreased total construction period; and,
– Reduced total project cost by using locally available materials.

With regards to client financial limitations, the first stage of the road rehabilitation with 5 km length was approved to be performed applying cold recycling method with foam bitumen and cement.

4 MIXTURE DESIGN

Two mixture designs were selected for foam bitumen stabilized base layers. For the main road pavement, 100 mm of the existing asphalt material and 150 mm of the existing sub-base material were mixed together. For the shoulder area, the existing sub-base was used only. The final aggregate gradations of these mixtures are shown in Figure 6. It can be seen that both gradations were suitable for producing foam bitumen stabilized bases according to South African's Technical Guide [1].

Foam bitumen mixes containing different amounts of cement and lime (at low level cement and lime contents) were tested under Marshall and ITS (Indirect Tensile Test) tests. Because of the poor coating of the aggregate particles with foam bitumen process (in contrast with the case of conventional HMA mixes), all the principal five Marshall parameters could not be determined [2]. Hence, stability and flow values were determined only.

ITS testing was performed on both dry samples and the samples were kept in water for 24 hours at 25°C. From these, Tensile Strength Ratio (TSR), defined as the ratio of tensile strength of the dry samples to the tensile strength of the saturated samples, was determined.

As for the project requirements, the key ITS parameters, Marshall Stability and Marshall Quotient (Q) were set to meet the following minimum limits:

– Dry ITS: 300 kPa,
– Soaked ITS: 200 kPa,
– TSR: 50%;
– Marshal Stability: 700 Kg
– Maximum Marshal Quotient (Marshall Stability/Flow): 150–600 kg/mm

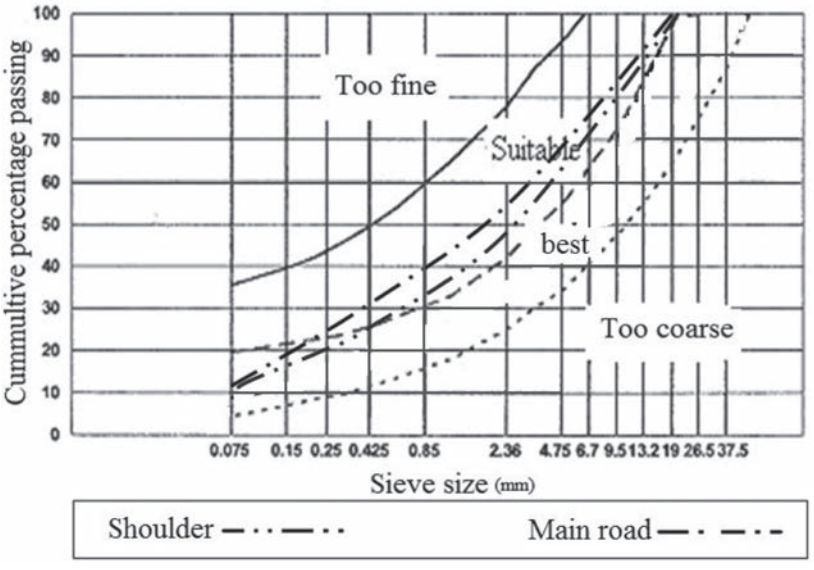

Figure 6. Aggregate gradations of foam bitumen stabilized base layer.

4.1 *Foam bitumen characteristics*

With regards to the cold location of the project, a 85/100 penetration grade bitumen was chosen for making foam bitumen. A laboratory foam making unit, a WLB10 Wirtgen type was used to make foam bitumen samples [3]. Two main characteristics of the foam mixes were determined (Expansion ratio: maximum volume of foam relative to original volume and half life: time taken in seconds for the foam to collapse to half of its maximum volume). The characteristics of the designed foam bitumen were as it follows:

- Bitumen temperature (as it is recommended [1 and 4]): 170° C
- Added water: 3%,
- Expansion ratio: 12; and,
- Half life time: 8 seconds.

4.2 *Mechanical testing*

In order to perform the mix design and determine the optimum bitumen content value, prepared samples (compacted at 75 blows of Marshall Hammer) were tested under dry and soaked ITS conditions.

The results indicate that a value corresponding to 3.1% and 3.8% bitumen content could be considered as the optimum bitumen content value for the main road and shoulder stabilization respectively. However, with mixes having both ITS and Marshall Stability values, these should not be expected to perform properly. In order to strength these conventional foam bitumen mixes, cement and hydrated lime powder were added as the bonding and strengthening agents [5 and 6]. The reasons of adding hydrated lime powder could be summarized as the bellow:

- Sub base material plasticity modification (Sub-base PI = 12),
- Increased frost resistance of the sub-base material,
- Decreased the swelling effect of the existing clay material in the sub base layer,
- Decreased foam bitumen and cement recycled base rigidity.

While the bitumen amounts was kept fixed at above mentioned levels, samples containing different amounts of cement and lime powder were prepared. For the main road, the optimum cement and lime contents were 1.2% and 1.0% respectively. For the shoulders, the

optimum cement and lime contents were 1.0% and 1.5% respectively. At these percentage of cement and lime, both ITS and Marshall testing results were above the specification limits.

5 CONSTRUCTION

For constructing foam bitumen layers, a train of cold recycling machineries were used, as shown in Figure 7. Hydrated lime powder was spread on top of the existing HMA layer and cement was applied in slurry form from a mixing unit and it was injected into the chamber of the main recycler machine while being mixed with aggregates. The stabilized layer was then compacted using a heavy roller to achieve the specified densities. After performing the compaction process, the prepared pavement was overlaid with a 60 mm hot mix asphalt layer.

One of the main advantageous of using this method was minimizing traffic disruption. As it can be seen in Figure 8, the road was open to traffic while the cold recycling train was operating.

6 QUALITY CONTROL TESTING

For quality control testing of the constructed layers, several tests were performed at different locations. ITS and Marshall testing were performed on cold recycled materials and field densities were performed after compaction of the recycled layer. These testing results showed that the properties of the stabilized base were satisfactory. Table 1 summarizes the testing results.

7 CONCLUDING REMARKS

Using cold recycling with foam bitumen and cement in Ardebil-Khalkhal main road resulted in several achievements as listed below:

- The construction time was reduced and appreciable time saving was achieved. These resulted in the project to be completed in one single working season (i.e. before the start of winter conditions).
- Several other savings were resulted from the reduction in total pavement thickness. In addition, locally available materials were used, limiting the use of high quality virgin aggregates.
- Environment protection was resulted from minimizing the raw materials mining and their transportation to the site.
- Using cold-in place recycling machinery chain minimized the traffic disruption.
- The addition of lime and cement to foam stabilized base resulted in increased strength properties and reduced moisture susceptibility and swelling effect of clay material.
- Quality control tests, carried out after construction showed great improvements in pavement properties. This approves suitability of the laboratory mix design used in constructing the new runway (i.e. the recycling train adopted).

Temperature and confinement effects on the stiffness of a Cold Central-Plant Recycled mixture

Brian K. Diefenderfer

Sara D. Link
University of Virginia, Charlottesville, VA, USA

ABSTRACT: Pavement recycling is a technology that has been shown to be a cost-effective and environmentally sensitive means for pavement rehabilitation. One recycling technique, Cold Central-Plant Recycling (CCPR), produces a paving mixture from reclaimed asphalt pavement without heating the recycled pavement materials. Although there is a significant amount of information in the literature on the fundamental engineering properties of asphalt concrete, there is comparatively little published related to 100% recycled mixtures. This information is essential for the pavement design practitioner when using mechanistic or mechanistic-empirical design procedures for 100% recycled mixtures.

This study describes the effects of temperature and confinement pressure on the results of dynamic modulus testing of a CCPR mixture having foamed asphalt as the recycling agent and hydraulic cement as an active filler. This mixture was produced in the field at a mobile plant, and test specimens were compacted in the laboratory using a gyratory compactor. The results of this study showed that the effects of temperature were statistically significant for nearly all comparisons. The results also showed that the effects of confinement were more pronounced at higher temperatures and slower loading rates. The practical significance of these results can be determined after further study of the long-term performance of recycled materials.

Keywords: pavement recycling, cold central-plant recycling, dynamic modulus, confinement

1 INTRODUCTION

Pavement recycling has been shown to be an effective technology to rehabilitate deteriorated flexible pavements. In general, pavement recycling remixes the existing pavement material (either in-situ or within a mobile plant) and reuses it in the final pavement as a stabilized base layer. Pavement recycling techniques include the processes of hot in-place recycling, cold recycling, and full-depth reclamation. Cold recycling includes the processes of cold in-place recycling and Cold Central-Plant Recycling (CCPR). The most common recycling agents include foamed asphalt, emulsified asphalt, hydraulic cement, fly ash, and lime [1]. These techniques have been shown to produce less greenhouse gas emissions, are often times less costly, and can sometimes be used to rehabilitate a pavement more rapidly than traditional pavement rehabilitation practices [2–4]. Unfortunately, there is relatively little information about the fundamental engineering properties (in particular the dynamic modulus) of recycled materials when compared to the wealth of information that exists for Asphalt Concrete (AC). As dynamic modulus is the primary material input [5] used in current Mechanistic-Empirical (M-E) pavement design procedures (e.g., AASHTO's Pavement M-E), more information about the response of recycled materials in this test is needed if pavement design

practitioners are to use the various pavement recycling techniques within the framework of an M-E design procedure.

The pavement recycling technique explored in this study is CCPR. CCPR can be used as an alternative to newly produced AC base mixtures when stockpiles of quality Reclaimed Asphalt Pavement (RAP) are available. A CCPR plant may consist of a screening and crushing unit to control the maximum particle size, a feed hopper and a conveyor belt with weight scale, computerized controls for recycling agent(s) and water addition, and a pug mill for mixing [1]. An example of a CCPR plant is shown in Figure 1. After the

Figure 1. CCPR plant.

Figure 2. CCPR mixture paving.

CCPR mixture is produced, it may be stored in silos or stockpiles or immediately placed using traditional AC paving techniques. During placement, the CCPR mixture can be deposited directly into a conventional AC paver or in a windrow for pickup and deposit into an AC paver. The CCPR material is then compacted, much like an AC mixture, typically with a series of pneumatic-tire and steel-drum rollers using a control strip to establish a density target. A photograph of a CCPR mixture paving operation is shown in Figure 2.

2 OBJECTIVE AND SCOPE

This objective of this study was to determine the influence of temperature and confinement on the stiffness of a CCPR mixture as measured by the dynamic modulus. Test specimens of a CCPR mixture produced in the field using a mobile plant were compacted in the laboratory using a gyratory compactor. The CCPR mixture was produced from RAP originally obtained during a 2011 pavement recycling project on Interstate 81 in Virginia and was a combination of surface, intermediate, and base AC mixtures [6].

3 MATERIALS

The CCPR materials used for this study were placed on three sections at the pavement test track of the National Center for Asphalt Technology in Auburn, Alabama, as part of a structural study during the 2012 research cycle. The RAP used to produce the CCPR was stockpiled in Virginia for nearly two years and then hauled to the project site in Alabama for construction. The RAP was crushed prior to production in the CCPR mobile plant as large chunks had formed within the RAP stockpile. Prior to construction, a mixture design was developed using procedures described by Wirtgen [7]. The design procedure establishes a recycling agent content offering the desired laboratory properties. In this case, foamed asphalt was used as the primary recycling agent, with hydraulic cement as an active filler. Active fillers may often be combined with recycling agents to improve resistance to the detrimental effects of moisture and improve the early strength [8].

The results of the mixture design procedure found the optimal properties to occur with 2.0% foamed asphalt with 1.0% hydraulic cement. The Indirect Tensile Strength (ITS) is the most often used laboratory test to guide the assessment of CCPR using foamed asphalt during mixture design. A dry ITS value of greater than 310 kPa (45 psi) and a tensile strength ratio (determined as the tensile strength after soaking divided by the dry strength) of greater than 70% are often cited as providing sufficient strength for high-traffic pavements [7]. These tests were conducted to establish the mixture design and then repeated during construction to verify the properties of the CCPR material; the results of these tests conducted during construction are shown in Table 1. The gradation of the CCPR material was in accordance with the requirements of AASHTO T 27 [9] and is shown in Figure 3. Figure 3 also shows the gradation envelope recommended by Wirtgen [7] as a shaded area bordered by two dashed lines. From this figure it can be seen that the CCPR material placed was of a finer gradation than that recommended by Wirtgen [7].

Table 1. CCPR indirect tensile strength results.

Condition	Dry			Soaked

4 METHODS

4.1 *Dynamic modulus specimen fabrication*

Dynamic modulus specimens were fabricated from loose materials collected at the mobile plant during construction of the test track sections. As the moisture content at production is an important parameter for compaction, the sampled materials were placed in buckets and then sealed for transport to the on-site laboratory. The loose materials were then combined to create one approximately 25-kg batch. About 16 specimens were fabricated per batch. When additional materials were needed, additional buckets were unsealed and combined to create another approximately 25-kg batch.

Dynamic modulus test specimens were fabricated using a gyratory compactor such that they had about the same bulk density as the mixture design ITS specimens; approximately 2202 kg/m^3. For each dynamic modulus specimen, a calculated mass of material was added to a 152.4-mm-diameter gyratory compactor mold and compacted to a desired height of about 170 mm. The mass of material for each dynamic modulus specimen was calculated by multiplying the mixture design ITS specimen mass by the proportional change in volume between the mixture design ITS specimen and the dynamic modulus specimen. The number of gyrations was not recorded but typically ranged from 30 to 50 gyrations. All fabricated specimens were cured in a forced draft oven for 72 hours at 40°C after compaction.

4.2 *Dynamic modulus testing*

The fabricated specimens were stored at approximately 21°C and 70% relative humidity for approximately 6 months prior to testing. The long time between fabrication and testing was due to a backlog of other testing in the laboratory rather than to any specific curing or waiting period. Prior to testing, the fabricated specimens were cored and trimmed to produce test specimens having a 101.4-mm diameter and a 152.4-mm height. The dynamic modulus testing was conducted using an Asphalt Mixture Performance Tester (AMPT) in accordance with AASHTO TP 79 [10] with slight modifications; a reduced set of temperatures was used. Testing was conducted in the axial mode at temperatures of 4.4, 21.1, 37.8, and 54.4°C. At each temperature, testing was conducted at loading frequencies of 25, 10, 5, 1, 0.5, and 0.1 Hz. The test specimens were also tested at different levels of confinement pressure. Four levels of confinement were used: 0, 34.5, 68.9, and 137.9 kPa. For each condition, five replicates were tested.

5 RESULTS AND ANALYSIS

5.1 *Results*

The dynamic modulus of a CCPR mixture was tested in the axial mode at four temperatures, six frequencies, and four confining pressures as stated previously. Each specimen was re-used throughout the testing regime and tested in an increasing order of temperature and a decreasing order of frequency at each temperature to minimize the potential for damage. In general, the between-specimen repeatability values were not within the ranges recommended in AASHTO TP 79 [10] at the higher temperatures and longer loading times. However, this was expected based on the authors' past history with testing recycled mixtures and is important to consider when comparing the results from other recycled mixtures.

Figure 4 shows the results of the dynamic modulus testing at the four test temperatures and four confining pressures and at frequencies of 25, 10, 1, and 0.1 Hz (the results at 5 and 0.5 Hz are not shown for brevity but followed the same trend). The error bars indicate plus/minus one standard deviation. These results show the average unconfined dynamic modulus at 10 Hz to be approximately 7500, 4200, 2300, and 1000 MPa at test temperatures of 4.4, 21.1, 37.8, and 54.4°C, respectively.

5.2 *Analysis*

By visual inspection of the data shown in Figure 4, several trends can be noted: (1) the dynamic modulus of the CCPR materials decreases with increasing temperature at each test frequency; (2) the dynamic modulus of the CCPR materials increases with increasing test frequency at each temperature; and (3) the influence of confinement on the dynamic modulus appears to increase with increasing temperature. These results show trends that are similar for AC materials. Similar observations on the influence of temperature for recycled materials

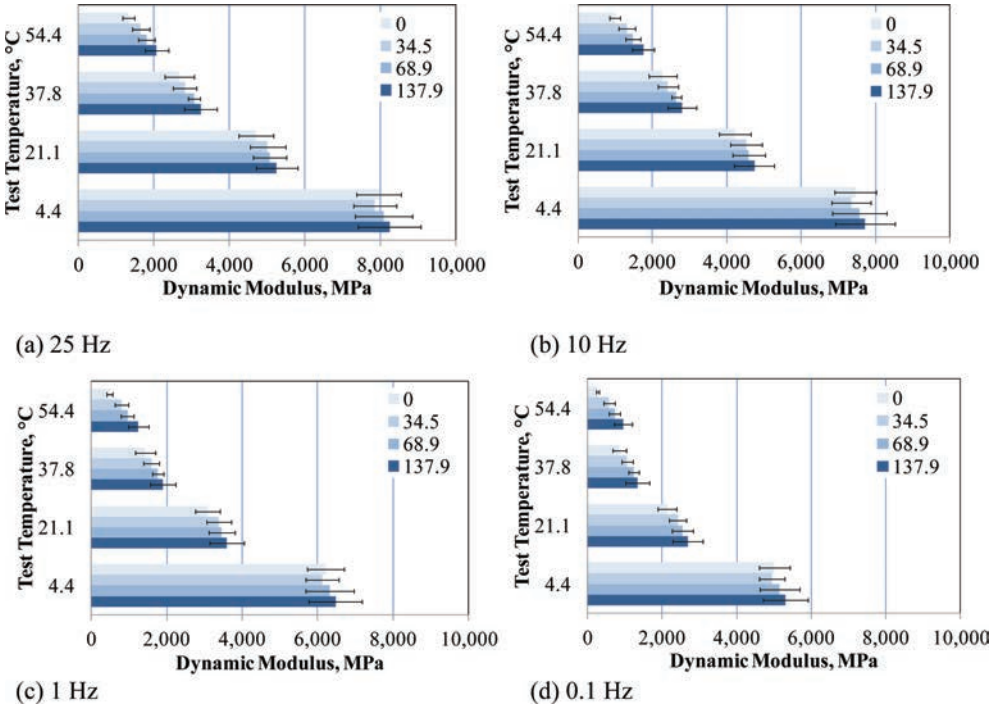

Figure 4. Results of dynamic modulus testing t four confinement pressures: (a) 25 Hz, (b) 10 Hz, (c) 1 Hz, and (d) 0.1 Hz. Error bars represent plus/minus one standard deviation.

have been reported by others [11–13]. These studies also documented stiffness values for recycled materials similar to those shown herein.

5.2.1 *Specimen variability analysis*

The dynamic modulus Coefficient Of Variation (COV) calculated from the five replicates for all tests ranged from approximately 5% to 25% with generally larger COVs at the higher test temperatures and lower test frequencies. The dynamic modulus COV at 4.4, 21.1, 37.8, and 54.4°C tests ranged from approximately 7% to 11%, 9% to 15%, 5% to 24%, and 12% to 25%, respectively, across all confining pressures. The COV values were highest for the 137.9 kPa confinement pressure, but there was no consistent trend across the other three confinement pressures. Bonaquist [5] conducted a study to investigate the precision of the dynamic modulus test for AC using an AMPT. Bonaquist reported that the repeatability COV increased with decreasing stiffness. The study included tests at 4, 20, and 40°C and reported precision statistics with respect to the measured dynamic modulus value, as shown in Table 2. The CCPR materials tested were most similar to the 9.5 mm Nominal Maximum Aggregate Size (NMAS) shown in Table 2 (the other NMASs are shown to illustrate how the variability was found to increase with increasing particle size as could be found for some recycled mixtures containing AC base courses). When compared to those in Table 2, the CCPR dynamic modulus COV values were nearly all outside the range recommended by Bonaquist [5]. However, the information from Table 2 is based on AC materials and extends only to a test temperature of 40°C. The between-specimen variability in this study is higher than that typically found for most AC materials but is consistent with that in other recycled materials studies [11,12].

5.2.2 *Statistical significance analysis for temperature and confinement*

As stated previously, the purpose of this study was to investigate the influence of temperature and confinement on the stiffness of a CCPR mixture as measured by the dynamic modulus. To consider the effects of temperature, a two-tailed Student's *t*-test was applied to determine if differences in the mean dynamic modulus with respect to temperature were statistically significant. The *t*-test was conducted to compare the mean dynamic modulus results of two neighboring test temperatures. That is, the results at 4.4°C were compared to the results at 21.1°C; next, the results at 21.1°C were compared to the results at 37.8°C and so on. If the results at these smaller temperature differences were significant, then differences across larger temperature ranges would also be significant. The *t*-test was performed separately at each test frequency and confinement level. The results showed that the mean differences in dynamic modulus with respect to temperature were all significant (considering a significance level [α] of 0.05) except for the comparison of 37.8°C vs. 54.4°C at 0.1 Hz at 137.8 kPa confinement. The p-value for this condition was found to be 0.10. The reason the difference in dynamic modulus across this temperature difference was found to be not statistically significant stems from the high COV values at 37.8°C and 54.4°C for this condition, approximately 24% and 25%, respectively.

Table 2. Dynamic modulus (|E*|) precision statistics [5].

	Within-laboratory repeatability, |E*|, s_r%			
Average |E*|, MPa	9.5 mm[a]	12.5 mm	19 mm	25 mm
≥137 to <200	15	17	20	24
≥200 to <500	13	14	16	19
≥500 to <1000	11	12	14	16
≥1000 to <2000	9	10	12	13
≥2000 to <5000	8	8	9	11
≥5000 to <10000	7	7	8	9
≥10000 to <16400	6	6	7	7

[a]Nominal maximum aggregate size.

To consider the effects of confinement, an analysis of variance (ANOVA) was conducted. The ANOVA was conducted to determine if differences in the mean value of the dynamic modulus at the four levels of confinement were statistically significant at the six frequencies and four test temperatures. A significance level (α) of 0.05 was used. Although the ANOVA was used to determine if differences between the means were statistically significant, a Tukey's HSD test was used to group like means together. Normally the Tukey's HSD test is not conducted if the ANOVA shows that the differences are not significant, but the results are easy to interpret visually in both cases and so are presented here. Table 3 shows the results of the Tukey's HSD test using grouping letters for the test frequencies of 25, 10, 1, and 0.1 Hz (the results at 5 and 0.5 Hz are not shown for brevity but followed the same trend). The confinement pressures shown in Table 3 having the same grouping letter indicate that the differences in mean dynamic modulus values were not statistically significant. Table 3 shows that the difference in the dynamic modulus resulting from changes in confinement was not statistically significant for the 4.4°C temperature at all test frequencies. Table 3 shows that the difference in the dynamic modulus resulting from changes in confinement was statistically significant for the 54.4°C temperature at all test frequencies. Table 3 also shows that as the test frequency increased, confinement was found to be not statistically significant at the 21.1 and 37.8°C test temperatures.

Previous studies of AC materials also found that confinement is more influential at higher temperatures and slower loading rates [14–16]. Schwartz and Khosravifar [12] found similar results for laboratory- and field-produced CCPR materials and stated that temperature and loading rate had a greater influence on the dynamic modulus than confining stress.

5.2.3 *Practical significance analysis for confinement*

Another way to consider the results is in terms of a practically significant difference. Figure 5 shows select data from the confined dynamic modulus master curve at three confinement pressures plotted with respect to select data from the unconfined dynamic modulus master curve at four temperatures. The solid diagonal line in Figure 5 is the line of equality; the bold dashed lines represent plus/minus 20% of unity; and the thin dashed lines represent

Table 3. Tukey's HSD results[a].

	Confinement pressure, kPa	Test temperature, °C								
		4.4	21.1		37.8		54.4			
25 Hz	0	A	A		A		B			
	34.5	A	A		A		B	A

	34.5	A	B	A	B	A		B		
	68.9	A	B	A		A		B	A	
	137.9	A		A		A			A	

[a]Confinement pressures having the same grouping letter indicate that the differences in mean dynamic modulus values are not statistically significant.

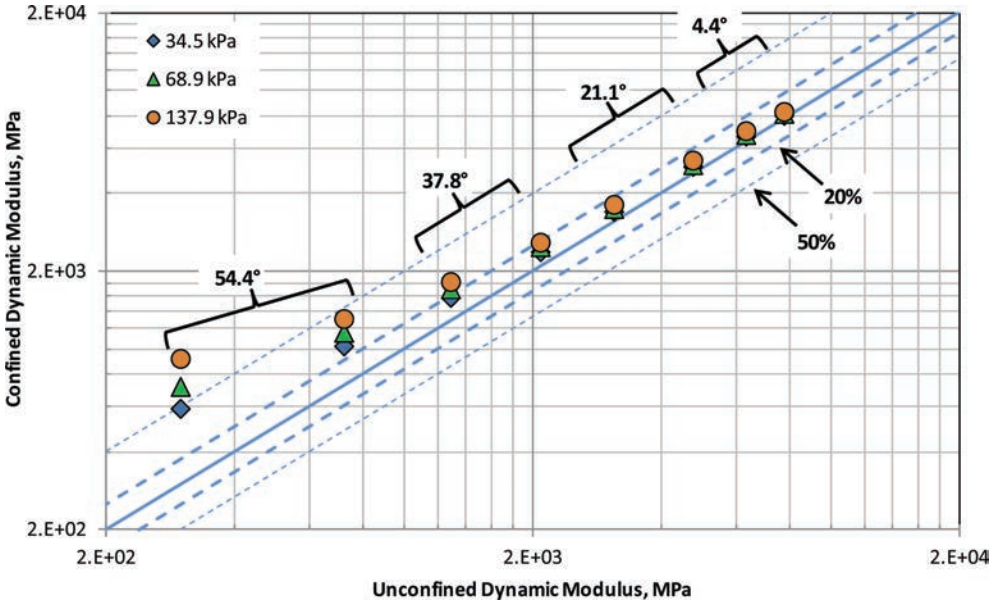

Figure 5. Unconfined dynamic modulus master curve data versus confined dynamic modulus master curve data.

plus/minus 50% of unity. The data points shown in Figure 5 were calculated by using the fitting parameters (α, β, δ, γ) to calculate the dynamic modulus master curve data at select reduced frequency values that were representative of the data at each temperature. The eight sets of data points shown in Figure 5 include two values at each test temperature to illustrate the trend from the complete master curve.

From Figure 5 it can be seen that the data representing the 4.4 and 21.1°C test temperatures are close to the line of equality and are within the +20% dashed line. That is, the confined dynamic modulus is less than 20% stiffer than the unconfined dynamic modulus at these two temperatures. Figure 5 shows that the data representing the 37.8°C test temperature begin to depart more from the line of equality and approach the +20% dashed line. That is, the confined dynamic modulus is approximately 20% stiffer than the unconfined dynamic modulus at 37.8°C. Figure 5 also shows that the data representing the 54.4°C test temperature begin to depart significantly from the line of equality and approach and exceed the +50% dashed line. That is, the confined dynamic modulus is approximately 50% stiffer than the unconfined dynamic modulus at 54.4°C.

The difference between confined and unconfined dynamic modulus is likely not practically significant at the 4.4 and 21.1°C test temperatures. The difference between confined and unconfined dynamic modulus is likely practically significant at the 54.4°C test temperature. It is yet unclear if the differences at the 37.8°C test temperatures are practically significant. This can be determined once a study involving multiple mixtures, operators, and laboratories is completed to determine typical material variability and more in-depth study of the long-term performance of pavements with recycled materials is completed.

6 SUMMARY

This paper presents the results of dynamic modulus testing of a CCPR mixture having foamed asphalt as the recycling agent and hydraulic cement as an active filler. Testing was performed at four temperatures, six loading frequencies, and four levels of confinement to evaluate the effects of temperature and confinement. The study found the differences in mean dynamic modulus

with respect to temperature were all statistically significant except for the comparison of 37.8°C versus 54.4°C at 0.1 Hz at 137.8 kPa confinement. The study found that the differences in mean dynamic modulus with respect to the level of confinement were not statistically significant for the 4°C temperature at all test frequencies. Further, the study found that the differences in mean dynamic modulus with respect to the level of confinement were statistically significant for the 54.4°C temperature at all test frequencies. For the 21.1 and 37.8°C tests, the study showed that as the test frequency increases, confinement was found to be not statistically significant.

In addition to statistical significance testing, the study considered the differences in dynamic modulus with respect to confinement in terms of a practical difference. The study found that the confined dynamic modulus is less than 20% stiffer than the unconfined dynamic modulus at 4.4 and 21.1°C. The confined dynamic modulus was found to be approximately 20% stiffer than the unconfined dynamic modulus at 37.8°C. The differences at the lower two temperatures are not expected to be practically significant. At 54.4°C the confined dynamic modulus was found to be approximately 50% stiffer than the unconfined dynamic modulus. The differences at 54.4°C are expected to be practically significant. It is difficult to determine the implications of these findings as a full-fledged laboratory study involving multiple mixtures, operators, and laboratories has not yet been conducted for recycled materials. In addition, studies of the long-term performance of pavements containing recycled materials and comparisons of the distresses predicted by M-E design methodologies versus those found in-situ have also not been completed.

Laboratory performance evaluation of RAP/RAS mixtures designed with virgin and blended binders

Alireza Zeinali
University of Kentucky, Lexington, KY, USA

Phillip B. Blankenship
Asphalt Institute, Lexington, KY, USA

Kamyar C. Mahboub
University of Kentucky, Lexington, KY, USA

ABSTRACT: When developing blending charts for RAP/RAS mixtures, it is presumed that laboratory testing of blended and virgin binders match the performance characterization of the plant-produced mixtures with the recycled materials. However, the thoroughgoing blend of the virgin binder into the RAP/RAS material is not guaranteed in an asphalt mix plant. In some cases, blending charts results in a virgin binder which is two performance grades softer than the target binder. Kentucky Transportation Cabinet was interested in determining if using a two-grades-softer binder would have a deleterious effect on pavement performance. In this study, four RAP/RAS field mixtures were collected from highway projects in Kentucky. The mixtures were subjected to beam fatigue, IDT creep/strength, and DC(t) fracture tests at the Asphalt Institute laboratory. Furthermore, a laboratory standard mixture was utilized as a control for the expected performance from the mixtures in central Kentucky. The results showed that using virgin binders, which were two grades softer than the target performance grade, resulted in drastically softer mixtures, as compared to the control mixture. This finding suggests the rutting potential of the pavement could escalate by using such a soft virgin binder. Nonetheless, the fracture energy of the mixtures did not improve by using a two-grades-softer binder. In summary, the mixture with one-grade-softer virgin binder exhibited a closer performance to the control mixture.

Keywords: performance testing; reclaimed asphalt pavement; shingles; recycled materials

1 BACKGROUND

Utilizing recycled materials in pavement construction can significantly reduce the environmental impact of highway construction projects. Reclaimed Asphalt Pavement (RAP) and Reclaimed Asphalt Shingles (RAS) are valuable recyclable materials that contain significant amounts of reusable asphalt binder and aggregate. The energy and cost analysis has shown that using 15 percent of RAP materials in a new asphalt pavement results in 5.5 to 6.8 percent savings in the overall cost when compared to a conventional Hot-Mix Asphalt (HMA) pavement. Additionally, this typical 15 percent use of RAP results in a reduction in energy consumption as well as the production emissions by 6 to 7 percent [1].

Despite all these benefits, RAP and RAS may lack some critical mechanical properties, which are essential to a new flexible pavement. RAP is produced by milling off an old asphalt pavement and grinding the material to appropriate size proportions. Post-consumer asphalt shingles are removed from roofs and are separated from construction debris. In both cases the

recycled materials have been extracted from an environment in which they have been exposed to weathering and aging for a long time. This in-service aging and weathering of RAP and RAS normally result in embrittlement of their asphalt binders, and has a deteriorating effect on the mechanical properties of the RAP and mixtures. It has been a challenge to modify the material properties of RAP/RAS to obtain the desired performance characteristics for their inclusion in a new asphalt pavement.

Under the current practice, the RAP/RAS materials are mixed with a softer binder in order to compensate for the brittleness of the aged binder. A set of blending charts is constructed to find the grade of the softer asphalt, which would bring the total blend to the desirable stiffness for use in a new asphalt pavement. Blending charts help determine the critical high, intermediate, and low temperatures for the blended binders with different amounts of RAP/RAS. For a known RAP/RAS content (percentage of the mixture), the blending charts yield the type of the softer virgin binder. In case the design is restricted to a specific virgin binder, the blending charts help determine the amount of RAP/RAS materials [2]. In either case, the aged asphalt binder is extracted and recovered from the RAP/RAS material and subjected to binder testing.

The validation of using blending charts was evaluated in a research by National Cooperative Highway Research Program [3]. Designing the RAP/RAS mixtures by testing the virgin and blended binder testing is essentially based on the assumption that the aged binder from the recycled materials would completely blend into the softer virgin binder during the mixing process. Based upon this assumption, the recovered RAP/RAS binder is completely blended with the virgin binder in the laboratory and subjected to binder testing. However, the thoroughgoing blend of the virgin binder into the RAP/RAS material is not guaranteed in an asphalt mix plant.

Another method is also suggested by Ma et al. to conduct the binder tests without extracting the binder from the recycled materials. In this method, fine RAP materials are used to fabricate the binder test specimens in conjunction with the virgin binder [4]. Although this method avoids chemical extraction and recovery of recycled binders, it does not seem to simulate the incorporation of RAP/RAS into the new material in a mixing plant.

Performance of RAP/RAS mixtures depend on various properties of both recycled and virgin materials. Generally the mixtures with RAS are stiffer at high temperatures [5] and the fibers present in the waste shingles improve the cracking resistance of the mixture [2]. However, RAS mixtures are more susceptible to low temperature cracking due to the high stiffness of their recycled binder. RAP mixtures on the other hand are stiffer at the intermediate temperatures and more susceptible to fatigue cracking [5]. Krishna et al. evaluated the impact of RAP content on volumetric properties and stiffness of HMA. The results showed that the volumetric properties of the mixtures were affected by the amount of RAP and mixtures became stiffer as the amount of RAP increased [6].

In the recent years the processing technology of the post-consumer shingles has improved considerably and an increasing number of agencies are allowing the use of RAS. This necessitates a thorough analysis of the RAS and its combination with RAP material to determine the optimal method of using RAP/RAS in asphalt mixtures.

2 RESEARCH OBJECTIVES

Economic and environmental benefits of using RAP and RAS have been a driving force in using higher percentage of these recycled materials by the construction community. The highway agencies, on the other hand, are concerned that incorporating too much RAP/RAS may lead to premature distress. If such early failure occurs, using RAP/RAS not only yields no benefits, but also imposes additional costs in terms of repairing, resurfacing, and even reconstruction operations. In short, the goal of the asphalt industry is to recycle as much as possible, and yet, take all the precautionary measures to prevent costly failures.

Kentucky Transportation Cabinet (KYTC) has been using the combination of 10 percent RAP and 3 percent RAS in pavement projects for the past few years. Furthermore, KYTC

requires the development of blending charts to determine the grade of virgin binder, which should be added to the RAP/RAS mixture. Considering the environmental conditions of Kentucky, the target performance grade of the blended binder is PG 64-22. In some cases, the stiffness of the RAS combined with its relatively high asphalt content has resulted in the use of a PG 52-34 asphalt binder. The Cabinet has expressed concerns about using a virgin binder grade that is two grades softer (PG XX-34) than their general purpose PG 64-22 grade of binder. Additionally, it has been observed that the final m-value of the recovered asphalt from the mixtures is sometimes lower than the required amount of m = 0.30. This may increase the potential for cracking of pavements containing RAP and RAS.

The main objective of this project was to evaluate the effect of using RAP and RAS under the current practice in Kentucky on the cracking performance and durability of asphalt pavements. The resistance of the mixtures containing RAP and RAS against fatigue and low-temperature cracking was compared to a conventional mixture typically used in Kentucky highways without any recycled materials. Furthermore, the research answers if the expected performance derived from the binder testing and blending charts matches the cracking performance of the mixtures containing RAP/RAS obtained from mixture performance testing.

3 EXPERIMENTAL PLAN

3.1 *Materials*

Hot mix asphalt specimens were collected from four different highway projects in Kentucky. According to the contractors, the specimens were mixed at 149°C (300°F), and the specimens were collected from the hauling trucks before placing in the paver. The mixtures from Bullitt, Flaming, and Robertson Counties contained 10 percent RAP and 3 percent RAS. The mixture from Grant County contained only RAS and it was blended with PG 52–34 asphalt binder. The Bullitt County mixture was designed and utilized as a binder course between the base and surface course of the highway, whereas other mixtures were surface courses. Table 1 contains the design properties for the mixtures used in this study. In addition to the field mixtures, a laboratory standard mixture with design and aggregate properties similar to the typical design of Kentucky surface layers was used as the control. This mixture has been used in several highway projects and has proved to perform satisfactorily in the climatic conditions of the central Kentucky. Since the field performance of this mixture was already known, it could be used as a reference performance point for the RAP/RAS mixtures.

3.2 *Specimen preparation*

The field samples were kept in five gallon metal buckets in a controlled temperature room. Prior to testing, the buckets were heated in an oven at 135°C (275°F) and were divided into

Table 1. Mixture properties.

Property	Bullitt	Fleming	Grant	Robertson	Lab standard
NMAS, mm	25.0	9.5	9.5	9.5	9.5
VMA, %	12.6	15.8	16.9	15.6	15.2

Virgin AC, %	3.0	4.2	5.0	4.2	5.4
Virgin asphalt grade	PG 58-28	PG 58-28	PG 52-34	PG 52-34	PG 64-22

smaller portions using a Quartermaster Asphalt Sample Divider in order to avoid segregation. As per the requirements of the AASHTO R 30 standard, the field-collected mixtures were not subjected to additional laboratory short-term conditioning, since they had already undergone the mixing and hauling processes in the field. The compaction temperature for all the samples was 135°C. To reach this compaction temperature, the mix samples were heated in covered pans. Since this was a comparative study between the mixtures, a similar sampling and conditioning method was applied on all the mixtures to avoid any bias in the test results.

3.3 *Test matrix*

A laboratory test matrix was developed according to the primary focus of the research, which was early cracking in RAP/RAS mixtures. Flexural beam fatigue test, low temperature creep compliance test, indirect tensile strength test (IDT), and disk-shaped compact tension [DC(t)] test were conducted on the mixtures to evaluate their performance with respect to fatigue and low-temperature cracking. All the tests were performed on triplicate specimens, and using annually calibrated equipment in the Asphalt Institute laboratory.

4 MIXTURE PERFORMANCE AND CHARACTERIZATION

4.1 *Fatigue cracking*

A series of flexural constant-strain four-point beam fatigue tests were conducted at 1000 με and 10-Hz loading to evaluate the effect of using reclaimed asphalt pavement and shingles materials on fatigue cracking of the HMA mixtures. This test is performed on a beam shaped specimen which is supported at four points. A repetitive force is applied at the center-point of the specimen to gain the designated strain level of the test. The number of load cycles to initiation of a fatigue crack in the specimen is an indication of the pavement performance under fatigue loading.

Three beam specimens were compacted at 8.0 ± 1.0% air void and tested at the moderate temperature of 20°C for each mixture shown in Table 1. The fatigue failure of each sample was determined in accordance with the ASTM D7460 standard method [7], and based upon the variations of the normalized complex modulus of the specimen during the test. The beam fatigue test results are presented in Figure 1. The dashed lines in this figure represent the average number of cycles to failure for each mixture. It should be noted that the 1000 με corresponds to the condition of extremely heavy loads, or mimicking reflective cracking from underlying pavements. Comprehensive examination of a mixture's fatigue performance requires running the fatigue test at a spectrum of various strains and temperatures. In this study, however, the beam fatigue test was utilized to investigate the brittleness and possibility of early cracking at moderate temperatures. It should also be noted that the frequency of load repetition in an actual asphalt pavement is much lower than in the beam fatigue test. Therefore, the rest period between the loads along with the self-healing property of asphalt material [8] delay the growth of fatigue cracks in asphalt pavements. Consequently, the laboratory cycles to fatigue failure is considerably lower than the real fatigue life of the pavement. The fatigue criterion for asphalt pavements developed by the Asphalt Institute is based upon the suggestion that the pavement fatigue life is 18.4 times greater than the laboratory cycles to failure [9].

As Figure 1 illustrates, except for the Bullitt County mixture, all the RAP/RAS mixtures exhibited a considerably higher fatigue life as compared to the laboratory standard mix. Considering the fact that the control laboratory mixture did not contain any recycled materials, a satisfactory fatigue performance would be expected from the RAP/RAS mixtures under this test conditions.

Statistical Analysis Of Variance (ANOVA) was conducted at 95 percent confidence level ($\alpha = 0.05$) to evaluate the effect of binder type on the fatigue life cycles of the mixtures. The results from the analysis of variance showed that the effect of performance grade of virgin

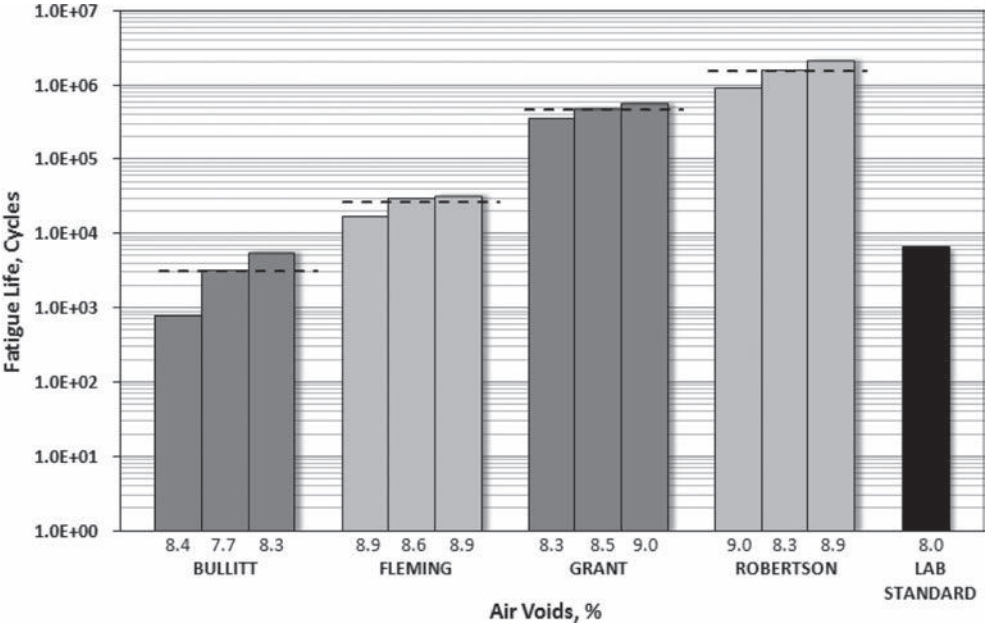

Figure 1. Flexural beam fatigue test data.

binders was highly significant on fatigue life of the samples. Changing the binder type from PG 58-28 to PG 52-34 increased the average fatigue life cycles from 26,000 cycles for Fleming mix to 1,530,000 and 460,000 cycles for Robertson and Grant mixtures, respectively. As can be seen in Figure 1, the Fleming County mixture with PG 58–28 virgin binder still showed better fatigue performance compared to the control mixture.

The Grant County mixture with 3 percent RAS and no RAP showed a significantly higher fatigue life in comparison with the other mixtures. Considering the high strain level of the fatigue test, coupled with PG 52-34 virgin binder, and 5.6 percent effective binder content of this mixture, one might conclude that the mixture was perhaps overdesigned for fatigue cracking. It is noteworthy to mention that the slight differences between the volumetric properties of the mixtures could also contribute to the differences between the fatigue performances. However, these volumetric differences are minimal between the Fleming, Grant, Robertson, and lab standard mixtures. According to the studies on the influence of volumetric parameters on HMA fatigue life [10], the drastically higher fatigue life of the Grant and Robertson mixtures could not only be resulted from slight volumetric variations.

4.2 *Creep compliance and tensile strength*

Creep compliance and tensile strength of the mixtures with RAP/RAS were determined at low temperatures using the indirect tensile test (IDT) configuration, and in accordance with the AASHTO T 322 standard method. In the IDT creep test, a disk shaped specimen is subjected to a static load along its vertical diametric axis, and the deformation of the sample at its center point is measured along the test duration. The creep compliance of the asphalt specimen is then determined based upon the load magnitude and the deformations in vertical and horizontal directions.

For each mixture in this study, samples were tested at three different temperatures and three replicates were fabricated for each test temperature. The time-temperature superposition was then employed along with a power function to determine the master creep compliance curve of the mixtures. The creep compliance tests were conducted at –20°C, –30°C, and –40°C on the Fleming, Grant and Robertson County mixtures. The test temperatures for Bullitt

County mixture were –10°C, –20°C, and –30°C due to its low binder content and high brittleness. Figure 2 displays the final creep compliance master curves at –30°C.

It is expected that HMA mixtures with higher creep compliance would have better ability to relax the stresses caused by rapid thermally induced tensile stresses. In other words, higher compliance means a more compliant mix. The Bullitt mixture, as depicted in Figure 2, did not show considerable change in creep compliance for the first 1000 seconds of reduced loading time. The mixtures with PG 52-34 asphalt binder showed considerably higher creep compliance than the lab standard and Fleming County mixtures with PG 58-22 binder. However, the creep compliance curve for the Fleming mixture appeared to be closer to the one for the control mixture.

The stiffness of the HMA mixtures is inversely related to their creep compliance. In fact, the stiffness decreases by increasing the temperature and/or the loading time. The slope of the stiffness-loading time curve is also an indication of how a mixture relaxes the applied stress. In general, the slope of the stiffness curve varies between zero and 0.5. A horizontal stiffness line (zero slope) represents a fully elastic material and does not relax the stress; whereas, a slope of 0.5 indicates a completely viscous material. Mixtures with higher stiffness curve slope are able to relax the thermally induced stresses much more rapidly. Table 2 shows

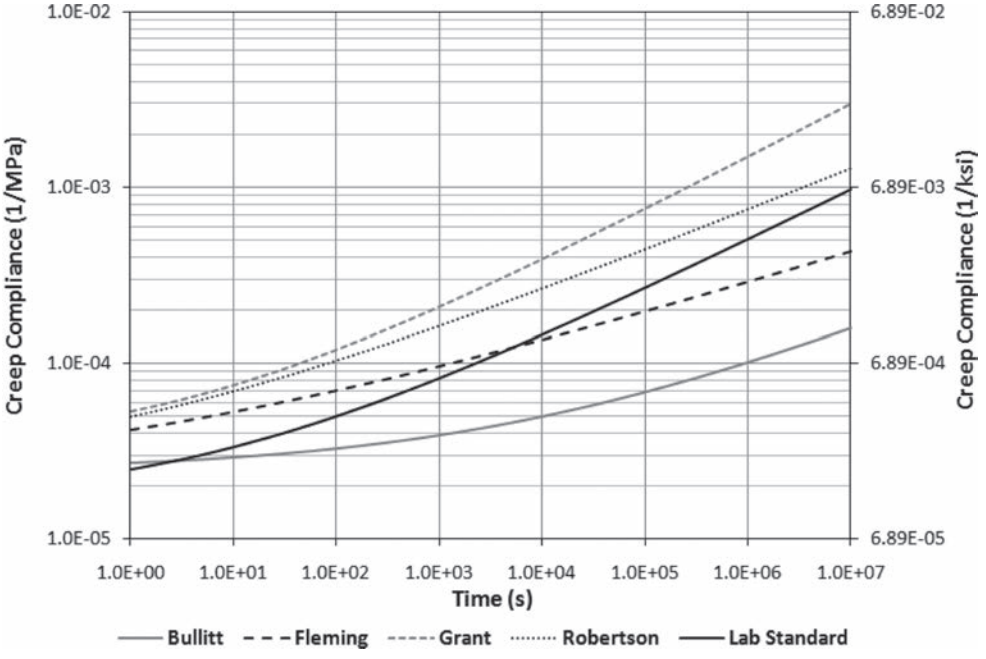

Figure 2. Creep compliance master curves at –30°C.

Table 2. Slope of the stiffness curves at –22°C.

		60 seconds		3600 second	
Mixture	Virgin binder	Stiffness (MPa)	Slope	Stiffness (MPa)	Slope
Bullitt	PG 58-28	23148	0.11	13297	0.16
Fleming	PG 58-28	10549	0.14	5632	0.16
Grant	PG 52-34	5737	0.25	1891	0.27
Robertson	PG 52-34	6640	0.20	2751	0.22
Lab Standard	N/A	12048	0.24	4237	0.26

Note: N/A = not applicable.

the stiffness values as well as the slope of the stiffness curves at –22°C (low temperature of the target binder grade). As seen in this table, the Grant and Robertson mixtures with PG 52-34 binder exhibited a much lower stiffness than the lab standard. Furthermore, their slopes indicate high stress relaxation capability. The Bullitt mixture, as expected from its low binder content, showed a high stiffness with a poor stress relaxation potential.

In overall, the Grant County mixture showed a substantially higher softness than the other mixtures, particularly for higher loading times. Although Grant mixture was mixed with 3% RAS and contained no RAP, mixing it with PG 52-34 resulted in a relatively soft mixture. The increased compliant behavior indicates a softer mixture in the field. This softness may increase the durability of the mixture in terms of low-temperature cracking; however, the potential of rutting distress could increase significantly by using a two grade softer binder.

Indirect tensile strength test was also conducted for each mixture with three replicates at the same temperatures as those employed for the creep compliance tests. The results of the tensile strength tests are presented in Table 3. In order to estimate the critical cracking temperature for different mixtures, a temperature cooling scenario was assumed based on the climatic conditions of central Kentucky. The linear thermal expansion coefficient of the HMA was assumed to be 0.00002/°C. The temperature drop was assumed to start at 5°C and continue to decrease at 2°C/hr rate. Based upon the creep compliance data, the stress relaxation function for each mixture was determined using a numerical method and the data was utilized to calculate the accumulated tensile stress in the pavement surface layer. Comparing the tensile strength data and the viscoelastic stress result, the critical cracking temperature for each mixture was estimated as presented in Table 3.

The critical cracking temperature analysis implied that the mixtures with PG 52-34 virgin binder were highly resistant to low-temperature cracking; however, their critical cracking temperature was much lower than the minimum low temperature expected in the climatic region of the central Kentucky. On the other hand, the critical cracking temperature of the Fleming mixture with PG 58-28 binder was fairly lower than the control mixture and it could be a better representative for the typical surface mixtures used in this area. Considering the difference between the unit cost of two binders, using the PG 58-28 instead of the PG 53-34 binder could result in $2.75/ton of savings in the total price of the asphalt mixture, which could translate into 4.5 to 5 percent of the total price of HMA.

Since the Bullitt mixture was employed as a binder course between the surface and base layers, it would have lower exposure to the sudden drops in air temperature. However, the analysis showed that this mixture was susceptible to low-temperature cracking. Although the cracks in the binder course could not be observed on the pavement surface at their early stages of field performance, they could increase the potential of bottom-up cracking in the surface layer. The low-temperature cracks in this layer in combination with the tensile strain at the bottom of the surface layer could accelerate the initiation of fatigue cracks in the surface layer and reduce the overall service life of the pavement significantly.

Table 3. Tensile strengths and critical cracking temperatures.

Mixture	Tensile strength, MPa				Critical cracking temperature (°C)
	–10°C	–20°C	–30°C	–40°C	
Bullitt	3.45	3.35	2.02	N/A	–21.0
Fleming	N/A	2.77	3.18	3.08	–33.2
Grant	N/A	1.94	2.81	3.42	–46.5
Robertson	N/A	1.91	2.86	3.53	–42.0
Control	N/A	4.08	3.81	N/A	–29.0

Note: N/A = not available.

4.3 *Fracture energy*

In order to evaluate the effect of using RAP/RAS on low temperature cracking, a series of disk-shaped compact tension tests [DC(t)] were conducted to determine the fracture energy of the mixtures. The analysis on the IDT creep and strength data indicated how thermally induced stresses can initiate a crack in the mixtures. Once the crack is initiated, however, the mixtures can exhibit different resistance to growth and propagation of the cracks. This resistance is a function of how the mix can maintain its cohesion and ductility at low temperatures. The DC(t) fracture test manifests how an asphalt mixture would resist against crack growth. In a DC(t) test, a pre-notched sample is subjected to tensile loading, and Crack Mouth Opening Displacement (CMOD) is recorded during the test. The fracture energy is then determined by measuring the area under the load-CMOD curve. Higher fracture energy implies higher resistance to crack growth.

The DC(t) test in this study was conducted according to ASTM D7313-07 standard test method and at –12°C, ten degrees higher than the low temperature grade of the target blended binder.. The dashed line plotted on each dataset in Figure 3 represents the average fracture energy for that particular mixture. Considering the climatic conditions of the central Kentucky, the DC(t) were conducted at –12°C in order to simulate low temperature induced cracking conditions.

The coefficient of variation for the fracture energy data varied between 1 and 11 percent. A minimum threshold of 400 J/m^2 is recommended for the fracture energy of HMA mixtures in order to prevent thermal and reflective cracking [11,12]. As depicted in Figure 3, Bullitt, Fleming and Robertson mixtures demonstrated adequate fracture energy compared to the suggested minimum threshold, while the Grant County mixture had an average fracture energy of 386 J/m^2, which is slightly lower than the suggested minimum.

Fisher's Least Significant Difference (LSD) method was employed to make a statistical pairwise comparison on the fracture energy data. The last column in Table 4 shows the results of the comparisons, and the grouping of the mixtures based on their fracture energy values. The mixtures with similar group letter do not have significantly different fracture energy. For example, the average fracture energy of the Grant mix was not significantly different from Bullitt and Robertson mixtures.

Although Grant and Robertson mixtures were made with PG 52–34 virgin binder (two grades softer than the target blend), they had significantly lower fracture energies than the

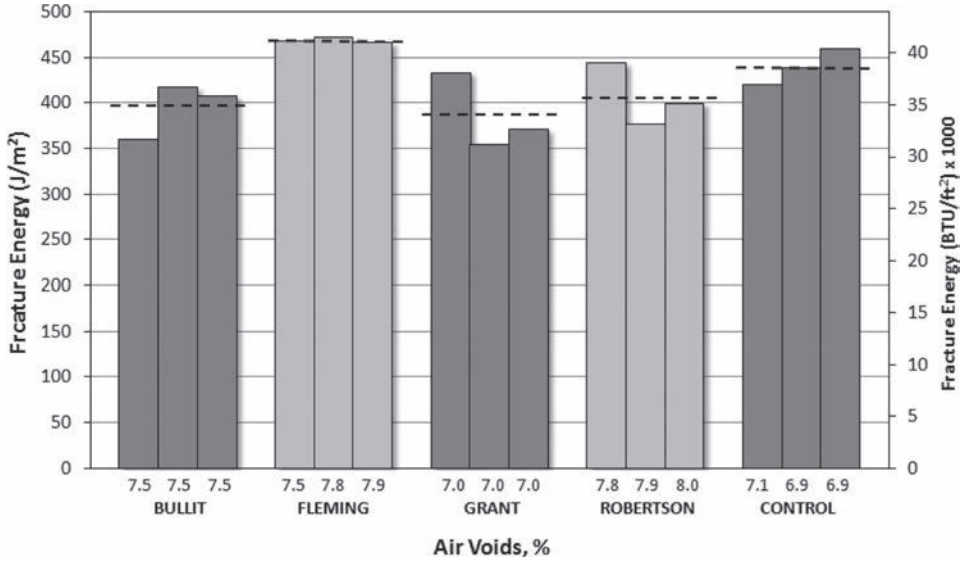

Figure 3. Dc(t) fracture energy data.

Table 4. Pairwise comparison of the mixtures fracture energy.

Mixture	Number of samples	Average fracture energy (J/m^2)	Fisher's grouping	
Fleming	3	467.77	A	
Lab standard	3	438.93	A	B
Robertson	3	406.33		B
Bullitt	3	394.60		B
Grant	3	385.83		B

mixture for Fleming County with PG 58-28 virgin binder. In fact using a virgin binder with two performance grades softer than the target binder resulted in lower fracture energy for the combined mixture. This may indicate that there is an optimum point beyond which adding softer virgin asphalt may not necessarily translate into better resistance to cracking.

As shown in Table 4, there was no significant difference between the Robertson, Bullitt, and Grant mixtures. It should be noted that the Bullitt mixture was a binder course with only 4.1% binder content, 1.3 to 1.6 percent lower than the other mixtures. Again Robertson and Grant mixtures with PG 52-34 binders did not exhibit higher fracture energies than the Bullitt mix with PG 58-28 and much lower binder content.

5 SUMMARY AND CONCLUSIONS

The primary objective of the research was to evaluate the impact of using the current practice of designing RAP/RAS mixture in the states of Kentucky on their cracking performance. This design, which involves the development of the blending charts, sometimes results in a virgin binder which is two grades softer (PG XX-34) than the target blended binder grade in Kentucky (PG 64-22). Four plant-produced hot-mix asphalt mixtures were collected, and subjected to laboratory performance testing. Beam fatigue test, creep compliance test, indirect tensile strength test, and DC(T) fracture energy test were conducted on the specimens containing various amounts of RAP/RAS and different virgin binders. The results of the performance tests were compared to the performance of a laboratory standard mixture with no recycled materials, which has proved to perform satisfactorily on several pavements. The following conclusions were made based upon the laboratory performance test results:

- The performance of mixtures with the PG 58-28 virgin binder and RAP/RAS material in this study was comparable to the lab standard mixture with no recycled material. The mixture with PG 52-34 virgin binder had a higher fatigue life, however more susceptiblity to rutting and low temperature crack growth.
- Using PG 52-34 virgin binder instead of PG 58-28 increased the total cost of the asphalt mixture by about 5%.
- Using PG 52-34 binder instead of PG 58-28 drastically increased the fatigue life of the HMA samples. However, the mixture with PG 58-28 virgin binder could provide adequate resistance against fatigue cracking.
- Creep compliance master curve of the mixture with PG 58-28 virgin binder and 9.5 mm NMAS was the most similar to the master curve of the lab standard mix.
- Mixtures with RAS/RAS and PG 52-34 virgin binder had significantly higher compliance, which could increase the potential risk of rutting.
- Mixture with RAP/RAS and low binder content (4.1%) was susceptible to low-temperature cracking.
- Mixtures with PG 52-34 virgin binder did not have a higher fracture energy level than those with PG 58-28 binder. In other words, PG 52-34 did not provide additional resistance against crack growth compared to the PG 58-28 binder when mixed with the RAP/RAS.

ACKNOWLEDGEMENT AND DISCLAIMER

This material is based upon work supported by Federal Highway Administration through a cooperative agreement with the Asphalt Institute, DTFH61-08-H-00030. Testing materials were collected and provided by Kentucky Transportation Cabinet. The authors wish to thank John Bukowski (FHWA), Allen Myers (KYTC), and Michael Anderson (Asphalt Institute) for their support of the testing program and analysis. Finally, the support of the Member Companies of Asphalt Institute is gratefully acknowledged. Without their active interest in and support of Asphalt Institute, none of the work presented could have been accomplished. Effect of rejuvenator on performance properties of HMA mixtures with high RAP contents

Nam Tran, Adam Taylor & Richard Willis
National Center for Asphalt Technology, Auburn, AL, USA

ABSTRACT: Rejuvenators have been used as recycling agents to restore some performance properties of oxidized Reclaimed Asphalt Pavement (RAP) binders for cold in-place recycling and as surface treatments to preserve weathered asphalt pavements. However, they have not been widely used in Hot Mix Asphalt (HMA) containing high recycled asphalt contents because of the uncertain effect of rejuvenators, concern about the lack of adequate mixing of the old binder and the rejuvenator, and the required reaction time on performance properties of the recycled binders and asphalt mixtures. The objective of the study presented in this paper is to evaluate the effect of using a rejuvenator pre-blended with a virgin asphalt binder on performance properties of HMA with a high RAP content. The study consisted of the determination of optimum content for rejuvenator, mix design, and conducting binder and mixture tests to assess the performance characteristics (moisture susceptibility, mixture stiffness, top-down cracking, low-temperature cracking, and rutting) of two recycled asphalt mixtures—50% RAP mix and 50% RAP mix with rejuvenator—relative to those of a virgin mixture. The use of rejuvenator in the recycled mixture improved its cracking resistance without adversely affecting its resistance to moisture damage and permanent deformation.

Keywords: Rejuvenator, performance properties, reclaimed asphalt pavement

1 INTRODUCTION

The cost of materials and energy has significantly increased during the last few years. As a result, Reclaimed Asphalt Pavements (RAP) have been increasingly used in asphalt mixtures to replace virgin asphalt and aggregate materials to reduce production costs. Each year, it is estimated that about 100 million tons of asphalt pavement materials are milled off roads [1]. Using RAP in Hot Mix Asphalt (HMA) reduces not only costs for contractors and agencies but also the negative environmental impacts associated with the extraction, transportation and processing of virgin materials.

Currently, most highway agencies allow asphalt mixtures containing low percentages of RAP (i.e., less than 25% by weight of aggregate). The reason is that the recycled binder in the RAP is aged and stiffer than the binder in a virgin mixture selected from the same location. The recycled binder is less strain-tolerant, consequently more susceptible to various modes of cracking (i.e., fatigue, thermal, and reflection cracking). As the percentage of recycled binder increases, the proportion of the aged binder in the total binder blend increases, likely resulting in higher mixture stiffness and lower resistance to cracking.

To offset the higher binder stiffness and to improve the mixture resistance to cracking when high RAP contents are used, one approach is to use a recycling agent (i.e., a rejuvenator) to restore the performance properties of recycled binder. Rejuvenators have been used as recycling agents to restore some performance properties of oxidized RAP binders for cold in-place recycling and as surface treatments to preserve weathered asphalt pavements. However, they have not been widely used in HMA containing high recycled binder contents because of the uncertain effect of rejuvenators, concern about the lack of adequate mixing of the old

binder and the rejuvenator, and the required reaction time on performance properties of the recycled binders and asphalt mixtures. If an appropriate amount of rejuvenator is added and properly mixed and required reaction time is allowed, the recycled RAP binder may meet the target performance grade, resulting in improved cracking resistance of the asphalt mixture without adversely affecting its resistance to rutting and moisture damage.

The objective of this study is to evaluate the effect of using a rejuvenator pre-blended with a virgin asphalt binder on performance properties of recycled binders and HMA mixtures with high RAP contents.

2 BACKGROUND

The structure of petroleum asphalt is regarded as a colloid in which asphaltenes are the dispersed phase and maltenes are the dispersion medium. Most paving asphalt binders have micelles of asphaltenes diluted in a fairly well-structured dispersion medium. In the dispersion medium, the asphaltenes form aggregates but are unable to create a continuous network [2]. Physical changes in asphalt binder over time are dependent on changes in its chemical composition. As asphalt binder ages, some of the maltene medium is transformed into the asphaltene phase, resulting in higher asphaltene and lower maltene contents. When there are fewer maltenes available to disperse the asphaltenes, the asphaltenes will flocculate. This leads to higher viscosity and lower ductility, which influences the ability of asphalt binder to stretch without breaking [3]. In other words, when the asphaltene micelles are not sufficiently mobile to flow past one another under the applied stress, the resistance of asphalt binder to cracking or fracture is decreased [4].

The aging of asphalt binder occurs in two stages: short-term and long-term. Short-term aging is mainly due to volatilization and/or absorption of oily components in the maltenes during mixing and construction. Long-term aging happens in the field and is due to changes in composition through reaction between asphalt constituents and atmospheric oxygen, chemical reaction between molecular components (polymerization), and formation of a structure within the asphalt binder (thixotropy) [5].

To restore its rheological properties, an aged asphalt binder may be mixed with a recycling agent, which can be a softening agent or a rejuvenator. While softening agents, such as asphalt flux oil, lube stock, and slurry oil, can lower the viscosity of the aged binder, rejuvenators help restore the physical and chemical properties [5]. Rejuvenators often consist of lubricating oil extracts and extender oils, which contain a high proportion of maltene constituents—napthenic or polar aromatic fractions—that help re-balance the composition of the aged binder that lost its maltenes during construction and service [6]. While rejuvenators should have a high proportion of aromatics, which are necessary to keep the asphaltenes dispersed, they should contain a low content of saturates, which are highly incompatible with the asphaltenes [7, 8].

The effectiveness of a rejuvenator depends on the uniform dispersion of the rejuvenator within the recycled mixture and the diffusion of the rejuvenator into the aged binder coated outside of the aggregate. The dispersion of rejuvenators within recycled mixtures at different plants was investigated by Lee et al. [9]. The researchers visually detected the dyes that had been mixed with the rejuvenators. The authors concluded that uniform distribution of the rejuvenators could be accomplished through mechanical mixing at the plants.

Past studies reported that the diffusion process may not be completed after the construction [10, 11]; thus, higher rutting rates were initially observed on roadways and on test sections subjected to accelerated pavement testing [12]. Rejuvenated asphalt mixtures also showed higher susceptibility to low-temperature cracking compared to virgin mixtures when they had not been sufficiently rejuvenated [13]. According to Terrel and Fritchen [14] and DeKold and Amirkhanian [15], the moisture susceptibility of recycled mixtures was similar to or improved over that of virgin mixtures. However, if stripping-susceptible mixtures were recycled, the moisture susceptibility may increase, and anti-stripping additives should be used appropriately [15]. The type of rejuvenator used had little effect on moisture susceptibility [16].

Rejuvenated RAP can be mixed with a virgin binder and aggregate to achieve a desired Performance Grade (PG) and design gradation for an asphalt mixture. The performance of the blended binder, which is affected by the diffusion and/or mixing of the recycled and virgin binders in the blend, significantly affects the performance of the resulting asphalt mixture. The diffusion and mixing of binders in a blend depends upon a number of factors, including compatibility of binders, temperature of mixing, performance grade of virgin and recycled binder, and the percentage of recycled binder in the blended binder [17].

3 EXPERIMENTAL PLAN

A laboratory testing plan was set up to evaluate the effect of a rejuvenator on the performance of HMA mixtures with high RAP contents. Virgin aggregates and RAP used in this study were sampled from the East Alabama Paving (EAP), Inc. plant in Opelika, Alabama. The RAP material had been crushed to pass a ½-in. sieve at EAP. Two 9.5-mm mix designs, including a virgin (control) mix design and a 50% RAP mix design, were used in this study. The virgin binder used in the mix designs was a PG 67-22. For each mix, 0.5% liquid anti-strip AD-here® LOF 65 (by weight of the virgin asphalt binder) manufactured by ArrMaz Custom Chemicals was added to the virgin binder before mixing.

The rejuvenator selected for this study is Cyclogen® L, which does not contain asphalt binder, provided by Tricor Refining, LLC in California. While the diffusion of rejuvenator into the recycled binder would be better if the rejuvenator was mixed with RAP before the RAP materials were added to the mix, this process would be difficult to implement in the field. Hence, in this study, the rejuvenator was added to the virgin binder, and then the blend was added to the mix of virgin aggregate and RAP materials. A total of three mixtures, including a control mix, a 50% RAP mix, and a 50% RAP mix with rejuvenator (hereafter also referred to as rejuvenated 50% RAP mixture), were evaluated in this study.

3.1 *Plan for binder testing*

Testing of virgin and recycled asphalt binders was conducted in two experiments. The first experiment, as shown in Table 1, was to determine: (1) the effect of the rejuvenator on the performance properties of the recycled binders extracted from RAP; and (2) the amount of rejuvenator required to restore the performance properties of the recycled binders to meet the requirements for a PG 67-22, which is the performance grade of the virgin binder used in

Table 1. Binder testing experiments.

Attribute	Level	Description
First experiment—determining rejuvenator content		
Materials		
RAP binder	1	Binder extracted from RAP
Rejuvenator (Cyclogen L)		
Blending rate for RAP	3	0, 12, 20% by weight of RAP binder
No. of blends	3	$1 \times 3 = 3$
Response variable		True grade
Second experiment—determining performance grades of blended binders		
Materials		
Control	1	Virgin binder (PG 67-22)
50% RAP	1	Virgin binder + extracted RAP binder
50% RAP with rejuvenator	1	Virgin binder + extracted RAP binder + rejuvenator
No. of blends	3	1 + 1 + 1 = 3
Response variables		Performance Grade (PG)

the mixtures. The second experiment, as shown in Table 1, was to determine the properties of the blends of recycled binders, virgin binder, and rejuvenator. The rejuvenator was mixed with the virgin binder at the optimum content determined in the first experiment. Then, the blend was mixed with the binders extracted from RAP based on the amount of each binder determined in the 50% RAP mix design. The purpose of this testing was to verify the true grade of each blend and to rule out any compatibility issues.

3.2 *Plan for mixture testing*

Three mixtures, including a control mix, a 50% RAP mix, and a 50% RAP mix with rejuvenator were tested in both Short-Term Aging (STA) and Long-Term Aging (LTA) conditions. The STA and LTA properties were used to evaluate the mixture resistance to permanent deformation and cracking, respectively.

To prepare an asphalt mixture for this study, the virgin binder, virgin aggregates and RAP were heated in an oven to the target mixing temperature of 300°F. The liquid anti-strip was pre-blended with the virgin binder. The rejuvenator was also pre-blended with the virgin binder at its optimum content determined in the first experiment of binder testing. The mixing process was done in several steps. The virgin aggregates were first poured into a mixing bowl. If used, the RAP was then added into the bowl and mixed with the virgin aggregates. After that, the virgin binder, which had been pre-blended with the liquid anti-strip and rejuvenator (if used), was added and thoroughly mixed in the mixture. The mix was then short-term aged in an oven according to AASHTO R 30 for determining the volumetric properties and for mechanical testing. The asphalt sample was then compacted, and the specimen was prepared for further testing.

The Tensile Strength Ratio (TSR) test was conducted to determine the mix resistance to moisture damage. Two tests, including the dynamic modulus (E*) and the Asphalt Pavement Analyzer (APA), were conducted on the short-term aged specimens to determine the short-term aged stiffness and to evaluate the mix resistance to permanent deformation.

To determine the long-term properties, the test specimens cored/cut from the gyratory specimens were long-term aged in an oven at 85°C for 120 hours according to AASHTO R 30. Three tests were performed on the long-term aged specimens: the E* test to determine stiffness of the long-term aged mixture, the Indirect Tensile (IDT) test to determine the critical low-temperature cracking properties, and the Energy Ratio (ER) test procedure to determine the mix resistance to cracking at intermediate temperatures.

4 RESULTS AND ANALYSIS

In this section, the determination of optimum rejuvenator content is first discussed, followed by the analysis of results of binder and mixture tests. In the interest of length, other information on aggregate materials and volumetric properties of asphalt mixtures is not presented in this section but is available elsewhere [18].

4.1 *Rejuvenator content*

As shown in the plan for testing binder, the rejuvenator was blended at three contents with the binders extracted from the RAP. Then, the performance grades of the blends were determined in accordance with AASHTO M 320. Figure 1 shows the effect of the rejuvenator contents on the performance properties of the RAP binder. The correlations between the rejuvenator contents and the critical high and low temperatures of the RAP binder are almost linear, as the R^2 values are greater than 0.95. Based on the correlations, a content of 12% by the total weight of recycled binder was selected based on the critical low-temperature criteria. At this content, the critical high-temperature criteria were also satisfied, and the performance properties of the recycled binders would be restored to meet

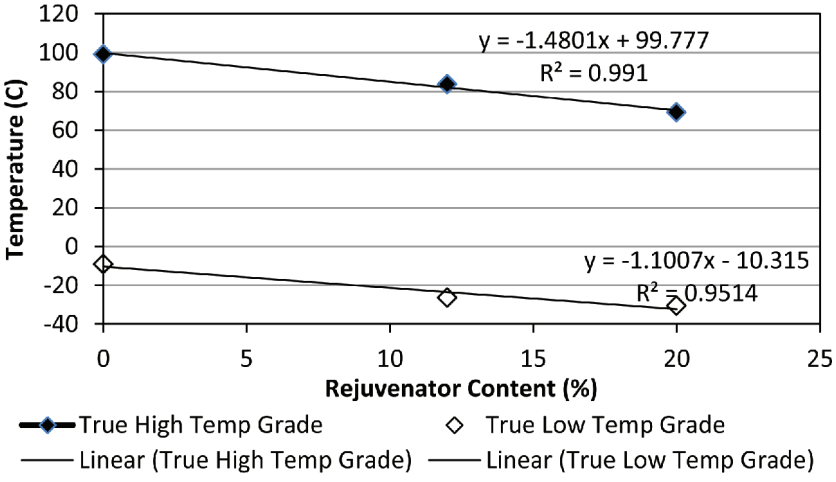

Figure 1. Effect of rejuvenator contents on RAP binder.

Table 2. Performance grades of binders.

Properties	Virgin	50% RAP	50% RAP + RA
Virgin AC*	67.0–23.2	67.0–23.2	67.0–23.2
RAP*		99.1–9.2	99.1–9.2
RA used	No	No	Yes
Total blend	67.0–23.2	85.2–18.2	79.9–21.2

*Performance grade of binder before blending with the rejuvenator.

the requirements for a PG 67-22, which is the performance grade of the virgin binder used in the mixtures.

4.2 *Performance grading of binder blends*

Table 2 summarizes the performance grades determined for the virgin binder, the two binder blends, and each component of the blends. The rejuvenator was able to restore the low-temperature performance grades of the 50% RAP blend from PG 85.2-18.2 to PG 79.9-21.2. Since the rejuvenated blend barely failed the low critical temperature requirements for a PG 67-22, it was decided that the rejuvenator content was kept at 12% by the total weight of recycled binder for further testing in this study.

4.3 *Performance properties of asphalt mixtures*

All mixtures tested in this study were conducted using laboratory-prepared mixes. To prepare a sample in the laboratory, the aggregate was first carefully batched based on the design gradation. The aggregate, base binder, and RAP were heated to the mixing temperature (300°F) in ovens. The liquid anti-strip agent was pre-blended in the base binder at its recommended dosage prior to mixing. If the rejuvenator was used in the mixture, it was also pre-blended in the base binder at the selected content of 12% by weight of recycled binder. After the aggregate, base binder, and RAP (if needed) had reached the mixing temperature, they were mixed in a mixing device. The mixture was then short-term aged in an oven in

accordance with the short-term aging procedure listed in AASHTO R 30-02 and then compacted in a gyratory compactor. The compacted HMA specimens were then tested or long-term aged further in accordance with AASHTO R 30-02 for testing. In this section, results of the following mixture tests are discussed:

- TSR test to evaluate moisture susceptibility
- E* test to evaluate stiffness of short-term and long-term aged mixtures
- ER test on long-term aged specimens to evaluate fracture resistance
- IDT test on long-term aged specimens to evaluate low-temperature cracking resistance
- APA test on short-term aged specimens to determine rutting resistance.

4.3.1 *Mixture resistance to moisture damage*

Moisture susceptibility testing was conducted in accordance with AASHTO T 283-07. Both the saturation and air void requirements specified in AASHTO T 283 were met for each specimen tested. The TSR values for the control mix, 50% RAP mix, and 50% RAP mix with rejuvenator were 0.92, 0.80 and 0.87, respectively, which are equal or greater than the commonly accepted failure threshold of 0.8. The use of rejuvenator at the percentage used in the RAP mixture did not negatively affect the TSR but help increase it slightly.

4.3.2 *Mixture stiffness*

Dynamic modulus (E*) testing was conducted in accordance with AASHTO TP 79-09 on specimens that were prepared in accordance with AASHTO PP 60-09 to 7 ± 0.5% air voids. For each mix, two sets of three specimens were long-term and short-term aged and then tested to assess the effect of aging on the mixtures. The specimens were tested with the temperatures and frequencies recommended in AASHTO PP 61-09 using an IPC Global Asphalt Mixture Performance Tester (AMPT). Based on E* test results, master curves were generated in accordance with the procedure outlined in AASHTO PP 61-09 using the MasterSolver® program in EXCEL®. A reference temperature of 20°C was used for this study.

Figure 2(a) and 2(b) compare the E* master curves at the reference temperature of 20°C for the short-term and long-term aged specimens, respectively. For the short-term aged specimens, compared with the E* master curve of the 50% RAP mixture without rejuvenator, the E* master curve for the rejuvenated 50% RAP mixture is closer to that of the virgin mixture. However, for the long-term aged specimens, the rejuvenated RAP mixture appears to age faster than the other RAP mixture; the E* master curve of the rejuvenated mixture is shifting closer to that of the 50% RAP mixture without rejuvenator. The use of rejuvenator at the determined content in the RAP mixture softened the stiffness of this mixture; however, this mixture was still stiffer than the virgin mix.

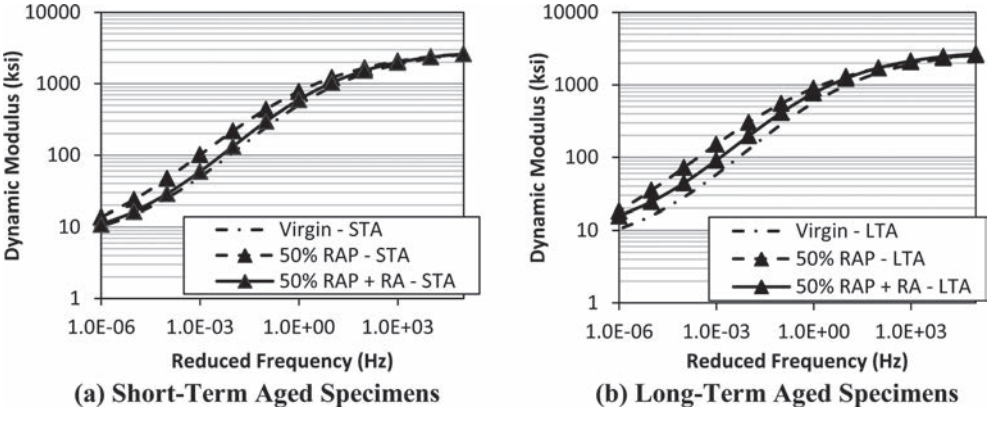

Figure 2. Comparison of E* master curves.

4.3.3 *Mixture resistance to top-down cracking*

The resistance of the three asphalt mixtures to top-down cracking was evaluated using the Energy Ratio (ER) test procedure developed at the University of Florida [19]. The ER test procedure includes three individual tests—resilient modulus, creep compliance, and indirect tensile strength. These tests are performed at 10°C using a universal testing device. Four specimens 150 mm in diameter by approximately 38 mm thick, cut from gyratory compacted samples, are used in the three tests. The target air voids for these samples are 7 ± 0.5%. Based on the data obtained from the three mixture tests, the ER and Dissipated Creep Strain Energy at failure ($DCSE_f$) are determined. An asphalt mixture with higher values of $DCSE_f$ and ER would have better resistance to top-down cracking. Based on an extensive study [19] performed on 22 field test sections gathered from cracked and uncracked sections throughout the state of Florida to evaluate top-down cracking performance, the following criteria were recommended for evaluating the top-down cracking performance of asphalt mixtures:

- The minimum dissipated creep strain energy is 0.75 KJ/m^3.
- The minimum ER is 1.95.

Figure 3(a) and 3(b) compare the fracture properties—dissipated creep strain energy at failure, and energy ratio—for the three mixtures evaluated in this study. Based on the $DCSE_f$ and ER plots, the virgin mix has the best resistance to top-down cracking, followed by the rejuvenated 50% RAP mix, and then the 50% RAP mix without rejuvenator. All the mixes, except the 50% RAP mix without rejuvenator, meet the proposed minimum $DCSE_f$ and ER requirements.

4.3.4 *Mixture resistance to low-temperature cracking*

The resistance of the three mixtures to low-temperature cracking was evaluated using the IDT test procedure in accordance with AASHTO T 322-07. The test procedure includes two individual tests to measure creep compliance of each mixture at three temperatures –0, –10, and –20°C—and tensile strength at –10°C. Four specimens were prepared for each mix. The first specimen was used to find a suitable creep load for that particular mix at each testing temperature. The remaining three specimens were tested at this load for data analysis. Specimens used for the creep and strength tests were 38 to 50 mm thick and 150 mm in diameter. Specimens were prepared to 7 ± 0.5% air voids.

The results were used to determine the critical cracking temperature for each mix tested in this study. A complete description of the thermal stress analysis can be found elsewhere [20, 21]. Figure 4(a) shows the critical temperatures determined at the points where thermal stresses exceed the tensile strengths. The control mixture exhibited the lowest critical failure temperature (–27.7°C), followed by the rejuvenated 50% RAP mixture, and then the 50% RAP mix without rejuvenator. A mix with a lower critical failure temperature would have better resistance to low-temperature cracking.

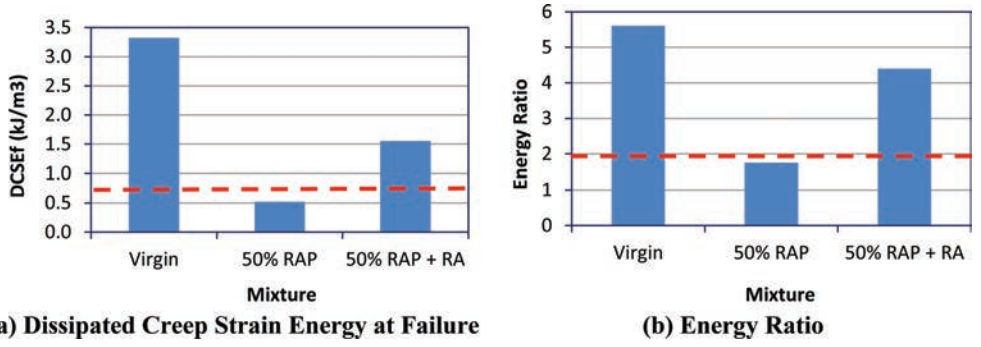

Figure 3. Energy ratio test results.

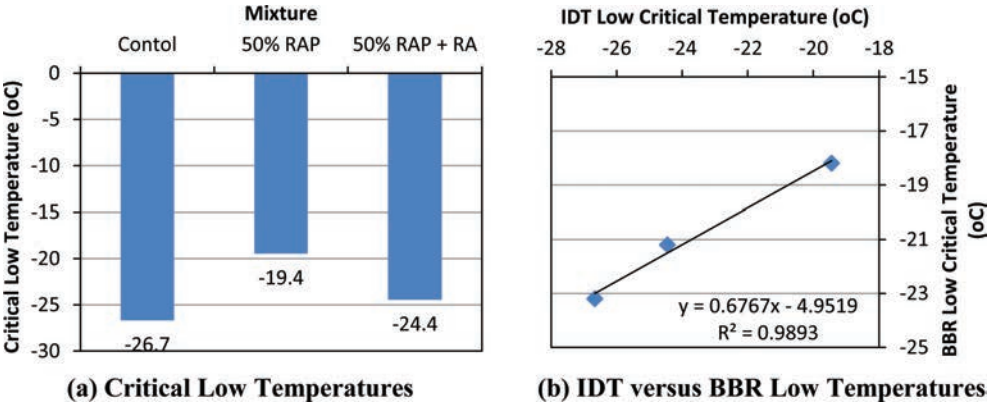

Figure 4. Low temperature cracking testing results.

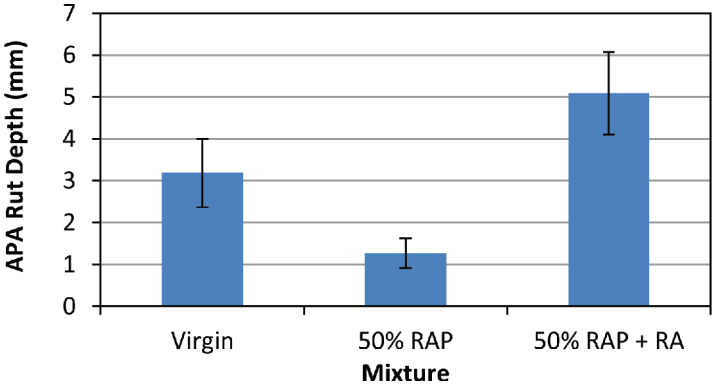

Figure 5. APA testing results.

Figure 4(b) demonstrates a good correlation between the critical low temperatures determined using the IDT and BBR tests for mixture and binder testing. While the critical low temperatures from the IDT test are lower than those of the BBR test, the ranking of the mixtures is similar to that of the binders in terms of their resistance to low-temperature cracking.

4.3.5 *Mixture resistance to permanent deformation*

The rutting resistance of the three mixtures was evaluated using an Asphalt Pavement Analyzer (APA) in accordance with AASHTO T 340-10. The specimens used for this testing were prepared to a height of 75 mm and an air void level of 7 ± 0.5%. Six replicates were tested for each mix. The samples were tested at a temperature of 64°C (the 98 percent reliability temperature for the high PG grade of the binder in Opelika, Alabama). The samples were loaded by a steel wheel (loaded to 100 lbs) resting on a pneumatic hose pressurized to 100 psi for 8,000 cycles. Manual depth readings were taken at two locations on each specimen before and after the loading was applied to determine the specimen rut depth.

Figure 5 compares the average values and variability of the manually measured rut depths for the three mixtures. It can be seen that the rejuvenated mixture has higher manually measured APA rut depths than the control mix, and the 50% RAP mix without rejuvenator has the lowest APA rut depth. A past study at the National Center for Asphalt Technology (NCAT)

Pavement Test Track has shown that if a mixture has an average APA manual rut depth less than 5.5 mm, it should be able to withstand at least 10 million Equivalent Single Axle Loads (ESALs) of traffic at the test track without accumulating more than 12.5 mm of field rutting [22]. Considering this threshold, all three mixtures are expected to pass in terms of rutting.

5 CONCLUSIONS AND RECOMMENDATIONS

This study evaluated the effect of using a rejuvenator on the mechanistic and performance properties of recycled binders and mixtures with high RAP contents in the laboratory. The testing plan for this study consisted of the determination of optimum content for rejuvenator, mix design, and conducting binder and mixture tests to assess the performance characteristics (moisture susceptibility, mixture stiffness, top-down cracking, low-temperature cracking, and rutting) of the two recycled asphalt mixtures—50% RAP mix and rejuvenated 50% RAP—relative to those of the control mixture. The following conclusions and recommendations are offered based on the results of this study.

- The desired amount of rejuvenator can be determined based on a linear relationship between the rejuvenator content and critical low temperature of the blend of recycled binder and rejuvenator. In this study, a rejuvenator content of 12% by the total weight of recycled binder was selected to restore the performance properties of the recycled binder to meet the requirements for a PG 67-22, which is the performance grade of the virgin binder.
- The moisture resistance of the mixtures was evaluated using the Tensile Strength Ration (TSR) test. The TSR values for all the mixtures tested in this study were equal or greater than the commonly accepted failure threshold of 0.8. The use of rejuvenator at the determined content in the 50% RAP mixture did not negatively affect the TSR but help improve it slightly.
- Dynamic modulus testing was conducted to evaluate the mixture stiffness after being short-term and long-term aged. The rejuvenated mixture appeared to age faster than the other mixtures. The use of rejuvenator at the determined content in the recycled mixture softened the stiffness of the mix; however, this mixture was still stiffer than the virgin mix in both long- and short-term aging conditions.
- The resistance of the three asphalt mixtures to top-down cracking was evaluated using the Energy Ratio (ER) test procedure. The use of rejuvenator improved both the fracture properties—$DCSE_f$ and ER—for the 50% RAP mix. All the mixes, except the 50% RAP mix without rejuvenator, meet the proposed minimum $DCSE_f$ and ER requirements.
- The resistance of the three mixtures to low-temperature cracking was evaluated using the Indirect Tensile (IDT) test procedure. The control mixture exhibited the lowest critical failure temperature, followed by the rejuvenated 50% RAP mixture, and then the 50% RAP mix without rejuvenator. The critical low temperatures determined using the IDT correlated well with those determined using the BBR test. The ranking of the mixtures is similar to that of the binders in terms of their resistance to low-temperature cracking.
- The rutting resistance of the three mixtures was evaluated using the APA test. All the mixtures exhibited APA manual rut depths less than 5.5 mm, which was determined based on the past research at the NCAT Pavement Test Track. Thus, all three mixtures were not suspected to fail in terms of rutting.

In summary, the use of rejuvenator in the recycled mixture improved its cracking resistance without adversely affecting its resistance to moisture damage and permanent deformation. The rejuvenator, which is pre-blended with the virgin binder, should be considered to improve the cracking resistance of asphalt mixtures with high RAP contents. However, since the virgin binder pre-blended with the rejuvenator may be much softer than the normal grade of asphalt being used, good mixing of the binder pre-blended with the rejuvenator, aggregate, and recycled material is important to produce a good asphalt mixture that can avoid premature rutting failures. Further research should be conducted to evaluate other rejuvenators

and the use of rejuvenators in asphalt mixtures with higher recycled contents and with recycled asphalt shingles.

Testing asphalt concrete in diametral tension-compression

Eyal Levenberg
Technion—Israel Institute of Technology, Technion City, Haifa, Israel

ABSTRACT: Testing of asphalt concrete in diametral tension-compression is suggested. Given that asphaltic layers experience stress reversals in the field, the underlying motivation is reducing systematic characterization errors. The required experimental setup is shown to be composed of usual testing gear with slight modifications. It is described in detail, validated on an aluminum disk, and then demonstrated for an asphalt concrete specimen. The application of force history that includes several load-unload-rest cycles is advocated. So doing allows separation of the measured response into recoverable and irrecoverable components with only the former being consistent with viscoelastic solid behavior. Reversing the direction of applied force is also beneficial; it effectively confines the accumulation of irrecoverable deformations to a narrow 'band', thereby protecting the mechanical integrity of the specimen. The resulting directional differences in mechanical behavior are demonstrated.

Keywords: Asphalt concrete, linear viscoelasticity, diametral tension, diametral compression, material characterization

1 INTRODUCTION

The response to load of Asphalt Concrete (AC) is best captured with a thermo-sensitive anisotropic nonlinear viscoelastic-viscoplastic constitutive theory [1–6]. For pavement design purposes, AC modeling is currently limited to small-strains and taken as a thermorheologically-simple linear isotropic viscoelastic solid [7–9]. Such parsimonious description, which is inconsistent with observed behavior, is driven by practicality: (i) it involves a relatively small set of material parameters and hence easy to comprehend; (ii) it is simple to calibrate and therefore allows substantial reduction in laboratory workload for characterization; and (iii) it greatly accelerates subsequent pavement modeling computations, mainly due to the legitimacy of applying superposition. When such a limited-complexity model is imposed on calibration test data, systematic errors are included in the inferred material parameters. Unlike random errors, systematic errors cannot be reduced by repeated measurements; they can only be minimized by: (i) constraining the calibration space to the domain of interest; and (ii) using experimental data that cover a broad information range within the domain.

The most basic method for linear viscoelastic characterization of AC [10, 11] partially addresses these requirements; it entails measuring the relaxation modulus in the frequency domain under different isothermal conditions to enable master curve construction. Tests involve the application of haversine stresses in uniaxial compression mode to a cylindrical specimen, 50 mm in radius and 150 mm in height. Axial deformations are measured on-specimen along the mid-height of the cylinder with Linear Variable Displacement Transducers (LVDTs). The 'calibration space' is constrained to small deformations by placing limits on the allowable transient strain amplitude (75 με) and on the irrecoverable strains accumulating throughout the test (1500 με). Broad information range is obtained by combining several temperature levels (from −10C to +54C) and test frequencies (from 0.1 Hz to 25 Hz). Switching between tension and compression is not routinely done despite the fact that AC materials exhibit directional sensitivity [12–14]. This aspect is of practical importance because stress

and strain reversals are produced within AC layers by passing vehicles [15–18]. This means that common calibration results are biased towards compressive properties. Complex modulus in tension-compression is mentioned in [19–23].

Cylindrical AC specimens with the abovementioned dimensions are not standard in size, difficult to fabricate, and impossible to core from as-constructed layers. For these reasons the indirect tensile test has been suggested as a practical alternative to the uniaxial mode [24–29]. The tested specimen is disk-shaped, typically 50 to 75 mm in radius; it is compressed diametrically from opposite sides by two metallic loading strips. Resulting deformations are often measured with on-specimen LVDTs, mounted close to the center of the disk. A similar instrumentation arrangement is used on each side, consisting of one LVDT placed along the loading direction and another placed transversely; a relatively small gauge length of 38 mm is specified. Analysis of AC in diametral tests is traditionally based on two-dimensional elastic theory [30, 31] and on the elastic-viscoelastic analogy. The modeling assumes an isotropic and homogenous disk with forces applied to the outer circumference in the radial direction (i.e., no shear); the theoretical solution is essentially indifferent between tension and compression. With these assumptions the stress intensity at any point in the disk is linearly related to the applied loading and independent of the material properties. Biaxial stress conditions are generated in the disk, with principal stresses that are opposite in sign (except close to the loaded arcs). However, it should be acknowledged that the first stress invariant, at any point, never changes sign; this means that all disk elements are spherically compressed or tensioned depending on the direction of applied force. Consequently, only compressive constitutive behavior is exposed in a typical diametral test [32].

Herein, an idea is explored to test AC in diametral tension-compression. Based on the aforementioned discussion, the underlying motivation is to broaden the information extracted from the test (still constrained to small-deformations) and therefore remove part of the systematic error integrated in the results. Moreover, to further improve consistency with viscoelastic theory, a pulse-rest type of loading history is employed. So doing facilitates the separation between recoverable and irrecoverable deformations in order that the former can used for calibration; this has been demonstrated in a recent study dealing with compressive conditions only [33]. In this connection, reversing the load direction restricts the accumulation of permanent deformations and therefore safeguards the integrity of the specimen, especially under elevated characterization temperatures. The purpose of this paper is to expose and demonstrate the experimental aspects involved in performing a diametral tension-compression test for AC. In-depth analysis for inference of viscoelastic properties is not included due to space restrictions.

2 DIAMETRAL TENSION-COMPRESSION

2.1 *Instrumentation for deformation*

Whenever material characterization is done under small deformations, on-specimen measurement devices must be used to offset compliance issues. This requirement is followed herein, employing LVDTs, with a non-traditional mounting sequence and arrangement. Short thin screws, each 3 mm in diameter and 25 mm in length, are anchored into the tested specimen; these should be fixed to a depth of about 10 mm by a combination of drilling and gluing. A stainless-steel drilling mold can be used to semi-automate this process and ensure repeatability in positioning. These screws serve as 'gauge-points' for mounting four LVDTs, each essentially reading the change in distance between a pair of screws. Anchoring of the gauge-points in the material ensures stability at elevated temperatures, when the material is very soft.

Two optional gauge-point arrangements are shown in Figure 1, superposed over a disk specimen that is 150 mm in diameter. This arrangement is essentially mirrored on the other side of the disk. A Cartesian coordinate system is positioned at the center point, such that the y-axis is parallel to the loading direction. Five gauge-points are shown, denoted as P1 .. P5 with coordinates indicated in brackets (values are in millimeters). The vertical LVDTs

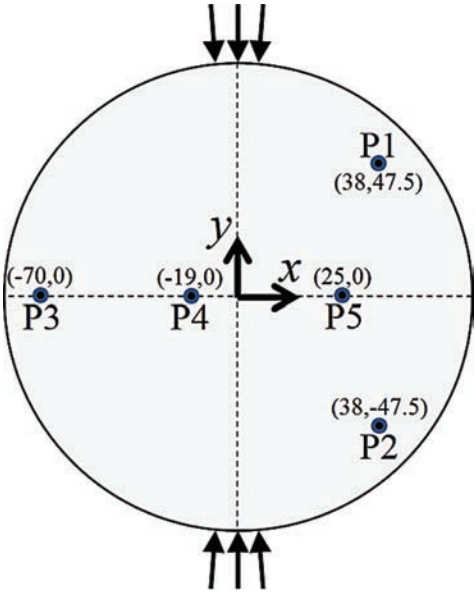

Figure 1. Proposed arrangement of LVDT gauge-points.

span P1-P2 with a gauge length of 95 mm; horizontal LVDTs span either points P3-P4, with a gauge length of 51 mm (Arrangement I) or points P3-P5 with a gauge length of 95 mm (Arrangement II). Two main advantages are provided by these arrangements: (i) better compliance with representative volume element requirements compared with the usual (rather short) gauge lengths [34]; and (ii) retention of some post-peak measurement ability as the off axis instrumentation can potentially function even after the specimen splits in half (not an issue in the current study).

2.2 *Loading setup*

Any standard diametral loading apparatus and single-axis load frame can be used for performing a diametral tension-compression test. The main difference is that the tested disk must be glued to the top and bottom loading strips and the apparatus must be secured to the load frame to permit tension. An off-the-shelve diametral apparatus was employed herein (purchased from Wille Geotechnik). It consists of an aluminum beam sliding vertically over two stainless steel rods, serving as guides. Linear bushings on each side of the beam ensure near-frictionless motion. The bottom loading strip is stationary, attached to the foot of the apparatus; the top strip is attached to the underside of the aluminum beam. Both strips are fixed with hex cap screws and are therefore easy to disconnect; consequently, a glued specimen can be quickly removed from the apparatus if needed (with strips though).

An Instron ElectroPuls (model EP10000) was used as the single-axis load frame. The diametral apparatus was carefully centered and fastened to the EP10000 on top of a 10 kN precision load-cell. The loading piston was attached to the upper side of the beam via a special load-transfer device [20]. This device is composed of two rectangular stainless-steel frames, one attached to the beam and the other fastened to the piston. The frames are interlinked so that there is a certain motion range for which they are not touching; beyond this range they must move together. In their 'neutral' position the EP10000 and diametral apparatus are completely disengaged; tension or compression can only be produced after the frames are brought into contact. The application of pulse-rest loading cycles is greatly simplified with this device. The linked frames help produce fast unloading to true zero stress conditions without any overshooting; they also help produce long true rest intervals without the negative

effects of electromechanical drifts. The only limitation is that the testing must be operated in deformation control mode because of the existence of a neutral range that breaks the feedback loop between load-cell readings and piston movements.

A picture of a glued AC specimen in the diametral apparatus is shown in Figure 2. Callout arrows are included to identify the different setup elements. The LVDTs in this figure are of loose-core type (manufactured by Singer—Instruments and Control), mounted according to Arrangement II. Their precision level, as determined by the driving electronics, was about ±0.1 micron for a measurement range of ±5 mm. As indicated, rubber pads were inserted between the disk and the metallic loading strips; this was done to better comply with the zero friction assumption in theoretical model. A consumer-grade fast setting Epoxy was used for the gluing.

2.3 *Calibration check*

In order to experimentally evaluate the concept and functionality of the setup, a thin aluminum disk, 20 mm thick and 150 mm in diameter, was instrumented and tested. Four LVDTs were positioned according to Arrangement I; readings in the horizontal and vertical directions were separately averaged for subsequent analysis. Positive sign is used to indicate compressive load and also to indicate that gauge points moved closer to each other. LVDTs were pre-calibrated against an optical encoder with submicron accuracy; their effective precision level was considerably improved by oversampling and subsequent smoothing with a quartic kernel smoother. Loading was applied in increasing intensity steps, first in compression mode and then in tension. Deformation response vs. load-cell readings are plotted in Figure 3 by dotted and dashed lines.

As can be seen, applied compressive forces were as high as 6 kN while tensile forces did not exceed 0.7 kN. The latter were essentially limited by the tensile capacity of the glue and rubber

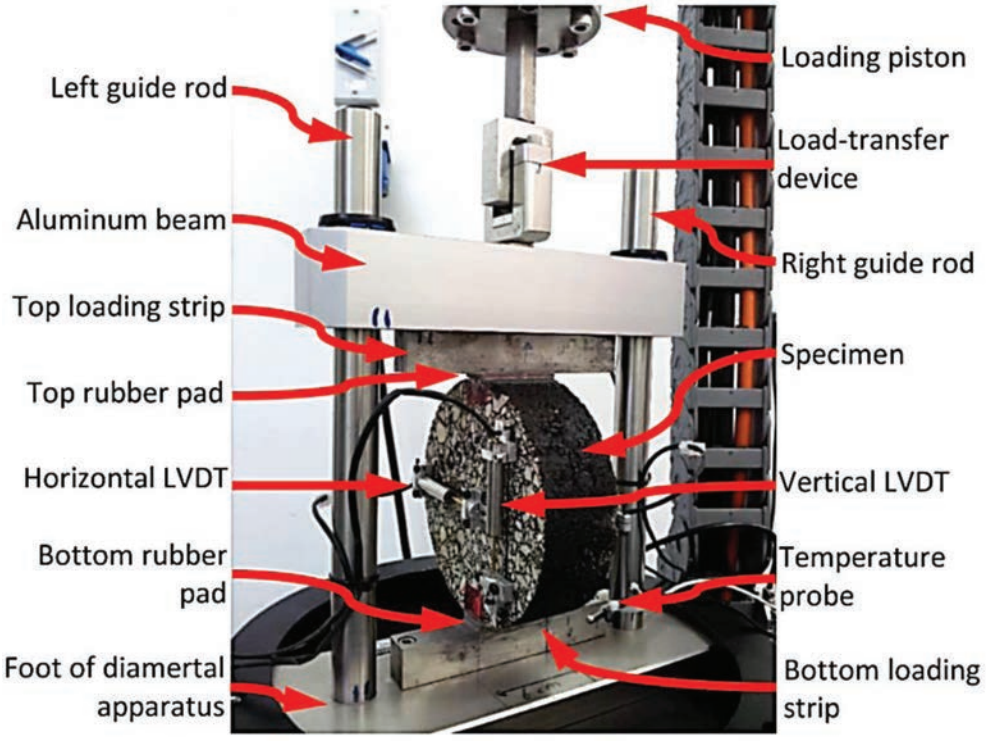

Figure 2. Diametral tension-compression setup.

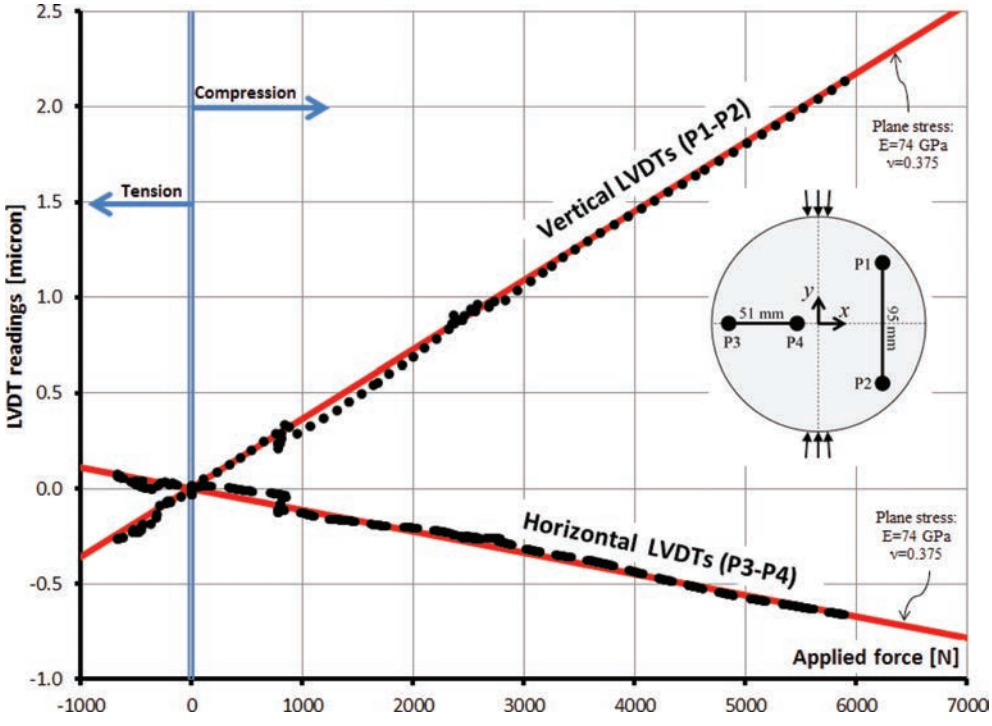

Figure 3. Diametral tension-compression for a thin aluminum disk.

pads. Considering the small contact area, a tensile force of 0.7 kN is equivalent to an average tensile stress intensity of 1.84 MPa. It may also be noticed that the deformation levels are very small; the ordinate in the figure spans a mere 3.5 microns (from +2.5 to −1.0). Visible imperfections in the response are partially related to time-dependent effects; forces where applied in position controlled steps and the aluminum exhibited some stress relaxation. Nonetheless, the overall behavior is graphically consistent with linear elastic theory for both tension and compression directions. Under compression, the vertical LVDTs (P1-P2) were compressed while the horizontal LVDTs (P3-P4) measured tensile deformation. When the loading direction was switched to tension, LVDT readings were reversed along the same trend.

In a two-dimensional linear elastic model the ratio of vertical to horizontal LVDT readings is only a function of the materials' Poisson's ratio. Experimentally, this ratio was measured to equal −3.291. In a plane stress model of Arrangement I, this value corresponds to a Poisson's ratio of $\nu = 0.375$. The slope of the LVDT readings in the figure is controlled by both Young's modulus (E) and ν. As indicated by the two oblique solid lines in the figure, a value of $E = 74$ GPa was obtained from matching the test data. Both inferred E and ν are correct, indicating that the system is accurate and performs well under small deformations.

3 APPLICATION TO ASPHALT CONCRETE

3.1 *Loading*

The proposed setup is hereafter demonstrated for an AC specimen composed of limestone aggregates and unmodified PG 70–10 binder. The aggregate blend was coarse-graded with a nominal maximum aggregate size of 19 mm. Aggregates and binder (4.7%) were mixed at 170°C, allowed to age for two hours at 155°C, and subsequently densified in a gyratory compactor (75 gyrations). The resulting 150 mm diameter pill was trimmed from both sides to arrive at a disk thickness of 58 mm having an air void content of 4.5%. After instrumentation

and gluing to the diametral apparatus, but before any force application, isothermal conditions were imposed until all LVDT readings stabilized. This was done by controlling the laboratory room temperature with an air-conditioning system. In addition, to lessen fluctuations in the vicinity of the apparatus, a controller connected to a temperature probe (see Fig. 2) was used for switching on and off an industrial space heater that faced the specimen. Consequently, a stable temperature level was maintained throughout the test with an average of 25.3°C and standard deviation of 0.23°C.

History of applied forces is shown in Figure 4; consisting of four load-unload-rest cycles with an overall duration of almost 10000 seconds (2 hours and 45 minutes). During the first and third cycles (C1 and C3) tensile forces were applied while the second and fourth cycles (C2 and C4) were compressive. The rest periods, numbered $m = 1 \,..\, 4$ were increasing in duration; the last being 5400 seconds (1.5 hours) long. Such loading history can be used to calibrate the viscoelastic time function over almost six decades in logarithmic scale, between 10^{-2} to 10^{4} seconds [33]. If a similar loading sequence is repeated under additional temperatures, a master curve can be constructed. The advantage here is that two or three temperature levels should suffice to cover any practical range of interest.

Forces were applied in position controlled mode by instructing the piston to move at a constant rate. At the same time, load-cell readings were monitored until a predefined threshold was reached. This was done mainly for the tensile cycles, to protect against gluing failure. Once the preset load level was attained, the piston was instructed to hold its position for two seconds and then retract quickly to produce fast unloading (and subsequent rest interval). The outcome of this sequence is shown in Figure 5, where a magnified view of Cycle 3 is provided. Loading commenced at about $t = 2549$ seconds, after rest period $m = 2$ ended. Tension was induced for a duration of about 4 seconds to a level of approximately −1400 N, at which point the piston movement was stopped for about 2 seconds. During this time the stress level relaxed, mainly due to the specimen

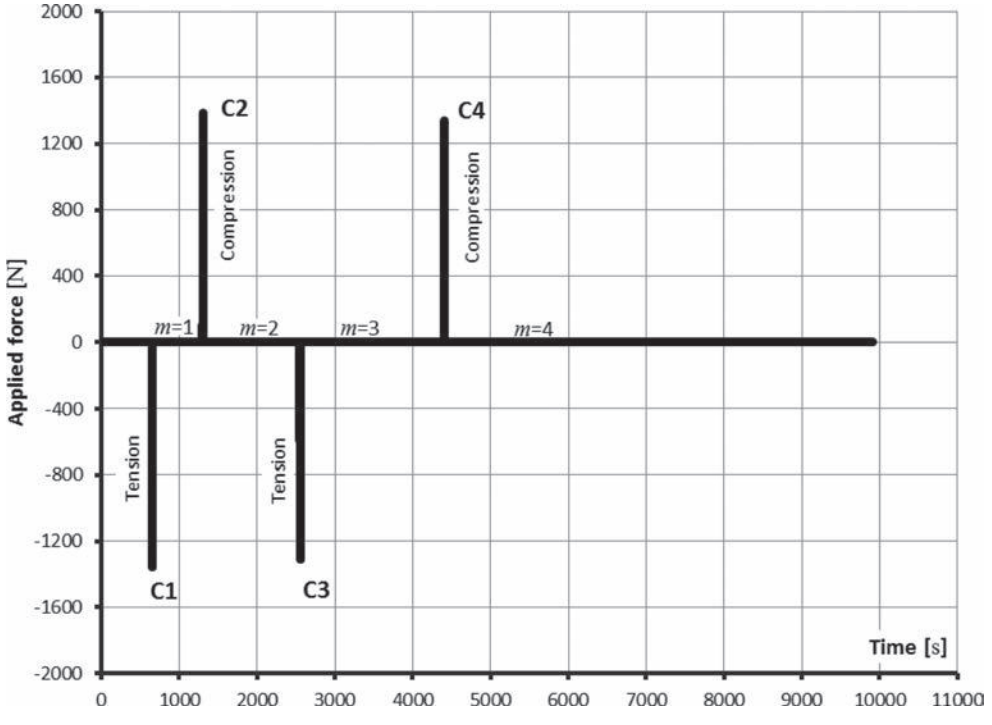

Figure 4. History of applied diametral forces—asphalt concrete disk.

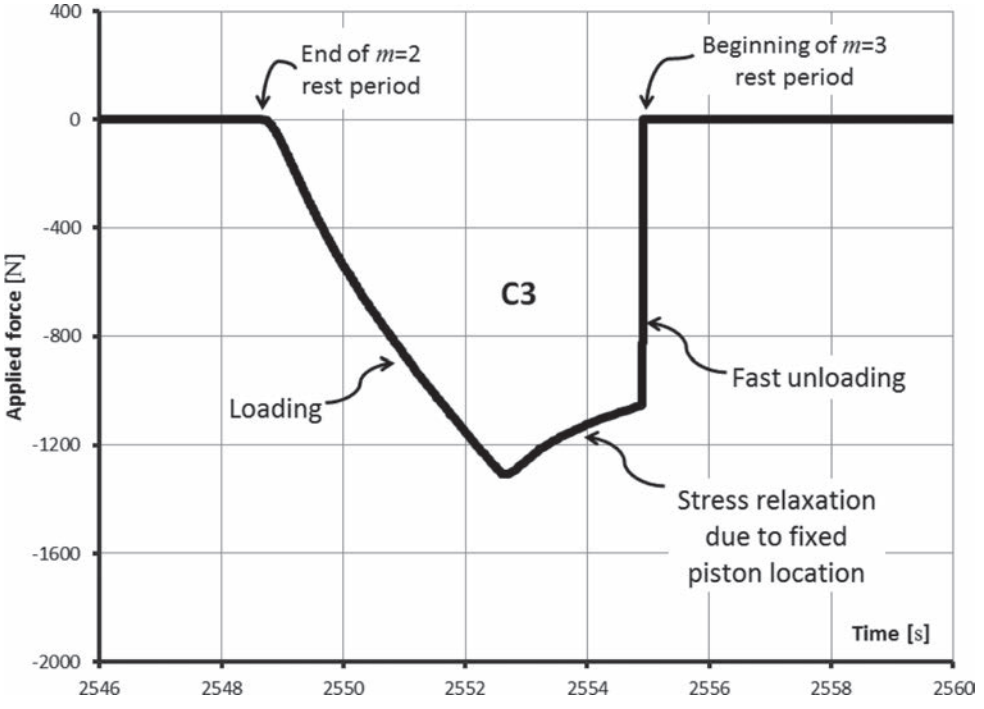

Figure 5. Applied diametral force—magnified view of cycle 3.

deforming; this is clearly seen in the load-cell measurements (and indicated in the figure). From $t = 2555$ seconds the specimen was rapidly unloaded. With the help of the special load-transfer device the force was removed completely within 0.02 seconds, launching another rest period ($m = 3$). It is important to note that the actual (applied) shape of the load-unload pulse is used for interpretation and therefore the above described irregular behavior is not problematic. The most important loading attributes for characterization are: (i) generation of small deformations, (ii) ultra-fast unloading, and (iii) long uninterrupted rest intervals.

3.2 *Deformation response*

Deformations recorded by the vertical and horizontal LVDTs are shown in Figure 6. The individual responses to the four loading cycles are indicated by R1 .. R4. The overall deformation level in the test was very small, as readings varied within a narrow range of ±10 micron. With reference to Figure 1, every micron change in the vertical LVDTs is approximately equivalent to a strain change (in absolute terms) of 15 and 25 microstrains at the disk center in the x and y directions (respectively). The center is the most strained point in the diametral configuration. Even for such small deformation levels irrecoverable response of the order of 25% of the total readings was present in every cycle. This is graphically indicated by the flat asymptotic behavior during the end of the rest intervals. It should also be noticed how the transition between tension and compression confined the permanent deformation component to a narrow band.

A close view of the response in the different cycles is offered by Figure 7. Four charts are included, each displaying 500 seconds of data, from about 100 seconds before the load-unload sequence until approximately 400 seconds afterwards (i.e., the early part of the subsequent rest period). The viscoelastic recovery shape can clearly be noticed, as well as the existence of permanent deformations.

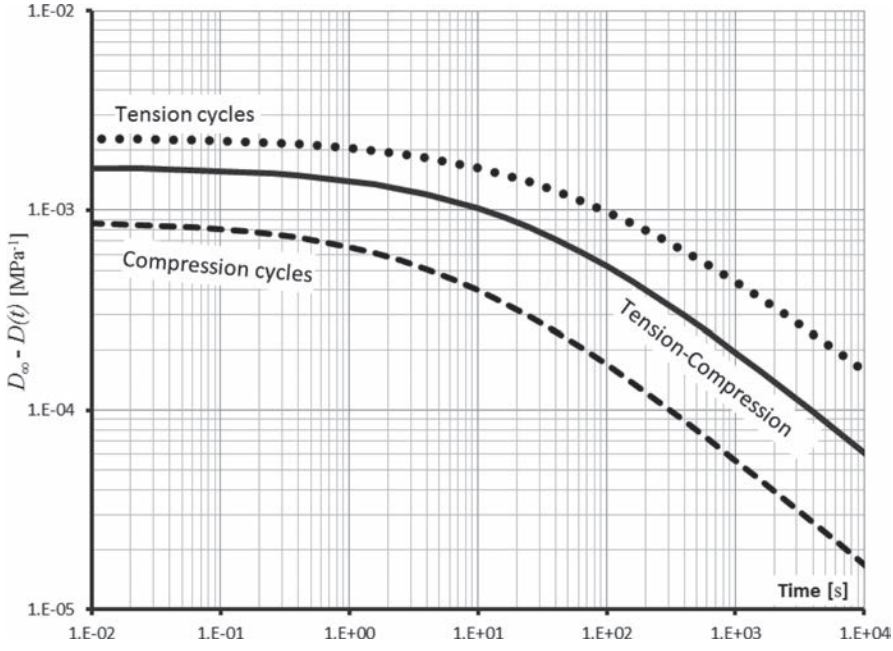

Figure 8. Influence of diametral testing direction on inferred viscoelastic properties.

4 SUMMARY AND COMMENTS

The possibility of performing diametral tension-compression was investigated, and shown to be experimentally feasible with usual testing gear. The underlying motivation is to broaden the calibration range of AC materials for engineering design and analysis of pavements. A pulse-rest type of loading history was offered for characterization as it allows reliable separation between recoverable and irrecoverable deformations. Under the usual application of sinusoidal loads such separation is not possible. A demonstrative test involving one AC specimen under room temperature showed that permanent deformations can be significant, in either loading direction, even in the domain of very small deformations. Reversing the load direction in the test effectively restricted the accumulation of these deformations to remain within a narrow band.

Figure 8 presents the outcome of a preliminary investigation on the influence of loading direction on the inferred viscoelastic properties (for the tested AC specimen). In general terms, the analysis involved simulating the applied force history in a linear viscoelastic model, and matching the LVDT readings (in both directions) during the recovery intervals—when the material was completely unloaded and irrecoverable response assumed inactive. The ordinate represents the viscoelastic creep compliance $D(t)$ subtracted from the long-term (equilibrium) compliance D_∞; the abscissa represents time. There are three curves in this figure: the solid line is associated with matching the entire available dataset from the diametral tension-compression experiment; the dotted line represents the viscoelastic properties when only tensile data is considered in the calibration; and the dashed line is associated only with compressive conditions. Directional differences can be clearly noticed; also the bias involved in calibrating properties for a single direction can be quantified. Utilizing the middle curve for pavement design and analysis should minimize systematic errors.

ACKNOWLEDGEMENTS

The author wishes to thank Mr. Nir Michaeli and Mr. Meir Ovadia for providing experimental assistance. This work was financially supported by the Israeli National Roads Company

(INRC); it is part of a larger research project carried out by the Transportation Infrastructure Laboratory in the Technion, aimed at introducing warm mix technologies into the country in a controlled and systematic manner.

The Reflective Cracking Tester: A third-scale accelerated pavement tester for reflective cracking

Andrew D. Wargo, Shuvo Islam & Y. Richard Kim
North Carolina State University, Raleigh, NC, USA

ABSTRACT: A third-scale accelerated pavement test setup, known as the *Reflective Cracking Tester* (RCT), was developed for this research project to study reflective cracking. Together with Digital Image Correlation (DIC) technology, the RCT was used to investigate the differences in reflective crack propagation seen in layered Asphalt Concrete (AC) pavements, with and without chip seal interlayers. This investigation found that interfacial sliding and separation occurred in both types of pavement, although the samples with chip seal interlayers saw more interfacial movement than those without chip seal interlayers due to the weaker bond between the layers in the chip seal samples. This increased movement meant that the pavement with the chip seal interlayer had a lower number of cycles to failure than the pavement without a chip seal interlayer. Also, this research confirmed that double cracking and triple cracking are possible in pavements with high differential deflections. Further investigation is needed with this test method to determine its ability to capture the benefits of other reflective crack mitigating systems.

Keywords: Reflective cracking, Digital Image Correlation, chip seal interlayer

1 INTRODUCTION

Throughout the world, many kilometers of roadway are surfaced with Asphalt Concrete (AC). Therefore, the maintenance and rehabilitation of these roadways are primary concerns for many highway agencies. One common form of rehabilitation for these roadways is the use of thin AC overlays. These overlays usually consist of one or two courses placed on an existing pavement that may or may not have been cold-milled prior to the placement of the overlay. These treatments are widely used because of their ability to provide a new wearing surface while still taking advantage of the remaining fatigue life and load-carrying capacity of the existing pavement. However, in many cases, stress concentrations due to cracks in the existing pavement cause the formation and rapid propagation of cracks in the overlay. Because these cracks exhibit the same pattern as those in the underlying pavement, this phenomenon is known as *reflective cracking*. The major problem with reflective cracks is that they allow water to enter the pavement structure. Thus, their prevalence in the overlay can be a significant contributing factor to the further deterioration of the overall pavement structure.

Because of this fact, many types of interlayer treatments have been used in an attempt to mitigate reflective cracking over the last fifty years. These treatments include crack sealing, fabrics, grids, Stress-Absorbing Membrane Interlayers (SAMIs), chip seals, fine-graded asphalt layers, and fiber-reinforced asphalt mixtures, just to name a few [1]. Of these, chip seals (which consist of a heavy application of emulsified asphalt binder and the placement of a cover aggregate) are of particular interest to highway agencies due to the fact that they are already used extensively as a wearing surface on low- to medium-volume pavements. As such, equipment for their placement is widely available and construction personnel are familiar with their construction. It is believed that these treatments, as interlayers, can help to absorb the stress that propagates reflective cracking and provide a barrier to water infiltration into

the pavement layers if cracks in the overlay occur. Past research has shown that chip seals used as reflective crack mitigating interlayers are generally effective at delaying reflective cracking, but as with most interlayer types, are unable to prevent it altogether [1, 2].

In order to better understand the performance of these systems, it is desirable to have a means to investigate their behavior in the laboratory. Because of the complicated loading history that is created when a moving wheel passes over a pavement, the realistic simulation of reflective cracking due to traffic loading has been difficult to achieve in the lab, with many researchers opting to use simplified loading conditions to evaluate interlayer behavior. In order to provide a better simulation of field behavior, several researchers have utilized small-scale accelerated pavement tests on layered asphalt samples in an attempt to characterize interface behavior. Most often these tests use a moving wheel, although actuators have been used in some cases [3, 4, 5, 6]. In general, these types of tests have shown that interlayer behavior can be studied in the lab under more controlled conditions than in the field, but care must be taken when interpreting the results, as the conditions of the test protocol may be somewhat different than those typically experienced in the field.

2 RESEARCH OBJECTIVES

- Develop a small-scale accelerated pavement tester to evaluate reflective cracking.
- Employ DIC technology to better understand the mechanisms involved with reflective cracking.
- Test various reflective crack mitigating interlayer systems, such as chip seals, using the RCT and DIC technology.

3 MATERIALS & METHODS

The asphalt concrete mixture used for specimen fabrication in this study was a typical surface mix (S-9.5B) used in North Carolina. This 9.5-mm mixture was collected in metal buckets at the asphalt plant and stored in a climate-controlled room until use. A CRS-2 emulsion was used as both a tack coat for the asphalt layers and as bitumen for the chip seal interlayer. The cover aggregate used for the chip seal interlayer was typical #78M stone used in North Carolina.

In this study, DIC technology was used to study the deformations and displacements of the tested samples. The DIC method works by taking a reference image of the sample before loading and subsequently taking multiple images (known as *test images*) throughout the testing. Next, software (specifically, Vic-2D in this research) is used to compare all of the test images to the reference image, and any differences between the reference image and the test images are explained as deformations or motions of the sample that occurred at the time the test image was taken. In this way, full-field displacements and strains of the sample can be monitored throughout the test procedure. The DIC system has two important advantages for studying reflective cracking. First, it allows for easy tracking of the differential movements seen across the interlayers of a layered AC sample, which otherwise might be difficult to track using traditional gauges. Second, strain contour plots allow for easy visualization of the crack location within the sample, because cracks in the surface show up as areas of extremely high strain. Detailed explanations of DIC methods can be found in the literature and are outside the scope of this paper [7, 8].

4 REFLECTIVE CRACKING TESTER (RCT)

The North Carolina State University pavement laboratory has been using a one-third scale wheel load device known as the MMLS3 for various pavement research projects since the late 1990s. This device typically is used to apply 2.7 kN wheel loads at a rate of 6,000 cycles per

hour. As such, the development of a test device to allow small-scale accelerated simulations of reflective cracking in layered asphalt pavements in the laboratory was seen as a reasonable methodology to study the phenomenon of reflective cracking further. The basic concept of this test method is to construct layered asphalt systems on top of steel plates and subject this pavement system to wheel loads by the MMLS3 (Fig. 1). A compaction frame and vibratory roller are used to compact the pavement layers (Fig. 2).

The reflective cracking test setup is as follows: First, steel tubing and I-beams are attached to the base plate of the testing area. Next, two 914 mm × 610 mm × 12.7 mm grooved A514 steel plates are placed on top of the tubing and the I-beams. The steel plates are then bolted to the tubing. Next, the I-beams are bolted to the plates using clamps (Fig. 3a). This effectively creates two cantilevered plates with a 15.86-mm gap between them. By loosening the clamps and adjusting the position of the I-beams, the length of the cantilever on each side of the joint can be controlled, thus controlling the deflection amplitude of the system under loading.

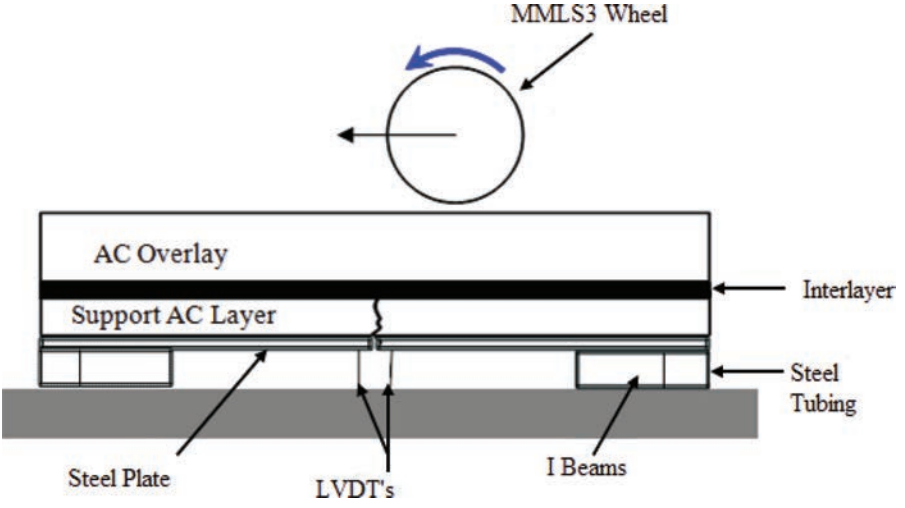

Figure 1. Schematic of the final configuration of the RCT.

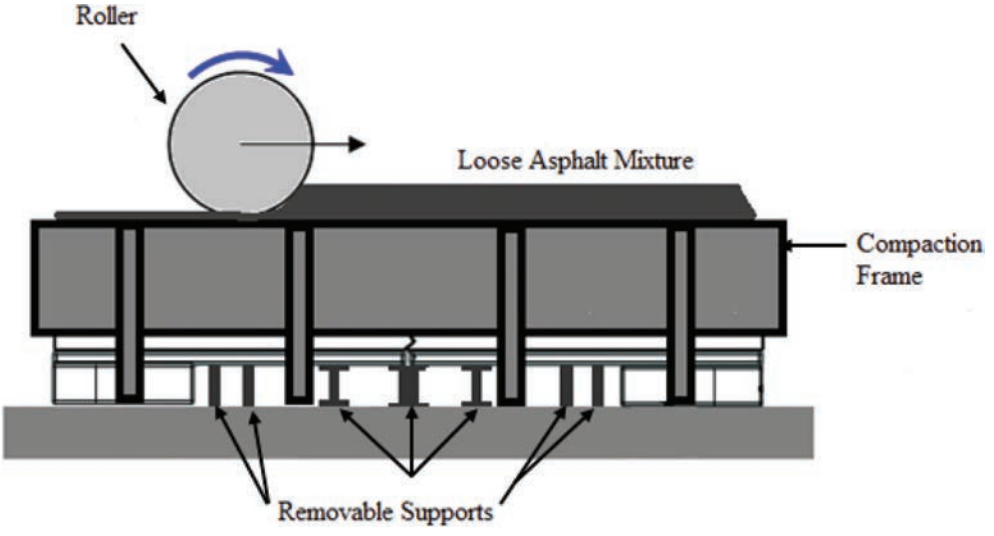

Figure 2. Schematic of the RCT during compaction.

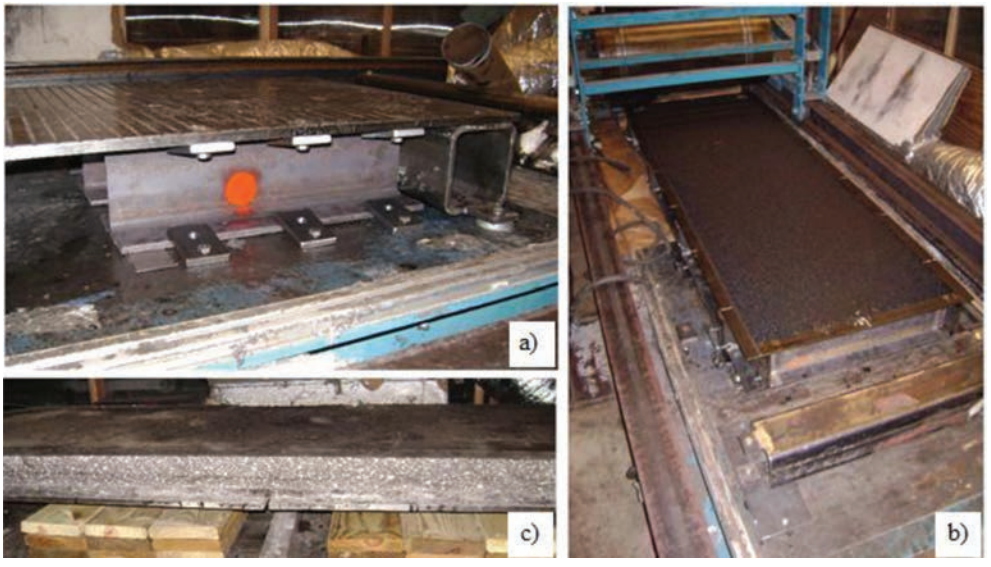

Figure 3. a) Close-up of steel plates bolted to supports, b) RCT and compaction frame during compaction, and c) Final layered system with smoothed surface.

Next, additional supports are provided beneath the steel plates, and a compaction frame is placed around the RCT. The compaction frame is adjusted to the correct height, and a 21-mm layer of AC is compacted using a vibratory steel wheel roller (Fig. 3b). Once the first layer has cooled, a full-depth saw cut is made at the center of the slab at the gap between the two steel plates to simulate a transverse crack in the existing pavement. The RCT is loosened, the two slabs are pushed together slightly to reduce the width of the crack to 3.18 mm in order to match typical crack widths seen in the field, and the RCT is retightened. Next, the desired interlayer is constructed, and the compaction frame is used to construct a second AC layer, bringing the total height of the compacted pavement layers to 59 mm. Once the second layer adequately cools, the vertical edge of the sample is smoothed to provide a flat surface perpendicular to the DIC camera (Fig. 3c). This surface is painted white and then speckled with black spray paint in order to be viewed by the DIC camera. The end result of this procedure is a layered slab specimen of approximately 1845 mm × 584.2 mm with a transverse joint at the middle of the bottom AC layer, supported by two cantilevered steel plates. Typical air void values of the AC layers are approximately 10 percent. This high air void level is due solely to the physical limitations of the laboratory compaction equipment available.

Prior to testing, the removable compaction supports are taken out from beneath the RCT and four spring Linear Variable Differential Transducers (LVDTs) are placed near the joint between the steel plates (two LVDTs at the center of the steel plates and two near the edge). These LVDTs allow the monitoring of deflections of the steel plate during loading to provide independent validation of the DIC measurements and to ensure that the deflections in the center of the slab are similar to those measured at the edge. Next, an environmental chamber is placed around the testing area in order to maintain the temperature of the slab at 20°C ± 1°C. This chamber has a window to allow the placement of the DIC camera and lights outside of the chamber.

Once all the instrumentation is in place, the MMLS3 is placed inside the environmental chamber on top of the RCT slab and wheel loads are run over the pavement at a rate of 1,500 applications per hour until the crack is seen to propagate all the way to the surface. These loads produce deflection amplitudes on the order of that seen in the field (0.76 mm).

5 REFLECTIVE CRACKING TEST RESULTS

In addition to the many trial slabs tested during the design and development of the test method, two reflective cracking tests were performed using the final configuration of the RCT. The first test that was performed in the final configuration utilized a chip seal interlayer and was constructed as follows. The first AC layer was constructed as previously described and saw cut. Next, 1.81 L/m^2 of CRS-2 emulsion was placed on the surface, and 8.14 kg/m^2 of #78M aggregate was placed on the surface and rolled, followed by an application of CRS-2 emulsion of 0.36 L/m^2 as a tack coat. This interlayer was allowed to cure completely before the placement of the second AC layer. The vertical edge was cut and speckled, the compaction supports were removed, and the pavement was subjected to MMLS3 wheel loads until failure.

After failure, the RCT was dismantled and cleaned, and a tack coat only pavement was constructed and tested to provide a basis of comparison for the chip seal test. This control test consisted of a 21-mm S9.5B support layer, 0.32 L/m^2 CRS-2 tack coat, and a 38-mm S9.5B overlay.

5.1 *Crack propagation*

As mentioned previously, cracks in AC samples show up as areas of high strain in the DIC analysis. Contour plots of von Mises strains (Eq. (1)) were used to identify areas of cracking. Figure 5a shows that high strains at the interface of the chip seal sample occurred very rapidly. Interface separations were seen within 700 cycles, and full debonding was observed before 10,000 cycles. As the test progressed, the size of the opening at the interface increased. At around 16,060 cycles, a crack began to propagate vertically approximately 60 mm to the left of the joint and an area of damage began to appear 32 mm to the right of the joint. The crack on the left side of the joint continued to grow until around 44,000 cycles; then, a second crack began to propagate vertically around the interface 124 mm to the left of the joint. It was this second crack that eventually reached the surface of the overlay, just outside of the viewing area of the DIC camera. It is believed that this type of cracking was caused by the rebounding of the right slab while the left slab was still under wheel loading (Fig. 4). It should be noted that at the time of this failure, cracks were also present to the right of the joint and directly above the joint. The total life of this system was around 55,000 cycles.

$$\varepsilon_{von\_Mises} = \frac{\sqrt{2}}{3}\left[\left(\varepsilon_1 - \varepsilon_2\right)^2 + \left(\varepsilon_2 - \varepsilon_3\right)^2 + \left(\varepsilon_3 - \varepsilon_1\right)^2\right]^{1/2} \quad (1)$$

where
ε_1, ε_2, ε_3 = principal strains in x, y, z directions respectively.

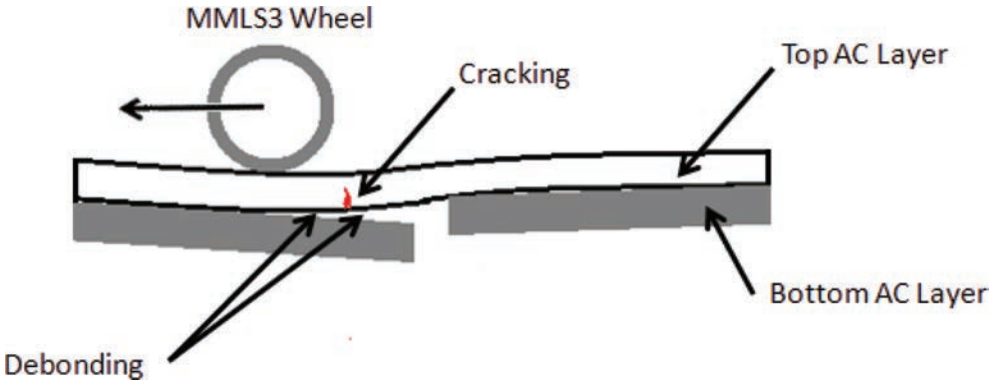

Figure 4. Mechanism of debonding in RCT.

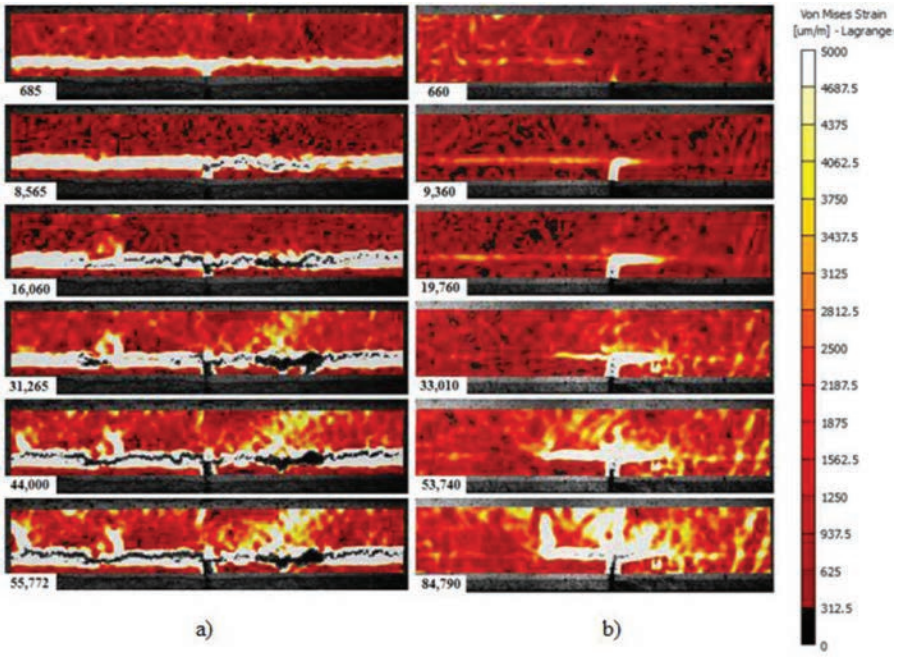

Figure 5. Von mises strain levels for RCT tests: a) Chip seal and b) Tack coat only.

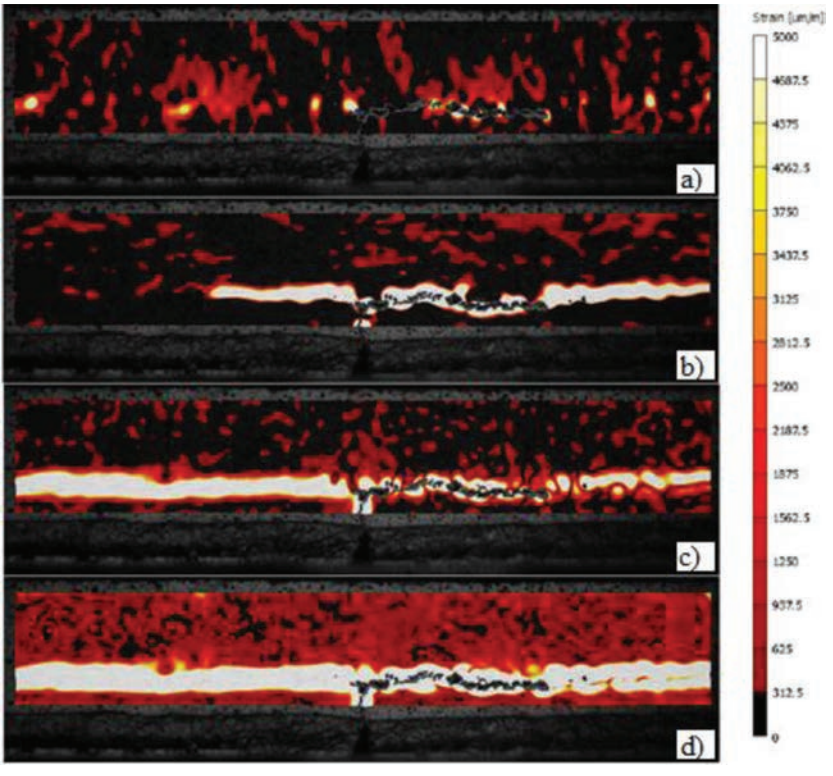

Figure 6. Chip seal strain contour plots: a) Horizontal strain (ε_{xx}), b) Vertical strain (ε_{yy}), c) Absolute value of shear strain ($|\varepsilon_{xy}|$), and d) Von mises strain ($\varepsilon_{Von\text{-}Mises}$).

Figure 5b shows the results from the tack coat only test. These plots indicate that the initial strain along the interface, particularly for the left slab, was significant, but did not result in the large-scale debonding that was evident in the chip seal tests. Next, a crack grew horizontally along the interface on the right slab beginning around 9,000 cycles. After growing for approximately 30.5 mm, the crack stopped at around 33,000 cycles, and a second crack formed on the left slab and propagated about 43.2 mm. At 55,000 cycles both cracks on the right and the left began to propagate upwards, and a third crack began to propagate directly above the joint. Over time, it was this center crack that was the first to reach the surface of the sample. The total number of cycles to failure was approximately 84,000 cycles.

5.2 *Interfacial movements*

Although the von Mises strain contour plots shown in Figure 5 are useful for tracking crack propagation, contour plots of the component strains can give a better understanding of deformations occurring in the system. In order to exemplify this phenomenon, four different plots were made from the same DIC image from the chip seal test showing the four different components of strain at cycle number 11,000 (Fig. 6). These plots indicate that the high von Mises

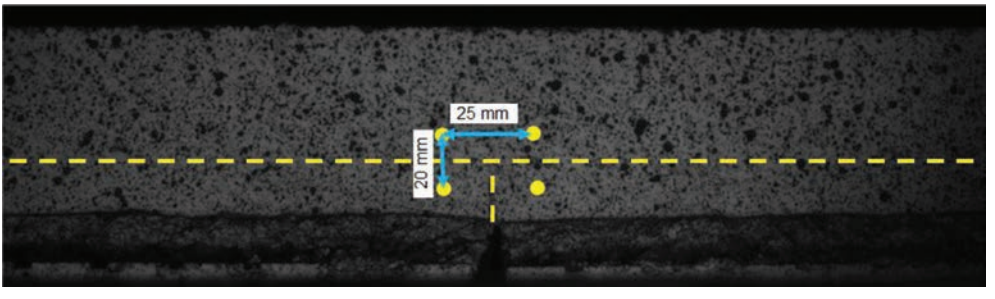

Figure 7. Virtual gauge locations for differential deflections.

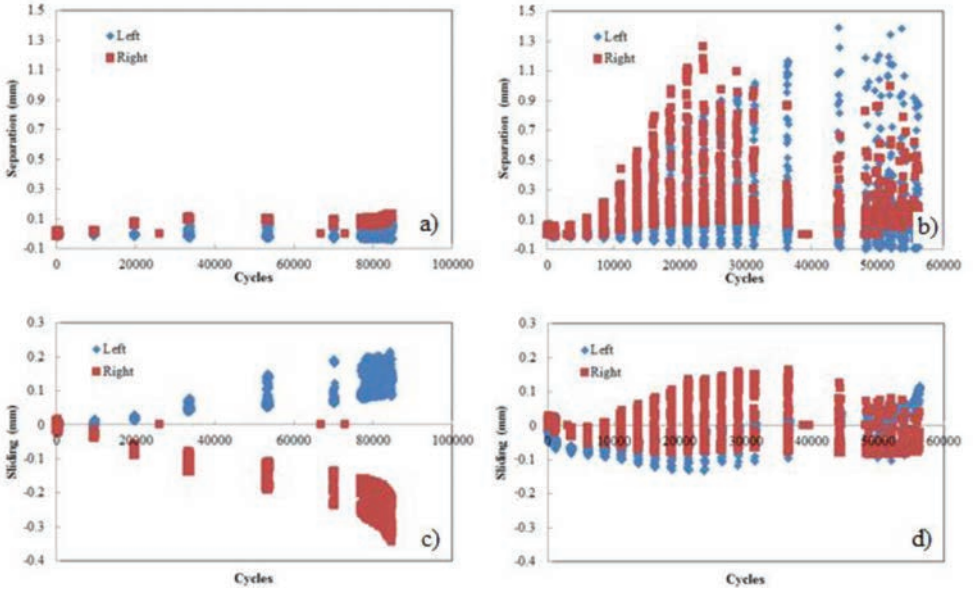

Figure 8. Differential deflection plots: a) Tack coat only separation, b) Chip seal separation, c) Tack coat only sliding, and d) Chip seal sliding.

strain levels seen at the interface are composed of both layer separation and sliding. However, because these strain contour plots can be hard to interpret quantitatively, virtual gauge points were placed on the DIC image, as shown in Figure 7 (the horizontal and vertical dashed lines represent the interface and the joint location, respectively). Because the displacements of each of these points can be tracked independently using the DIC algorithm, the calculation of the differential movements of these points can be used to track both sliding and separation at the interface. Plotting these results can provide a history of these deformations throughout the test. Figure 8 shows that both types of samples experienced sliding movement along the interface between the pavement layers, with the chip seal sample experiencing 2.5 times the sliding amplitude of the control sample (0.23 mm vs. 0.09 mm). Also, both types of samples saw separation at the interface, with the magnitude of the separation in the chip seal sample being over ten times that of the separation seen in the control sample (1.54 mm vs. 0.13 mm).

6 DISCUSSION

The results from the reflective cracking tests indicate that interfacial movement occurred in both types of pavement (with and without chip seal interlayers) and has an effect on the pavement life. The weaker interfacial bonding of the chip seal layer indicates that this pavement experienced more sliding and separation of the layers than the control pavement. This increased movement led to more rapid failure of the overlay. This behavior fits with previous research that suggests that excessive debonding causes high stress concentrations in the pavement and accelerates failure [9, 10]. As such, the common assumption used in the pavement design of complete bonding between pavement layers may lead to inaccurate predictions of the pavement life. Also, these two sets of reflective cracking test results confirm previous research efforts that discuss the possibility of double or even triple cracking in pavements where large relative deflections across the joint in the existing pavement are seen [11, 12, 13, 14, 15, 16, 17]. It is believed that the tendency for both pavement systems to exhibit this type of cracking in the RCT was due to high differential deflections across the joint, and that the reflective cracking test conditions correspond to an extreme case compared to most field uses of chip seal interlayers. These findings help to explain that the chip seal sample performed worse in the RCT than the tack coat only sample, but that chip seal samples have been reported to be generally more effective in the field. Further research is needed using this test method to determine the suitability of the RCT to investigate reflective cracking in pavement systems that utilize different types of interlayer treatments.

7 CONCLUSIONS

- DIC technology is an effective tool for studying layered pavement systems because it allows the calculation of full-field displacements, strains, and the tracking of crack propagation.
- Both types of samples (with a chip seal layer and without a chip seal layer) saw significant separation and sliding of the interface between the pavement layers. This finding suggests that the assumption of complete interfacial bonding commonly used in pavement design may not be realistic.
- Weak interfacial bonds between pavement layers can cause accelerated failure under certain loading conditions.
- Double cracking and triple cracking are possible in cases where differential deflections across the transverse joint are high.

Contact characterization of asphalt mixture using image process

Liya Jiao, Na Zuo & Jun Yang
Southeast University, Nanjing, Jiangsu Province, China

ABSTRACT: The internal skeleton structure of asphalt mixtures has great effects on the rutting resistance. However, currently, rutting performance of asphalt mixtures is mainly evaluated through macroscopic tests at high temperature, which is lack of link with the internal structure. Based on image processing technology and X-ray CT detection, the contact properties of asphalt mixtures were studied at microscopic level. Four image analysis indices were developed in this research, namely: number of aggregate contact points, contact length, contact area and contact plane orientation. The results demonstrated a good correlation between the internal contact indices and the mixture rutting performance, which successfully proved the rationality of contact indices.

Keywords: Asphalt mixture, rutting, image processing, contact of aggregate, flow number

1 INTRODUCTION

Asphalt mixture is a kind of typical visco-elastic material. When asphalt pavement is exposed to heat and heavy traffic repetition effect, deformation under wheels will gradually form, which results in rutting in the end. Rutting has a negative impact on the driving comfort and safety. In order to control the severity of rutting and expand the service life of pavement, a full and detailed understanding of rutting and proposal of representative evaluation indices are very necessary. Currently, macroscopic tests are common methods to evaluate the high temperature stability of asphalt mixtures, including Marshall test, triaxial shear test and wheel-track test.

Microstructural study of asphalt mixtures is an important way to characterize macroscopic performance. Digital image processing is a relatively new research tool. The initial studies focused on morphological analysis of coarse aggregate, such as circumference, diameter, flat and elongated particle content, the long axis orientation and so on. With further research, more and more studies focus on the composition features of asphalt mixtures such as porosity and segregation. Yue Z.Q.[1,2] used CCD (Charge-coupled Device) camera to capture the asphalt mixture internal structure and identified particles that were larger than 2.36 mm, which pioneered the use of digital image processing to study the orientation, shape and distribution of coarse aggregates in asphalt mixture quantitatively. With the development of no dilapidation technology, X-ray CT has also been gradually applied to the study of internal structure. Eyad Masad[3] studied the differences in internal structure of specimens compacted with the Superpave Gyratory Compactor and the linear kneading compactor. Specimens compacted with the SGC were found to have aggregates with more preferred orientation and fewer contacts than specimens compacted with the LKC.

Asphalt mixture is a heterogeneous multiphase material that consists of aggregates, asphalt binder, and air voids. These components constitute a complex microstructure. Based on the contact mechanism analysis, Zhu and Nodes[4] demonstrated that the transmission of load in the asphalt mixture is mainly determined by the interaction of aggregates and binder at the contacts of adjacent aggregates. According to Zhu and Nodes[4], changes in mechanical and geometrical parameters in aggregates and binder will affect the overall stress-strain distribu-

tion in an asphalt mixture. The contact based stress-strain equations and models for asphalt mixtures show that the geometrical properties of the contact such as contact area, number of contact zones and contact orientation affect the stress distribution in the mixture as a whole. The features that have been captured and quantified using 2-D imaging processing in most published research have been limited to simplistic analysis of aggregate structure. Features of contacts among coarse aggregates in internal structure captured by X-ray CT are studied in this paper. Additionally, indices including number of contacts, contact area, contact area and contact plane orientation are proposed to relate to and explain rutting resistance of asphalt mixture.

2 LABORATORY TEST

To verify the capability of new indices to regular mixes used in practice, a comparison was done among mixes of the same gradation but different binder additive types, and also mixes of the same binder type but with different gradation. Mixes with significantly different mechanical performances in terms of rutting resistance, as measured by the Flow Number (FN), were chosen for the verification. The following comparisons of image analysis shown in Table 1 were conducted.

2.1 *Binder*

The asphalt binder has significant effect on the behavior of mixture. 50# basic, SBS modified and high-viscosity asphalt binders were selected in this paper. Basic properties of three kinds asphalt binder are shown in following Tables 2 to 4.

2.2 *Aggregate*

Previous researches[5] indicate that the greater density of sample is, the greater value of CT will be and as a result, brightness in the image will be higher. So, samples composed of higher density aggregates should be adopted for X-ray CT scanning. Samples of AC-13 and PA-13

were made of basalt while those of AC-20 were made of limestone. Properties of basalt and limestone are shown in Table 5.

2.3 *Design of mixture parameters*

Three types of gradation commonly used in practice were chosen for analysis, as shown in the following Table 6.

The asphalt content for AC-13 with SBS, AC-13 with 50#, AC-13 with high-viscosity asphalt, AC-20 with SBS and PA-13 with high-viscosity asphalt is 5.4%, 5.2%, 5.5%, 4.9% and 3.8% respectively, which was decided based on Superpave mixture design method.

Samples were all compacted with a Superpave Gyratory Compactor. Porosity of AC-13, AC-20 and PA-13 respectively reached to 4%~5%, 4%~5% and 18%~19% with 100,83,70

AC-20	SBS modified asphalt binder	260

gyrations correspondingly. Cylinder specimen with size of Φ50 mm × 150 mm were obtained through coring and cutting, which can ensure the clarity of image.

After adjusting the position of the specimen and parameters of X-ray CT, scanning will start. In order to reduce the density differences between the upper and lower parts of samples due to rotation compaction, the midpoint of height will become the benchmark for symmetry. Two vertical orthogonal planes with size of Φ50 mm × 54 mm were captured of each sample. The X-ray CT image of an asphalt mixture sample consists of aggregate particles, asphalt mastic, air voids and background.

2.4 *Simple performance test*

Flow Number is chosen to quantify the rutting resistance of asphalt mixture, which has a good relationship with high temperature performance. The greater of flow number is, the stronger the resistance to permanent deformation will be.

Five structures which consist of two parallel specimen with the size of Φ100 mm × 150 mm were compacted with a Superpave Gyratory Compactor. Simple performance test was operated under the condition that temperature was 60°C and the stress level was 700 kPa. The results of test are shown in Table 7.

3 IMAGE PROCESSING AND ANALYSIS

3.1 *Contact parameters*

Aggregates provide the skeleton of the asphalt mixture and carry most of the load. The number of aggregate contacts in the asphalt mixture represents the connectivity of the internal aggregate structure. Increasing the number of contact points leads to a better stress distribution with less stress concentrations. The effectiveness of contact between adjacent aggregates is dependent on the contact area (contact length in 2-D images) and contact plane orientation (measured from horizontal axis). The increase in contact length raises the friction and interlocking between aggregates. Additionally, the closer the normal to contact plane orientation is to the loading direction, the more effective it is in resisting deformation under loading. The following list represents the internal contact indices that are believed to dictate the rutting resistance of the mixture:

- Number of aggregate contacts
- Contact length

- Contact area
- Contact plane orientation

In this study, contact is defined when two aggregates's perimeter pixels are within a distance. Former studies[6] have shown that if two adjacent particles contact completely, the edges of two particles should be less than 2 pixels apart.

3.2 *Image processing*

Laith Tashman[7] proposed an feasible method in his paper which can capture contacts between aggregates using image processing. Figure 1 shows an automated algorithm developed to measure the aggregate contact length, contact area, contact orientation as well as the number of contacts. The image is first thresholded to convert it to a binary image. The second step is applying the Watershed Filter, which erodes the aggregates until they disappear then dilates them again, up to the point prior to coming in contact as shown in Figure 1b. This image is combined with the binary image(a) using MINUS operator. This operation requires that pixels at the same location in both images have the opposite color in order to be retained in the resultant image(c). The resultant image consists of segments of lines representing the regions of aggregate contacts as shown in Figure 1c.

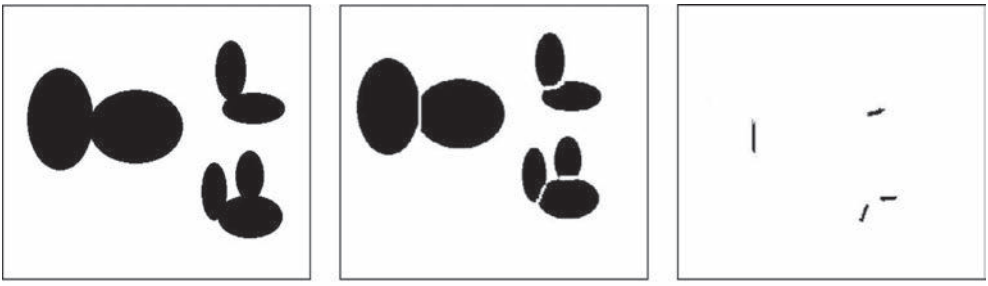

Figure 1. Imaging algorithm to capture aggregate contacts.

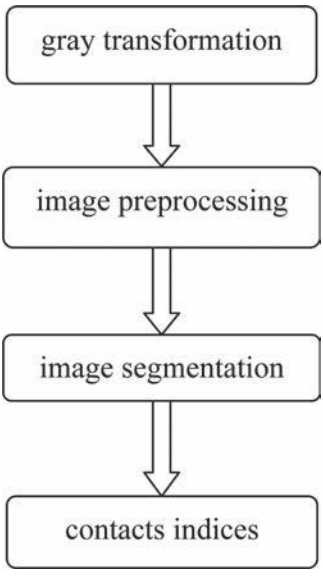

Figure 2. Image processing.

The image processing consists of the following modules.

To reduce the effect of geometric distortion and noise, image preprocessing includes smoothing filter and enhancement process. Segmentation of image is to highlight the shape of aggregates, while asphalt and background are ignored. The ideal segmentation will completely separate aggregates from the asphalt mastic with closed edges, no internal isolated pixels and clear boundary between the particles. However, current segmentation methods cannot meet these requirements, so it is necessary to make a comparison of different processing algorithms to select one which both has fast process speed and ideal segmentation results. Bernsen algorithm which can dynamically changes threshold according to the position of pixel is discovered to satisfy the requirements above.

As smaller aggregates have poor precision in image analysis and permanent deformation is mainly resisted by coarse aggregates, particles smaller than 2.36 mm will be filtered in the image processing (Fig. 3c). Figure 4 shows how to get contact parts among aggregates of PA-13.

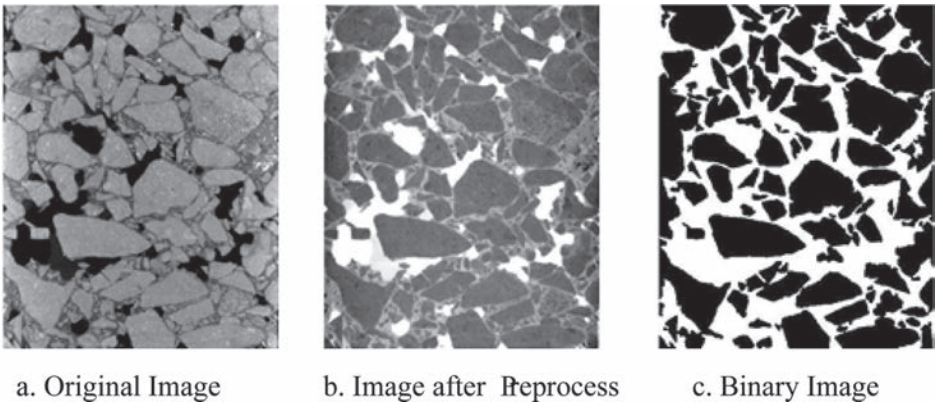

Figure 3. Image processing of PA-13.

Figure 4. Contact parts of PA-13.

Table 8. Analysis results of samples.

Mixture		Number of contact	Contact area/pixel^2	Contact plane orientation/degree	Contact length/pixel
AC-13	High-viscosity asphalt	59	1989	49.3	917
	50# basic asphalt binder	22	745	47.9	301
	SBS modified asphalt binder	26	944	49	371
PA-13	High-viscosity asphalt binder	26	789	43.7	321
AC-20	SBS modified asphalt binder	22	787.5	38.6	282

3.3 *Analysis of contact parameters*

Contact parameters were measured after images had been processed. The number of contact, summary of contact area/length and the average of contact orientation of each sample were calculated as shown in Table 8.

The FN values are plotted in Figure 5 versus contact parameters calculated for AC-13 mixtures with different kinds of binder. As shown in Figure 5, a strong correlation between contact parameters and flow number exists, which supports the aforementioned hypothesis.

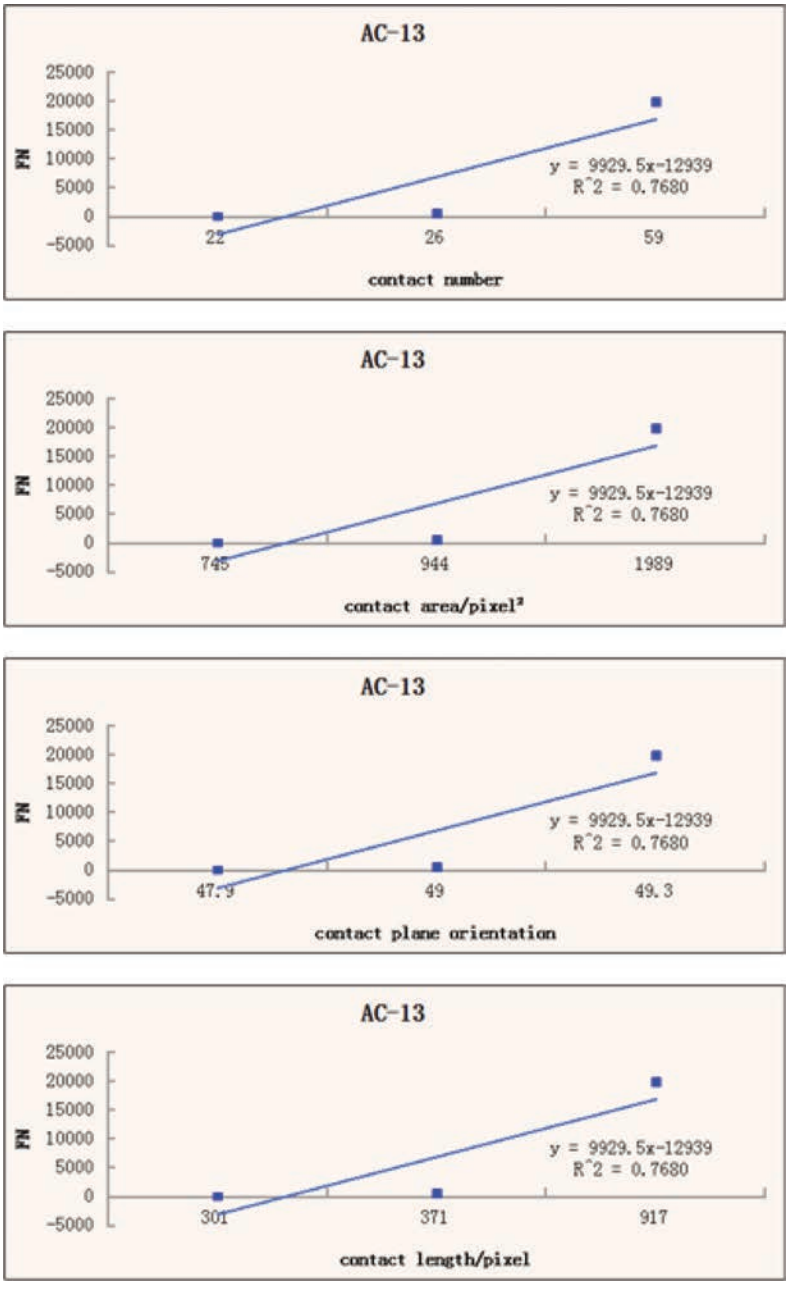

Figure 5. Correlation of different indices with flow number of AC-13.

In addition, as shown in Tables 7 and 8, there is a strong exponential trend between contact indices and flow number of mixtures with the same binder and different gradation.

4 CONCLUSION

In this research, new indices derived from imaging processing are proposed to characterize the internal structure of asphalt mixtures. According to these aggregate contact indices, mixtures with different internal structures could be ranked similar to their mechanical responses to repeated loading as quantified by the Flow Number.

Compared to traditional test, images captured by X-ray CT can effectively can be used to study microscopic internal structure of asphalt mixtures. Besides, after the scanning, samples can also be used for other mechanical test, which improves the utilization efficiency of the material.

The new contact indices, namely: number of contact, contact area, contact length and contact orientation, were measured and compared for a set of mixtures with different rutting performance. The results show that there is a strong correlation between the contact indices and the rutting performance of mixtures.

Reduction of low temperature asphalt binder stiffness using a Renewable Additive

Gerald Reinke & Stacy Glidden
MTE, Onalaska, WI, USA

Susan Listberger & Suzanne Stauduhar
Cargill, Plymouth, MN, USA

ABSTRACT: As crude sources for asphalts have changed it has become more difficult to obtain quality asphalt with adequate low temperature properties to satisfy consumer demand. Many different products have been tested to determine if they can be added to asphalt and provide a lower temperature PG without having a significant negative affect on the high temperature properties of the asphalt. The other concern when using additives to reduce the stiffness of asphalt is that it will have a detrimental effect on the mix properties. Cargill and MTE have investigated a Renewable Additive (RA) that appears to be able to maintain the original mix properties, while also reducing the low temperature stiffness of the asphalt binder. Neat asphalt as well as Polymer Modified Asphalt (PMA) were tested in lab and field trials. The results have shown that the RA can be used to reduce the PG low temperature by 6°C or more and still maintain binder and mixture properties comparable to those obtained from conventional binders of the same PG grade. Furthermore lab and field trials have shown that the RA can be used in the field while still maintaining the quality of the finished product.

Keywords: proprietary renewable additive, reduced low temperature stiffness, modified asphalt, recycled asphalt pavement, recycled asphalt shingles

1 INTRODUCTION

Asphalt binders with low temperature stiffness have always been in high demand. This trend continues as more RAP and RAS are being used in asphalt mix designs. Many RAP designs require a low temperature PG one grade lower than would typically be used to balance out the RAP asphalt that has low temperature stiffness properties higher than the virgin asphalt that would be used. RAS drives the low temperature stiffness of the asphalt binder in the mix even higher. Lee et al. recommended using binder with reduced low temperature and found it to be more effective than lowering design air voids [1]. Mogawer evaluated using rejuvenators to mitigate potential problems with mixes containing RAP and RAS [2]. There is continued demand for higher and higher contents of RAP in asphalt mixes which compounds the problem even further.

In an effort to provide a better asphalt product while still maintaining the high standards that have been set by the asphalt industry. Cargill and MTE entered a partnership to determine if a RA could be used to lower asphalt stiffness while maintaining all the original properties of the asphalt binder. Virgin asphalt was blended with the RA to produce a material that was a PG below the original virgin asphalt (Ex. 64-22 blended to a 58-28). This blend was then compared to virgin asphalt with the same PG as the blend with RA. The RA was also blended with PMA to produce a blend one PG lower and compared to a similar PMA without RA. SHRP PG was done on all the asphalts and the asphalts with the RA performed as well as the asphalts without. Further testing was done in the lab to compare the asphalt

in mix designs using rut testing, AMPT and torsion bars. The blended asphalt performed as well on all of these tests as the asphalt without the RA. Finally two field trials were completed using the RA in polymer modified asphalt with a control section in 2011 and 2013. To date the test and control sections have performed similarly.

The RA has the ability to provide asphalt binders with lower temperature stiffness without compromising asphalt binder or mix properties. It is a useful alternative that can be used immediately to alleviate the continued and growing demand for asphalt binder with lower temperature stiffness that cannot be obtained through many refineries at this time. It blends in easily and can be incorporated into almost any type of asphalt terminal or hot mix plant without a significant capital expense.

2 MATERIALS AND METHODS

2.1 *Asphalt blending and SHRP testing*

The asphalt binders chosen for evaluation were a PG 58-28, 64-22, 64-34P and 70-28P. All materials were characterized using standard SHRP PG. Blending with the RA was done on a hotplate at 165°C for about an hour. The RA is a liquid and easily homogenizes into the asphalt. Blends were left in an oven overnight at 165°C before SHRP testing was commenced. Binders used for mix design testing and field trials were also characterized using standard SHRP PG.

2.2 *Mix designs and testing*

The lab trial mix designs used an E-3, 12.5 mm mix, limestone aggregate and 20% RAP. Pills were compacted to complete rut testing per AASHTO T324-11 and torsion bar testing per ASTM D7552-09. A set of the torsion bar pills was aged in an oven at 85°C for five days prior to cutting torsion bars.

2.3 *Field trials and testing*

The asphalt for both field trials was blended in a tank at an asphalt terminal using a 70-28P with 4% RA to make a 64-34P. The tank used for blending is equipped with a central mixer. All SHRP PG testing was completed to confirm that the AC met the required specifications prior to it being shipped to the plant site. The control asphalt was a 64-34P made with 52-34 base asphalt. The 2011 field trial mix design was an E-3, 19 mm mix; containing trap rock and 20% RAP with 6.2% AC. The percentage of virgin AC added to the mix was 3.8% with a total of 5.2% AC. The 2013 field trial mix design was an E-10, 12.5 mm mix; gravel aggregate and 11% RAP with 5.2% AC. The percentage of virgin AC added to the mix was 5.2% with a total of 5.5% AC.

Field mix was obtained from truck samples for the control and the asphalt binder with RA. Lab compacted specimens were prepared for the 2011 field trial. Half of the pills with each AC type were aged in an oven at 85°C for five days prior to testing. Pills were compacted for torsion bar testing per ASTM D7552-09 and AMPT per AASHTO T342-11. All four pill types also had and extraction and recovery per ASTM D2172. The AC was characterized using standard SHRP PG, WRI 4 mm low temperature testing [3–4] and asphaltene analysis per ASTM D3279-12.

3 RESULTS

3.1 *SHRP testing of asphalt binder*

PG 58-28 binder was modified with 5% RA to make a 52-34 which was compared to a typical 52-34. The RA modified binder had similar high and low temperature properties as the

52-34 without the RA added. A 64-22 was modified with 5% RA to produce a 58-28 which also had similar properties to a 58-28 without RA. For the 2011 field trial a sample of 70-28P was taken from a terminal and modified with 4% RA. The same blend was also done at a terminal. The temperature spread as can be seen in Table 1 for the control 64-34P was 100.9°C, control 70-28P was 102.8°C and for the 64-34P with RA was 101.6°C.

Asphalt cement was recovered from lab compacted pills for the 2011 field trial. One set of the pills had been aged for five days in a forced convection oven at 85°C. Grading was determined based on a DSR of 2.2 which is comparable to RTFO PG material. Low temperature grading was done using the 4 mm DSR procedure developed by WRI [3–4]. The RAP that was used in the field trial was also recovered and tested. All the recovered binder data can be found in Table 2.

3.2 *Mix testing on lab samples*

A set of pills was compacted using the control and the RA containing asphalt from the lab mix. Pills from each aging condition were cut into torsion bars and tested. This data was used to generate the complex modulus curves in Figure 1 [5].

Rut pills were also compacted using the field mix. A set of unaged pills from the control and the RA set were tested and the data plotted in Figure 2.

3.3 *Field trials*

A set of the pills that were made from the mix for the 2011 field trial were used for torsion bar testing. This data was used to generate the complex modulus curves in Figure 3 [5].

A set of AMPT pills were made from the mix used on the 2011 field trial. Testing was conducted on those and used to generate the complex modulus curves in Figure 4 [5].

4 DISCUSSION

Lab testing of asphalt binder with and without the RA showed the binder to have similar qualities for materials with comparable SHRP PG. Through all of the aging processes

the RA binder performed as well as the material without the RA. Further study using lab prepared mixes and unmodified base binders with and without RA showed similar results. In Figure 1 the complex modulus showed that the RA modified binder reduced the aging of the mix and led to lower long-term stiffness. The rut data in Figure 2 shows the RA modified binder rutting more quickly than the material without the RA. Comparing this to the data in Table 1 shows that the RA binder was less stiff initially and thus it would rut more quickly. This can be alleviated if necessary by using less RA in the binder as was done for the field trials.

The terminal blending of the polymer modified asphalt with the RA and paving of the field trial showed that the material with the RA performed similar to the control asphalt binder mix during all stages of mixing and compaction. The mix that was brought to the lab and compacted and aged showed some variation from the information that was obtained with the lab prepared mix. The recovered binder with the RA showed characteristics of stiffening more than the binder without the RA at both high and low temperatures as can be seen in Table 2. The torsion bar data in Figure 3 and the AMPT data in Figure 4 test show that the material with the RA had a slightly higher stiffness at high temperature in the unaged mix pills which also resulted in a higher stiffness in the aged pills. At low temperature the materials appears to be very similar. The higher stiffness of the asphalt with the RA in the recovered asphalt correlates with the amount of asphaltenes that were found in the recovered binders. It is possible that variation in the RAP asphalt properties is responsible for this difference. This will be monitored in the field to determine if that correlation pertains to actual field aged samples. Further testing of field cores from the field trials will be conducted at two years and five years. The test sections will be monitored and compared to the control sections for a minimum of five years to determine if there are any long-term differences between the two sections.

The RA is an effective alternative to provide asphalt binder with reduced low temperature stiffness to meet the growing demand. It is a readily available material that is economically competitive in current markets. It provides a way to modify asphalts while meeting the current SHRP PG specifications. It also allows for asphalt to be modified that would be able to meet MP19 specifications if the need arose. This additive may be an effective way to lower virgin asphalt cement stiffness and allow for higher RAP contents to be used in mix designs. The RA is very compatible with all current regulatory and field processes and provides a much needed alternative to reducing low temperature stiffness of asphalt cement as demand continues to rise.

ABSTRACT: The objective of this study is to develop the testing methods of Asphalt Release Agent (ARA) performance and the degree to which they may damage the asphalt. The testing of ARA performance observed their ability to reduce the adhesion between the asphalt and the surface of steel (asphalt tools, truck beds…) by the asphalt slide test. The testing of the safety of the ARAs consisted of the measurement of the degree to which the compacted asphalt is damaged by the ARA including CBR resistance, indirect-tensile strength and bitumen degradation testing. It was found that the indirect tensile strength test provided more consistent results than CBR resistance. Also included is the study of bio-sourced chemicals and their ability to function as ARAs.

Keywords: asphalt release agents, asphalt testing, ARA, bio-sourced

1 INTRODUCTION

The most important component of an asphalt mixture is bitumen, which through adhesion keeps the aggregates together and the asphalt cohesive. These same adhesion properties can make it very difficult to clean surface of equipment that has been used to work or transport bitumen. For the truck beds used for transporting asphalt for example, the adhesion prevents the asphalt from smoothly sliding out of the bed as the truck attempts to discharge its load. In such cases, workers must manually coax the residual asphalt out of the truck bed, exposing workers to hazardous chemicals [1].

Asphalt Release Agents (ARAs) are used for spraying surfaces that come into contact with asphalt during the asphalt construction process, such as truck beds, pavers, finishers, tools and various other (usually metal) items. The bitumen non-adherence is based on the interaction of the agent, the bitumen and the metal surface. There are three main types of asphalt release agents: petroleum based, fatty-oil based and non-oil based [2,3]. As opposed to bitumen removers, asphalt release agents are not intended to break down the bitumen, but to protect the equipment used to produce and place asphalt from bitumen residue. Therefore, it is important that asphalt release agents do not cause damage to the asphalt when coming into contact with it.

Petroleum-based ARAs function by softening the bitumen on the surface, that is, reducing its viscosity and thereby the adherence. Petroleum products such as diesel fuel however, are

skin irritants and emit volatile compounds harmful to human health [3,4]. For this reason, the U.S. Department of Transportation as well as many state departments have restricted the use of diesel fuel as an asphalt release agent [1]. Petroleum ARAs that will come into contact with the new asphalt on the asphalt truck bed or an accidental spill will cause damage to the bitumen leading to soft spots which are exacerbated by factors such as heat and light. The deterioration effect is also increased with increasing time of contact with the bitumen [2,5,6].

Alternative ARAs include bio-sourced fatty-oil based agents. They consist of purified or partially purified fats and oils including synthetic or naturally occurring glycerides or triglycerides of fatty acids that are sometime etherified or emulsified in water. They work as a surfactant to reduce the interfacial tension between bitumen and the contact surface as well as the friction, forming a separating layer [2,6]. There has also been damage to asphalt observed from the use of bio-sourced ARAs. The agents may have less power to damage the bitumen than petroleum-based ARAs, but will stay in contact with the asphalt for a longer time due to their higher evaporation temperatures [1,7].

Escadeillas et al. [8] mixed gasoil and a vegetable-based ARA with bitumen and observed the changes in penetration (ASTM D5-EN 1426) and softening point (ASTM D36-EN 1427). It was found that the penetration increases significantly with gasoil and ARA addition while the softening point decreases. These were strong indications of the gasoil and the vegetable-based agents deteriorating the bitumen.

The American Association of State Highway and Transportation Officials (AASHTO) National Transportation Product Evaluation Program (NTPEP) for asphalt release agents [9] has two tests for evaluating ARA performance and one for safety. However, their results are pass/fail and subjective the in their implementation.

Asphalt release agents are widely used to protect tools and truck beds from the residue of asphalt; however, the study of their performance or of the damage that they can cause to asphalt has been minimal. The purpose of this paper is to present the testing methods of Asphalt Release Agent (ARA) performance and the degree to which they may damage the asphalt. The objectives of the test development are to provide testing that (i) reflects as much as possible the on-site conditions, (ii) can differentiate between various ARAs, (iii) can provide new insight into the interaction of ARAs and asphalt and (iv) that are relatively simple and cost effective to implement. The testing of ARA performance was done by the asphalt slide test. The testing of the safety of the ARAs consisted of CBR resistance, indirect-tensile strength and bitumen degradation testing. The products tested included gasoil, 3 bio-sourced ARAs and 2 bio-sourced BRs used for reference.

2 MATERIALS AND METHODS

2.1 *Materials*

2.1.1 *Bitumen*

The bitumen used for testing was Total 35/50 as classified by EN 12591, indicating a penetration (ASTM D5-EN 1426) value of between 35 and 50 mm. The bitumen had to be heated before being used and it was taken care not to heat the bitumen more than once due to the volatiles that are lost by the bitumen during the heating process.

2.1.2 *Asphalt*

The asphalt mixes were manufactured in accordance with EN 12697-35+A1 with Total 35/50 bitumen and limestone/silica aggregates. The aggregates, as shown in Table 1, consisted of coarse aggregates, fine aggregates and limestone filler that were graded in accordance with EN 13108-2. The asphalt was separated into 1 kg samples and stored in aluminium containers. As with the bitumen, it was taken care to only reheat the asphalt once before the compaction of the samples.

Table 1. Typical composition of asphalt mixture.

Material	(% by mass)
Sand 0/2 mm	23.69
Aggregates 2/6.3 mm	23.31
Aggregates 6.3/10 mm	44.97
Limestone filler (<80 µm)	2.55
Bitumen total 35/50	5.60
Total mass	100

Table 2. Technical information for commercially available ARAs and BRs.

Product	Origin	Density @ 20°C (kg/L)	Evaporation point (°C)	Kinematic viscosity @ 40°C (mm^2/s)
Gasoil	Petroleum	0.82–0.86	60	9.5 (@20°C)
ARA 1	100%	0.88	250	11
ARA 2	Vegetal-	0.89 (@25°C)	250	14
ARA 3	based	0.86–0,90	350	12.5
BR 1		0.88	170	10–11
BR 2		0.86 (@25°C)	250	5.7

2.1.3 *Commercial asphalt release agents*

The asphalt release agents tested consisted of 3 bio-based ARAs available on the French market. Additionally, gasoil, a petroleum product historically used as an ARA and bitumen remover in the past was also used. Although this product is currently not permitted for use as an ARA on construction sites, it was nevertheless tested as a reference. Additionally, 2 vegetal-based Bitumen Removers (BRs) were used as products that are known to cause damage to asphalt in order to test ARA safety. Technical information for these products is shown in Table 2.

2.2 *ARA performance*

The objective of ARA performance testing is to measure the ability of the ARA to reduce the adherence of bitumen to tools and machinery for asphalt construction (generally metal surfaces). The challenge in this testing is to develop a qualitative analysis that best represents the conditions in the field and is as cost and time effective as possible to implement.

2.2.1 *ARA performance evaluation apparatus*

The ARA Performance Evaluation Apparatus (ARA-PEA) is a device developed by LR Vision of Castanet-Tolosan and LMDC of Toulouse for evaluating the performance of ARAs in reducing the adhesion between bitumen and construction materials (Fig. 1). The device consists of an interchangeable plate (usually steel) that can be adjusted to an incline from 0–70°. The principle of the device is that when an ARA is applied to the plate, sliding asphalt or bitumen from the top of the plate can allow us to observe the performance of the ARA as the asphalt slides or bitumen flows on the incline. In order to facilitate this, a heating mechanism is installed beneath the plate that is capable of heating it to over 200°C.

In order to allow for the quantification of the asphalt release agent performance, there are several measurement devices installed on the apparatus, all though not all of these may be useful for our study as of yet:

– Gage for setting the angle of inclination;
– Temperature gage for adjusting the heating underneath the plate;
– Laser temperature gage over the plate to measure the temperature of the asphalt/bitumen;

Figure 1. ARA Performance Evaluation Apparatus (ARA-PEA).

Figure 2. Asphalt Slide Test: applying ARA (left), asphalt spread on the plate (centre), load of 2,5 kPa distributed on top of the asphalt (right).

– Camera in order to film the flow of the bitumen, allowing for the measure of its speed and the observation of the shape of the bitumen flow;
– Depth gage in order to measure the depth of the bitumen flow on the plate.

2.2.2 *Asphalt slide test*

The mixture slide test is found in the AASHTO program for asphalt release agents [9]. The test developed in this article follows the same principle as the AASHTO one, while adding the ability to quantify ARA performance. The principal of the test is performance of an ARA on a scaled version of an asphalt truck bed using the ARA-PEA.

The test (Fig. 2) involves spraying an ARA over an area of 21.5 × 40 cm on a steel plate resting horizontally. This is followed by placing 1000 ± 10 g of hot asphalt (150 ± 10°C) on the surface of the plate, so that is spread out as evenly as possible. The plate is maintained horizontal and a sheet of wax paper is placed on top of the asphalt to prevent sticking, followed by a wooden board (21 × 40 cm, 883 g). On top of the board, a load of 20 kg is placed creating a distributed pressure on the asphalt of 2,5 kPa. This simulates the transportation of the asphalt where there is a pressure on the asphalt in contact with the truck bed form the asphalt resting on top. The plate rests horizontally for a certain period of time (0,5–1 h), after which it is placed on the ARA-PEA and immediately inclined at a certain angle (0–70°), simulating the discharge of the asphalt from the truck. It is also possible to heat the plate when it is on the device. With the application of an ARA, the asphalt falls off the plate, and from this action, the following data can be taken for judging the performance of the ARA:

– The mass of asphalt residue left on the plate;
– The area of asphalt residue left on the plate (by image analysis);
– The time that it takes the asphalt to slide down after the plate is inclines.

2.3 *ARA effects on asphalt*

The propensity of the ARA to degrade the asphalt needs to be evaluated before it can be determined to be suitable for road construction.

2.3.1 *Asphalt compaction*

Two types of asphalt compaction methods were considered in this study: by proctor and by compression.

2.3.1.1 Compaction by proctor

The first method was similar to the French NF P 18 127 standard for compacting asphalt. The asphalt was heated to around 160°C and placed in a Ø100 mm mould (EN 13297-30). The asphalt is then proctor compacted by 2 series of 25 drops, cleaning the proctor head of bitumen and turning the mould 45° between the series. The mould is removed and placed to cool to around 40°C. The samples produced are Ø100 mm with a height of 60 ± 2 mm.

2.3.1.2 Compaction by compression

The second method of compaction is by compression and is based on the compaction method from the French NF P 98-251-1. This method was adapted in this study for use with Ø100 mm moulds (EN 13297-30). The asphalt was heated so that it was at 160°C before compaction and placed in the mould. The asphalt was compacted by a piston pressed (preheated to 50°C) on the asphalt through a compressor and maintained for a certain period of time at a constant pressure. While the standard provides a pressure of 11.94 MPa for 5 min as the compaction, it was found that these specifications were not necessary or practical for this test. A pressure of 2.55 MPa for 2 min was found to be adequate in keeping the samples under 10% voids (9.2% as determined by NF EN 12697-6). The samples produced were Ø100 mm with a height of 60 ± 2 mm.

2.3.2 *Measuring the resistance to loading of asphalt in contact with ARAs*

2.3.2.1 ARA application

The ARA is applied to the centre of the sample by a graduated burette. This is done either just before compaction or after compaction of the asphalt. The ARA is applied at the centre of the sample via a graduated burette in one pour. It was determined from preliminary testing that a dosage of 5 mL was adequate for the first series of testing (CBR loading).

2.3.2.2 Resistance of asphalt by vertical CBR loading

To test the degradation of the sample by the ARA, the samples were subjected to loading by California Bearing Ration (CBR) piston as in [10] at 1.27 mm/sec. The samples were allowed to rest for 7 days before they are subject to testing in order for the ARA to demonstrate its effects with time. The temperature was checked at each point after the asphalt was heated, before compaction, after compaction and before demoulding.

2.3.2.3 Resistance of asphalt by indirect tensile loading

An alternative to CBR loading was also investigated: resistance by Indirect Tensile (IT) loading, which places the sample on its tangential side and proceeds to load it from the top creating tension forces in the middle of the sample. A test such as this on asphalt can be found in NF EN 12697-34 "Marshall Tests Stability and Flow". The samples are tested 7 days after the application of the ARA and the loading rate is 1.27 kN/mm. The temperature was checked at each point after the asphalt was heated, before compaction, after compaction and before demoulding.

2.3.3 *Bitumen degradation testing*

The degradation of bitumen directly by the ARA is determined by the Bitumen Degradation Test (BDT) as shown in Figure 3. The samples are prepared by pouring 10 ± 1 g of hot

Figure 3. BDT silicon sample moulds (left), sample submerged in product (center) and beakers after test (right).

bitumen (150 ± 10°C), heated at 160°C for 2 h, into circular silicon moulds. This produces "cone with flat top" shaped samples with the dimensions: Ø37 mm top, Ø31 mm bottom, h = 10 mm. The samples are left to cool for 8 ± 4 h after which they are demoulded, and weighed to the nearest 0.01 g. The samples are placed into 150 mL graduated glass beakers of known mass, and the product is poured over it so that the bitumen sample is submerged in it completely. The sample is left for another 24 h, after which, the product is drained out, with the bitumen sample now sticking to the bottom of the beaker. The sides of the beaker above the bitumen sample are wiped with a cloth and the remains of the samples are weighed to the nearest 0.01 g. The Bitumen Degradation (BD%) is taken as the difference between the mass of the bitumen sample before (BB) and after (BA) the test as shown in. Eq. (1).

$$BD\% = 100\% \times (BB - BA)/BB \quad (1)$$

3 RESULTS

3.1 *ARA performance*

3.1.1 *Asphalt slide test*

A number of parameters were used in developing the test in order to find the ones that can lead to the most indicative results; they are shown in Table 3.

For test No. 1, the ARA was applied at around 20 mL/m^2 and the plate was not heated during the test. The asphalt did not move from the plate when inclined, requiring the top of the asphalt to be pushed lightly before the start of the sliding, even at the maximum possible inclination of 70°. The light pushing did not appear to move the control sample.

For test No. 2, the ARA was applied at around 20 mL/m^2 and the plate was heated to around 70°C before ARA application and was heated during the inclination part of the test at 70°C. This time, the asphalt slid after inclination, indicating the necessity of heating the plate before the asphalt slides. A cooling time of 30 min was found to be adequate for the asphalt to develop some adherence to the plate as there was a certain delay between when the plate was inclined and when the asphalt slid as shown in Table 4, allowing for the measuring of time to the beginning of the slide after the inclination as a performance characteristic for the ARAs. An angle of inclination of 45° was found adequate for the sliding as well.

For test No. 3, the cooling time was set at 30 min and the angle of inclination at 45°. The plate was not heated before the asphalt was applied; however, the ARA-PEA was heated at varied temperatures. It was found that for a temperature of 60°C at inclination, the samples with ARAs slide, but the control samples do not. A temperature of 60°C was therefore set for the plate at inclination.

With the optimum parameters for the test determined, the test was conducted with Gasoil, ARA 1 and ARA 2. The photos of the plates after the test are shown in Table 5 and the results of the test in terms of residual mass and time to beginning of slide are shown in Table 6.

Table 3. Parameters for asphalt slide test.

Test no	Quantity of ARA (mL/m²)	Heating of plate before ARA application (°C)	Cooling time	Plate at inclination (°C)	Inclination angle (°)
1	20	–	1 h	–	45–70
2	20	70	30 min	70	45
3	25	–	30 min	Variable	45
Final	25	–	30 min	60	45

Table 4. Results for asphalt slide test for test no. 2.

Product	Asphalt (°C)	Quantity ARA (mL/m²)	Time to beginning of slide
Control	160	–	–
ARA 1	160	20.90	13 s
ARA 2	160	21.41	1 s

Table 5. Images of plates after asphalt slide test.

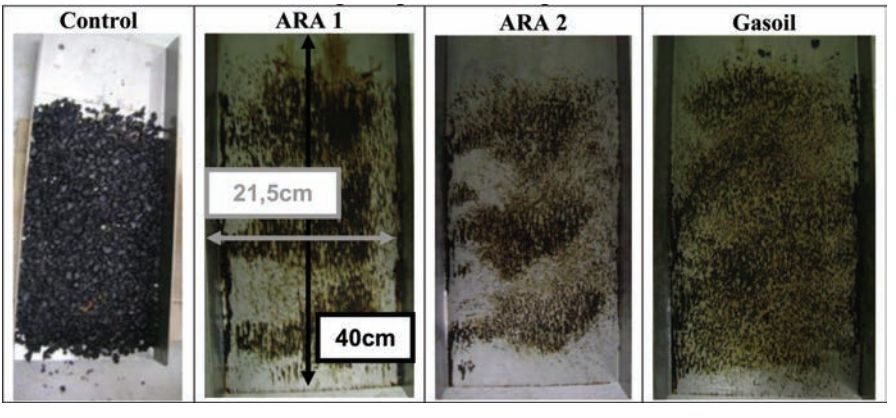

Table 6. Results for asphalt slide test results.

Product	Quantity ARA (mL/m²)	Residual mass %	Time to beginning of slide
Control	–	100%	–
Gasoil	28.65	0.22%	1.00 s
ARA 1	27.00	0.12%	92.67 s
ARA 2	27.57	0.27%	100.00 s

ARA 2 was found to have the least residual mass, which is confirmed by the images of the plate. Gasoil excelled in terms of time to beginning of slide, with the asphalt sliding in under 1 second after inclination.

3.2 *ARA effects on asphalt*

3.2.1 *Asphalt degradation by ARAs*

In evaluating the tests for the degradation of asphalt by ARAs, there were several aspects observed. They included the state of the moulds, the resistance of the ARA to CBR/Indirect Tensile loading and the partition of the ARA inside the sample itself.

3.2.1.1 Resistance of asphalt by vertical CBR loading

All of the samples for CBR loading were made with proctor compaction and had a 5 mL dosage of ARA. The resistance to CBR loading of the control samples manufactured 10 days apart, shows a significant difference in both the shape of the resistance (kN) vs. displacement (mm) curve and the maximum resistance with a Coefficient of Variability (CVAR) of 0.220 for the 6 samples. As this was not acceptable, another set of tests was completed to see if the source of the error was the asphalt, taking extra precautions to keep the asphalt homogenous. The second set of control samples also has a high variability coefficient of 0.133. In addition to this, some ARAs appear to actually increase the resistance of the asphalt relative to the control samples. The images in Figure 4 show the leaching of the bitumen onto the moulds as was observed in [10] as well as the tendency of the ARAs to move to the sides of the samples due to the centre of the samples having a higher density through proctor compaction process.

3.2.1.2 Resistance of asphalt by indirect tensile loading

For IT Trial No. 1, samples were manufactured by compression and the ARA quantity was 5 mL applied immediately after compaction at an asphalt temperature of around 120ºC. The coefficient of variability for the IT control samples (all made on different days) was 0.051, lower than for the CBR samples. The reduction of IT resistance (RR%) represents the difference between the maximum resistance of the ARA and the control samples. It is shown that all of the RR% values are above 50%, indicating that the quantity of ARA should be reduced. This is confirmed by Figure 5 (left) where there is significant leaching on the moulds, which would reduce the repeatability of the test.

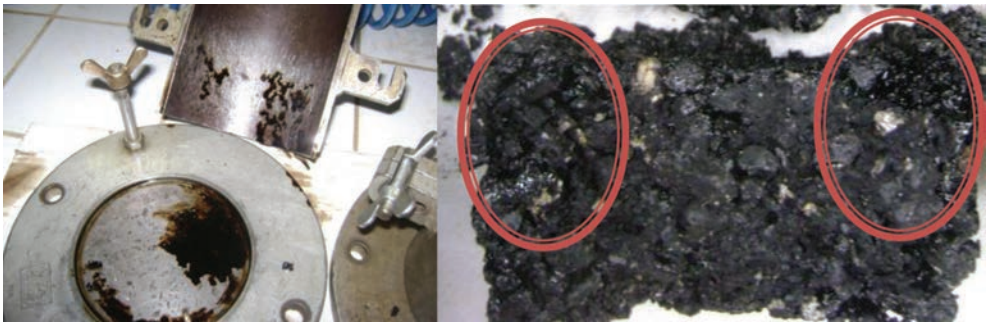

Figure 4. Proctor-CBR loading samples showing leaching of bitumen onto moulds as was observed in [10] and flow of ARA towards the side of the sample.

Figure 5. Compressor compacted IT loading samples showing leaching of bitumen with 5 mL ARA applied after compaction (left) and 2 mL ARA applied before compaction (right).

Table 7. Resistance reduction for IT Trial No. 1 IT (5 mL ARA applied after compaction), IT Trial No. 2 (2 mL ARA applied before compaction) and % BD from bitumen degradation test.

Product	Evaporation on surface	% Resistance reduction		% Bitumen degradation
		5 mL after compaction	2 mL before compaction	
Gasoil	Some	71.4	–	–
ARA 1	Negligible	65.8	55.2	36.22%
ARA 2	Negligible	58.3	54.7	33.79%
BR 1	Negligible	–	66.9	52.90%
BR 2	Negligible	68.9	–	–

For IT Trial No. 2, samples were manufactured by compression and the ARA quantity was 2 mL applied immediately before compaction at around 160ºC. Table 7 shows that all of the RR% values are above 50%, indicating that the ARA quantity is still too high. However there is a clear difference between the ARA resistance values and that for the BR. Additionally, the leaching of bitumen on the moulds (Fig. 5, right) is almost negligible, indicating that nearly the entire quantity of the ARA stays in the sample.

3.2.2 *Bitumen degradation by ARAs*

The results for the bitumen degradation test are shown in Table 7. The mass of all of the bitumen samples are reduced in this test, including the BR, which at 52.9% has a higher reduction than the two ARAs.

4 DISCUSSION

4.1 *Validity and limits of the test methods*

4.1.1 *ARA performance*

The Asphalt Slide Test was tested with ARAs using three different sets of parameters. The ARA-PEA (ARA Performance Evaluation Apparatus) provides a good platform for this test. While the pre-heating of the plate is not necessary, the heating of the plate during inclination is for the asphalt to slide down by itself. A cooling time of 30 min appears to be adequate to allow for the asphalt to adhere to the plate. There were three types of results observed during the testing:

1. Mass of asphalt residue retained on the plate after inclination;
2. Time the asphalt stayed on the plate after inclination.

The parameters are qualitative results that can be used to compare the performance of various ARAs.

4.1.2 *ARA effects on asphalt*

The evaluation of asphalt degradation by ARAs involved testing two different methods of loading with two different methods of compaction. The samples tested with CBR loading and proctor compaction did not provide results that were repeatable. Even though samples manufactured at the same time had similar resistance values, both control samples and samples with ARA addition did not correlate if they were made on different days. Additionally, many of the samples where ARAs were used, showed similar or higher resistance to CBR loading than the control samples.

It was clear that the ARAs had caused the leaching of bitumen of the samples from the observation of moulds after the samples were demoulded as was observed by [10]. However, this effect was not easy to understand from the results of CBR loading. It was interesting to note that from the photos of the insides of the asphalt samples after testing; the ARAs

appeared to move towards the sides the samples. Conversely, the CBR loading tested the middle 50 mm diameter of the sample.

IT (Indirect Tensile) loading was attempted as an alternative to the CBR. As opposed to only loading the middle part, IT loading tests an entire mid-section of the sample. Additionally, the resistance to IT of the samples depends more on the properties of the bitumen (the part of the asphalt affected by ARA degradation). By comparison, CBR loading depends more on the position of the aggregates than with IT.

Compaction with a compressor was used as opposed to proctor compaction in order to have a more evenly distributed density in the sample. The voids content was determined to be 9.2% in accordance with NF EN 12697-6 for a compression pressure of 2.55 MPa for 2 min. With this method, the CVAR for resistance to loading for the control samples was much smaller than with the CBR-proctor samples.

For an ARA quantity of 5 mL applied after compaction, the results in loss of resistance for Gasoil the ARAs and the BRs were all over 50% for the samples. In addition, there was significant leaching of the asphalt by the ARA onto the moulds, indicating that the dosage had to be lowered. There was however, a significant difference in loss of resistance for the IT test between the ARA 2 and BR 2, indicating that the test is able to distinguish between products that are meant to degrade bitumen and those that are not.

For the second IT test, the ARA was applied at 2 mL before compaction of the sample, allowing it to be applied at around 160ºC, which is the peak temperature in asphalt fabrication. After the fabrication, the moulds did not show much presence of bitumen leaching by the ARA, indicating that almost all of the ARA stayed in the sample. This is important because too much bitumen leaching could vary the quantities of ARA that act on the asphalt sample to sample. The loss of resistance was still over 50% for all of the applied products. However, there was a clear difference between the values for the two ARAs and BR 4, indicating a test that can differentiate good and bad ARA products. The difference of adding the ARA before and after compaction should be considered as two relevant tests with this method.

The bitumen degradation test is able to differentiate the degradation from ARAs and BRs on bitumen and is a repeatable test that is relatively simple to implement.

4.2 *Evaluation of ARAs*

4.2.1 *ARA performance*

For the Asphalt Slide Test; ARA 1, ARA 2 and Gasoil (all commercial bio-sourced ARAs, available on the French market) were evaluated. It was found that ARA 2 left the least residual bitumen while with Gasoil, the asphalt slid down almost instantly upon inclination. Although the residual masses were not that far apart, the gasoil performed much better in retention time after inclination than the vegetable based agents. This indicates that there is a performance benefit in using gasoil despite in being banned on most construction sites due to worker health and environmental issues.

4.2.2 *ARA effects on asphalt*

In testing ARA for their effects on asphalt gasoil was tested along with ARA 1, ARA 2 and ARA 3. The gasoil was found to have the most destructive effect (in terms of reducing the resistance of asphalt to IT loading), one similar to a BR, even when applied to the asphalt at high temperatures (130 ± 5ºC). Despite the fact that gasoil is much more volatile (evaporation at around 60ºC) compared to the bio-sourced ARAs (evaporation at 250ºC+), there is always a significant part of gasoil that stays in the sample and degrades the asphalt. The deterioration of asphalt by gasoil has also been described in [2,5,6], added to the fact that it is banned for use as an ARA and BR on construction sites in many countries [3,4]. It should also be added, that under laboratory conditions, many effects that would increase evaporation (and decrease the degradation of apshalt by gasoil) such as wind and UV-rays are not possible to replicate.

In terms of the bio-sourced ARAs, ARA 2 and ARA 3 were found to be less destructive that BRs by asphalt and bitumen degradation testing. More testing still has to be performed on ARA 1 to draw conclusions.

5 CONCLUSIONS

The conclusions in developing test methods for the determination of the performance and safety of bio-sourced ARAs are as follows:

- The asphalt slide test provides three indicators of ARA performance including area of asphalt residue, mass of asphalt residue and time for asphalt to begin sliding after inclination;
- Heating under the plate is needed for the asphalt to begin sliding in the asphalt slide test, making the ARA-PEA ideal for this test;
- Gasoil performs better than the vegetable-based agents in the asphalt slide test in terms of retention time after inclination;
- The testing of asphalt degradation by ARAs with the CBR-loading does not produce reproducible or coherent results;
- The testing of asphalt degradation by ARAs with IT loading produces reproducible results and is able to differentiate the damage from ARAs and BRs;
- Compaction of the asphalt by compression as opposed to proctor produces a more consistent sample in terms of density distribution;
- The bitumen degradation test is able to differentiate the damage from ARAs and BRs on bitumen and be repeatable, making it possible to test bitumen degradation from ARAs.

Civil Engineering Department, NIT Hamirpur, Himachal Pradesh, India

ABSTRACT: Flexible pavements with bituminous surfacing are widely used in India. The high traffic intensity in terms of commercial vehicles, overloading of trucks and variations in daily and seasonal temperature of the pavement have been responsible for the early development of distresses like ravelling, undulations, rutting, cracking, bleeding and shoving of bituminous surfacing. So it is essential to build a durable and long lasting road pavement. Designing a road with a strong bituminous base course like Dense Bituminous Macadam (DBM) can provide the load-bearing capacity needed to handle heavy axle loads. Strong base course also provides the load-spreading ability to relieve stresses and strains coming on to the subbase course and subgrade layers. Quality and quantity of binder have greater influence upon performance and durability of flexible pavements. Quality of binder may be modified by using certain modifiers such as polymer, crumb rubber, sulphur and use of these modifiers is dependent upon the type of construction, availability of material, equipment, and climatic conditions. The objective of this study is to evaluate the efficacy of Sulphur Extended Asphalt Modifier (SEAM) to improve the durability and rutting potential of a bituminous base course mix like DBM. Various laboratory tests like Marshall Stability, Tensile Strength Ratio, Retained Stability and Unconfined Creep were conducted on specimens prepared by two different types of binders namely asphalt of penetration grade 60/70 and another with 60% Asphalt + 40% SEAM. The results indicate that with the use of SEAM, reduction in asphalt usage can be significant.

1 INTRODUCTION

In early 1970s, due to concern over asphalt cement supply issues and an anticipated overabundance of elemental sulphur, many organizations such as, Société Nationale des Pétroles d'Aquitaine (SNPA), Gulf Oil of Canada, Sulphur Development Institute of Canada (SUDIC), Texas Chemical Company, U.S. Bureau of Mines, and the Texas Transportation Institute began to evaluate the potential for sulphur to substitute for asphalt as a binder extender; this became known as Sulphur Extended Asphalt (SEA). At the time, it was projected that there would be an abundant amount of sulphur from many sources: pyrite processing into sulphuric acid, natural gas recovery, crude oil refining, coal usage, other chemical processes, and desulphurization from smoke stack emissions. 68 test sections were constructed between 1975 and 1984; 18 of these were monitored under FHWA Demonstration Project No. 54 (DP54). This was initiated in 1979 and provided design, construction, and evaluation assistance. The Demonstration Projects Division organized a task force, with the Sulphur Institute to conduct a comparative performance review of the SEA pavements with that of conventional Asphalt Concrete (AC) pavement control sections. Twenty-six projects in 18 states were evaluated. The results of this review indicated that sulphur could potentially

be used as an asphalt extender with no significant deleterious effect on performance and durability (FHWA, 1990).

SEAM, is a patented additive developed by M/S Shell Global solution for use in asphalt paving mixtures. It is both a binder extender and an asphalt mixture modifier. It improves road strength and reduces pavement cracking and rutting, which results in safer roads and longer road life. It is in the form of pallets as shown in Figure 1.

Important key features of SEAM include:

- An odourless pellet containing sulphur, plasticizer and additives to control fume and odour during asphalt mixing.
- Melts easily on contact with hot asphalt mix; disperses quickly during mixing.
- Meets related health and safety emissions standards.
- No risk of environmental leaching.

It is added into the hot mixture of aggregates and asphalt during the mixing process. It is not pre-blended with asphalt. A portion of the SEAM is chemically combined with the asphalt and acts as an extender. One part of SEAM is dissolved in the asphalt and modifying the asphalt properties, viscosity is lowered and its ductility is increased and another part of SEAM, as free sulphur, when the blend cools, crystallises. Depending on the amount of SEAM added, the crystallisation gives different levels of strengthening. Sulphur crystallisation acts as a structuring agent in the asphalt mixture. This is shown in Figure 2.

Figure 1. SEAM pellets.

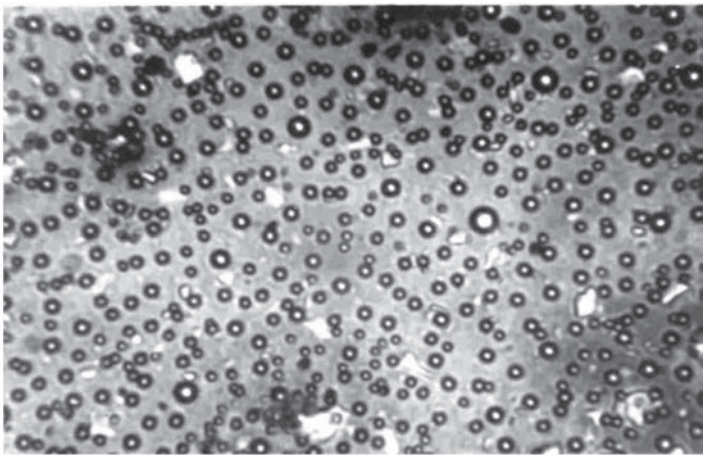

Figure 2. SEAM in the asphalt mixture.

2 EXPERIMENTAL PROGRAMME

In this study, design of DBM was analysed in terms of durability and performance with the help of various laboratory tests like stability, tensile strength ratio, retained stability and unconfined creep. The tests specimens were prepared by two different types of binders namely asphalt of penetration grade 60/70 and with 60% Asphalt + 40% SEAM.

2.1 *Design of DBM*

Bituminous mix design is a delicate balancing act among the proportions of various aggregate sizes and asphalt content. For a given aggregate gradation, the Optimum Bitumen Content (OBC) is estimated by satisfying a number of mix design parameters. Following steps were considered in the case of DBM mix design.

- Selection of materials for DBM:
  Asphalt: 60/70 penetration grade asphalt was used for preparation of DBM mix.
  Additive: Sulphur Extended Asphalt Modifier (SEAM) is used as an additive by replacing 40% asphalt.
  Aggregate: Mix consisted of three types of aggregate; coarse aggregate, fine aggregate, and filler as available in the laboratory. Aggregates were tested for their physical properties and were found suitable for use in DBM Mix. 2% lime and 3% stone dust was used as filler in the mix.

Aggregate were proportioned suitably to get the designed grading for 80–100 mm thick DBM as shown in Table 1.

2.2 *Modified Marshall Method of bituminous mix design*

Modified Marshall Method was developed for mixes composed of aggregates with maximum size up to 38 mm. The procedure is basically the same as the original method, except some differences as given in Table 2.

Table 1. Grading of DBM mix for 80–100 mm thickness.

IS sieve (mm)	Used grading (% passing)	Recommended by MORTH (% passing)
45	100	100
37.5	97–100	95–100
26.5	78	63–93
13.2	65	55–75
4.75	46	38–54
2.36	35	28–42
0.3	14	7–21
0.075	5	2–8

Table 2. Parameters of Marshall method.

Parameter	Marshall method	Modified Marshall Method
Max. size of aggregate	25 mm	38 mm
Height of sample	63.5 mm	95.2 mm
Diameter of sample	102 mm	152.4 mm
Weight of hammer	4.5 kg	10.2 kg
Weight of sample	1200 gm	4000 gm
Compaction level (Number of blows)	75	112

(Source: Asphalt Institute Manual Series No. 2 (MS–2)).

Figure 3. Mixing and compaction of DBM sample.

For making the DBM samples, aggregates were taken as per the grading and heated to a temperature of 180ºC. Hot asphalt (135ºC) was added and mixed by mixture for 2 minutes. The Marshall mould is heated separately in the oven at 160ºC and hot mixture is poured in to the mould kept in the mould assembly. The specimen was prepared by giving 112 blows on each face by 10.2 kg hammer (Fig. 3). The compaction temperature of the mix was kept at 125ºC. Samples with SEAM were prepared in the similar manner. The SEAM was added to hot mixture of aggregate and asphalt at a temperature not less than 125 ºC.

2.3 *Determination of Optimum Binder Content with 60/70 asphalt*

According to Asphalt Institute Manual Series No. 2 (MS–2), the Optimum Binder Content (OBC) is the percentage of asphalt corresponding to four percent air voids.

3 TESTS ON ASPHALT MIXES

The following laboratory tests were carried out to evaluate the performance and durability of IntregraBase modifier in Dense Bituminous Macadam (DBM) course. IntegraBase is an asphaltic modifier which when added to bitumen reacts chemically when mixed with the aggregate. The result is an asphalt with increased workability, a 50%–200% increase in pavement strength, higher fatigue resistance (and therefore, longer life), and increased resistance to rutting and stripping.

3.1 *Stability test*

Marshall Stability of a test specimen is the maximum load required to produce failure when the specimen is preheated to a prescribed temperature is placed in a special test head and the load is applied at a constant strain. While the stability test is in progress, dial gauge is used to measure the vertical deformation of the specimen. The deformation at the failure point expressed in mm is called the Marshall flow value of the specimen (as shown in Fig. 4).

3.2 *Moisture susceptibility*

Presence of moisture in a bituminous mix is a critical factor, which may lead to premature failure of the flexible pavement. The loss of adhesion of aggregates with asphalt was studied

Figure 4. Measurement of stability and flow value.

by utilising Tensile Strength Ratio test (TSR) and Retained Stability test to examine the effect of modifier on resistance to moisture damage.

- Tensile strength ratio test
  The tensile strength ratio of asphalt mixes is an indicator of their resistance to moisture susceptibility. The test was carried out according to AASHTO T283-89 specifications. The specimen was placed and submerged in vacuum container filled with water at room temperature. A vacuum of 13–67 kPa absolute pressure (10–26 inches Hg partial pressure) is applied for 30 minutes. Remove the vacuum and leave the specimen submerged in water for 5 to 10 minutes. There after place the specimen in water bath at 60ºC +/– 1ºC for 24 hours and the remove the specimen from hot bath and place in water bath maintained at 25ºC +/– 0.5ºC for 2 hours. Tests for indirect tensile strength for conditioned and un-conditioned specimens were done at 25°C temperature. The ratio of the tensile strength of the water-conditioned specimens to that of dry specimens is the tensile strength ratio.
- Retained stability test
  This test measures the stripping resistance of a bituminous mixture. The standard modified Marshall specimens of 152.4 mm diameter and 95.2 mm height were prepared. The specimens were kept in water bath maintained at 60°C for 24 hours, and thereafter tested for stability value. The results are reported as the percentage of marshall stability determined in normal condition of the test.

3.3 *Static creep test*

It was developed as a better means of designing and assessing mixtures for resistance to permanent deformation. Laboratory specimen is subjected to unconfined, uniaxial loading with a constant force and the resulting axial deformation is measured with time. The reversible part of the total deformation also determined by removing the load and measuring the deformation after a recovery time that is usually equal to the loading time. Specimen was preloaded at the test temperature (30ºC) for 10 minutes with conditional load to provide a stress equivalent to 10% of the normal applied stress of 100 kPa and any axial deformation is recorded. The load is then quickly increased to the test load and the axial deformation is measured with time. The time intervals for the readings are 10, 40, 100, 400, 1000, 2000, 3000 and 3600 seconds. Loading and unloading conditions are shown in Figure 5.

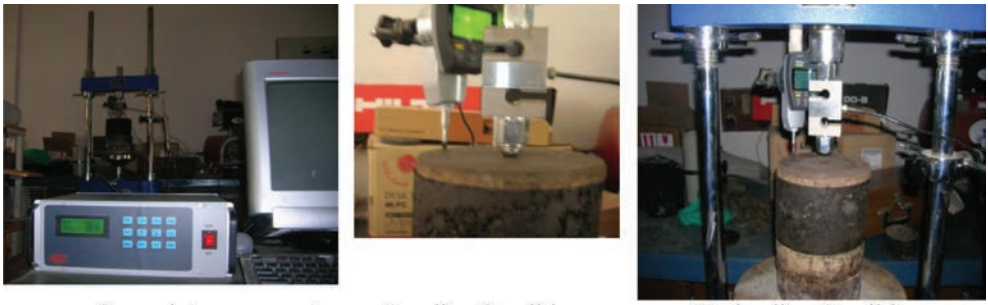

Figure 5. Static creep test for different conditions.

Table 3. Specific gravity of ingredients.

Material	Specific gravity
Coarse aggregate	2.695
Fine aggregate	2.699
Filler	
Rock dust	2.569
Lime	1.242
Asphalt (60/70)	1.020
SEAM	1.230

4 TEST RESULTS AND ANALYSIS

4.1 *Specific gravity of ingredients*

Specific gravity of ingredient was measured according to the guidelines given in Indian Standard Code IS-2386. Values are shown in Table 3.

4.2 *Determination of optimum binder content*

Volumetric and mechanical parameters obtained for DBM with 60/70 asphalt such as Bulk Density, Marshall Stability, Flow, and other volumetric properties are given in Table 4. The test values obtained are plotted graphically and shown in Figures 6 to 9. Using the above parameters, optimum binder content was found to be 4.4% by weight of mix. The Optimum Binder Content (OBC) was determined corresponding to 4% air voids and values of other parameters were checked at this binder content. Durability and performance tests on two types of mixes were conducted at this OBC.

4.3 *Design parameters at OBC with 60/70 asphalt*

The values obtained at the optimum binder content are indicated in Table 5.

4.4 *Mechanical and water susceptibility properties of DBM mixes*

SEAM effect on mechanical and water susceptibility properties of DBM mixes such as bulk density, stability, flow, retained stability, tensile strength ratio was studied. The results are discussed below.

- Unconfined creep test
  The result of Creep test on DBM mixes are shown in Table 6.

Table 4. Volumetric and mechanical parameters obtained for DBM with 60/70 asphalt.

Sample no.	Asphalt content (%)	Sp. gravity of mix (G_t)	Bulk density (G_b) (g/cc)	Stability value (S) (kg)	Flow value (mm)	% Voids in asphalt (V_b)	% Voids in Mineral Aggregate (VMA)	% Voids Filled with Asphalt (VFB)

6 CONCLUSION AND RECOMMENDATIONS

Two types of DBM are evaluated in this study, one with 60/70 Asphalt and another with 60% Asphalt + 40% SEAM. The optimum binder content for both mixes was kept 4.4% by weight of total mix. Marshall stability, retained stability, tensile strength ratio and unconfined creep test were conducted there after results were compared and following conclusions are drawn:

- The Marshall stability of DBM with 60/70 binder is 2734 kg. It increases to 4389 kg when 40% of asphalt is replace by SEAM.
- Retained stability of modified mix is 75.7% only which is less than minimum requirement of 80%. It indicated that some stripping of material might have occurred during immersion of sample in hot water.
- Tensile strength ratio which is also moisture susceptibility property of the mix is satisfactory in both the cases.
- Results of static creep test shown in Figure 10 indicate that modified mix has low rutting potential as compare to mix with 60/70 binder.
- The creep modulus of mix with SEAM is around 37% higher than that of mix with 60/70 binder.
- Use of SEAM is likely to reduced consumption of asphalt by weight of 40% which is remarkable considering depleting resources of cured oil.
- This product can be used without harming environment, provided the mixing and compaction temperature are strictly controlled in filed.

Moisture susceptibility of Nano-sized Hydrated Lime-modified foamed Warm Mix Asphalt mixes

Aboelkasim Diab & Zhanping You
Department of Civil and Environmental Engineering, Michigan Technological University, Houghton, MI, USA

ABSTRACT: Despite the obvious benefits of Warm Mix Asphalt (WMA) technologies are stealing the spotlight from classic Hot Mix Asphalt (HMA), there are concerns regarding moisture susceptibility of the mixes especially when it comes to the technologies that mainly depend on applying water (i.e., foaming). The primary objective of the research was to investigate the moisture susceptibility of foamed WMA mixes modified with Nano-sized Hydrated Lime (NHL). Hydrated lime materials in this study included, NHL with particle sizes of 50-nm and 100-nm along with Regular-sized Hydrated Lime (RHL). The Tensile Strength Ratio (TSR) and dynamic modulus (|E*|) tests were employed to accomplish this objective. A secondary objective of this research was to assess the validity of the two utilized TSR and |E*| tests. The |E*| samples passed one and five freeze-thaw cycling processes before each testing. The TSR and |E*| results revealed that foamed WMA mixes are more susceptible to moisture damage in comparison to the control mix. Also, the NHL-modified mixes performed much better than the RHL for both unconditioned and after multiple conditioning. The |E*| test seems more reasonable than the TSR test for moisture susceptibility testing.

Keywords: Foamed warm mix asphalt, nano-sized hydrated lime, tensile strength ratio, dynamic modulus, moisture susceptibility

1 INTRODUCTION

The use of WMA helps drastic reduction of the temperature of an asphalt mix during production, transportation, and compaction. The benefits of WMA technologies are not limited to the heart of potentially mitigating emissions and fuel-use concerns, it also offers the prospect of greater flexibility when transporting, placing and compacting the mix. Different benefits documented by applying the WMA concept have increased the attention to this technology [1–4]. Lower production temperatures are achieved by means of various WMA technologies broadly classified as organic and chemical additives and foaming technologies (either by using water-bearing additives or water-based processes). Organic additives are used to decrease the asphalt binder's viscosity above the melting point of the binder, whereas below the melting point, they tend to increase the stiffness of the binder [5, 6]. Additionally, the organic additives provide not only reduced binder viscosity at mixing and placement temperatures but also increased viscosity at service temperatures, which is an added benefit specific to this type of process [7]. Chemical additives are used to improve the ability of asphalt to coat the aggregate particles at lower temperatures rather than reduce the binder's viscosity. The mechanism of chemical compounds is based on its surfactant activity, which adds lubricity to individual microscopic asphalt particles and that develop slip planes which let the asphalt particles move more easily, requiring lower levels of energy [8, 9].

The foaming concept is based on the cool water expanding when it comes in contact with hot asphalt binder, and increasing the binder's volume and surface area, consequently

decreasing the overall viscosity of the asphalt binder [10–13]. A number of current WMA water-bearing additives use hydrophilic materials such as Aspha-min® and Advera® to produce foamed asphalt. Hydrophilic materials are framework silicates that have large vacant spaces in their structure that allow space for large cations such as sodium, potassium, barium and calcium, and even relatively large molecules and cation groups such as water. The water-based foaming process is another technology to produce the foamed WMA which add benefits by eliminating the need for expensive additives and special asphalt cement by mixing a small amount of water (usually with a mass ratio of 1% to 5% to the asphalt binder) into the hot asphalt to create microscopic bubbles [14]. These small bubbles act to reduce the overall mix viscosity and increase aggregate coating on the rock allowing the mix to be workable at lower temperatures.

However, as the WMA use increases, more research is needed to ensure its performance since questions remain to be answered especially when it comes to susceptibility to moisture damage and rutting in comparison to HMA [15–20]. The rutting susceptibility of WMA mixes is beyond the scope of this investigation. Preliminary laboratory testing has shown that when producing WMA, the combined effect of the initial aggregate moisture content and reduced mixing temperature can have a dramatic impact on the performance of the produced mixes, especially with respect to the resistance to moisture susceptibility. Unfortunately, it is often difficult to control these parameters outside the laboratory testing [9]. The foaming in general transfers water molecules in hot asphalt to lower the overall viscosity of the asphalt binder. The released water molecules may be entrapped in the asphalt pavements during compaction which cause moisture damage and lead to the failure of asphalt pavements. Inadequately dried aggregates due to lower production temperatures, and even the possible introduction of additional moisture to the WMA from the various foaming technologies, may affect the binder-to-aggregate adhesion which likely increases the moisture susceptibility of the mixes. Therefore, more attention is being paid to WMA susceptibility to moisture especially for mixes produced using the foaming methods. As a result, water may be left in close contact with the aggregate surface, which impairs the bond between aggregate and asphalt and increases the susceptibility to moisture damage. Besides, lower mixing temperatures can cause less hardening of the asphalt, thus reducing adhesion to aggregates. Previous researches have shown that WMA may be more susceptible to moisture damage compared to HMA when tested in the laboratory [15, 21, 22].

The hydrated lime with its regular size (which is referred to herein as RHL) has been used as an additive for asphalt mixes from their very beginning. However, the usage of NHL (particle sizes ≤ 100-nm) in asphalt binder materials has only been investigated by the authors. In studies by Diab et al. [13, 23], the effectiveness of hydrated lime to the foamed WMA was investigated and it was concluded that the performance is particle size dependent. This paper extends the authors pioneer work to study the effect of NHL modification on moisture susceptibility of the foamed WMA mixes. The foamed mixes were produced by using the water-bearing additive, Advera®, and a water-based laboratory foaming method. The |E*| test was performed along with the TSR test since the latter shows variability and less connectivity to the moisture susceptibility in the field [24, 25]. The |E*| test was performed on dry samples and one and five cycles-conditioned samples. This will help address the short- and long-term performance of the mixes' moisture susceptibility.

2 MATERIALS, MIX DESIGN, AND SAMPLES PREPARATION

Aggregates used in this study were obtained from Hancock, Michigan. The nominal maximum aggregate size for the asphalt mix gradation was ½″ (12.5-mm) sieve. The E3 mix design traffic level for this gradation is used which is designed to withstand traffic levels greater than 1 million ESALS (Equivalent Single Axle Load) and lower than 3 million according to Michigan Department of Transportation specifications [26]. One original asphalt binder (PG 58-28) from Gladstone, Michigan was used throughout the entire study. The optimal asphalt binder content for the control asphalt mixes using this gradation is 5.7% (by the weight of

the mix). Adjustments were made to the number of gyrations during compaction to achieve desired air voids about 7 ± 1% which simulates the air void content in early stages after pavement construction [27, 28]. All samples were compacted using a Superpave™ gyratory compactor to 51 gyrations to obtain samples that are 100-mm in diameter and approximately 150-mm in height.

Hydrated lime materials used in this study included RHL and NHL (50-nm and 100-nm). The Scanning Electron Microscopy (SEM) images of RHL and NHL materials are shown in Figure 1a, and b, respectively. The RHL was added to the asphalt binder with the ratio of 20% (normal dose in the field), while the NHL was added with the ratios of 5, 10, and 20%, all by the weight of the binder. To ensure the dispersion of the NHL particles into asphalt binder after mixing, the deagglomeration within the NHL-modified asphalt admixture is discussed in the following section. Advera® is a mineral foaming additive used to produce WMA. The SEM image of the crystalized structure of Advera® material is shown in Figure 1c. Advera® WMA is a synthetic mineral of a standard size contains 18–20% moisture, is released at temperatures above 100°C. The release of moisture out of the sub-micron pore causes micro bubbles which decrease the overall viscosity and enhance the workability of the asphalt mix. The Advera® foaming effect lasts for about 6 to 7 hours which gives long lasting workability [29, 30]. The foaming effect is minimized to a certain time due to loss of water in the bag-house at the asphalt plant [31]. The foamed mixes were produced by adding Advera® to the binder with the ratios of 3, 4.5, and 6% (all by the weight). The corresponding ratios were selected to represent 0.15, 0.25 (normal dose in the field), and 0.35%, all by the weight of the mix, respectively. A laboratory water foaming setup also was used to produce the foamed WMA. The water was injected in the asphalt binder by the ratio of 1.5% (by the weight). A detailed procedure to produce the foamed asphalt using the laboratory setup is reported

Binder descriptor	Range of mixing temp. (°C)	Range of compaction temp. (°C)
Control	152–156	137–142
50-nm (20%)	167–171	152–158

in details elsewhere [32]. More information about different materials and preparation can be found in related studies [13, 23]. The detailed description of binders used to prepare different WMA and HMA mixes is presented in Table 1. Hydrated Lime (RHL and NHL) and Advera® materials were added with no additional mix design. To avoid the deviation of mix gradation, the percent hydrated lime added was substituted for a portion of the baghouse fines and the asphalt content remained constant for all mixes. The volumetric properties of the all mixes were evaluated again to make sure the target air voids ratio is within limits. Three samples were prepared for each mix type. The TSR samples were prepared by sawing the |E*| samples to a final size of 100-mm diameter and approximately 63.5-mm height. All WMA mixes prepared using Advera® and laboratory water foaming method were mixed and compacted at a temperature of 130°C. Using the rotational viscosity test, the mixing and compaction temperatures for the HMA mixes were determined by using the viscosity against temperature relationship from which the viscosity was 0.17 ± 0.02 Pa-s and 0.28 ± 0.03 Pa-s for the mixing and compaction temperature, respectively. The HMA mixes were prepared according to the mixing and compaction temperatures range shown in Table 2.

3 STUDYING THE DISPERSION AND DEAGGLOMERATION OF NHL INTO THE ADMIXTURE

Concerns have arisen of the excessive agglomeration of NHL particles after mixing with asphalt binder especially if the NHL is added with higher percentages (20%). The agglomeration problem is one challenging issue for pavement scientists and unfortunately there is no unified and accurate method to quantify the dispersion and deagglomeration of the modifier into the admixture. This study employed the so-called Energy Dispersive X-ray Spectroscopy (EDX or EDS) technique to study the dispersion and deagglomeration potential within the admixture. EDX is a relatively simple yet powerful technique used to qualitatively and quantitatively identify the elemental composition of as little as a cubic micron of material. The theory behind EDX technique is that each element into the material has a unique atomic structure allowing unique set of peaks on its X-ray spectrum [33]. The equipment is attached to the SEM machine to allow for elemental information to be gathered about the specimen under investigation. EDX works by detecting X-rays that are produced by a sample placed in an electron beam. The electron beam excites the atoms in the sample that subsequently produce X-rays to discharge the excess energy. As the electron beam can be precisely controlled, EDX spectra can be collected from a specific point/particle on the sample, maps can be acquired which depict a localized chemical analysis across the specimen. In this study, the technique was used to depict a qualitative analysis by mapping the concentrations of Calcium (Ca) element present in the NHL ($Ca(OH)_2$)-modified asphalt binder. A 50-nm NHL (20%)-modified binder sample was cryo sectioned and placed uncoated onto a copper grid and then mounted on an Al mount and imaged using the SEM. The EDX was run using Aztec, Oxford system at Clemson University. From the acquired image shown in Figure 2, there is a small concentration of the NHL particles in some parts of the sample, and almost no concentration in most parts of the sample. The small concentrations can be attributed to the less capability of the high shear mixer to completely disperse and deagglomerate the nanoparticles in the asphalt binder. However, the majority of the image shows satisfactorily dispersed and deagglomerated NHL particles within the asphalt binder.

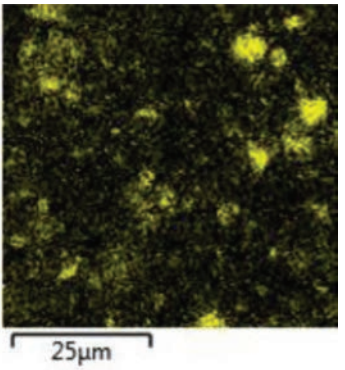

Figure 2. Ca element mapping of 50-nm NHL (20%)-modified binder admixture.

4 MOISTURE CONDITIONING

For the TSR testing, the samples were split into two sets: one of the sets was used unconditioned and the second set was conditioned with one freeze-thaw cycle. |E*| and the second set of TSR samples were vacuum saturated for 5 to 10 minutes at 13–67 kPa. It is worth noting that the |E*| test first was performed on the dry samples according to the AASHTO TP62-03 procedure [34] before passing any conditioning (one and five freeze-thaw cycles). After vacuum saturating, the samples (TSR or |E*| samples) were left submerged in a water bath for 5 to 10 minutes. The degree of saturation was calculated for the samples. If the degree of saturation was between 70% and 80%, the next step proceeded. The vacuum saturation is repeated if the degree of saturation is less than 70%, and the sample is considered damaged and discarded if saturation is greater than 80%. The next step is to bring each valid vacuum saturated sample tightly covered with a plastic wrap and placed into a plastic bag with approximately 10 ± 0.5-ml of water, and sealed. The one freeze-thaw cycle includes: placing the plastic bags in a freezer at –18°C for 16 hours and then placing the samples in a water bath at 60°C for 24 hours with a minimum 25-mm of water above the samples. After the cycle is done, the TSR samples were then placed in a water bath at 25°C for 2 hours with approximately 25-mm of water above the samples before the Indirect Tensile Strength (ITS) testing. The |E*| samples were dried and kept in the Universal Testing Machine (UTM-100) environmental chamber that was set to the designated testing temperature. After |E*| testing, the same samples were brought to four more freeze-thaw cycles prior to another testing.

5 EVALUATION OF MOISTURE SUSCEPTIBILITY

5.1 *Tensile Strength Ratio (TSR)*

The testing procedure of TSR followed the AASHTO T283 procedure [35]. The testing was run after one freeze-thaw cycle conditioning of the samples as described before. The UTM-100 machine was used to determine peak ITS. The TSR value is calculated as the ratio, $[ITS]_{cond.}/[ITS]_{dry}$ of conditioned ITS ($[ITS]_{cond.}$) and dry ITS ($[ITS]_{dry}$). In Superpave™ design, if the average retained strength of the conditioned sample strength is less than 80% of the dry sample strength, the mix is considered to be moisture susceptible. Although the AASHTO T283 is predominately used in the Superpave™ system to evaluate moisture susceptibility of asphalt mixes, many studies have shown the AASHTO T283 to be highly variable. In a study by Zhu and Liang [24], it was found that the AASHTO T283 is highly variable due to specified allowable saturation levels. It was stated that more research work is needed to develop an alternative to the AASHTO T283. In a study conducted by National Cooperative Highway Research Program [25], the laboratory moisture susceptibility tests of the mixes did not satisfactorily match the observed behavior of the field for a number of data groups.

Therefore, adequate moisture susceptibility tests need to be developed for proper evaluation. Diab and You [36] presented a conditioning procedure and evaluation parameter of the mixes' moisture susceptibility based on the |E*| testing.

5.2 *Dynamic modulus (|E*|)*

The |E*| is a fundamental test that captures the viscoelastic behavior of the asphalt mixes, has been used by researchers for moisture susceptibility evaluation on samples conditioned using the environmental conditioning system [37]. Following the AASHTO TP62-03 [34], the test was performed at the temperatures of 4.4°C (40°F), 21.1°C (70°F) and 37.8°C (100°F), and frequencies at each temperature of 0.1, 0.5, 1, 5, 10 and 25 Hz. The samples used in this testing were 100-mm in diameter and approximately 150-mm in height. Load levels were determined by trial and error so that the resulting recoverable axial micro-strain was between 75 and 125 to ensure that the material is in the viscoelastic range [38]. The applied stress and the resulting recoverable axial strain response of the specimen are measured and used to calculate the |E*|. Because the material is being tested in its linear viscoelastic range, no damage is induced and the accumulating strain is due to viscoelasticity only [39]. Therefore, the test can be performed many times on the same samples (dry samples, one and five cycles-conditioned samples). For better explanation of the asphalt mix's performance, |E*| values measured over a range of temperatures and frequencies of loading can be shifted into a master curve for analysing. In general, the master curve can be mathematically represented by a sigmoidal function [40].

6 RESULTS AND DISCUSSION

6.1 *Tensile Strength Ratio (TSR)*

The TSR is used to characterize the moisture susceptibility of asphalt mixes. The minimum TSR necessary to ensure good pavement performance has not yet been identified positively; however, a TSR of 0.8 after one freeze-thaw cycle is generally considered to be a reasonable minimum value under the current Superpave™ mix design system. Figure 3 shows the TSR values calculated from the average dry and conditioned ITS values. The Advera® foamed mix experienced a TSR lower than 0.8 after one freeze-thaw cycle. This proves that the Advera® foamed mixes are more susceptible to moisture damage than the control counterpart. The decrease of the TSR can be attributed to the loss of adhesion between aggregates and

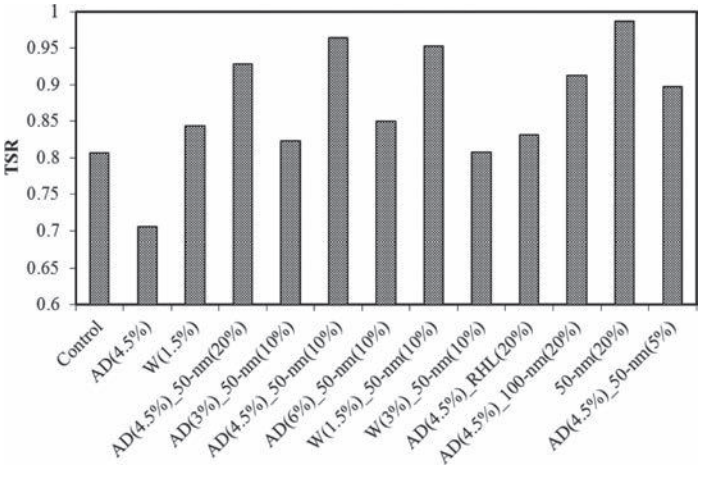

Figure 3. TSR results for different mixes.

asphalt due to the released water. Additionally, the lower compaction temperature used when producing WMA mixes may increase the potential for moisture susceptibility due to inadequate drying of aggregates. The increase of TSR for the control mix can also be attributed to the over aging of the binder compared to the foamed mix. On the other hand, all hydrated lime (RHL and NHL)-modified mixes passed the TSR criteria (>80%). However, the NHL is more competitive in comparison to the RHL. The 50-nm (20%) mix showed a higher TSR value among all the studied mixes. The shown results prove that the hydrated lime particle sizes play an important role in the mitigation of the moisture susceptibility of the asphalt mixes. Generally, the effect of hydrated lime in reducing the moisture susceptibility of mixes has several mechanisms which have been proposed to account for its beneficial effect [41]. The unfoamed NHL-modified mix (50-nm (20%) showed a higher TSR value in comparison to the foamed mix (AD (4.5%)_50-nm (20%)). The increase of water foaming ratio from 1.5% to 3% sharply decreases the TSR values of the NHL-modified mix. However, there is no definite trend of the TSR values for the mixes foamed with different Advera® ratios (3%, 4.5% and 6%). Due to the variability and less connectivity between TSR results and field performance [24, 25], the |E*| also was performed to evaluate the moisture susceptibility since it has been recognized as a fundamental test for asphalt mixtures. Performing the |E*| test would manage the inconsistency encountered from the TSR test results.

6.2 *Dynamic modulus (|E*|)*

The |E*| is suggested to be the best indicator for asphalt pavement distresses [42]. A higher value of the |E*| at a high temperature or low frequency indicates that the asphalt mix has higher rutting resistance and a lower |E*| value at a low temperature or high frequency indicates that the asphalt mix has lower fatigue cracking potential [43]. The test was utilized in this study to evaluate the moisture susceptibility of different asphalt mixes. In order to have a better comparison between different mixes throughout all the temperatures and frequencies, sigmoidal master curves were constructed at a reference temperature of 21.1°C (70°F). The master curves were constructed for dry mixes and one cycle-conditioned mixes as shown in Figures 4 and 5, respectively. Based on the test results shown in Figure 4, it was seen that the addition of NHL increases the |E*| value when compared to the unmodified mixes (control and foamed). It can also be seen that the |E*| of the dry control mix is much lower than the modified mixes and is a little higher than the Advera® and water foamed mix. The increase

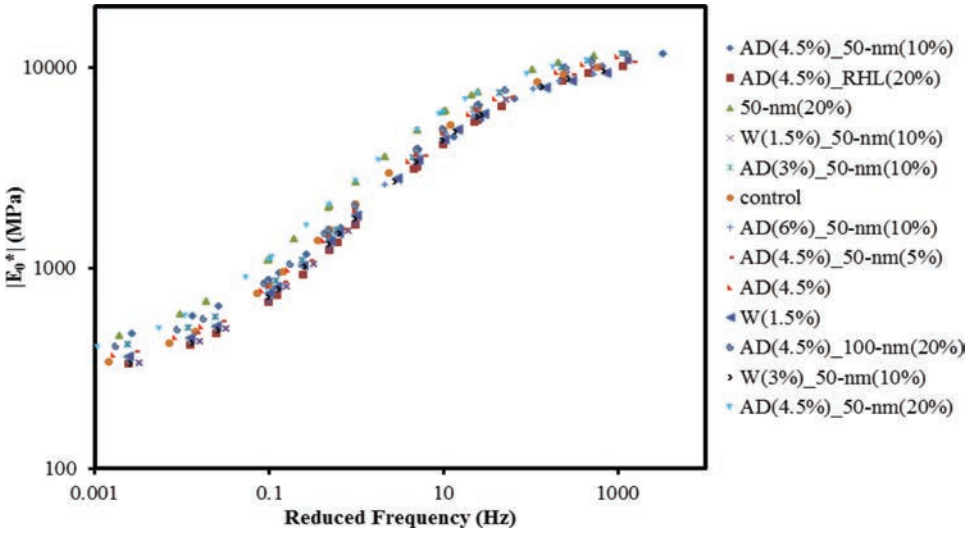

Figure 4. Master curves for dry mixes.

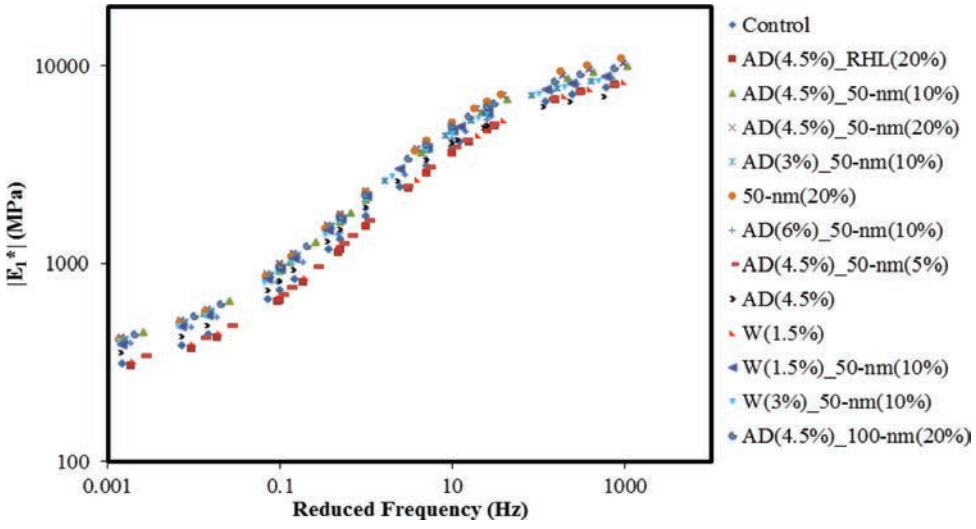

Figure 5. Master curves for one cycle conditioned mixes.

of |E*| of control mix can be attributed to the over aging of the control mix compared to unmodified WMA mixes. However, the water foamed mix shows much lower decrease of the |E*|. The 50-nm (20%) showed a higher |E*| compared to the foamed mix (AD (4.5%)_50-nm (20%)), but this probably can be due to the 50-nm (20%) being over aged since it was prepared as HMA mix (Table 2). The |E*| results of the 100-nm mix are slightly lower than that of the 50-nm. The NHL-modified mixes are more competitive than RHL.

This proves the importance of hydrated lime particle size on the mechanical properties of the mix. The RHL results are very close to the 5% NHL (50-nm)-modified mix results. Comparing the 50-nm (10%) mixes foamed with two percentages of water (1.5% and 3%), it is quite clear that the increase of water significantly decreases the |E*| of the mix. The water foaming adversely affects pavement moisture susceptibility. The existence of water in the asphalt-aggregate matrix is often one of the major factors affecting the durability of mixes. Figure 5 shows that the hydrated lime-modified mixes show higher |E*| values compared to the unmodified mix. The unfoamed NHL-modified mix (50-nm (20%)) slightly increases the |E*| compared to the AD (4.5%)_50-nm (20%) after conditioning. The NHL-modified mixes show higher |E*| values compared to the RHL.

Two ratios were suggested, $R_{0-1} = (|E_0^*| - |E_1^*|)/|E_0^*|$ and $R_{0-5} = (|E_0^*| - |E_5^*|)/|E_0^*|$ to imply how much the dry modulus, $|E_0^*|$, decreased after one and five cycles conditioning ($|E_1^*|$ and $|E_5^*|$, respectively). These ratios would give more information about the effect of short- and long-term conditioning on |E*| for these mixes. The average ratio for all testing temperatures and frequencies was calculated for the control and unmodified foamed mixes and plotted in Figure 6. It should be noted that the two ratios were calculated from mater curves results. It is quite clear from this figure that the foamed mixes exhibited more moisture deterioration after conditioning compared to the control mixes. The control mix deteriorated more slowly compared to the foamed mixes after five cycles conditioning. The Advera® foamed mix deteriorated much more than that foamed with water.

This study suggests that one cycle conditioning is not enough to measure the moisture susceptibility of different mixes. The long-term susceptibility is also essential to completely understand the moisture susceptibility.

6.3 *Comparison between TSR and |E*| results*

Several laboratory test methods have been developed to assess the moisture susceptibility of HMA mixes. Although providing useful information, these tests still do not entirely simulate

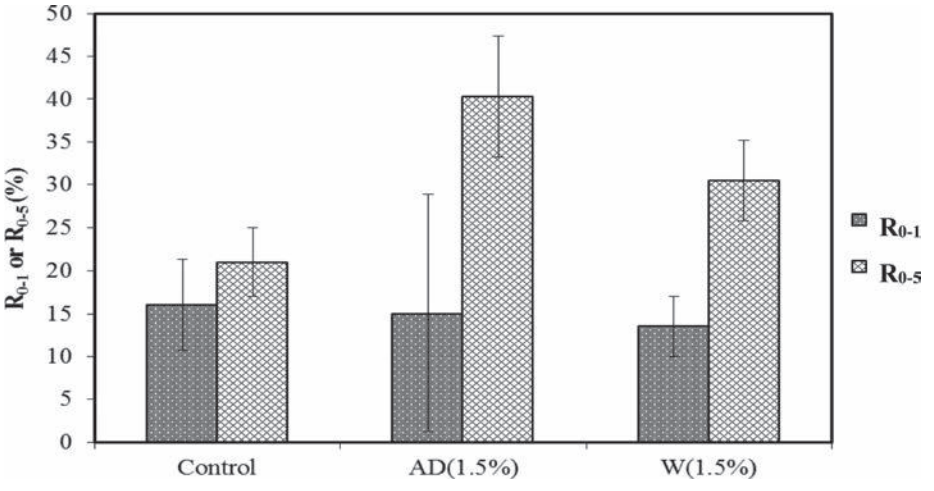

Figure 6. Effect of different conditioning cycles on |E*| ratios (R_{0-1} and R_{0-5}).

field conditions. Most state highway agencies use the AASHTO T 283 test, although they still have concerns about the variability of the test results. Since the current AASHTO T 283 is highly variable [24], Hicks et al. [44] pointed out the need of updating the moisture susceptibility test method that can accurately determine moisture damage resistance of Superpave™ mixes.

By comparing the |E*| and TSR tests results presented above, although the |E*| does not provide a criterion of moisture susceptibility, it seems more representative and comparative than TSR since the test has been run on the same sample after conditioning. The |E*| values of the water foamed mixes are lower than the Advera® foamed, contradicting the TSR results. In another study [36], the authors developed test and parameter to evaluate a moisture influence on asphalt durability based on the |E*| test. Future work will be implemented to validate that methodology and present evaluation criterion based on the |E*| test.

7 CONCLUSIONS AND RECOMMENDATIONS

The primary objective of this research was to investigate the effectiveness of the moisture susceptibility of NHL-modified foamed WMA using the TSR and |E*| tests. A secondary objective of this research was to assess the validity of the two utilized TSR and |E*| tests. RHL was used along with the NHL in this investigation. The NHL was used with two particle sizes of 50-nm and 100-nm. The foamed asphalt was produced by adding Advera® and by using the water-based laboratory foaming method. From the study results, the Advera® foamed mixes did not pass the TSR requirement which means that it is more susceptible to moisture damage compared to the control mixes. The NHL-modified mixes showed less susceptibility to moisture damage compared to the RHL mixes. The Advera® and water foamed mixes are more sensitive to long-term conditioning compared to the control mixes. This study suggests investigating the long-term performance of the moisture susceptibility by using multiple conditioning cycles. The |E*| test has been run on the same sample after conditioning, therefore, it is more representative to the moisture susceptibility of the asphalt mixes than the TSR.

ACKNOWLEDGEMENTS

The authors would like to express their gratitude to Joan Hudson, senior scientist and director of Clemson University Electron Microscopy Facility for assisting in Energy Dispersive X-Ray Spectroscopy images.

Microstructure-property relationships of Sasobit modified Warm Mix Asphalts

Qian Qin
GAF Materials, Ennis, TX, USA

Adam T. Pauli & Michael J. Farrar
Western Research Institute, Laramie, WY, USA

ABSTRACT: Driven by the economic and environmental concerns over the burning fuel emission from asphalt industry, the Warm Mix Asphalt (WMA) technology has been drawing substantial attention in the past decade by achieving a mixing temperature reduction of about 18–54 °C. This paper focuses on effect of one of WAM additives (Sasobit) on asphalt properties and explores the microstructure-property relationships of Sasobit modified asphalts. A 3-D network or pseudo-solid like structure of 3% Sasobit modified WMA is demonstrated both rheologically and morphologically. The network microstructure not only contributes to the blend stiffening resulting in the limiting high temperature being expanded by 5–16 °C, but also accounts for the breakdown of time-temperature superposition at temperature above 30 °C. At Sasobit loading concentration of 1%, dendrites rather than typical "bee structure" are observed. The pseudo-solid or dendritic microstructure only depends on the Sasobit concentration, regardless of asphalt types and grades investigated. Additionally, by using 4 mm parallel plates DSR at low temperatures after proper machine compliance corrections, we were able to obtain the limiting low temperatures, suggesting Sasobit doesn't influence low temperature performance of asphalts in an undue adverse manner.

Keywords: warm mix asphalt, rheology, Sasobit, microstructure, wax

1 INTRODUCTION

As an alternative for Hot Mix Asphalt (HMA), Warm Mix Asphalt (WMA) technology has been drawing substantial attention in the past decade [1–5]. By achieving significant mixing temperature reduction, WMA technology is highly desirable economically and environmentally with the immediate benefit of reducing energy consumption and reducing emission from burning fuels and fumes at asphalt plants and paving sites [1–2].

The focus of this paper is on one of the WMA organic additives called Sasobit®. It is a crystalline, long-chain aliphatic hydrocarbon compound with the melting temperature between 70 °C and 120 °C [3–5]. The melting temperature is high enough to make Sasobit maintain its crystalline structure at pavement service temperatures, imparting a stiffening effect. At temperatures above its melting point, Sasobit acts as a flow improver by lowering the viscosity of the asphalt enabling mixing and compaction temperatures to be reduced by 18 to 54 °C [4, 6].

There have been numerous studies on Sasobit modified binders [7–14], however, only limited systematic work on the correlation between structure and viscoelasticity has been performed. Recently, Polacco and coworkers conducted a comprehensive study regarding the effect of different types of waxes on asphalt morphology, residual crystallinity and mechanical properties [15]. A gel structure of asphalt blends with Fischer-Tropsch (FT) type waxes was suggested by observed high penetration index and low values of phase angle (55 °–65 °) [15].

In this paper, we present direct rheological and morphological evidence for a gel-like or pseudo-solid structure of Sasobit modified WMA. Further, we suggest the sol-gel transition not only on the surface of those blends as depicted by Atomic Force Microscopy (AFM), but also extends to the bulk. The effects from binder types and grades are also investigated in terms of how they impact microstructures and viscoelasticity of Sasobit blends. The objective of this work is to explore the microstructure-property relationship of Sasobit modified binders so as to have a better understanding of their linear viscoelasticity and applications.

2 EXPERIMENTAL

2.1 *Materials*

Four asphalt binders with different types and grades were used as control binders in this study and they are listed in Table 1.

1% and 3% Sasobit loading concentrations (by weight) were selected for this study because 3% is typically the maximum loading concentration above which the low temperature performance of Sasobit modified WMA would be negatively affected [4, 16].

Sasobit modified binders were prepared by heating asphalt to 150 °C, followed by addition of pre-weighted Sasobit and subsequent gentle stirring. The modified asphalt blend was maintained at 150 °C for approximately one hour with occasional stirring to achieve a homogeneous blend. With this type of treatment asphalt should only undergo mild oxidation.

2.2 *Experimental methods*

2.2.1 *Characterization of thermal properties*

Thermal properties were measured using a TA instruments Q2000 Differential Scanning Calorimeter (DSC). Melting temperature (T_m) and heat of fusion (ΔH_f) of Sasobit component were determined from the heating scan made at 10 °C/min, after cooling from 165 °C to –90 °C at 5 °C/min and subsequently isothermal holding at –90 °C for 5 minutes.

The glass transition temperatures of the asphalt component were measured using Temperature Modulated DSC (TMDSC) technique. TMDSC can clearly separate glass transition from other complex overlapped effects, such as cold-crystallization and enthalpy recovery by dividing the total heat flow into reversing and non-reversing parts [17]. The sample was first heated and equilibrated at 165 °C before cooling down to –90 °C. At –90 °C, the sample was held isothermally for 5 minutes, which was followed by a heating scan to 165 °C. Both the cooling and subsequent heating scans were run at the average rate of 2 °C/min with modulation amplitude of 0.5 °C every 80 seconds. The limiting fictive temperature T_f' was determined from the reversing heat flow curve during the second heating scan. T_f' was used as the glass transition temperature T_g due to the widely accepted concept that T_f' is approximately equal to T_g obtained from the cooling scan at the same scan [18, 19].

Table 1. Description of control binders.

Asphalt binder	PG grade	Description
MB	PG 58-28	Unmodified binder from Manitoba, Canada, 150/200 pen, Canadian blend
MN1-3	PG 58-28	Unmodified binder from Rochester Minnesota, Canadian blend
MN1-4	PG 58-28	Unmodified binder from Rochester Minnesota, Blend: Arab heavy, Arab medium, and Kirkuk
YNP	PG 58-34	SBS modified binder from Yellow Stone National Park

2.2.2 *Rheological measurements*

The rheological experiments of the control binders and Sasobit modified binders were conducted with 4 mm diameter parallel plate geometry and a 1.75 mm gap over a temperature range from –30 °C to 30 °C. At 50 °C and 70 °C, the 25 mm diameter parallel plate and a 1 mm gap were used. The dynamic data presented are corrected for machine compliance. The detailed procedure for rheometer compliance correction and equations for obtaining true sample moduli are listed in the literature [20].

2.2.3 *Morphological characterization by AFM imaging*

A Quesant Q-Scope™ 250 Atomic Force Microscopy (AFM) was used to image thin films of asphalt binders and Sasobit modified binders in dynamic wave mode. The thin films were prepared by spin casting of toluene solution of asphalt onto a borosilicate glass microscope slide at 400 rpm. Resultant films were annealed at 64 °C for 2 hours, then rapidly cooled to room temperature prior to imaging. Samples were imaged in the intermittent contact mode (BB Wavemode® per Ambios terminology) under dry nitrogen at room temperature (~24 °C). Topography, phase contrast, and error (derivative) images were collected simultaneously for each sample. All of the images shown are 80 × 80-μm, and all were collected using a scan rate of 1 Hz.

2.2.4 *Fourier Transform Infrared Spectroscopy (FTIR)*

The infrared spectroscopy was performed with a Perkin Elmer 100 FTIR spectrometer equipped with a Universal Attenuated Total Reflectance (ATR) accessory. The Sasobit was molded into a small disk with a flat surface and then smeared onto the ATR diamond. All IR spectra were obtained over a wave number range of 4000–600 cm^{-1} at a resolution of 4 cm^{-1} and 32 scans.

3 RESULTS

3.1 *Thermal analysis and structural characterization*

The limiting fictive temperatures or equivalent glass transition temperatures are listed in Table 2. No significant shifts in glass transition temperatures of the Sasobit blend were observed. Although the heat flow curves and temperature derivative of heat capacity (dC_P/dT) are not shown, it was found that no broadening of glass transition occurs upon the addition of Sasobit into asphalt binders. Those facts imply an absence of strong interactions between Sasobit and asphalt moieties.

The DSC endotherm of Sasobit wax exhibits two characteristic peaks with the onset melting temperature of 77 °C and peak melting temperatures of about 95 °C and 110 °C shown in Figure 1. Given the apparent linear molecular arrangement of Sasobit suggested by FTIR spectrum in Figure 2, two endo-peaks of Sasobit are ascribed to the mixture of linear long chain aliphatic hydrocarbons with melting temperatures of 95 °C and 110 °C.

Table 2. Limiting fictive temperature (T_f') of sasobit modified asphalts.

	T_f' (°C)		
Samples	0% Sasobit	1% Sasobit	3% Sasobit
MB	–18.6	–18.9	–19.0
MN1-3	–18.3	–18.7	–19.0
MN1-4	–23.0	–22.5	–23.3
YNP	–21.4	–21.2	–20.1

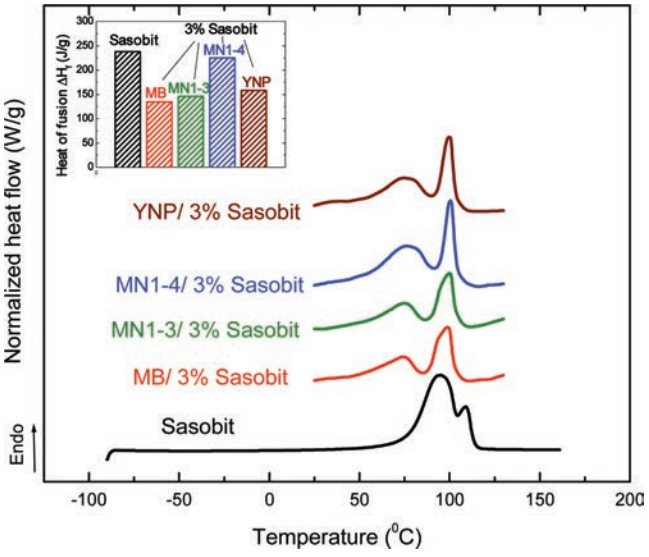

Figure 1. DSC endotherms and heat of fusion (inset plot) of sasobit and 3% sasobit modified binders. (The heat flow was normalized by the sasobit weight).

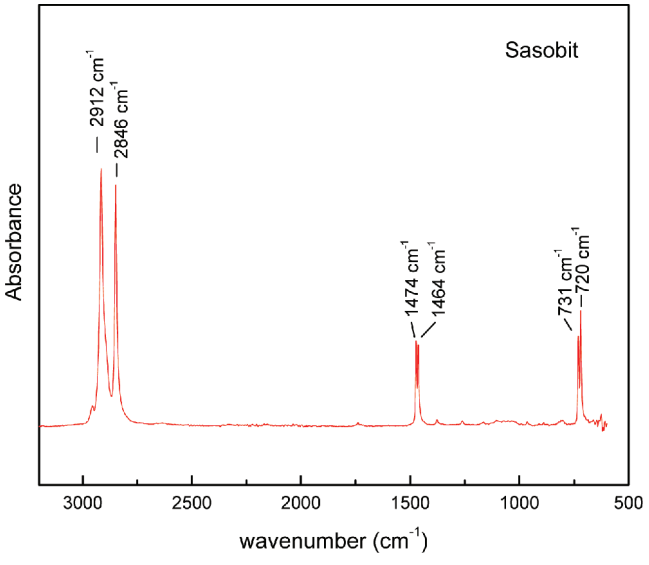

Figure 2. FTIR spectrum of sasobit illustrating the dominance of the linear chains in sasobit. (Strong absorptions at 2912 cm^{-1} and 2846 cm^{-1}: C-H stretching; 1474 cm^{-1}: C-H scissoring; 1464 cm^{-1}: C-H bending; weak absorption at around 720 cm^{-1}: C-H long chain (rocking). No significant absorbance at ~1375 cm^{-1} indicates little branching).

Upon blending the binders with 3% Sasobit, both the melting point and heat of fusion of Sasobit are depressed as seen in Figure 1. Based on the Gibbs-Thomson effect [21, 22], the depressed melting point suggests a smaller crystal size is favourable for Sasobit modified asphalt binders. The observed decrease in the heat of fusion is attributed to the finite size effect or reduced Sasobit crystal size, which is consistent with literature results for small molecules confined in controlled porous media [22–24] and melting of metallic nanocrystals [25].

3.2 *Rheological properties*

Figure 3 is the rheological results for the MN1-4 asphalt binder and its Sasobit blends. The van Gurp-Palmen plots [26] were used to test the applicability of time-Temperature Superposition (tTS) principle. tTS holds for the control binder. Upon the additon of 3% Sasobit, the van Gurp-Palmen plots lose their single curve characteristics above 30 °C, suggesting the break-down of tTS. Although not shown, 3% modified MB, MN1-3 and YNP binders also exhibit deviation from tTS. The DSC results on these samples indicated the onset melting temperature of Sasobit component is higher than 30 °C, therefore, the melting of Sasobit crystals cannot totally account for the failure of tTS for 3% Sasobit modified binders. That fialure is thought to be due to microstructural changes in the blends, leading to different relaxation functions within the binder. This concept will be discussed in more detial later in the paper.

3.2.1 *Low temperature rheology*

Creep stiffness S(t) and creep rate (m-value) have been widely accepted as two important parameters to characterize the low temperataure properties of asphalt binders. The results are listed in Table 3. Instead of using Bending Beam Rheometer (BBR), an estimate of creep stiffness and m-value was obtained from low temperature 4-mm DSR data after machine compliance correction by converting the dynamic modulus to the relaxation data [27].

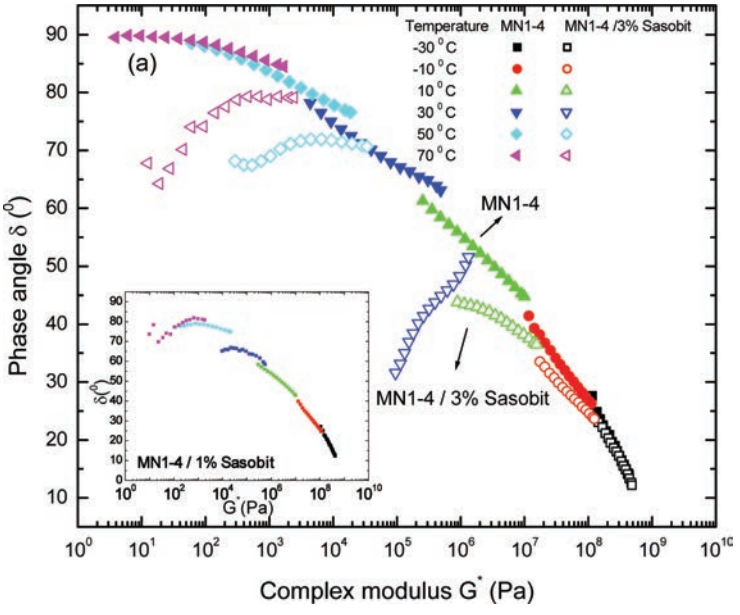

Figure 3. Van Gurp-Palmen plots for MN1-4 binder and sasobit blends.

Table 3. The "limiting low tempertatures" at which S(t) ≤ 300 MP and creep rate m-value ≤ –0.3.

	Calculated "limiting low temperature" (°C) based on S(t) and m-value		
Samples	0% sasobit	1% sasobit	3% sasobit
MB	–42.9	–42.1	–41.2
MN1-3	–40.5	–41.7	–38.2
MN1-4	–45.0	–45.0	–41.5
YNP	–45.2	–45.3	–43

The results suggest an increase in the "limiting low temperature" by about 2 ˚C for 3% Sasobit modified MB, MN1-3 and YNP binders. The increase in the "limiting low temperature" of the YNP Sasobit blends is found to be associated with its slower relaxation of accumulated stress even though its creep stiffness and modulus are lower than the base binder. A slightly larger upshift in "limiting low temperature" (3.5 °C) is found for the 3% MN1-4 Sasobit blend, which is attributed to the unusually large presence of natually occuring wax.

Overall, it does not appear that Sasobit at concentration levels of 3% or less exerts undue adverse effect on binders' low temperature properites.

3.2.2 *High temperature rheology*

The limiting high temperatures are expanded by 5 °C, 9 °C, 13 °C and 16 °C for Sasobit modified MN1-4, MB, MN1-3 and YNP binders respectively as shown in Figure 4, which is highly desirable for high temperature rutting resistance improvement.

At 50 °C, which is far above the glass transition temperature of asphalt binders, the base asphalt binder MB displays typical liquid behavior, i.e., the storage modulus (G′) is proportional to the frequency squared (ω^2) and the loss modulus (G″) is proportional to the frequency (ω) at low frequencies shown in Figure 5. Upon the addition of Sasobit, especially 3% Sasobit by weight, a dramataic change in rheological properties occurs. Instead of keeping the classic liquid response, 3% Sasobit modified MB exhibits the pseudo-solid or semi-solid behavior with the G′—ω slope of less than 0.5. Although loss modulus is generally believed to be insensitive to structure change, its sluggish variation as a function of frequency can be clearly observed for 3% Sasobi modified MB at low frequencies. Those results strongly suggest the formation of pseudo-solid like structures in 3% Sasobit modified binders at 50 °C. Considering the previously observed unchanged glass transition temperatures upon incorporation of Sasobit, the semi-solid structure for 3% systems are more likely to be due to the interactions among Sasobit crystals, where Sasobit might act as physical crosslink joints inside asphalt matrix.

Such pseudo-solid like or gel-like rheological behavior can be seen in Figure 6 where complex viscosity is plotted against complex modulus. Without Sasobit modifications, all binders except YNP demonstrate nearly Newtonian viscosity, which represents typical liquid response. With 3% Sasobit modifications, the viscosity tends to diverge at a finite value of complex modulus, which has been considered as a measure of the yield stress [28]. The presence of nearly diverging viscosity or yield stress is consistent with semi-solid characteristics. Based on the above linear viscoelasticity at 50 °C, the previously observed deviation from time-temperature superposition at temperatures above 30 °C for 3% Sasobit modified binders is attributed to microstructure change, where a gel-like or semi-solid structure is formed as opposed to isolated Sasobit crystals dispersed among binder liquids. The network or semi-solid structure formation alters the temperature dependence of stress relaxation and

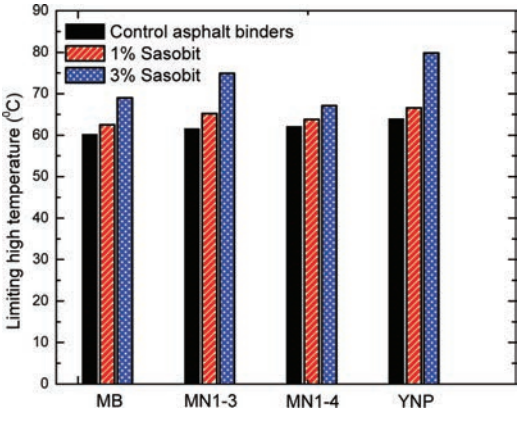

Figure 4. The limiting high temperatures corresponding to $G^*/\sin\delta = 1.0$ kPa ($\omega = 10$ rad/s).

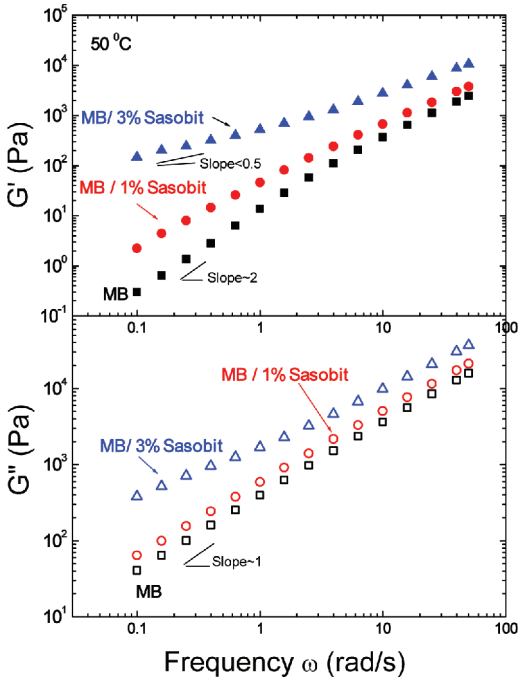

Figure 5. Storage and loss moduli of sasobit modified MB binders at 50 °C.

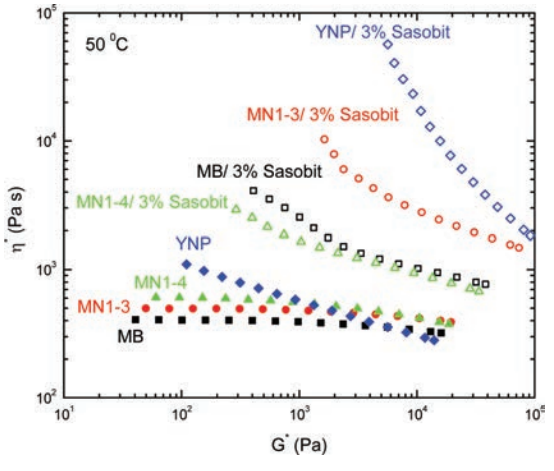

Figure 6. Plots of complex viscosity vs complex modulus for MB, MN1-3, MN1-4, YNP binders and their blends with 3% sasobit at 50 °C.

consequently results in the inapplicability of time-temperature superposition principle. In addition to the rheological analysis, a morphological study was conducted to provide direct visualization for the microstructure change within Sasobit modified WMA.

3.3 *Morphology of asphalt binders and sasobit modified WMA*

In the past decades the concept of a surface microstructure present in asphalt binders has attracted much attention regarding the so-called "bee structures". Bee structures, characterized

as small (~10 μm) oblong shaped structures with rippled interiors, have been observed in a host of neat and aged asphalts [29–32]. By AFM examination on asphalt fractionations extracted through SARA (saturates, aromatics, resins and asphaltenes) chromatography and ion-exchange chromatography, followed by wax separation, Pauli and coworkers investigated the morphology of asphalt fractions before and after wax removal as well as fractions with and without asphaltenes. Their work strongly suggests that the "bee structure" is attributed to wax rather than asphaltene micelles [33].

AFM topography images of MB binder exhibit relative homogenous morphology without apparent structural features as seen in Figure 7 (a). Upon incorporation of 1% and 3% Sasobit, micro-phases develop as seen in Figure 7 (b) and (c), which is attributed to the introduction of Sasobit. But instead of forming "bee structures", the presence of Sasobit gives rise to crystal dendrites in 1% systems [34]. By comparison, the images in Figure 7 (c) illustrate the development of a network gel structure resulting from a 3% Sasobit/MB binder.

Dendritic and network surface microstructures are also observed for 1% and 3% Sasobit modified YNP binders, respectively. Compared with the unmodified MB binder, the YNP binder initially exhibits a micro-phase structure as shown in Figure 8 (a). One possible interpretation for this structure is SBS reported to be present in the YNP binder. The other possibly may be the presence of natural wax in the neat binder. By comparison to 1% Sasobit/MB binder, 1% Sasobit/YNP binder also exhibits dendrite structuring, and by comparison to 3% Sasobit/MB binder, 3% Sasobit/YNP also exhibits a network structure. These findings strongly illustrate Sasobit concentration dependence with the observed surface structuring independent of the binder source. The images depicted in Figure 7(b) and 8(b) may also suggest that Sasobit dendrites preferentially develop at the surface due to interfacial thermodynamic effects [34, 35].

It is presently unknown why dendrite crystals rather than bee structures form in these particular materials with this type of high molecular weight wax (Sasobit), but Pauli *et al*. [33] observed that higher molecular weight waxes, specifically hexacontane doped into SHRP asphalts AAA-1 and AAG-1, exhibited both bee structuring as well as dendrite branching lending to speculation that wax molecular weight may partially contribute to the structuring reported here. Dendritic crystallization is normally characterized as a rapid unstable solidification process driven by steep thermal and concentration gradients. The samples reported in the present studies were, for all practice purposes, prepared at moderate to high wax concentrations (compared to naturally occurring wax concentrations) and quench cooled. Lower Sasobit concentrations and slower cooling processes may produce the familiar bee structures from this type of wax.

Regarding morphology and rheological results of 3% Sasobit modified WMA, we remark that the network structure develops not only on the sample surface, but also in the bulk region of the blends. On the one hand, our AFM images in Figure 7 & 8 suggest the surface microstructure belongs to much larger amount of Sasobit component than 3%, implying the Sasobit structuring preferentially forms at the asphalt surface by molecules diffusing and transporting to the film surface. On the other hand, our rheological results indicate that the network structure does happen in the bulk, providing additional insight on Sasobit microstructures.

4 CONCLUSIONS

We examined the thermal, morphological and linear viscoelastic properties of Sasobit modified Warm Mix Asphalts (WMA) with Sasobit weight concentration of no greater than 3%. Four asphalt binders with different types and grades were investigated. Those Sasobit/binder blends exhibit both depressed melting temperatures and reduced heat of fusion, suggesting a smaller crystal size of Sasobit is favourable in the blends.

The time-Temperature Superposition (tTS) fails for 3% Sasobit blends at temperatures above 30 °C, which is below their onset melting points. The results suggest it is the formation of network or semi-solid like structure that is responsible for the breakdown of time-temperature superposition.

Sasobit at concentration levels of 3% or less doesn't exert undue adverse effect on binder low temperature properties. Sasobit reinforces asphalt binders with the limiting high temperature expanded by 5 °C, 9 °C, 13 °C and 16 °C for 3% Sasobit modified MN1-4, MB, MN1-3 and YNP binders respectively. More importantly, the stiffening or reinforcing effect is closely correlated with the microstructure of Sasobit blends. Linear viscoelasticity analysis at 50 °C demonstrates the gel-like or pseudo-solid behavior of 3% Sasobit modified WMA.

Consistent with the rheological results, the AFM images depict an inter-connected network structure for 3% Sasobit modified WMA, which proves to be dependent on the Sasobit concentration rather than asphalt sources. For 1% Sasobit blends, instead of forming the familiar isolated "bee structure" of wax, a dendritic microstructure is observed, which is thought to be partially due to the high molecular weight of Sasobit as well as its relatively larger concentration compared with natural wax in asphalts. Morphology and rheological results suggest that a network structure exists not only on the surface of the sample, but also inside the bulk.

ACKNOWLEDGEMENTS

ABSTRACT: There has been a growing interest in the pavement community to study the structures and properties of asphalt concrete from a microscopic view. In this paper, a microstructure and micromechanical model of asphalt concrete is developed based on Discrete Element Method (DEM), calibrated, and applied in virtual triaxial tests of asphalt concrete. In the asphalt concrete microstructure modelling, a new generation algorithm of creating coarse aggregate phase, and a new approach of introducing air void phase, is proposed. The constructed microstructure model is further calibrated based on the aggregate gradation of asphalt concrete. Parameters of the micromechanical model are determined through calibrating virtual mastic test results with laboratory test data. In the virtual triaxial tests based on DEM, the influence of asphalt concrete compositions on the virtual test results and the micromechanical responses of the microstructure of asphalt concrete in the loading process are tracked and analyzed. The simulation results are in good agreement with observations from real laboratory tests, which verifies the feasibility of the algorithms and methodologies developed in this study.

Keywords: Triaxial shear test, microstructure and micromechanical analysis, Discrete Element Method, asphalt mixture, virtual test

1 INTRODUCTION

In the design of asphalt concrete mixtures used in pavement construction, mixture constituents are rationally selected and mixed with the aim to improve properties of asphalt mixture such as resistance of rutting, fracture, and fatigue. However, most of the mix design procedures used presently are strictly empirical such as Marshall Design method. This empirical result can be attributed to vague definition of design method for one specific asphalt mixture. Actually, asphalt mixture is composed of two main parts, composition of constitutes and their distribution in the specimen. However, the specification of asphalt mixture only provide instruction of constitute composition for the designers. As for the other aspect, the different distribution fashions of constitutes mean different structural types of the material. Moreover, it can have different distributional fashions of constitutes for the same type of asphalt mixture specified by the specification. As a result, one specific type of asphalt mixture can not be precisely determined according to the design specification. Therefore, the constitute composition is rather a necessary than a sufficient condition. Herein, one

sufficient and necessary condition can be obtained for a specific property of asphalt mixture if a definition for microstructure of asphalt mixture could be provided besides the composition of each constitute phase.

As it is well known that mechanical characteristics of asphalt mixture significantly depends on load condition. Therefore, it has much point in setting the boundary condition or initial stress environment as real as possible. In reality, the bituminous materials in a pavement structure are under a complex three dimensional stress which has a significant effect on its deformation properties. The triaxial test method is well established, especially in the field of soil mechanics. It has been shown to be suitable for evaluating the strength of asphalt concrete mixtures [1]. The triaxial test has been used to evaluate many mechanical characteristics of soils under various conditions of axial loadings and confining pressures such as shearing resistance, stress-strain, and other properties. However, the usage of the triaxial test for testing bituminous paving materials is slow in acceptance by pavement engineers and the main cause should be attributed to the complexity of the test and high expenses of such an exercise [2].

Therefore, the difficulties of launching the micromechanical analysis of asphalt mixture under the laboratory condition can be easily seen. The microstructure study of asphalt mixture has been kept focused for last two decades, especially in terms of the microstructure reconstruction. As so many successful applications of discrete element method in rock mechanics occur, the method draws attention of researchers in pavement fields. And many meaningful studies have been done. For example, the micro-fabric discrete element method for the microstructure of asphalt mixture in two-dimensional was proposed by Buttlar and You [3]. Then the idealized model in three-dimensional was established to simulate the dilation behavior of asphalt concrete [4]. Afterwards many researchers have adopted the image-based models for reconstruction of asphalt concrete [5–8]. The randomly created model was built for asphalt concrete [9–10]. In the randomly created model, gradation, shape, angularity, orientation, and distribution can be created to represent microstructure of asphalt concrete. However, the distribution of the air voids phase has not been focused in the studies mentioned above. In this paper, one randomly created model is established and utilized to finish the microscopic analysis of asphalt concrete and the distribution of the air voids phase is considered.

To avoid the difficulties of a study under the laboratory condition, the increased usage of numerical techniques can be taken as one available option for the researchers. Virtual test can be utilized to simulate the laboratory test and make microstructure analysis of asphalt concrete under a specific load condition such as displacement, stress and strain status, and coordinate number of coarse aggregate [11–14]. And these microstructure response analyses can be used to explain the fundamental material properties of asphalt concrete and provide a rational mechanical approach for the design and testing of asphalt pavements.

2 OBJECTIVES AND TASKS

Based on discrete element method, a microstructure model for Asphalt Concrete (AC) is established based on its three component phases. It should involve aspects including volume content, distribution, particle shape and orientation and other necessary factors. All of above are for the preparation of the virtual triaxial shear test of asphalt concrete. Finally, the microstructure analysis of asphalt concrete under the triaxial load condition can be made. The following tasks have to be performed in order to achieve that objective:

- A new algorithm used to generate aggregate elements is developed, which could be easily utilized to create a particle with an irregular shape and a designated size. The assembling for all coarse aggregate elements is also a key step in establishing the microstructure of asphalt mixture when single particle could be simulated. Both the distribution characteristics of orientation and location of coarse aggregate phase determine the microstructure or the configuration of material.

- For air voids phase for DE model of AC, this paper introduced statistic regression method into its establishment based on a statistical regression method in DE model. A program will be developed to establish the phase according to analysis result from relevant studies by means of X-ray.
- The virtual test is launched to analyze the microstructure response of AC under triaxial and uniaxial load condition. Some variables, which are used to represent microstructure characteristics of AC, are created and tracked in the simulation process in order to obtain microscopic response of coarse aggregate element. Meanwhile, algorithms are compiled to finish analyzing the influence of the components on the simulation result, including orientation of coarse aggregate phase and distribution of air voids phase.

In this paper, a commercial discrete-element code called Particle Flow Code in 3-Dimensions (PFC3D) is used. The microstructure construction of AC is presented using the PFC3D based on discrete element method.

3 ESTABLISHMENT OF MICROSTRUCTURE MODEL FOR ASPHALT CONCRETE

The Asphalt Concrete (AC) material is a bonded mixture of aggregates, asphalt binders and air voids. The anisotropy of AC was ascribed mainly to the nonrandom distribution of preferential orientation of aggregate particle, air void shape and aggregate particle constitutes.

3.1 *Algorithm for coarse aggregate*

In this section, a new algorithm for coarse aggregates (aggregates that are retained on the 2.36-mm sieve) is developed and implemented to establish a Discrete Element (DE) model of asphalt concrete. A precise control of aggregate particle size, irregular shape, and arbitrary orientation can be easily achieved with the algorithm.

Based on the mechanism of sieving, the size of an aggregate is determined by the minimum cross section area of the aggregate. A plane that is parallel to such cross section is defined as the critical projection plane. For example, for the cuboid shown in Figure 1[a], projection on the XOY plane gives the minimum projection size (Fig. 1[c]), which is 80 by 80 in terms of square opening sieve size. Therefore, XOY plane is the critical projection plane.

Therefore, based on the mechanism of sieving mentioned above the establishment of coarse aggregate can be finished by virtue of three steps as follows:

1. A model with spheres can be created to initiate the physical information of coarse aggregates based on the gradation of asphalt mixture, including radii and coordinates shown in Figure 3[a]. And a regular polyhedron with 14 vertexes could be established shown in Figure 2. By obtaining and altering the coordinates of each vertex of this polyhedron in

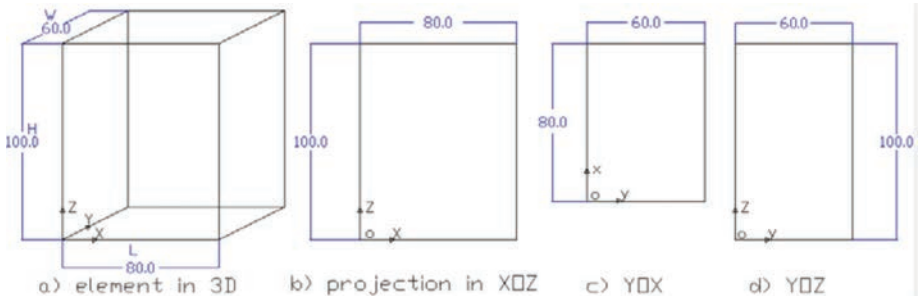

Figure 1. Projections of a particle on three planes.

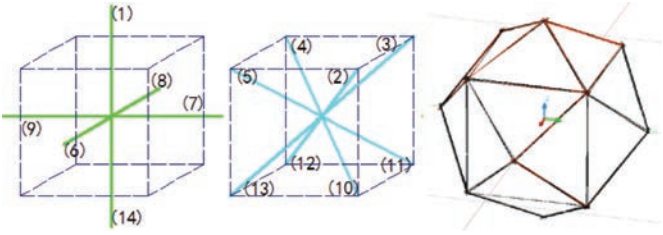

Figure 2. Preliminary polyhedron space for coarse aggregate element.

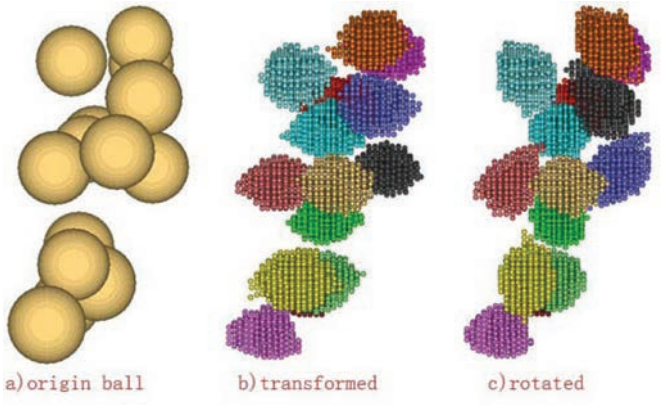

Figure 3. The transformation from the initial sphere model to target model.

the local coordinate system, the main frame the aggregate element is transformed, subjecting to the constraint that the aggregate size remains constant.

2. According to the relative location relationship between endpoints and the projection plane, there are 10 endpoints (vertexes) whose z components can be changed shown in Figure 2. By adjusting the values of the 10 projection components, a variety of shapes can be achieved for one aggregate element, while the aggregate size remains unchanged, no matter whether the final aggregate element becomes thinner (flatted) or thicker (elongated) after the transformations. As might be expected, a particle with more irregular shapes can be easily obtained when various component changes are assigned to different line segments of the main frame shown in Figure 3[b]. However, it can be seen that the orientation of each particle is parallel to the projection plane.
3. To randomize the particles orientations, a method similar to Euler angle rotation is used. If the vertices of the aggregate polyhedron are rotated by the same angle around one, two, or three axes of the local coordinate system, the aggregate's orientation is changed. For the aggregate model in this study, the rotation will give 14 new coordinates of the end points. The shape of the aggregate element essentially remains the same while the orientation changes shown in Figure 3[c].

A Fish program is compiled to eliminate the floaters (contact coordinate number is less than 2 for each unit spheres) on the surface of each coarse aggregate.

3.2 *The establishment of air void phase and asphalt sand mastic phase*

Research has shown that the stiffness of the mixture is highly dependent on the air voids content of the mixture, which is recognized in all stiffness predictive models such as the Shell model, the Witczak et al. model [15–16].

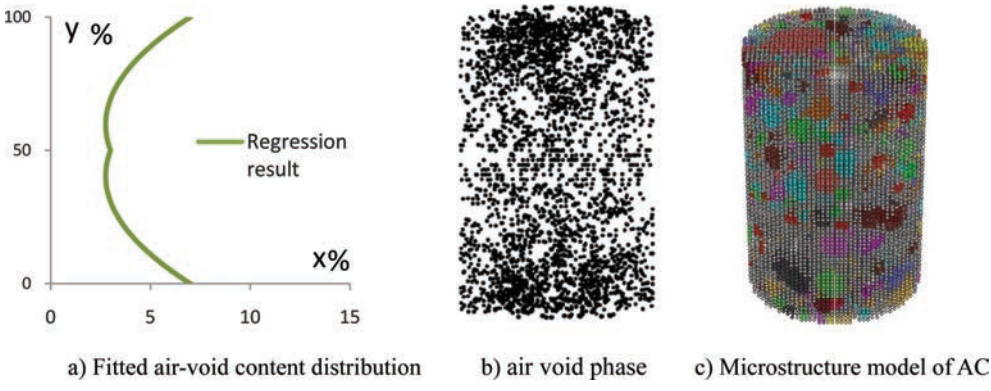

Figure 4. An example of air void distribution introduced in the DE model (air voids are represented by black spheres).

According to the study of air void distribution inside the specimen fabricated by Superpave gyrated compactor using X-ray, a statistical model is proposed to establish the air void phase instead of a model with random distribution shown in Figure 4 [17–18]. The air void phase of microstructure for the virtual specimen is established shown in Figure 4[b].

Finally, the physical components information of the virtual specimen can be calibrated by the basic gradation of asphalt concrete. The left unit spheres in the model compose the asphalt sand mastic phase. So far, the microstructure of asphalt concrete has been established based on DEM. To improve computational efficiency of the three dimensional model, the size of virtual cylinder specimen is reduced to 60:40 mm (height: diameter) and the radius of the unit sphere is 0.5 mm. The virtual specimen of asphalt mixture (Sup-13) is shown in Figure 4[c].

4 MICROMECHANICAL MODEL FOR MICROSTRUCTURE OF ASPHALT CONCRETE

4.1 *Burger model*

The Burger model is utilized to represent the viscoelastic characteristics of asphalt sand mastic. In order to obtain the parameters of burger model, static creep test is carried out in the laboratory. The experimental conditions are as follows: the asphalt mixture is Sup-13, test temperature is 40°C, uniform loading stress is 40 Kpa. The aggregate is granite, the binder is the asphalt modified by SBS. And the aggregate gradation of the tested asphalt mixture is shown in Table 1.

The macroscopic parameters of burger model are shown in Table 2, which are obtained through the regression analysis for laboratory static creep test.

On the basis of the conversion relationship between microscopic parameters and the macroscopic parameters, the microscopic parameters can be obtained [19]. Then the virtual creep test can be utilized to verify the feasibility of the contact model adopted for the microstructure. Finally, the laboratory test result, regression result and the simulation result are shown in Figure 5 respectively.

4.2 *Contact bond model*

According to the conversion relationship between microscopic parameter (bond strength) and the macroscopic parameter (material strength), the indirect tensile test of asphalt sand mastic is carried out to obtain the indirect tensile strength of asphalt mixture. Meanwhile, the virtual indirect tensile test is carried out to calibrate the microscopic parameter obtained from above [20].

a) Virtual creep test b) regression result and simulation result

Figure 5. Virtual test result of asphalt sand mastic.

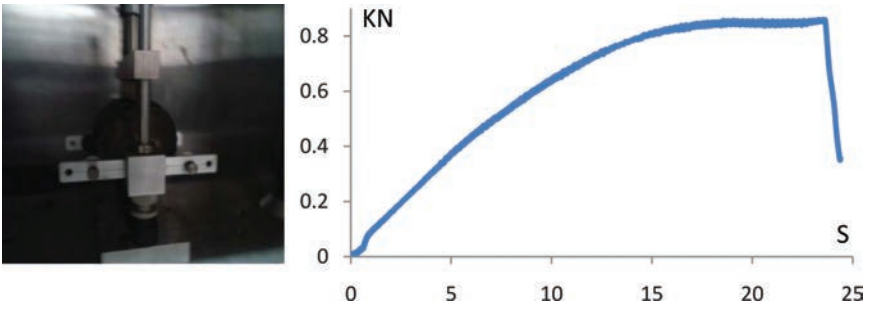

Figure 6. Indirect tension test and test result of asphalt sand mastic.

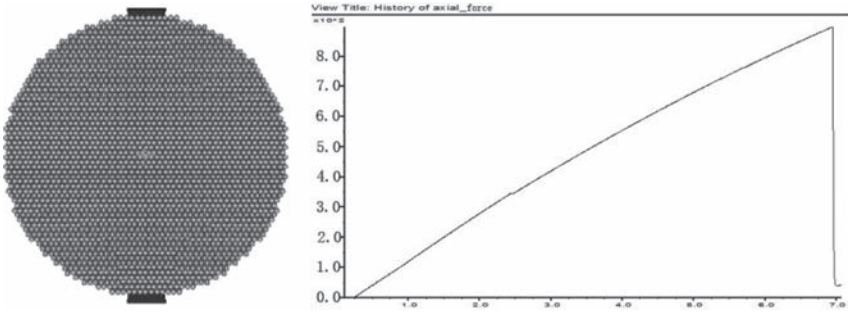

Figure 7. Virtual indirect tensile test and simulation result.

4.2.1 *Laboratory test and result*

Test temperature is 40°C, Loading velocity is 50 mm/min, Specimen size is 101.6 by 63.5 mm (diameter by height).

Three specimens are utilized to obtain the average peak force of the asphalt sand mastic under the same laboratory test condition. Finally, the average result of the three parallel specimens is 859 N.

4.2.2 *Virtual test and result*

The virtual test is launched to calibrate the microscopic parameters, which are obtained according to the abovementioned conversion method. The main experimental condition is same to the laboratory test, including the specimen size, load velocity and so forth. The parameters of the microstructure are as follows: the radius of the unit ball is 1 mm and the ball of the model is in a diamond arrangement. The contact model adopted in the numerical model is the burger model and the parameters have been obtained in last section.

The peak axial force of the virtual specimen acquired in the simulation is 876 N. And the microscopic bond strength value is 0.5 N when the conversion and assumption is made: the value in the normal direction equals the value in the shear direction. However, the value need to be modified according to the virtual triaxial test result of asphalt mixture, and the following assumption should be made: the property of the contact between asphalt sand mastic and coarse aggregate phase is the same to the contact inside the asphalt sand mastic phase.

5 VIRTUAL TRIAXIAL TEST SIMULATION AND MICROSCOPIC ANALYSIS

5.1 *Laboratory triaxial test and calibration of the discrete element model*

To calibrate the micromechanical models adopted in the discrete element model, the triaxial test is launched. Three confine pressure levels are set including 0, 138 Kpa, 276 Kpa [21]. The load equipment is Universe Test Machine (UTM-25). The discrete element model of asphalt mixture (Sup-13) is calibrated on the basis of the laboratory triaxial test results. Finally, simulation result of the calibrated model is reasonable compared with the experimental result shown in Table 3.

The specimen before and after virtual test is shown Figure 8, and the shape change of the specimen can be observed. Meanwhile, a shear band can be differed from the contact failure distribution zone (the red dots represent the tension failure while the black dots represent the compression failure). Apparently, the changes or responses inside the specimen can be easily measured in the virtual test. This advantage of the virtual test should be taken sufficiently in the future.

5.2 *Micro-structural and micromechanical analysis of asphalt mixture*

In this section, the influences of components on the simulation result are analyzed, including the orientation of the coarse aggregate phase, the distribution characteristics of air void phase.

Table 3. Triaxial test result of Sup-13.

	σ_1 (KPa)		
	Laboratory test result		
σ_3 (KPa)	Peak stress	Average	Virtual test result
0	921	964	871
	1007		
138	1499	1583	1513
	1667		
276	2095	2176	2113
	2257		

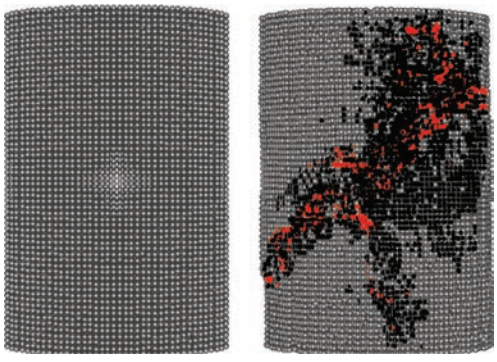

Figure 8. Virtual specimen before and after virtual triaxial test.

Meanwhile, some variables are defined and used to track the micromechanical responses of the microstructure in the loading process, such as coordination number of coarse aggregate, stress distribution of coarse aggregate phase and its evolution characteristics.

5.2.1 *Influence of component characteristics on the simulation result*

As is mentioned above, the algorithm of creation for coarse aggregate can be used to analyze the effect of the orientation of coarse aggregate particle on the simulation result. Therefore, the two special scenarios are established to make the analysis, including vertical orientation distribution and horizontal orientation distribution. These two special scenarios are used to explain the effects of the orientation on the simulation result. Through modifying the algorithm of coarse aggregate developed in this paper, those two special scenarios can be easily established. To differ them clearly, the particles with sieve size between 10 mm and 12 mm are separated from the discrete element model of asphalt concrete shown in Figure 9.

They are particles with horizontal orientation, vertical orientation and arbitrary orientation shown in Figure 9, respectively. The virtual triaxial test result can be seen in Figure 10, including confess pressure equals 0 KPa, and 138 KPa, respectively.

It can be seen that the model of coarse aggregate phase with horizontal orientation shows a poorer property of resistance to vertical loading, and the model of coarse aggregate phase with vertical orientation shows the best property resistance to vertical loading of all three scenarios shown in Figure 9.

Compared with the conventional discrete element model of asphalt mixture, the difference is that the air void phase is established based on the real distributional characteristics instead of a random distribution. To learn the effect of the distribution of air void phase on the simulation result, virtual triaxial shear test for two microstructure models with two air voids distribution are carried out. However, the two microstructure models can have the same coarse aggregate phase. The results of the virtual tests could be found in the following figure.

It can be seen that the model with the real distributional characteristics shows a better test result than the model with a random distribution. Therefore, the proposed establishment method of air void phase in the paper is of more momentous significance than the conventional method. Meanwhile, the result explains that the distribution of the air void phase plays an important part in the property of resistance to deformation.

5.2.2 *Micromechanical responses of the microstructure*

In this section, some key parameters representing microstructure of the model are tracked in the simulation process, including the skeleton particles (defining coarse aggregate with coordinate number > 3), the stress statuses of the coarse aggregates in the loading process. To learn the stress evolution law of the coarse aggregate phase in the loading process, three typical stages are selected: the stable stage, ultimate stage and collapse stage. At the same time, it includes multiple confess pressure level scenarios, namely equal 0, 138 KPa, or 276 KPa.

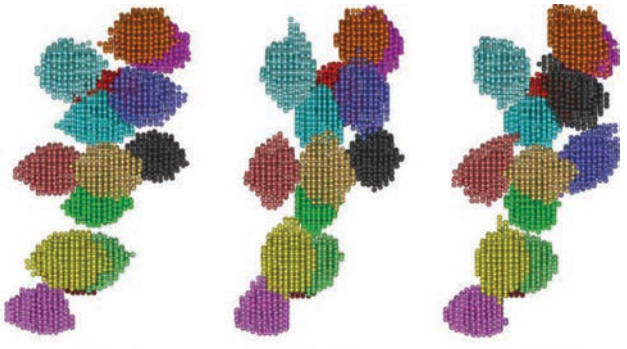

Figure 9. Orientation alignment of coarse aggregate phase.

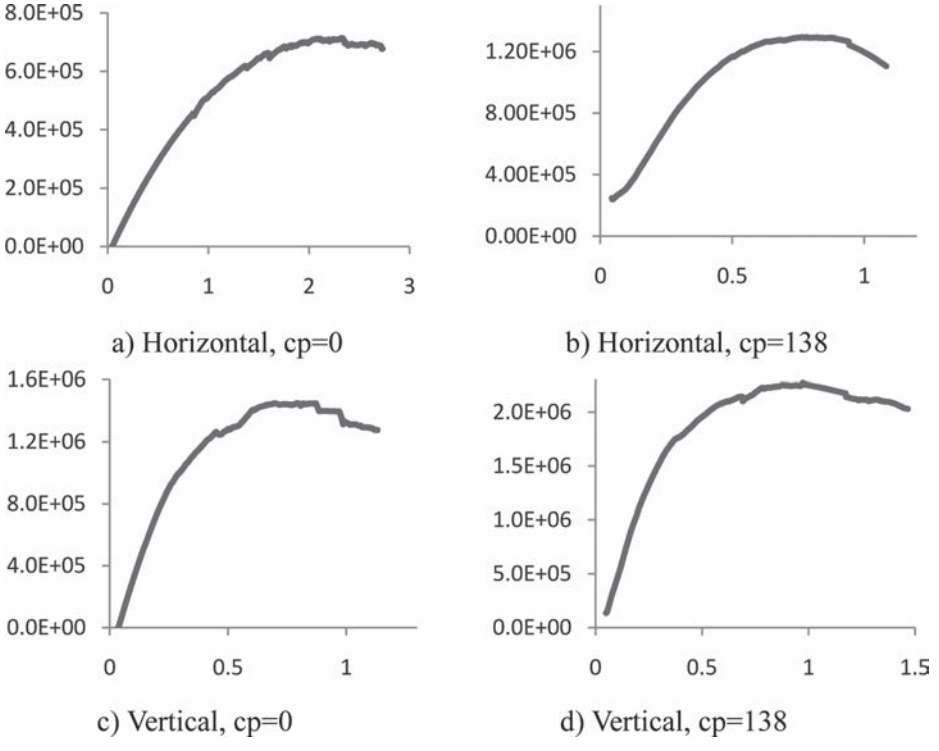

Figure 10. Virtual triaxial test results for coarse aggregate phase.

5.2.2.1 Evolution law of total number of skeleton particles

In three dimensional space a particle with coordinate number larger than three could be taken as a skeleton particle.

At the ultimate state of the specimen in the loading process, the axial stress show different levels at different confess pressure levels. As the confess pressure level increases, the peak load stress of the specimen becomes larger. Meanwhile, the number of the skeleton particles in microstructure at the ultimate load state shows different values at uniaxial load state and triaxial load state. However, that value remains the same when the confess pressure level is elevated to a higher value (276 Kpa). Apparently, the elevated range of the cp can not change the old response mechanism, which is established under cp = 138 KPa or lower, of the virtual

specimen. Accordingly, a higher value would be needed if the number of the skeleton particles was altered for the same specimen.

5.2.2.2 Evolution law of stress statuses of coarse aggregate phase

The internal structure stress distribution of AC in the load condition can not be easily obtained in the laboratory condition. However, the internal structure mechanical response and its evolution law must be very helpful for researchers to understand the relationship between microstructure characteristics and macro properties of AC. Nevertheless, they can be easily obtained through the virtual test simulation. In order to obtain the typical micromechanical response law of coarse aggregate phase in the loading process, three stages are selected to represent the stress statuses of coarse aggregate to explain the evolution law,

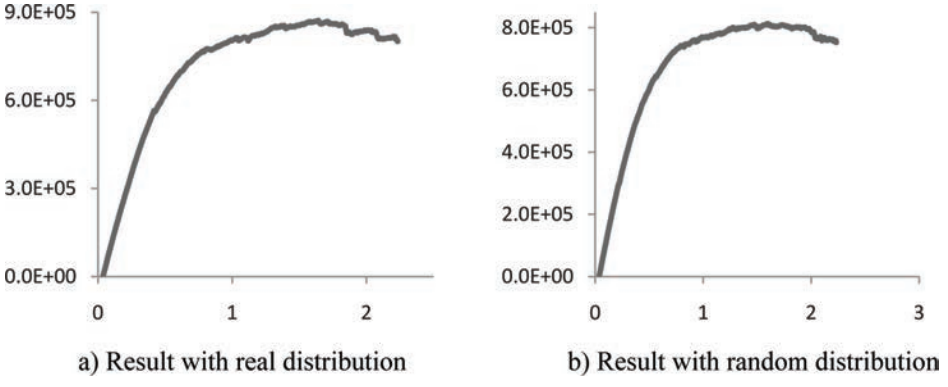

Figure 11. Virtual triaxial test result for air voids phase.

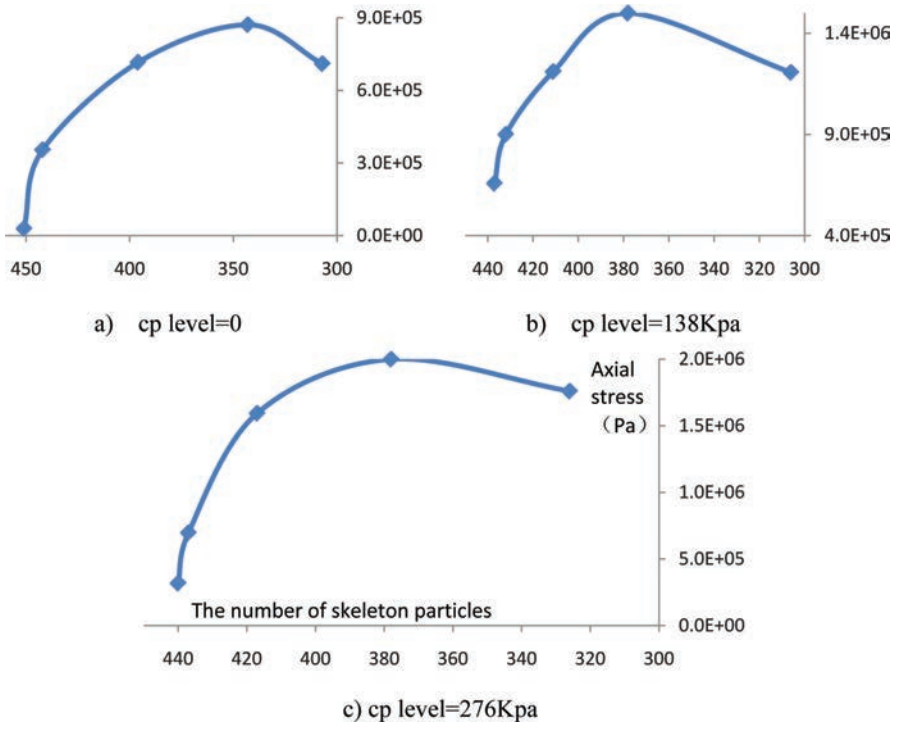

Figure 12. The number of skeleton particles at different confess pressure levels.

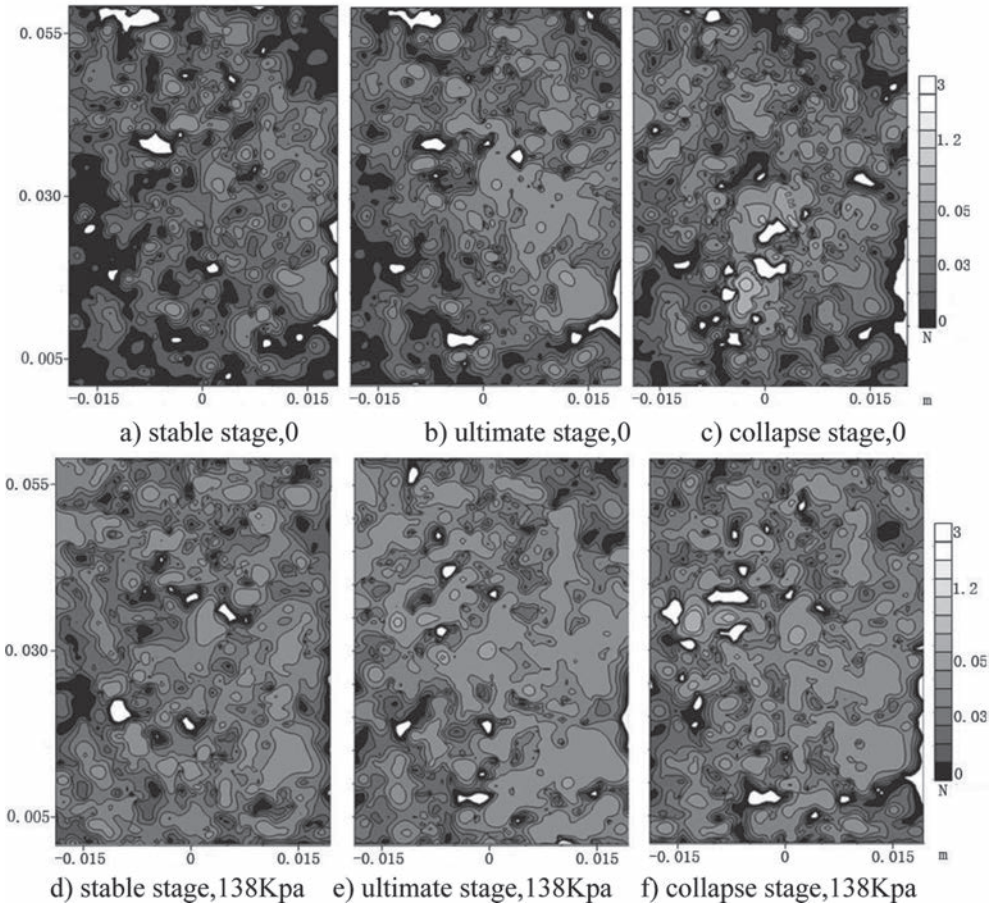

Figure 13. Stress statuses evolution law of coarse aggregate phase.

including the stable stage, ultimate stage, and collapse stage of AC. Meanwhile, the load condition involves two confine pressure level scenarios, namely 0 (shown in Fig. 13[a, b, c]), and 138 KPa (shown in Fig. 13[d, e, f]).

As it is shown in Figure 13, the stress concentration band can be easily differed in the stable stage under the uniaxial load condition. And the dispersed concentration blocks get coalesced, which means the adjacent coarse particles forms a very stable skeleton in the ultimate stage of loading. Typically, this phenomenon becomes more obvious in the triaxial load condition shown in Figure 13[e]. However, the skeleton effect is broken when the microstructure collapses with the accumulating load. For example, the concentration band is broken into many relatively dispersed blocks shown in Figure 13[c]. The stress concentration band of the microstructure is less clear than the one in the uniaxial load condition when the confine pressure is considered in the stable stage. And this result is in good agreement with the result of total number of skeleton particles shown in Figure 12.

6 CONCLUSIONS

A microstructure model of asphalt concrete is established on the basis its components, including the establishment of individual Coarse Aggregate (CA) element, the assembly of CA and air void phases in AC, the acquisition of contact model parameters. Finally, the virtual test is

launched to analyze the microstructure response mechanism under uniaxial and triaxial load condition. The work of this paper and the results of this study are summarized as follows:

- Based on the sieving mechanism, an algorithm for the CA element was developed. This algorithm is proved to be very efficient in creating the CA element with irregular shapes. By adjusting the orientations and lengths of the line segments, an aggregate with more variable irregular shapes and arbitrary orientations can be obtained without changing its size.
- Statistical regression models were developed to introduce varying air void distributions along pavement depth. Uniform distribution was assumed for air voids in the horizontal direction of pavements.
- The simulation of laboratory triaxial shear test was done and the virtual test result was in good agreement with the laboratory test result verifying the feasibility of the numerical model of AC established in this paper.
- On the basis of the numerical model established in this paper, the microstructure analysis of AC in the loading process was done to analyze the factors influencing the virtual test result such as the orientation of the coarse aggregate phase, and the distribution characteristics of air voids phase. The results said the orientation has a large influence on the virtual test result and the distribution of the air voids phase has an influence on the virtual test result too.
- Some variables were defined and used to track the microstructure response to the accumulating load in the test, such as number of skeleton particles, and stress statuses of CAs. And the statistical results are feasible and persuasive that the virtual test had great potential in helping the researchers understand the internal structure responses mechanism in the load condition.

Effect of micro-scale morphological parameters on meso-scale response of Asphalt Concrete

Ibrahim Onifade, Denis Jelagin, Alvaro Guarin, Björn Birgisson & Nicole Kringos
KTH—Royal Institute of Technology, Stockholm, Sweden

ABSTRACT: With recent advancement in the use of X-Ray Computed Tomography to capture the internal structure of Asphalt Concrete (AC), results have shown several possibilities to account for the distribution of the different phases in the mix and quantify them in a reliable way. The morphology of asphalt mixtures which includes the aggregate size gradation and the distribution of the air-voids and bitumen phase are captured in a single morphological parameter called the Primary Structure (PS) coating thickness—(T_{ps}). In this study, the effect of variations in the morphological micro-structural property on the meso-scale response of three (3) AC samples is examined using the 3D Finite Element Method (FEM). The AC internal geometry is acquired using X-Ray Computed Tomography (CT); the distribution of the aggregates, mastic and air-voids phase is considered and obtained using Digital Imaging Processing (DIP) techniques. Using a surface-based cohesive behavior and assuming a predominant adhesive failure at the interface between the mastic and aggregate, a maximum traction criterion is used to obtain the damage propensity of the different mixtures. The result of the analysis shows that the microstructural morphological parameter T_{ps} adequately captures the meso-scale response of the mixtures; there exist an inverse relationship between mixture strength characterization and the morphological parameter T_{ps}.

Keywords: X-Ray Computed Tomography, asphalt concrete morphology, Digital Image Processing, damage, micromechanical modeling

1 INTRODUCTION

The morphology of asphalt mixtures (i.e. everything related to the shape and size, and ratio of the different phases that makes up the asphalt mixture) plays an important role in the resulting performance. The morphology of asphalt mixtures is such that the different constituents are very inter-dependent; as a result changes in one of the constituents effect a change in the other mixture constituents. For instance: the distribution of bitumen inside the mixture depends on the aggregate gradations and the required air voids. It should therefore be possible to express the morphology of the mixture with meaningful morphology parameters to be utilized in homogenized meso- and macro scale AC models.

Recently, a new morphology framework was developed [1] which allows for the determination of a morphological parameter called 'Primary Structure' (PS) coating thickness (T_{ps}). The T_{ps} considers the size gradation and distribution of the stones, the distribution of the bitumen and the distribution of the air-voids in the asphalt mixture matrix and hence it is a parameter which can be used to characterize the morphology of asphalt mixtures. Asphalt mixtures with different gradation and volumetric properties have distinct T_{ps} values.

Several researchers have studied the influence of the aggregate morphology on asphalt mixture performance. In [2] the effects of aggregate angularity and binder content on bituminous mixture was related to Fracture Performance. It was concluded that the fracture energy is increased as the aggregate angularity is decreased and the binder content increased. In [3] the influence of coarse aggregate shape on the AC mixture was examined. The different

particle shapes considered in the study were cubical, rod, disk, and blade. A measure of the combined effect of the particle shape, angularity, and surface texture referred to as Particle Index (PI) was used in the study to define the stability of an aggregate in the mix. From the study it was found that since the cubical particles have the highest PI value, they gave a desirable increased aggregate internal friction and improved rutting resistance.

The air-void and bitumen distribution are also important morphological parameters that, together with the aggregates contributes to the resulting response of asphalt mixtures. The Voids in Mineral Aggregates (VMA) which is the volume of the mixture occupied with the effective bitumen content together with the air-voids has been related to the durability of mixtures and its ability to resist changes in the HMA properties. Inadequate VMA can result to rapid oxidization of the asphalt which could make the pavement too brittle [4]. Inadequate air-void content can have an adverse effect on the mixture performance and is mainly manifested in asphalt pavements as bleeding and rutting of the asphalt pavement [5].

The essence of the study presented in this paper is to investigate the influence of T_{ps} value for asphalt mixtures on the overall mixture behavior. X-Ray CT and image processing techniques have been used in the study and characterization of asphalt concrete mixtures by various researchers [6] [7] [8] [9]. In this study, an X-Ray CT system is used to acquire the internal structure of three different asphalt samples. Digital image processing and analysis technique is used to obtain the distribution and quantify the different phases in 3D space. The morphology of the three different asphalt field core samples is defined by their PS coating thickness (T_{ps}) and numerical simulation is performed to characterize the mixtures so as to obtain the effect of changing mixture morphology on mixture performance.

The methodology presented and discussed in this paper can be used to further understand the contribution of mixture morphology to mixture performance. The technique can be used to identify key material parameters and can be used to characterize field mixtures after construction thereby giving a good indication of field performance of different asphalt mixtures and thus reducing the bias between laboratory prepared and field compacted mixtures.

2 OBJECTIVES AND SCOPE

The main objectives of this study are to:

1. Characterize the AC morphology to obtain the PS coating thickness T_{ps} using X-Ray CT and imaging processing techniques to capture the asphalt morphology
2. Characterize the AC mixtures using micromechanical simulations to obtain effect of varying mixture morphology on mixture performance.
3. Evaluate the possibility of the use the morphological parameter T_{ps} in homogenized meso- and macro scale AC models.

3 X-RAY COMPUTED TOMOGRAPHY AND IMAGE PROCESSING

Three different AC field core samples are used in this study. The asphalt cores are scanned using the KTH X5000 X-Ray Computed Tomography (CT) scanner at the Highway and Railway Engineering Laboratory. The scanning resolution is 105 μm without beam filtration. Each scanned samples reveals three distinct lift of AC layers. The scanned samples are labeled Sample A, Sample B and Sample C as shown in Figure 1.

Image processing techniques is used to carefully process and analyze the samples to obtain quantities needed to calculate the T_{ps} value for each sample. The procedure for the digital image processing and analysis developed by Onifade et al. [9] is used. In this study, the median filter not used but instead, an edge-preserving filter together with an anisotropic diffusion filter is used to improve the quality of the segmented image and thus obtain reliable microstructural information needed for the particle size distribution. In this procedure, Avizo

Figure 1. Images of samples A, B and C used in this study.

Fire© is used for the image processing and analysis while Simpleware ScanIP© is used for volume reconstruction and mesh generation.

One lift from each AC sample which results in a cylindrical geometry of approximately 100 mm diameter and 57 m height is quantified and used for the calculation of the T_{ps} values of each sample. The geometry from each sample with known T_{ps} value is used in the micromechanical simulation for material characterization. The same geometry size is used to eliminate errors due to size variation in T_{ps} characterization and numerical simulation.

4 CALCULATION OF PS COATING THICKNESS

The quantities needed to calculate the T_{ps} values are as follows:

a. Size gradation of the aggregates
b. Max specific gravity of the mixture (G_{mm})
c. Binder specific gravity (G_b)
d. Percent binder (P_b)
e. Aggregates bulk specific gravity (G_{sb})
f. Percent absorbed binder (P_{ba})
g. Percent of air voids (V_a)
h. Voids Filled with Bitumen (VFA)

Gradation of the stones is obtained from the image processing and analysis quantification results. The equivalent sphere diameter of the aggregates is used for the particle size distribution of the stones. The minimum Feret diameter is not used as it doesn't adequately represent the aggregate size since the aggregate size in the third direction have to be considered for 3-Dimensional (3D) aggregate quantification. Another advantage of using the equivalent sphere diameter is that the shape is then in conformity with the theory on which the development of T_{ps} is based upon i.e. packing theory. The sieve sizes that have been considered are 19 mm, 12.5 mm, 9.5 mm, 4.65 mm, 2.36 mm and 1.18 mm. Sieve sizes smaller than 1.18 mm have not been considered because aggregate sizes smaller than 2.36 mm are considered as part of the mastic for the micromechanical modeling. The results from the calculation of the T_{ps} show that the interacting aggregate size range is between 12.5 mm and 4.65 mm. This is the rationale for the consideration of aggregate sizes less than 2.36 mm as part of the mastic in the Finite Element simulations. The particle size distribution is shown in Table 1.

The volumes of the mastic and air-voids are obtained directly from the quantification results. The volume of the mastic together with the specific gravity of the mastic is used to

Table 1. Aggregate particle size distribution.

Sieve size (mm)	Sample A	Sample B	Sample C
19	100	100	100
12.5	92.4	81.88	92.8
9.5	77.6	67.32	76.9
4.75	53.3	60.57	47.5
2.36	51	56.13	43.5
1.18	32	30.02	18.2

Table 2. Volume relationship (% volume) for the three different samples.

	Sample A	Sample B	Sample C
Air-voids	3.68	8.80	2.75
Mastic	47.51	38.27	52.05
Aggregates	48.81	52.92	45.21

Table 3. Mixture volumetric properties.

Volumetric properties		Sample A	Sample B	Sample C
Max specific gravity of the mixture	G_{mm}	1.88	2.00	1.81
Binder specific gravity	G_b	2.70	2.70	2.70
Percent binder	P_b	27.08	21.62	30.50
Aggregates bulk specific gravity	G_{sb}	1.66	1.83	1.56
Percentage absorbed binder	P_{ba}	2.13	2.61	1.71
Percentage volume of air voids	V_a	3.70	8.81	2.80
Voids filled with bitumen	VFA	82.19	60.01	87.19

obtain the mass of the binder in the mixture. The specific gravity of the mastic and aggregates are assumed to be 1.035 and 2.7 respectively for all three samples. Table 2 shows the volume relationship for the different phases in the AC samples.

The mixture volumetric properties are obtained using the volume of the three different phases obtained from the quantification and the specific gravity of the mastic and aggregates. The bulk specific gravity of the mixture needed for calculation of the Void in Mineral Aggregate (VMA) and the Percentage Binder Absorbed (P_{ba}) is obtained from the effective specific gravity as shown in Eq. (1).

$$G_{sb} = (0.9397 * G_{se}) + 0.0795 \tag{1}$$

Table 4 is used for classification of the aggregate structure into the 4 different groups. The relationship between the mixture volumetric properties and the porosity of the primary structure is shown in Eq. (2) where $V_a^{SS}$and V_a^{PS} are the volume of secondary structure and primary structure respectively, V_b^{eff} and V_v^{eff} are the effective volume of the binder and voids in the mixture, $V_b^{abs(PS)}$ and $V_b^{abs(SS)}$ are the volume of binder absorbed by the primary and secondary structures respectively.

$$\eta_{ps} = \frac{V_a^{SS} + V_b^{eff} + V_b^{abs(SS)} + V_v^{eff}}{V_a^{PS} + V_a^{SS} + V_b^{eff} + V_b^{abs(PS)} + V_b^{abs(SS)} + V_v^{eff}} \tag{2}$$

There exist several relationships between PS coating thickness index I_{ct} and the porosity of the primary structure η_{ps} for ideal packing arrangements i.e. simple cubic, orthorhombic,

Table 4. Identification of different groups based on aggregate gradation.

	Condition	Four different groups
	$D_{avg} \geq 0.703\overline{D_n} + 0.297\overline{D_{n+1}}$	*Oversized Structure (OS)*: Larger particles than the PS
	$0.703\overline{D_n} + 0.297\overline{D_{n+1}} \geq D_{avg} \geq 0.311\overline{D_n} + 0.689\overline{D_{n+1}}$	*Primary Structure (PS)*: Interactive grains form the load caring network
	$where,\ D_{avg} = \frac{\varphi_n \cdot \overline{D_n} + \varphi_{n+1} \cdot \overline{D_{n+1}}}{\varphi_n + \varphi_{n+1}}$	
	$D_{avg} \leq 0.311\overline{D_n} + 0.689\overline{D_{n+1}}$	*Secondary Structure (SS)*: Fills the gaps between the PS and provides stability
	Particles passing 0.0075 sieve	*Filler Particles*: Fills the gaps between the SS and improves stability

Note: D_{avg} is the weighted average size of two consecutive sieves n and n + 1. Whereas, φ_n and φ_{n+1} are the concentrations for two contiguous sieves with mean particle size $\overline{D_n}$ and $\overline{D_{n+1}}$ respectively (with $\overline{D_n} > \overline{D_{n+1}}$).

Table 5. PS coating thickness for the three different samples.

	Sample A	Sample B	Sample C
PS coating thickness (T_{ps})	1.99	2.80	1.76
PS range (mm)	4.65–12.5	2.36–12.5	4.65–12.5

tetragonal, rhombohedral packing. However, the packing of the aggregates in the AC mix is in a non-ideal manner and hence prompted the establishment of a relationship between the PS coating thickness index and porosity of the primary structure for non-ideal packing arrangements [10]. Eq. (3) shows the established relationship for the non-ideal packing arrangements.

$$I_{ct} = 0.95(\eta_{ps})^{1.28} \tag{3}$$

Eq. (4) shows the relationship between the PS coating thickness (T_{ps}), the PS coating thickness index (I_{ct}) and the weighted average diameter (d_p) of the PS particles. The PS coating thickness is obtained from equation 3.

$$T_{ps} = I_{ct} * d_p/2 \tag{4}$$

5 NUMERICAL SIMULATION

Micromechanical analysis is carried out to investigate the influence of T_{ps} on asphalt mixture performance i.e. how T_{ps} correlates with mixture behavior. To achieve this purpose, three different samples with the same geometry, material properties, boundary conditions, but different morphology is analyzed to characterize their performance. The morphology is captured and characterized by the PS coating thickness T_{ps}.

The aggregates are considered as linear elastic materials with Young's Modulus of 25 GPa [6] and a Poisson's ratio of 0.3. The mastic is made up of the secondary structure, filler material and the bitumen. The mastic is considered as a viscoelastic material and modeled as a generalized Maxwell's model with springs and dashpots connected in series. The mastic master curve used in this study is generated using the Christensen Anderson Marasteanu (CAM) model. The CAM model can be used to model the rheological behavior of the pure bitumen and mastic and it relates the glassy modulus, the rheological index and the cross-over frequency to the complex modulus of the mastic. The master curve shown in Figure 2 is used to model the viscoelastic response of the mastic.

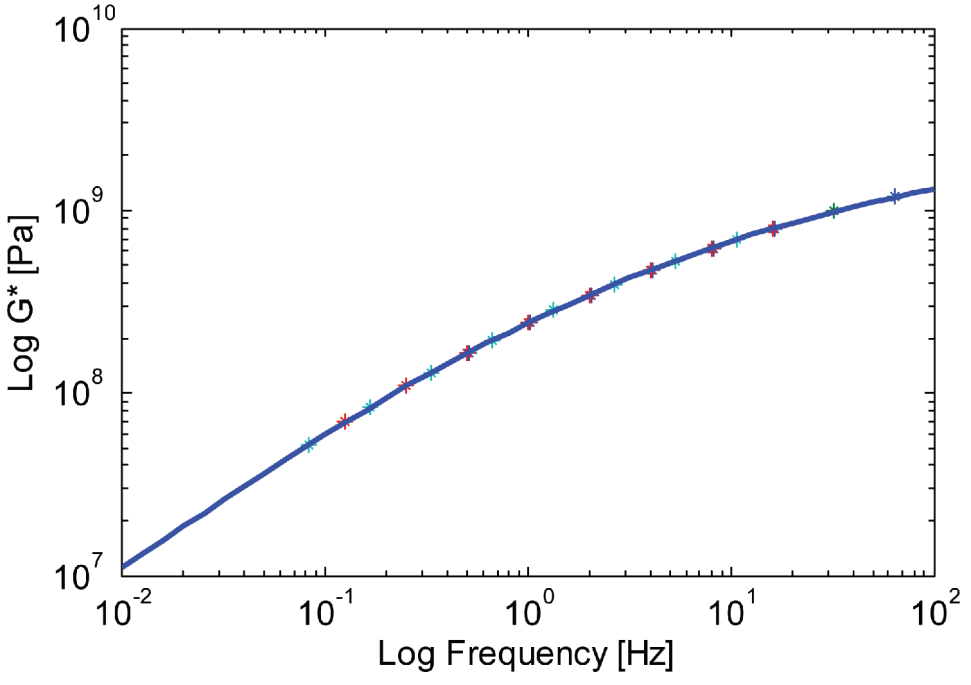

Figure 2. Master curve used to model mastic viscoelastic response.

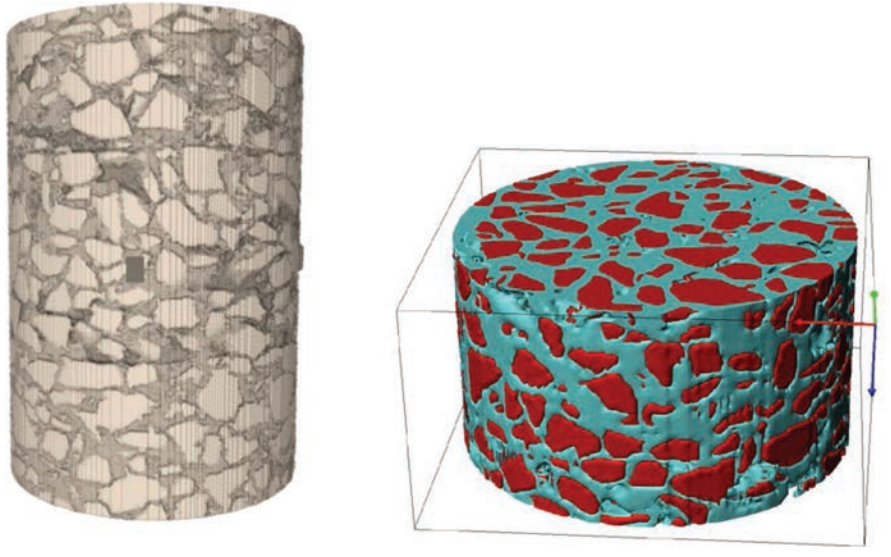

Figure 3. 3D-reconstructed image and geometry of sample A used in numerical simulation.

A uniaxial displacement controlled test is performed to characterize the three different mixture using numerical simulations. The bottom of the samples constrained in the axial direction and the top is subjected to a constant displacement rate of 1e-2 mm/s for 100 s resulting in a final displacement of 1 mm. The final geometry used for the numerical simulation consists of approximately 1.5 Million tetrahedral elements. Figure 3 shows the 3D-reconstructed image and geometry for sample A used in the analysis.

To evaluate the effect of changing microstructural morphological parameter on mixture response, two sets of analysis is considered. In the first set of analysis, it was assumed that there is perfect bonding between the aggregates and mastic phase and in essence there are stress continuities at the interface. Figure 4 shows the plot of the stress and strain in the mastic for the three samples considered in this analysis. The effect of changing morphology is reflected in the amount of stresses developed in the mixture with the mixture with the highest t_{ps} value having the lowest stresses in the mixture vice-versa.

The second sets of analysis consider the inclusion of the interface interaction between the mastic and the aggregate. Surface-based cohesive behavior is used to model the interface behavior in Abaqus. The surface-based cohesive behavior used assumes a linear elastic traction-separation law and is used to obtain the traction at the interfaces. The formulation for the interface behavior is shown in eq. (5).

$$t = K\delta \tag{5}$$

where t is the traction at the interface, K is the elasticity matrix and δ is the separation at the interface.

The components of the elasticity matrix in the normal and shear directions can be varied to check different interface conditions. The components of the elasticity matrix are uncoupled and the value of the normal stiffness and shear stiffness used is shown in Table 6.

A maximum stress-based damage criterion is used to model the initiation of damage. The maximum stress criterion is shown in eq. (6).

$$D = \max\left\{\frac{\langle t_n \rangle}{t_n^0}, \frac{t_s}{t_s^0}, \frac{t_t}{t_t^0}\right\} = 1 \tag{6}$$

where t_n^o, t_s^o, t_t^o represents the peak stress values purely in the normal direction and purely in both shear directions respectively. The peak stress value is chosen arbitrarily as 3 MPa in this study. Compressive normal stresses doesn't not contribute to damage when assuming

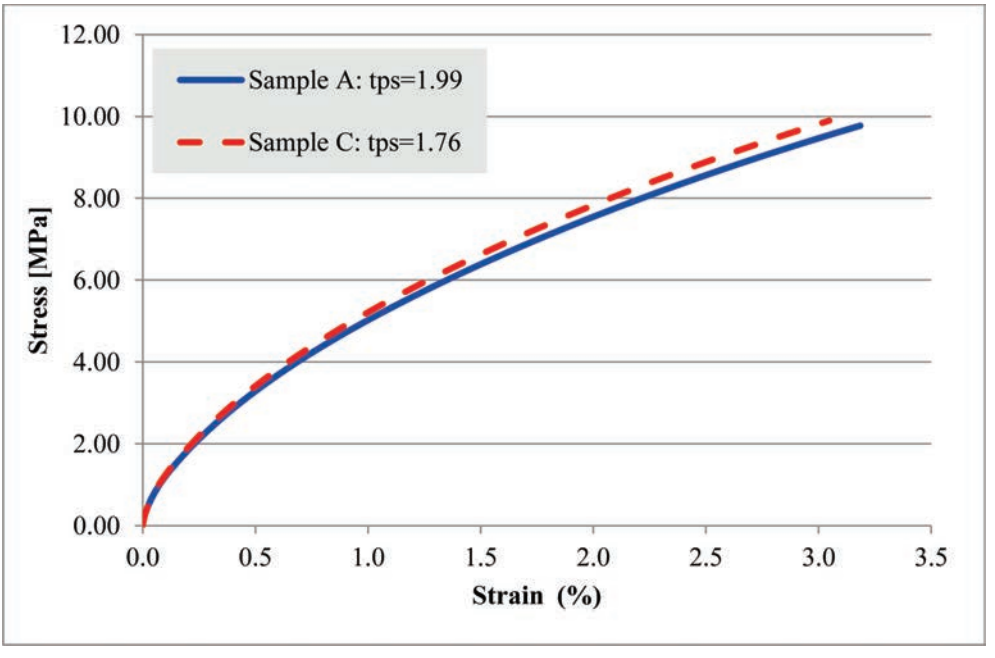

Figure 4. Stress-strain diagram without interface interaction.

Table 6. Interface properties.

	Stiffness (MPa/mm)
Normal stiffness	1500
Shear stiffness	1000

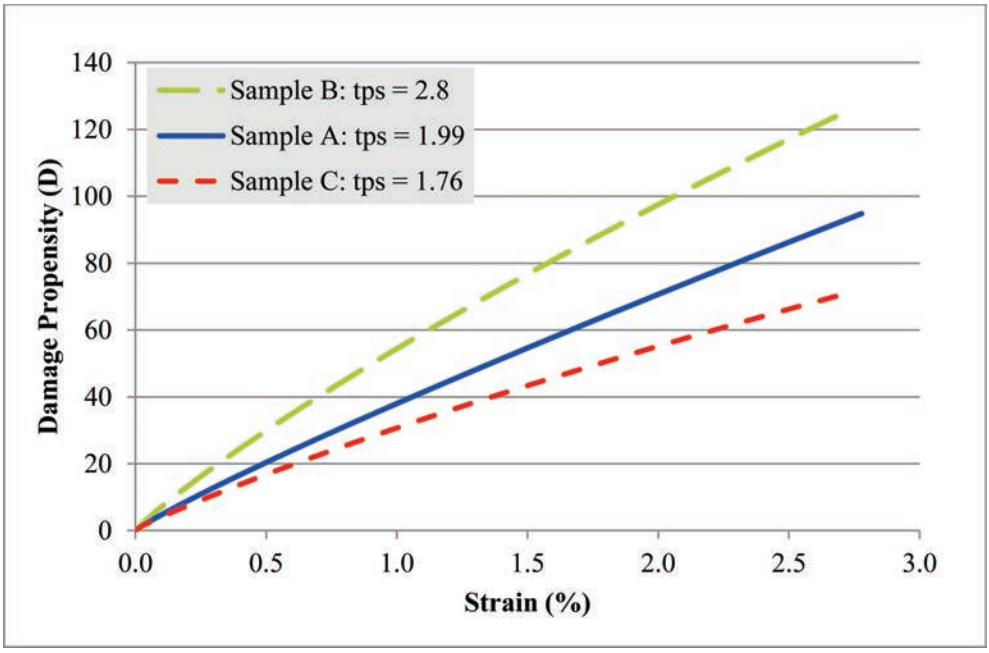

Figure 5. Damage propensity for the three different mixtures.

cohesive behavior at the interface, hence the use of Macaulay brackets in eq. (6). The damage criterion in eq. (6) is used to quantify the damage and obtain the damage propensity of the different mixtures.

Figure 5 shows the plot of damage criterion (D) against strain for the three different mixtures. The material with the highest value of t_{ps} has the highest damage propensity and vice-versa.

Considering adhesive failure, asphalt-based materials tend to lose its integrity due to degradation of the bond at the interface between the mastic and the aggregate. This loss of material integrity leads to damage in the material and which eventually results in failure. With the mastic and aggregate material properties the same for the three mixtures and assuming that the damage is adhesive in nature, we can draw the conclusion that the damage and eventual failure is mainly dependent on the conditions at the interface. For all three mixtures, there will be a nominal traction value for which there will be a complete separation at the interface for the three samples which will result in failure of the material. From Figure 5, it follows that as the value of the nominal traction increases, the strength at the interface increases and the associated failure strain increases. The failure changes from an adhesive failure at the interface to a cohesive failure in the different phases when the value of this nominal traction is more than the cohesive strength of the constituent materials. This means, the nominal traction will not be reached before failure occurs in the material, if the failure is cohesive in nature.

For comparison purpose, a failure criteria which is dependent on the condition at the interface is assumed to be the value of the ratio of the nominal traction to the peak stress value and chosen to be 40 i.e. $D_{crit} = 20$, we can then obtain the failure strain associated with

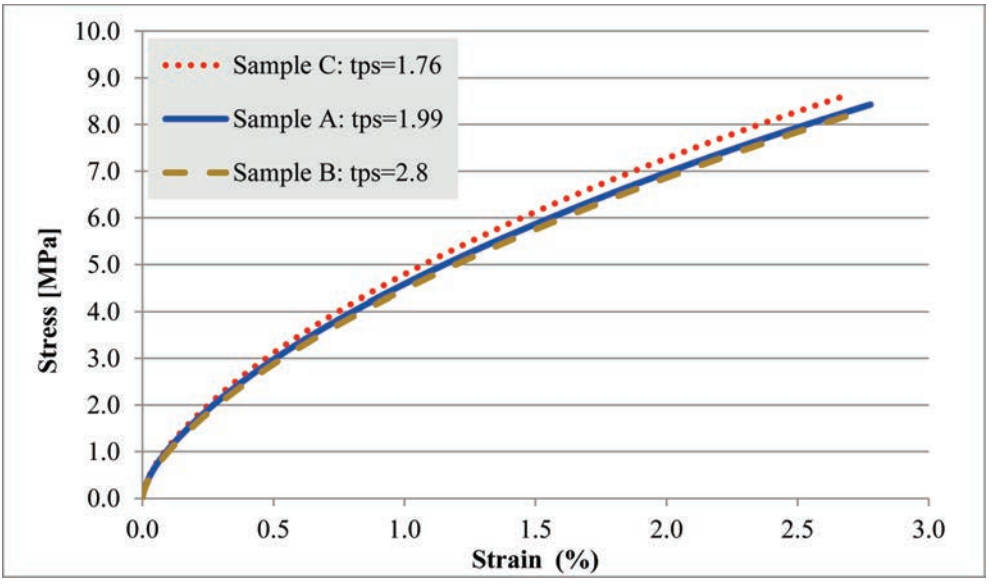

Figure 6. Stress-strain curve considering interface interaction.

Table 7. Summary of results.

Sample	T_{ps}	Failure strain (%)	Failure strength [Mpa]	Fracture energy [kJ/m^3]
A	1.99	0.49	2.96	8.9
B	2.80	0.32	2.14	4.1
C	1.76	0.62	3.55	13.3

the failure criteria for the three mixtures. Failure in materials is characterized with failure strain and failure strength. With the failure strain of each material known, we can obtain the failure strength and then the fracture energy of the different mixtures from the stress-strain diagram in Figure 6.

From Table 7, as the value of T_{ps} increases, the failure strain, failure strength and the fracture energy decreases. There is a good trend and an inverse relationship between the T_{ps} values of the different mixtures and their corresponding mixture strength characteristics. The microstructural morphological parameter T_{ps} can be used as an internal parameter in homogenized meso- and macro scale AC models and can also be used as input in design procedures to predict bulk material properties. Changes in the microstructure due to damage accumulation have not been considered in this approach. Consideration of the damage in the material as a function of loading will further improve the practicality and applicability of the approach. There is also a need for further studies of interfaces in asphalt materials combining experimental techniques and micromechanical modeling approach.

ABSTRACT: Asphalt Concrete (AC) pavements are exposed to both atmospheric oxygen and moisture-induced conditions. In this paper, the combined effects of oxidation and moisture inclusion on asphalt binder, in the form of energy and density changes, are studied by Molecular Dynamic (MD) simulation. Two hypothetical models of asphalt binder, before and after oxidative aging, are developed and simulated with different moisture contents. The simulation results demonstrate that before moisture inclusion, the oxidized asphalt binder shows hardening phenomenon in the form of energy and density increases, compared to the unoxidized asphalt binder. After moisture inclusion, energies and densities of both unoxidized and oxidized binders decrease with an increase of moisture content. In addition, with the same moisture content, energies and density of the moisture-induced oxidized asphalt binder decrease faster than the moisture-induced unoxidized asphalt binder. From study, the decrease of density is caused by the increase of volume of asphalt binder, which is due to stretching of asphalt binder molecular chains with presence of water molecules. The stretching of molecular chains might cause damage in asphalt binder. Furthermore, Energy losses and density decreases are key indicators of damage in AC. Therefore, Moisture-induced oxidized asphalt binder is most susceptible to be damaged.

Keywords: Asphalt binder, oxidative aging, moisture, molecular dynamic simulation

1 INTRODUCTION

Asphalt binder durability is affected by the resistance of the molecules' chemical composition to change when reacting with atmospheric oxygen, which is called oxidative aging. Oxidative aging is the major factor leading to the hardening and embrittlement of asphalt [1]. Meanwhile, moisture-induced damage can be defined as the loss of strength and durability in Asphalt Concrete (AC) due to the effects of moisture [2]. The sources of moisture into AC are from rainfall and melting ice from the top of the AC pavement and seepage and capillary actions of high water table from the bottom of the AC pavements [3]. Moisture diffuses through asphalt binder and aggregate. Both chemical and mechanical actions take place while moisture diffuses through AC. These chemical and mechanical actions of moisture reduce stiffness of asphalt binder.

Oxidative aging and moisture-induced damage mechanisms are very complex phenomena and many attempts have been made to simplify them [4]. This study is focused on determining aging and damage by measuring energy losses and density changes from a microscopic view using Molecular Dynamic (MD) simulation. The objective of this study is to understand the

oxidation and moisture damage mechanism, and the properties of asphalt binder changes before and after oxidative aging with moisture inclusion. An understanding of these will be substantially helpful in improving the durability of asphalt binder in the future.

2 MOLECULAR STRUCTURES OF ASPHALT BINDER BEFORE AND AFTER OXIDATIVE AGING

Asphalt molecules are composed mainly of carbon and hydrogen atoms; however, most molecules contain one or more heteroatoms such as sulfur, nitrogen and oxygen. Asphalt can be separated into two broad groups: maltenes and asphaltenes. Maltenes can be further divided into a series of fractions with increasing polarity: saturates, aromatics, and resins [1, 5].

2.1 *Molecular structures of asphalt before oxidative aging*

2.1.1 *Maltenes—saturates*

Saturates are composed of alkanes [6]. Saturate fractions lack polar chemical functional groups. They are liquid at ambient temperatures and seldom change with time. Saturates show the least change under oxidation [1]. Figure 1 shows the hypothetical molecular structure of saturates used for this study drawing by Culgi 7.0.2. The black is carbon, and the white ball is hydrogen.

2.1.2 *Maltenes—aromatics*

The molecular structure of aromatics is comprised of condensed non-aromatic rings and at least one aromatic ring structure similar to benzene. They may contain the heteroatoms oxygen, nitrogen and sulfur and are liquid at ambient temperatures. Aromatics are the softening component in asphalt (good solvents for paraffin waxes) and are more polar than saturates [6–7]. The structure of Aromatics is illustrated in Figure 2.

2.1.3 *Matenes—resins*

Resins consist of a much higher polar end group than the other maltene fractions and contain heteroatoms such as oxygen, sulfur and nitrogen, as well as long, nonpolar paraffinic groups. The resins are attracted to the asphaltene micelles through their end group. The resin fraction is solid or semi-solid at ambient temperatures and is also one of the aging fractions in asphalt. Resins can be converted to asphaltenes by oxidation [6–7]. The hypothetical structure of resins is represented by Figure 3. The red ball represents oxygen, and the yellow ball represents sulfur.

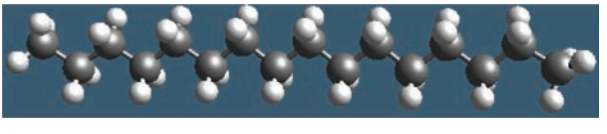

Figure 1. Hypothetical structure of saturates $C_{16}H_{34}$.

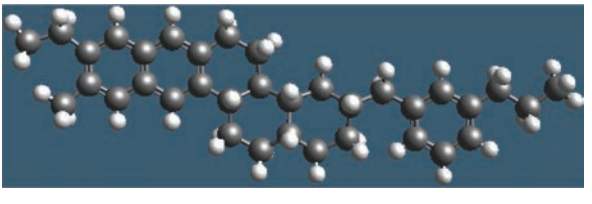

Figure 2. Hypothetical structure of an aromatic molecule $C_{35}H_{44}$ [6].

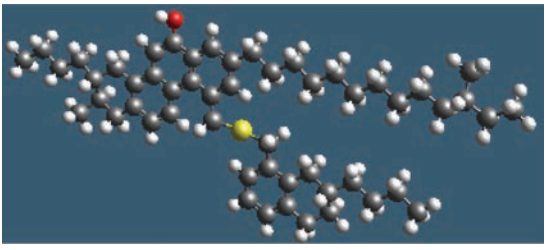

Figure 3. Hypothetical structure of a resin molecule $C_{53}H_{76}OS$ [6].

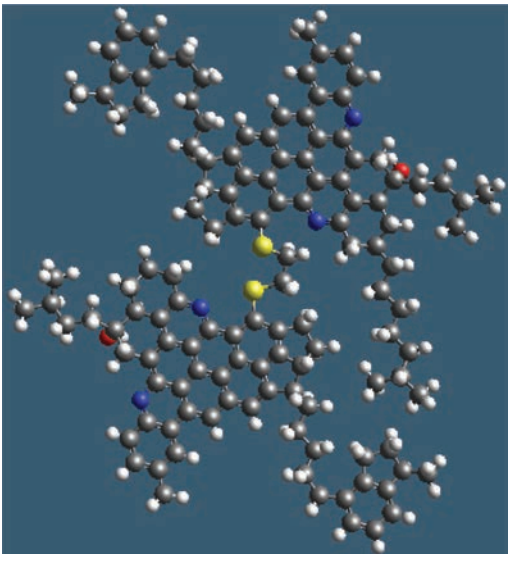

Figure 4. Hypothetical structure of an asphaltene molecule $(C_{67}H_{76}N_2OS)_2$ [6].

2.1.4 *Asphaltenes*

Asphaltenes are the most polar of asphalt's component fractions and act as the viscosity-building ("bodying") agents in asphalt. Therefore, they have a very high tendency to interact and associate. They are not only composed of condensed aromatic and naphthenic molecules, but they also contain a large amount of heteroatoms (O, S, and N) and metal (V and Ni) content from heavy oils incorporated in their polar molecules. Asphaltenes are solid or semi-solid at ambient temperatures [6–7]. Figure 4 illustrates the molecular structure of the fraction of asphaltenes. The blue ball represents nitrogen.

2.2 *Oxidation mechanism*

Many asphalt molecules of different composition have similar chemical functionalities that in turn cause similar effects on the physical properties of asphalt. If the different chemical functionalities, which compose and dominate the properties of the various asphalt molecules are considered, the analysis of asphalt oxidative aging is narrowed to a manageable number of types of functionalities [8].

Asphalt exposed to atmospheric oxygen in pavements rapidly oxidizes with the formation of polar, strongly interacting, oxygen-containing chemical functional groups that greatly increase viscosity and alter complex flow properties [1]. Figure 5 shows the important chemical functionalities before and after aging which are an integral part of large asphalt molecules.

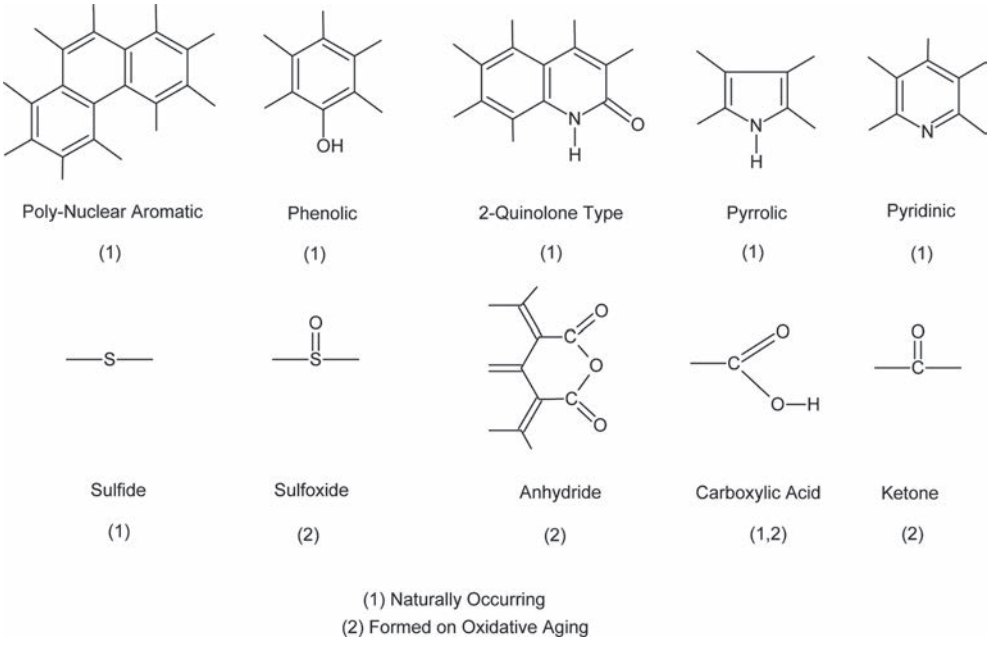

Figure 5. Functional groups present in asphalt molecules [11].

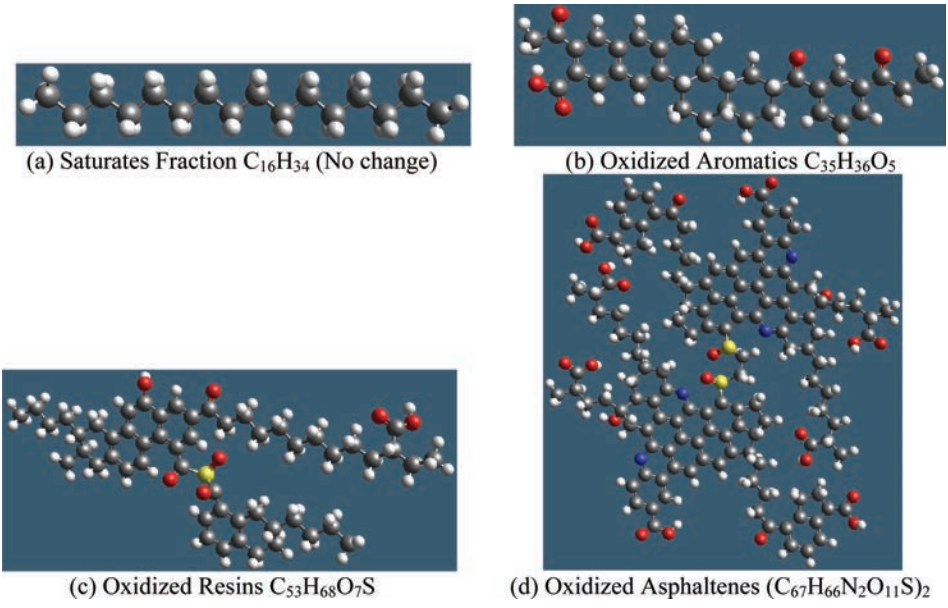

Figure 6. Chemical composition of asphalt after oxidative aging.

Petersen indicated the oxidation products formed are consistent and in good agreement with the hydrocarbon types in asphalts and the general chemistry of hydrocarbon oxidation [1]. The formation of carbonyl compounds through the hydroperoxide intermediate is the major reaction pathway of hydrocarbon air oxidation [9–10]. The most sensitive hydrocarbon moiety present in asphalt is the carbon atom adjacent to an aromatic ring system—a benzylic carbon. The hydrogen atom attached to the carbon atom is relatively easy to displace,

forming a free radical on it. Branching in the attached hydrocarbon chains also increases the sensitivity of the asphalt to oxidation. Generally, ketones and sulfoxides are the major oxidation products.

2.3 *Hypothetical structures of asphalt components after oxidative aging*

Figure 6 shows the hypothetical molecular structures of the four fractions in asphalt after oxidative aging. The amount of fractional components changes from the more nonpolar to the more polar fractions. Saturates show the least change in oxidation in Corbett's analysis [12], while there was a significant increase in the fraction of asphaltenes along with the decrease of aromatics and resins.

3 MD SIMULATION

3.1 *Asphalt composition models*

According to Corbett's studied on composition of asphalt, some unoxidized asphalt is comprised of 5–15% saturates, 30–45% aromatics, 30–45% resins, and 5–20% asphaltenes [13]. Storm and co-workers's studied on asphalt fractions suggests C_{16} to C_{36} average chain lengths of saturate structure [14]. Based on the above references, 10% satures, 30% aromatics, 40% resins, and 20% asphaltenes by weight, respectively, are selected for the unoxidized asphalt in this study. In addition, the chain length of 16 for the saturate fraction is chosen. The four asphalt fractions are put into a simulation box to represent unoxidized asphalt, with the size of 24.8*24.8*24.8 $Å^3$. The size of simulation box is selected considering the smallest box size for containing all the asphalt fractions. The oxidative aged asphalt for simulation is used the same size of simulation box and contains the same number of molecules of each fraction as the unoxidized asphalt.

3.2 *Simulation methods and conditions*

The MD simulation is conducted by Culgi 7.0.2 software and an all-atom model is used to explicitly represent each atom in a molecule [15]. In addition DREIDING force field is selected to define the interaction between the atoms, and atom based method is used to handle long-range interactions. Initial temperature and pressure for all the simulations are set as 298 K (25 ºC) and 101.325 kPa (1 atm), respectively. This study first minimizes the energies of both unoxidized and oxidized asphalt simulation boxes to a reasonable level by the Monte Carlo minimization algorithm implemented in Culgi, and then sets the statistical mechanical ensemble NPT for the MD simulations. The simulation time step is 0.5 fs and the running steps is first set as 1,000,000 to guarantee the system that can reach equilibration.

To analyze how the properties of asphalt change under the combined effects of oxidative aging and moisture inclusion, MD simulations are conducted for both unoxidized and oxidized asphalts with water molecule inclusion at 0% 1%, 2%, 4%, 6%, 8%, 10%, 12%, 14%, 16%, 18%, and 20%, by the weight of simulation box, respectively. The reason to select the moisture content range is based on multiple attempts of the MD simulations. This range can truly show the trend of energy and density changes (from rapid to steady) of both unoxidized and oxidized asphalt binders, and explicitly compare the differences between unoxidized and oxidized asphalt binders, after different moisture content inclusion. There are total 24 simulations conducted by this study. Figure 7 (a) and (b) show two examples of the simulation box with 20% water in unoxidized and oxidized asphalt system, respectively.

3.3 *Results and discussions*

3.3.1 *Density changes*

Figure 8 indicates that densities of both unoxidized and oxidized asphalts decrease with an increase in water content, except the density changes during initial moisture inclusion. It can

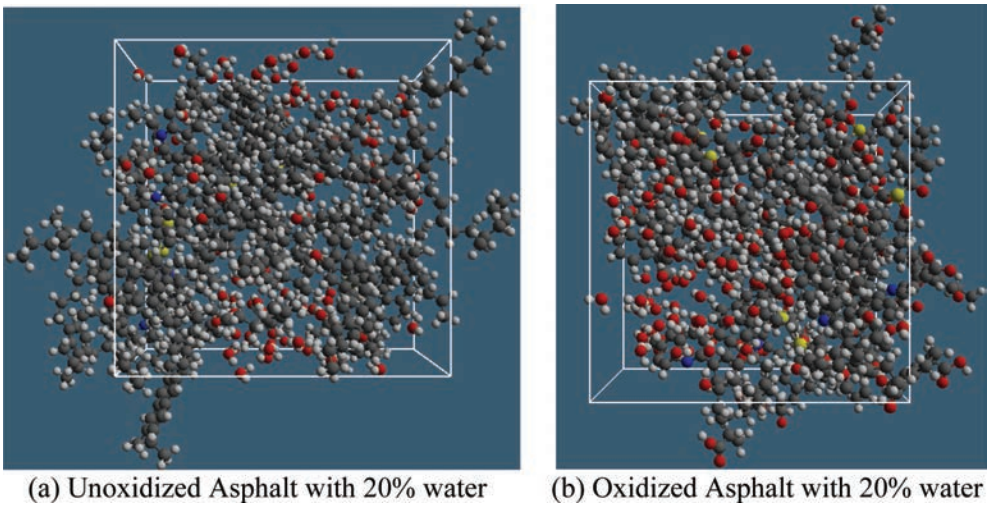

Figure 7. Simulation boxes for both unoxidized and oxidized asphalt with 20% water.

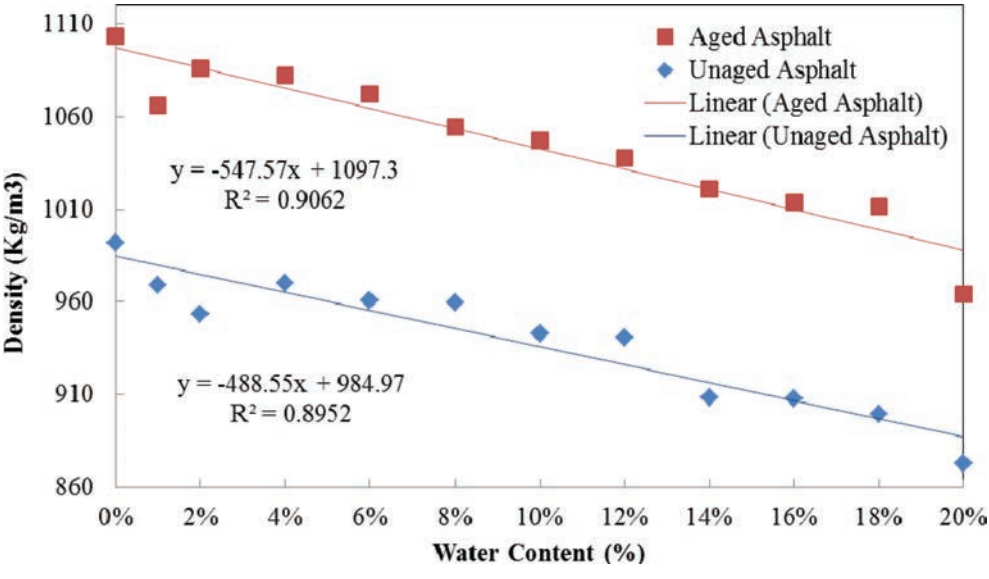

Figure 8. Water content-density relationships for asphalt before and after oxidative aging.

be seen that the densities of both unoxidized and oxidized asphalts decreases significantly during the initial water inclusion and reach a relative low point, as 2% water content for unoxidized asphalt and 1% water content for oxidized asphalt. After the first decrease, the densities show a slight rise and start to decrease with an increase in water content. The reason behind this is that initial moisture inclusion might increase more volume of the system with less weight rise. In addition, density decrease caused by volume increase of the asphalt binder is due to stretching of asphalt binder molecular chains with presence of water molecules. The stretching of the molecular chains might cause damage (stiffness reduction) in asphalt binder. Figure 9 illustrates that bond stretch energies of both oxidized and unoxidized asphalt decrease with the increase of water content. This proves that the addition of water molecules stretches the molecular chains of asphalt to make them lose bonding strength, and

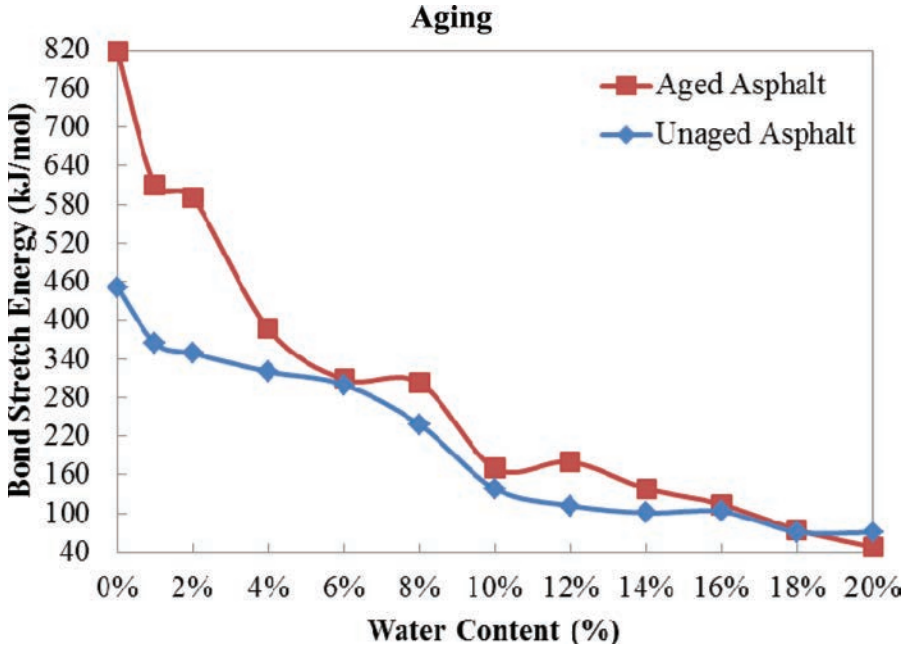

Figure 9. Bond stretch energies of oxidized and unoxidized asphalt vs. water content.

reduces the stiffness of asphalt. Also the bond stretch energy of oxidized asphalt is higher and decreases faster than the unoxidized asphalt, while after 20% water inclusion, the energy of oxidized asphalt is lower than the unoxidized asphalt.

Figure 8 also shows that the density of asphalt after oxidative aging is higher than the one before oxidation at the same water content. This result suggests hardening of asphalt occurs after oxidative aging. Moreover, the oxidative aged asphalt shows a better linear relationship for density vs. water content than the unoxidized asphalt, and the slope of oxidized asphalt linear line is higher than the unoxidized asphalt, which means that the density of oxidized asphalt decreases faster than the unoxidized asphalt with an increase in moisture inclusion. This indicates that oxidative aged asphalt is easily damaged than unoxidized asphalt by moisture inclusion.

3.3.2 *Energy changes*

Energy changes in asphalt before and after oxidative aging combined with moisture inclusion can also reveal the physical property changes. Energies can be grouped into kinetic energies (which are due to particle movement) and potential energies (which are stored energies—energy that a piece of matter has because of its position or because of the arrangement of its parts) [16].

Andersen developed a constant pressure MD based on the, so called, extended system method [17]. This approach is used in the simulation by Culgi 7.0.2 [15]. The simulation system is coupled to an external variable, the volume of the system, which mimics the action of a piston on a real system. The piston is a 3-dimensional virtual piston. If the system has a volume V and the piston has a mass M, the kinetic energy K_V within time t associated with the external variable is,

$$K_V = \frac{1}{2} M \left(\frac{\partial V}{\partial t} \right)^2 \tag{1}$$

The potential energy (E_P) for an arbitrary geometry of a molecule in MD simulation under the Dreiding force field is expressed as a superposition of valence (or bonded) interactions

(E_{val}) that depend on the specific connections (bonds) of the structure and non-bonded interactions (E_{nb}) that depend only on the distance between the atoms [18]:

$$E_P = E_{val} + E_{nb} \tag{2}$$

The valence interactions include bond stretch (E_B), bond-angle bend (E_A), dihedral angle torsion (E_T), and inversion terms (E_I):

$$E_{val} = E_B + E_A + E_T + E_I \tag{3}$$

While the non-bonded interactions are composed of van der Waals or dispersion (E_{vdw}), electrostatic (E_Q), and explicit hydrogen bonds (E_{hb}) terms:

$$E_{nb} = E_{vdw} + E_Q + E_{hb} \tag{4}$$

Table 1 shows the energy changes of both oxidized and unoxidized asphalts with different water content. It can be seen that the differences of kinetic energies between oxidative aged and non-oxidative aged asphalts are almost the same at different water contents. However the

Table 1. Energy changes of unoxidized and oxidized asphalt at different levels of moisture inclusion.

	Unoxidized asphalt			Oxidized asphalt		
Water content (%)	Potential energy (kJ/mol)	Kinetic energy (kJ/mol)	Total energy (kJ/mol)	Potential energy (kJ/mol)	Kinetic energy (kJ/mol)	Total energy (kJ/mol)
0	1159	371	1530	1898	370	2268
1	919	285	1204	1458	285	1742

20	175	60	235	129	60	189

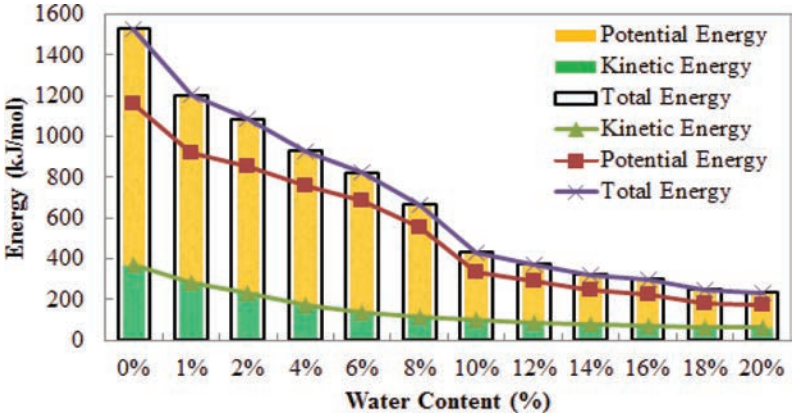

Figure 10. Energy changes of unoxidized asphalt at different water content.

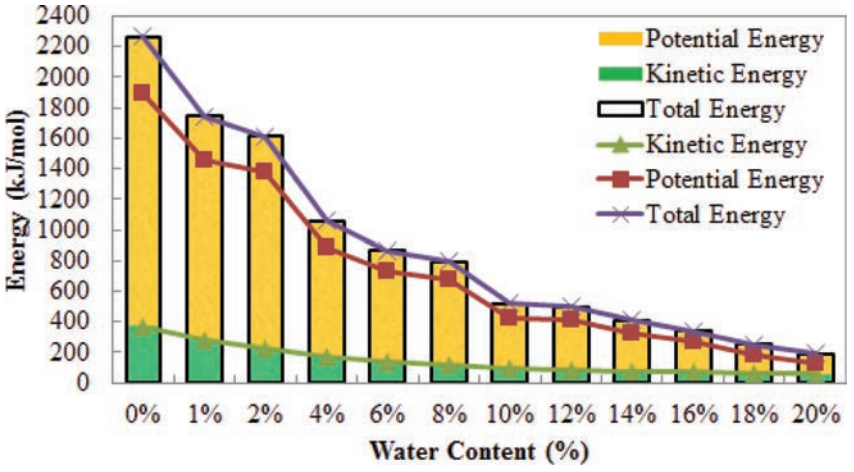

Figure 11. Energy changes of oxidized asphalt at different water content.

potential energies of asphalt after oxidative aging are much higher than the asphalt before oxidative aging at low water content. This suggests the formation of strongly interacting components in oxidative oxidized asphalt, which are responsible for increasing viscosity and altering complex flow properties.

With higher water content, the differences of potential energies between oxidized and unoxidized asphalts tend to be smaller. When water content reaches 20%, the potential energy of oxidized asphalt is lower than the unoxidized asphalt. In addition, total energies of both oxidized and unoxidized asphalt (the sum of kinetic energy and potential energy) show the same trend as potential energies. Figure 10 and Figure 11 illustrate the energy changes vs. water content for unoxidized asphalt and oxidized asphalt, respectively. It can be seen that the potential and total energy of oxidized asphalt decrease faster than the unoxidized asphalt with the increase of water content. This indicates that moisture-induced oxidized asphalt binder is more susceptible to be damaged.

4 CONCLUSIONS

The following conclusions can be made from this study:

Oxidative aging is the main factor that causes the hardening changes of asphalt over time. However, moisture inclusion destroys the bonding strength of asphalt molecules. The simulation results show that for density changes, the decreased densities of both oxidized and unoxidized asphalts with the increase of water content are caused by the expansion of the volume of asphalt system with presence of water molecules. In addition, the densities of oxidized asphalt are higher and show better linear relationship than the densities of unoxidized asphalt at different water content. This indicates that the hardening happens to asphalt after oxidative aging and oxidized asphalt is much more easily affected by moisture inclusion.

The energy changes of asphalt with combined effects of oxidative aging and moisture inclusion show that oxidative aging is responsible for the formation of strongly interacting components in asphalt by increasing energies, while moisture inclusion is accountable for decreasing the potential energies in asphalt system or the strength of asphalt. MD simulation results show that moisture inclusion plays a more significant role in asphalt damage than oxidative aging. The energies (potential energy, kinetic energy) of both oxidized and unoxidized asphalts decrease with the increase of water content. Moreover, potential energy of oxidized asphalt decreases faster than the unoxidized asphalt with the increase of water content. This indicates that moisture-induced oxidized asphalt binder is more susceptible to be damaged than moisture-induced unoxidized asphalt.

From this study, it can be seen that suppressing oxidation of asphalt binder and choosing a stiffer binder (strong bonding strength) are very important for the AC pavement exposed in more humid climates.

The MD simulation used by this study shows its advantages comparing with traditional laboratory test. First, MD simulation realizes the study of internal changes of asphalt in microscopic perspective, since the external property changes of asphalt under different conditions are determined by its internal structure and energy changes. Moreover, it is difficult to determine the property (especially mechanical property) of unoxidized (virgin) asphalt under room temperature in laboratory test, while MD simulation can simulate both unoxidized (virgin) and oxidized asphalt under any temperature and pressure. However, further laboratory tests need to be done to validate MD simulation results of this study.

ABSTRACT: Life Cycle Assessment (LCA) models and approaches for comparing the environmental impacts of different pavement decisions continue to be developed and improved. These improvements include methods for making data more regionally applicable, more agreement on methodology, more comprehensive consideration of the life cycle, and application of LCA to a broader range of important decisions. This paper summarizes advances over the past several years in the science and practice of LCA and its application to find ways to reduce the environmental impact of asphalt pavements. The paper summarizes recent studies using LCA methodology to evaluate the effects of smoothness at the network level, as well as mix design, pavement structure, recycling and tire technology at the project level, on green-house gas emissions and energy use. Finally the paper discusses possible next steps in the implementation of LCA for pavement in North America and the role of industry.

1 INTRODUCTION

1.1 *Increasing competition based on sustainability*

The US economy relies on its pavement networks at the interstate, state and local levels to move people and goods safely and cost-efficiently. The Maintenance and Rehabilitation (M&R) of existing pavement and construction of new pavement for the US highway system are estimated to annually consume about $160 billion and 320 million metric tons of raw materials (1,2). Operating this national pavement network incurs the use of enormous amounts of energy, more than 120 million gallons of gasoline and 35 million gallons of diesel and other fuels per year on U.S. highways alone (3), and results in the emission of significant quantities of *Greenhouse Gases* (GHG) and regulated air and water pollutants. In addition, the energy consumed by the vehicles operating on the national road system and its economic value are much greater than the energy consumed by pavement operations, and pavement characteristics influence vehicle fuel economy as well.

Traditionally, there has been competition between different pavement products and industries based primarily on cost, but also based on frequency of maintenance, construction speed and other factors. Experience and familiarity with a given pavement type or M&R approach on the part of designers, maintenance engineers and construction

engineers has often also had an influence, particularly in a design-bid-build environment where much of the design is done by state agencies or at the local level by consultants, and high risk-averseness is a part of the culture. However, the recent and rapidly increasing public and policy attention given to environmental concerns, particularly driven by concern about human-influenced climate change caused by GHG, has increased the likelihood that the environmental impacts of different pavement engineering decisions may also play a role in owner decision-making, and may begin to play a role in the procurement process.

Already, legislators in some states have passed laws with the intent of reducing the impact of pavement on the environment. For example, in California the most important legislation is Assembly Bill 32 (AB32, 2008) which commits the state to meeting Kyoto Protocol reductions in GHG emissions: a return to 1990 levels by 2020 and to 20 percent of 1990 levels by 2050, targets based on modeling of reductions needed to avoid certain global warming levels thought to be critical for planetary life systems. An attempt to reverse AB 32 through the initiative process was stopped by a 61:39 margin several years after signing in 2008. All parts of the state economy have been engaged investigating how to reach these targets. In addition, there are laws setting targets for use of rubberized asphalt (AB 338, 2005) to help reduce the stockpiles of tires in landfills, mandates the state to develop specifications for use of at least 40 percent Reclaimed Asphalt Pavement (RAP) in mix designs (AB 812, 2012), and mandating development of guidelines and specifications for use of "cooler" pavement based on urban heat island considerations (AB 296, 2012). Similar legislation has been introduced in some other states.

For building projects and pavements, various pavement features have been incorporated into the "points" calculated to obtain different levels of certification for "greenness" or "sustainability". The well-known LEED system used for buildings has a number of alternatives for gaining points with pavement design, and there are a number of pavement ratings systems that have been established by government and private foundations across North America specific for pavement projects.

In addition to legislation, marketing around various environmental aspects of pavement engineering and policy has also been increasing.

1.2 *Avoiding unintended consequences*

Determining the environmental impact of any civil infrastructure such as pavement can be complex, and it is often difficult to develop simplified policies and categorizations that can capture impacts across widely different situations or sensitivity to conflicting variables. It can also be difficult to determine what the best decision is when the goals of the decision-making have not been clarified. There is the possibility that policies and ratings systems intended to reduce environmental impacts from pavement can cause unintended negative consequences that can actually increase environmental harm. The risk of unintended negative consequences is greatest when changes are made that affect one part of a system or life-cycle phase, but the effects of the changes on the rest of the system and the other life-cycle phases are not evaluated. These gaps in assessing unintended consequences elsewhere within the system can be serious enough that supposedly "green" solutions may actually produce net negative impacts on the environment, thus violating the concept taken from medical practice of "first, do no harm" when prescribing remedies in the face of uncertainty. *Life Cycle Assessment* (LCA) is an approach for investigating the consequences of changes that, when properly applied, considers *system-wide effects* and the entire life cycle.

LCA provides a comprehensive approach to evaluating the total environmental burden of a product, examining all the inputs and outputs, from raw material production to the end-of-life. For pavement, this cycle includes the material production, construction, use, maintenance and rehabilitation (M&R), and End-Of-Life (EOL) phases. These phases and some typical inputs and outputs are shown in Figure 1.

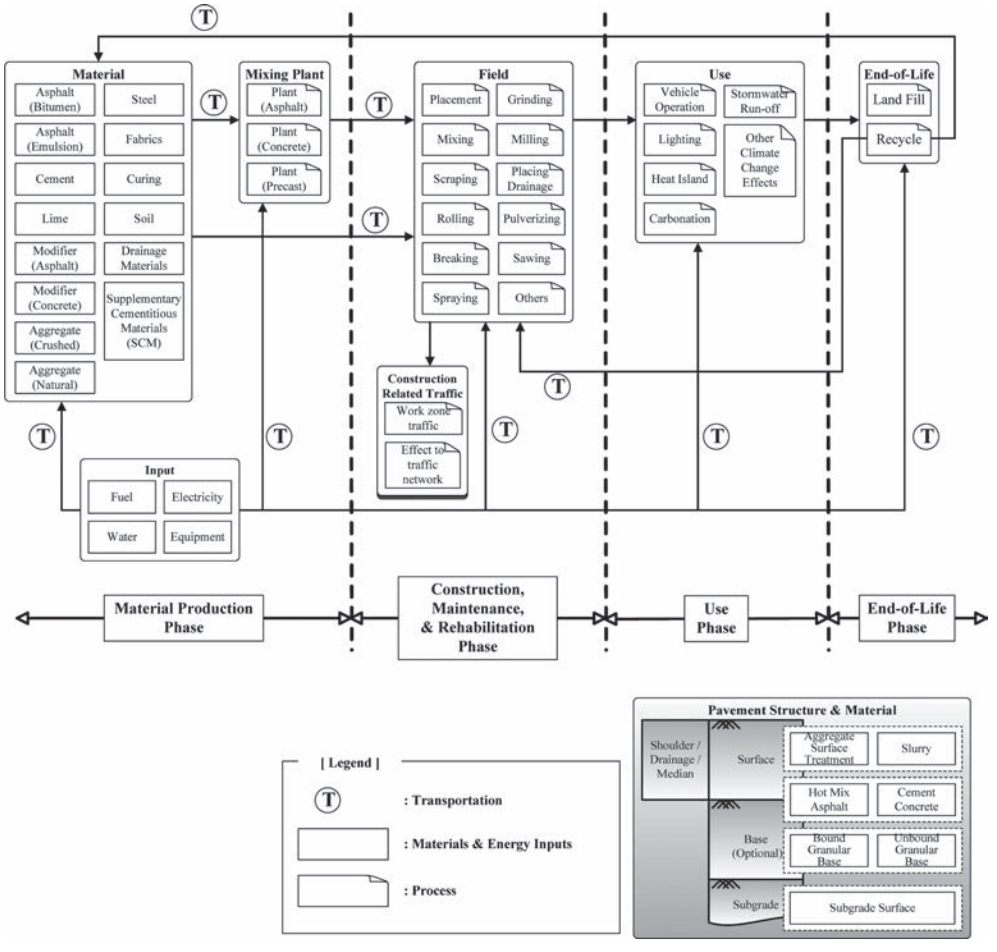

Figure 1. UCPRC pavement LCA framework (adapted from [4]).

2 LIFE CYCLE ASSESSMENT

2.1 *Overview of life cycle assessment*

LCA is an accounting and analysis of the inputs, outputs, and potential environmental impacts of a *product system* throughout its life cycle (International Organization for Standardization [ISO]). The standard ISO 14040:2006 (5) describes the principles and framework for Life Cycle Assessment (LCA) including: definition of the goal and scope of the LCA, the Life Cycle Inventory analysis (LCI) phase, the Life Cycle Impact Assessment (LCIA) phase, the interpretation phase (which occurs throughout the assessment), and reporting and critical review of the LCA, which should include limitations of the LCA, the relationship between the LCA phases, and conditions for use of value choices and optional elements. The standard covers LCA studies and LCI studies, but it neither describes the LCA technique in detail nor specifies methodologies for individual phases of an LCA. Because the standard is meant to apply broadly to any product or system evaluated using LCA, it does not provide recommendations or guidance tailored to pavements, or any other product or system.

A life cycle inventory is the stage of *life cycle assessment* involving the compilation and quantification of inputs and outputs for a product throughout its life cycle (5). An LCI can also be conducted separately, without being part of an LCA study.

Based on *ISO 14040:2006,* the following stages should be followed for conducting an LCA, as shown in Figure 2:

1. *Goal and Scope.* In this first stage, the LCA practitioner should identify the purpose of the LCA and the LCA's intended audience. The scope of the study must also be defined which includes defining the system boundaries and the function, and *functional unit*.
2. *Life Cycle Inventory.* This stage compiles and quantifies the inputs and outputs from the analyzed product at each stage of its life cycle. It requires data collection and modeling of the product. Examples of inventory items include inputs of *primary energy, materials, water and other resources that are consumed, and outputs of solid and hazardous waste flows, air emissions,* and *water pollutants* caused by the product over its life cycle.
3. *Impact Assessment.* The Impact Assessment stage translates the environmental flows compiled during the LCI into indicators of impacts to humans and the environment. The first step in this stage is to assign the appropriate inventory results to the selected Impact Categories. For example, in Europe pavement materials are generally required to have an Environmental Product Declaration (EPD, ISO 14025:2006 [6]) that considers the impact in the following five categories: climate change, photochemical ozone creation, eutrophication, stratospheric ozone depletion and acidification. Additional impact categories can include: fossil fuel depletion, waste disposal, ecotoxicity to land, higher level nuclear waste, ecotoxicity to freshwater, human toxicity, mineral extraction and water extraction (BRE). EPDs are developed following Product Category Rules (PCR, ISO 14025:2006 [6]),which are sets of specific rules, requirements, and guidelines for developing Type III environmental product declarations for one or more Product Categories (PCRs and EPDs are discussed more later in this paper). Once environmental flows are assigned to categories of impact they will be characterized, meaning the extent of their impacts will be quantified. For example, GHGs assigned to the category of climate change will typically be characterized by applying a global warming potential to yield CO_2e emissions, the indicator of choice for climate change. (Note: CO_2e means equivalent CO_2 emissions, accounting for the global warming potential of different types of gases in terms of equivalent mass of CO_2). The final step is *valuation,* which integrates across impact categories using weights or other approaches, thus enabling decision-makers to assimilate and consider the full range of relevant outcomes. This step is optional in the ISO framework.
4. *Interpretation.* The Interpretation stage is an analysis from which conclusions are drawn and recommendations are made, or that is used to otherwise inform the decision-making

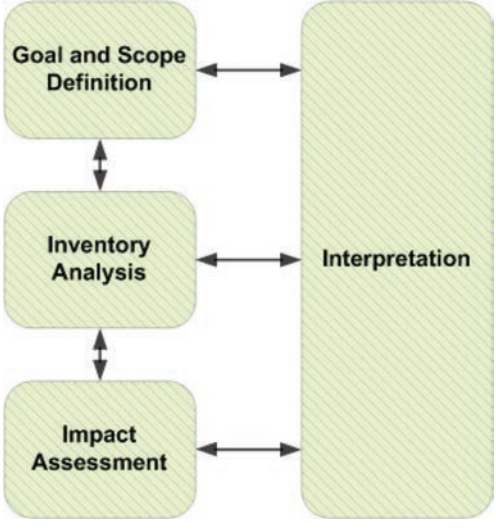

Figure 2. Stages for life cycle assessment (5).

process. Usually, a *sensitivity analysis* and an *uncertainty analysis* are included to confirm any conclusions. Although most studies do not include this review process, as required in ISO 14040:2006, an independent critical review is required by ISO at this stage, especially for comparisons that will be available in the public domain.

2.2 *Developments in the application of LCA to pavement*

An incomplete summary of developments of the application of LCA to pavement is presented in this section. It is intended to illustrate the arc and rapidity of development of LCA for pavements, and not a comprehensive summary of reports, papers and software.

The earliest application of LCA in a software tool in North America is Palate (7) developed by Horvath and his colleagues at UC Berkeley beginning around 2002.

A number of early applications of LCA to pavement and particular studies that had been published up to about 2010 were summarized in several papers by Santero and his colleagues (8). Their results included a critical review of pavement LCA studies to date, which identified problems with:

- Definitions of functional unit
- System boundaries: studies were found to use widely varying system boundaries, and often did not consider the use phase (see Fig. 1), often did not have realistic understanding of M&R schedules, and did not follow consistent practice for consideration of feedstock energy.
- Data quality and uncertainty: studies were found to often not include assessments of data quality or checks on regional and temporal applicability, and often did not use sensitivity analyses or other methods to consider uncertainty in the data.
- Life Cycle Inventories and Life Cycle Impact Assessment: studies generally did not include impact assessment after development of the LCI, and therefore not necessarily providing information useful for decision-making.
- Other problems: studies often did not include adjustment of energy production and other regional differences in development of inventories.

Santero et al. also provided recommendations for filling the gaps in LCA with respect to traffic delay, rolling resistance, albedo, concrete carbonation, roadway lighting, leachate, and end of life considerations (9).

The application of LCA to pavement and more generally to civil construction materials and products has been underway in Europe for a number of years. Early databases were developed in the 1980s in Switzerland, many of which are still referred to today. A European Platform on LCA was established in 2005 (10). Beginning in the same decade, the Netherlands national public works agency sponsored development of an LCA based design software tool called *DuBoCalc* (11), which is used for both design assessment and calculation of an Environmental Cost Indicator (MKI in Dutch) that is used in the preparation of bids, where environmental impact is a part of selecting contractors for Design-Build and Design-Build-Maintain public work projects along with life cycle cost (12).

OFRIR (a French acronym for "Monitoring of Road Infrastructure Recycling") is a project in France, begun in 2002 and coordinated by the French national Central Laboratory for Bridges and Roads (LCPC, now called IFSTTAR) in association with the public research organizations Ademe (environment), Inéris (industrial risks), BRGM (geology), Setra (road engineering) and a significant number of regional LCPC laboratories. The project has generated an original collection of data for the entire country in the field of road-based recycling. The information provided by the project's public partner institutions, in addition to that from members of the data exchange group formed over the course of this project, has gradually been made available to the road community via a website (http://ofrir.lcpc.fr), and more recently to the general public. The project developed underlying principles, structures and systems for the Internet database and the protocol for exchange between participants. OFRIR's primary purpose was to offer the French road community a source of information that had been

sorted, synthesized and, to a certain extent, validated so as to promote protocols for recycling and using local alternative materials (i.e. wastes and byproducts) while indicating the various obstacles, especially those in the geotechnical and environmental fields. The project was intended to assemble the requisite range of skills as well as to provide a forum for exchanges between project drivers and targets, for the purpose of: 1) creating a data exchange platform between participating laboratories and specialists; and 2) offering a research support system in the field of sustainable development (13).

Members of the French road-building community developed and introduced in 2010 another software tool for environmental evaluation of alternatives called *Seve* (14). In the past year, France has begun considering environmental impact using LCA based tools for selection of winning bids for road construction projects.

Following up on the identification of gaps in the application of LCA to pavement by Santero et al. and others, a workshop was held in Davis, California in May 2010 with invited participants from the international community of pavement engineers, LCA experts, contractors, materials producers, and international, federal, state and local government pavement policy-makers (15). The goal of the workshop was to discuss and reach consensus, where possible, regarding many of the issues identified by Santero et al. (8, 9) and others (4). After discussion, recommendations were made by expert teams on particular aspects of pavement LCA. These recommendations were incorporated into a document including guidelines for application of LCA to pavement, and a "transparency document" that is a checklist for documenting assumptions and approaches used in a pavement LCA (4). The move towards standardization of LCA practice for pavements and other building materials was continued at a recent conference in Nantes, France (16).

Several more recent LCA tools have been developed in North America to address different goals, and with different assumptions and definitions of the system boundaries (17, 18). The studies have used life cycle inventories that are available, some developed with more regionally applicable data and some consideration of the use phase.

Addressing other gaps in pavement LCA that were identified in 2010, the Miriam project was created to develop new methods for measuring rolling resistance of pavements (primarily texture), and consideration of rolling resistance due to roughness and texture in pavement management systems (19). Zaabar and Chatti calibrated mechanistic-empirical fuel economy models using field measurements as a function of vehicle type (from cars through heavy tractor-trailer combinations) based on pavement roughness and texture (20).

Wang et al. used Chatti's models and used them and materials and construction inventories for M&R treatments to evaluate the net effects of maintaining smooth pavement considering the materials and construction to keep them smooth and the improved fuel economy of vehicles using smoother pavement for several case studies (21). Wang et al. have more recently extended their models to identify optimal International Roughness Index (IRI) values for triggering several typical M&R treatments as a function of traffic volumes on all segments of the California state highway network (22). The results showed that roughness trigger levels for M&R on the order of 1.6 m/km (100 inches/mile) minimize GHG emissions for the highest traffic volume routes, balancing the improvements in fuel economy from smoother pavement with the increased emissions from more frequent treatment. For the lowest traffic volume routes, benefits from fuel economy never exceed the emissions caused by materials production and construction.

The concrete industry recently sponsored an extensive and rigorous LCA based study looking at methods for reducing the environmental impacts of the materials production and use phases of concrete pavement (23). Eurobitume, the European asphalt producers association produced an Environmental Product Declaration (EPD) following European LCA protocols using typical data from producers for its most widely used products: conventional asphalt, polymer modified asphalt and asphalt emulsion (24).

Another area of increased research is the influence of energy dissipation caused by pavement deflection and increased GHG emissions from vehicles as a result of the decreased fuel economy. Zaabar and Chatti found some influence of pavement structure on fuel economy, developing some data regarding stiffer and more elastic structures (concrete) versus softer

and more viscoelastic structures (asphalt surfaced). Their results indicated that there was a statistically significant difference of several percentage points in fuel economy for the case of heavy trucks operating at slower speeds (about 55 km/hr [35 mph]) when the asphalt pavement was hot, while for other vehicle/speed/temperature conditions the differences were not significant (15). These and other less comprehensive experimental results indicate that this may be a topic requiring additional consideration for designers, and additional research looking at more pavement types, such as composite, semi-rigid, stiff and thick long-life asphalt, as well as a range of vehicles, speeds and climates.

Modeling of energy dissipation due to deflection is the second half of the concrete industry sponsored MIT study (25) and models indicate substantial savings in energy based on their assumptions and extrapolation to the national highway network and several state subnetworks.

2.3 *Current projects*

The Federal Highway Administration (FHWA) is currently developing guidelines for improving the sustainability of pavements. The pavement life cycle (Fig. 1) and LCA concepts form the organizational framework for that document which is expected to be published by early 2014.

Another study is currently underway for the FHWA under the leadership of the University of Illinois to investigate the effects of introducing new generation wide base tires on lower volume asphalt pavement structures. The study includes a preliminary LCA evaluating the net benefits of this change in tire technology considering potential fuel economy improvements and changes in M&R treatment frequency.

The Chicago Tollway Authority is sponsoring work by several organizations to develop an LCA tool in 2014, and to use LCA concepts to evaluate various pavement design and recycling strategies. Part of this work is the development of current, regional databases for materials, construction and other inventory variables.

Studies underway at the University of California Pavement Research Center sponsored by Caltrans and/or the California Air Resources Board include:

- Use of LCA, including climate modeling, to evaluate the impacts of pavement albedo and other properties on urban area temperatures and the impacts on GHG emissions and energy use in buildings and temperature influenced air pollution, with results expected in 2015.
- Modeling of energy dissipation from pavement deflections using models developed by Pouget et al. (26).
- A two phase study of deflection energy dissipation models, with the first phase consisting of evaluation of existing models and comparison of results for a set of different types of pavement structures/vehicles/temperatures/speeds; and the second phase consisting of field validation of fuel economy changes on the same set of variables.
- Evaluation of the net effects on GHG emissions and energy use of various in-place and plant mix recycling strategies for a range of scenarios.
- Extension of previous California studies to consider category air and water pollutants.
- Development of regional inventory data for materials production and construction where possible through the studies described above.

3 DISCUSSION

It is hoped that the summary of LCA and previous and current work provides an indication of the many uses of LCA to answer important pavement questions, as well as some of the problems facing its use. From the review of the development and implementation of LCA in Europe and North America to date, it appears that:

- Knowledge about LCA is growing in the pavement community.
- Practice is becoming more standardized, although further discussion and consensus is needed (compare with list of gaps prepared by Santero et al).

- There is a lack of good, new inventory data for many important products and processes.
- There is some new software becoming available, but good software needs good data to be truly useful.
- How to move forward in North America to obtain better data and more standardization of practice is not clear.
- There are still some fundamental gaps in the life cycle phase models that need further research.
- What is the future range of uses for LCA is not clear beyond research and information dissemination and some policy analyses. It is not clear to what extent, if any, it will be used for project-level design, consideration in tendering, or network-level pavement management decision making.
- Industry must be involved in the development of better data, and in the discussion regarding the use of LCA for pavement.

One major incremental issue is the development of current, regionally applicable inventory data. The technical approach laid out by ISO, and being moved forward in Europe as well as North America, albeit with various difficulties, is the development of Product Category Rules (PCR) for conducting LCA studies on materials (becoming common in Europe and beginning to occur in North America), and potentially on pavement systems consisting of those materials as well as construction (not common). These are used to then create Environmental Product Declarations (EPD), such as the EPD produced by Eurobitume for its typical products (24). According to ISO, Type III environmental declarations as described in this International Standard (14025) are primarily intended for use in business-to-business communication, but their use in business-to-consumer communication under certain conditions is not precluded. Clearer definition of the future roles of LCA in the world of pavement will help define their use. It appears likely that until there is more definition, a large use of pavement LCA will be for business-to-consumer communication, where the consumer is the pavement designer, the policy-maker, and potentially pavement system (as opposed to materials) providers and procurers.

The process of creating PCRs includes a PCR proposal, development of a draft, open consultation, a panel review, and approval and publication. PCRs are developed and regulated by "program operators" who host the PCR, verify the EPDs and register the EPDs. To date the following organizations have established PCR programs in the North America that are known to the authors, not limited to pavements:

- Underwriter's Laboratories
- National Science Foundation
- ASTM (formerly American Society for Testing and Materials)
- Institute for Environmental Research and Education
- National Ready Mix Concrete Association
- Scientific Certification Systems
- Building and Industrial Furniture Manufacturer's Association
- Canadian Standards Association
- FP Innovations

(27, 28)

A PCR for pavement preservation products was produced by IERE in 2011 (28). A review of the status of PCRs and EPDs in North America was recently prepared for the National Institute of Standards and Technology (29). It is not clear what governmental or other organizing may occur in North America with respect to pavement PCRs. The role of academia in helping to sort out both organizational and methodology issues is also unclear. This process has followed the enactment of legislation at the national level in Europe, and industry and government have generally had their roles defined by that legislation, albeit with a great deal of discussion. Whether the process will be similar in North America is unclear at this time, as most governmental organizations dealing with pavement are just moving up the learning curve with regard to LCA in general.

While this uncertainty regarding organization and regulation is vexing and confusing, it is a sign that the use of LCA in pavements is maturing.

4 RECOMMENDATIONS

Industry should be involved in the establishment of the organizations, processes and data development for LCA for pavement. Good data can only come from industry. All industry participants, including the refining industry and asphalt pavement materials producers and constructors, need to be involved in the set-up and operation of these organizations and processes to ensure that there is full transparency, and that all aspects of the complexity of pavement systems are considered. The asphalt industry also needs to be involved in all aspects of the use of LCA for pavement so that their innovations to reduce the environmental impact of pavements can be correctly and fairly measured.

ABSTRACT: The use of titanium dioxide (TiO_2) coating for pavements has received considerable attention in recent years to improve air quality near large metropolitan areas. However, the proper method of applying titanium dioxide to asphalt pavements is still unclear. This study evaluated the benefits of incorporating titanium dioxide in the preparation of Warm-Mix Asphalt (WMA). Two application methods to integrate TiO_2 were evaluated, a water-based titanium dioxide solution applied as a thin coating and using TiO_2 as a modifier to asphalt binder in the preparation of WMA. Based on the results of the experimental program, it was determined that the photocatalytic compound was not effective in degrading NOx in the air stream when used as a modifier to the binder in the preparation of WMA. This could be attributed to the fact that only a small amount of TiO_2 is present at the surface. When used as part of a surface spray coating, TiO_2 was effective in removing NOx pollutants from the air stream with an efficiency ranging from 31 to 55%. The maximum NOx removal efficiency was achieved at a coverage rate of 0.05 l/m^2. However, durability of the surface spray coating requires further evaluation. In addition, the increase in flow rate and relative humidity negatively impacted the effectiveness of NOx reduction efficiency. In contrast, the increase in UV light intensity improved the NOx removal efficiency of the surface coating.

Keywords: Titanium dioxide, sustainable asphalt pavement construction, photocatalyst, nitrogen oxides

1 INTRODUCTION

The US faces a significant challenge in controlling air pollution resulting from transportation activities. Although attempts are made to lower vehicle emission standards, a method is needed to remove these pollutants once they are emitted to the atmosphere. The potential of titanium dioxide (TiO_2) as an air purifier in urban and metropolitan areas, which suffer from high concentration of air pollutants, has been widely recognized in literature [1, 2]. Evaluation of concrete pavement treated with TiO_2 provided promising results as recent research by the authors and others show that a thin surface coating

is able to remove a significant portion of Nitrogen Oxides (NO_x) and Volatile Organic Compounds (VOC) pollutants from the atmosphere when placed as close as possible to the source of pollution [3–6]. However, with 94% of the US road network covered with asphalt, it appears that widespread use of titanium dioxide in air purification applications can only be achieved by the development of a novel asphalt mixture that does not affect the mechanical properties of the mix while incorporating a photocatalytic compound into current highway construction practices [7]. In addition, the use of Warm Mix Asphalt (WMA) will have the added benefits of reduced energy and the associated pollution emissions during production.

The objective of this study is to test the hypothesis that TiO_2 can function as a photocatalytic compound when used in the preparation of WMA. To achieve this objective, a crystallized anatase-based titanium dioxide powder was blended with two grades of asphalt binder classified as PG 64-22 and PG 70-22 at three percentages by binder weight (3, 5, and 7%). In addition, a second application method was also evaluated, specifically useful for coating existing pavements, by spraying a water-based solution of TiO_2 on the pavement surface at three coverage levels (0.026, 0.05, and 0.074 l/m^2). Prepared blends were characterized using fundamental rheological tests (i.e., dynamic shear rheometer, rotational viscosity, and bending beam rheometer), the Semi-Circular Bend (SCB) test for fracture resistance, and by measuring the environmental efficiency of the mixture in removing NO_x pollutants from the air stream before and after durability tests.

2 BACKGROUND

Initial interest in environmental photocatalysis began in the 1970s, initiated by Fujishima and Honda's research in photo-electrochemical solar energy conversion [8]. Through biomimicry of plant photosynthesis, the researchers attempted to replicate the photo-induced redox reactions, by oxidizing water and reducing carbon dioxide, using a semiconductor irradiated by UV light. To accomplish this, the semiconductor is used as an electrode, which is connected to a counter electrode to generate electrical work while driving the redox chemical reactions [1]. TiO_2 was the semiconductor chosen, due to a positive valence band edge that theoretically can oxidize water to oxygen [2]. Fujishima and Honda found that when the surface was irradiated, a current was created such that oxidation occurred at the TiO_2 electrode and reduction at the counter electrode [1]. This proved that water could be decomposed into oxygen and hydrogen from solar irradiation, preferred since solar energy equates to roughly 5 x 1024 J per year [9].

The photo-electrochemistry concepts described were extended to research in heterogeneous photocatalysis applications by removing the external circuit [2]. In 1977, Frank and Bard were one of the first to demonstrate this, by illustrating the decomposition of cyanide in water. Since then, increased interest in environmental photocatalysis was realized, which caused TiO_2 to be applied to glass, tile, paper, and pavements for self-cleaning materials, water purification, air purification, sterilization, and oil spill remediation. From these studies, it has been shown that organic and inorganic compounds can be completely decomposed and that the TiO_2 surface has the ability to self-regenerate [2]. Therefore, rather than an absorption of pollutants that is common to traditional air purification methods, heterogeneous photocatalysis can decompose pollutants to nonhazardous waste products with little energy requirements [10]. In the presence of UV light, TiO_2 produces hydroxyl radicals and superoxides, which are respectively responsible for oxidizing and reducing environmental contaminants including VOC and NO_x [1]. A proposed mode of oxidation of NO_x via hydroxyl radical intermediates in the presence of the photocatalyst is described by the following equations:

$$NO + \dot{O}H \xrightarrow{Ti_2O} NO_2 + H\cdot \quad (1)$$

$$NO_2 + \dot{O}H \xrightarrow{Ti_2O} NO_3 + H\cdot \quad (2)$$

Based on this heterogeneous photocatalytic oxidation process, NO_x are oxidized into water-soluble nitrates; these substances can be washed away by rainfall. Available titanium dioxide technologies have been mostly directed towards concrete applications in which a fine mixture consisting of cement, sand, TiO_2, and water is applied as a thin surface layer or slurry to the surface. While few studies are available for asphalt pavements, TiO_2 has been incorporated into asphalt pavements by integrating it into the binder and as a thin surface layer that is sprayed on existing pavements [11, 12]. For the spray application, various TiO_2 nanoparticles were dispersed in a water-based emulsion [11]. The water-based emulsion was then applied by two different methods, referred to as hot and cold method; distinguished by the spraying of the emulsion during asphalt paving laying operations when the pavement temperature is over 100°C or on existing pavements at ambient temperatures. The study results showed that the reduction efficiencies were highly dependent on the TiO_2 nanoparticles used in which efficiencies ranged from 20% to 57% of NO_x reductions. Meanwhile, researchers in China also mixed TiO_2 with an asphalt binder at a 2.5% content of the binder weight to an emulsified asphalt pavement [12]. Evaluation presented in this study showed that a maximum efficiency in removing nitrogen oxide near 40% was achieved.

3 EXPERIMENTAL PROGRAM

Asphalt cement binder blends were prepared by mixing a conventional WMA binder (WMA additive Evotherm was used at 1% by weight of the binder) classified as PG 64-22 and PG 70-22 with a commercial crystallized anatase-based TiO_2 powder at three percentages 3, 5, and 7% by weight of the binder. The blends were prepared at a mixing temperature of 163°C. While short-term aging was simulated using the Rolling-Thin Film Oven (RTFO), long-term aging was simulated using the Pressure Aging Vessel (PAV). The RTFO test simulated construction hardening and asphalt binder aging by subjecting the material to circulating hot air for 85 min. The PAV test simulated long-term oxidative aging for a period ranging from 5–10 years by subjecting the binder to pressurized air for 20 hrs and a temperature maintained at 100°C.

Prepared blends were characterized using fundamental rheological tests (i.e., dynamic shear rheometry, rotational viscosity, and bending beam rheometer) and by comparing the Superpave Performance Grade (PG) of the modified blend to the unmodified WMA binder. To assess the influence of the photocatalytic compound on the binder aging mechanisms and to ensure that TiO_2 does not oxidize the binder, both the control and modified blends were prepared in thin films and were subjected to UV light for a period of seven days. Binders were characterized using the entire suite of PG grading system as per AASHTO M 320-09 (Standard Specification for Performance-Graded Asphalt Binder). Using the same experimental mix design parameters, two replicas of asphalt concrete samples were prepared for both the fracture and environmental tests and were compacted by a gyratory compactor according to AASHTO TP4.

Fracture resistance was assessed by the Semi-Circular Bending (SCB) test using the procedure suggested by Wu et al. [11]. This test characterizes the fracture resistance of HMA mixtures based on fracture mechanics principals, the critical strain energy release rate, also called the critical value of J-integral, or J_c. To determine the critical value of J-integral (J_c), three notch depths of 25.4, 31.8, and 38 mm were selected based on an a/rd ratio (the notch depth to the radius of the specimen) between 0.5 and 0.75. Test temperature was selected to be 25°C. The semi-circular specimen is loaded monotonically till fracture failure under a constant cross-head deformation rate of 0.5 mm/min in a three-point bending load configuration. The load and deformation are continuously recorded and the critical value of J-integral (J_c) is determined using the following equation [11]:

$$J_c = \left(\frac{U_1}{b_1} - \frac{U_2}{b_2} \right) \frac{1}{a_2 - a_1} \tag{3}$$

where,

b = sample thickness;

a = the notch depth; and

U = the strain energy to failure.

A second application method consisting of applying a thin surface coating was also evaluated at three coverage rates (0.11, 0.21, and 0.31 kg/m^2). The spray coat used was a mixture of TiO_2 anatase nanoparticles suspended in an aqueous liquid at 2% by volume. A thin film was spray coated on each asphalt sample in layers using in a cross hatch formation at each of the three defined coverage rates.

3.1 *Photocatalyst material characterizations*

The photocatalytic nanoparticles used were characterized by X-Ray Diffraction (XRD), Brunauer Emmett Teller (BET), and Transmission Electron Microscopy (TEM). Since surface area is an important characteristic for photocatalytic activity, the surface area was obtained using the BET isotherm by nitrogen physisorption. The XRD patterns obtained by a Rigaku, D/Max 2500 PC instrument using CuKα radiation were used to determine the crystal structure and phase composition ratio. The diffraction peaks were analyzed and indexed by match peak using Search Match software.

The resulting nanoparticles were characterized also by TEM using the Tecnai G2 field emission gun (200 kV). The TiO_2 powders were deposited on a 3-mm copper grid for TEM imaging. The copper grid was cleaned with acetone and chloroform before the powders were deposited. The TEM imaging illustrated the morphology of the nanoparticles used.

3.2 *Environmental test setup*

The environmental benefit of the fabricated asphalt blends in trapping and degrading NO_x pollutants from the air stream through a photocatalysis mechanism was investigated. A laboratory test setup that is capable of quantifying the photocatalytic efficiency of asphalt and concrete specimens was used, Figure 1. The test setup was adapted from the Japanese standard JIS TR Z 0018 "Photocatalytic materials—air purification test procedure." The developed experimental setup consists of a pollutant source, zero air source, calibrator, humidifier, photoreactor, and a chemiluminescent NO_x analyzer as shown in Figure 1. The setup simulates different environmental conditions by allowing for control of light intensity and air humidity. The pollutants are introduced through an inlet jet stream to the photoreactor, a photocatalytic testing device. A zero air generator is used to supply the air stream, which is passed through a humidifier to simulate the desired humidity level.

The photoreactor creates an enclosed controlled environment where the light and the atmosphere can be simulated. Fluorescent lamps, attached to the photocatalytic device, are

Figure 1. Experimental laboratory setup.

used to imitate natural sunlight radiation required for photocatalytic activity. The pollutants measured from the recovered air before and after the photoreactor allowed for determination of the absorbed level of pollutants. In this study, NOx and removal efficiency was measured using the Thermo 42i chemiluminescent NOx analyzer. Nitrogen oxides were blown over the surface of the asphalt specimens at a concentration of 450 ppb. All tests were conducted at room temperature while the relative humidity was kept constant at 20%.

4 RESULTS AND ANALYSIS

Results of XRD patterns for the two synthesis methods are shown in Figure 2. Both the nanoparticle powder and the aqueous suspended nanoparticles were indexed as pure anatase using Search Match software anatase.

In spite of the agglomerate formation, Figure 3 reveals two different types of particle morphologies, nanoparticles from the powder (a) and nanorods from the aqueous spray coat (b). The nanorods are clearly larger in size compared to the nanoparticles from the powder. The average diameter of the nanoparticles used was 15 nm. The average diameter of the nanorods was 12 nm and average length was 75 nm. The surface area characterized by BET was 73.3 m^2/g for the nanopowder and 84.8 m^2/g for the aqueous spray coat nanorods.

The samples with TiO_2 in the binder were tested at 1 l/min flow rate and 2 mW/cm^2. Results presented in Table 1 show low NO_x reduction suggesting that the method of incorporation of

7% TiO_2 70-22	2.9%	4.5%

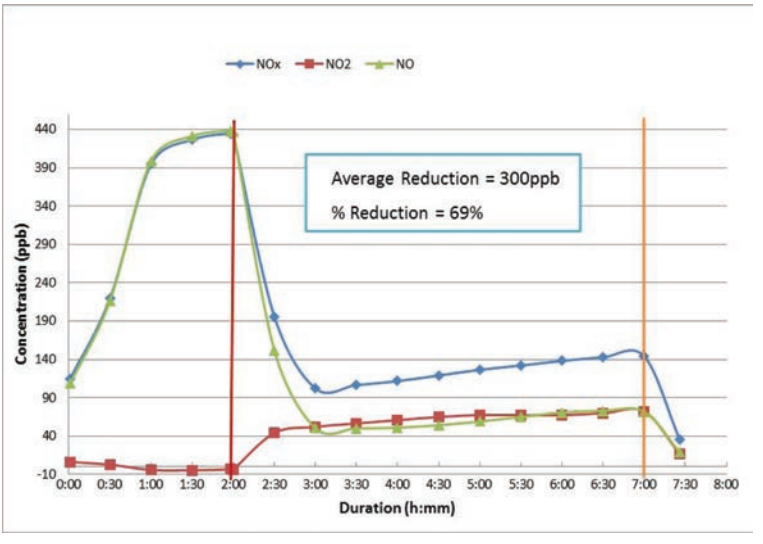

Figure 4. Variation of NO_x concentration during the environmental experiment (TiO_2 applied at a 0.21 kg/m^2 coverage).

TiO_2 into the asphalt binder may not be environmentally-effective. It is noted that the low NO_x reduction measured may be due to a small amount of TiO_2 nanoparticles lost in the photoreactor during handling and testing of the samples. The low efficiencies could be attributed to the fact that only a small amount of TiO_2 is actually present at the surface. Other possible explanations could be that the asphalt binder inhibits the photocatalytic reaction at the surface. While surface weathering due to traffic may expose part of the TiO_2 to UV light, this has not been validated. Therefore, further research is needed to evaluate photocatalytic efficiency over time.

For the second application method consisting of applying a surface spray coating, samples were tested using a flow of 1.5 l/min and a luminosity of 2 mW/cm^2. Figure 4 illustrates the variation of NO_x concentration during the course of the environmental experiment for the asphalt sample treated with a TiO_2 surface spray coat with a coverage rate of 0.21 kg/m^2. The UV light is turned on 2 hours after the start of the experiment in order to ensure equilibrium condition. The inlet concentration reached equilibrium at 430 ppb before the light was turned on. After the light is turned on, a fast drop of NO concentration in the outlet air stream is exhibited and NO_2 is created from the NO oxidation. During the photocatalytic experiment, the NO_x concentration slightly increased. After 5 hours of testing, the light and gas supply was turned off allowing for any desorption to occur. For the test condition shown in Figure 4, the use of TiO_2 photocatalyst coating had an NO removal efficiency of 83% and the overall NO_x reduction was 69%.

The rest of the results for all of the samples are shown in Table 2. As shown in this table, the efficiency of the sample without TiO_2 was negligible validating the efficiency of the photocatalytic compound in removing part of the NO pollutants in the air stream when used as a spray coating. By comparing the effect of the TiO_2 coverage rate, it appears that the improvement of NO_x reduction is not linear. In fact, the maximum environmental performance was achieved at the 0.21 kg/m^2 coverage rate. The increase in TiO_2 application rate beyond an optimum coverage rate may block nanoparticles' access to light and contaminants, and therefore, decrease NO_x removal efficiency.

4.1 *Effects of TiO_2 on rheological properties*

Table 3 presents the measured rheological properties of the TiO_2 modified and unmodified WMA binders based on laboratory testing conducted using rotational viscometer, dynamic shear rheometer, and bending beam rheometer. Results are presented for four types of specimen: PG 70-22 conventional WMA binder, PG 70-22 + 7% TiO_2, and PG 70-22 conventional and + 7% TiO_2 subjected to UV light for seven days. Since UV light will only influence the long-term behavior of the binder, rheological testing of specimens subjected to UV light was only performed on the aged samples (RTFO + PAV). Ultra-violet light initiates the photocatalytic process for the sample with TiO_2. Results presented in Table 3 indicate that

Table 2. Average NO_x reduction and NO reduction for TiO_2 used in a thin surface coating.

Control	0.29
3.0%	0.45
5.0%	0.46
7.0%	0.28

the addition of TiO_2 only marginally affected the rheological properties of the conventional binder.

Results presented in Table 3 also show that exposing the binder to UV light did not accelerate the aging mechanisms in the material as compared to the sample that was not subjected to UV light. In addition, the use of TiO_2 as an air purification agent did not accelerate the aging mechanisms in the binder. This trend was desirable to ensure that UV light, which is necessary to initiate the photocatalytic process, did not negatively affect the binder rheological properties.

4.2 *Effects of TiO_2 on the mix fracture resistance*

Table 4 presents a comparison of the critical strain energy (J_c) data for the mixtures evaluated in this study. High J_c values are desirable as indicative of fracture-resistant mixtures. As shown by these results, the use of TiO_2 as a binder modifier improved the mix fracture resistance at 3, and 5% while it did not have a noticeable effect when used at a content of 7.0%.

5 SUMMARY AND CONCLUSIONS

This study evaluated the benefits of incorporating titanium dioxide (TiO_2) as an additive to asphalt binder in the preparation of WMA. Two commercial crystallized anatase-based titanium dioxide powder were blended with a conventional WMA asphalt binder classified as PG 64-22 and PG 70-22 at three modification rates (3, 5, and 7%). Prepared blends were characterized using fundamental rheological tests and the SCB test. Two application methods to integrate TiO_2 were evaluated, a water-based titanium dioxide solution applied as a thin coating and using TiO_2 as a modifier to asphalt binder in the preparation of WMA. Based on the results of the experimental program, the following conclusions may be drawn:

- When used as a modifier to asphalt binder in the preparation of WMA, the photocatalytic compound was not effective in degrading NO_x in the air stream. This could be attributed to the fact that only a small amount of TiO_2 is present at the surface.
- When used as part of a surface spray coating, TiO_2 was effective in removing NO_x pollutants from the air stream with an efficiency ranging from 38 to 77%.
- Rheological test results indicated that the addition of TiO_2 did not affect the physical properties of the conventional binder. In addition, exposing the binder to UV light did not appear to accelerate the aging mechanisms in the binder.
- The use of TiO_2 as a binder modifier improved the mix fracture resistance at 3, and 5% while it did not have a noticeable effect when used at a content of 7.0%.

This study represents a step towards evaluation and implementation of photocatalytic asphalt pavements as a feasible solution to mitigate near roadway air pollution problems. Based on the results presented in this study, further research is needed to evaluate the long-term effectiveness and durability of the photocatalytic coating in the field.

ACKNOWLEDGMENTS

This work was funded under NSF award number 1032288. The authors would like to acknowledge the assistance of Cristal Millennium and PURETI for providing this research with nano and ultrafine titanium dioxide, for testing and the Louisiana Transportation Research Center (LTRC) for granting access to their laboratory.

Clear asphalt concrete for energy saving in road tunnels

Edoardo Bocci & Maurizio Bocci
Polytechnic University of Marche, Ancona, Italy

ABSTRACT: Nowadays the interest in clear pavements for road tunnel applications is rapidly increasing, as their high photometric properties assure an important reduction of power consumption for electric lighting and an improvement of safety conditions. One of the solutions for manufacturing clear pavements consists in mixing light-colored mineral aggregates with particular transparent asphalt binders. This production technique was used in 2012 to manufacture the clear asphalt concrete for wearing courses of two road tunnels in the north of Italy. The present paper deals with the mix design and the evaluation of mechanical and photometric properties of the clear asphalt concrete used for paving these tunnels. In particular, tests were carried out on the raw materials and on both lab-manufactured and plant-manufactured mixes.

At the end of the tests clear mixtures showed good mechanical properties, similar to a traditional "black" asphalt concrete in terms of indirect tensile strength and indirect tensile stiffness modulus. In addition clear mixtures showed very high photometric properties after five months from the opening to traffic.

Keywords: Clear pavement, clear asphalt concrete, transparent binder, tunnel lighting, photometric properties

1 INTRODUCTION

Application of clear pavements in tunnels, with the aim to reduce the power consumption for electric lighting and improve safety conditions, represents a very interesting topic in the field of road engineering.

According to European Asphalt Pavement Association (EAPA) clear pavements are better than traditional "black" asphalt concretes both in terms of luminance (capability of reflecting light waves) and of contrast with road markings [1]. In addition, recent studies estimated that light-colored surfaces allow an energy saving in tunnel lighting up to 30–40% [2].

It is known that road surface is polished by vehicle tires. After the laying of the wearing course aggregates are still covered with binder but, after some months, the upper faces of the aggregates are polished and the binder is visible only in form of mastic (binder and filler) between coarse particles. So the pavement clear color depends mainly on aggregate and binder colors.

The choice of clear aggregate is related to its availability in a certain area and the incidence of hauling costs.

About the binder, one solution is represented by rigid pavements in Portland cement concrete. Besides the white/grey color, these pavements present the advantages to have a longer fatigue life in general and to be fireproof, which is very important for tunnels in case of fire. On the other hand, cement concrete pavements are very expensive and difficult to be constructed. Moreover, frequent maintenance interventions are necessary in order to assure adequate adhesion levels for drivers' safety.

An alternative solution consists in manufacturing flexible pavements with synthetic resins [3–4] or bitumens with low asphaltene content [5]. These asphalts, characterized by a very clear amber color and a marked transparence, are mainly used with aesthetic purposes in

order to integrate road pavements with the surrounding landscape in important natural and historical places [6]. Moreover, clear binders can serve the purpose of improving urban climate by working on the mitigation of the urban heat island effect and other local warming phenomena [7–8].

Clear asphalts can be manufactured through three different techniques [8–9]:

- extraction of asphaltenes from traditional bitumen;
- production of synthetic binders containing transparent polymeric materials;
- blending resins with particular bio-oils in order to obtain clear materials with rheological properties similar to those of bitumen.

In some cases clear asphalts are used with pigment addicted [10]. These additives, generally metallic oxides in form of powder, have the effect to make the pavement clearer or give it a particular color (red, yellow …).

2 PHOTOMETRIC PROPERTIES

The capability of clear pavements to reflect luminous radiations can be quantified through a property called luminance. Luminance (L) is a photometric measure of the luminous intensity that is emitted or reflected from a surface, per unit area. The luminance indicates how much luminous power will be detected by a driver's eye looking at the surface from a specific angle of view. The luminance is expressed in candela per square meter (cd/m^2) and can be measured through a proper machine called luminance meter.

The luminous intensity reflected by a pavement is strictly dependent on the amount of light that reaches the pavement itself. So, in order to make a comparison between luminance measurements performed in different lighting conditions (between the lab and the road tunnels), two further photometric quantities has to be defined:

- illuminance (E), that is the total luminous flux incident on a surface, per unit area. It is expressed in lux (lx = cd · sr · m^{-2}) and can be measured through an illuminance meter;
- reflectance or reflection coefficient (ρ), that represents the capability of a material to reflect a luminous radiation and it is dimensionless.

As the reflectance depends only from the type of material, the comparison between the clear pavement laid on the tunnel and the mixtures manufactured in the lab was made in terms of ρ.

Known luminance L and illuminance E, reflectance ρ can be determined through Eq. (1):

$$\rho = \frac{L}{E} \cdot \pi \tag{1}$$

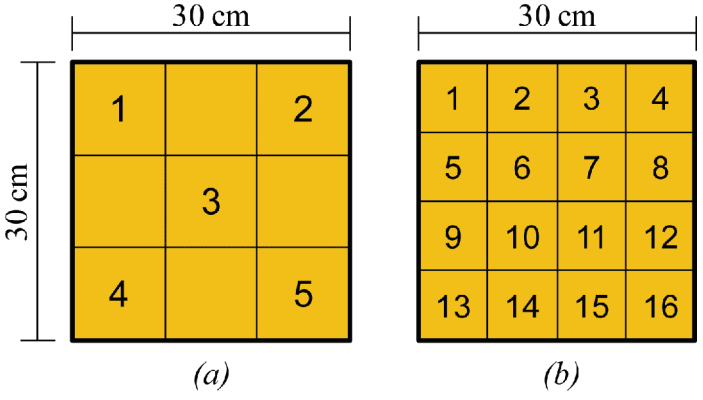

Figure 1. Measurement area for illuminance (a) and luminance (b).

Photometric properties were measured on surface samples with dimensions 30 × 30 cm. Illuminance and luminance were respectively calculated as mean of 5 and 16 values determined in the middle of defined sub-areas, as shown in Figure 1.

3 EXPERIMENTAL PROGRAM

In July 2012 a clear asphalt concrete was used to build the wearing course of two road tunnels in the north of Italy. In the present paper, mix design and mechanical and photometric characterization of this clear mixture are discussed.

The mix design was carried out according to SHRP specifications in order to evaluate the compactability of the mixture and define the binder percentage. Once the job mix formula was found, tests were performed on two mixtures: the first was manufactured in the laboratory, the second was manufactured in a batch plant and was taken from the tunnel construction site.

The experimental program includes:

- Indirect Tensile Strength (ITS) and Indirect Tensile Stiffness Modulus (ITSM) tests on specimens compacted with Shear Gyratory Compactor (SGC);
- determination of skid resistance and photometric properties in situ, directly on the tunnel pavements in 4 locations, and in the laboratory, on slabs compacted with Roller Compactor (RC).

Table 1 shows the detailed scheme of the experimental program.

The aim of the study is to verify that the mechanical behavior of clear mixtures is similar to an ordinary asphalt concrete and quantify the benefits, in term of photometric properties, related to the use of clear mixtures.

4 MATERIALS

4.1 *Aggregate*

The granular mixture was composed using grey porphyry coarse aggregate (in two fractions), white-colored limestone sand and filler containing Calcium Carbonate ($CaCO_3$) naturally micronized in powder. Besides, 0.5% by aggregate weight of powdered titanium dioxide (TiO_2) was added as a pigment (Fig. 2). Mechanical properties of coarse aggregate are shown in Table 2.

The different fractions were proportioned in order to build a gradation curve inside the reference envelope [11]. Then the original curve was modified by increasing the percentage of filler (Fig. 3), in order to obtain a more consistent mastic when mixed with the clear binder.

4.2 *Binder*

The clear binder used in this research was a bitumen subjected to asphaltene extraction, so that finally it only included lighter fractions (aromatics, saturates and resins). In order to restore adequate consistence and stability, the binder was than modified by adding a high percentage of elastomeric polymers. Binder mechanical properties are shown in Table 3.

5 MIX DESIGN

Mix design was carried out on 4 series of 3 samples, each series containing respectively 5.0%, 5.5%, 6.0% and 6.5% of clear binder by mix weight. Samples were compacted with 180 revolutions of shear gyratory compactor. For each series Air Void Content (AVC), Voids in the Mineral Aggregate (VMA) and Voids Filled with Bitumen (VFB) were determined at revolution No. 100 (N_{design}). According to SHRP, the following target values were fixed:

- AVC = 4%
- VMA ≥ 13%
- 65% ≤ VFB ≤ 78%

Mix design results are shown in Table 4 and Figure 4.

The volumetric analysis on the compacted specimens showed that all the different mixtures ensured adequate compactability and a good sensitivity to compaction energy, similarly to traditional asphalt concrete. In the light of the results obtained from the mix design procedure, a binder content of 5.66% by mixture weight (6.00% by aggregate weight) was fixed.

6 ANALYSIS OF RESULTS

6.1 *ITS and ITSM tests*

As shown in Table 5, for both lab and plant manufactured clear mixes ITS values were considerably higher (about 50%) than ordinary "black" asphalt concrete for wearing courses. An explanation for this result is that the clear binder was evidently more crack-resistant than traditional bitumen, thus the aggregate-binder adhesion was stronger. In addition it has to be considered that the mastic composed by clear binder and filler is noticeably stiff, as the filler content is very high (about 13%).

From Table 5 it can be observed that ITSM values at 20°C were comparable with that of a traditional asphalt concrete for wearing courses, denoting suitable performance at intermediate temperatures. On the contrary, when the temperature increased to 40°C, ITSM values resulted quite low. This indicates that clear mixtures has a higher thermal sensitivity than ordinary asphalt

concretes and consequently they could be subject to early rutting when used in hot areas. However, this risk should be averted in the present applications as in this area climate is generally cool even during summer and pavements are not directly exposed to solar light inside tunnels as well.

6.2 *Skid resistance tests*

Table 6 shows results from skid resistance tests, express in BPN (British Pendulum Number). From the results it can be noticed that BPN values have been similar for all the clear mixtures

Figure 5. Clear asphalt concrete compaction in the road tunnel.

tested (lab and plant manufactured, lab and in situ measurements). Compared with the reference mixture, consisting in a wearing course "black" mixture with porphyry aggregates, clear asphalt concretes showed a lower skid resistance (about 10% of reduction). However BPN values were around 60, which represent the limit defined by Italian specifications [11]. In addition it has to be considered that this result is probably related to the clear mastic that creates a smoother film around aggregates. Once this film is removed by traffic, skid properties should be uniform to the reference mixture.

6.3 *Photometric properties*

Table 7 shows the results from photometric tests. From Table 7 it can be noticed that the reflectance calculated for clear pavements is considerably higher than the one found for the reference mixture. In particular the lab-manufactured mix and the plant-manufactured mix tested in the lab denoted photometric properties at least 6 times higher than the black concrete.

However, the same plant-manufactured mix, when laid in situ, showed a halved reflectance in all the 4 locations inside the tunnels. As in situ measurements were carried out five months after the opening to traffic, this result is probably related to the binder natural darkening process that led the pavement to assume a darker yellow color. Nevertheless, reflectance ρ was still 3 times higher than the reference mixture determining a noticeable improvement of lighting distribution in the tunnels (Fig. 5). Besides, photometric properties are supposed to increase once the mastic film that covers the aggregate is removed by traffic and the light-grey color of the aggregate comes out. It has to be taken into account that also surface texture, in both micro and macro scale, influences pavement photometric properties and may have contributed to the different results between lab and field compacted mixture.

7 CONCLUSIONS

The present paper deals with mix design and mechanical and photometric characterization of a clear asphalt concrete for the application in road tunnels. The dense graded mixture was composed by grey porphyry coarse aggregate, limestone sand, calcium carbonate-based filler, titanium dioxide and transparent bitumen with low asphaltene content. The experimental program consisted of traditional and performance-based tests, carried out on the lab-manufactured mix and on the plant-manufactured mix laid on two tunnels in the north of Italy.

According to the results from the mix design, a binder content of 5.66% by mixture weight (6.00% by aggregate weight) was determined. A particular detail of the job mix formula was represented by the high filler-to-binder ratio adopted, in order to have a more consistent mastic.

Clear mixtures showed about 50% higher ITS values than ordinary "black" asphalt concrete for wearing courses, probably due to the sticky binder and the high filler content. ITSM tests pointed out a high thermal sensitivity for this mixture. Thus, particular attention should be paid to avoid early rutting for the application in hot areas.

Skid properties proved to be adequate for all the clear mixtures tested. In addition, skid resistance is supposed to increase once the smooth mastic film the covers the aggregates is removed by traffic.

Finally, as calculated reflectance ρ was at least 3 times higher than ordinary asphalt mixture, clear asphalt concretes demonstrated to be an effective solution in terms of photometric properties, determining a noticeable improvement of lighting distribution in the tunnels and of road marking visibility.

Optimization of thermoelectric system for pavement energy harvesting

Philip Park, Gwan S. Choi, Ehsan Rohani & Ikkyun Song
Texas A&M University, College Station, TX, USA

ABSTRACT: With the increasing emphasis on renewable resources and green technologies, energy harvesting from asphalt pavement has gained momentous attention in the recent years. Thermoelectric energy harvesting is one of the promising methods for collecting and transmitting solar energy into electrical power using temperature gradient along the pavement depth. However, the low energy conversion efficiency must be mitigated in order for this method to be viable for various practical applications. Henceforth, the objectives of this study are to investigate the key factors affecting the energy conversion efficiency and to derive optimal mechanical and circuit configurations. The goal is to compose a thermoelectric energy harvesting system tailored for the pavement application. The design under study is typical and it consists of a thermoelectric generator and thermally conductive rods for transferring heat. The effects of the generator type, circuit design, the shape of the conductive rod, and its insulation are investigated. The results indicate that the controlling of the heat transfer from the pavement to the thermoelectric generator is central to effective thermoelectric energy harvesting. Among the tested thermoelectric systems, the best device configuration yielded 42 mW; about 26 times higher power than the default case in this study.

Keywords: Energy harvesting, pavement, thermoelectric generator, optimization

1 INTRODUCTION

Transportation system is one of the largest and most important infrastructures in modern society. According to Federal Highway Administration (FHWA), a total lane mile of the public roads in the US is 8.6 Million miles in 2012 [1]. In the US, 28% of total produced energy was consumed by transportation sector in 2012. While the moving of vehicle is the major energy consumption of the transportation sector, the transportation facilities uses 25×10^{12} BTU of electrical energy for the roadway lighting, signal, and various sensing and monitoring systems [2]. Additionally about 51×10^{12} BTU, which is about twice that actually consumed, is lost from transmission during power delivery. This is caused by the widespread nature of roadways.

Energy harvesting reclaims otherwise dissipated or wasted energy, and is highly sustainable power generation approach. While energy harvesting technology has successfully been explored in numerous electronics and mechanical systems applications, its application to roadway pavements is currently at its infancy. Since asphalt pavement is a huge storage of solar energy, the pavement energy harvesting technology promises a significant breakthrough in attaining renewable energy at a massive scale. The specific attributes of harnessing energy from pavements are: 1) the size of roadways is massive, and hence, relatively large amount of energy can be collected, 2) there exist various types of available energy sources, e.g. geothermal, solar, mechanical, etc., and 3) a long-distance power transmission is not necessary because the collected electrical energy can be consumed in place by traffic facilities. In situ generation of electrical power can decidedly offset the aforementioned transmission loss of electrical energy. In addition, it can eliminate the installation and maintenance cost of power delivery infrastructures.

The pavement energy harvesting technology has gained attention from various researchers and transportation agencies in the recent years [3]. Mallick et al. suggested collecting energy from pavements by installing water pipes under pavement surfaces [4–5]. Lee and his colleagues tried the water pipe installation [6] and solar panels [7–8] to harvest energy. The method of converting the mechanical energy from traffic loads into electrical energy was suggested by Abramovich et al. [9–11], and investigated by various investigators [12–17]. Bhattacharjee and his colleagues compared the pyroelectric effects of various energy converting materials for the pavement application [18–19].

Another promising energy harvesting method from pavement is using the temperature gradient along the depth of pavements. Thermoelectric Generator (TEG) is a device converting temperature difference into electric potential and vice versa. The efficiency of the thermoelectric energy harvesting is known to be relatively low. However, this method is still promising because the most abundant form of energy on pavements is heat. Wu and Yu [20–21] suggested a thermoelectric energy harvesting system for the pavement application. This system was composed of a commercial TEG connected to aluminium rods at both ends to transfer heat between the surface and the subgrade of an asphalt pavement. A circuit was designed in order to manage generated electric energy, and the energy used to blink a light-emitting diode. In the Wu and Yu's experiment, the applied temperature difference to the system including the heat exchanging rods was 50°K, and the temperature difference across the TEG was 20°K. At this condition, the power generated from the system was 0.05 mW, which was the power to blink the LED with 90 sec interval [21]. Using the commercially available TEG, Wu and Yu suggested a practically feasible thermoelectric system. On the other hand, the low efficiency in energy conversion and the corresponding micro-level low power remain to be the next avenue of the research.

Aiming to optimize the thermoelectric energy harvesting system for the pavement application, the effects of various factors on the efficiency of the system are investigated through the presented study. The electrical impedance matching, selection of TEG and corresponding thermodynamic effect, and the effect of the heat exchangers/insulation are discussed herein. Section 2 states the background knowledge in thermoelectric power generation, Section 3 describes the design and experimental setup, Section 4 discusses the results, and Section 5 draws several observations and concluding remarks.

2 BACKGROUND

2.1 *Principle of thermoelectric generator*

TEG device consists of the circuit connecting a number of p-type and n-type semiconductor devices in series and a pair of dielectric plates, typically made of a ceramic material that contains these junction devices in between them. A TEG device creates voltage when there is a different temperature on each side of the plates. At the junctions, an applied temperature gradient causes charge carriers in the material to diffuse from the hot side to the cold side. This physical phenomenon is referred to as Peltier effect. The result is, when the temperatures at each end of the semiconductors are different, the semiconductors generate electric current flowing in certain direction. As shown in Figure 1, the generated electric current at each semiconductor can be controlled by arranging those semiconductors and covering those with thermally conductive but electrically insulating ceramic plate [22].

2.2 *Temperature gradient in pavement*

An example temperature gradient obtained from an actual pavement in Montana, USA is illustrated in Figure 2. The data is obtained at four different times of a day (4-23-1993). The temperature at the surface widely varies with time while the temperature below 80 cm from

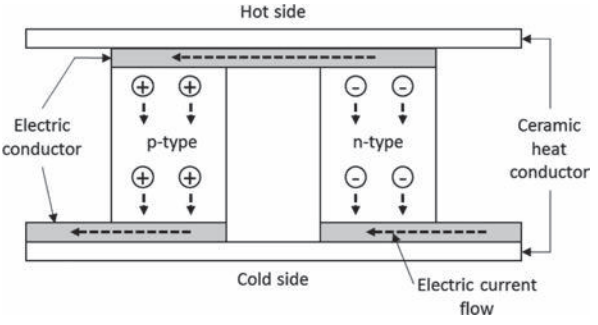

Figure 1. Schematic diagram of TEG.

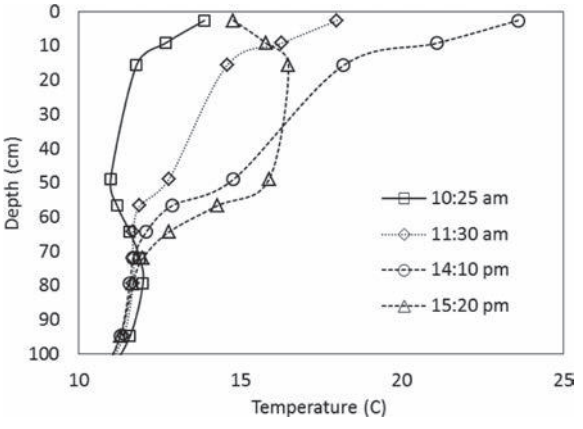

Figure 2. Variation of temperature gradient along the pavement depth: LTPP data from Montana, 4-23-1993 [23].

the surface is almost constant. The maximum temperature difference of this specific example was 13 °C.

3 THERMOELECTRIC SYSTEM DESIGN AND EXPERIMENTAL SET-UP

A thermoelectric system is manufactured for the experiment. Figure 3 illustrates the thermoelectric system used in this study. The design is similar to that proposed by Wu and Yu [21]. The system is composed of a TEG contacted to a pair of heat exchangers. The heat exchangers and TEG are stacked in horizontal direction not to transfer the mechanical force from traffic loads. The amount and loss of heat flow is one of the important factors for the efficiency of the system. To provide high thermal conduction, aluminium bars with 200 (W/m · °K) of thermal conductivity are selected for the heat exchangers. As shown in Figure 3, an extra space around TEG is needed to fasten bolts between the two heat exchangers. To minimize the heat loss, the extra space is filled with the insulation tape with 0.06 (W/m · °K) of thermal conductivity and plastic bolts and nuts were used as the fastener. In most of the tests, the heat exchangers were wrapped up with six layers of the same insulation tape to minimize the heat loss between the heat exchanger and the ambient environment.

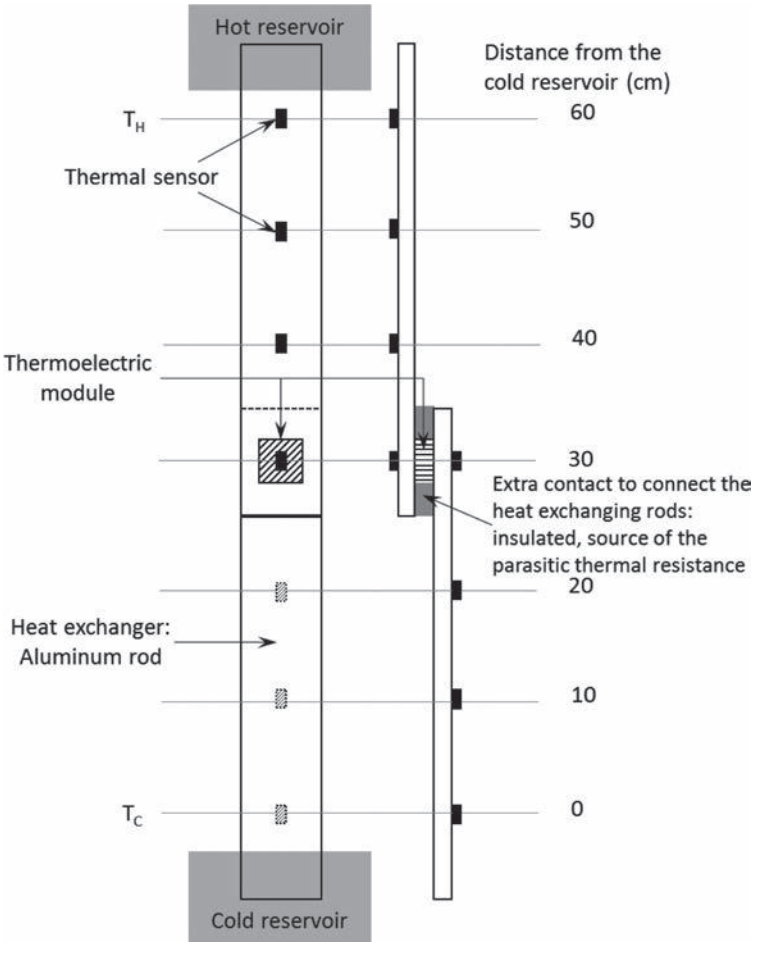

Figure 3. Experimental set-up of the thermoelectric energy harvesting system.

As displayed in Figure 4, three types of cross-sectional shape are tested. The selection of the TEG is another important factor for the effective energy generation. The characteristics of the four different TEGs used in this study are summarized in Table 1. With the assumption of a small temperature difference (up to 40°K) between the top and bottom surface of the TEG, the electric potential generated from TEG can be approximated to be linearly proportional to the temperature difference [22], as shown in Eq. (1).

$$V = \alpha \Delta T_{TEG} \tag{1}$$

where, V is the electric potential (voltage, V), ΔT_{TEG} is the temperature difference (°K) at the TEG, and α is the coefficient (V/°K). Two values of α are given in Table 1. The first column of α values shows the calculated values from the specification, and the second column of α values lists the measured α in the lab. For the latter discussion of this paper, the measured values will be used. As shown in Table 1 and Figure 5, the voltage generated at the same ΔT_{TEG} is approximately proportional to the number of p-n junctions rather than the size of the TEGs. The order of the generated voltage by each TEG is A > B > D > C.

In addition to the electrical considerations, thermodynamic heat flow between the heat exchangers and TEG will affect the efficiency of power generation. To evaluate the heat flow through the system, eight thermal sensors are attached as shown in Figure 3.

4 RESULTS AND DISCUSSION

4.1 *Electrical impedance matching*

Figure 6 shows a simple circuit model composed of a battery and a load, which consumes electric energy. In the thermoelectric energy harvesting system, the TEG will take the role of the battery. According to Ohm's law, a voltage is linearly proportional to the resistance and current. As shown in Figure 5, the voltage generated by TEG solely depends on ΔT_{TEG}. When the switch in the circuit is open, the voltage output can be obtained by Eq. (1). The work can be done by connecting an electrical load with a resistance, R_L—the situation of closing the switch in Figure 6. Since the TEG has its own internal resistance, R_{TEG}, the total voltage generated by the TEG, V_{TEG}, will be shared by R_{TEG} and R_L. From Ohm's law, the voltage of the electric load, V_L, can be calculated by Eq. (2).

$$V_L = \frac{R_L}{R_L + R_{TEG}} V_{TEG} \tag{2}$$

Since the useful work will be done at R_L, the useful power, P, of this circu it can be calculated by Eq. (3) with the combination of Eq. (2).

$$P = \frac{V_L^{\,2}}{R_L} = \frac{R_L}{R_L + R_{TEG}^{\,2}} V_{TEG}^{\,2} \tag{3}$$

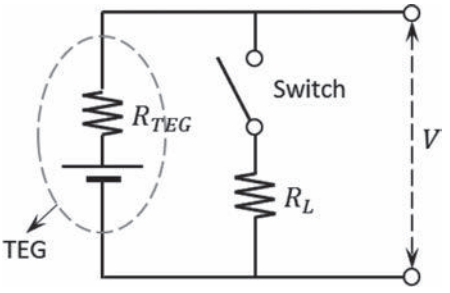

Figure 6. Electric circuit for maximum power output.

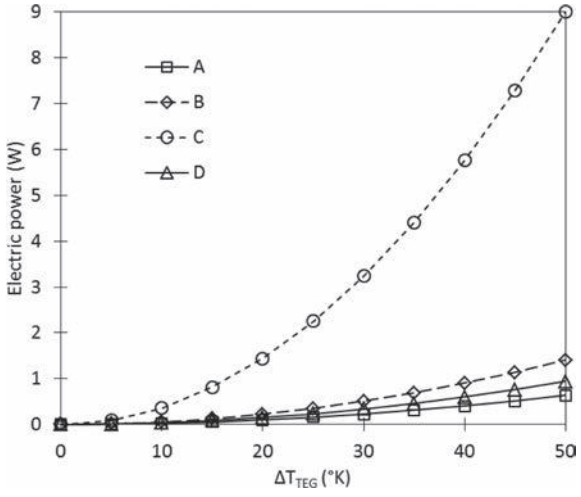

Figure 7. The relationship between electric power and temperature difference of TEG.

In theory, the maximum useful power can be obtained when is $\partial P/\partial R_L = 0$, in other words, $R_L = R_{TEG}$. This implies that the TEG of the pavement energy harvesting system has to be selected in order to match with the impedance of the application. Figure 7 compares the theoretically maximum power of the TEGs used in this study. Because of the low electric resistance, the highest power is obtained from the TEG type C and followed by B, D, and A. In terms of the useful power, the efficiency of the TEGs shows a completely different order from the case of the voltage in Figure 5. For the TEGs used in this study, V_L of each TEG is measured with the resistors with, $R_L = R_{TEG}$ as listed in Table 2. By matching the impedance of the electric load, V_L of each TEG is approximately a half of V_{TEG} as expected.

4.2 *Thermal impedance matching*

The control of the heat flow through the heat exchangers and TEG is another critical factor for improving the energy efficiency. Figure 8 shows the thermal impedance model of the pavement energy harvesting system. T_H and T_C are the temperatures at the hot and cold reservoirs, respectively. $\Delta T_{HC} = T_H - T_C$ is the total temperature difference of the system, which will be the temperature difference between the pavement surface and the subgrade (see Fig. 2) in the actual application. The model has two separated resistors representing the heat exchangers and two thermal resistors at the TEG connection. θ_{HE}, θ_{TEG}, and θ_{par} are thermal resistances of the heat exchanger, TEG, and the extra space around the TEG for fastening (parasitic area), respectively. The combined thermal resistance of the TEG contact, θ_{con}, can be calculated from θ_{TEG} and θ_{par} as shown in Figure 8. The resistors placed horizontally in Figure 8 represent the heat loss between the heat exchanger and the environment, which would be asphalt and soil layers in pavements, but the ambient air in our lab. T_{amb} is the ambient temperature.

Stevens [24] suggested a similar model composed of 3 resistors (equivalent to two $\theta_{HE}/2$ and θ_{con} in Fig. 8), and investigated the thermodynamic optimization. Since the heat exchangers and the TEG are connected in series, the heat flow, Q, is constant throughout the system. Eq. (4) shows the relationship between Q and the thermal resistances.

$$Q = \frac{\Delta T_{TEG}}{\theta_{con}} = \frac{\Delta T_{HC}}{\theta_{con} + \theta_{HE}} \tag{4}$$

Considering that the output voltage of a TEG is proportional to ΔT_{TEG} (Eq. (1)), Eq. (4) implies that the ΔT_{TEG} and corresponding output voltage are functions of θ_{HE}, θ_{TEG}, and θ_{par}. Assuming that the energy conversion efficiency is η, the power generated from the TEG can be calculated using Eq. (5), which is modified version of Stevens' equation [24] tailored for the model in Figure 8.

$$P = \Delta T_{HC}{}^2 \frac{\theta_{con}}{\theta_{con} + \theta_{HE}{}^2} \frac{2\eta}{T_H + T_C} \tag{5}$$

For the given ΔT_{HC} and η, two different scenarios are available for the maximum power output: 1) a specific heat exchangers are pre-selected (θ_{HE} is fixed), and selecting a TEG for the maximum power output, and 2) θ_{con} (calculated from θ_{TEG} and θ_{par}) is given, and designing a heat exchanger. For the first scenario, one extreme case is $\theta_{TEG} \approx \theta_{con} \approx 0$, then the heat flows through the TEG easily, and the TEG will not generate power because $\Delta T_{TEG} \approx 0$. Another extreme case is when $\theta_{TEG} >> \theta_{HE}$, then $\Delta T_{TEG} \approx \Delta T_{HC}$, but the heat flow will be very small (Eq. (4)). Therefore, the maximum P can be obtained when $\partial P/\partial \theta_{con} = 0$, i.e. $\theta_{con} = \theta_{HE}$. The second scenario is the case when a specific TEG is pre-selected. In this scenario, Eq. (5) and Eq. (4) suggest that the maximum power can be obtained when $\theta_{HE} \approx 0$ (the heat exchanger allows infinite heat flow) and hence, $\Delta T_{TEG} \approx \Delta T_{HC}$.

The experimental results shown in Table 2 and Figure 9 and 10 are obtained by using the flat aluminium bar ($\theta_{HE} = 18.6$ °K/W) as the heat exchanger (fixed θ_{HE}), and verify the argument on the first scenario. Compared to θ_{HE} (18.6 °K/W), the thermal resistance of type A

* Stacking of TEG. For AA, two A type TEG were stacked, and for AAAA, four TEG were stacked in series.

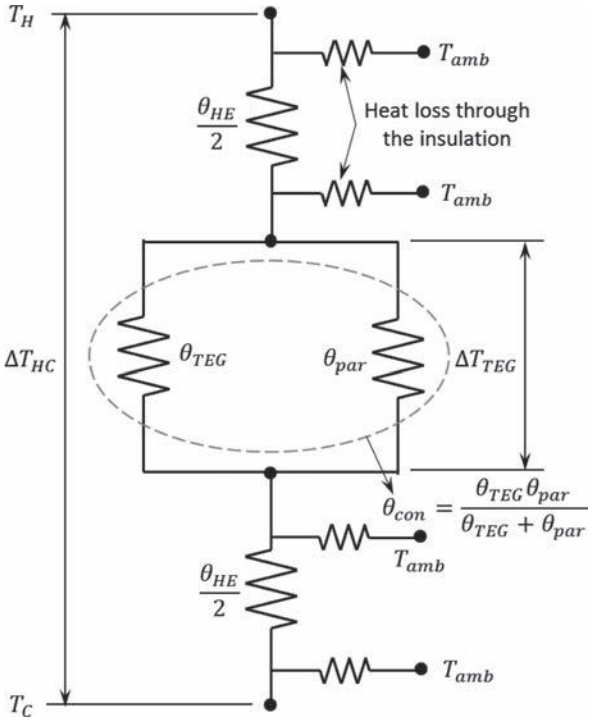

Figure 8. Thermal circuit model of the thermoelectric energy harvesting system.

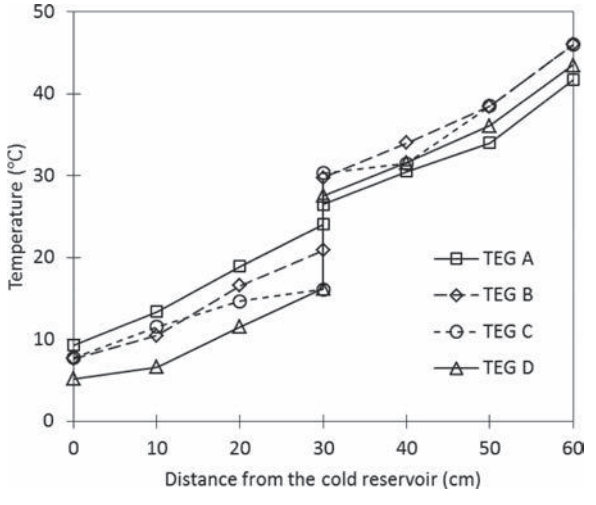

Figure 9. Effect of the TEG types: tested with the flat rod.

TEG is relatively small (θ_{con} = 2.98 °K/W), and the temperature difference used for generating energy, $\Delta T_{TEG} = 2.4 << \Delta T_{HC} = 32.4$ (°K). As a result, although the coefficient α of the type A TEG is larger than other TEGs (Table 1), the generated voltage and power output are smaller than those of type B. θ_{con} of type B, C, and D TEGs are relatively close to θ_{HE}, and resulting in fairly higher ΔT_{TEG}. However, the measured ΔT_{TEG} were smaller than the calculated values from Eq. (4): the measured ΔT_{TEG} are 54–70% of the calculated values. It is inferred that this

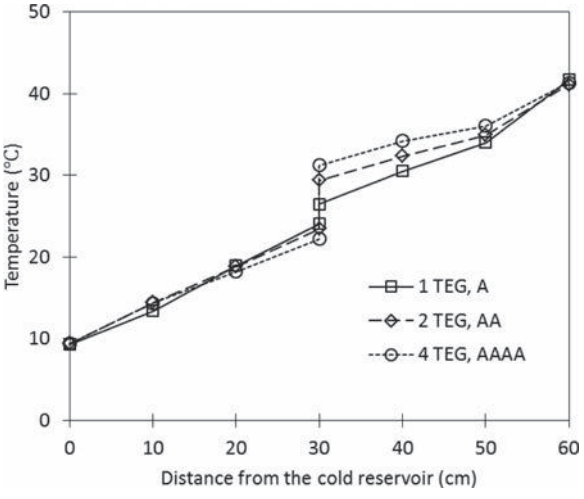

Figure 10. Effect of the TEG stacking: tested with the flat rod and TEG A.

error caused from the heat loss through the insulation between the heat exchanger and the ambient air (T_{amb} in Fig. 8).

The effect of stacking multiple TEGs is investigated by using the type A TEG. It is expected that the stacking TEGs will increase θ_{TEG} and corresponding θ_{con}. Figure 10 compares the temperature gradient along the heat exchangers. As shown in Figure 10 and Table 2, the thermal resistance (θ_{con}) and useful temperature difference (ΔT_{TEG}) proportionally increase by stacking two and four type A TEGs (denoted by AA and AAAA), but the increases in voltage outputs (V_{TEG} and V_L) are smaller than the increase in ΔT_{TEG}. On the other hand, the produced power from the four TEGs is smaller than the two TEGs because of the higher electric resistance. This shows that the stacking of multiple TEGs is not an effective way of improving power generation. From the given condition, $\theta_{HE} = 18.6$ °K/W and $\Delta T_{HC} \approx 50$ °K, the type B TEG generates highest power ($P = 6.9$ mW).

4.3 *Effect of rods and insulation*

The second scenario described in the previous section is investigated by changing the heat exchanger. The type B TEG, which showed the best performance in generating power, was used for examining the effect of θ_{HE}. The dimensions of the flat, rectangular, and rounded heat exchangers are shown in Figure 4, and their θ_{HE} values are 18.6, 9.3, and 4.0 (°K/W), respectively. It is expected that the smaller thermal resistance allows the more heat flow at the heat exchanger, and leads the higher ΔT_{TEG}. Figure 11 compares the temperature gradients along the heat exchangers. As expected, a substantial increase in ΔT_{TEG} is observed at the rounded heat exchanger. The ratio of ΔT_{TEG} to ΔT_{HC} for the rounded bar is 77%, which means that the heat loss of the heat exchanger is 23%. $\Delta T_{TEG} = 36.5$ °K obtained using the rounded heat exchanger and type B TEG under $\Delta T_{HC} = 47.8$ °K is the maximum ΔT_{TEG} among the all tested cases, and the corresponding power output is 42 mW. This is 800 times higher power than the previously reported pavement energy harvesting devices using a TEG.

Another factor that should be included in the thermal flow analysis is the loss of heat between the heat exchanger and environment. The thermal circuit model in Figure 8 shows this factor. But a quantitative analysis is not made in this study because the lab environment (ambient air) is different from pavements. However, the comparative tests with different insulation indicate how significant the insulation is. The temperature gradations with the different number of insulation layers are compared in Figure 12. Compared to the case without the insulation, 1, 2, and 4 insulation layers bring 20, 27, and 31% increase in ΔT_{TEG}, respectively.

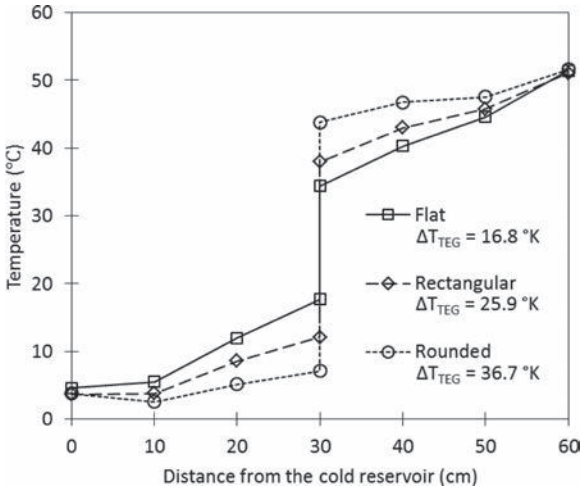

Figure 11. Effect of the heat exchanger: tested with TEG B.

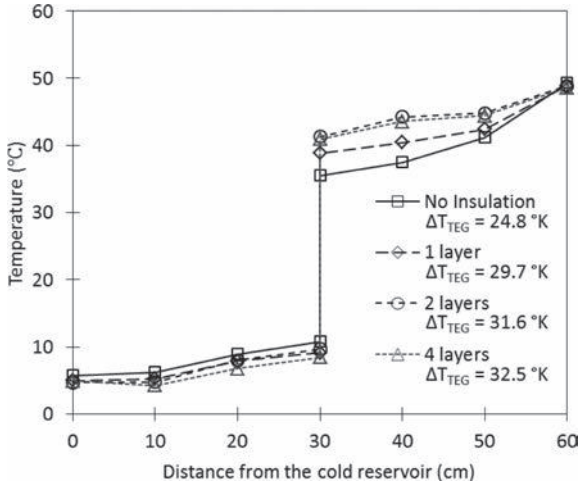

Figure 12. Effect of the insulation: tested with the rounded rod and TEG B.

This shows that the effect of the first insulation layer is remarkable, and the improvements due to the additional layers are less significant.

5 CONCLUSION

With the goal of optimizing the thermoelectric energy harvesting system for the pavement application, various factors affecting the efficiency of the energy harvesting system were investigated. A series of experiments are conducted using a prototype thermoelectric energy harvesting system composed of the heat exchanger and TEG. The results obtained from the theoretical and experimental investigations indicate that the controlling of the heat flow within the system has significant effect on the useful power output. The methods of electrical and thermal impedance matching in selecting an efficient TEG are proposed and experimentally verified. The effects of the thermal impedance and insulation of the heat exchanger are also evaluated. Among the various combinations of the TEGs and the heat exchanger geometries, the best

combination of the device configuration and setup yielded over 40 mW at the load. Design optimization process has produced a system that achieves power output greater than 25 times that of the default design in this study. Given the stated temperature differential, and the device capacities, the power results obtained is about 800 times higher than the power output of the one of the most recently reported study on the pavement energy harvesting using TEG.

Investigation of limiting criteria for asphalt mixture low temperature cracking

Augusto Cannone Falchetto

Mihai Marasteanu
University of Minnesota, Minneapolis, MN, USA

ABSTRACT: This paper proposes a new low temperature limit criteria for asphalt mixtures, similar to what is currently available in the standard specification for asphalt binder. The investigation is based on extensive experimental work that includes Bending Beam Rheometer (BBR) creep tests on asphalt binders and asphalt mixtures at low temperature, on the rheological Christensen, Anderson and Marasteanu (CAM) model and on the semi-empirical Hirsch model. Limiting asphalt mixture creep stiffness values are predicted from creep stiffness data obtained on long term aged binder, and then compared with results available in literature. The BBR creep results determined on short term aged asphalt binder are then used to predict creep stiffness of the corresponding short term aged asphalt mixtures. Based on these results, a range of limiting stiffness values is obtained. A limiting value for the relaxation parameter *m*-value could not be recommended due to large variations in the calculated slopes of the mixture creep stiffness curves.

Keywords: Creep stiffness, CAM model, Hirsch model, low temperature cracking, limiting criteria

1 INTRODUCTION

One of the most significant achievements in the area of asphalt paving materials characterization was the development of the Strategic Highway Research Program (SHRP) Performance Grade (PG) specifications [1] at the beginning of the 1990's. The PG tests and analyses, detailed in a number of AASHTO specifications [2–4], are used to specify the asphalt binders used in pavement applications and also serve as the primary tool to investigate the behavior of asphalt binders in many research studies. The success of the PG system can be attributed on one hand to the innovative application of fundamental concepts to asphalt binder material characterization and on the other hand to the reasonable level of complexity of the tests and analyses required as part of these specifications. However, this level of complexity is the result of a number of simplifying assumptions that, in the past years, have been investigated by a number of researchers who proposed additional tests and analyses to improve the material selection process for the specific use.

The development of the asphalt binder criterion for low temperature cracking was based on previous work performed by Readshaw [5] who analyzed the low temperature cracking resistance of pavements in British Columbia. By using binder penetration index, the corrected Ring & Ball softening point, and assuming a loading time of 2 hours in the Van der Poel's nomograph, he concluded, that cracking could be minimized by using an asphalt binder that

does not exceed 2×10^8 N/m^2 (200 MPa) stiffness values at the lowest temperature experienced. The SHRP research team based on additional information changed the value to 300 MPa, and used the time-temperature superposition principle to reduce testing time by demonstrating that, in general, the binder stiffness at 60 seconds at T_1°C is approximately equal to the stiffness at 2 hours at T_1–10°C [1]. In addition, the slope at 60 seconds of the stiffness vs. time curve on a double logarithmic scale, the *m*-value, was introduced as an additional parameter to control the rheological type of asphalt binders and to eliminate heavily blown asphalts, which in fact were associated with poor fatigue performance. This criterion was based on the idea that a low *m*-value corresponded to slower relaxation of the thermal stresses that build up at low temperatures, which is very detrimental for material performance.

It is important to note that in the pioneering research performed in Canada in the 1960's there is very limited information about mixture low temperature properties. The only reference is found in the paper by Burgess et al. [6] and the discussion provided by N. W. McLeod. Based on McLeod's analysis of data from St. Anne Test Road and other pavements in Canada, he concluded that the critical low temperature pavement modulus of stiffness at which transverse pavement cracking is likely to occur is 1,000,000 psi or 7 GPa, a value twice as high as that previously proposed. These values were obtained for a paving mixture compacted to 3% air voids, Voids in the Mineral Aggregate (VMA) of 14.5%, and a loading time of 20,000 s (5.5 hours).

2 PROBLEM STATEMENT

In the past years, a number of models were developed that allow predicting asphalt mixture properties from binder properties and volumetric information [7–9]. One interesting application is to determine the mixture creep stiffness that corresponds to a binder creep stiffness value of 300 MPa, which is the current PG specification limit. This can provide insight into the possibility of developing a similar criterion for asphalt mixture creep stiffness that can be used, for example, in quality control testing.

3 RESEARCH APPROACH

The main challenge in performing such an investigation is to reasonably match the aging condition of the binder and of the mixture. Since it is generally accepted that binder after Rolling Thin-Film Oven Test (RTFOT) [10] matches the aging condition of the mixture after short term aging or as loose mix, the analysis performed in this paper is based on RTFOT binder data and short term aged mixture data. Calculations were also performed using Pressure Aging Vessel (PAV) [11] binder data to compare the predicted mixture stiffness to the values proposed by McLeod (equal to 7GPa) [6]. The research approach, therefore, consists of the following steps:

1. Bending Beam Rheometer (BBR) binder creep tests [3] are performed on a set of binders for both RTFOT and PAV aging conditions.
2. BBR mixture creep tests are performed on short term aged mixtures prepared with the set of binders in step 1 using the procedure described elsewhere [12].
3. Binder creep stiffness and *m*-value at 60 seconds, at the critical temperatures are calculated from the PAV binder creep testing.
4. Hirsch model [7] is used with the PAV binder data to predict long term aged mixture creep stiffness and compare it to the value proposed by McLeod (= 7GPa) [6].
5. Creep stiffness and *m*-value at 60 seconds, at the critical temperatures (obtained in step 3 for PAV binders), are calculated for the binders in RTFOT condition.
6. Hirsch model is used with the RTFOT binder data from step 5 to predict short term aged mixture creep stiffness and *m*-value at the critical temperatures obtained in step 3.
7. The mixture values predicted in step 6 are compared to the experimental mixture data obtained from BBR mixture testing [12].

4 MATERIALS AND TESTING

In this study, eight different asphalt binders and sixteen corresponding asphalt mixtures were prepared with two different types of aggregate: granite and limestone. Detailed information on the materials used in this study can be found elsewhere [12,13]. Table 1 describes the asphalt binders and corresponding mixtures used in this study.

All asphalt binders were short and long term aged according to RTFOT [10] and PAV [11] procedures and BBR creep tests [3] were performed for both aging conditions at three different temperatures: PG + 10ºC, (PG + 10) – 6ºC and (PG + 10) – 12ºC. All mixtures were short term aged by conditioning the gyratory compacted samples for 2 hours at 135ºC. Then BBR creep stiffness tests for asphalt mixture [12] were performed at three different temperatures, PG + 10ºC, (PG + 10) + 12ºC and (PG + 10) – 12ºC. Two and ten replicates were used per each testing condition for asphalt binder and asphalt mixture respectively.

For BBR binder testing, the standard constant load of 100 g (= 980 ± 50 mN) was applied to the asphalt binder beams (102.0~125.0 mm × 12.7 ± 0.5 mm × 6.25 ± 0.5 mm) and maintained for 240 s. In case of asphalt mixture, BBR creep tests were performed with the same BBR device used for asphalt binder testing. Mixture specimens consisted of thin asphalt mixture beams (102.0~125.0 mm × 12.7 ± 0.5 mm × 6.25 ± 0.5 mm); due to the higher material stiffness, a higher constant load of 4,000 mN, was applied to the specimen, and extended test duration of 1000s, were used [12]. In both test methods, BBR binder and BBR mixture creep tests, mid span deflection, $\delta(t)$, was recorded for the entire duration of the test to compute creep stiffness, $S(t)$, and m-value, $m(t)$. Figure 1 presents the testing setup.

The creep stiffness of asphalt binder and asphalt mixture was calculated as:

$$S(t) = \frac{\sigma}{\varepsilon(t)} = \frac{P \cdot l^3}{4 \cdot b \cdot h^3 \cdot \delta(t)} \tag{1}$$

Table 1. Tested binders and corresponding mixtures.

	Binder		Mixture

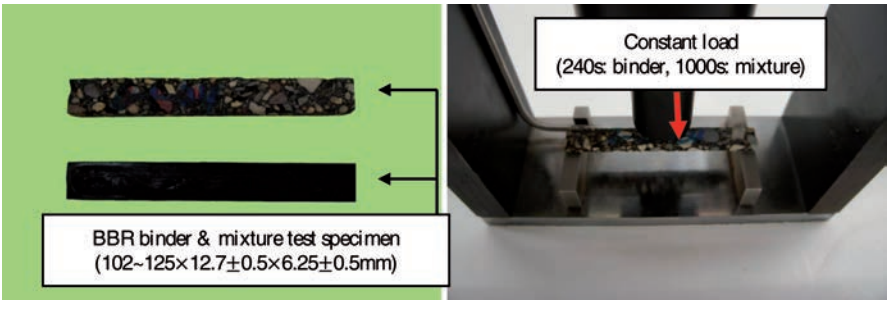

Figure 1. BBR binder and mixture creep testing set up.

where $S(t)$ is the time dependent flexural creep stiffness (MPa), σ is maximum bending stress in the beam (MPa), $\varepsilon(t)$ is the time dependent bending strain in the beam (mm/mm), P is the constant load used (mN), l is length of specimen, (102.0~125.0 ± 1 mm), b is the width of specimen, (12.7 ± 0.5 mm), h is the height of specimen (6.25 ± 0.5 mm), $\delta(t)$ is deflection at the mid span of the beam (mm) and t is the time (s).

The m-value, which is the slope of log stiffness versus log time curve, is computed according to:

$$m(t) = \left| d\log S(t) / d\log t \right| \tag{2}$$

The m-value can be also calculated by fitting a second order polynomial expression to the $\log S(t)$ versus $\log(t)$ curve as: $\log S(t) = a \cdot \log^2(t) + b \cdot \log(t) + c$; m-value can then be obtained as the derivative: $m(t) = |2a\ \mathrm{a} \cdot \log(t) + b|$. According to AASHTO specifications [3,4], critical cracking temperature of asphalt binder is obtained as the lowest temperature at which the following two conditions are met for long term aged binder [11]: $S(t_{60\ \mathrm{sec}}) \leq 300$ MPa and $m(t_{60\ \mathrm{sec}}) \geq 0.300$.

5 MODELING

In this study, the semi-empirical Hirsch model [7] was used to predict asphalt mixture creep stiffness, $S(t)_{\mathrm{mix}}$, from asphalt binder creep stiffness, $S(t)_{\mathrm{binder}}$, data at the critical cracking temperature, T_{CR}. In Hirsch model, the effective modulus is generated by combining aggregate, asphalt binder and air void phases in parallel and series. Figure 2 shows the schematic of Hirsch model.

The Hirsch model formulation for creep stiffness can be expressed as:

$$S_{mixture} = P_c \cdot \left[E_{agg} V_{agg} + S_{binder} V_{binder} \right] + \left(1 - P_c\right) \cdot \left[\frac{V_{agg}}{E_{agg}} + \frac{\left(1 - V_{agg}\right)^2}{S_{binder} V_{binder}} \right]^{-1} \tag{3}$$

where $S_{mixture}$ is the creep stiffness of the mixture (GPa), E_{agg}, V_{agg} are modulus (GPa) and volume fraction (%) of the aggregate, S_{binder}, V_{binder} are stiffness (GPa) and volume fraction (%) of the asphalt binder. P_c is the contact volume (empirical factor) defined as:

$$P_c = \left[\left(P_0 + \frac{VFA \cdot S_{binder}}{VMA} \right)^{P_1} \right] \Big/ \left[P_2 + \left(\frac{VFA \cdot S_{binder}}{VMA} \right)^{P_1} \right] \tag{4}$$

where VFA are the voids filled with asphalt binder (%), VMA are the voids in the mineral aggregates (%) and P_0, P_1, P_2 are fitting parameters.

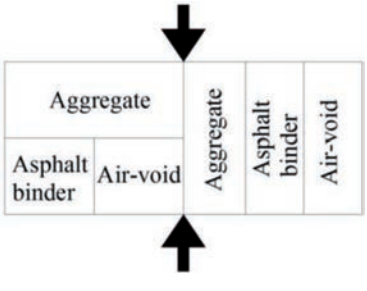

Figure 2. Hirsch model [7].

Zofka et al. [14] investigated the effectiveness of the Hirsch model [7] to predict the BBR mixture stiffness from the properties of the binder and proposed a simplified expression for P_c:

$$P_c = 0.1 \cdot \ln\left(E_{binder} / a\right) + 0.609 \tag{5}$$

where E_{binder} is the relaxation modulus of binder (GPa) and a is a constant equal to 1 GPa.

Input to Equations 3 and 5, which were used to predict mixture creep stiffness from binder creep stiffness, came from laboratory measurements [9], [13]. For granite mixtures E_{agg}, VMA and VFA were set as 4,200,000 psi (= 30 GPa), 16.3% and 75.9%, and for limestone mixture E_{agg}, VMA and VFA were set as 3,600,000 psi (= 25 GPa), 16.2% and 75.0%, respectively. In order to obtain creep stiffness data at 20,000 s and to compare the predicted asphalt mixture creep stiffness to the experimental mixture creep stiffness, stiffness master curves were generated using a form of CAM model [15] expressed in terms of stiffness:

$$S(t) = S_g \cdot \left[1 + \left(t_c / t\right)^v\right]^{-w/v} \tag{6}$$

where S_g is the glassy creep stiffness asymptote (3 GPa for binder and 30 GPa for mixture), t_c is the crossover time (s) and, v and w are fitting parameters. The shift factor, a_T, was expressed as $a_T = 10^{C_1 + C_2 \cdot T}$ where C_1 and C_2 are fitting parameters and T is the reference temperature (ºC).

6 LONG TERM AGED MIXTURE STIFFNESS FROM PAV BINDER STIFFNESS

The first step in the analysis consisted in using the binder PAV data and predicting the corresponding mixture creep stiffness using Hirsch model [7] previously described. The results of predicted mixture S(60 s) are shown in Table 2.

Then, the prediction of asphalt mixture creep stiffness at 20,000 s, $S(20{,}000\text{ s})_{mixture}$, obtained with the Hirsch model and the stiffness value of PAV asphalt binder at 20,000 s, $S(20{,}000\text{ s})_{binder}$, at critical temperature, T_{CR}, were compared to the 7GPa limit proposed by McLeod [6]. To obtain the creep stiffness values at 20,000 s, CAM model [15] was used. First, based on PAV binder creep stiffness, master curve was generated. Then, based on the calculated critical temperature, T_{CR}, (Table 3), the value of shift factor, a_T, at T_{CR} was obtained. Hence, by setting t = 20,000 s in Equation (6), $S(20{,}000\text{ s})_{binder}$ of PAV aged binder at T_{CR} was determined. Finally, the S(20,000 s) for long term aged mixture was calculated from binder

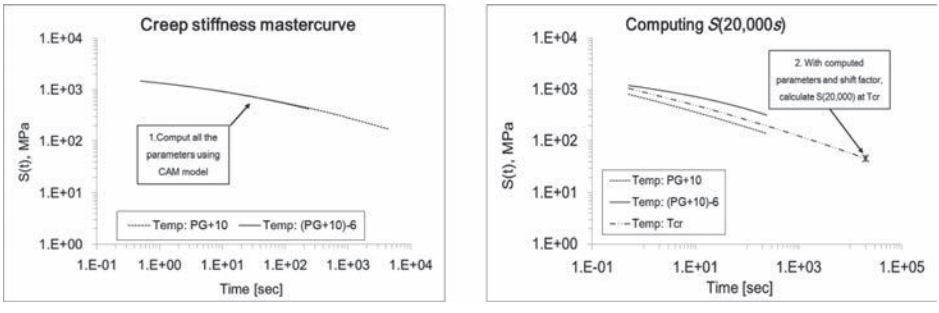

Figure 3. Computation process of PAV binder S(20,000 s) using CAM model.

S(20,000 s) using Hirsch model and finally compared to 7GPa limit [6]. The schematic computation process is shown in Figure 3 while the results of $S(20{,}000\text{ s})_{\text{binder}}$ and $S(20{,}000\text{ s})_{\text{mixture}}$ are presented on the right two columns in Table 2. Note that since master curves were generated for this purpose, the values are slightly different for the eight mixtures.

From the results in Table 2, slightly different T_{CR} values were observed for binder having same PG; this is most likely due to the different types of the modifiers. Using Hirsh model, the mixture creep stiffness, $S(60\text{ s})_{\text{mixture}}$, corresponding to the PAV binder low temperature limit criteria of 300 MPa was calculated: a value of 12.2 GPa and 10.6 GPa were obtained for granite and limestone mixtures, respectively. For asphalt binder an average value of $S(20{,}000\text{ s})_{\text{binder}}$ equal to 46 MPa was determined with a small coefficient of variation, CoV = 9.9%. Finally, $S(20{,}000\text{ s})_{\text{mixture}}$ was calculated from the corresponding $S(20{,}000\text{ s})_{\text{binder}}$. The average values of $S(20{,}000\text{ s})_{\text{mixture}}$ were 6.7 GPa and 5.7 GPa for granite and limestone mixtures, respectively (CoV = 4%). This indicates that the average limiting stiffness values for the two types of mixtures were relatively close to the 7 GPa limit proposed by McLeod [6].

7 SHORT TERM AGED MIXTURE STIFFNESS FROM PAV AND RTFOT BINDER STIFFNESS

In order to determine the creep stiffness of short term aged asphalt mixture, the creep stiffness of the RTFOT asphalt binder at the PAV binder critical temperature, T_{CR}, has to be first determined. Assuming a linear relation between log$S$(60 s) and the test temperature for both PAV and RTFOT creep stiffness data, a corresponding RTFOT binder stiffness value at T_{CR} is easily obtained, as shown in Figure 4.

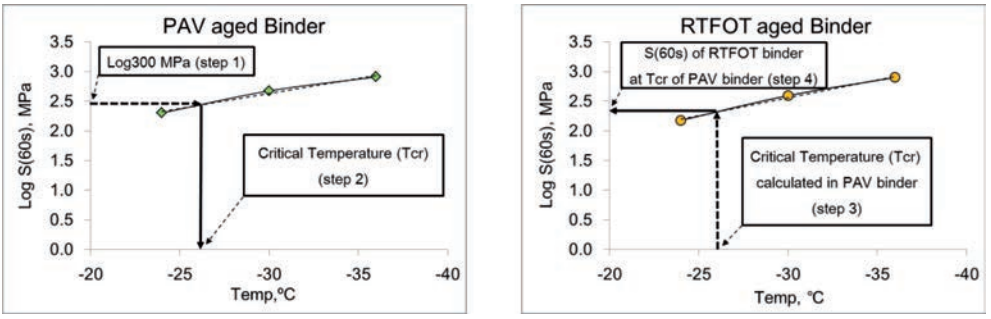

Figure 4. Predicting RTFOT binder S(60 s) at PAV binder critical temperature, T_{CR}.

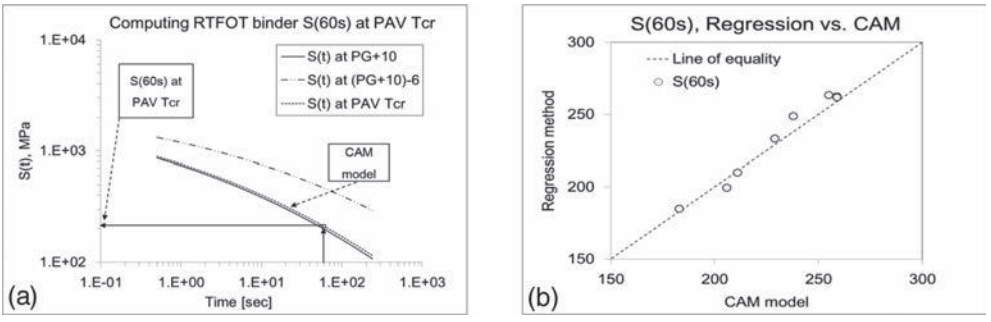

Figure 5. (a) Computing process of RTFOT Binder S(60 s) using CAM Model and (b) Comparison of RTFOT binder S(60 s) at T_{CR} of PAV binder based on regression and CAM model extrapolation.

The schematic computation process of RTFOT binder S(60 s) at the PAV binder critical temperature, T_{CR}, can be explained as follow:

1. Critical temperature, T_{CR}, is determined from the experimental results of PAV binder Log S(60 s) using current low temperature limit specification of asphalt binder (steps 1–2 in Fig. 4).
2. Based on T_{CR} the value of RTFOT binder S(60 s) is easily obtained (step 3–4 in Fig. 4).

Even though high values of coefficient of determination, R^2, were observed for most binders ($R^2 > 0.95$), CAM model [15] was also used to validate the results since small deviations from the linear relation were observed for some binders. A computation procedure similar to section 6 was used for obtaining RTFOT S(60 s) values at the PAV binder T_{CR}. First, based on RTFOT binder creep stiffness experimental results, master curve was generated and the shift factor, a_T, at T_{CR} determined. Then, the RTFOT binder S(60 s) at PAV binder T_{CR} was calculated using CAM model and compared to the results of RTFOT S(60 s) obtained using the simple regression method shown in Figure 4. The schematic procedure for obtaining RTFOT binder S(60 s) at PAV binder T_{CR} using CAM model [15] is shown in Figure 5a while the graphical comparison between regression and CAM model extrapolation of RTFOT S(60 s) $_{\text{binder}}$ are presented in Figure 5b (correlation coefficient, $\rho = 0.989$). The computed results including the values of the coefficient of determination, R^2, are presented in Table 3.

Then simple regression RTFOT binder stiffness values, S(60 s), were used in Hirsch [7] model to predict the mixture creep stiffens S(60 s) at the critical temperature, T_{CR}, obtained from the PAV binder creep stiffness experimental data. The results are shown in Table 4 and Figures 6. In addition, BBR mixture creep data were used with CAM model to obtain mixture S(60 s) at the same critical temperature, T_{CR}. The same calculation process previously

used for RTFOT binder S(60 s) at PAV binder T_{CR} based on the CAM model [15] was followed. These results are also included in Table 4 and Figure 6 to compare the S(60 s) values predicted through Hirsch model with the experimentally obtained S(60 s).

No significant differences were observed, except for three limestone mixtures: D, E and H, with differences little above 15%. The average values of S(60 s) from Hirsch model prediction were 11.4GPa and 9.9GPa for granite and limestone mixtures, respectively, with small variations (C.V. = 3.8% for two mixture groups). Limited differences of S(60 s) were observed between the average Hirsch model prediction and the average extrapolations obtained by the CAM model. This suggests that the creep stiffness of mixtures has similar values, both when predicted from the binder data using Hirsh model and when obtained by the CAM model on mixture experimental measurements. The results indicate that for short term aged asphalt mixtures, the 300 MPa limit imposed on PAV binders result in limiting value S(60 s) for mixture in the range of 9 to 12GPa.

8 SHORT TERM AGED MIXTURE M(60 S) AT PAV BINDER T_{CR} FOR M(60 S) = 0.300

The m(60 s) of short term aged asphalt mixture at the corresponding T_{CR} for PAV binder were also calculated using Hirsch and CAM model, similarly to the creep stiffness calculations. The results are shown in Table 5 and Figure 7.

Based on the results in Table 5 and Figure 7, large differences were observed between the values of m(60 s) predicted with Hirsch model and those extrapolated through CAM model. This is most likely due to fitting difficulties experienced when the log stiffness slopes are close to zero and therefore, it makes the use of mixture m-value as a limiting parameter questionable.

Table 5. Mixture m(60 s) values at PAV binder T_{CR}.

9 SUMMARY AND CONCLUSIONS

The possibility of developing low temperature limit criteria for asphalt mixture, analogous to that used for asphalt binder, was investigated in this paper. Experimental data were obtained from BBR creep tests on eight asphalt binders and sixteen short term aged asphalt mixtures prepared with two different types of aggregate. The critical temperature of PAV aged binder was calculated and the limiting stiffness value for PAV binder data was used to predict long term aged mixture stiffness using Hirsch model. Then, the creep stiffness of PAV and RTFOT binders was used in combination with Hirsch model to predict the corresponding creep stiffness and m-value limits for short term aged asphalt mixtures at the binder critical temperature. It was then shown that similar results were obtained from mixture BBR creep stiffness experimental data.

Based on the analysis performed, three main conclusions can be drawn:

1. The predicted creep stiffness of long term aged asphalt mixtures at 20,000 s is in the range of 5.7 ~ 6.7 GPa. These values are in reasonable agreement with the 7.0 GPa limit previously proposed by McLeod.
2. The limiting creep stiffness, S(60 s), for short term aged mixtures, predicted from RTFOT binders creep stiffness data is comparable to that obtained through extrapolation from experimental BBR mixture creep stiffness. The values range between 9 GPa and 12 GPa for all mixtures investigated. These results support the idea of using BBR creep mixture testing as a routine test to discriminate mixtures that are too stiff and more prone to cracking. More research is needed to further validate and refine these findings.
3. Due to large variations in the mixture m(60 s) values, a limiting value for this relaxation parameter cannot be proposed at this time.

Netivei Israel—National Transport Infrastructure Company, Or Yehuda, Israel

ABSTRACT: A PRS—Performance Related Specifications QA/QC program is under development in Israel. The literature review revealed that in the last decade, two systems for performance based QA/QC—NCHRP 9-22 and in California, were developed. They are similar in their approaches. They both address QA/QC of asphalt layers. They use regressions and/or data bases derived from runs of the AASHTO Guide or WesTrack results and Monte Carlo simulations to compute reliability. It was found that both systems have several limitations. It was decided to develop a new program that will (a) reproduce reliably AASHTO Guide results; (b) include a calibration of the transfer functions to local climatic and materials conditions (c) include all pavement layers and subgrade, and (d) be used in LCCA (Life Cycle Cost Analyses).

The new program uses the models from the Guide and (a) Hourly temperature distribution in the AC layers; (b) One design ESAL (Equivalent Single Axle Load); (c) No traffic wander (The effect of wander is taken into account via calibration functions); (d) Distress variability is computed analytically from the variability of the pavement properties using Rosenblueth-Harr approach. After preliminary calibration, the results of fatigue cracking, rutting and IRI (International Roughness Index) obtained from the new program fit very well with those of the Guide. A comprehensive calibration and verification steps are scheduled in the next few years. The short running time of the program, less than one minute, justifies its use in both QA/QC and LCCA analyses.

1 INTRODUCTION

A Performance Related Specifications (PRS) QA/QC (Quality Assurance / Quality Control) program is under development in Israel. The objectives of the program are to (a) Provide a system with models to predict flexible pavement performance from both as designed and as constructed structure; (b) Include all pavement layers, both unbound and asphalt layers (c) Develop correlations between material properties defined in the models (such as moduli, transfer functions) and properties from construction (such as air void, moisture, asphalt content, back-calculated moduli), from literature survey and testing of local materials and (d) Calibrate the models for local conditions. The predicted pavement performance will be used in LCCA (Life Cycle Cost Analyses). The paper will describe the first step of developing a reliable prediction system that will be used in both QA/QC and LCCA.

The literature review revealed that in the last decade, two systems dealing with performance based QA/QC—NCHRP 9–22 [1–2] and in California [3–6], were developed. The systems are similar in their approach and deal only with the construction of the asphalt layers.

They use regressions and/or data bases and Monte Carlo simulations to compute reliability. They could not be adopted in Israel because: (a) Only asphalt layers are considered; (b) The reliability of their prediction was judged inadequate for both QA/QC and LCCA; (c) Calibration of the models requires new development of the regression equations or data bases. Therefore the literature review was directed toward flexible pavement design systems that predict performance.

Two programs for flexible pavement design were developed in the last decade—NCHRP 1–37 A (known as MEPDG—Mechanistic Empirical Pavement Design Guide, AASHTO—American Association of State Highway and Transportation Officials Guide or DARWin-ME—[7]) and CalME in California [8–11]. The programs are in essence similar and represent the state of the art in pavement distress predictions, mainly rut depth and fatigue cracking. A slightly different scheme for computing permanent deformation during the design period was proposed by Uzan [12]. These three sources were reviewed with the aim to adopt models and computation scheme that will serve for the prediction of performance, with the highest reliability and shortest running time possible.

The paper presents: (a) A critical literature review of the three sources for predicting performance; (b) A description of Rosenblueth and Harr approaches to deal with the effect of variability of pavement properties on the variability of the performance; (c) A description of the proposed models and analysis scheme and finally (d) A comparison of the verification results using MEPDG and the proposed program.

2 REVIEW OF THE FLEXIBLE PAVEMENT DESIGN PROGRAMS

The flexible pavement part of MEPDG was developed by Witczak and his group. CalME was developed under the guidance of Monismith. (Another program is being developed at Texas A&M [13]). Both programs are mechanistic—empirical in the sense that they compute the pavement response (stresses, strains and displacement) using elastic multilayer systems (JULEA—Jacob Uzan Linear Elastic Analysis and LEAP—Linear Elastic Analysis Program), they implement transfer functions to predict distress and they calibrate their predicted results with field or accelerated testing results. The strategy is to analyse the entire history of the distress development under varying climatic conditions and load distribution.

There is a basic difference between these programs in the way the evolution of damage is evaluated. In CalME, the approach is incremental and recursive, i.e. the material properties vary after every load pass and with temperature change. In the MEPDG, the approach is incremental and global, i.e. the material properties remain unchanged by damage (fatigue cracking and permanent deformation) but vary with temperature and moisture. The damage effect is indirectly included in the transfer functions which are calibrated during the entire pavement life.

As a consequence of the above, the approach of generating seasons which represent the pavement condition during the design period is different. In CalME, every month is represented by the hourly (24) temperature distributions during one day of the month. In the MEPDG and for every month of the design period, the temperature distributions are grouped into five bundles. The average monthly moisture content is used, unless frost depth indicates the need for subdividing the month into two sub seasons. The five temperature bundles do not cross each other, thus they may represent only part of the temperature distributions. Uzan [12] proposed to use all the hourly distributions for the entire design period and to group them into a finite number of temperature bundles (or season bands), 5 to 10C wide. The seasons may cross each other. Every hourly temperature distribution of the analysis period is then identified with one season. The number of seasons depends on the local conditions, the asphalt layer thickness and the width of the band, and may vary between 20 to about 50. This approach produces temperature distributions similar to the ones in CalME. The total number of seasons, for which either JULEA or LEAP is called, is 5*12*N for MEPDG, 24*12*N for CalME, where N is the analysis period in years, and 20–50 for Uzan approach.

The incremental recursive approach used in CalME is claimed to be more rational, however it is not flexible and is running time consuming. Therefore its use is not practical for QA/QC and LCCA analyses. The approach proposed by Uzan [12] seems more realistic and attractive than the approach in MEPDG if only temperature effects are considered, i.e. the moisture content at equilibrium in the unbound layers and aging of the asphalt layers are set at the beginning of the analysis period and kept unchanged during the design period. This moisture assumption holds for Israeli conditions, where the moisture condition reaches equilibrium in a relatively short period after construction, a few months or years. This may not be the case for sites where freeze-thaw and/or varying water table conditions exist. Similarly, aging in the upper AC layer occurs in the first 30 months. Fluctuations after reaching equilibrium are considered a second order effect. Since in this case, the total number of seasons is 20 to 50, the computation effort and running time are reduced drastically. It is worth to mention that temperature and moisture variations and aging effects are considered in the design programs, but not in the QA/QC programs. Therefore inclusion of seasons in the new program is a sensible improvement compared to existing QA/QC programs.

The above approach of generating season bands together with the MEPDG models and transfer functions are implemented in the new QA/QC program. The reliability system included in the MEPDG [7] does not consider directly the variability of the properties such as layer thickness, moduli and, as such, is not adequate for QA/QC programs. Even for a reduced number of seasons, Monte Carlo simulations used in QA/QC programs, of the order of thousands, can be very time consuming and thus, may not be considered. The theory of component analysis developed by Harr [14] seems to provide a solution to the problem. It is described in the next paragraph.

3 RELIABILITY

The point estimate method in probabilistic analyses was developed by Rosenblueth [15]. The statistical moments of a random function (Y) of several n variables $X(x_1, x_2, \ldots, x_n)$ are computed at a finite number of concentration points of X. The two points estimate, together with the assumption that the distribution of X is normal (symmetric) is widely used and will be presented hereafter. It states that the first, second and third moments (mean, standard deviation and coefficient of skewness) of Y can be computed from 2^n realisations of Y. Different weighting functions of the correlation coefficients between $x_1, x_2, \ldots, x_n$ are assigned to each concentration point. Rosenblueth approach is used in QRSS (Quality Related Specifications Software [2]) in the thermal cracking evaluation where the number of independent variables is small ($n = 4$). The thermal cracking program, without any approximation is run 16 ($=2^4$) times, and the mean and the standard deviation are evaluated. When the number of variables X is large, the approach becomes less attractive and unpractical.

In 1989, Harr [14] extended Rosenblueth [15] two point estimate method and reduced the number of realisations from 2^n to 2n. In this case only the first two moments can be evaluated. Harr's approach is based on the principal component analysis (similar to the principal stresses analysis, Harr [16]). The correlation matrix representing the statistical relationship (or dependence or correlation) among the variables X is rotated to the principal axes. The resulting correlation matrix is diagonal. The concentration points are now located on the principal axes. The rotation of the correlation matrix leads to $i = 1$ to n eigenvalues (similar to principal stresses) and to the corresponding normalized matrix of eigenvectors $E(i,j)$, with $j = 1$ to n (similar to the direction cosine vectors of the principal stresses). For each eigenvalue λ_i, two sets of concentration points— $x_{ij}^{(1)}, x_{ij}^{(2)}$ $j = 1, n$ at which the function Y is computed— $Y_i^{(1)}$ *and* $Y_i^{(2)}$, are given by:

$$x_{ij}^{(1)} = \bar{x}_j + sign(E(i,j)) \cdot s_j \cdot E(i,j) \cdot \sqrt{n} \tag{1}$$

$$x_{ij}^{(2)} = \bar{x}_j + sign(E(i,j)) \cdot s_j \cdot E(i,j) \cdot \sqrt{n} \tag{2}$$

where: $\bar{x}_j$ —mean value of x_j and s_j—standard deviation of x_j with $j = 1$ to n. Each of the $i = 1$ to n realisations uses two concentration points for each variable. Therefore the total number of realisations is $2n$.

The mean and the variance of Y are computed using the following:

$$E[Y] = \frac{1}{n}\sum_{i=1}^{n}\{Y_i^{(1)} + Y_i^{(2)}\}/2 \tag{3}$$

$$E[Y_i^2] = (Y_i^{(1)})^2 + (Y_i^{(2)})^2/2 \tag{4}$$

$$Var[Y] = \left\{ \sum_{i=1}^{n} \{E[Y_i^2] - (E[Y])^2\} \cdot \lambda_i / n \right\} \tag{5}$$

where: $E[a]$—expected value of a, $Y_i^{(1)}, Y_i^{(2)}$ are the computed values of Y at the two sets of concentration points.

Hong [17] presented a procedure to compute higher moments of the variable Y by $m \times n$ point estimates, where m is the number of concentration points per variable X. He developed a $2n + 1$ point estimates that can consider skewness and kurtosis of the probability distribution of Y.

The program developed for QA/QC and LCCA uses Harr's approach. Every realisation of Y requires one call to JULEA multilayer system. Therefore the number of X variables—n should be kept to minimum and include only variables with a sensible effect on Y. It is limited to $n = 30$ in the program. In the adopted computation scheme, the number of JULEA calls is of the order of 500 to 1500 (20–50 seasons bands times 2*n).

4 DESCRIPTION OF THE QA/QC PROGRAM

4.1 *Input data*

The input data includes:

1. Project information.
2. Traffic: Number of ESAL (Equivalent Single Axle Load) in first year, growth, design period and truck speed. In Israel the ESAL is a 13 tons dual wheel.
3. Two climatic files generated using EICM (Enhanced Integrated Climatic Model) program, *.icm and thermal.tmp files [7].
4. Structure description: Up to four AC (Asphalt concrete) layers, one base, one subbase, one fill and one subgrade layers. The modulus of the AC layers can be computed using Witczak equation [7] or be entered as a 6 parameters describing the time-temperature shift and the relaxation modulus functions. Table 1 summarizes the variables required for each layer. In the table, the number of X-variables is $4 \times$ nAC + 4, where nAC is the number of AC sub layers.
5. Correlation matrix of all variables X: In most cases, we have two independent correlation matrices, one for the AC layers and the other for the unbound layers. It is important to input the dependence between variables. Assuming independence between variables may lead to unrealistic results. It is also very important to input a clean standard deviation of the variables, without the added variability due to testing, results interpretation and other [3].
6. Transfer functions for asphalt cracking at the bottom AC layer and permanent deformation for all layers. For the AC layers, the transfer function shapes correspond to those in MEPDG. The user may change the coefficients. For unbound layers, a permanent deformation transfer function shape similar to that of the AC layer was chosen, with moisture content replacing temperature (Wang et al. [18]). It is worth mentioning that each layer has its own transfer function, a sensible improvement compared to MEPDG.

4.2 *Generation of season bands*

The thermal.tmp file includes hourly temperatures at the surface, half inch and every two inches below the surface for several years. From these temperature distributions, the program computes the minimum and maximum temperatures at the surface and at the bottom of the AC layer. The temperature variation range is divided into m_1 (at the surface) and m_2 (at the bottom AC layer) intervals 7 C or less wide. Then $M = m_1 \times m_2$ season bands are generated, and every hourly temperature distribution is identified with one season. A finer and more elaborate subdivision can be found in Uzan [12]. The value of M is limited to 30 in the program. When the number of seasons is larger than 30, the width of the bands is increased until this limit is reached.

For each season band an average temperature distribution at all depths is computed. It is based on averaging all hourly temperatures that enter the band. Then, the temperature at mid depth of each AC layer is interpolated and stored to represent the temperature distribution for the season band.

Each season is assigned an identification number between 1 and M. The program then generates one long vector ($iseq(1,k)$, k = 1 to 8760 N) where every hour in the design period (N years) is identified by the corresponding season number. The damage/distress computation follows the season sequence in vector *iseq*.

4.3 *Pavement response computation*

Eigenvalues λ_i and eigenvectors $E(i,j)$ of the correlation matrix, and then the means of all variables ($\overline{x}_j$ in equations 1 and 2) for all M seasons are computed first. The AC moduli are computed at the prevailing temperature and loading time at mid depth of each sub layer. Using equations 1 and 2, the concentration points are generated, leading to 2n × M different structures. Input data for JULEA is generated and the pavement response is computed for all $2n \times$ M structures. The response from JULEA includes: (a) Tensile strain at the bottom of the AC layers and (b) Deflections at the pavement surface and at all interfaces between layers. The elastic deformation of each AC sub layer and unbound layers is computed by subtracting the deflection at the bottom interface from the deflection at the upper interface.

It is worth mentioning that JULEA can easily be replaced by a 2D-FE (Finite Element) program and reproduce level 1 of MEPDG. The reliability of the response and of the entire system may be improved by introducing nonlinear, more realistic characterization of the materials. The running time is expected to increase to about fifteen to thirty minutes.

4.4 *Analysis scheme*

The analysis scheme begins with hour $k = 1$ at:

a. Reading season number m from vector *iseq*(1,k).
b. Computing the hourly traffic.
c. Reading the pavement response at $x^{(1)}$ and season m.
d. Computing the corresponding distresses $Y^{(1)}$ (fatigue cracking, permanent deformation of all AC and unbound layers, AC and total rut depth and IRI).
e. Reading the pavement response at $x^{(2)}$ and season m.
f. Computing the corresponding distresses $Y^{(2)}$ (fatigue cracking, permanent deformation of all AC and unbound layers, AC and total rut depth and IRI).
g. Computing the mean and standard deviation of each distress at hour k.
h. Paragraphs 1 to 7 are repeated with $k = k+1$ until k reaches the end, i.e. $k = 8760$ N hours in the analysis period.
i. The output summarizing month number, accumulated number of ESAL, fatigue cracking, rut depth in the AC layers, IRI and their standard deviations is printed out in tabular form (see Fig. 1) and EXCEL diagrams.

4.5 *Preliminary calibration and verification of the system*

The system was developed to reproduce reliably AASHTO Guide results with the smallest running time. Previous studies showed that a significant part of the running time of MEPDG was consumed by the computation of the distresses, at different lateral distances for a non-zero traffic wander. Therefore the present system uses a zero traffic wander and all response computations were made under the centre of one wheel. The calibration for correcting the lack of traffic wander was made using 8 pavement structures with different AC layer

Figure 1. Output table.

thicknesses. Since the transfer functions for permanent deformation in the unbound layer is different from the one in MEPDG, the calibration involves only fatigue and rut depths in the AC layers.

It was found that the effect of traffic wander on damage D (the ratio of actual to failure number of load repetitions) for the fatigue cracking and on the rut depth RD of the AC layers is a power law of the AC layer thickness, i.e.:

$$\frac{D_{new}}{D_{MEPDG}} = 0.92815 \cdot h_{AC}^{\ 0.18253} \tag{6}$$

$$\frac{RD_{new}}{RD_{MEPDG}} = 0.1704 \cdot h_{AC}^{\ 0.3310} \tag{7}$$

where: h_{AC}—AC layer thickness, in mm. It should be noted that the damage ratio in Equation 6 (between 2 and 2.6) is very close to the ratio between pass to coverage for highways.

After the above calibration, the IRI coefficients were evaluated using nonlinear regression between IRI predicted by MEPDG and the distresses computed by the new program (without the longitudinal cracking which is not computed in new program). The corrected equation for the IRI is:

$$IRI = 69.96885 + 28.38803 * RD + 0.658362 * FC + 5.24977 * SF \tag{8}$$

$$SF = age * (0.000577 * (PI + 1) + 0.007947 * (Rain + 1) + 0.000636) \tag{9}$$

where: IRI—inch/mile, RD—mean rut depth, inch, FC—mean fatigue cracking, percentage of total area, SF—Site Factor, age—years, PI—subgrade Plastic Index, percentage and Rain—annual average rainfall, inch.

Six additional structures were used to verify the new program against MEPDG. The results are presented in Figures 2 to 5. The numbers in the legend correspond to the structure number. It is seen that the fitting is very good, except for the total rut depth. This is due to the fact that the transfer functions for permanent deformation in the unbound layers are different.

It should be noted that the number of structures for calibration and verification is small. However, this is a preliminary calibration intended to take care of the few simplifications introduced in the program, compared to MEPDG. A comprehensive calibration to local conditions is planned in the next few years.

4.6 *Remarks*

Countries outside North America (like Israel) may encounter some difficulties in implementing MEPDG, by not having the climatic input, *.hcd files or by not collecting all climatic variables included in *.hcd files. For example, cloud cover is not measured in Israel. Fortunately, the global radiation, affected by cloud cover and other factors is measured. The cloud cover during daylight is computed using the relation in the EICM between global radiation, computed direct radiation and cloud cover. The cloud cover during night hours is assumed to be equal to the computed cloud cover at sunset. The effect of this assumption on temperature distribution is relatively small.

5 CONCLUSIONS

A new program for performance related QA/QC and LCCA is described. It uses the models and transfer functions of MEPDG and is calibrated against MEPDG. The program includes the following simplifications and improvements, compared to MEPDG:

a. The traffic distribution is replaced by its ESAL.
b. The effect of wander is included via calibration.
c. Initial moisture changes of the unbound materials and aging of upper asphalt layers are assumed to take place instantaneously. Only temperature effects on the AC layers are considered. This assumption holds for Israeli conditions but this may not be the case for sites where freeze-thaw and/or varying water table conditions exist.
d. The generation of season bands proposed by Uzan [12] is adopted. It represents the temperature distributions in the AC layers better than MEPDG.
e. The running time of the program, less than one minute, is suitable for QA/QC and LCCA purposes.
f. The reliability of the distresses is computed analytically using Harr [14] approach.

ABSTRACT: Mechanistic-Empirical (ME) pavement design is being implemented for pavement rehabilitation and reconstruction in California. ME design lends itself to the development of Performance Based Specifications (PBS) for Hot Mix Asphalt (HMA) incorporating both locally available materials and properties needed to achieve desired service lives. This integration of ME design and PBS presents challenges for quality control and quality assurance, particularly for design-bid-build project delivery, more so when both ME and PBS are being introduced for the first time. This paper summarizes recent experience with integration of ME and PBS in California and ideas for addressing challenges that were identified from that experience.

Keywords: mechanistic-empirical, performance based specifications, design, construction, quality assurance

1 INTRODUCTION

Mechanistic-Empirical (ME) design tools allow the designer much greater flexibility to consider alternative materials, pavement structures, and construction quality specifications (particularly compaction) than do empirical design methods. ME design is able to consider specific materials properties in its response and performance models for both conventional and alternative materials, such as stiffness, fatigue resistance, low-temperature cracking properties, permanent deformation resistance and thermal expansion. ME design can also consider placement of different materials and compaction requirements in the structure to make best use of their unique properties, while taking into consideration constructability. ME design permits the development of reasonable designs even for materials and structures that have not been used before.

ME design also provides calculation of damage and development of each type of distress (cracking, rutting) and roughness (based on correlation with distresses, or more directly through calculation of longitudinal distribution of rutting in the wheelpaths), which allows the designer to consider alternative trigger levels for maintenance and rehabilitation and therefore their required frequency. This permits the designer to mechanistically consider pavement preservation through the life cycle based on either damage, distress or time.

Performance Based Specifications (PBS) have been defined as: "Quality Assurance Specifications that describe the desired levels of fundamental engineering properties (e.g. resilient

modulus, creep properties, and fatigue) that are predictors of performance and appear in primary prediction relationships (i.e. models that can be used to predict stress, distress, or performance from combinations of predictors that represent traffic, environment, supporting materials, and structural conditions) (1).

The advantages of integrating PBS and ME design are clear. PBS permit the designer to assume that materials constructed on the grade will have similar properties to those that are being used in the ME design structural analyses. They also permit the tailoring of specific materials requirements, such as stiffness, rutting and cracking properties, to unique features of a given project. These unique features include the particular traffic, climate, subgrade and existing pavement layers, and to locally available materials including local Reclaimed Asphalt Pavement (RAP). PBS also allow the designer to "raise the bar" with regard to specific expectations for performance related mix properties compared to what is possible with specifications that rely on aggregate and binder specifications, volumetric mix design and empirical mix tests.

The development of PBS for pavement and asphalt has been a subject of a great deal of research, including the first Strategic Highway Research Program which included the development of two approaches to mechanistic-empirical performance models and testing methods for performance-based specifications for asphalt binders and mixtures to control three distress modes: rutting, fatigue cracking and thermal cracking (2, 3). There was significant early work in this area in The Netherlands (4), particularly with regard to development and use of four-point bending for stiffness and fatigue. There has been ongoing work in Europe, mostly through RILEM, towards development of performance based testing methods and specifications going back to the 1960s (References 5, 6, 7 provide snapshots as of 1997, 2003, 2009) towards the development of international standards for characterizing and specifying mix performance properties. Several European countries are regularly using PBS for asphalt, primarily for Design-Build (DB) and Design-Build-Maintain (DBM) projects where the designer has access to precise understanding of the materials to be used and some control over their properties as part of the design process. There has been extensive work in Australia and New Zealand towards developing tests and PBS for granular bases (8, 9, 10). In addition to go/no-go specifications, performance-based incentive/disincentive pay factors for asphalt have been developed based on mechanistic-empirical performance estimates (11).

While the benefits of implementation of PBS are clear, there are a number of issues that have been identified throughout the literature, and in discussions with early implementers. One example was identified in Reference (1): "Because most fundamental engineering properties associated with pavements are currently not amenable to timely acceptance testing, performance-based specifications have not found application in highway construction".

The purpose of this paper is to provide a summary of California experience regarding development and implementation of PBS, integration of ME design and PBS, challenges that have been identified, and ideas for overcoming those challenges from an owner's headquarters perspective.

2 SUMMARY OF CALIFORNIA PRACTICE AND EXPERIENCE

California's initial implementation of PBS based on ME design began in the late 1990s when the asphalt industry was faced with the challenge of building Long-Life Asphalt Pavements (LLAP). Together, industry, the California Department of Transportation (Caltrans) and the University of California Pavement Research Center (UCPRC) determined that existing mix and pavement design methods and specification frameworks were not adequate to achieve desired goals.

The initial project was for the long-life rehabilitation of I-710 in Long Beach in southern California, designed to handle more than 200 million 80 kN (18 kip) equivalent axles, including overlays of existing concrete pavement and full-depth asphalt pavement beneath overpasses. The concepts of 1) increased compaction, 2) use of stiffer binders in thick sections and polymer modified binders in the surface layer, 3) Rich Bottom layers (better compaction,

4) slightly more binder) for bottom-up fatigue cracking and moisture sensitivity, and 5) flexural beam and repeated simple shear (RSST) laboratory testing, were implemented in the pavement designs and specifications from previous UCPRC and SHRP research (12). The designs and specifications were based on 50 percent loss of stiffness in the flexural fatigue test, repetitions to five percent permanent shear strain in the RSST, and flexural stiffness at 20 C, 10 Hz (13). The baseline materials were high quality well crushed alluvial aggregate, standard AR-8000 and special polymer modified asphalt that were locally available, but selected to provide improved performance. Use of these concepts permitted a reduction in thickness of the asphalt layers in the full-depth section of more than 35 percent, which was essential for meeting the required construction schedule with 55 hour weekend traffic closures. Phase 1 construction was completed in 2002, followed by two more phases resulting in about 100 lane-km total rehabilitated. Surveys of change in back-calculated stiffness after more than five years showed little damage, and no distresses other than some localized raveling in the sacrificial open-graded wearing course (14).

Beginning in 2000, UCPRC, Dynatest Consulting Inc and Caltrans developed the *CalME* design software which is based on incremental-recursive damage models and materials parameters from repeated load tests for fatigue and rutting (currently flexural and RSST), and frequency sweeps for testing (currently flexural). *CalME* was calibrated using accelerated pavement testing from different studies and some field sections, and evaluates reliability using Monte Carlo analysis and variability of existing layers using back-calculated stiffness measurements (15).

Ten years after the initial project, Caltrans decided to implement ME design using CalME and PBS on three northern California interstate highway rehabilitation projects, with heavy long-haul truck traffic, although fewer E80 s per year than on I-710. Design goals were at least 40 year fatigue (bottom-up or reflective) and rutting (asphalt and unbound layers) lives. Each project involved a new contractor/materials producer, and two districts also went through the process for the first time. These projects were also the first to use 25 percent RAP in the asphalt layers below the surface layer as opposed to the previous maximum 15 percent, and ME design was intended to help with consideration of the unfamiliar materials properties in the design.

All of the projects were delivered using the Design-Bid-Build (DBB) low bid approach, with the designs and specifications prepared by the owner and construction bid on by the contractor/supplier. This presents additional challenges compared to practice in Europe, where PBS have mostly been used for DB or DBM. There, the contractor prepares the design for their own materials, or can compare designs and costs for alternative materials that they can consider using. In DBM contractor develops the life cycle cost, and can consider cash flow, balancing initial construction and future preservation or maintenance activities, as well as total net present value of cost. In California, the designer must prepare specifications which are biddable, and the contractor must bid, with neither knowing beforehand exactly what the contractor can or will deliver.

2.1 *Materials and structures*

Pavement cross-sections for the three projects designed using *CalME* are shown in Table 1. Each project included milling off of thick layers of existing cracked, and at times moisture damaged asphalt to provide RAP. The thickness of the middle layer with 25 percent was the main variable changed in the structural design.

2.2 *Specifications*

The RSST (based on AASHTO T-320 [ASTM D7312]) was used to select the design binder content for each of the mixes, except the Rich Bottom materials, where 0.5% was added to the binder content found with the RSST to facilitate better compaction. To determine mix fatigue response at the selected design binder content, the flexural fatigue test (AASHTO T-321, ASTM D7460) was utilized. The moisture sensitivity response of each of the mixes was evalu-

ated using the Hamburg WTT (AASHTO T-324). All of the specimens for the performance tests were prepared using Rolling Wheel Compaction (RWC) because the aggregate structure prepared by this method is similar to that obtained in mixes during pavement construction. RWC was developed during SHRP (AASHTO PP3-94.4). In developing the test data used to define the performance requirements, the AASHTO procedures were subsequently modified published in the Caltrans Flexible Pavement Test Method LLP-AC1 (16),(17).

Specification limits were selected based on the 95 percent confidence interval for the given property based on replicate tests as shown in Figure 1. Caltrans accepts 95 percent of the risk of laboratory test variability. The procedure for developing the specification limits was developed by Tsai et al. (18). An example of the PBS is shown in Table 2. The specification requires that the PBS be applied to plant produced mix. Two contractors used plant mix and one contractor used laboratory mix to develop preliminary mix designs. All three contractors used plant mix for mix design acceptance testing as per the specification.

2a. At proposed asphalt binder content (mix containing 1.2% lime) and with mix compacted to 3%+/–0.3% air voids.

2b. At proposed asphalt binder content (mix containing RAP and 1.2% lime) and with mix compacted to 3%+/–0.3% air voids.

3. In repeated simple shear test at constant height (RSST-CH) at a temperature of 55°C at 100 kPa.

4. Minimum test value measured from tests on three specimens.

5a. At proposed asphalt binder content (mix containing 1.2% lime) and with mix compacted to 6%+/-0.3% air voids (determined using AASHTO 209 [Method A]).

5b. At proposed asphalt binder content (mix containing RAP and 1.2% lime) and with mix compacted to 6%+/–0.3% air voids (determined using AASHTO 209 [Method A]).

5c. At proposed asphalt binder content (mix containing 1.2% lime) and with mix compacted to 3%+/-0.3% air voids (determined using AASHTO 209 [Method A]).

6. At proposed asphalt binder content, the average mix stiffness at 20°C and a 10 Hz load frequency must be in the range 2859 to 3349 MPa (415,000 to 486,000 psi). At proposed asphalt binder content, the minimum stiffness at 30°C and a 10 Hz load frequency must be equal to or greater than 1516 MPa (220,000 psi).

7a. At proposed asphalt binder content (mix containing RAP and 1.2% lime), average stiffness at 20°C and a 10 Hz load frequency must be in the range 5589 to 6890 MPa (870,000 to 1,000,000 psi).

7b. At proposed asphalt binder content (with 1.2% lime), average stiffness at 20°C and a 10 Hz load frequency must be in the range 5443 to 6890 MPa (790,000 to 1,000,000 psi.).

8. At 400×10^{-6} strain, results shall be reported for this strain level but may be obtained by extrapolation. Minimum number of repetitions required prior to extrapolation defined within test procedure.

9. At 200×10^{-6} strain, results shall be reported for this strain level but may be obtained by extrapolation. Minimum number of repetitions required prior to extrapolation defined within test procedure.

10. Minimum number of repetitions for rut depth of 12.5 mm (0.5 in.) at 50°C (average of two specimens).[1]

11. The Rich Bottom (RB) mix contains the same binder as the mix with RAP, i.e., the PG 64-10; the binder content of this mix is increased 0.5% (mix basis) above the binder content used for the mix containing RAP.

Conventional Hveem mix design requirements are also included in the specification, including air void content under Hveem kneading compaction (for bleeding), aggregate specifications, voids in the mineral aggregate, voids filled with asphalt, dust proportion and tensile strength ratio (untreated and lime treated). The district where the Red Bluff and Weed projects were built generally requires lime treatment because of historical moisture sensitivity problems. Quality control and quality assurance testing during construction was based on conventional tests listed above because of the time requirements for performance related repeated load tests. The contractor had to provide new specimens for testing if the aggregate or binder source or the job mix formula changed.

The Red Bluff and Weed projects have been successfully completed in 2012. The Dixon project is paving in 2013 and 2014.

2.3 *Challenges*

A number of challenges were encountered on these three projects, including:

1. Selection of baseline material to develop specifications that are locally achievable but get the best performance possible at the lowest cost.
2. Communication of what specifications mean to potential bidders.
3. Procurement of representative local materials for design properties, especially RAP.
4. Writing of PBS, description of reliability and statement of quality requirements for different layers, and relationship to expected distress modes.
5. Communication of specification language to district materials engineers for writing of final specifications and bid package, and district construction engineers for administration of the process, including:
   a. Mix properties with respect to distress modes,
   b. Reliability, and
   c. Reasons for selection of air-void contents for each material and test.
6. Procurement of lab testing services.
7. Comparison of laboratories for performance-related tests not included in AMRL (auditable reference testing system). A similar challenge has just been experienced with tests using the AMPT testing device.
8. Assistance in advising contractor during mix design with regard to:
   a. Producing specimens,
   b. What tests mean and dealing with variability,
   c. Performance based mix design considering sensitivity of rutting, fatigue and stiffness to changes in mix, and
   d. Meeting values for conventional specifications at same time.
9. Performance-related testing values for laboratory versus plant produced mix.
10. Schedule pressures and time to perform performance-related tests.
11. Consideration of interaction of stiffness and fatigue test values from actual material on predicted structural life if materials exceeded one property by a wide margin but missed other property.

4 APPROACHES AND PROPOSED ALTERNATIVES TO DEAL WITH CHALLENGES

The approach used to meet the challenges listed in the previous section, or in some cases ideas for how to improve the PBS/ME design process are briefly discussed in this section, with number from the previous section.

Challenge 1. To obtain a better idea of what is available in the region, Caltrans/UCPRC will likely continue testing of more materials to establish regional databases. There is discussion internally and with the state industry association (CalAPA) regarding how high to set the bar within locally available materials. Experience to date shows that explicitly setting mechanistic properties will result in mix design changes to improve those properties, while under the old system those properties were unknown for the materials purchased by the state.

Challenge 2. Considering the many alternatives for aggregate in a geologically diverse state and multiple (although diminishing) sources of binder, Caltrans and industry are working to provide more explicit direction to contractors prior to bidding, particularly to address major gaps in common knowledge in a low-bid system. For example, a statement similar to this may be included on a slide in the pre-bid meeting: "Binder source for a given PG grade can possibly have a large influence on the ability of HMA to meet stiffness and fatigue specification requirements. PG grade specification only controls binder properties at the high and low temperatures, not the temperatures in between, and does not address fatigue."

Similarly, information regarding the improvement in chances of meeting stiffness and rutting requirements when using 100% crushed (>2 faces) coarse and fine aggregates will likely

also be provided. Getting the message out through industry/Caltrans meetings is also underway based on lessons learned from these three projects.

This is not a trivial matter. Bidders/contractors generally didn't seem to understand the "seriousness or severity" of the PBS requirements, and had no idea when preparing paving schedules whether mixes previously accepted by the state based on Hveem mix design would meet PBS by the date assumed. This became critical in project management after award of the contract more due to time constraints of changing plant operations and then testing time from iterations on the mix design rather than the cost of testing.

Challenge 3. Obtaining regionally representative materials in a DBB environment for laboratory testing to establish mechanistic properties for design presented some challenges, but designers relied primarily on the experience of district materials engineers. Use of properties for design from other regions is much more problematical. It was much easier to identify the effects of RAP on mix properties when the RAP samples could be milled from the existing project by district forces. On projects where the RAP was not coming from the existing pavement, obtaining representative RAP samples is more difficult, and there is risk for both the contractor and the state if RAP used is particularly different.

Overall, it is expected that as the effort to expand regional databases of properties continues there will be less need to do as much pre-testing for design (19). It is desired that contractors will become more aware of the properties of their mixes, and if there is sufficient opportunity to bid on and win PBS/ME projects this will incentivize innovation, the "if" condition being critical.

Challenge 4. Attention needs to be given to the testing and specification of properties for the polymer modified layer for top-down cracking. A bigger issues is the current approach to specifying huge numbers of required repetitions based on extrapolation of results from reasonable testing times and load repetitions for fatigue and rutting repeated load tests to specified limits initially caused consternation on the part of both contractors and district engineers. The approach used for the Caltrans specifications is described in Reference (16). It is also known that 50 percent loss of stiffness is a conservative criteria for many polymer and rubber modified binder mixes, and estimation of cracking initiation or some other "failure" criteria, as well as extrapolation is an area of additional investigation on the part of various researchers, as is discussed in References (20,21) which compare methods developed by Rowe, Franken, Hopman, Ghuzlan and Carpenter, and Pronk as well as a more recent comparison by Rowe et al. (22). *CalME* uses a damage function fit to the entire damage curve from the test in incremental-recursive analysis, and 50 percent loss of stiffness is only used for specification. A better parameter for specification of fatigue and to a lesser extent rutting, based on the damage curves, needs to be developed.

Based on discussions of The Netherlands approach and other ideas at the recent 4 Point Bending Conference, a new simpler approach for classifying materials based on the three performance tests is also being considered. The approach would require a critical mass of projects (dollars and numbers of projects) each year over a five year or longer period, for contractors to justify the cost of testing, and for commercial laboratories to consider developing equipment and human resources. In this system there would be categories of performance for rutting (Repeated Load Triaxial [RLT] or RSST), fatigue (flexural fatigue) and stiffness (flexural or compressive). Results for repeated load tests would be based on the log of the repetitions to failure to produce a linear scale of loss of stiffness for fatigue and permanent strain for RLT or RSST. How to handle two strains for fatigue needs to be determined, or a single point might be used, such as the strain that results in one million load cycles used in The Netherlands. On the order of five to ten categories might be considered. A mix may then have an A through J category for fatigue, 1 through 10 for rutting, and a through j for stiffness.

Contractors could then test their current most used mixes in advance, and know whether their mix will meet the specifications, or be close enough that they can reasonably adjust the mix design to meet them. Designers would use regional materials in the ME analysis for several mix types that should be available in the region, such as an E2f or an F3e, and determine the mixes that will provide at least the minimum required performance in the specific

structural design. While considering allowable differences in grade elevations for rehabilitation projects, alternative designs with different materials might be prepared for design by the state.

Challenge 5. Interaction headquarters and the district for each project has been found to be the best way to communicate the intent and requirements of the PBS. Some prior training may be useful for basic background, but the experience of working through a first project with assistance is invaluable. Having sufficient headquarters resources to answer questions and address problems as they arise is critical.

Challenge 6. As mentioned previously, for the laboratory testing to be moved from research laboratories to commercial or even contractor laboratories will require a multi-year commitment of enough projects to amortize the equipment and recoup the investment in human resources with a profit. Concern about whether equipment manufacturers will/can produce equipment and provide long-term service at affordable prices is also an issue. For this reason, the recent wave of investment in AMPT equipment is leading to consideration of moving to RLT testing for rutting with that device, not because the RSST is not an excellent test (and can test field cores), but because it does not have a critical mass of numbers of deployed devices. There is a concern on the part of California that initial enthusiasm for the AMPT may wane, as it did for the RSST.

Challenge 7. Certification of any repeated load testing equipment will be an issue. Quality control procedures are available, such as standard materials with known properties (developed after SHRP for SST and flexural devices), as is round robin testing of the same materials. These again need a critical mass of projects and laboratories to be worthwhile. Based on experience comparing RSST results with the University of Nevada, Reno for the Red Bluff project, and recently completing a round robin comparison of flow number and dynamic modulus results (AMPT) with three laboratories for NCHRP 9–52 shows that there will need to be clarification of steps and procedures in test methods as a part of this process.

Challenge 8. Production of rolling wheel core and beam specimens using the Caltrans method (16) was not found to be a problem using contractor built molds at the plants. Contractor training of their staff to strictly follow the specimen preparation process eliminated most problems. Similar experience has been found with Superpave gyratory specimens for RLT.

Although contractors have extensive experience with Hveem, and are learning Superpave volumetric mix design, there is not much experience balancing sometimes opposing specific performance related properties, namely fatigue and rutting. Applying in practice the "theoretical" ideas that most contractors are familiar with for balancing mix design to achieve these requirements requires additional experience. Working with contractor staff on the three recent projects showed that in a relatively short time that this experience was obtained. Having an experienced consultant (mix design and plant operations) for guidance and assistance communicating with the state also seemed to be helpful to the contractors.

Challenge 9. The time and materials required to produce plant mixed materials are considerable. However, for several mixes there was a notable difference between the properties from the plant and laboratory produced mixes. Although an exact cause was not determined, indications were that interactions of the lime treatment and mixing may have played a role, as well as binder aging. This challenge will require more investigation, however, the state wants to reduce its risk by requiring that final acceptance be based on plant mixed material which can add a significant amount of time to the testing process.

Challenge 10. It is apparent that Caltrans/UCPRC working with industry needs to improve the specifications and acceptance process, while maintaining the shared commitment to achieving the benefits of PBS combined with ME design, or else there will not be future bidders. Going up the learning curve noted in this process, while faced with the schedule delays and cost of adjusting a mix to meet PBS for the first time is a stressful experience that few contractors would want to repeat. The requirement that plant produced mix is used to pass the specification, and the length of time for low strain fatigue testing, were found to be the largest contributors to the schedule. Making adjustments to balance shear, fatigue and laboratory compaction (three variable decision-making instead of just adjusting binder content) was the biggest mix design issue. The proposed specification scheme (Challenge 4), where

contractors would test their mixes prior to bidding, is intended to help address this. However, few contractors at this time would be willing to go through that relatively expensive testing process without having already won the contract. The taking on of some additional risk by the owner by some reductions in the amount of fatigue testing, or increasing the strain levels, is one alternative that is being considered.

Because of schedule constraints for the flexural and shear tests used for acceptance of the mix design, quality control and assurance during construction relies on standard tests including checking of the job-mix formula proportions and standard aggregate and mix tests. Rapid tests that can be performed in the field and that are reasonably well calibrated with the repeated load tests used for design and mix acceptance are currently being investigated for Caltrans by the UCPRC and corresponding researchers (23).

Challenge 11. Different combinations of stiffness and fatigue behavior will produce a structure that meets the design fatigue requirements for a given project. In addition to providing a more transparent specification framework for contractors, the proposal described for Challenge 4 is intended to provide more flexibility for designers to consider alternative combinations of these properties.

5 CONCLUSIONS AND RECOMMENDATIONS

Performance based specifications and mechanistic-empirical designs provide a means to produce materials and designs that decrease life cycle cost for the state, and a framework for competitive innovation to "raise the bar" for contractors and materials producers. Challenges have been identified, many particular to the design-bid-build project delivery method, and lessons learned from the three projects described in this paper. These should result in changes to the current process to reduce risk for contractors and the state, and particularly to improve transparency and understanding of what they need to do to be successful for contractors.

It is recommended that Caltrans, industry and academia work together, as they have in the past in California, to meet these challenges.

The use of performance specifications to improve pavement design and sustainability in the UK

Bachar Hakim & Richard Elliott
URS Infrastructure & Environment, Nottingham, UK

ABSTRACT: Recent developments in UK pavement design using performance specification and end-product testing, have helped designers to optimise the materials and improved construction quality, future performance and sustainability. Assessment of unbound and hydraulically bound materials performance using the Springbox and the Light Weight Deflectometer (LWD), permit the use of a wide range of binders including cement, lime, slag and fly ash with marginal, recycled and secondary local aggregates. The Springbox characterises stiffness and deformation resistance of unbound and weakly bound materials to ensure durability. The LWD is a hand held device that measures the in-situ foundation surface stiffness during construction. Asphaltic materials are also specified in terms of performance rather than recipe to ensure the design parameters are met during construction. This paper describes the recently introduced UK pavement design, testing and specification requirements. Case studies are presented which demonstrate the implementation of the procedures in order to improve pavement performance and sustainability.

Keywords: Pavement design, performance specification, materials optimisation, sustainability

1 INTRODUCTION

Traditionally, the UK pavement specifications were based on a recipe approach, where selected materials are laid and compacted with specified plant in a specified manner to achieve a minimum level of performance. However, performance specifications and end-product testing have gradually been introduced to the UK standards in order to optimise the range of materials used (including recycled, locally won, and industrial by-products), to improve both quality and sustainability. Therefore, the impact of improved material properties on the pavement design thickness and expected life can be considered. This paper presents the design development and testing requirements together with practical case studies to demonstrate the advantages achieved.

2 UK PAVEMENT DESIGN DEVELOPMENT

2.1 *Foundation design*

UK pavement foundation design was based primarily on the use of the California Bearing Ratio (CBR) to characterise the subgrade, capping and sub-base materials [1]. The thicknesses of sub-base and capping materials are determined from the subgrade CBR to achieve a "standard pavement foundation" (see Fig. 1). The foundation design was independent of traffic levels and had no impact on upper pavement bound layer thicknesses. The benefit of using a stiffer foundation, such as a cement bound sub-base below the asphalt, did not reduce the upper pavement layer thickness in this design method; even though it would improve pavement support and overall bearing capacity.

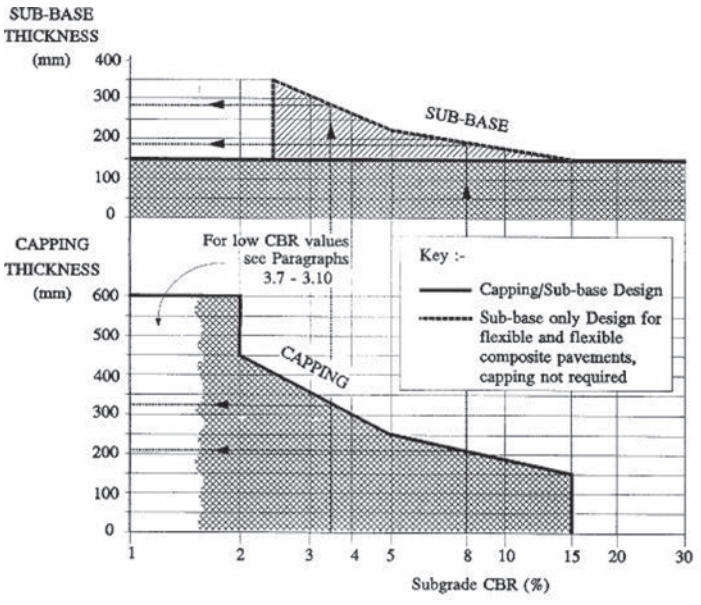

Figure 1. UK standard pavement foundation design [1].

Although CBR has been correlated with pavement performance in many countries over many years and provides a trusted empirical indicator of material behaviour, the use of CBR as a performance parameter is widely acknowledged as being not wholly satisfactory [2]. Furthermore, the need for a fundamental engineering property (such as stiffness) to describe the unbound and weakly bound materials has become important for use in analytical/mechanistic design methods. The stiffness modulus of a pavement foundation is a measure of the quality of support which is provided to the overlaying asphalt or concrete layers. Advances in the in-situ testing of pavement foundation materials now allow the performance parameter of stiffness (and, more indirectly, strength and resistance to permanent deformation) to be measured on a routine basis during construction. This in turn enabled a performance based specification for road foundation layers to be introduced in the UK, hence facilitating the use of secondary aggregates, marginal materials and stabilised ground.

The Falling Weight Deflectometer (FWD) and Light Weight Deflectometer (LWD) measure the composite foundation stiffness under a transient load pulse, which is applied to the ground by dropping a weight onto a bearing plate via a rubber buffer (see Fig. 2). The deflection of the ground is measured and combined with the applied load to calculate the stiffness using conventional Boussinesq analysis. However, the LWD is a hand held device and hence more practical for compliance monitoring during foundation construction.

The Springbox was developed by URS/Scott Wilson as part of a UK Highways Agency sponsored project [3], in response to the fact that over the last 10 years, pavement designers have been moving towards the use and measurement of stiffness modulus for pavement foundations and away from traditional empirical index tests such as CBR. One of the objectives of this recent approach is to allow a wider range of materials to be used for capping and subbase construction, based on their mechanical properties, within the general move towards end-product based specifications. The Springbox (see Fig. 3) is used to assess the stiffness and deformation properties of unbound and weakly bound materials in the laboratory. The equipment enables a realistic material compaction level to be applied during preparation, followed by repeated vertical loading with various magnitudes to represent trafficking during construction with appropriate pavement confinement. The device can be used to characterise the fundamental material properties, considering various mixtures with different moisture

Figure 2. Falling Weight Deflectometer (FWD) and Light Weight Deflectometer (LWD) tests on a trial foundation.

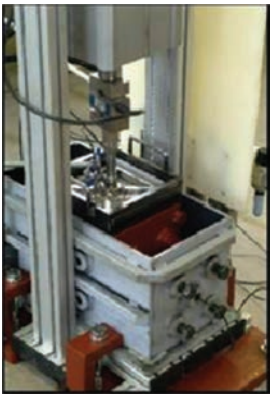

Figure 3. The springbox test.

contents and binder types, as well as ageing, temperature and saturation levels, for use in the analytical/mechanistic pavement design approach.

The recent UK pavement design method [4] considers four foundation classes defined by a long term in service "Foundation Surface Modulus":

- Foundation Class 1 ≥ 50 MPa (typically capping layer over subgrade).
- Foundation Class 2 ≥ 100 MPa (typically unbound sub-base over subgrade).
- Foundation Class 3 ≥ 200 MPa (weakly bound sub-base over subgrade).
- Foundation Class 4 ≥ 400 MPa (strongly bound sub-base over subgrade).

The "Foundation Surface Modulus" is based on application of a known load at top of the foundation (e.g. by LWD) and represents a composite value with contribution from all underlying layers. A "Layer Stiffness Modulus" is assigned to a given foundation layer to represent the in-situ condition and account for long term degradation and cracking. An "Element Stiffness Modulus" is assigned to a discrete sample of material and usually characterised

by laboratory testing (e.g. Springbox) of an intact sample with no account of degradation and cracking. Therefore, the foundation layers are characterised in the laboratory and then assigned a "Layer Stiffness Modulus" to account for future deterioration. The design charts (or a multi-layered elastic model) are then used to calculate the layer thickness over a given subgrade stiffness to meet the specified Foundation Class. A demonstration area is constructed and tested to assess the actual expected foundation performance for the site under consideration; and finally end-product testing is carried out to ensure that the foundation design requirements are met during construction. The details of laboratory and in-situ testing, demonstration area and compliance testing during construction are presented in the foundation design guidance [4].

Figure 4 shows a typical design chart for Foundation Class 2 with a "Foundation Surface Modulus" of 100 MPa. However, using a multi-layered elastic model provides the flexibility to consider multiple foundation layers and/or different layer stiffnesses to meet the "Foundation Surface Modulus" requirements.

Figure 4 shows that 225 mm of unbound subbase (typically with a layer stiffness of 150 MPa) over a subgrade with 5% CBR (stiffness modulus of 50 MPa) is needed to meet the Foundation Class 2 requirements. However, a sub-base thickness of 160 mm with a layer stiffness of 350 MPa (typically stabilised) can also meet the above foundation class. Therefore, using marginal, recycled and secondary aggregates with the appropriate binder content to achieve the subbase layer stiffness can justify foundation thickness reduction, leading to cost and sustainability benefits, provided end-product performance testing (e.g. LWD) is carried out. This option was not permitted in the previous design standard as shown in Figure 1. An additional advantage of introducing the four foundation classes is the possible reduction of upper pavement layers to account for the contribution of stronger/stiffer foundations as detailed in next section.

The design standard still permits the use of recipe foundation design, but with thicker construction compared with the performance design to account for materials variability. This option would be used on the smaller projects where the cost of additional materials testing is not justified.

2.2 *Hydraulically bound mixture*

The recent UK pavement design standard allows the use of a wide range of Hydraulically Bound Mixtures (HBM) with cement, lime, slag and fly ash binders with marginal, recy-

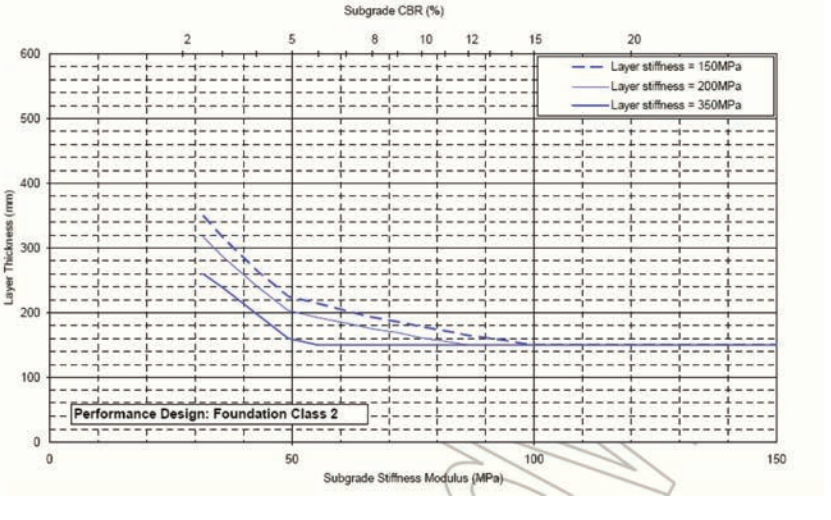

Figure 4. Foundation performance based design—foundation class 2 [4].

cled and secondary local aggregates, provided their fundamental properties are assessed during the design and monitored during construction. HBM can be used in the foundation to meet the above foundation classes or as a lower base in flexible composite constructions, where HBM base thickness and category are specified during the design stage and monitored for compliance during the construction stage. Examples of HBM categories and strength requirements for various binder and aggregate types are shown in Table 1. Cement Bound Granular Mixtures (CBGM), Slag Bound Mixtures (SBM) and Fly Ash Bound Mixtures (FABM) with various compressive/tensile strengths are presented in Table 1 to comply with HBM categories and design requirements.

2.3 *Asphaltic material*

The UK asphaltic material includes various types such as Hot Rolled Asphalt (HRA), Dense Bituminous Macadam (DBM) and High Modulus Base (e.g. EME2) materials with different mix design, stiffness and binder properties. The design allows the use of thinner constructions if stiffer asphaltic materials are used (see Fig. 5). The asphaltic mixtures are specified in terms of laboratory stiffness during the design stage and monitored for compliance during construction by testing samples extracted from the pavement. Additional testing to assess the deformation resistance, water sensitivity and durability of the asphaltic mixtures are also recommended during the mix design stage. Other mixtures such as those containing percentages of reclaimed asphalt and cold/hot in-situ/ex-situ recycled materials are permitted, provided their properties are assessed and tested. The use of recipe mixtures is also permitted in the current standard if required.

Figure 5 shows an asphalt thickness of 265 mm incorporating EME2 binder/base compared with 320 mm incorporating DBM50 binder/base over foundation class 3, to carry a traffic loading of 80 millions of equivalent standard axle load (msa). Another advantage of the design method is the reduction in asphalt thickness when stiffer (e.g. stabilised) foundation is specified. Figure 5 indicates an asphalt thickness incorporating DBM50 binder/base of 280 mm over Foundation Class 4, compared with 360 mm over Foundation Class 2 to carry future traffic of 80 msa.

2.4 *Pavement quality concrete*

The use of jointed reinforced/un-reinforced concrete pavements for new construction is restricted due to high maintenance cost, construction delay, noise and poor ride quality. However, Continuous Reinforced Concrete Pavement (CRCP) and Continuous Reinforced

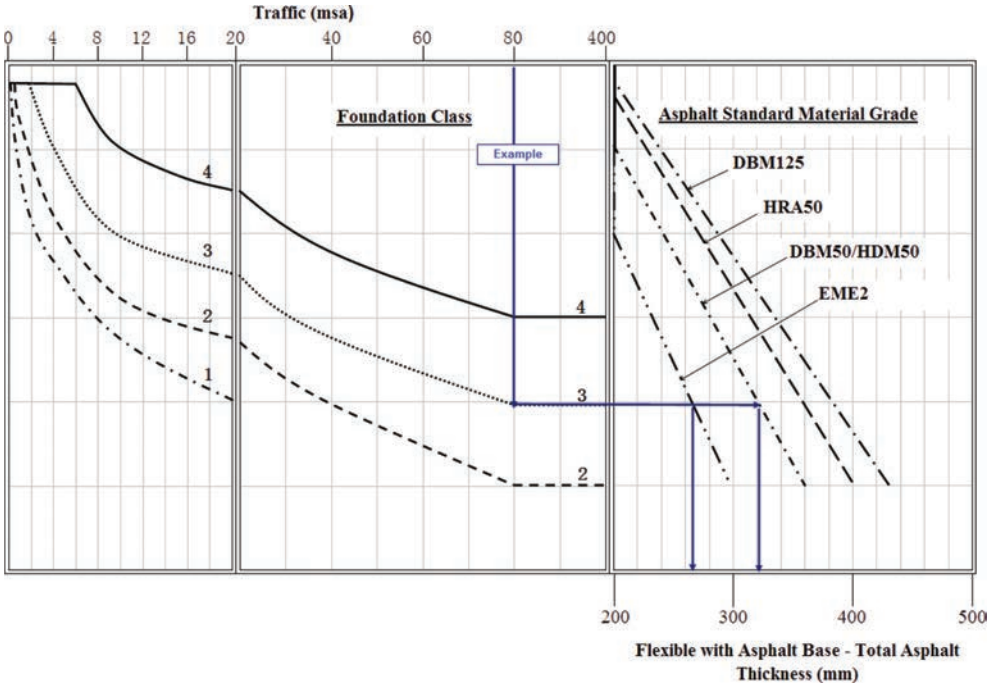

Figure 5. Extract from the UK flexible pavement design guide [5].

Concrete Base (CRCB) with asphalt surfacing are recommended for heavy traffic and poor subgrade, if initial construction and life cycle cost is appropriate. The recent design standard [5] has introduced various concrete grades with flexural strength of 4.5, 5.0, 5.5 and 6.0 MPa to allow the use of wider design options. The previous design was based on a single concrete compressive strength, and limited to 40 MPa.

3 ENVIRONMENTAL BENEFITS

Potential benefits to the environment from using the recent standard can be expected as a result of a number of factors such as; using marginal, secondary, local and recycled aggregates with a wider range of binders including slag and fly ash in foundation design, reducing foundation thickness when stabilised, and using thinner upper bound layers with a stiffer foundation. Advantages of using thinner but stiffer pavements include; reducing aggregates and binder use; reducing aggregate production (crushing, processing and transportation); reducing the effort of mixing, transporting, laying and compacting the asphalt/concrete mixes and associated vehicle movements during construction; reducing fuel cost and CO_2 emissions; and reducing project time, resources requirements, noise and disruption to the public.

The performance testing improves construction quality and provides a better material durability with longer service life and/or less maintenance work. This helps reduce the requirement for premium aggregates for maintenance or resurfacing works.

4 CASE STUDIES

Case studies carried out before and during the introduction and implementation of the performance specification are presented. Foundation material design optimisation, ex-situ recy-

cling using "Foamix" base, stabilised surfacing for a cycle track, and asphalt mixture design for an airport taxiway are detailed in the following section.

4.1 *Use of secondary and marginal materials in pavement foundation*

The use of local secondary and marginal materials in pavement construction has environmental and economic advantages, such as reducing the importation of virgin graded granular materials. However, these materials do not usually comply with the current standards in terms of grading and mechanical properties. Therefore, performance specifications rather than those based on recipes need to be implemented in order to ensure that the design assumptions are met during construction. Examples of UK projects where secondary and marginal materials have been used in pavement foundations are:

- A2—M2 (Kent): Various subgrade improvement materials including cement stabilised chalk, Ragstone (local sandstone) and recycled crushed concrete.
- A27 Polegate (Sussex): Lime/cement stabilised Weald clay.
- A43 Towcester to M40 (Northampton): Oolitic limestone and planings.
- Doncaster North Bridge: Urban widening of road incorporating marginal materials.
- A63 Selby Bypass: Sand subgrade improvement and sand/PFA/cemented sub-base.
- Tilbury Docks: Berths 41–43: Crushed concrete capping and sub-base.

The test results were used to support and validate the recent design standard [4]. Various performance tests were carried out during field trials and actual constructions to ensure quality control. These tests are summarised by Brown [6]. The test results of a section of the A63 Selby Bypass project are shown in Figure 6, where an in-situ initial foundation surface stiffness of 500 MPa was specified for all but two from ten consecutive tests, with an absolute minimum stiffness of 250 MPa.

4.2 *Pavement foundation design optimisation, Romania*

The Transylvanian motorway, sponsored and owned by the Government of Romania, is one of the largest highway projects in Europe. The construction of the new 26 m wide dual two-lane motorway, stretching 415 km northwest from Brasov in central Romania to Oradea on the country's border with Hungary is particularly important for Romania's integration into the European economy. The indicative pavement design raised a number of sustainability issues and recommended optimising the foundation design using local aggregates for the production of a cost effective sustainable solution. The design team visited the country in order to gather useful local knowledge and to identify the most economic and sustainable pavement design.

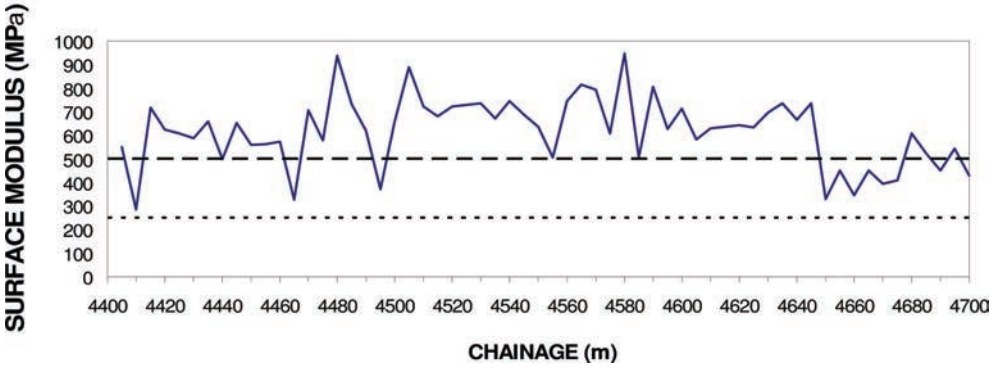

Figure 6. A63 Selby Bypass FWD foundation stiffness at 28 days.

The Springbox equipment was used to assess the mechanical properties of unbound and weakly bound materials. Various mixes with different binder contents were tested to measure stiffness. For subgrade improvement, silty-clay subgrade, local sand and gravel, and crushed rock subbase, as well as cement treated base materials were tested. The effect of high moisture content on stiffness was also investigated.

The design presented a number of benefits for the client including:

- Minimum performance requirements specified for locally sourced cement bound base, which otherwise shown to have a high impact on the life of the overall pavement.
- In situ foundation performance specification introduced, and technology transfer.
- Designs mitigated against early wheelpath rutting failure.

4.3 *Using ex-situ cold mix base materials*

Ex-situ cold mix base using recycled aggregates offers an alternative, environmentally friendly pavement solution. However, the mixture properties in terms of stiffness and durability need to be established in order to design pavements incorporating such materials. Experiments with seven variants of cold recycled mixes were conducted at a Quarry. These included natural aggregates, processed demolition waste, blast furnace slag, crushed concrete and reclaimed asphalt planings. Cement was added to all but one section, which incorporated granulated blast furnace slag and PFA activated by steel slag fines as a hydraulic binder (see Fig. 7). The recycled base was laid to a thickness of 150 mm, in 15 m long and 3 m wide test sections. The test pavements were monitored for a period of one year, with all sections instrumented with stress and strain gauges in an attempt to evaluate the response of the pavement to traffic loading. FWD data showed strength steadily increasing over the first six months, at which point curing appeared to be substantially complete as shown in Figure 8. Design stiffnesses of 2500 MPa were achieved after 1 year, comparable to conventional hot-mix asphalt.

4.4 *A9 Millennium Route cycleway, Scotland*

Site investigation along selected sections of the A9 Millennium Route cycleway in Scotland showed that the natural ground generally consisted of topsoil and soft material (with CBR of less than 5%) ranging from 50 mm to over 1000 mm in depth, on a non-cohesive subgrade capable of achieving over 15% CBR.

The investigation and optimisation work included tests carried out on virgin land along the proposed cycle track route; advice on construction that made best use of local resources; in-situ and laboratory based testing carried out over selected lengths during construction; and finally, in-situ and laboratory based testing carried out over the length of the completed cycle track. The design used a geotextile to 'float' the track across

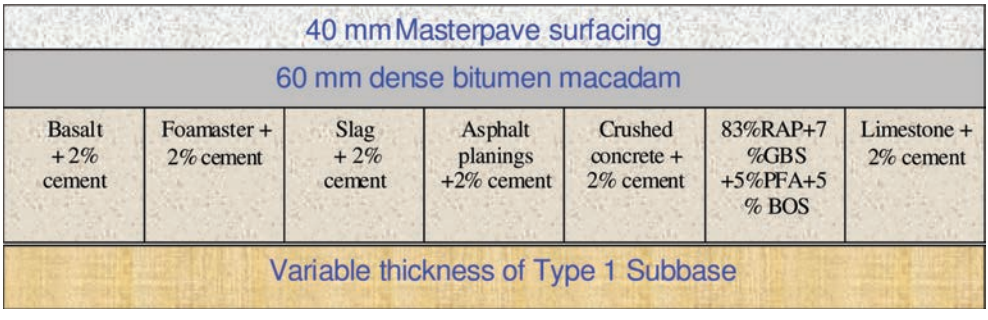

Figure 7. Ex-situ cold mixes with recycled aggregate trials.

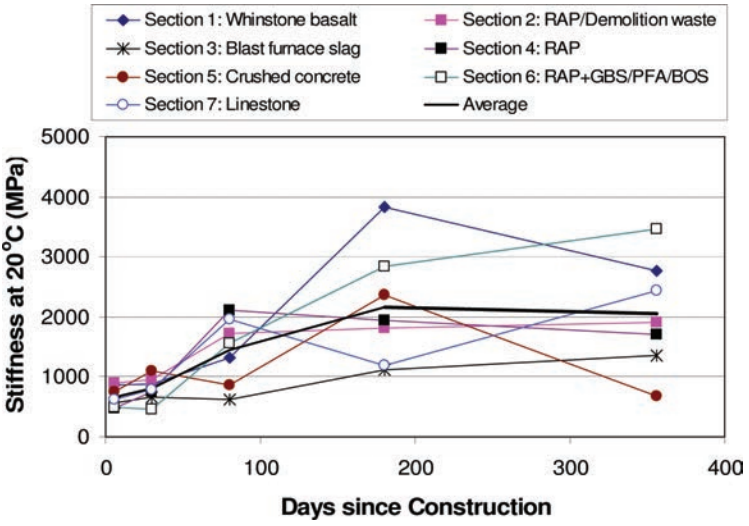

Figure 8. Ex-situ cold recycled mix trials and FWD stiffness development over one year.

lengths of deep peat subgrade, and a slag-bound subbase (comprising 5% GGBS with 2% cement and 93% granular material—i.e. making good use of locally available raw and secondary materials), surfaced with Fibredec, to provide a cheaper and more environmentally friendly alternative to conventional bituminous materials. Fibredec is a unique combination of bitumen emulsion, chopped glass fibres and aggregate. Final testing, around 18 months after construction began, revealed good structural performance characteristics, with only one localised crack defect, coinciding with a length of peat subgrade being visible. It was recommended that laying of hydraulically bound materials incorporating slow setting binders should be restricted to the summer months, when there is no risk of the minimum air temperatures falling below 10°C, if the potential strength and stiffness properties of such materials are to be achieved in-situ. Furthermore, due to the slow strength of HBM, particular attention should be given to protecting the surface of the material with a surface seal (e.g. surface dressing, slurry surfacing or a proprietary product) applied to ensure water is shed, and the long term durability of the pavement structure is improved.

4.5 *Airport pavement design, Isle of Man Airport, UK*

A detailed pavement investigation indicated that the airport taxiways were in poor condition and required reconstruction to carry future traffic loading. An alternative pavement option (to the conventional asphalt reconstruction) using cold in-situ recycling to meet the technical and financial requirements was considered for the taxiway strengthening. The design process included materials testing and performance specification to ensure the appropriate HBM category (incorporating existing aggregates) would be met during construction. The pavement rehabilitation consisted of in-situ cold recycling of 250–265 mm of existing pavement with 100 mm new asphalt surfacing to carry future traffic loading.

The design considered the Waste and Resources Action Programme (WRAP) Halving Waste to Landfill Initiative and negated the need to dispose hazardous tar bound materials found during the pavement investigation. The recycling option delivered a sustainable solution with substantial reductions in cost (40%), energy consumption (44%) and carbon dioxide emissions (32%), when compared against the conventional reconstruction design. Full details of the project are given by Hakim and Ferguson [7].

5 CONCLUSIONS

The advantages of pavement design using performance specifications include; wider construction options; using local, marginal, secondary and recycled materials; better quality control and durability; and improvements to pavement sustainability and whole life cost.

The use of improved foundations with stiffer/stabilised materials to reduce the pavement layer thicknesses is permitted in the recent design approach. These advantages, together with the flexibility of using a wider range of Hydraulically Bound Mixtures (HBMs), plus asphaltic and concrete materials, have helped designers to optimise the pavement construction and materials compared with the previous design requirements. However, there is the need for associated laboratory and end-product performance testing to assess the fundamental material engineering properties as part of the design and construction process.

Case studies have demonstrated the successful introduction of the design approach where material development, laboratory testing and performance requirements were carried out, and design solutions with sustainability and cost benefits were developed.

Impact on the use of Reclaimed Asphalt Shingles on mixture and recovered binder properties

Gerald Reinke, Stacy Glidden, Steve Engber, Mary Ryan & Doug Herlitzka
MTE Services Inc., Onalaska, WI, USA

ABSTRACT: The use of reclaimed asphalt shingles in bituminous mixtures has increased significantly in recent years. The information reported is part of a series of on-going investigations into the impact of RAS (Reclaimed Asphalt Shingles) and RAP (Reclaimed Asphalt Pavement) at 20% or higher levels of binder replacement. Laboratory mixtures using recovered shingle binder blended with virgin PG 58-28 and PG 52-34 were compared to mixtures produced with 20% binder replacement using reclaimed shingles. Rutting tests on unaged and Overlay Tester evaluation of mixes before and after aging at 85°C were conducted. Results indicate that initial properties of RAS mixtures appear acceptable, however mixture properties after aging show severe degradation, especially with regard to fatigue for all mixtures. In 2012 a field study was initiated to evaluate mixes produced with 20% RAS and 10% RAP binder replacements. Both PG 58-28 and PG 52-34 virgin binders were used. Control sections of 20% and 31% RAP only were constructed using PG 58-28. Initial evaluation of field cores followed by laboratory aging indicate that the RAS containing mixtures' stiffness and recovered binder properties deteriorated at a faster rate than RAP only mixtures. Increases in asphaltenes with aging are highly correlated to a significant increase in the m-value failure temperature of the RAS mix recovered binders. Cores procured approximately one year after construction show substantial aging, especially of recovered binders. Also reported are data from cores removed after 2 and 3 years in service wherein the binder lifts were constructed using 20% RAS binder replacement.

Keywords: shingles, RAS, RAP, binder replacement, mixture fatigue, 4 mm DSR (Dynamic Shear Rheometer) test

1 INTRODUCTION

In the past several years the rising cost of crude oil has pushed the price of paving grade asphalt binders to historically high values. There is little reason to believe that this situation will revert. As a consequence pressure has increased to use higher levels of binder replacement from Reclaimed Asphalt Pavements (RAP) and more recently from Reclaimed Asphalt Shingles (RAS). While historically the amount of binder replacement in bituminous mixtures averaged in the 15–20% range in states that embraced the use of RAP, recent economic pressures have resulted in efforts to allow upwards of 50% binder replacement and higher in some locations. The burgeoning growth and sophistication of the post-consumer waste shingle grinding industry has added another dimension to the issue of binder replacement. Ready access to reliably available ground shingles coupled with the knowledge that shingles typically contain 20% or more bituminous material has further increased pressure on agencies to allow 20% or more binder replacement from RAS plus 10% or more binder replacement from RAP in bituminous mixtures. Some states were early adopters as they saw the use of shingles as a means to reduce the need to use more expensive polymer modified binders to reduce pavement rutting. Some agencies had reservations about the wisdom of using high levels of binder replacement derived from the very stiff and brittle binder present in shingles.

Regardless of the position taken on the use of RAS in bituminous mixtures there does not appear to have been an evaluation of the long term impact of binder replacement obtained from RAS on pavement performance, especially with respect to fatigue and thermal cracking performance. The information provided in this report is an effort to introduce data on the aging characteristics of RAS containing mixtures and initiate discussion and evaluation of these mixtures within the asphalt research community with a view towards the long range benefit to user agencies and the paving industry of using RAS materials in bituminous pavements.

2 INVESTIGATIONS

2.1 *Initial laboratory research*

An initial experiment was designed to investigate the impact of aging on a Wisconsin 3 million ESAL limestone aggregate mix produced with 22% RAS binder replacement in PG 58-28 and PG 52-34 binders. Most of the blends were produced with the addition of 5.4% RAS into the mix, but two sets of mixes were produced with PG 58-28 and PG 52-34 blended with 22% RAS binder which had been extracted and recovered (using ASTM D5404) from the shingle source used in the study. The complete list of samples tested is shown below:

1. PG 58-28 virgin binder mix control
2. PG 58-28 + 22% recovered shingle binder
3. PG 58-28 + 5% RAS (=22% binder replacement)
4. PG 58-28 + 5% RAS + 0.5% warm mix additive
5. PG 58-28 + 5% RAS treated with 5% of a Proprietary Renewable Additive (PRA) bio oil added by wt. of binder in the RAS
6. PG 52-34 + 22% recovered shingle binder
7. PG 58-28 + 5% RAS (=22% binder replacement)
8. PG 52-34 + 5% RAS treated with 5% a PRA bio oil added by wt. of binder in the RAS

All mixes were produced at 135°C, conditioned for 2 hours at 135°C and compacted at 135°C. One set of specimens was tested without further aging and another set was aged for 5 days at 85°C prior to testing. Hamburg testing under water at 50°C and dry at 58°C was performed on the unaged mix. That data will not be presented, but is available. Overlay tests [1] were performed at 20°C on both the unaged and aged mix samples. The results are shown in Figure 1. The PG 58-28 unaged virgin mix shows very good results, but there is substantial reduction in cycles to failure after 5 days of aging. Several of unaged RAS mixes performed at an acceptable level; most notably the PG 52-34 + 22% recovered shingle binder, the PG 52-34 with 5.4% RAS and the PG 52-34 with 5.4% RAS to which the PRA oil had been added. After 5 days of aging at 85°C the overlay results of those mixes, as well as all the other mixes containing either preblended shingle binder or RAS shingle additive, collapsed to 8-18 cycles to failure. The results for the unaged mixes produced with PG 58-28 preblended with shingle binder, PG 58-28 with 0.5% M-1 warm mix additive plus 5.4% RAS, and PG 58-28 plus 5.4% RAS were nearly identical. The results of mix produced with PG 52-34 preblended with shingle binder and mix produced with PG 52-34 where the RAS was added to the aggregate showed similar overlay results. These data indicate that for short term aged mixes (2 hours prior to compaction) there is little or no difference between whether the shingle binder is intimately blended with the virgin binder or the virgin binder and RAS binder are combined at the time of mixing.

As a further investigation of the impact of shingle binder on mix behaviour mixture stiffness modulus was determined using a DSR torsion bar test (ASTM D7552). Mixture stiffness was measured in 10°C increments from –40°C to +40°C over a frequency range of 100 to 0.02 radians/sec. Using RHEA™ software published by Abatech [2] the measured complex modulus mastercurves was interconverted to relaxation modulus mastercurves. Figure 2 is plot of selected relaxation modulus mastercurves at a reference temperature of 20°C. Not all data has been plotted so that what has been shown is readable. As the mixes are aged the

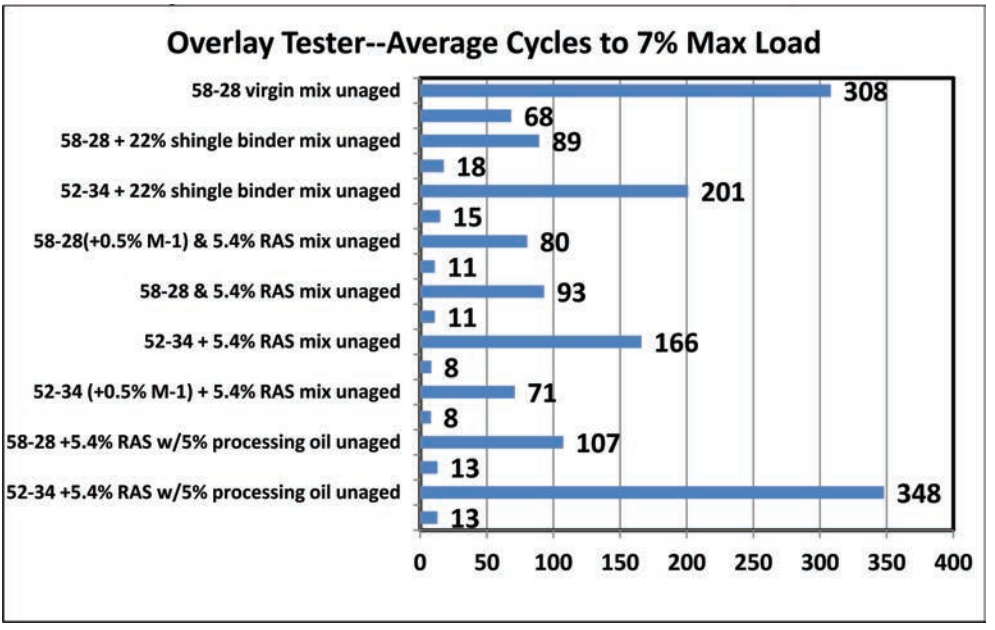

Figure 1. Overlay test results for unaged and aged mix specimens.

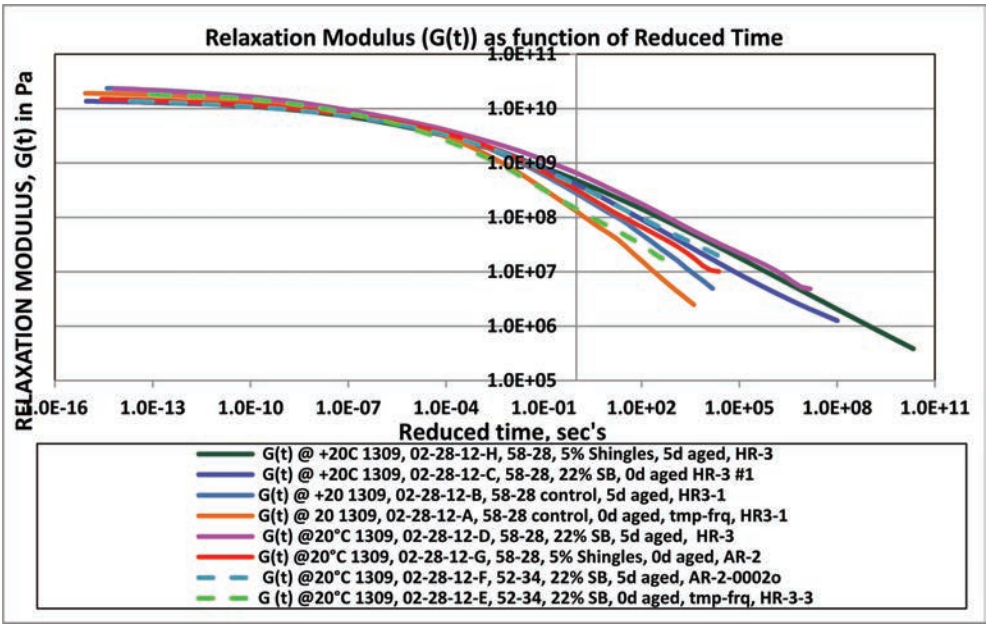

Figure 2. Relaxation modulus of unaged and 5 day aged mixes.

slopes of the relaxation modulus mastercurves begin to flatten as relaxation time increases. The PG 58-28 virgin control mix has been plotted to provide a reference for comparison. It is important to note that the relaxation modulus for the PG 58-28 + 22% added shingle binder and the PG 58-28 + 5.4% RAS are nearly identical for both the unaged and the 5 day aged condition. The moduli of these mixes is a more fundamental property than the overlay test,

but the modulus data also demonstrates that whether there is 100% preblending of the shingle binder with virgin binder or the shingle binder is introduced into the mix via the ground shingles the relaxation properties of the unaged and 5 day aged mixes are the same. The relaxation moduli of the unaged and 5 day aged PG 52-34 + 22% shingle binder mixes has also been plotted. Unlike the overlay test result where the 5 day aged mix exhibited the same cycles to failure as the aged PG 58-28 shingle mixes, the PG 52-34 + 22% shingle binder 5 day aged mix has a relaxation modulus plot comparable to the unaged PG 58-28 shingle binder and RAS containing mixes. However this result does mean that the PG 52-34 shingle binder mix suffered substantial stiffening and is now comparable to the unaged PG 58-28 shingle containing mixes whereas the unaged PG 52-34 + 22% shingle binder mix was comparable to the PG 58-28 virgin control.

2.2 *RAS and RAP shoulder paving research study*

In September of 2012 Mathy Construction Company placed four test sections using varying levels of RAS and RAP on the shoulder of a project on USH 14 east of St. Charles, Minnesota. The project consisted of the following test sections produced with a 3 million ESAL mix:

1. PG 52-34 binder, 6% RAS (22% binder replacement), 11% RAP (12% binder replacement)
2. PG 58-28 binder, 6% RAS (22% binder replacement), 11% RAP (12% binder replacement)
3. PG 58-28 binder, 31% RAP (32% binder replacement)
4. PG 58-28 binder, 20% RAP (21% binder replacement), the control mix for the project

2.2.1 *Initial testing of mixes*

In November of 2012 three cores were cut from each test section and tested. One unaged core, one core aged 5 days at 85°C and one core aged 10 days at 85°C from each test section was cut into torsion bars for mixture modulus testing at –40°C to +60°C. Following these mix tests binder from the torsion bars of each section and aging condition were extracted and recovered and the binder tested using a 4 mm DSR test procedure [3] at –40°C to +60°C following procedures developed by Western Research Institute (WRI). The 4 mm DSR test enables determination of full mastercurves of the binders, which were generated at +20°C. In addition using procedures developed by WRI the low temperature PG properties of the binders were determined [4]. Lastly Iatroscan [5] testing was performed on the recovered binders to obtain asphaltene, cyclic (aromatic), resin and saturate fractions of each recovered binder.

2.2.2 *Follow-up testing of mixes*

In August of 2013 four cores were obtained from each test section. These cores for each section were taken within approximately a 3 meter length of pavement. The top 12 mm and second 12 mm layers were cut from one core and the binder from each layer was extracted and recovered. The top 12 mm and second 12 mm layers were cut from another core and each layer was cut into torsion bars for mixture modulus testing. Testing of both layers was performed to ascertain the extent of mix and binder aging with depth. The other two cores were set aside if additional follow-up testing was needed. The binder and mixture testing performed was similar to that described for the initial cores.

2.2.3 *Findings from initial and follow-up testing*

The low temperature recovered binder properties based on 4 mm DSR testing is shown in Table 1; the asphaltene content is also shown.

Asphaltenes were determined as the n-heptane insoluble fraction. Based on the recovered binder testing of the initial cores, the m-critical temperature is highly correlated to the per cent asphaltenes in the recovered binder. This is shown in Figure 3.

Table 1. Asphaltene and low temperature critical data for 2012 & 2013 cores USH14 shoulders.

Mix type	Days of 85°C core aging (or as noted in table)	Asphaltenes	m-critical temp, °C (mcT)	S-critical temp, °C (ScT)	ΔTc (S-critical-m-critical)

2nd 12 mm	11 months field	22.1	–32.3	–31.9	+0.4

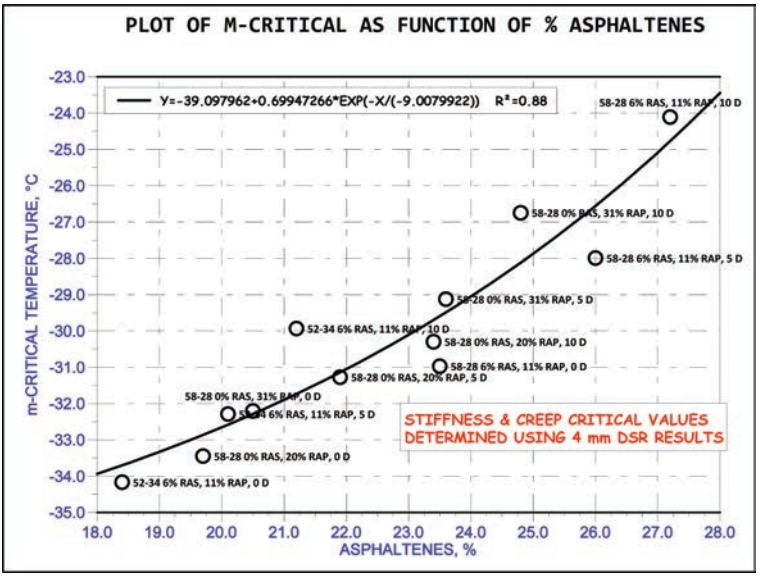

Figure 3. m-critical temperature as a function of per cent asphaltenes for 2012 cores.

When the asphaltene data for the top and second 12 mm mix layers of the 2013 cores is plotted on this same data set (Fig. 4) it is apparent that the binder from the top 12 mm layers have moved substantially towards that of the 5 day aged 85°C aged mixes. The PG 58-28 RAS/RAP recovered binders from the both layers plot much closer to the 5 day aged data than the unaged. The data for the PG 58-28 with 20% RAP has not been plotted on this chart so the other data is easier to visualize. For the 20% RAP mix Table 1 shows about a 1°C increase in m-critical for the recovered binder, but the asphaltene content for both layers has increased from 19.7% to 22.7%, which is comparable to the increases for the other mixes. At the same time the ΔTc for the 20% RAP only mix and to a lesser extent the 31% RAP only has not increased by the same amount as the ΔTc increase for the RAS containing mixes when compared to the ΔTc increases for the binders recovered from original unaged cores taken in 2012. This increase in the rate at which ΔTc increases for the binder in RAS containing mixes may well be a causative factor in the poorer fatigue performance and loss of relaxation properties in these mixes. What is not known however is a mechanism by which this process occurs and a means of altering or stopping it.

Mixture stiffness modulus was obtained on the top two 12 mm layers using the DSR torsion bar test procedure. Mastercurves were determined at a reference temperature of 20°C. Results for Test Section 2, the PG 58-28 mix containing 6% RAS and 11% RAP is plotted in Figure 5. There was a moderate increase in mixture stiffness between the unaged and 5 day aged mixture samples; however, there was a more substantial increase in stiffness for the 10 day aged core specimens. For the 11 month field cores taken in 2013 the stiffness modulus of the top 12 mm of mix is greater than the stiffness of the 5 day aged core from 2012, while the second 12 mm layer has stiffness equal to or slightly less than the original unaged core. Figure 6 is a similar plot for the Section 1 cores. Only the top 12 mm mixture modulus results are shown and again the mixture stiffness after 11 months in the field shows that the mix is as stiff as the 5 day aged core in 2012. The second 12 mm layer stiffness for the 2013 core was similar to the unaged 2012 core.

The top layer of the 11 month field core for the 31% RAP mix had stiffness comparable to the 5 day aged core taken in 2012; however the 5 day aged mix from 2012 was only moderately

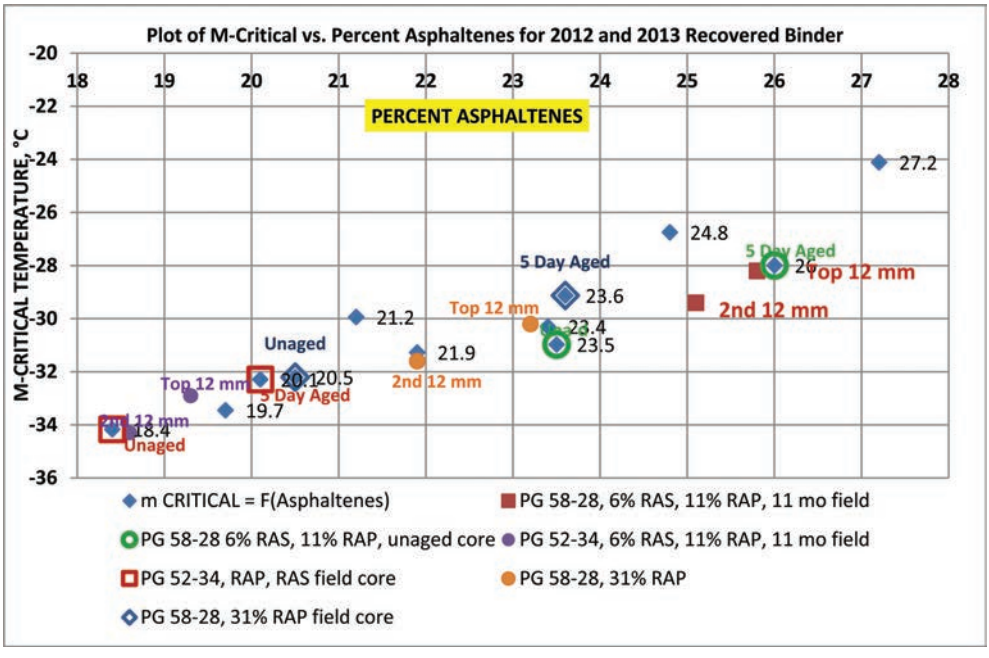

Figure 4. m-critical versus asphaltenes for 2013 top and 2nd layer recovered binder.

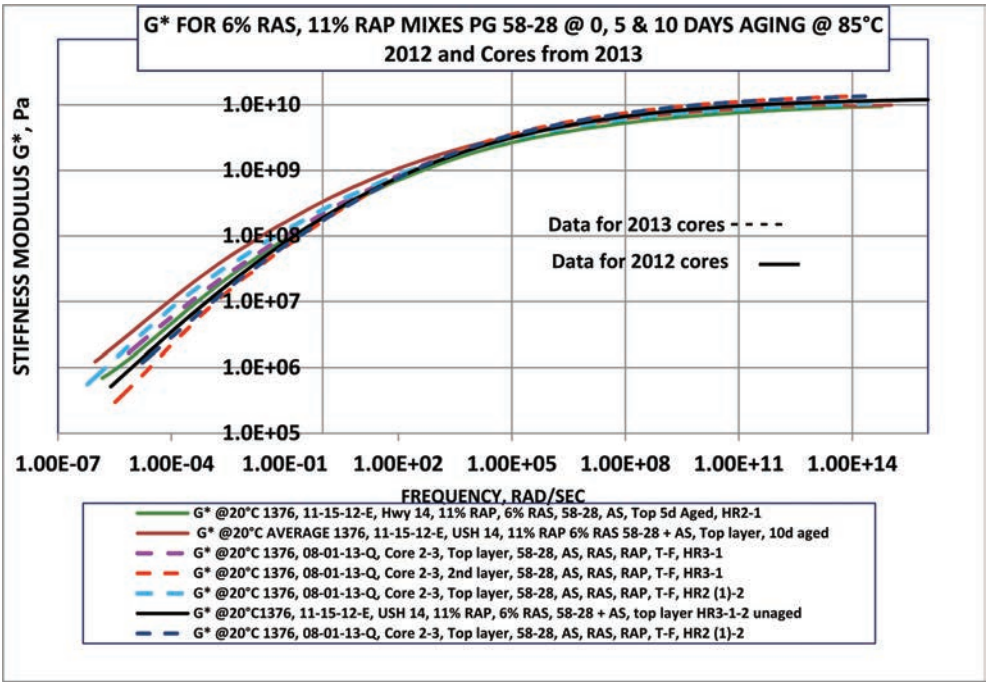

Figure 5. Compare torsion bar complex modulus for section 2, PG 58-28, 6% RAS, 11% RAP, 2012 and 2013 cores.

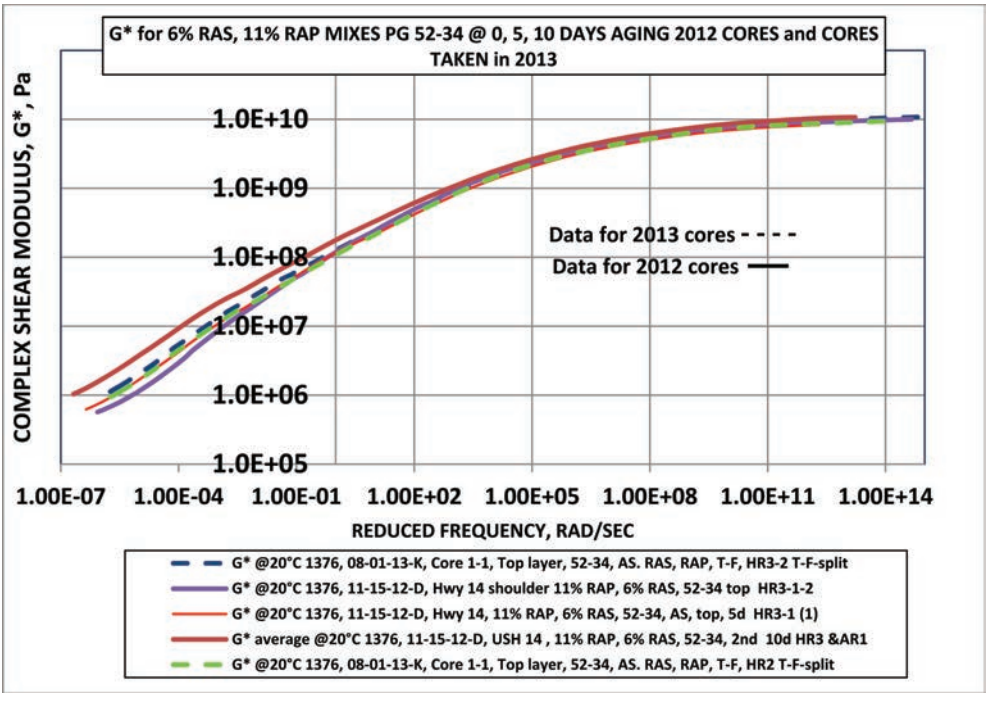

Figure 6. Compare torsion bar complex modulus for section 2, PG 52-34, 6% RAS, 11% RAP, 2012 and 2013 Cores.

stiffer than the unaged core taken in 2012. The top layer of the 11 month field core for the 20% RAP mix was stiffer than the unaged mix from 2012 but not as stiff as the 5 day aged mix. Those data are not shown in this report.

2.3 *Testing of binder lift mixes using RAS placed in 2010 and 2011*

In 2010 and 2011 Mathy Construction Co. placed RAS & RAP containing mixes using PG 64-22 on the two lower lifts of Interstate paving projects conducted in those years. The design was a 19 mm 30 million ESAL mix. Cores were taken in 2012 and again in 2013 to ascertain whether the same apparent accelerated rate of aging was occurring in those mixes as was being observed in laboratory studies and in the USH 14 initial core aging investigation. After coring the upper lift (PG 70–28, 20% RAP, 12.5 mm) was removed and two 12 mm layers were cut from top of the binder lift. These two layers were cut into torsion bars for DSR stiffness testing and were extracted and recovered for asphaltene determination and binder rheological characterization using the 4 mm DSR test procedure. Table 2 summarizes the asphaltene and low temperature properties of the recovered binder from the cores. In 2012 only one layer of binder was recovered and based on the similarity of the data for the two layers in 2013 there would have been little information to glean from the second layer data in 2012. Although the original mix design called for the use of RAS and RAP it is apparent from these data that the specific west bound cores obtained in 2012 contained no RAS and the cores from 2013 may have contained a low amount of RAS. The projects were approximately 14 miles long and cores were purposely not taken in the same location in 2012 and 2013 primarily because of the west bound core data from 2012. Evaluation of the quality control data from 2010 showed a span of approximately 4.5 miles when, due to RAS feeding problems, only 15% RAP binder replacement was used. There were also several days when 3% RAS (16.7% binder replacement) and 11% RAP (15.3% binder replacement) was used. The majority of the 2010 paving used 4% RAS (18.6% binder replacement) and 12% RAP (14% binder replacement). While there was some variability during the project the 2011 paving was much more consistent with an average of 24.5% RAS binder replacement and 8.4% RAP binder replacement. The asphaltene and low temperature data shows that no apparent aging is taking place over the course of the one year time period between the 2012 and 2013 cores for either project. The variations in results between cores taken in 2012 versus 2013 are most likely due to variations in the RAS and RAP content of the mixes. Only additional data can answer the extent to which RAS containing mix placed 75 or more mm below the surface is impacted by aging time. What does appear clear from the 2010 versus the 2011 I-94 data is the substantial impact that the presence of shingles in the 2011 mix has on the low temperature properties of that mix compared to the specific 2010 mix samples tested, which appear to have contained little or no shingle additive.

Table 2. Asphaltene and low temperature critical data for 2012 & 2013 cores of I-94 pavements.

Sample location (WB-West Bound) (EB-East Bound)	Core year	Asphaltene, %	m-critical temp (mcT)	S-critical temp (ScT)	ΔTc (ScT-mcT)	High temp PG grade $1/\sin(\delta) = 2.2$
WB 2010	2012	22.4	–28.96	–29.82	–0.86	70.3
WB 2010 top 12 mm	2013	23.3	–26.86	–28.2	–1.34	75.9
WB 2010 2nd 12 mm	2013	23.5	–28.23	–28.75	–0.52	74.6
WB 2010 base top 12 mm	2013	21.8	–27.99	–28.36	–0.38	72.8
WB 2010 base 2nd 12 mm	2013	22.3	–27.80	–28.0	–0.20	71.7

EB 2011 base top 12 mm	2013	26.1	–24.16	–25.97	–1.81	80.7
EB 2011 base 2nd 12 mm	2013	25.6	–26.07	–27.86	–1.78	79.1

Mastercurves for the recovered binders from 2012 and 2013 are shown in Figure 7. The mastercurve data supports the asphaltene and low temperature data showing the west bound sections had recovered binder properties that were much less stiff than the east bound recovered binders.

Figure 8 shows plots of the torsion bars complex modulus at a 20°C reference temperature. Data from both 2012 and 2013 cores are plotted showing minor variation within the east and west bound mix stiffness between the two years, but also showing a substantial difference in mixture stiffness for the east bound mix compared to the west bound mixes over those two years.

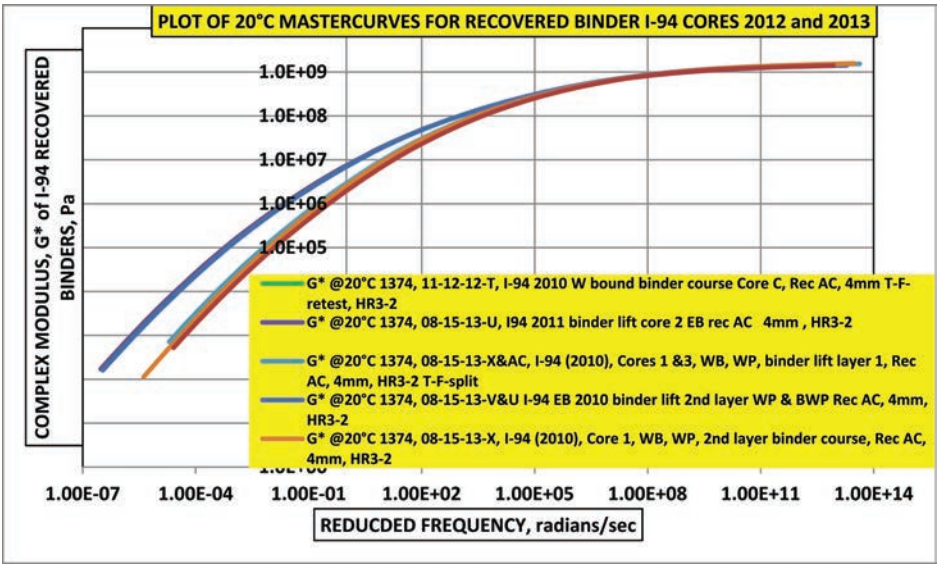

Figure 7. Mastercurves @ 20°C of recovered binder for 2012 & 2013 cores.

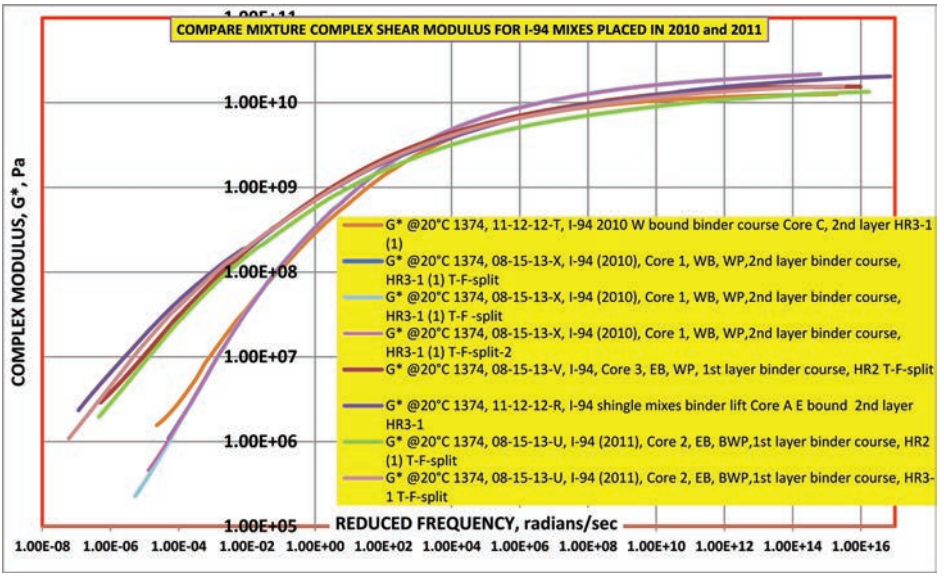

Figure 8. Mixture mastercurves @ 20°C for 2012 & 2013 cores.

3 DISCUSSION

Much of the discussion regarding the impact of RAS on mix and binder aging has been included within each section in the body of the paper. The field data presented supports the initial laboratory investigation findings of rapid mixture aging when shingle binder is present in the mix and exposed to oxidation. The laboratory investigation supports, in the authors' opinion, that regardless of whether intimate blending of shingle binder with virgin binder occurs prior to mix production or the shingle binder is introduced via ground shingles (RAS) there is no appreciable difference in mixture performance and more importantly the impact that shingle binder exerts on the aging rate of mixtures. Until a different or better mechanism can be developed it appears as though the presence of shingle binder in bituminous paving mixtures is the causative factor in the rapid aging of the binders in the mixtures and therefore deterioration of the low temperature and relaxation properties of the binders and consequently the mixtures produced with those binders. Based on the I-94 core data it does appear that sequestering the RAS containing mix in a lower lift can reduce and perhaps retard the aging impact of shingle binder on mix properties. Further testing must be performed to substantiate this observation. It is prudent however to keep in mind that today's binder lift could well become tomorrow's binder replacement material for a new wearing course. The shoulder mix placed on US Highway 14 is only one year old and already the upper 12 mm of the RAS containing mixes are showing characteristics comparable to a 5 day 85°C aged mix especially with respect to the divergence of low temperature limiting stiffness temperature and the limiting temperature value based on the binder relaxation characteristic. This is concerning and the aging rate of the RAS containing mixes compared to the high RAP only mix will be tracked over time to determine if there is in fact a mixture performance difference between similar levels of binder replacement but binder replacement that is composed of RAP and RAS compared to RAP only.

Mode II fatigue and reflective cracking performance of GlasGrid-reinforced asphalt concrete under repeated loading

Amirshayan Safavizadeh & Y. Richard Kim
NC State University, Raleigh, NC, USA

ABSTRACT: The main purpose of this research is twofold: to study the shear fatigue and fracture characteristics of GlasGrid-reinforced asphalt concrete and to examine the effects of different interfacial conditions on the performance of GlasGrid-reinforced asphalt concrete beams using four-point bending beam fatigue testing. In order to fulfill the first objective, a double shear test device and a method for determining crack lengths, referred to as the *bisectional approach*, were developed and used to track the length of cracks along the interface under Mode II fracture. The asphalt concrete interface was reinforced with GlasGrid 8501 with and without a tack coat. The four-point bending beam fatigue test plan included an additional interface condition, which was a tack coat without GlasGrid. The shear tests and beam fatigue tests were conducted at temperatures of 20°C and 23.2 ± 0.5°C, respectively. The results indicate that the presence of a tack coat improves shear fatigue resistance and extends the four-point bending beam fatigue life of GlasGrid-reinforced specimens. The four-point bending beam fatigue test results show that GlasGrid-reinforced specimens outperform non-reinforced specimens.

1 INTRODUCTION

Given the increase in demand for roads and attention to safety concerns, pavement maintenance and rehabilitation costs continue to rise. These demands and rising costs are all happening in an economic environment where budgets are decreasing and the market is becoming more competitive. Therefore, it is becoming more and more important to construct long-lasting asphalt pavements and find better ways to rehabilitate old pavements.

Reflective cracking is one of the most common distresses in asphalt pavements and is a major problem for the pavement industry. Reflective cracking is a mechanism found in new overlays and is caused by the inability of the overlay to withstand movement of the underlying pavement. Such movement may be due to traffic loading and/or thermal loading. Reflective cracking destroys the continuity of the pavement surface, decreases the structural strength of the pavement, and allows water to penetrate the pavement system, which subsequently leads to further deterioration [1].

Several remedial techniques have been used to control reflective cracking, including placing a thin layer between the old and new layers, rubberizing the existing concrete pavement, cracking and sealing the existing pavement, and increasing the thickness of the Hot Mix Asphalt (HMA) overlay. Among these techniques, interlayer systems have been the most effective in controlling reflective cracking. The effectiveness of the interlayers depends on the selection of the type of interlayer system, the interlayer conditions, installation procedures, and the conditions and characteristics of the existing pavement and HMA overlay [2].

One of the interlayer systems that have been proven effective is geotextile. Three uses of geotextiles in asphaltic concrete overlays are strain relief, reinforcement, and under sealing.

Strain relief occurs in cases where geotextile has a lower elastic stiffness value than the surrounding asphalt concrete. Geotextiles with higher elastic stiffness values than the asphalt concrete are able to reinforce the pavement system. Polypropylene grids and glass fabrics and grids are classified as reinforcing geotextiles and, if constructed properly, can redirect reflection cracks and retard the cracking process. Under sealing geotextiles prevent or reduce penetration of water into the pavement once the crack occurs, and so prevent further deterioration [1].

Laboratory performance evaluation of different geotextiles requires careful consideration of different contributing causes of reflective cracking. These factors include traffic loads and volume, crack spacing, temperature changes, temperature gradient, subgrade stiffness, presence or absence of voids beneath the pavement surface, degree of aggregate interlock across the crack in the old and new pavements, overlay thickness, geotextile position, and tack coat type and application rate [1]. Also, the interlayer bond plays an important role in making the pavement system structurally stiff and also has an important role in stress-strain distribution. So, the long-term performance of pavements and also the cracking pattern depend on interlayer bonding and conditions [3–5].

A large part of the pavement life cycle includes crack propagation prior to failure. Therefore, a primary reason for using geogrids in asphalt pavements is to retard the reflective crack propagation process. As such, it is critical to understand how different interlayer conditions affect crack propagation in both Mode I (opening mode) and Mode II (shearing mode) fracture. In order to study and understand the mechanical behavior of GlasGrid-reinforced asphalt concrete pavements, fracture mechanics concepts and test methods must be applied. So far, Mode I fracture has been the main focus of most of the previous research efforts, and even though some of them have targeted Mode II cracking of asphalt concrete interfaces, more investigation on this Mode seems to be needed in order to fully understand all the mechanisms. The number of studies that address Mode II fracture of grid-reinforced asphalt concrete under repeated loading is even fewer. Since reflective cracking of GlasGrid-reinforced asphalt pavements usually includes cracks that turn and move along the interface, understanding the characteristics of Mode II fatigue and fracture of the interface is vital for an accurate prediction of pavement performance and pavement life. This study seeks to provide a better understanding of the Mode II fatigue performance and fracture characteristics of GlasGrid-reinforced asphalt concrete.

2 EQUIPMENT, TESTS, AND MEASUREMENT METHODS

2.1 *Equipment*

2.1.1 *Development of Double Shear Tester (DST)*

After reviewing different types of shear tests, including direct and simple shear tests and single and double interlayer shear tests, the double shear test concept appeared to offer the best options for this study. In this type of shear test, the side parts of the sample are fixed and its middle part is free to move and is subjected to loading (Fig. 1(a)). The advantage of double shear test over single interlayer shear test methods is that the two interfaces symmetrically undergo a relatively pure shear stress, whereas in single interlayer tests normal forces are applied to the interface at areas that are close to the ends of the specimen in addition to the shearing load. In other words, bending problems usually are associated with single interlayer shear tests [6].

For this study, a specific Double Shear Tester (DST) was designed and fabricated based on the optimum required size of the specimen and GlasGrid opening size (Fig. 1(b) and (c)). The dimensions of the interface were chosen to be 152.4 mm in the direction of compaction and loading by 101.6 mm in the transverse direction to allow for acceptable shear stress distribution and also to provide enough ribs in each specimen interface.

The device was modified at different stages to attain desired characteristics, such as stiffness, test repeatability, and interface area visibility. Figure 1(d) shows the modified DST in

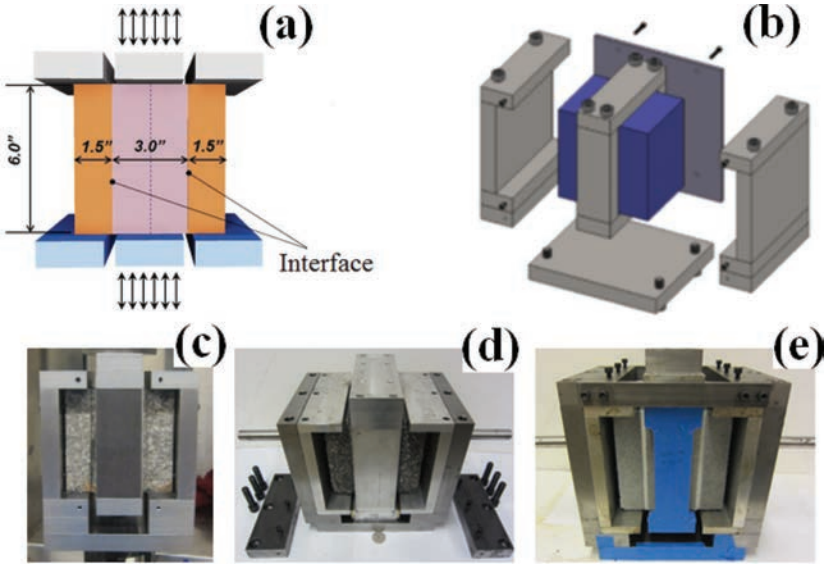

Figure 1. (a) DST concept, (b) DST schematic, (c) Original DST, (d) Modified DST parts, and (e) Final version of DST.

which aluminum parts were added to make the device capable of running more tests per day. Figure 1(e) shows the final version of the DST after a few more minor modifications.

2.1.2 *Four-point beam fatigue test apparatus*

A Cox and Sons four-point beam test apparatus was accommodated for use in the MTS 811 universal testing machine. In this apparatus the spacing between the clamps is 119 mm and the length of the beam between the outside clamps is 357 mm.

2.2 *Tests and test conditions*

2.2.1 *Double shear test*

In order to gain a better understanding of the interface shear fatigue performance of specimens reinforced with GlasGrid, double shear tests were conducted on DST specimens. Different interface conditions, i.e., GlasGrid with an asphalt binder tack coat with an application rate of 500 g/m² (GGTC), and GlasGrid without a tack coat (GGP), were tested. The test temperature was 20°C and the number of replicates for each condition was three. All the specimens were kept at 20°C inside the testing climate chamber for three hours before testing. The tests were carried out under load control mode. A sinusoidal alternating load with a frequency of 5 Hz and a zero mean was applied to the middle part of the shear specimens using an MTS 810 servo-hydraulic material testing system. Different load levels were used for different conditions because of the considerable difference in shear strength under the different interlayer conditions. Table 1 presents the load levels for each condition.

2.2.2 *Four-point bending beam fatigue TEST*

In order to investigate crack propagation patterns and fatigue performance of GlasGrid-reinforced asphalt concrete, four-point beam fatigue tests were carried out on beam specimens. Beam specimens with four different interlayer conditions were tested. The conditions were the same as Double Shear Test conditions (GGTC, and GGP) plus an asphalt binder tack coat with an application rate of 300 g/m² without GlasGrid (TC). The tests were performed according to ASTM D7460. The interlayer was located at one-third depth from the bottom

Table 1. DST load levels (Kgf).

Specimen	GGTC	GGTF	GGP
1	612	227	204
2	567	204	147
3	567	204	147

of the beam. All the specimens were kept in the testing room and at the temperature of 23.2°C ± 0.5°C for at least six hours before testing. The tests were carried out in displacement control mode. A sinusoidal displacement with zero and maximum negative bending deflection peaks was applied to the specimen at a frequency of 5 Hz. That is, the beams were pushed down to reach the maximum strain level of 1400 micro strain and then pulled back to the zero position. The number of test replicates for each condition was two. Some extra tests with only one replicate were performed at different maximum strain levels ranging from 1200 to 1600 micro strain to obtain more crack propagation data for specimens with different interlayer conditions.

2.3 *Digital Image Correlation (DIC)*

Digital Image Correlation (DIC) was used to track and measure the deformations, displacements, and strains on the surface of the specimens and especially at areas around the interlayer. Using spray paint, the specimens were speckled with a white background and black dots in a certain pattern to allow for image analysis and a 5 MP camera was used for capturing images. The distance of the camera from the surface of the specimen was kept the same and in the range of 76 cm to 89 cm for each type of test. VIC-2D software was used for analyzing the images and calculating the displacements and strains on the surface of the specimens.

3 MATERIALS AND SPECIMEN PREPARATION

3.1 *Materials*

A RS9.5B mixture with PG 64-22 binder was used for this study. A PG 64-22 asphalt binder was used as the tack coat. One type of geogrid, GlasGrid 8501, was used for the reinforcement of the HMA interlayer. This geogrid was supplied by Saint-Gobain ADFORS America. GlasGrid 8501 is a self-adhesive glass fiber grid with 12.5-mm wide openings and impregnated with acrylic polymer resin. This polymer resin makes the grid compatible with the asphalt binder [7].

3.2 *Specimen preparation*

Double-layer slabs were compacted using a roller compactor. GlasGrid was installed on top of the first layer and immediately before compaction of the second layer. The double shear test specimens consisted of two double-layer specimens from the same slab bonded together. The first step in fabricating the shear specimens was to make a rough cut using a hand-held saw. Then, using an automatic saw, the top and bottom layers were trimmed to a 38.1-mm thickness and the sides were trimmed to provide a 152.4-mm long, 114.3-mm wide, and 76.2-mm thick specimen. The final step was gluing the top surface of the two specimens together using a two-part metal-filled epoxy glue. Figure 2 shows these steps schematically. By following this method of sample preparation, both interfaces have the same characteristics in terms of compaction, roughness, interlayer systems, tack coat application rate, etc.

The beam specimens were cut out of the slab using a hand-held saw. Then, the bottom and top layers of each beam were trimmed to thicknesses of 18 mm and 36 mm, respectively.

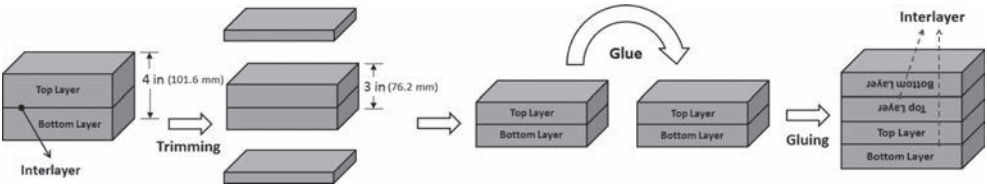

Figure 2. DST specimen preparation procedure.

Finally, the sides were trimmed to provide a 380-mm long and 63-mm wide beam specimen. The length of each beam was in the same direction as grid rolling and slab compaction.

4 CRACK LENGTH DETERMINATION

The main challenge in the analysis of the double shear test data was determining the crack tip during the tests. Three different approaches were evaluated for determining the crack tip: using strain contours, visual detection, and a bisectional approach. Shear and von Mises strain contours of the surface of the shear specimens were obtained during the tests utilizing DIC analysis. Von Mises strain is an equivalent strain and is used as a yielding criterion. This strain provides the equivalent uniaxial strain of the existing strain state from the yielding point of view. The von Mises strain can be calculated using Equation (1).

$$\varepsilon^e = \frac{\sqrt{2}}{3}\left[\left(\varepsilon_1 - \varepsilon_2\right)^2 + \left(\varepsilon_2 - \varepsilon_3\right)^2 + \left(\varepsilon_3 - \varepsilon_1\right)^2\right]^{1/2} \tag{1}$$

where ε_1, ε_2, and ε_3 are the principal strains at an element, and ε^e is the von Mises strain.

Figure 3 presents the evolution of the von Mises strain contour of the specimen GGP_2. The observed increase in the von Mises strain at high numbers of cycles is more obvious around the interlayer and represents the failure process of the interface. Two main problems are associated with using this approach as the failure criterion. The first problem is the error or noise of the strain results, which is a considerable portion of the calculated strain at areas with high strain levels and is inevitable with current DIC analysis. The other problem is determining the threshold of cracking or failure for the different samples and test conditions.

The second approach, i.e., visual observation, was investigated using a speckled sample that was painted white along both interfaces (Fig. 4(a)). The images were examined after the test to determine the crack length. This approach failed because the crack was especially fine around the crack tip and difficult to detect. Also, another problem was that the paint and interface conditions were not compatible, and thus, a crack in the paint might not necessarily be indicative of an interface crack.

The third approach is the bisectional approach. As shown in Figure 4(b), virtual gauges were used at certain positions to track the displacement of two sides of the interlayer during the test. Each of these virtual gauges is composed of 101 points, which is the default number of points in VIC-2D software and more than enough for a precise measurement. The displacement of each gauge is assumed to be equal to the average displacement of these points. After calculating the displacements using image analysis and drawing the relative displacement of two sides versus the number of cycles, it was observed that relative displacement increases linearly with an increase in the number of load cycles until the interface crack reaches the evaluation point. After this point the curve starts to deviate from the virtual line (Fig. 5). Romanoschi et al. [8] reported the same interface behavior under shear fatigue testing.

This deviation point is the failure point. By looking at the relative displacements versus the number of cycles at different positions along the interface, the crack tip can be tracked,

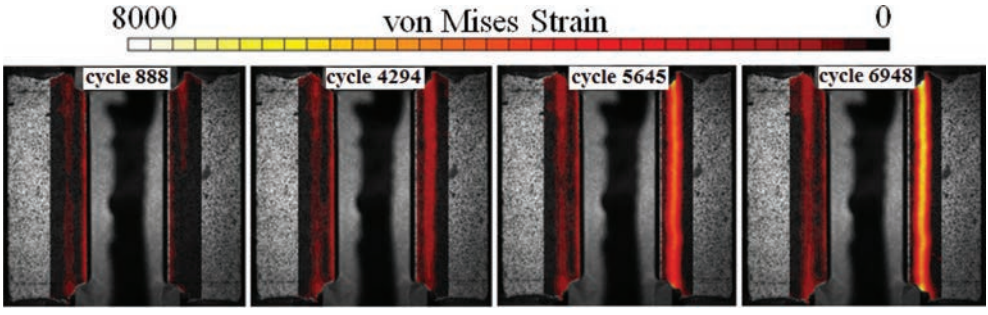

Figure 3. GGP2 shear specimen's von mises strain contour evolution.

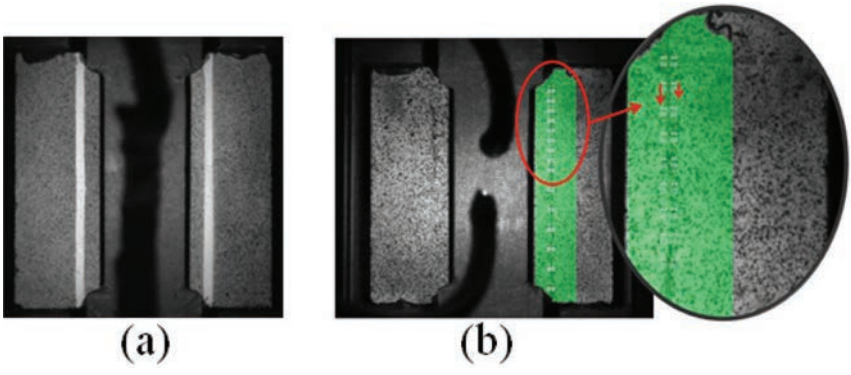

Figure 4. (a) White paint along the interlayers (the second approach) and (b) Virtual gauges defined at certain positions (third approach).

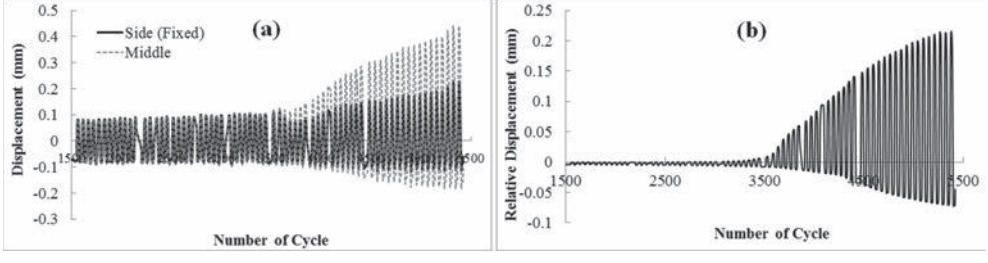

Figure 5. (a) Displacement and (b) Relative displacement of gauges located on opposite sides of the interface and at the same level.

and the crack growth rate and Paris law parameters can be found for each sample. Figure 6 displays an example of how this bisectional approach works.

5 RESULTS AND DISCUSSION

5.1 *Double shear test*

The bisectional approach was used to find the length of the cracks at different numbers of cycles for all the shear tests. Figure 7(a), and (b) shows the crack growth rate ($\Delta a/\Delta N$) versus

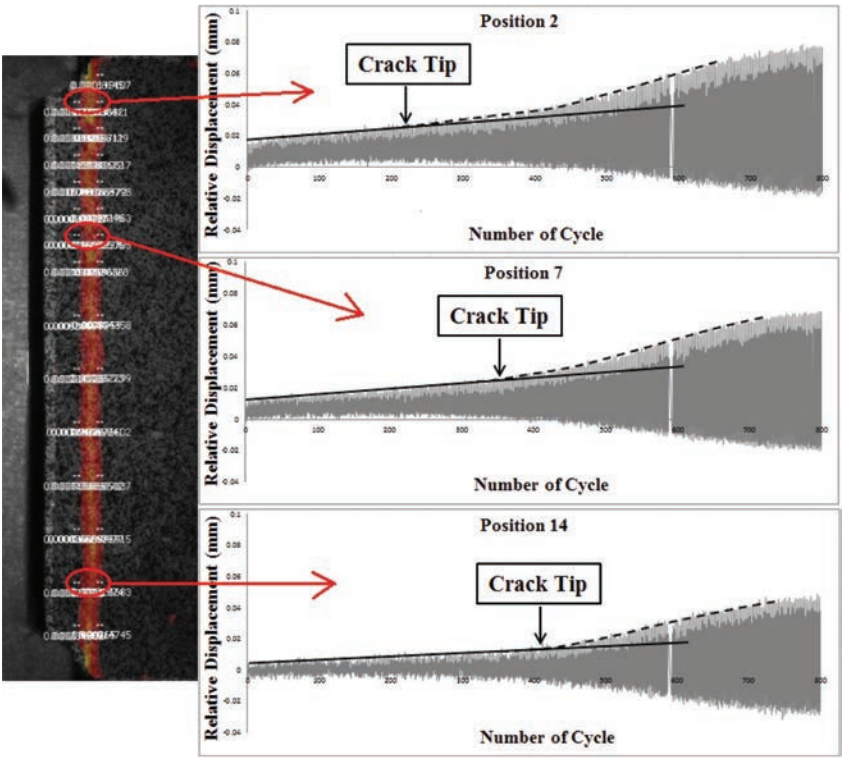

Figure 6. Bisectional approach for finding the crack tip.

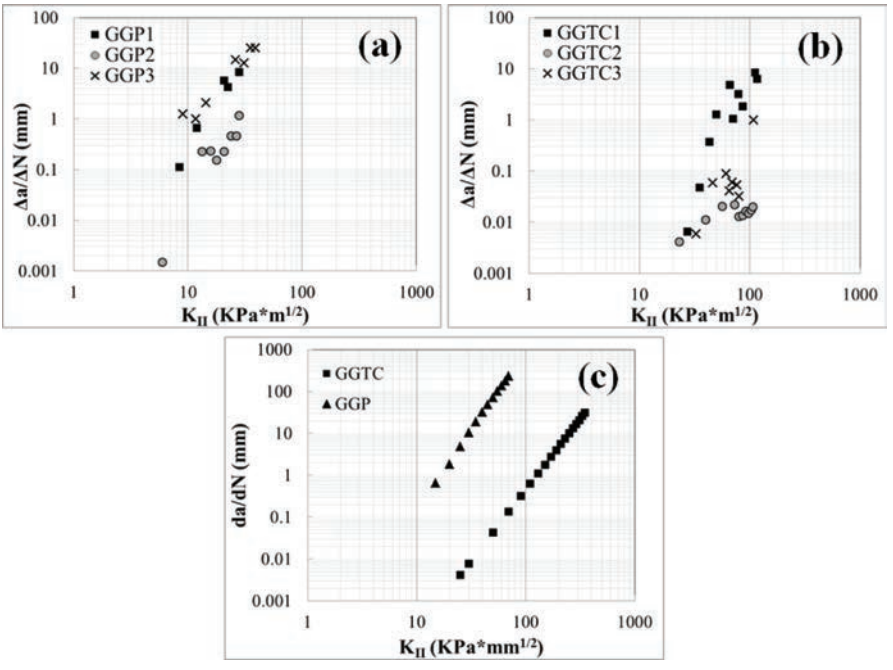

Figure 7. Measured crack growth rate for: (a) GGTC, (b) GGTF, and (c) GGP specimens, and (d) Fitted average crack growth rate for each interlayer condition.

the Mode II stress intensity factor (K_{II}) for all the replicates of the GGTC, and GGP specimen tests. All the results were fitted into the Paris law equation, Equation (2), using regression analysis. The fitting was performed separately for each specimen, and the average of the fitted data for each interlayer condition was calculated.

$$\frac{da}{dN} = A \cdot K_{II}{}^{n} \tag{2}$$

where a is the length of the crack, N is the number of cycles, K_{II} is the Mode II stress intensity factor, and A and n are the Paris law constants.

Figure 7(c) presents the fitted average crack growth length for each interlayer condition. This figure shows that the specimens with a tack coat (GGTC) have a much lower rate of crack growth comparing to the specimens without tack coat (GGP). This observation shows that existence and quality of tack coat can make a big difference in performance of reinforced interlayer.

5.2 *Four-point beam fatigue test*

In order to find the number of cycles to failure (N_f) for each beam fatigue test, the stiffness value times the number of cycles was plotted versus the number of cycles. The maximum or peak of the plotted curve was considered as the failure point. In some cases where no obvious peak was evident, the phase angle drop was used as the failure criterion. Figure 8 presents all the results for the number of cycles to failure versus the strain levels. By comparing the number of cycles to failure at different maximum strain levels, it was found that the GGTC specimens exhibit the best performance, and the numbers of cycles to failure for the GGP specimens are a little bit higher than those for the TC specimens. At the strain level of 1400 μstrain, it was observed that the use of GlasGrid with a tack coat (GGTC), and only GlasGrid (GGP) improved the fatigue life of the reference beam specimens (TC) by 82%, and 24%, respectively.

The DIC results were used for a deeper investigation of fatigue performance and reflective cracking in GlasGrid-reinforced asphalt concretes beams. The von Mises strain was calculated on the surface of the middle span of the beam specimens using VIC-2D software. A good understanding of the effects of the GlasGrid and interlayer conditions on crack propagation and reflective cracking mechanisms can be attained by looking at the strain contours during the tests.

The changes in the strain contours of beam specimens were monitored during the tests to see how the crack propagates across the beam. The GGP specimens showed very high strain levels around the interlayer area even before any cracks initiated at the bottom of the beams.

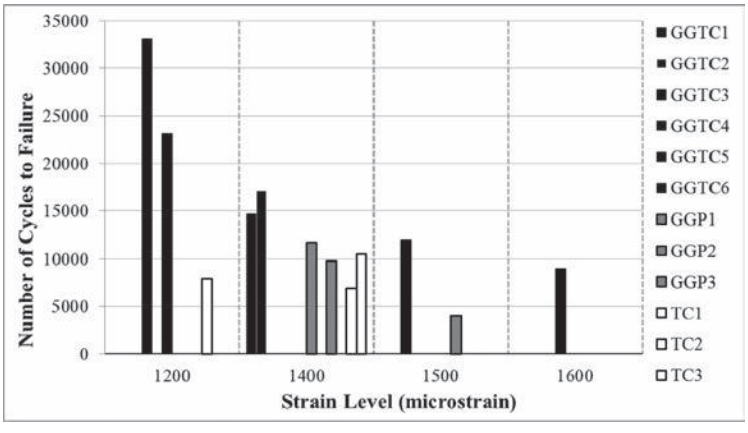

Figure 8. Number of cycle to failure vs. strain level for four-point beam fatigue tests.

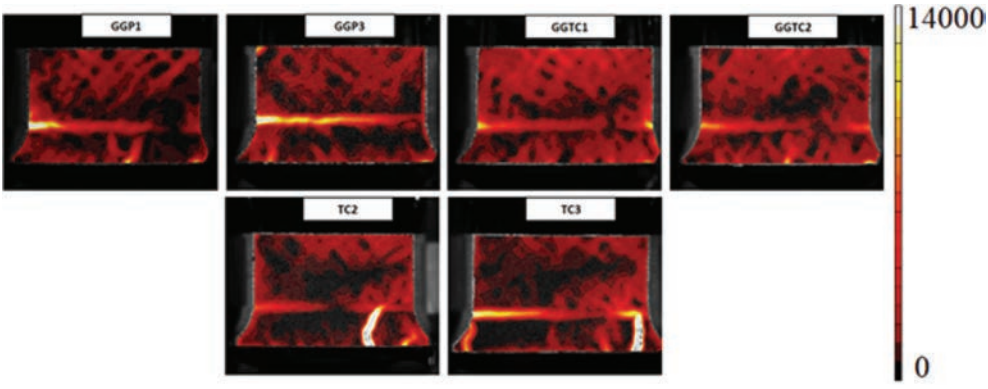

Figure 9. Von mises strain contours at cycle number 9000 (1400 μstrain).

For the GGTC specimens, in most cases the formation of high strain levels around the interface occurred simultaneously with the formation of bottom-up cracks, or in some cases, the interface strain levels started rising quickly after the bottom-up crack reached the interface. In all the GlasGrid-reinforced beam specimens, once the bottom-up crack reached the interface, it turned horizontally or joined the interface horizontal crack. So, it seems that GlasGrid is able to stop or delay the cracking and not allow it to penetrate the interlayer. However, in these cases a top-down crack formed and propagated downward toward the interlayer. Depending on the interlayer condition and maximum strain level, the formation of interface and top-down cracks took place either simultaneously with the formation of a bottom-up crack or after the bottom-up crack intersected with the interface. Similar types of crack propagation have been reported in previous studies [1, 9-11]. In all the non-reinforced beam specimens, it was observed that the bottom-up crack passed the interface and moved toward the top surface of the beam specimen.

In order to make it easier to compare the fatigue performance of beam specimens with different interlayer conditions, the von Mises strain contours of all the beam specimens subjected to a maximum strain level of 1400 μstrain at cycle of loading number 900 are shown in Figure 9. This figure shows an evenly distributed strain across the GGTC, high strains at the interface of the GGP, and bottom-up cracks penetrating the interface of TC specimens.

6 CONCLUSIONS

Based on the materials and methods used in this research, the following conclusions can be drawn:

- A DST and a bisectional crack tip determination approach were developed and used in this research for measuring the length of interface cracks under Mode II loading.
- The relative displacement of the opposite sides of the interface under Mode II repeated loading increases linearly until the interface cracks. At this point the relative displacement deviates from the line and starts growing faster.
- Under the same shear fatigue loading conditions, DST specimens that have GlasGrid and a tack coat have a much lower crack growth rate compared to specimens without a tack coat. This observation emphasizes the role that bond quality plays in interface fatigue shear resistance.
- Specimens with GlasGrid and a tack coat show the best performance in four-point bending beam fatigue tests. GlasGrid without a tack coat, and non-reinforced interface with a tack coat hold the next positions in the ranking, respectively.

- The strain contours determined from the four-point bending beam fatigue tests show that the bond quality between the layers is important in the development of interlayer cracks and slippage.
- Beam fatigue test strain contours show that specimens with GlasGrid and a tack coat have a more even distribution of strain and stress across the beam compared to the other interlayer conditions discussed in this paper. Also, the GlasGrid and no tack coat specimens show more even strain distributions comparing to the TC specimens.
- The results suggest that GlasGrid prevents reflective cracking by providing some constraints at the crack tip and turning the crack direction horizontally. Also, the results indicate that GlasGrid reduces the stress concentrations by means of transferring the load along the interface that becomes possible through the bonding provided by tack coat and interlocking between the GlasGrid and the aggregate.

Evaluating the effects of volumetric properties on the electrical resistivity characteristics of asphalt mixes

Seyed Arash Forough & Fereidoon Moghadas Nejad
Highway Division, Department of Civil and Environmental Engineering, Amirkabir University of Technology, Tehran, Iran

ABSTRACT: The relationships between the electrical resistivity characteristics, E_r, and the volumetric properties of asphalt mixtures, i.e., bulk specific gravity, G_{mb}, air voids in mixture, V_{bm}, and voids in mineral aggregates, V_{ma}, were investigated through a novel approach. To this end, 455 Marshall specimens containing calcareous crushed type stone aggregate with 60/70 penetration asphalt binder were fabricated and tested at five different aggregate gradations and seven bitumen contents with thirteen replicate specimens for each experimental combination. Statistical analysis of variance and significance tests were conducted on the test data and the effects of volumetric properties on the electrical resistivity of the specimens were evaluated. Finally, regression analysis method was used to develop some simple correlations between the two data sets.

Keywords: asphalt mixture, volumetric properties, electrical resistivity, simple correlation

1 INTRODUCTION

It is well known that the volumetric properties of asphalt mixes including bulk specific gravity, G_{mb}, air voids in mixture, V_{bm}, and voids in mineral aggregates, V_{ma}, are frequently used in the mix design process and/or as quality control measures during the construction operations. So far, many different methods have been proposed to measure the G_{mb} of compacted asphalt mixes among which the dimensional analysis method, as defined by AASHTO T269, water displacement or saturated surface dry method, as defined by ASTM D2726 or AASHTO T166, and paraffin coating method, as described by AASHTO T275, may be the most important ones. Then, V_{ma} may be calculated using the G_{mb} together with the bulk specific gravity of solids (G_{sb}) and binder content (P_b). In addition, to calculate the V_{bm} of an asphalt mixture, the maximum theoretical gravity, G_{mm}, of the mix must first be determined using the Rice method.

The present study was undertaken with the aim of proposing a novel testing method to determine the electrical resistivity of both the laboratory-fabricated or field-drilled asphalt mixture specimens [1], and to correlate the electrical resistivity, as a physical property, to all the mentioned volumetric properties of asphalt mixtures. Generally, electrical current may be conducted through a material in two ways: (1) the material, e.g. iron or copper, is a natural electrical conductor, in which the electrical current is conducted via numerous free electrons, (2) the material, e.g. cement paste, cement concrete or soil, is a natural electrical insulator (dielectric), but it may be changed to an electrical conductor using a chemical combination or an artificial method; thus, the electrical current is conducted electrolytically via the ionic conduction.

Asphalt mixture is a composite material, which comprises of the following constituents: (a) coarse and fine aggregates, (b) filler, (c) bitumen, (d) air, and (e) other additives such as anti-stripping agents [2]. Asphalt mixture, as a blend of aggregates and bitumen, is an electrical insulator (dielectric) with a high electrical resistivity of around 10^{13} Ohms. Thus, no free electrons exist in the mix to directly conduct the electrical current. However, if an asphalt mixture specimen becomes an electrical conductor by an artificial method, it is possible to

obtain its electrical resistivity within a reasonable range and to relate this electrical resistivity to the volumetric properties of the specimen [1].

Comparatively little work has been undertaken on the electrical properties of asphalt mixture, especially on the relation of electrical resistivity to its volumetric properties. Almost all the earlier work in this field has been undertaken on the electrical conductivity of asphalt mixtures containing electrically conductive materials such as basalt aggregate, limestone powder, carbon black, graphite particles and steel wool for generating heat by passage of an electrical current through the asphalt mixture to prevent the accumulation of frozen precipitation thereon [3]. It is theoretically feasible to improve the electrical conductivity of asphalt mixtures by the addition of electrically conductive additives to melt and remove snow and ice on asphalt pavement thermo-electrically [4, 5]. Furthermore, adding electrically conductive materials into an asphalt mixture has been previously used to monitor fatigue damage mechanism [6], softening temperature, storage modulus, damping capacity and electrical resistivity of modified asphalt mixture [7]. According to the previous studies [8, 9, 10], the electrical conductivity of the asphalt mixture is proportional to the concentration of electrically conductive additives.

Unlike the asphalt mixtures, various works have been undertaken on the electrical properties of cement mortars, cement pastes and even more on cement concretes, especially on the variation of electrical resistivity during the stages of initial setting and subsequent hardening [11, 12, 13, 14]. The conduction of electricity by moist concrete could be expected to be essentially electrolytic. The electrolytic conduction of moist concrete is linked to the circulation of fluid through the pore network [15]. Thus the electrical resistivity of concrete is sensitive to the volume of porosity and to the porous interconnectivity degree [16]. Moist concrete behaves essentially as an electrolyte with a resistivity of around 10^4 ohm-cm, a value in the range of semiconductors. Oven-dried concrete has a resistivity in the order of 10^{11} ohm-cm, a reasonably good insulator [17].

During this research, the conduction of electricity through the asphalt mixture specimens was performed similar to the electrolytically conduction of cement concrete. This aim was possible by saturating the interconnected air voids of the specimens using an electrolyte solution. Asphalt mixture, saturated by an electrolyte solution is electrically conductive by virtue of its interconnected pore network partially or fully filled with the electrolyte solution containing mobile ions. Thus, the electrical conductivity of such an asphalt mixture is related to the volume fraction of pores, the conductivity of pore solution and the interconnectivity of the porosity. In fact, the electrical resistivity is a measure of this interconnectivity.

2 EXPERIMENTAL PROGRAM

2.1 *Material properties*

Continuous aggregate gradation was used to comply with the gradation limits given by the Iran Highway Asphalt Paving Code [18] for wearing course. The gradations used in this study and the gradation limits are plotted in Figure 1.

The aggregates were calcareous type crushed stone obtained from the local resources. The filler was Portland cement (type II) with apparent specific gravity of 3.13 g/cm^3. The 60/70 penetration bitumen, corresponding to PG 64-16, obtained from a local oil refinery was used as binder for the specimen fabrication.

2.2 *Specimen fabrication*

The variables of bitumen content and aggregate gradation were selected to study in the experimental design. Seven bitumen contents of 3.5% to 6.5% in 0.5% increments and five different gradations form the coarsest, gradation 1, to the finest, gradation 5, as shown in Figure 1, were used to make 455 asphalt mixture specimens.

Thirteen replicate specimens (one replicate as the 1st group for the G_{mb} additional tests, five replicates as the 2nd group for the volumetric (G_{mb}, V_{bm}, and V_{ma}) tests, two replicates

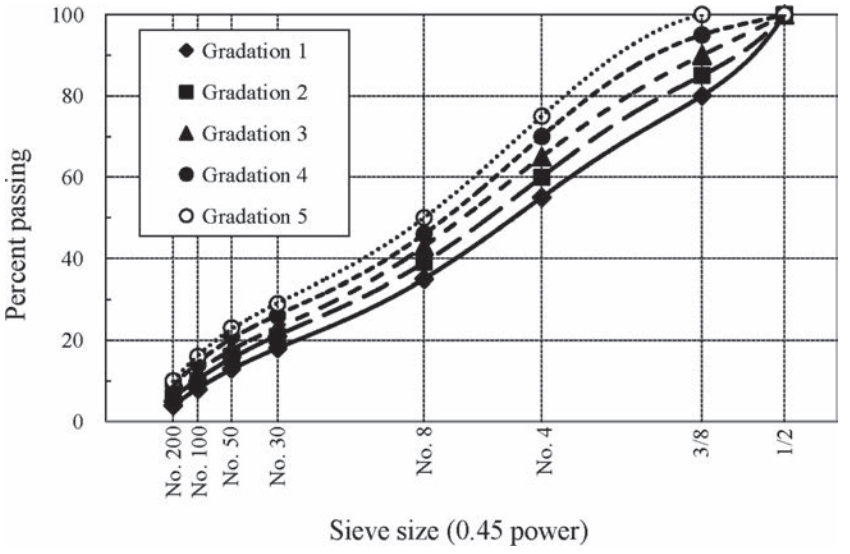

Figure 1. Aggregate gradations used in this study.

Table 1. Experimental design used in this study for testing.

Experimental variables	No. of levels	Variable levels
Bitumen content	7	3.5%, 4%, 4.5%, 5%, 5.5%, 6%, 6.5%
Aggregate gradation	5	The coarsest to the finest
Replication 1 (1st group)	1	G_{mb} additional tests
Replication 2 (2nd group)	5	Volumetric tests
Replication 3 (3rd group)	2	Saturating tests
Replication 4 (4th group)	5	Electrical resistivity tests

as the 3rd group for the saturating tests and five replicates as the 4th group for the electrical resistivity tests) were fabricated for each experimental combination. The experimental design used in this study is shown in Table 1.

Laboratory asphalt mixture specimens were fabricated in accordance with the Marshall mix design method in a laboratory environment, utilizing 75 blows representing heavy traffic conditions as specified in ASTM D1559-76 [19]. All the specimens were compacted using the same load by the standard Marshall hammer.

2.3 *Conducted tests*

2.3.1 *First group: G_{mb} additional tests*

To capture advantages of both the saturated surface dry and paraffin coating methods, all the specimens of the 1st group were tested for the G_{mb} using both methods. Afterwards, an adjusting factor was calculated for each experimental combination to convert the inaccurate result of saturated surface dry method to the accurate result of paraffin coating method.

2.3.2 *Second group: Volumetric tests*

The volumetric tests were carried out on the specimens of the 2nd group. To this end, all the specimens of the 2nd group were tested for the G_{mb} using the saturated surface dry method and the results were converted to the accurate G_{mb} of the paraffin coating method using

the adjusting factors of the previous section. Finally, all the specimens of the 2nd group were tested for the G_{mm} using the Rice method and both the properties of V_{bm} and V_{ma} were calculated.

2.3.3 *Third group: Saturating tests*

2.3.3.1 Electrical conduction through the specimens

Asphalt mixture, saturated in an electrolyte solution, becomes electrical conductor. The electrolyte solution, used in this study, was NaCl (sodium chloride in pure water). In addition, it was necessary to find the best concentration of the solution. For this purpose, different amounts of sodium chloride in 1 litter of pure water were examined, and it was found that 100 grams of sodium chloride in 1 litter of pure water (corresponding to the concentration of 9.1%) would be the minimum concentration for the solution by which the electrical resistance was readable for all the specimens.

2.3.3.2 Saturating the specimens

To saturate the interconnected V_{bm} of the specimens, they were immersed in the electrolyte solution under a high pressure. For this purpose, an apparatus was constructed. It consists of a pressure vessel equipped with a pressure gauge, an air-solution container, an air pump, two high pressure connective hoses, and a pressure control valve. Figure 2 shows configuration of the apparatus. The pressure vessel was capable to sustain a pressure less than or equal to 15 psi. Thus, the specimens of the 3rd group were placed in the pressure vessel filled by the NaCl solution under the pressure of 15 psi and the weight variations were monitored versus time. On the basis of weight variation as the controlling criterion, each specimen was expected to be saturated, when there was no more increase in its weight. It was found that all the specimens were saturated within 24 hours under this condition. If the pressure vessel was capable to sustain a pressure more than 15 psi, the required testing time would be decreased significantly.

2.3.4 *Fourth group: Electrical resistivity tests*

Electrical resistance tests were conducted on all the specimens of the 4th group at the saturated surface dry condition. Therefore, no electricity was allowed to conduct on the wet surface of the specimens. The tests were carried out using another apparatus constructed for this purpose. The apparatus consists of a mast frame, a main shaft, a rotational handle, a ring and

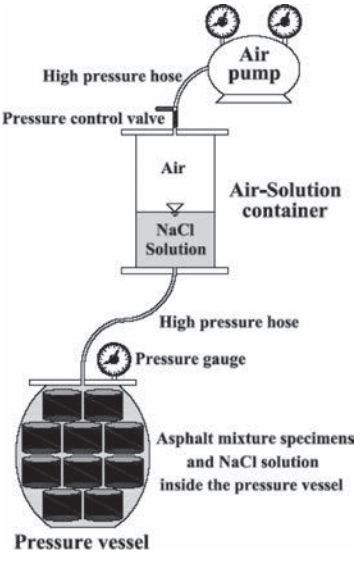

Figure 2. Configuration of the apparatus used for saturating the specimens under pressure of 15 psi.

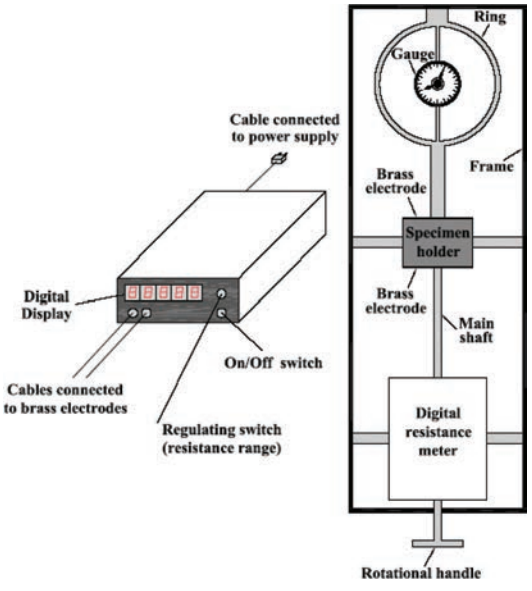

Figure 3. Configuration of the apparatus used for the electrical resistance measurements.

gauge set, a specimen holder, two electrodes, and a digital resistance-meter. Figure 3 shows configuration of the apparatus used in this study for the electrical resistance measurements.

The specimen holder can be used for either laboratory-fabricated or field-drilled specimens. The electrodes were made by brass with a diameter of 101.6 mm, equal to the diameter of the specimens. The main shaft was used to apply uniform axial compression on each side of the specimens through the brass electrodes by clockwise rotation of the handle. In addition, since the electrical resistance measurements should be carried out under the same conditions on all the specimens of the 4th group, the ring and gauge set was used to verify the equality of axial compression applied to the specimens. The measurement test set-up was done at room temperature of 25°C. To ensure a perfect contact between the electrodes and the specimens and to minimize the measurement error due to the jagged and rough texture of the asphalt mixture specimens, cement grout in a liquid-plastic form was used to fill the gaps between the electrodes and the specimens. It must be noted that the total contact resistance between the brass electrodes and the cement grout was less than 1 ohm, which was negligible with respect to the high resistance values, more than 1000 ohms, of the specimens. After the electrical resistance measurements, the electrical resistivity, E_r, of each specimen was obtained using the electrical resistance and dimensions, both the length in the current direction and the cross sectional area perpendicular to the current direction, of the specimen.

3 TESTS RESULTS AND DISCUSSION

3.1 *Volumetric test results*

Volumetric properties (G_{mb}, V_{bm}, and V_{ma}) of the specimens versus bitumen content, P_b, are shown in Figures 4 to 6 for the five selected gradations. These figures show the average results of the five replicate specimens for each experimental combination. Therefore, each figure represents the results of 175 specimens.

The test results on Figures 4 to 6 indicate that all the volumetric properties are sensitive to both the variables of aggregate gradation and bitumen content and they have very strong nonlinear quadratic relationships with these variables. All these observations are in agreement with the previous studies which are well established in the existing literature.

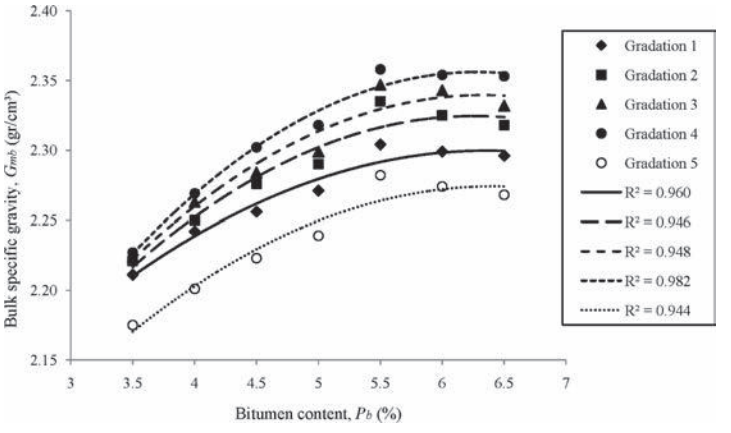

Figure 4. G_{mb} versus P_b for the five gradations.

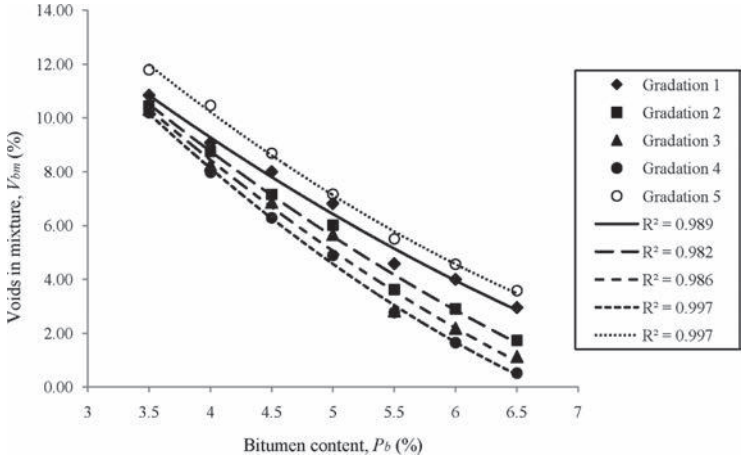

Figure 5. V_{bm} versus P_b for the five gradations.

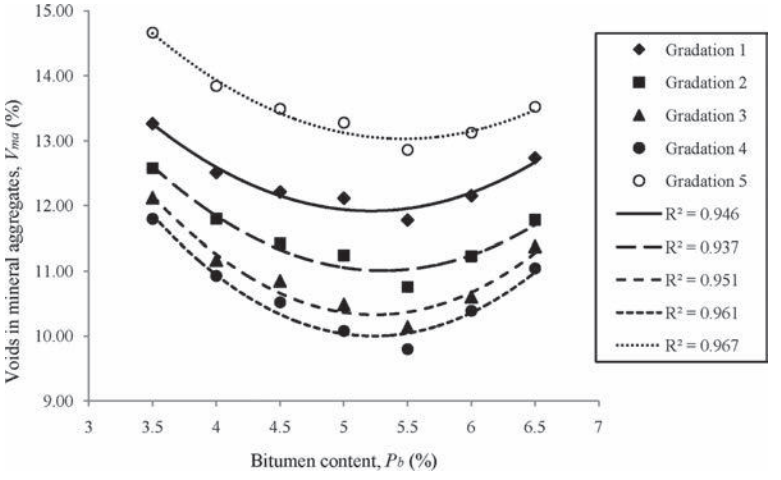

Figure 6. V_{ma} versus P_b for the five gradations.

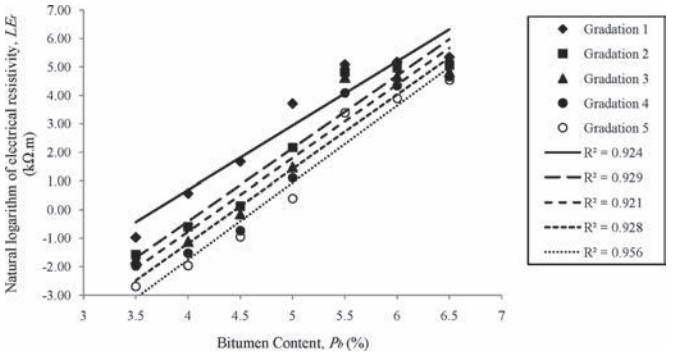

Figure 7. LE_r versus P_b for the five gradations.

3.2 *Electrical resistivity test results*

The electrical resistivity test results versus bitumen content, P_b, for the five gradations are shown in Figure 7. This Figure shows the average results of the five replicate specimens for each experimental combination. Therefore, it represents the results of 175 specimens. Because variation of the electrical resistivity values versus both the variables of aggregate gradation and bitumen content strongly follows an exponential pattern, it was decided to use natural logarithm of electrical resistivity, LE_r, instead of E_r in Figure 7. It is seen on Figure 7 that LE_r increases linearly as bitumen content increases under a constant gradation. This is because the interconnected V_{bm} and weight of the penetrating solution decrease as bitumen content increases under a constant gradation. In addition, it is clearly evident on Figure 7 that LE_r decreases linearly as gradation becomes finer from gradation 1 towards gradation 5 under constant bitumen content. As aggregate gradation becomes finer, the interconnected V_{bm} and weight of the penetrating solution decrease continuously; thus, LE_r is expected to increase. However, Figure 7 shows the results aren't in agreement with this expectation due to the following reason. The filler used in this study was cement which becomes an electrical conductor by the addition of water. Moreover, weight percent of the cement in the mixtures increases as aggregate gradation becomes finer. When the NaCl solution penetrates the asphalt mixture and combines with the cement, the electrical conductivity of the mixture increases and its electrical resistivity decreases. Therefore, as gradation becomes finer and weight percent of the filler increases, it seems the effect of high electrical conductivity of the combination of cement and water, in the initial setting phase before any hardening, is more significant on the electrical conductivity/resistivity of the asphalt mixture specimens. To examine this hypothesis, lime stone was used as a new filler to fabricate five extra specimens with the different gradations under a constant, 5.5%, bitumen content. The electrical resistance of these specimens were measured after saturating process. Unlike the previous trend for the specimens with the cement filler, the specimens having the lime stone filler showed more LE_r for the finer gradations than those for the coarser ones. In other words, based on the results of a limited laboratory experiment on the specimens with lime stone filler, it was realized that the effect of cement paste, in the initial setting phase before any hardening, prevails on the electrical conductivity/resistivity of the asphalt mixture specimens. However, more specimens with different aggregate gradations and bitumen contents are needed to investigate the real effects of lime stone filler on the electrical resistivity characteristics of asphalt mixtures and to reliably support the above hypothesis.

4 STATISTICAL ANALYSES

4.1 *Relationships between LE_r and the volumetric properties*

The volumetric test results versus LE_r for the five gradations are shown in Figures 8 to 10. It is seen on these figures that under a constant gradation, G_{mb} increases and V_{ma} decreases

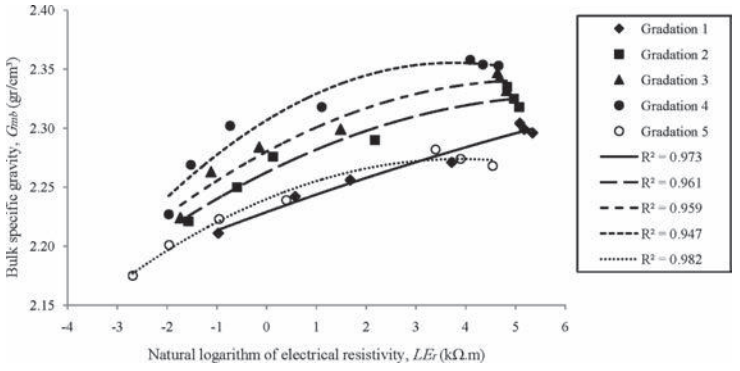

Figure 8. G_{mb} versus LE_r for the five gradations.

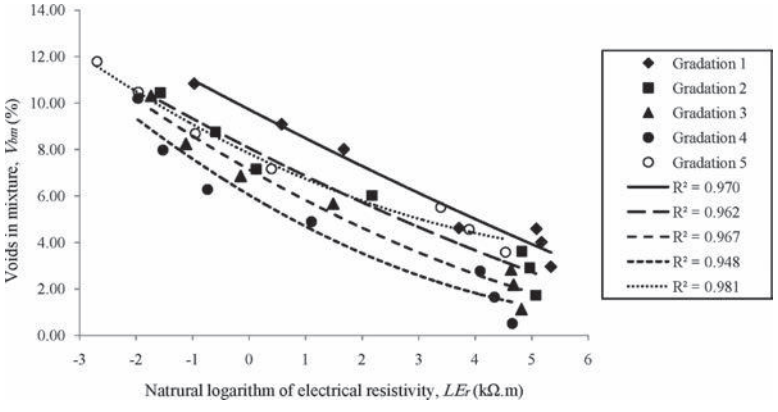

Figure 9. V_{bm} versus LE_r for the five gradations.

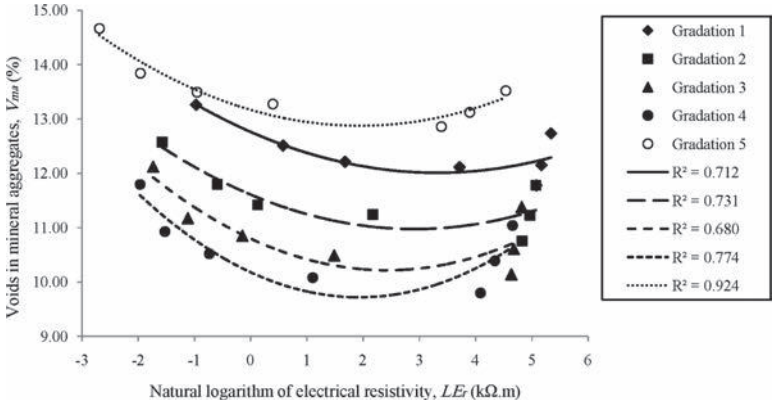

Figure 10. V_{ma} versus LE_r for the five gradations.

as LE_r increases up to a peak point and then as LE_r increases again, G_{mb} decreases and V_{ma} increases. However, under a constant gradation, V_{bm} decreases continuously as LE_r increases. These results show again that there is a significant direct linear relationship between bitumen content, P_b, and LE_r. On the other hand, as gradation becomes finer from gradation 1 towards gradation 4 under constant LE_r, G_{mb} increases and both the properties of V_{ma}

and V_{bm} decrease. Afterwards, as gradation becomes finer again from gradation 4 towards gradation 5, G_{mb} decreases and both the properties of V_{ma} and V_{bm} increase suddenly.

The test results on Figures 8 to 10 indicate that all the volumetric properties are sensitive to LE_r and they have very strong nonlinear quadratic relationships with this physical property of the asphalt mixtures.

Because of very strong nonlinear quadratic relationships between LE_r and the volumetric properties, Pearson linear correlation method cannot be used to determine the nonlinear correlation coefficients. Thus, the relationships between LE_r and all the volumetric properties are evaluated using the statistical analysis of variance (ANOVA) and significance tests. To this end, one-way ANOVA was conducted at 95% confidence level on G_{mb}, V_{bm}, and V_{ma} using the SPSS statistical package. The Fisher numbers and the probability of significance for LE_r at the given confidence level were calculated for each volumetric property and presented in Table 2.

It is understood from Table 2 that all the relationships between LE_r and the volumetric properties are significant at 95% confidence level. The significance levels can be compared for the volumetric properties using the calculated Fisher numbers. It is seen that V_{bm} is the most affected property by LE_r followed by the G_{mb} and the V_{ma}, respectively. In other words, the V_{bm} is strongly dependent on the LE_r having the largest Fisher number, 30.264, among the other volumetric properties. Similarly, the G_{mb} also proves a strong dependence on the LE_r and LE_r shows also a significant influence on the V_{ma} at 95% confidence level.

4.2 *Correlations between LE_r and the volumetric properties*

Regression analyses were carried out on the test data to develop simple correlations between LE_r and all the volumetric properties. Because variations of all the volumetric properties

	5	0.078	–0.302	13.166	0.924

versus LE_r strongly follow nonlinear quadratic patterns and due to the fact that LE_r has significant effects on all the volumetric properties, it was decided to develop simple correlations between LE_r and the volumetric properties for each gradation based on the general quadratic formulation of $a(LE_r)^2 + b(LE_r) + c$. Table 3 shows regression coefficients and coefficients of determination for correlation.

5 CONCLUSION

This study was to evaluate the relationships between electrical resistivity and volumetric properties of asphalt mixtures, i.e. G_{mb}, V_{bm}, and V_{ma}. To this end, all the volumetric properties were determined at various aggregate gradations and bitumen contents, and the electrical resistivity of each specimen was measured using a novel testing method. Correlation analysis, statistical analysis of variance and significance tests were performed on the test data, and simple correlations were formed between the natural logarithm of electrical resistivity, LE_r, and the volumetric properties for each gradation.

While the correlations developed for the tested specimens were characterized by high coefficients of determination, general application of these correlations to asphalt mixes having aggregate types, gradations, and absorptions, filler types, and bitumen types different than those tested would not likely yield accurate results. More research is needed to account for the effects of these important variables.

Asphalt Pavements contains the proceedings of the International Conference on Asphalt Pavements (Raleigh, North Carolina, USA, 1-5 June 2014), and discusses recent advances in theory and practice in asphalt materials and pavements. The contributions cover a wide range of topics:

- Environmental protection and socio-economic impacts
- Additives and modifiers for asphalt concrete
- Maintenance and rehabilitation
- Experimental characterization of asphaltic materials
- Life cycle cost analysis/modeling of compaction in the laboratory and in the field
- Perpetual pavements
- Pavement management systems
- Sustainable asphalt technologies
- Nondestructive testing of asphalt pavement
- Pavement condition survey/pavement smoothness/quality control/quality assurance
- Microstructural characterization and micromechanics of asphaltic materials
- Long-term pavement performance prediction
- Mineral aggregate in asphalt concrete/mix design methodology/novel methods to aid mix design
- Warm mix asphalt technologies
- Innovative pavement analysis and design
- Pavement response analysis under static and moving wheel loads
- Recycling
- Modeling of asphaltic materials and pavements
- Microstructural characterization and micromechanics of asphalt materials
- Asphalt pavement and environment
- Performance-related specifications

Asphalt Pavements will be of interest to academics and professional involved in asphalt engineering.
