Preface

We are very pleased to welcome you to the 2010 Construction Research Congress sponsored by the Construction Institute (CI) of the American Society of the Civil Engineers (ASCE) and the University of Alberta, in collaboration with the University of Calgary and the Canadian Society for Civil Engineering. The 2010 Construction Research Congress is being held at the Fairmont Banff Springs in Banff, Alberta, Canada - one of Canada's premiere hotels in the heart of the Canadian Rockies.

The theme of the Congress is "Innovation for Reshaping Construction Practice". The Congress aims to provide academics and industry professionals a forum to present and discuss revolutionary research findings, technological advances, emergent trends, and functional characteristics that are shaping the future of the architecture-engineering-construction industry. The purpose of the Construction Research Council is also to advance engineering knowledge and practice related to construction through stimulating and guiding research and assisting the financing thereof; to interpret and promote the utilization of the findings of research for the construction industry; and to identify future needs in the construction field and publicize them to stimulate appropriate research.

The two-volume Proceedings contain 156 peer reviewed papers covering the following 15 general state-of-knowledge research areas in construction engineering and management. There were 259 abstracts initially submitted that were reduced to 169 accepted draft papers following a peer review. From this, a final 156 papers were accepted for publication and presentation based on the same peer review process used in selecting abstracts.

- Automated/Real-Time Systems
- Construction Modeling and Simulation
- Disaster Planning and Mitigation
- Information Technology and Computer Applications
- Infrastructure Management and Underground Construction
- Knowledge Management
- Productivity, Benchmarking and Workforce Issues
- Organizational Leadership and Management
- Procurement, Contracting and Legal Affairs
- Project Planning and Control
- Project Risk Assessment and Management
- Quantitative Methods and Models
- Sustainable Construction and Facilities
- Construction Education
- CII Research

We are delighted to see that this event is truly global with representation from 14 countries including Australia, Canada, China, Egypt, Hong Kong, India, Indonesia, Korea, Netherlands, Saudi Arabia, Taiwan, Turkey, United Kingdom and United States.

We believe that you enjoy these Proceedings and have a memorable experience of both the Congress and spectacular Banff.

Janaka Ruwanpura, Ph.D., PQS
Technical Co-Chair
University of Calgary

Yasser Mohamed, Ph.D., P. Eng.
Technical Co-Chair
University of Alberta

SangHyun Lee, Ph.D.
Technical Co-Chair
University of Alberta

Acknowledgments

The 2010 Construction Research Congress Technical Program Committee is acknowledged for their dedication and contributions to the Congress program.

Conference Co-Chairs:
Dr. Aminah Robinson Fayek, University of Alberta
Dr. Mohamed Al-Hussein, University of Alberta

Technical Co-Chairs:
Dr. Janaka Ruwanpura, University of Calgary
Dr. Yasser Mohamed, University of Alberta
Dr. SangHyun Lee, University of Alberta

Track Coordinators:
Dr. Dilanthi Amarathunga, University of Salford
Dr. Sam Ariaratnam, Arizona State University
Dr. Ioannis Brilakis, Georgia Institute of Technology
Dr. Carlos Caldas, University of Texas
Dr. Patricia Carrillo, Loughborough University
Dr. Christine Fiori, Virginia Tech
Dr. Thomas Froese, University of British Columbia
Dr. Tarek Hegazy, University of Waterloo
Dr. Vineet Kamat, University of Michigan
Dr. Ming Lu, Hong Kong Polytechnic
Dr. John Messner, Pennsylvania State University
Dr. Moonseo Park, Seoul Nation University
Dr. Jeff Rankin, University of New Brunswick
Dr. Amarjit Singh, University of Hawaii
Dr. John Taylor, Columbia University
Dr. Tarek Zayed, Concordia University

The Technical Committee acknowledges the support of the reviewers and the student volunteers who helped in producing the proceedings.

Contents

Volume I

Automated/Real Time Systems

3D Visualization for Tunnel Boring Machine Steering and Alignment Control in Microtunneling **1**
Xiong Liang and Ming Lu

Automated Multiple Objects Tracking System (AMOTS) **11**
I. P. Tharindu Weerasinghe and Janaka Y. Ruwanpura

Resource Performance Indicators in Controlling Industrial Steel Projects **21**
Reza Azimi, SangHyun Lee, and Simaan M. AbouRizk

Application of Sensing Technology to Safety Management **31**
Matthew R. Hallowell, Jochen Teizer, and Wes Blaney

Automated Materials Tracking and Locating: Impact Modeling and Estimation **41**
D. Young, H. Nasir, S. Razavi, C. Haas, P. Goodrum, and C. Caldas

Automated Model-Based Recognition of Progress Using Daily Construction Photographs and IFC-Based 4D Models **51**
Mani Golparvar-Fard, Silvio Savarese, and Feniosky Peña-Mora

Construction Activity Classification Using Accelerometers **61**
Liju Joshua and Koshy Varghese

Evaluation the Electric Consumption of Residential Buildings: Current Practices and Future Prospects **71**
Mario Bergés, Lucio Soibelman, H. Scott Matthews, and Ethan Goldman

Automatically Tracking and Guiding Underground Tunnel Boring Machines during Microtunneling and Pipe Jacking Operations **81**
Xuesong Shen, Ming Lu, and Wu Chen

Geospatial Databases and Augmented Reality Visualization for Improving Safety in Urban Excavation Operations **91**
Sanat A. Talmaki, Suyang Dong, and Vineet R. Kamat

Real Time Information Integration via *i-Booth* **102**
Lahiru P. Silva, Janaka Y. Ruwanpura, Kasun N. Hewage, and Jamal Siadat

Real-Time Spatial Location Tracking of Construction Resources in Lay Down Yards **112**
Manu Venugopal, Tao Cheng, and Jochen Teizer

Semi-Automated As-Built Modeling of Light Rail System Guide Beams **122**
Pingbo Tang, Burcu Akinci, and Daniel Huber

Construction Industry Institute Research

Blind Spot Measurements for Real-Time Pro-Active Safety in Construction 132
Ben S. Allread and Jochen Teizer

Identification and Assessment of Cost Estimating Competencies..... 142
Anwar Alroomi, David Jeong, Oswald Chong, and Garold Oberlender

Improving Project Performance Using the Project Health Indicator Tool 151
Stuart Anderson and Adeniyi Olumide

Quality Management Systems in the Capital Facilities Delivery Industry: Analysisof Best Practices in Leadership and Third-Party Certification..... 162
Robert Ries, Kim LaScola Needy, Ankit Bansal, and Fikret K. Turan

Construction Education

An IDP-BIM Framework for Reshaping Professional Design Practices..... 172
D. Forgues and I. Iordanova

Construction Engineering Education: Need, Content, Learning Approaches..... 183
C. B. Tatum

Identifying Competencies for Baccalaureate Level Construction Education: Enhancing Employability of Young Professionals in the Construction Industry 194
Faisal Manzoor Arain

Interdisciplinary Team Learning in the Context of Integrated Design Studio..... 205
I. Iordanova, D. Forgues, M. Jemtrud, L. M. Farah, and T. Tidafi

Repositioning the Faculty Internship Experience in Construction Management 215
Ken-Yu Lin, Yong-Woo Kim, and Carrie Dossick

The Need and Challenges for Interdisciplinary Education in AEC..... 226
J. Irizarry, P. Meadati, and M. Gheisari

Virtual Construction Project Field Trips Using Remote Classroom Technology 236
Edward J. Jaselskis, Charles T. Jahren, Paul G. Jewell, Eric Floyd, and Timothy C. Becker

Construction Modeling and Simulation

A Case Study for Integrating Lean Six-Sigma and RFID Applications in Construction Processes through Simulation Approach..... 246
Myung Jin Chae, Sungmin Yun, Seung Heon Han, and Soon Wook Kwon

A Simulation Driven Visualization Framework for Construction Operations: Development and Application 257
Amr A. ElNimr and Yasser Mohammed

An Integrated System to Select, Position, and Simulate Mobile Cranes for Complex Industrial Projects 267
U. (Rick) Hermann, A. Hendi, J. Olearczyk, and M. Al-Hussein

An Optimization Model for Dynamic Multi-Project Environment in Construction..... 277
Lokman Hossain and Janaka Ruwanpura

BIM-Integrated Sustainable Material and Renewable Energy Simulation 288
Yong K. Cho, Sultan Alaskar, and Thaddaeus A. Bode

Exploring the Effects of Context Level Factors on the Structural Steel FabricationShop Operation 298
Amin Alvanchi, SangHyun Lee, and Simaan M. AbouRizk

Korean Real Estate Market and Mortgage Lending Policies: A Quantitative Approach 308
Sungjoo Hwang, Moonseo Park, Hyun-Soo Lee, and Wooyoung Kim

Lessons Learned from Utilizing Building Information Modeling for Construction Management Tasks 318
S. Kiziltas and B. Akinci

Multi-Objective Dynamic Simulation-Optimization for Equipment Allocation of Earthmoving Operations 328
Feifei Cheng, Yaowu Wang, and Xianzhang Ling

Real-Time Data Collection and Visualization Technology in Construction 339
Tao Cheng and Jochen Teizer

Simulation-Based Multiple Heavy Lift Planning in Industrial Construction 349
H. Taghaddos, S. AbouRizk, Y. Mohamed, and U. Hermann

Spatial Trajectory Analysis for Cranes Operations on Construction Sites 359
Jacek Olearczyk, Ulrich (Rick) Hermann, Mohamed Al-Hussein, and Ahmed Bouferguene

State-Based Simulation Mechanism for Facilitating Project Schedule Updating 369
Di Hu and Yasser Mohamed

Studying Dynamic Decision-Making in Construction Management Using Adaptive Interactive Simulations 379
Pei Tang, Amlan Mukherjee, and Nilufer Onder

System Dynamics Modeling of a Safety Culture Based on Resilience Engineering 389
SangUk Han, SangHyun Lee, and Feniosky Peña-Mora

Virtual Organizational Imitation for Construction Enterprises (VOICE): Managing Business Complexity Using Agent Based Modeling 398
Jing Du and Mohamed El-Gafy

Disaster Planning and Mitigation

A Method to Develop and Optimize the Placement of Road Barriers in Emergency Evacuation for University Campuses 409
Hubo Cai and Asadur Rahman

Developing Optimal Hazard Investment Strategies 420
Islam H. El-adaway and Omar H. El-Anwar

Development of an Index to Rate the Completeness and Quality of Mitigation Project Definition 430
Tadahisa Muramatsu and Cindy L. Menches

Optimizing Alternative Housing Projects in the Aftermath of Natural Disasters 440
Omar El-Anwar

Vulnerability Assessment of Critical Infrastructure, Associated Industries, and Communities during Extreme Events 449
Eun Ho Oh, Abhijeet Deshmukh, and Makarand Hastak

Information Technology and Computer Applications

2D Vision Tracking Methods' Performance Comparison for 3D Tracking of Construction Resources 459
Atefe Makhmalbaf, Man-Woo Park, Jun Yang, Ioannis Brilakis, and Patricio A. Vela

A Decision Support System for Integrating Corrective Maintenance, Preventive Maintenance, and Condition-Based Maintenance 470
Qi Hao, Yunjiao Xue, Weiming Shen, Brian Jones, and Jie Zhu

A GIS Framework for Construction Equipment Request and Deployment during Emergency Response 480
Albert Y. Chen and Feniosky Peña-Mora

Visually Scheduling Construction Projects 490
Saeed Karshenas and Anamika Sharma

Assessment of Internet Based Systems for Construction Product Information 500
Ung-Kyun Lee, Kim Sorrels, David Jeong, Ki-beom Ju, and Choonghan Han

BIM for Integration of Automated Real-Time Project Control Systems 509
Seokyon Hwang and Liang Y. Liu

Defining High-Level Project Control Data for Visual Information Systems 518
Namhun Lee and Eddy M. Rojas

Towards a Cyber-Physical Systems Approach to Construction 528
Chimay J. Anumba, Abiola Akanmu, and John Messner

Use of As-Built Building Information Modeling 538
J. Woo, J. Wilsmann, and D. Kang

Infrastructure Management and Underground Construction

A Novel Approach to Measuring Ground Movements Associated with Trenchless Construction Techniques 549
Jason S. Lueke and Samuel T. Ariaratnam

A Stochastic Method for Condition Rating of Concrete Bridges 558
S. Abu Dabous and S. Alkass

Analysis of Injury and Fatal Crashes in Highway Construction Zones 568
Tarek Elghamrawy, Khaled El-Rayes, and Liang Liu

Community-Driven and Reliability-Based Budget Allocation for Water Networks 578
O. Moselhi, T. Zayed, Z. Khan, and A. Salman

Development of an Innovative Free-Swimming Device for Detection of Leaks in Oil and Gas Pipelines **588**
Samuel T. Ariaratnam and Muthu Chandrasekaran

Analyzing Municipal Blockage Failure Datasets for Sewer Systems **597**
Yongliang Jin and Amlan Mukherjee

Framework for Web-Based Highway Construction Geospatial Data Management **607**
Thaddaeus Bode and Yong K. Cho

Infrastructure and Energy OR Energy and Infrastructure: How Energy Demandand Infrastructure Impact Each Other and What Carbon Limits Will Mean for Both **617**
Stephen Sewalk and Ken Strzepek

Integrating GPS and Laser Technology to Map Underground Utilities Installed Using Open Trench Method **627**
Alpesh Patel and Allan Chasey

Large-Scale Column Detection for Bridge Inspection **637**
Z. Zhu, S. German, and I. Brilakis

Review of Wireless Sensors for Road and Bridge Asset Management **647**
J. R. Kim, M. J. Chae, J. W. Park, G. Lee, and M. Y. Cho

Semantic Representation of Infrastructure Interdependencies: Rethinking Infrastructure Design and Management **656**
T. E. El-Diraby

Towards Optimum Condition Assessment Policies for Water and Sewer Networks **666**
Ahmed Atef, Hesham Osman, and Osama Moselhi

Knowledge Management

e-Society: A Community Engagement Framework for Construction Projects **676**
S. Kinawy and T. E. El-Diraby

Knowledge Management Systems for Construction **687**
Chimay J. Anumba and Doris Pulsifer

The Embedment of a Knowledge Management Program in an AEC Organization **697**
Amy Javernick Will

Using Lean Theory to Identify Waste Associated with Information Exchanges on a Building Project **708**
Craig R. Dubler, John I. Messner, and Chimay J. Anumba

Organizational Leadership and Management

A Game Theoretic Approach to Understand Opportunistic Behavior in Project Network Subcontractor Selection **717**
H. I. Unsal and J. E. Taylor

A Tool for Improving Construction Organizations' Innovation Capabilities **727**
T. Michael Toole, Paul Chinowsky, and Matthew R. Hallowell

Conflict Management in Concurrent Engineering: A Case Study **737**
S. J. Meijers, T. Hartmann, and G. P. M. R. Dewulf

Establishing a Collaborative Environment among Project Stakeholders **747**
Giovanni C. Migliaccio and Rebecca M. Martinez

Governance Challenges of Infrastructure Delivery: The Case for Socio-Economic Governance Approaches **757**
Raymond E. Levitt, Witold Henisz, W. Richard Scott, and Daniel Settel

Knowledge System Conflicts in Global Project Networks **768**

Abstract:

On tunneling projects, a tunnel boring machine (TBM) operator heavily counts on experiences to steer TBM and control tunnel alignment, which can be error prone due to lack of visualization of the underground working environment. Any alignment errors may considerably increase the chances of a TBM accidentally ramming into unexpected man-made barriers or hidden boulders, potentially damaging the drill bits of the TBM or even causing the TBM to be trapped underground. To improve the situation, an innovative TBM guidance system was developed by integrating automated site data collection technologies and 4D construction planning models. The as-designed tunnel, the existing facilities nearby are integrated in a 4D production model, and the data collected by total station and sensors are transformed to kinematic parameters through on-line computing which generates a 3D graphic interface for visualizing the underground situation and the orientations of the rear and cutter head of the working TBM.

Keywords: TBM; Alignment control; Automated data collection; 3D visualization

1. Introduction

As hardware and software for computer graphic processing advance, visualization technologies have expanded applications in science, education, entertainment, and engineering. The Architecture, Engineering and Construction (AEC) industry is also applying visualization technologies for improvement in various processes of a construction project, including but not limited to: architectural design and structural analysis, project planning and management, monitoring, inspection, and construction equipment teleoperation.

The visual perception is the main source of information that operators rely on for making decisions on controlling construction equipment. However, in contrast with construction aboveground, the underground workspace situation can not be

sensed through operators' naked eyes.

The alignment control is crucial for tunneling in a complicated underground space that is composed of a mixture of sand, clay, boulders and artificial obstructions. The Pipe Jacking Association (PJA, 1995) recommends that the acceptable tolerance for pipe jacking project is ±50 mm of a true line and ±75 mm of true level. Although a modern TBM is designed to tackle various ground conditions likely to be encountered, the TBM's head would tend to drill faster toward softer materials in the event of encountering boulders or manmade obstructions in the soft ground. If such abnormal rotations of TBM are not detected and corrected in a timely fashion, the TBM may rotate its body in unexpected and undesirable ways, potentially causing the TBM to be damaged or even trapped under the ground. In consequence, replacement of the damaged parts of the TBM or rescue of the stalled TBM would be time-consuming and costly, severely affecting project progress.

In current TBM guidance systems, the position and orientation of the TBM can be continuously tracked by instruments, such as laser, inclinometer, compass, and total station etc. However, the representation of the tracking information is largely two dimensional graphics that show the position of the laser point projected at the rear of the TBM and the dashboards that read the three orientation angles of the rear part of TBM(Yaw, Pitch and Roll in Figure 1, where the Y axis is the direction of TBM drilling). Figure 2 shows a TBM control station with a CCTV monitor, several dashboards and control switches.

Traditionally, when an operator detects that the lasor point deviates from the as-designed center, he will read the angles shown in the dashboards and imagine the complex status of the TBM by synthesizing all the parameters in his brain, so

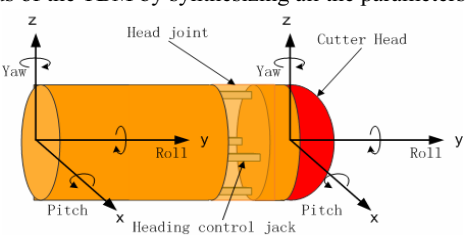

Figure 1. Three orientation angles at the rear and cutter head of the TBM

Figure 2. TBM control station

as to make decisions on how to adjust the heading control jacks to correct any

deviations. Due to the lack of straightforward visuals in three dimensions (3D), the operator heavily counts on experiences to steer TBM and control tunnel allignment, which is error prone. In contrast, the on-line 3D visulization can exactly show the orientation angles of the cutter head and the rear body of the TBM and relative angles bettwen them and the as-designed center line. All can be viewed by changing viewing positions, orientations, and by different zooming patterns.

Futhermore, the current visualization systems for TBM control are developed to cater for specific surveying systems, making it difficult to be used in a variety of scenarios. For example, the information important to TBM drilling operations such as the existing utilities in the vicinity of the designed tunnel cannot be easily modeled into the current TBM guidance visualization systems.

The theme of this research is to develop a generic framework for on-line 3D visualization of construction equipment operations by integration of computer graphic technology with automated data collection systems. In the following sections, the research background will be first described. Then a generic approach used for developing the on-line 3D visualization system for TBM alignment control is presented, followed by a detailed discussion on the issues involved in practical application process. Lastly, the developed system and the TBM steering simulation interface are presented.

2. Literature Review

Many emerging technologies such as robot, laser scanner, global positioning systems (GPS), total station, wireless networks etc. have been used for improving construction equipment control, among which computer supported visualization systems are widely applied to track the machine status and to maintain site situational awareness. Seo et al. (2000) addressed the development of graphical control interfaces with real-time updated graphical models of equipment and work environments. They also classified the architecture of graphical control interfaces into two categories, namely active and passive. Compared with passive graphical control interface, the active graphical control interface can directly control the equipment based on the preplanned and simulated operation. Although the active graphical control interface plays an important role in autonomous construction equipment systems which improve productivity and safety, it is required to model the entire objects in the workspace that could potentially affect the equipment operation.

In general, the models relevent to workspace will not be created during the design stage. Moreover, modeling the exact workspace is difficult in the complex construction environment due to the fast changing site situation and the uncertainty of underground soil profile. As suggested by Seo et al. (2000), when complete work environment models are not available, a passive graphical interface becomes a more appropriate approach. The passive type interfaces are more appropriate for the TBM steering in that (1). the operation is relatively simple; (2). the complete work environment models are not available and the

TBM operator in the control room must resort to on-line visual feedback frequently so to make critical decisions.

In the passive graphical control interface scheme, the operator controls the equipment based on graphical representations of the current status of equipment and work environments updated by sensor data. Seo et al. (2007) presented a tele-operated clinker clearing robot, in which a graphics technique was used to control the robot from a remote distance. Hirabayashi et al. (2006) integrated the visualization of haptic image, force feedback, and similar figure controller for teleoperation of an underwater construction machine. Their experiments demonstrated that the teleoperated control systems with computer aided visual aids are effective under the condition that the availability of direct visual information is not expected. While these systems prove that computer aided visualization of construction work environments and equipment statuses can improve equipment operations, the approach to leverage automated real-time quality control is yet to be developed for integrating the as-designed product model, the specifications of product dimensions and positions, and the as-built data.

The concept of the as-designed and the as-built integration in construction is motivated by the emerging data collection technologies such as laser scanner, embedded sensors, robotic total station and the advances made in integrated project models like 3D/4D CAD in AEC industry. Bernold (2002) proposed the integration of as-designed CAD data with the real-time site information, formalizing the concept of spatial integration in construction by giving three examples, namely, (1). remote position control; (2). design-integrated excavation; (3). design-integrated craning.

In order to leverage the as-built and as-designed integration for construction quality control, Akinci et al. (2006) proposed a formalism which has a project model composed of as-planned, as-built, specification, and defect models. The approach presented in this paper integrates the as-designed model, the specification model, and real-time data captured in the field to visualize the TBM tunneling process in 3D. However, instead of as-built construction product modeling, our approach is focused on visualization of the construction equipment and its interaction with the working environment. The proposed approach is intended to improve the construction equipment control process, enabling equipment operators to take timely corrective actions on any deviation detected by the on-line defects visualization model to avoid further build-up of defects.

3. Overview of the Approach

Although the approach presented in this paper is for improving TBM alignment control during tunneling operations, the system developed is a generic platform that can be adapted for other equipment. Figure 3 describes the architecture of the on-line 3D graphic control system for improving equipment handling and quality control during the course of construction operations.

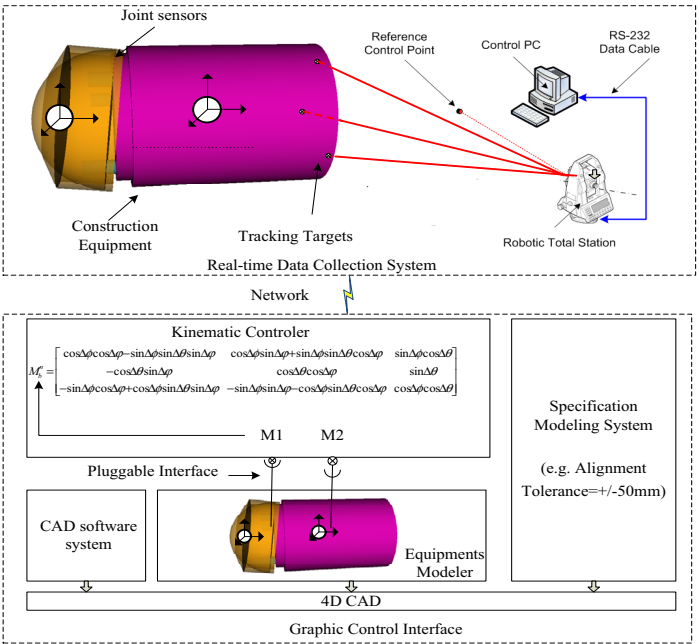

Figure 3. Architecture of the on-line 3D construction equipment control system

The system consists of a 4D CAD platform that enables on-line updating of the 3D models of the construction products and equipment over the timeline to reflect the current, as-built situation. The static models such as the as-designed products and existing facilities in the vicinity of an equipment can be imported from 3D CAD software such as AutoCAD, ArchiCAD, Google Sketch Up and Microstation etc. At present, the commercially available 4D CAD packages are so powerful that they can support various 3D formats, e.g. the Autodesk Navisworks 2010 can support more than forty formats. Nonetheless, there are few commercial 4D CAD systems that can support equipment modeling with kinematic control functions. In this research, we extended an in-house developed 4D CAD system, based on which an equipment modeler and a kinematic controller are developed to support the on-line visualization of the TBM tunneling process.

The equipment modeler enables the modeling of 3D equipment that can be manipulated with forward and inverse kinematic algorithms. However, different types of construction equipment have different joint configurations, and the structures of data captured also vary with the data collection technologies. Thus, the kinematic control algorithms are diverse. In order to develop a flexible and extensible system, we separate the kinematic controller from the equipment modeler and to link them with pluggable interfaces. The data collected by mutiple sensors are translated into the parameters of a kinematic algorithm through on-line

computing, which generates the geometric transformation matrices to control the orientation, position and joint angles of an equipment model. In order to compare the as-built with the as-designed models by 3D visualization, the specification on installation tolerances are modeled in 3D by using the specification modeling module.

The above as-designed, as-built and specification modules are integrated in a 4D CAD environment to generate the 3D graphic control interface for equipment operation control. The following sections further elaborate the approach for TBM alignment control.

3.1 Kinematic Controller

The kinematic controller determines the motion of an articulated equipment consisting of a set of rigid segments connected with joints based on the data collected and the forward and inverse kinematic algorithms. The forward kinematic algorithms generate the pose of the equipment given particular angles between joints. The inverse kinematic algorithms determine the joint angles given the desired configuration of the equipment. Compared with the forward kinematic problem, the inverse kinematic problem is much more difficult, which in general does not have analytical solutions. However, inverse kinematics may be solved via nonlinear programming techniques (Kamat and Martinez 2005).

In the case of the passive graphical interface for equipment control, in theory all the data required to determine the joint angles can be collected by using proper sensors. However it will drive up the system's cost while compromising the system's reliability. In practice, the one who designs the kinematic controller should make best efforts to use inverse kinematic algorithm so as to reduce the burden on data collection in the field. In order to calculate the kinematic parameters of TBM, we propose that three targets at the rear and the heading control jacks are monitored with automated data collection systems.

3.2 Data Collection System

When the control goals are identified and the kinematic controller is designed, the data required will be determined. Then one can select appropriate data collection methods, sensors and make a detailed data collection plan, such as the data collection frequency, communications, power supply, and sensors distribution.

The pipeline installation tolerances on tunneling projects are small thus requiring accurate data collection methods for control purpose. Nowadays, total stations have replaced transits and theodolites, increasingly becoming the predominant instrument used in the surveying practice (Ghilani and Wolf 2008). A modern total station can function like a surveying robot capable of (1) automatic target recognition (ATR) and (2) automatic target tracking directed by preprogrammed surveying procedures. Considering their automatic functions and high precision in surveying results, robotic total stations are used for collecting the data required by the 3D TBM alignment control system. The TBM alignment control needs several points to be automatically surveyed by a robotic total station

in high precision, and the more points to be tracked, the more time to be incurred for one cycle of surveying. In order to determine the attitudes of the TBM in the 3D underground space, at least three points should be tracked continuously. The methods used to transform the points to TBM attitudes can be found in Shen et al. (2009).

The time for tracking the three targets in one cycle is around 30 seconds, which means the 3D visualization system will update the status of TBM every half a minute. In some cases, for example, large scale steel components installation, real-time control is important, then several total stations can work in sychronization to track the targets. However, for TBM allignemnt control, considering the speed of progression is 2 to 15 meters per day depending on soil conditions, a fast update rate is not required. One total station is sufficient for TBM tracking and data collection in commonly seen straight drives.

3.3 Specification of Tolerances

Specification modeling enables defects detection by on-line 3D visualization, and releases the operators from looking up or recalling the specifications during the operation process. Different projects may have different tolerance requirements, hence the specification modeler should be flexible and scalable. Parametric modeling techniques can be appropriate for the modeling of tunneling projects' specifications. As shown in Figure 4 the tolerances on pipeline installation can be modeled as a cylinder with a larger diameter encaptulating the pipe being installed. The diameter difference between the two cylinders is the allowable tolerance on the pipeline alignment. By parametric modeling, the diameter of the tolerance cylinder can be easily changed to cater for different requirements on different projects. It also enables operators to specify a tolerance cylinder with a smaller diameter than the maximum tolerance allowable so as to achieve a higher accuracy.

Compared with 2D visualization of the specification, the proposed 3D visualization approach can give the operators direct guidance on the combined deviations in alignment (line and level) and TBM orientation. The left hand part of

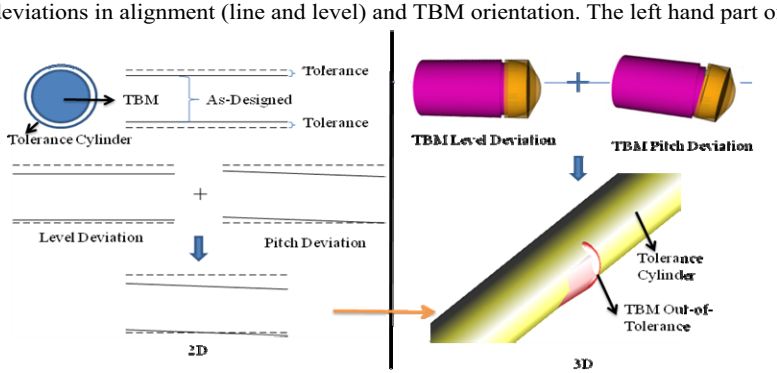

Figure 4: Demonstration of two combined deviations

Figure 4 illustrates a simple case with level and pitch deviations that can be visualized by 2D as well as 3D model. However, when a more complex deviation occurs (e.g. combining yaw, pitch, level and line, as shown in the right hand part of Figure 4 which has incurred orientation angles at the rear and cutter head of TBM), it's impossible to be visualized in one 2D graphic, in which case, complex calculations are required to determine whether the TBM is out-of-tolerance. In the 3D visualization system, all combined deviations can be automatically computed in the kinematic algorithms and visualized in an integrated view with different colours highlightling the out-of-tolerance deviations.

4. System Development and Simulation

To validate the presented approach, an on-line visualization system for TBM alignment control is developed. Figure 5 shows the graphical control interface of the system. On the left is the 3D view window that shows 3D models, such as the existing piles, the shaft, the tolerance cylinder and the TBM which is undergoing "out-of-tolerance" operations at the moment. An operator can adjust the angles of the view by clicking the buttons on the left toolbar, and can also zoom in and out using the buttons on the top toolbar. The right hand side of the user interface contains the two modules, namely, the kinematic controller and the data receiver that link to the site data collection system.

The three targets' coordinates are automatically collected by a total station which is linked with a control laptop via a RS232 serial cable. The total station is controlled by a computer program developed in-house, which provides an interface to initialize the total station, enter tracking commands, and perform on-line data processing (Shen et al. 2009). The data for 3D visualization of the cutter head is sourced from the heading control jacks system.

There are three virtual dashboards showing yaw, pitch and roll angles of the cutter head in Figure 5. The orientation of the cutter head which is important visual information to support the operator on TBM control is automated computed

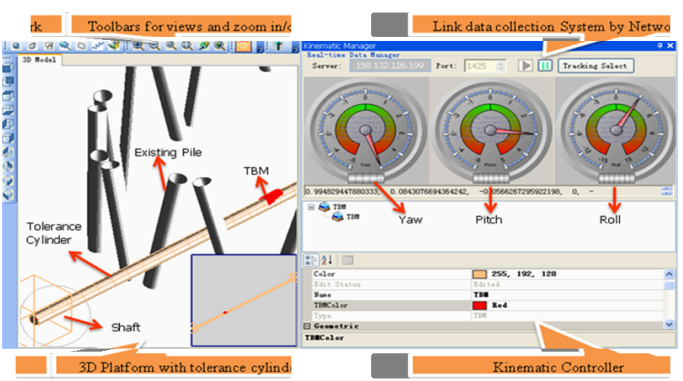

Figure 5. Graphical control interface of the TBM alignment control system

based on the lengh of heading control jacks result from the push-pull operation. In current TBM system, the operators need to estimate the orientations based on their experiences so as to adjust the heading control jacks. In order to give TBM operators guidance on how to control the jacks, the proposed system provides simulation interface.

An operator can use the system to simulate the control of each heading control jack. The system will immediately update the 3D model based on the input of simulation parameters. As shown in the Figure 6, the snapshot (a) shows the status of TBM without cutter head orientations, and the snapshot (b) and (d) show the results from pushing two heading control jacks respectively, and the snapshot (c) show the results from drawing back nother heading control jack. When the rear of TBM has roll angle, it's very difficult for operator to obtain the orientations of the cutter head without the support of the 3D visualization system. In constrast, an operator can verify his decision before pushing the real buttons on the TBM control system by using the developed system. Furthermore, the system can avoid the problem caused by being unaware of the limited orientation capacity of the cutter head, in which case it may be difficult to correct the excessive deviations of the tunnel alignment.

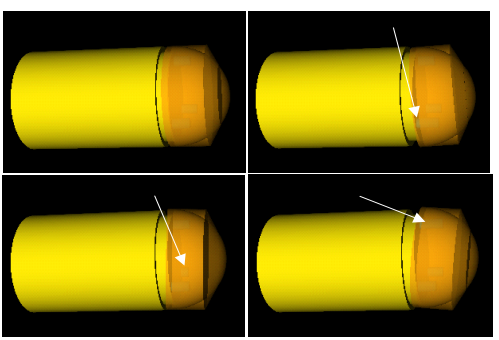

Figure 6. Simulation of the heading control jacks

5. Conclusions and Future Work

The advancement in field data capture and 3D/4D technologies has enabled the on-line 3D visualization of construction equipment operations. However, due to the dynamic nature of the construction environment, applications in construction should be well designed, tested and formalized. This paper has reported an ongoing research of formalizing a generic framework for developing passive graphic control interfaces for construction equipment control, based on which a on-line 3D visualization system for TBM alignment control in tunneling is developed. The system can support the TBM operator on making timely decisions to adjust the heading control jacks. The system will be more useful for complicated TBM systems that have several articulated joints and applied in the tunnel projects with the design of curves. The proposed approach can also be

applied to other fields that need accurate positioning control during construction, for example, the assembly of large-scale structural steel components.

The authors' on-going research will test the visualization system in the field and also will explore on extending the visualization system to be an autonomous TBM navigation system in the near future. There are also some opportunities to link the on-line 3D visualization system to project management tasks. Because the proposed approach integrates the as-design model of the tunnel, the quantity of excavated soil can be calculated automatically based on the progress data continually collected, and such information can be used for an automated material and cost tracking that assists in project management.

Abstract

A contractor usually employs observers or employees to collect information from construction sites to verify the progress. The accuracy level of these field data significantly decreases because of the human errors and limitations in data availability. This paper describes a novel conceptual model called "Automated Multiple Objects Tracking System (AMOTS)" using latest technologies such as audio and video surveillance. The system tracks objects (workers, tools, etc.) based on the characteristics of the objects (unique shape of the objects and the unique sound patterns of the tools). A well-known correlation method and image subtraction method are applied to detect and differentiate the objects of the site. AMOTS also measures the real time work performance of the workers.

Introduction

Technologies have increasingly been used in many applications in different fields, such as geotechnical, biomedical engineering and aviation. Even though the construction industry is one of the most influential sectors of the economy in any nation, it has made relatively limited progress in adaptation of these technologies. Construction field is identified as being deficient in the use of cutting edge technologies and data acquisition systems to improve performance and productivity of construction projects (Hewage and Ruwanpura 2008). As a result of that, most of the construction companies do not have a reliable information database to assess the ongoing construction progress. A contractor usually employs observers or employees to collect information from construction sites to verify the progress. The accuracy level of these field data significantly decreases because of the human errors and limitations in data availability. This paper describes a novel conceptual model termed the "automated multiple objects tracking system (AMOTS)" using latest technologies such as audio and video surveillance. Intelligent automated audio visual surveillance system aims to provide an attention-focussing filter to enable the system to extract necessary onsite information. Accurate data is required not only to monitor and control current projects, but also to update the historic database. Such accurate complete information can also provide feedback to designers and planners for future projects in terms of cost, schedule, labour allocation, etc. This paper explains an

integrated system to automatically capture site data using a number of sources to assess worker performance and productivity.

Background

A number of attempts have been made to develop systems for collecting data by researchers for construction management. For an example, a site inspector used a pen-based computer to input image information for a Field Inspection Reporting System (Rojas & Songer, 1997). This particular system sends inspection data to the internet web server to store in a common database, which is accessible to all parties involved in the project. Using a similar concept, a video camera and a microphone connected to a pen-based notebook computer were mounted on a hard hat (Liu 1997), which could be worn by site personnel while walking on site. The data was transferred by means of a wireless network to a desktop server in the site office. This device had the advantage of transferring images to remote experts in real time. Several of these systems were developed for analyzing the data after they were collected and input by the user. Some of the automatic data acquisition systems developed in the past, has limitations and may be applied only in certain circumstances or for a specific construction process (Ghandour 2007).

Furthermore, surveillance and web cameras have been used to monitor certain activities (for example, tracking of a hopper and a hook in concrete placement). The detection in this case was based on one characteristic of the activity, large motion of the hopper, and the properties of the hook (Almassi and McCabe 2008). That is a fully automated system focused only on a specific task and it did not demonstrate the capability to measure human activities.

An automated system which can analyse human poses for the determination of construction productivity in real-time was developed recently (Peddi et al. 2009). In that system, built-in neural network determines the working status of a worker by comparing in-coming images to the developed human poses. The labour productivity is determined from the comparison statistics. This system can only be applied for the selected activities which have specific/unique human poses when workers get involved in the work.

According to the work carried out by previous researchers, the author was able to find a knowledge gap in the following untouched areas. (a) Measuring work performance by analysing real time on site audio (b) Tool usage and the worker movement path

Summary of objectives

The primary objective of this study outlined in the paper is to develop a fully automated worker and tool sound tracking system using integrated audio and video signal processing techniques to extracts real-time information about construction work activities and worker movement patterns without any human involvement to enhance the construction productivity. Furthermore, the study focuses on measuring the tool time and the performance of construction workers.

This paper outlines the concepts of extracting the necessary on-site construction related real-time information from video files and audio files by using signal-processing techniques. This paper presents the conceptual details about how to track human figures from cameras and to use audio files to assess tool time. Figure 1 shows the general equipment arrangement of the proposed methodology. Conceptual research strategies to achieve the objectives are discussed in the paper.

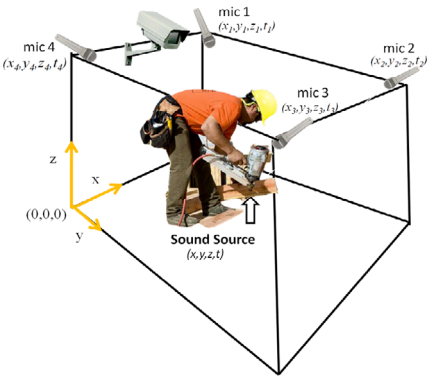

Figure 1: General equipment setup of the work space

Methodology of Tracking:

This study is about a real time and fully automated system using signal processing techniques for data extraction from audio and video files of construction activities This data extraction system is developed to detect the construction workers and their movements within a given work area to measure tool time and to assess worker productivity. The software used for processing the images is MATLAB. The AMOTS images are obtained from a high-end surveillance camera at a resolution of 640x480 pixels. Figure 2 shows the summary of the methodology using a flowchart.

Following assumptions are made for research purposes (1) All the site personnel use similar shaped hard hats when they are on site. (2) All the site personnel follow correct colour coded hard hats according to their job title. [Ex: yellow hard hats for labours, white hard hats for supervisors, etc]. In brief, the system tracks human figures of the video by detecting the hard hat shape. Then the tracked human is differentiated according to the colour of the hard hat. Audio sound monitoring is used to recognize the work activity of each worker and to track the location of the sound source. Consequently, location of each worker and the tool sounds are analysed. Following conditions are used to recognize the activity of each worker; (a) Closeness of the coordinates of workers and tools (b) orientation of the hard hat [if someone works with a tool, orientation of the hard hat should be towards the tool]. Furthermore, tool time of a worker is determined by analysing the time of occurrences of each tool sound at a given time period.

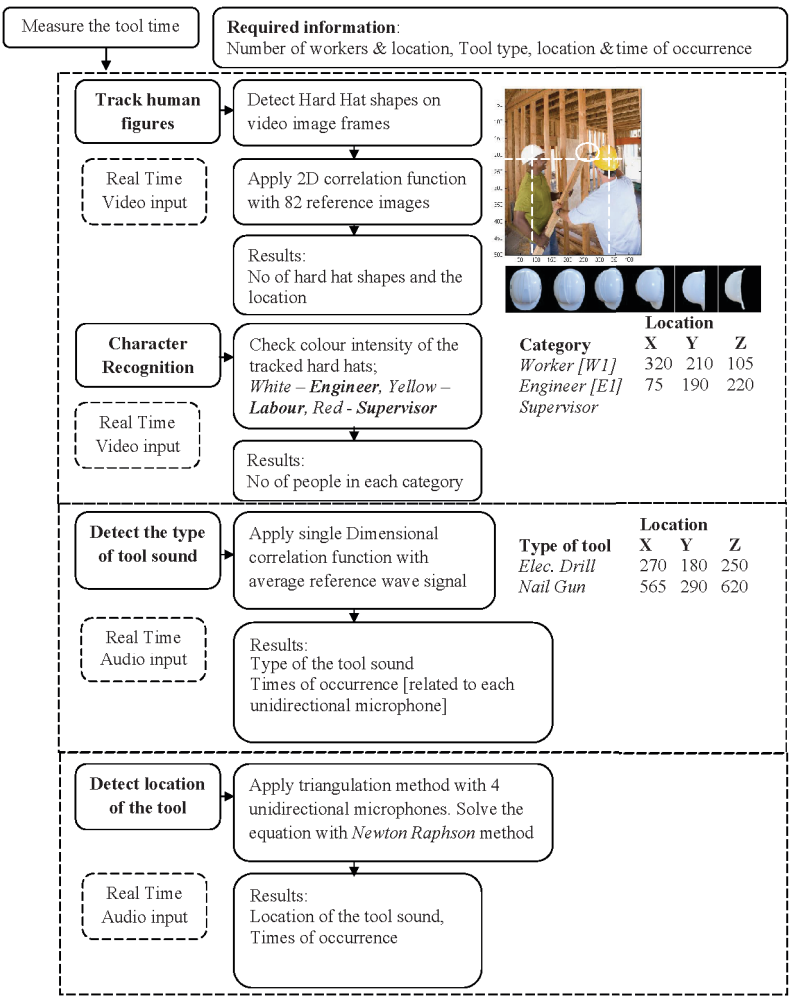

Figure 2: Flow chart of the methodology

Summary of algorithms

Track human figures:

To extract information about an activity from digital video files, the characteristics of that activity and its associated tools are important. In this case, three characteristics were considered: motion, shape and colour.

The method of choice for moving object segmentation in most tracking algorithms is background differencing. At time t, the difference and background images are calculated as follows:

$$\delta(r,c) = \begin{cases} 1 & |I(r,c) - B(r,c)| > T \\ 0 & \text{otherwise} \end{cases} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (1)$$

$$B(t) = \beta \times I(t) + (1-\beta) \times B(t-1) \quad \text{if } \delta(r,c) = 0 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (2)$$

Where r and c are the row and column subscripts of a single pixel, δ is the difference image, I is the input image, and B is the background image. If the difference δ(r,c) is greater than the threshold, T = 12, the pixel is labelled as foreground, while background pixels are modified by expression 2, where β=0.1 and controls the rate of the background update (Owens et al. 2002). After this process, object [hard hat] recognition algorithm is applied to the tracked moved objects. The worker tracking system is based on the characteristics [shape and colour] of the hardhat. A well known correlation method is used to track the hard hat shape (See equation 3).

In order to recognize objects, the researcher must first prepare a database against which the matching takes place. To do this, the researcher first takes a number of images of each object, covering the region on the viewing sphere over which the object may be sighted. Images of the object were taken against a clean black background over the whole viewing sphere. The exact number of images per object may vary depending on the features used and any symmetry present. Obtaining training images about every 20 degrees is sufficient in the case of a hard hat [Selinger and Nelson 2001]. To cover the entire sphere at this sampling requires about 82 images since the hard hat is symmetrical in shape.

The grid line distribution of the sphere is shown in Figure 3. All the reference images are taken from a distance of 45cm away from the camera. In addition, each image populates another 18 sub-images with 20 degree rotations and 18 mirrored images from each rotated angle. Therefore, the full database consists of 2916 reference images per unit distance. Figure 4 shows six reference hard hat images.

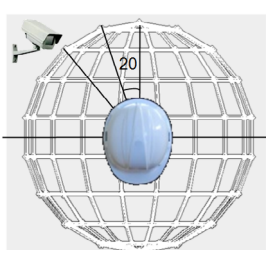

Figure 3: 20degree grid work of the object sphere

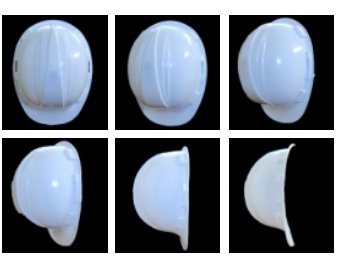

Figure 4: Reference images of the hard hat

Figure 5 shows the snap shot extracted from the digital video file. First, all the images are converted in to grey scale images. For every image obtained, the boundary extraction procedure is run. In order to obtain an edge/ boundary map, the Canny method is applied. After the original image is converted into an edge map, the similarity between the original image and the reference image is identified [Figure 6]. Correlation function can be used to separate a reference signal embedded in a noised signal from single dimension, two-dimensional or from any number of dimensional matrices (Proakis and Manolakis 1996). This method can be applied to detect the number of reference hardhat images embedded in the main video stream. If the video image matrix x has dimensions (N_1, N_2) and reference (hard hat) image matrix y has dimensions (N_1', N_2'), the 2-dimensional correlation v is;

$$v(K_1, K_2) = \sum_{N_1=1}^{N_1} \sum_{N_2=1}^{N_2} [x(N_1, N_2) \times y((N_1 - K_1 + 1), (N_2 - K_2 + 1))] \ldots\ldots (3)$$

Figure 7(a), 7(c): original reference images.
Figure 7(b): after 80 degree rotation of the image (a)
Figure 7(d): mirrored and rotated 260 degrees of the image (c)

A fixed distance of 45cm is maintained between the camera and the hard hat when taking reference images. The correlation starts from reference image scale factor 1.0 with the given video frame.
Then the reference image scale factor is gradually reduced with a fixed interval and matched for several times. The correlation between the reference image sizes and the distance from camera to the object (distance/size ratio) can be used to determine the location of the object along the z axis in the video frame.

It is recommended to use different coloured hard hats to differentiate the work force on site [e.g. white – Engineer, Yellow – Labourer, Red – Supervisor]. The average colour intensity in the region of the tracked hard hat shapes of the video image is checked. If it is linked with the above criteria, the system recognizes the type of the work group without identifying the personal information (Weerasinghe and Ruwanpura 2009). The proposed system is smart to tie the current work activity with each tracked worker. With an assumption of "Every tool generates a unique sound", it is proposed to track the sound pattern of the tool to support recognition of the current work activity.

Track Tool Sounds:
Four unidirectional microphones are installed at upper corners of the work space; real-time audio signal is transmitted to the central processing unit [see Figure 1]. The proposed system can recognize the sound pattern of the tools and measure the number of times the tool is used.

A database of reference wave signals for each construction activity is developed. Significant number of wave signals for a particular activity/equipment have been collected and populated in the database. This enables to determine the average wave pattern for each tool. Since the mono audio signal is considered as a single dimensional matrix, the following equation can be applied. If the real-time audio matrix x has dimension (N) and reference wave signal (nail gun) matrix y has dimension (N'), the single-dimensional correlation r is;

$$r(k) = \sum_{n=1}^{N} x(n) \times y(n - k + 1) \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

An average nail gun reference audio signal is shown in Figure 8. Figure 9 shows the main audio stream that comes from a unidirectional microphone system with different tool sounds in a noisy background. The correlation function is applied on the main audio signal with the reference signal. The resultant correlation map is shown in Figure 10. A certain threshold level is selected according to the features to be extracted (four peaks rose beyond the threshold level as shown in Figure 10). Therefore, the figure interprets that four similar reference signals are embedded in the main audio stream at the relevant time locations.

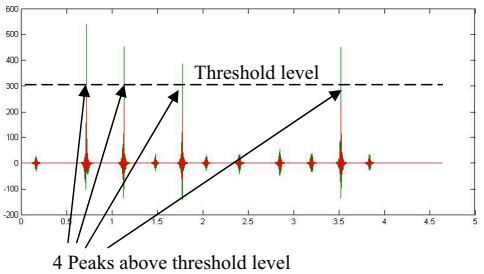

Figure 10: Resultant of correlation function.

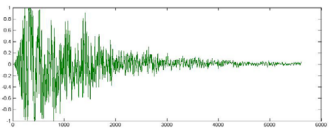

Figure 8: Reference audio signal [Nail Gun]

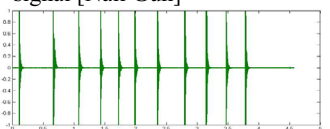

Figure 9: Main audio signal with different sounds patterns

Although human figures and tool sounds have been tracked, it appears as standalone information. Therefore the connectivity between tracked workers and the tool sounds are yet to be analysed. Determining location of the sound source and linking with the worker coordinates resolves the above problem.

Sound source tracking:

The sound triangulation scheme was influenced by the Global Positioning System (GPS), which triangulates the location of a receiver using satellites. The fundamentals of the triangulation idea are derived from the assumption that speed of sound is constant. Thus researcher was able to determine the distance between a microphone and the sound source using the speed of sound and the time it takes the sound wave to propagate to the microphone.

The equation below describes the relationship between the speed of sound, c, the location of the sound source (x,y,z), the location of the n^{th} microphone (x_n,y_n,z_n), the time of the sound source transmission (t), and the time of the sound source reception (t_n) .

$$f(x, y, z, t) = \sqrt{(x - x_n)^2 + (y - y_n)^2 + (z - z_n)^2} - c(t_n - t) \quad \ldots\ldots\ldots\ldots (5)$$

Following equation 6, Newton-Raphson method is used to solve the above non-linear equation. Given a function $f(x)$ and its derivative $f'(x)$, a first guess x_0, a better approximation x_1 is;

$$x_1 = x_0 - \frac{f(x_0)}{f'(x_0)} \quad \ldots\ldots\ldots\ldots (6)$$

After solving this equation, the sound source coordinates and the operated time can be determined. Consequently, the performance/tool time of the worker is determined. As an example, if W1 generates 12 numbers of nail gun sounds in a one hour time frame, then the performance of that worker is 12nails/hour. Tables 1 to 3 show the sample results based on the algorithms developed.

Expected Results

Table 1: Summery of the results

Time	Video				Audio			
	Category	Coordinates			Tool Type	Coordinates		
		X	y	z		x	y	z
8:31:05	W1	45	65	32	Nail Gun	40	60	30
	W2	105	95	50	Hammer	100	90	40
8:35:05	W1	50	70	30	Nail Gun	48	68	31
	W2	115	90	52	Hammer	120	90	45

Table 2: Detailed description [Worker W1]

Time	Tool Type	Coordinates		
		X	y	z
8:31:05	Nail Gun	40	60	30
8:35:05	Nail Gun	48	68	31
8:40:22	Nail Gun	50	80	33
8:35:05	Nail Gun	60	78	35

Table 3: Tool Usage [Nail Gun]

Time	Worker	Coordinates		
		x	y	z
8:31:05	W1	40	60	30
9:25:05	W1	48	68	31
9:40:22	W2	50	80	33
9:50:05	W3	60	78	35

Conclusion

This study presented in the paper outlines the development of a real time and fully automated system to measure tool time of the workers using audio and video analysis techniques. High-end surveillance cameras are used to detect the humans and to differentiate different human categories in a construction site. Digital image correlation aids to recognize hard hats of the workers and to assess the worker movements. Work activity is recognized by analysing the tool sounds. The proposed four unidirectional microphone system aids to identify the tool sound and its generated location. The triangulation method runs as a supportive function to solve the coordinates of the tool sound location. The link between tracked worker and the tool sound is tied by analysing the coordinates of the worker and the tool sound. As a output of this system, it provides; (1) number of workers working at a given time period (2) worker movement path (3) tool time and performance of each worker (4) tool usage of each tool.

Although it is proposed to use different coloured hard hats to differentiate the work force, deviations for the above is often observed in practice. However it is stressed that in order to acquire the benefits arising from the study, the construction industry must be flexible to adhere to the prerequisites proposed by the study. In conclusion, the novel approach proposed in the study is expected to provide more precise inputs in the assessment of tool time and the worker productivity.

Abstract

Industrial steel construction deals with the design, fabrication, and site erection of steel elements and encompasses many activities, interactions, and potential resources. An effective project control system for such an environment, as well as issues concerning traditional control systems, are important. This has motivated the authors to propose an integrated and real-time monitoring and control system for steel projects. This paper discusses the application of the concept of resource performance indicators in major components of the proposed system that deal with measuring project performance and the simulation of different scenarios. An object model is utilized and a control object is defined for steel projects to ease the control process. The focus of this research is on labour performance indicators in the fabrication phase of industrial steel projects. To improve the accuracy of the outputs of the system, the Markov Chain method has been used to forecast the values of the resource performance indicators that are fed into the simulation model.

Introduction

Industrial steel construction deals with a variety of buildings, from heavy industrial buildings and petrochemical refineries to sheds, shelters, and roofs. Reduced construction times, efficiency, and cost-effectiveness can be considered as the major benefits of using industrial steel elements. Detailing (designing), procurement, steel fabrication, shipment, and site erection are five major phases in a typical industrial steel construction project.

The complex nature of steel construction (i.e., the large number of potential resources, activities, and interactions required, the industry's growth, and the adoption of new fabrication technologies and materials) requires advanced and effective tools to estimate, schedule, monitor, and control industrial steel projects. The authors (Azimi et al. 2009) proposed an automated and real-time monitoring and control system for steel projects. With the help of a collaborative steel company, the components of the framework are being implemented in the fabrication phase of steel construction. Steel fabrication refers to the manufacturing of steel pieces through a series of operations, including cutting, fitting, welding, sand blasting, and painting, in a fabrication shop according to the engineering design. Steel fabrication is one of the most complicated phases in industrial steel construction projects because of the unique of steel elements, the huge number of fabricated pieces, material handling and inspection activities, the large variety of steel pieces produced in terms of dimension and processing requirements, and the variety of equipment and labour disciplines involved.

The focus of the paper will be on the resource performance indicators used in the system for automated analysis purposes. Generally speaking, resource performance indicators are used for reasoning (Li et al. 2005) and this paper explains how these indicators can be used and forecasted to improve the reliability of the outputs of the automated control system.

Background

Monitoring and control refers to measuring the actual values of the basic variables of a project (such as the percent completed, the quality of work, and cost), analyzing these data, determining if the project is meeting the targets of the work plan, and taking necessary actions to meet project objectives if there are any deviations in project performance (Oberlender 2000). The construction industry is an enormous industry in North America and a huge amount of money is spent in this industry. As an example, in the first eleven months of 2007, US$12.82 trillion was spent in construction projects in the US (www.researchandmarkets.com/reports/656143). This highlights the importance of the role of monitoring and control systems in construction due to the fact that a small variance in the performance of the ongoing projects leads to the loss of billions of dollars. Thus, issues regarding current monitoring and control systems have developed into a major field of interest for researchers. In terms of monitoring, project managers and control systems require a high quality and real-time data to take timely and proper corrective actions after any deviation occurs. The emergence of new technologies, such as Radio Frequency Identification (RFID), has helped researchers to capture performance data for in-progress projects in real-time (Chin et al. 2008; Navon and Sacks 2007; Ghanem and Abdelrazig 2006; Cheng and Chen 2002; Ciesielski 2000). To be effective, there needs to be integration between monitoring and controlling. Gaps between monitoring and controlling components (e.g., evaluation, analysis, and taking corrective actions) may lead to delays and cost overruns. To deal with this issue, integrated monitoring and control systems are under development (Diekmann and Al-Tabtabai 1992; Kim et al. 2008; Moselhi et al. 2004; Nasr 2005; Nassar et al. 2003;

Po-Han Chen 2008). However, current systems are suffering from at least one of the following shortfalls (Azimi et al. 2009):

- Lack of some important components of an integrated project control system, such as forecasting performance, analyzing variances, and recommending corrective actions.
- Manual data entry, which is slow and error-prone.
- Inflexibility and lack of interoperability.
- Difficulties in terms of sharing data (centralized and office-based systems).

To address these issues, Azimi et al. (2009) proposed a project control framework in which real-time, as-built information from a monitoring system is integrated with a control system that includes different components and simulation models (Figure 1). The framework, which uses High Level Architecture (HLA) concepts (IEEE 1516), enables project managers to monitor the progress and performance of each project in a timely manner and to be notified automatically of any deviations; this notification includes complete information regarding the impacts of these problems.

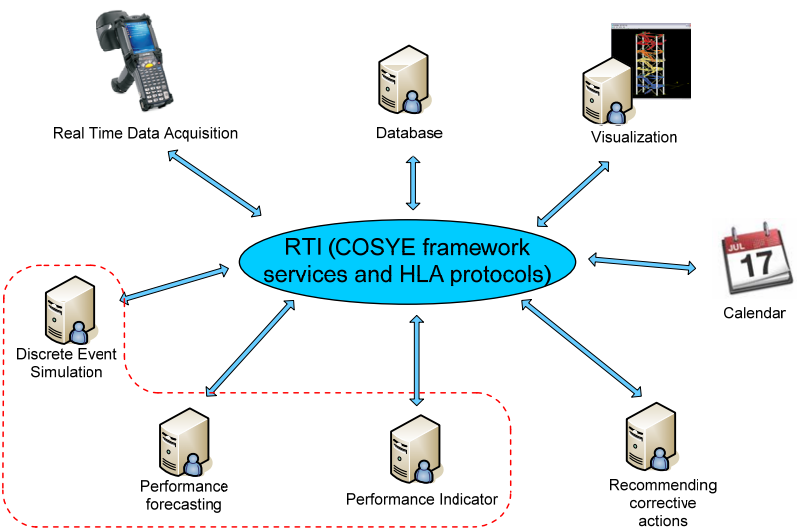

Figure 1. Proposed monitoring and control framework (Azimi et al 2009)

The infrastructure, the components, and the interactions between the components in the proposed framework have been discussed previously (see Azimi et al. 2009). This paper therefore deals specifically with the development and implementation aspects of the framework components marked with the red dashed line in Figure 1. A prototype of the framework has been implemented in the collaborative company. An automated data capturing system using RFID technology provides real-time information for other components of the system; evaluation and analysis regarding

project performance is carried out by other federates based on captured data. The following sections explain how current and predicted project performance are determined for controlling in the implementation phase of the framework.

Earned Value Analysis on Control-Objects

For control purposes, the level of detail for monitoring and analyzing project performance information needs to be determined. Figure 2 represents the Work Breakdown Structure (WBS) of a typical steel fabrication project.

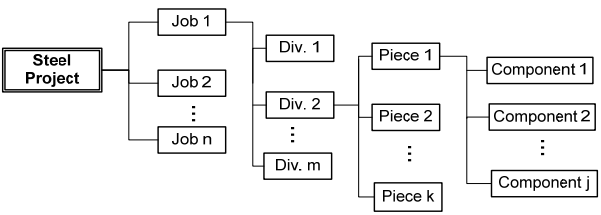

Figure 2. WBS of a typical steel fabrication project

In this research, division and project levels are monitored and controlled. Once progress and performance information at the division level is calculated with the bottom-up approach, project performance at the project level can be determined. A steel project is represented by a set of divisions, which are the control objects. Each division (control object) has its own resources (i.e., labour, material, equipment and, in rare cases, subcontractors) as well as as-planned and actual data, as shown in Figure 3.

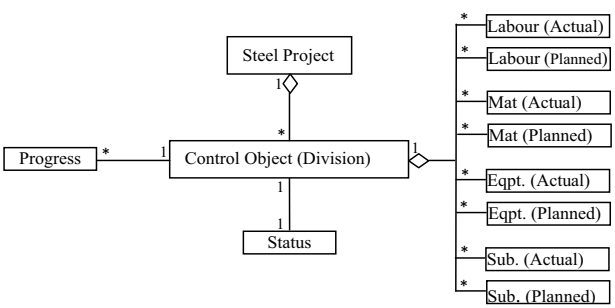

Figure 3. Proposed object model of a steel fabrication project

Status class refers to the actual start and finish time of a division. Additionally, progress of the division is considered as a class in the model.

To control project performance at the division level, the Earned Value Method (Li 2004) is used to disclose deviations in cost and time in project performance. This is done by calculating two indices: the Cost Performance Index (CPI) and the Schedule

Performance Index (SPI). The CPI determines if a budget is over or under run, while the SPI determines if a project is ahead of or behind schedule. To determine the performance indices at the division level, actual cost (man-hours spent in processing the division) and actual progress (percent completed) need to be calculated. Actual cost (man-hours) can be derived from the implemented actual data acquisition system by adding up the man-hours spent on processing pieces for the division. The implemented data acquisition system makes use of Radio Frequency Identification (RFID) technology to track labour and material in the fabrication shop (Azimi et al. 2009). The progress of each division is determined by dividing the weight of the fabricated pieces of that division (captured by the data acquisition system) by the weight of the division (recorded in the database). For performance variance at the division level, the cost and schedule performance indices (CPI and SPI) at the resource level are examined to determine the resource(s) that caused the deviation. A division with a variance in the CPI, for example, has reasonable cost performance indices (CPI≈1) for all resources except labour; labour then is considered to be the cause of the performance variance.

Resource Performance Indicators

Li (2004) introduced the concept of the resource performance indicators to identify the cause of variance in each performance index. Resource performance indicators therefore are used to detect problematic areas (Li et al. 2005). The monitoring and control system of this study is implemented in a collaborative company where labour is the major concern; this research thus takes into account three performance indicators suggested by Li et al. (2005) regarding labour performance in a control object (Table 1).

Table 1. Labour performance indicators used in the proposed control system.

Labor Performance Indicator	Indicator ratio
Division production	Qa / Qb
Unit productivity (fitting, welding & painting)	$\frac{Qa \times Mhrsb}{Qb \times Mhrsa}$
Crew attendance	$\frac{\sum_{t=1}^{n} N_t}{N_b \times n}$

Where:

Mhrsa : cumulative actual man-hours spent to process each steel division
Mhrsb : budgeted man-hours (cumulative)
Nb: planned number of crew members
Nt: actual number of crew members on the t^{th} day
Qa: actual number of processed divisions
Qb: number of divisions planned to be processed
n: the number of days that have been passed

The labour performance indicators are used for two purposes: reasoning and simulation. In terms of reasoning, a list of problem source factors is linked to a list of possible corrective actions and the best required action can be determined. For example, in the case of low unit productivity ratio (less than 1), inadequate skilled labor force or low work moral can be considered as two sources of problem. To deal with that, one can consider adding skilled workers and/or reallocating labour forces as possible corrective actions. Li et al. (2005) discusses in detail how the reasoning can be conducted using the resource performance indicators which is out of the scope of this paper.

Resource Performance Indicators in Simulating Steel Fab Shop

Simulation has been proved to be a powerful tool to analyze and evaluate complicated systems and processes such as steel fabrication process. The simulation in the proposed control system enables managers to experience and compare different scenarios in virtual reality and find the best solution for current or anticipated variances in a project(e.g. delays) as well as the fabrication shop (e.g. low utilization rate and long queues of steel pieces behind a station). To be reliable, the simulation model not only must be a good emulation of the operations and processes of a system in the real world, but the influencing factors as well. Given that in the collaborative company, the labour has the most contribution on the performance of projects, labour performance indicators have been involved in the simulation model.

While different scenarios (e.g. increasing active stations, overtime hours and etc.) can be tried, three scenarios are available for the simulation model regarding the labour performance indicators:

1. Fixed
2. User defined
3. Automatically forecasted

In the first scenario, the most recent value of each indicator captured by the data acquisition system is fed in to the simulation model and as the advances in the model, these variables don't change. Project managers can play with numbers regarding all the influencing factors and resource performance indicators in the second scenario to see the effects of changing each variable on the final results of the simulation. In the third scenario, the value of labour performance indicators at certain times in the future (e.g. on monthly basis) are automatically forecasted and are fed into the simulation model. In this case, the final simulation results are a better representation of the project performance and the fabrication shop in future.

Forecasting Labour Performance Indicators

A) Crew attendance indicator: Historical data has been used to predict the crew attendance indicator in this research. The database of a labour tracking system keeps records of timekeeping information on daily basis which forms the historical data. A preliminary analysis on the available data shows that on mondays and fridays or during certain months such as June, July and August crew attendance indicator is more likely deviating from its desired value which is one. Although crew attendance

indicator can be predicted on daily or weekly basis based on the past information, for the implemented system, this indicator is forecasted on monthly basis.

B&C) Unit productivity & Div. Production: Industrial steel projects typically have different stages and processes which are dynamic and complex. This makes it difficult to predict the labour Unit Productivity Indicator (UPI) and Division Production Indicator (DPI) and forecasting these indicators just based on historical data is not always accurate. There are many internal and external factors that can affect these indicators, and thus a system should be designed to model the dynamic nature of these indicators. A good forecasting embraces both historical data and reliable judgments based on construction experience and knowledge (Diekmann and Al-Tabtabai 1992). To address the stochastic nature of these two indicators, the concept of the Dynamic Markov Chain method introduced by Nassar (2005) is used in this research for predicting purposes. In this model, forecasting is based on current indicators as well as the influencing factors that affect the indicators. These influencing factors get involved in the model using the judgment of experts. Five states for UPI and DPI at time t, (i.e. A(t), B(t), C(t), D(t), & F(t)) are defined as in Table 2.

Table 2. List of states for the UPI & DPI

State	Indicator Rating	Ratio Range	Average Index (PI)
A	Outstanding	R>1.15	1.2
B	Exceeds Target	1.05<R<=1.15	1.1
C	Within Target	0.95<R<=1.05	1
D	Below Target	0.85<R<=0.95	0.9
F	Poor	R<=0.85	0.8

Once the states of the indicators are defined, probability transition matrices for each of the indicators can be established (Figure 4).

$$[P]_{UPI}= \begin{array}{c} State \\ A \\ B \\ C \\ D \\ F \end{array} \begin{array}{c} \begin{array}{ccccc} A & B & C & D & F \end{array} \\ \begin{bmatrix} P_{AA} & P_{AB} & P_{AC} & P_{AD} & P_{AF} \\ P_{BA} & P_{BB} & P_{BC} & P_{BD} & P_{BF} \\ P_{CA} & P_{CB} & P_{CC} & P_{CD} & P_{CF} \\ P_{DA} & P_{DB} & P_{DC} & P_{DD} & P_{DF} \\ P_{FA} & P_{FB} & P_{FC} & P_{FD} & P_{FF} \end{bmatrix} \end{array} \qquad [P]_{DPI}= \begin{array}{c} State \\ A \\ B \\ C \\ D \\ F \end{array} \begin{array}{c} \begin{array}{ccccc} A & B & C & D & F \end{array} \\ \begin{bmatrix} P'_{AA} & P'_{AB} & P'_{AC} & P'_{AD} & P'_{AF} \\ P'_{BA} & P'_{BB} & P'_{BC} & P'_{BD} & P'_{BF} \\ P'_{CA} & P'_{CB} & P'_{CC} & P'_{CD} & P'_{CF} \\ P'_{DA} & P'_{DB} & P'_{DC} & P'_{DD} & P'_{DF} \\ P'_{FA} & P'_{FB} & P'_{FC} & P'_{FD} & P'_{FF} \end{bmatrix} \end{array}$$

Figure 4- Probability Transition Matrices for UPI and DPI

Where,

P_{ij}= Transition probability of the indicators changing from state **i** at time **t** to state **j** at time **t+1** for i,j= A, B, C, D, and F.

For example, P_{CB} is the probability of unit productivity indicator changing from state **C**, (i.e. within target) at time ***t*** to state **B** (i.e. above target), at time ***t+1***.

Each P_{ij} and/or P'_{ij} can be defined by combining historical data and experts' judgments. The Analytic Hierarchy Process (AHP) is used to take into account judgment of the experts in terms of defining Probability Transition Matrices for UPI and DPI.

Since resource indicators with respect to UPI and /or DPI at any time *t* has to be one of the states (A, B, C, D, and F), so:

$$\sum_{j=A}^{F} P_{ij} = 1 \qquad \text{For i=A, B, C, D, and F} \qquad \text{Equation (1)}$$

A state probability vector for the proposed states for any indicator at any time *t* can be defined as follows:

$P(t) = [P_A(t), P_B(t), P_C(t), P_D(t), P_F(t)]$

Initial probability at the initial time t_0=0 can be defined by using the most recent data captured by the data acquisition system. For example if the actual UPI is equal to 0.97 we have:

$P_C(t_0)=1$ *and* $P_A(t_0)= P_B(t_0)=P_D(t_0)= P_F(t_0)=0$

In this method: $P(t+1)= P(t)*[P]^{t+1}$ Equation (2)

Where, $[P]^{t+1}$ represents the probability transition matrix, same as what is shown in figure 4 but at time (t+1). In current implementation, it's been assumed that the probability transition matrix does not change by time, in other words: $[P]^{t+1}=[P]$

Thus:

P_A(t+1)=Probability of outstanding performance in UPI at time *t+1*

$$=[\,P_A(t)*P_{AA}(t+1)+P_B(t)*P_{BA}(t+1)+P_C(t)*P_{CA}(t+1)+P_D(t)*P_{DA}(t+1)+P_F(t)*P_{FA}(t+1)]$$

$$=[\,P_A(t), P_B(t), P_C(t), P_D(t)\ P_F(t)] \times \begin{bmatrix} P_{AA}(t+1) \\ P_{BA}(t+1) \\ P_{CA}(t+1) \\ P_{DA}(t+1) \\ P_{FA}(t+1) \end{bmatrix} \qquad \text{Equation (3)}$$

The same calculation is carried out for determining other probabilities at time *t+1*. Based on the above, having the present value of the indicators (initial state), the forecasted indicator as at time *t* can be calculated as:

$$\text{UPI(t)}= \sum_{S=A}^{F} Ps(t) * PIs = P_A(t)*PI_A+P_B(t)*PI_B+P_C(t)*PI_C+P_D(t)*PI_D+P_F(t)*PI_F$$

$$= P_A(t)*1.2+P_B(t)*1.1+P_C(t)*1.0+P_D(t)*0.9+P_F(t)*0.8 \qquad \text{Equation (4)}$$

Where PI_A , PI_B , PI_C , PI_D ,and PI_F are the average PI values for different states as proposed in Table 2. As an example if current actual UPI(t_0)=0.92 (state D) then we have:

$P_D(t_0)=1$ *and* $P_A(t_0)= P_B(t_0)=P_C(t_0)= P_F(t_0)=0$

Assuming $[P]_{UPI}=\begin{bmatrix}0.5 & 0.2 & 0.1 & 0.1 & 0.1\\ 0.1 & 0.4 & 0.3 & 0.1 & 0.1\\ 0.1 & 0.2 & 0.5 & 0.1 & 0.1\\ 0.1 & 0.2 & 0.1 & 0.4 & 0.2\\ 0.1 & 0.1 & 0.1 & 0.3 & 0.4\end{bmatrix}$ & Eq. 3→ $P_A(t=1)=0.1$, $P_B(t=1)=0.2$, $P_C(t=1)=0.1$, $P_D(t=1)=0.4$ and $P_F(t=1)=0.1$.

Eq. 4→ UPI(t=1)= 0.88 (or state D)

According to the Probability Transition Matrix in this example, P_{DD} has the highest probability (i.e. 40%) and remaining in state D at time (t=1) is reasonable. The same approach can be followed to forecast DPI(t), the only difference is the transition matrix that should be involved (i.e. P'_{ij} instead of P_{ij}). It should be noted that different PI (average index) values can be used for each of the two labour performance indicators here. Project control philosophy of the company and the specific conditions of a project can also influence the PI values for the Unit productivity and Division Production indicators. Forecasting these indicators is on a daily basis due to the importance of them on the final results of the simulation model.

Conclusion

A monitoring and control system plays an important role in industrial steel construction owing to its complexity. The ability of the control system to accurately and reliably analyze the current and future situation regarding the project performance is a key to successful completion of the project. Project performance is so sensitive to the performance of the major resources involved. This paper proposes an approach in terms utilizing the resource performance indicators, which are originally defined as sensors for detecting troublesome areas, evaluating the current status as well as predicting the future status of the ongoing projects. Three labour performance indicators namely Crew attendance, Division production and Unit productivity that significantly influence the fabrication phase of the industrial steel projects were addressed and exploited in the paper. The Markov Chain method was deployed for forecasting the values of the performance indicators used in determining the future performance of projects. The project performance analysis discussed in this paper is a part of a comprehensive automated and integrated monitoring and control system which is under development and being implemented in the real world. Given the intricacy of the industrial steel projects, it is believed that this system can considerably help project managers to mitigate damages and loss in many projects.

Abstract
In recent years, researchers have made considerable efforts to develop proximity sensing technologies that provide workers and equipment operators with an audible warning when predefined proximity thresholds have been breached. Examples of such technologies include RFID and Ultra-wideband sensors. Despite the practical applications of these technologies to safety management, implementation of such devices on active construction projects is very rare. In this paper, the authors identify the potential barriers and enablers associated with integrating sensing technologies within existing safety management strategies by interviewing safety managers throughout the United States. Using the findings from these interviews, the authors offer a framework for effective integration. It is expected that this framework can be used by construction practitioners to better understand how sensing technologies can complement existing efforts and by researchers who aim to better understand the potential role of such technologies in safety management.

Keywords: Human Error, Safety, Sensing, Technology, Management

1. INTRODUCTION

The construction industry accounts for an injury and illness rate that is nearly five time the all-industry average (NSC 2006). While conditions have improved since the Occupational Safety and Health (OSH) Act of 1970, the industry still accounts for over 1,200 deaths and 460,000 disabling injuries per year (Center for Construction Research and Training 2008). According to the National Safety Council (2006) the annual cost of construction injuries is estimated to be over $15 billion. Within the

construction industry, the highway construction and maintenance sector is one of the most dangerous (BLS 2008). The Federal Highway Administration (2004) estimated that a work zone fatality occurs once every ten hours and a work zone injury occurs every thirteen minutes (FHWA 2004). Additionally, the estimated direct cost of work zone fatalities is $6.2 billion per year (Mohan and Gautam 2002). Unfortunately, despite efforts to improve work zone safety, the injury rate continues to increase. In fact, between 1999 and 2003 the number of annual fatalities in the highway sector increased by 18 percent and the number of non-fatal work zone injuries increased by over 40,000 despite the fact that the volume of construction work remained relatively constant (FHWA 2004; BLS 2008).

This paper focuses on recently developed technologies that show great potential for reducing injuries on highway construction worksites through the reduction of unsafe actions. This study focuses on highway work zones because these projects generally involve dynamic work sites with workers-on-foot and heavy mobile equipment. Furthermore, due to the increased use of rapid renewal strategies, highway construction work is commonly performed at night under poor lighting conditions. Such harsh environments provide excellent opportunities to apply, study, and validate sensor technology and computer algorithms to extract relevant data for advanced decision making.

The study described in this paper had several objectives. The authors first attempted to identify and describe sensing technologies that have a theoretical potential to improve site safety. Subsequent objectives include identifying the level of awareness of these technologies in the construction industry, the perceived barriers to implementation, and potential benefits of technology integration. Finally, the authors attempt to create a framework for effective technology integration based upon input provided through multiple structured interviews.

2. Background and Literature Review

The salient literature was reviewed to establish a point of departure and to inform the data collection process. This literature review includes highway work zone injury statistics, causes of highway work zone injuries, and potentially useful sensing technologies. Social psychology and human error literature is also used to establish the theoretical impact of real-time warnings on safe work behavior. A comprehensive discussion of traditional safety management strategies is provided in Hinze (2006). Such a review has been omitted from this paper for brevity.

2.1 Highway Work Zone Injuries

Safety has historically been a problem in infrastructure construction due to the inherent dangers that exist in highway work zones. Highway construction sites can be differentiated because of the additional distractions attributed to high-speed passing vehicles, heavy equipment, and repetitive work tasks. Each year more than 200 workers are killed and over 20,000 are injured in the highway construction sector alone (Center for Construction Research and Training 2008).

Several studies have focused on the causes of highway construction injuries. In 1999, statistics for fatalities occurring on highway construction and maintenance projects between 1992 and 1998 were published by the Bureau of Labor Statistics

(BLS). Among the 492 work zone fatalities, the leading occupations affected were construction laborers (42%), truck drivers (9%), construction trades supervisors (8%), and operating engineers (8%). The most common primary sources of injury were trucks (45%), road grading and surfacing machinery (15%), and cars (15%). According to NIOSH (2007), nighttime work, contact with heavy equipment, and being struck by passing vehicles are the leading root causes of fatalities.

Nighttime work

Highway construction and maintenance is frequently performed throughout the night due to the pressure from the public to minimize traffic delays during high volume times. Nighttime highway construction has been established to be more hazardous for both passing drivers and construction personnel because of decreased visibility. Furthermore, there is a higher probability of drivers impaired by drugs, alcohol, fatigue, or age-related vision impairments during night-time, all of which contribute to the frequency of accidents (Arditi et al. 2005). According to this study, the factors that most contribute the nighttime fatalities on highway construction and maintenance sites include poor lighting conditions (43%), unfavorable weather conditions (8%), poor performance of safety garments (7%), workers not wearing safety garments (14%), conditions of vehicle operator (64%), and other causes (32%).

Workers struck-by mobile equipment

The majority of fatal injuries incurred by road construction workers are attributable to vehicle- and mobile heavy equipment-related incidents. When compared to workers on all other types of construction sites, workers of many differing occupations on road construction sites were found more likely to be killed by vehicles and heavy equipment. According to McCann and Cheng (2006) the majority of deaths involving vehicle and heavy equipment in traffic work zones include construction laborers (29%), heavy equipment operators (23%), and construction managers (14%). An analysis of 240 incidents involving serious injuries to workers on highway and bridge construction projects in New York State confirms that highway workers are at risk of severe nonfatal injuries from being struck by traffic vehicles or construction equipment (Bryden and Andrew 1999). This analysis revealed that traffic accounted for 22% of worker injuries and 43% of worker deaths in New York from 1993 - 1997.

2.2 Sensor Technologies

Multiple potential technologies are technically available to the construction industry for hazard sensing. However, the advantages and limitations of some of these technologies make them the preferred approach to collect data or preclude them from use (Bohn and Teizer 2009). Candidate sensors are: (a) Radio Detection and Ranging (RADAR), (b) Ultrasound, (c) Ultra Wideband (UWB), (d) Radio Frequency Identification (RFID), (e) Laser Detection and Ranging (LADAR), (f) Global Positioning Sensors (GPS), (g) Visual video (stereo or mono, wide field-of-view, pan-tilt-zoom), (h) Thermal video, (i) Digital imaging (visual and still, thermal, 3D range), (j) Range video, and (k) possibly others. Of these technologies, vision and wireless sensing technologies (video cameras, passive and active RFID proximity and alerts, and UWB positioning) offer particularly promising approaches for acquiring

the data set needed to enhance safety, because of a unique combination of technical capabilities, form factors, and economics (Teizer 2007). It should be noted that these technologies have many current limitations including positioning error. Positioning error of less than a half of a meter has been achieved in outdoor environments (Teizer et al. 2008).

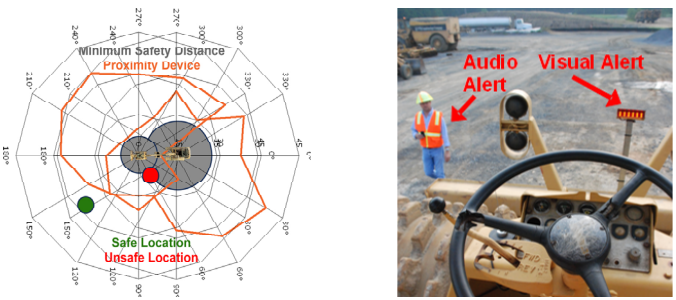

Figure 1: Implementation of active RFID alert device on worker/heavy equipment

Radio Frequency Technology

Safety in construction operations can be improved by utilizing embedded radio frequency technology and range imaging for real-time pro-active warning devices. Sensing technology has been developed that may assist ground personnel and equipment operators (trucks, forklifts) in detecting and recognizing hazardous environments. For example, the system may detect when workers are too close to equipment. In such an event of being too close, visual, acoustic, and vibration technology will activate alarms to the personnel through so called Personal Protective Unit and Equipment Protection Units (PPU and EPU), an active (battery powered) RFID device (see Figure 1). Since unsafe acts (e.g., mistaken entry into an unsafe work zone) are often not reported by workers or operators unless an incident occurs, the use of the proximity detection and recording technology will measure how often and how close construction workers are to heavy equipment. The current active RFID configuration allows to alert workers at average distances ranging from 2 to 50 meters, depending on the physical and ambient environment. Alert distances of more than several hundred meters can be achieved and were tested. A passive RFID configuration can achieve distances ranging from a few centimeters up to 10 meters.

Ultra Wideband (UWB) tagging and tracking is a relatively new field, particularly as applied to construction (Fontana 2004). Recent advances in miniature UWB tags and receivers have made it practical and economical to deploy UWB tags at a cost of $10-40 per tag. Teizer et al. (2008) compared in a series of experiments a UWB real time positioning system against a Robotic Total Station (RTS) surveying instrument. UWB tags offer precise positioning of tagged workers and objects. They can also exhibit long tracking range (up to 300m outdoors, max. 1,000m). The widespread use of real-time location tracking devices on individual workers (such as UWB tags) is not expected in everyday construction deployment scenarios until the tag cost decreases substantially and the battery life increases.

2.3 Theoretical Benefits of Technology Integration

Accident causation models provide strong and consistent evidence that accidents are the result of unsafe worker actions and uncontrolled hazardous exposures. The research aimed to improve decision making and prevent unsafe worker actions in hazardous work environments. Special attention was being paid to worksites that involve nighttime work, mobile heavy equipment, and workers belonging to minority groups that have shown statistically significant higher incident rates than the general workforce (Center for Construction Research and Training 2008)

Human error

Errors in judgment, decision making, and physical actions result in loss of productivity, the need for rework in industrial operations, and occupational injuries. In order to prevent human error organizations conduct training sessions, provide feedback to workers, and conduct inspections (Hinze 1996). These prevention activities rarely occur in real-time. That is, organizations rarely have the capability to systematically warn workers of their erroneous actions before negative consequences are realized. This is especially true in work environments where conditions continually change, mobile equipment is integrated within the workspace, and many distractions are present. Therefore, there is a clear need for a reliable real-time warning system that specifically targets the cessation of erroneous behavior.

According to Reason (1990), human error occurs in a limited number of forms. These forms include intentional erroneous actions (mistakes and violations) and unintentional erroneous actions (slips and lapses). The fundamental difference between these is that mistakes are planning errors (e.g., intentionally choosing an unsafe pathway through a worksite) while slips and lapses differ result in failures of execution (e.g., inattentiveness, distraction).

Mistakes are defined by Reason (1990) as, *"deficiencies or failures in the judgmental and/or inferential process involved in the selection of an objective or in the specification of the means to achieve it, irrespective of whether or not the actions directed by this decision scheme run according to plan*." According to Rasmussen et al. (1994), mistakes are relatively common and exist in two categories: Knowledge-based or rule-based. Rule-based mistakes involve the intentional application of a bad rule. These mistakes result from errors in standardized procedures and reflect and are caused by deficiencies in management. Unlike rule-based mistakes, skill-based mistakes are governed by stored patterns of pre-programmed instructions in the time-space domain. Errors in this domain are extremely common and occur when workers misjudge time or spatial characteristics of the worksite. Negative consequences resulting from skill-based mistakes are generally preventable when workers obtain feedback on their erroneous behavior before negative consequences occur.

Slips and lapses are defined by Reason (1990) as "*errors which result from some failure in the execution and/or storage stage of an action sequence, regardless of whether or not the plan which guided them was adequate to achieve its objective*." These errors occur when workers fail to make a cognitive attentional check because: (1) The process or behavior is not habitual (strong habitual intrusions), (2) A distraction prevents one from making required checks (omission); (3) Failures of prospective memory prevent safe work procedures (reduced intentionality), or (4)

Workers inadequately estimate durations within a sequence of actions (mistimed checks). These unintentional errors differentiated into two categories: (1) Those caused by distractions in a familiar work environment (slips), and (2) memory failures (lapses).

Detecting and preventing error

Typically, errors are detected through formal processes in the human body (i.e., self monitoring). Human beings constantly check their surroundings to ensure that our actions match our intent. These mental checks, however, are compromised by the cognitive errors discussed. The detection of errors must be supplemented by an external source. This is especially true in dynamic environments where time to make safe decisions is severely limited. According to Rasmussen et al. (1994) safe work practices are promoted when organizations establish effective safety feedback mechanisms that alert workers of deviations from prescribed practices, entry into unsafe work zones, and failure of standard controls.

Table 1: Relationship between human error, work environment, and prevention

Human Error	Definition	Environment	Technology-related Countermeasure
Mistakes	Intentional planning related error (e.g., skill-based errors)	Dynamic work environments are prevalent and standardized work processes do not ensure sufficient worker-hazard interactions	Prevents entry in unsafe work zones when ad hoc plans and work procedures cause entry into unsafe work areas
Slips	Unintended erroneous actions that result from mental distractions in familiar work environments	Typical work environments with one or more unusual external distractions	Provides workers with proximity warning when distractions prevent typical mental checks
Lapses	Unintended erroneous actions that result from temporary memory failure	Typical work environments	Provides a queue for workers who have temporarily forgotten safe work practices or tolerable distances

It has been shown that an adequate safety information feedback mechanism ranks second only to top management involvement in discriminating between safe and unsafe organizations (Kjellen 1983). However, safety feedback mechanisms are rarely implemented in construction and there is no technology or process currently used in construction that can provide feedback in real-time (Shell Safety Committee 1987). According to Reason (1990), attention can only be directed to a very small part of a total space in any given time and such attention must be focused on important problem spaces to prevent accidents. Table 1 provides simple definitions of the three human error modes, the environments in which they typically occur, and the countermeasures related to the implementation of the proposed technologies. This table was created based upon social psychology research conducted by Searle (1980), Norman (1981; 1983), and Mandler (1975). According to this literature, mistakes, slips, and lapses cause accidents because they result in a worker's failure to perceive that an event has occurred (e.g., that a bulldozer has begun to mobilize), failure to diagnose the nature of an event and to determine the necessary remedial actions (e.g., failure to recognize the need to change physical location when bulldozer's track has broken), and failure to implement those responses in a timely manner (e.g., duration

of time required to recognize a hazardous condition has exceed the time required to act safely) (Hall et al. 1982). In all such cases advanced warning of hazardous conditions would help to prevent failure in human actions (Wreathall 1982).

3. Research Methods

As previously indicated, some of the primary objectives of this study were to determine the perceived barriers and enablers associated with implementing sensing technologies, potential for injury prevention, and to establish a framework for integrating sensing technologies with traditional injury prevention strategies. To achieve these objectives the research team conducted a series of structured interviews with project managers and safety managers throughout the Unites States. Interviews were selected over surveys and expert opinion techniques for several reasons. First, interviews are an efficient means of collecting rich data with a high level of interaction between the interviewee and interviewer. Second, there are few individuals who would be qualified as 'experts' in the topic under investigation.

To ensure optimal external validity, interviews were conducted with safety managers and project managers of construction organizations throughout the Unites States and pattern matching was performed qualitatively by the researchers following data collection. It should be noted that the external validity is limited by the fact that the interviewees represented a convenience sample of contacts previously established by the research team. The internal validity of the study was enhanced by conducting multiple interviews with multiple interviewees. An important aspect of this study was to ensure consistent interpretations of the structure and application of the RFID and UWB sensing systems. Accordingly, a brief description of each technology and its application was provided to each interviewee prior to the interview date.

The interviewees were diverse in their positions and perceptions. In this pilot study interviews were conducted with five individuals who had an average of ten years of professional experience managing safety on highway construction projects in the US. While the interviewees were predominately located in Colorado, all had experience working outside of Colorado. Finally, interviewees included corporate safety managers, project safety managers, a Colorado Department of Transportation (CDOT) employee, and a project manager. During the interviews, the following questions were asked:

1. Are you aware of the potential application of RFID and UWB sensing technologies to prevent injuries in the construction industry?
2. Are there any reasons why RFID/UWB sensing systems would not work? Are there foreseeable logistical issues?
3. How might a real-time warning system prevent accidents? Could this warning system provide other benefits other than their intended use?
4. The tracking system can record the movement of workers throughout the site. How could this system prevent accidents? How could this be used to improve the effectiveness of the safety programs that you already have?
5. What are the potential limitations of the RFID/UWB systems?
6. How might these systems integrate with the existing Safety Program Elements (e.g., job hazard analyses, orientation, inspections)? Would the effectiveness of these, or some of these, improve with this technology? How?

4. Results

The results of this study are summarized below. Of the six interviewees, only one had heard of RFID or UWB technologies and no interviewees were aware of potential applications to construction. Therefore, the first step of each interview involved providing the interviewee with a description of the technologies. Additionally, a one page description of both technologies was created and distributed to the interviewees prior to the interview date.

The interview questions had three major themes: (1) potential logistical problems, (2) perceived benefits, and (3) specific framework for integration within existing injury prevention strategies. The first set of questions focused on the potential logistical problems associated with the technologies. These questions were asked to identify the perceived barriers to implementation in an effort to discover why the technologies have not seen widespread diffusion throughout the industry. The responses to the logistics questions indicate that the greatest perceived barriers to initial implementation are reliability of the technologies' warning systems (mentioned by 6/6 interviewees); technological complexity; lack of experts available to provide training (3/6); appropriate volume of warning systems (2/6); and potential overdependence of the workers (1/6).

The second set of questions focused on identifying the perceived benefits of the integration of the technological systems described. These questions were aimed to validate and supplement the theoretical benefits previously described in this paper. Interviewees identified many potential benefits of integration including minimization of unsafe worker actions near heavy mobile equipment, exposed edges, trenches, crane swing zones, and adjacent traffic. Simply, these interviewees believed that the technologies showed promise for increasing workers' and equipment operators' awareness of their proximity to an unsafe work zone or potentially dangerous interaction. The associated warning signals were believed to provide a sufficient warning to prevent unsafe actions that contribute greatly to severe injuries on highway construction sites.

There are some specific ways that the technologies may be integrated with existing injury prevention strategies. The UWB and RFID systems have the most potential to integrate with orientation and training, recordkeeping and accident analyses, activities performed by the site safety manager, and job hazard analyses. The technologies can integrate well with orientation/training, recordkeeping/accident analyses, and job hazard analyses in several ways. First, when UWB and RFID are used simultaneously, the technologies can be used to track workers throughout the site in an effort to determine the duration of time spent in unsafe work zones. Such data can be used to enhance recordkeeping/accident analyses by collecting unprecedented close-call information. Further, such information can be used to enhance orientation/training meetings by using actual tracking data and describing the potential risks associated with actual worker behavior.

The technologies also integrate well with the inspection, training, planning, and real-time management techniques used by effective safety managers. These systems could be integrated with a real-time alert system that provides the safety manager with a notification when unsafe interactions are occurring so that inspections

and monitoring can occur in regions of the worksite with the greatest potential for injury thereby optimizing his or her effectiveness. Additionally, the safety manager can use historical tracking data to enhance planning for subsequent phases or projects. For example, if workers spend time in unsafe zones due to lack of awareness, signage can be strategically located to proactively warn workers.

5. Conclusions and Recommendations

This study highlights several ways that RFID/UWB technologies can be employed to prevent injuries on construction worksites. Social psychology literature was used to create a theoretical basis for how the technologies could be used to prevent cognitive errors in dynamic and dangerous work environments. This theoretical foundation was validated and supplemented through interviews with a small sample of highly experienced safety managers in Colorado. The findings indicate that the technologies have particular application to real-time warnings of proximity to unsafe work zones, equipment, and materials. The technologies may also have potential for enhancing recordkeeping and accident analyses, job hazard analyses, orientation and planning, and enhancing management activities conducted by the safety manager. Despite these potential benefits, there are some significant barriers that may preclude the immediate use of these technologies including reliability, appropriate design for unique and dynamic work environments, and lack of expertise of typical safety and project managers.

The authors recommend future research that expands upon this study. Such research should involve case studies that produce recommendations for overcoming the perceived barriers. Research that produces empirical evidence of safety improvement would also be highly beneficial to the industry. Safety professionals and construction managers are encouraged to adopt the technologies and implement on a small sample population. It is expected that initial integration with a sample crew would involve a relatively low cost and have high short-term and long-term payback that could result in a safer worksite and a competitive business advantage.

Abstract

Successful, large scale field trials were conducted on two sites in Texas and Toronto using an integrated system of RFID tags, GPS technology, map software, and hand held computing to automatically track materials in the projects' respective lay down yards. This paper addressed the unresolved research question, that how will this technology impact projects if it is implemented upstream in the supply chain in an integrated and automated materials management system? This question is addressed by modeling the impact of automated materials tracking technology on increasing visibility within the construction supply chain. It is concluded that automated materials tracking has the potential to improve construction productivity, cost, and schedule performance.

Introduction

The Construction industry is characterized by the fact that every project is different from others in terms of planning, design, and execution. Likewise, the supply networks that fuel these projects with labour, equipment, and highly engineered materials are complex entities onto themselves. Improving the materials management process, particularly at the site level on large construction projects, has been identified as one area that can have a beneficial impact on the construction supply network and the construction process as a whole (Construction Industry Institute 1999; Kini 1999). The integration of Automated Materials Locating and

Tracking Technologies (AMLTT), namely Radio Frequency Identification (RFID) and the Global Positioning System (GPS), and the automation of part of the materials management process have been proposed and shown to be a viable means of process improvement. These technologies have thus far been shown to be well suited for application in the construction industry, especially with regards to accurately identifying, locating, and tracking material and equipment in a construction environment (Song et al. 2006; Ergen et al. 2007; Razavi et al. 2008).

However, what is currently lacking from the body of knowledge, on the application of AMLTT in construction, is an understanding of the impact that this technology could have on a project if implemented on a larger scale. Specifically, what impact(s) could AMLTT have if it were implemented within the construction supply network? The objective of the research presented in this paper is to investigate the theoretical impact that the application of AMLTT could have on the construction materials management process if implemented within different segments of the supply network. The specific area of the construction supply network that was chosen for investigation was the use of AMLTT to increase the level of visibility within the greater supply network. To examine the impact of AMLTT to increase the level of visibility within the supply chain, the process piping supply chain was modeled using EZStrobe, a commercially available modeling and simulation software package.

Background/Literature Review

The success of Supply Chain Management (SCM) in the manufacturing sector has lead to interest in its application in other industries, including the construction industry. The application of SCM principles, such as Just-In-Time (JIT) delivery, has seen some success in the construction industry. Tommelein (1998) was successful in demonstrating the theoretical ability of pull-driven scheduling to improve the performance of the pipe spool installation process by reducing on-site material buffers, decreasing the project duration, and identifying a means in which to increase crew productivity by altering their start date. Al-Sudairi et al (1999) simulated a steel erection process and concluded that a moderate material buffer on site could balance the impact of uncertainty in material delivery and productivity. Vrijhoef & Koskela (2000) went on to examine the supply chains of three construction projects (two residential projects and one office building). From their research it was determined that there exist significant problems (from a Lean perspective) in a typical construction supply chain, such as the inclusion of extra time in schedules to counteract uncertainties and the overall nearsighted management of the supply chain in general.

The difficulty in applying SCM to construction in all of the studies mentioned above can be recognized to originate from the fundamental differences between manufacturing and construction. The construction industry is dominated by ‘one-off’ projects; where ‘one-off’ refers to the lack of repetition in the construction of like facilities (Vrijhoef & Koskela 2000). Construction schedules vary considerably between projects, some schedules span years, while others span only a few months. Other constraints imposed on construction projects, such as weather, site conditions,

site fabrication, availability of resources (e.g. skilled and unskilled labour), and local laws and regulations can also be highly unpredictable and variable (Koskela 1992; Cox et al. 2006).

Materials management at the site level, in general, is focused on ensuring that the right materials are available for work crews at the right point in time. Common materials related issues that can arise include: lack of availability of required material, inaccurate warehouse records, damage of critical material or equipment due to improper storage, improperly sequenced deliveries, and large surpluses of material at project completion (Plemmons & Bell 1995; Thomas et al. 2005). The introduction of new technologies, which fall under the category of Automated Materials Locating and Tracking Technology (AMLTT) and the automation of specific aspects of the site materials management process have been proposed and shown to be a viable means of improving this process as a whole (Song et al. 2006; Ergen et al. 2007; Razavi et al. 2008).

Field Trials

Extensive field trials were conducted to investigate the possible impacts of AMLTT on construction productivity. The field trials were conducted at power plant construction projects in Rockdale, Texas and Toronto, Ontario, respectively. The Rockdale field trial was conducted at the Sandow Steam Electric Station Unit 5 project. The second field trial was conducted at the Portlands Energy Center (PEC) project, located in the port area of Toronto, Ontario.

RFID tags were attached to the construction materials. At the PEC, 224 pipe spools, 22 safety valves, and 100 globe valves were initially tagged with RFID transponders. In Rockdale, Texas, 400 structural steel components were tagged for one boiler. On both sites, data was collected on a daily basis to update and generate the positions of the tagged components. An individual carried a kit consisting of an integrated GPS unit, RFID reader, and a handheld computer. As the individual moved around the site, the GPS receiver determined its own position while the RFID reader identified the presence of the tagged components around that position at a rate of several thousand reads per second. The localization algorithms then processed the collected data to provide a more accurate estimate of the location of each tagged component. Details about these field trials and their results can be found in CII (2008).

Formulated Simulation Models

Simulation models were formulated for investigating the increase in visibility within the construction supply network due to the use of AMLTT. Models of the process piping supply chain, a typical component of industrial construction projects, were developed as the primary investigative tool for this research. Process piping, specifically the fabrication and installation of pipe spools, was chosen as the basis of the completed investigation due to the availability of literature which provided an understanding of its supply chain network and due to the authors' own field experience with this construction activity (Howell & Ballard 1996; Tommelein 1998;

Razavi et al. 2008). Two simulation models were developed. The first simulation model represents the existing process or situation as it typically exists in the construction industry today utilizing a material buffer. The subsequent model(s) represents a modified version of the existing process model in which AMLTT has been included thereby utilizing no material buffer. The EZStrobe: General-Purpose Simulation System (EZStrobe) was utilized to build the construction supply network models. EZStrobe is a discrete event simulation environment that is based on the STROBOSCOPE simulation platform.

Increasing Visibility within the Construction supply network

The series of models presented in this section were used to investigate the premise that an increased level of information transfer within the construction supply network, regarding the status of material and equipment, would subsequently reduce uncertainty at the site level. As a result, potential work opportunities would be created and taken advantage of. A work opportunity is defined as a task or series of tasks that could potentially be started and completed earlier in the construction schedule. These work tasks, however, are typically delayed due to uncertainty in the ability of the supply network to provide sufficient and/ or the required material to allow for an adequate and constant rate of production to be attained on site (i.e. the risk of delay is considered too great). Consequently, these work tasks are put on hold until a sufficient material buffer has been accumulated on site. For example, pipe spool installation is not typically started until a significant portion of the total pieces to be installed (60 to 80%) have been delivered to the site (Howell & Ballard 1996), thus utilizing a 60 to 80% material buffer.

Existing Supply Chain Model

The entire supply network for a typical construction project is composed of a complex system of elements. Modeling such a vast system was considered to be beyond the scale required to complete the intended investigation as part of this research. As such, only a single supply chain from within a greater construction supply network was modeled using EZStrobe. The chosen supply chain was that of a typical piping process on an industrial construction project. The piping supply chain model presented by Tommelein (1998) proved to be an essential resource. Industrial piping is also a segment of the construction supply network that is known to suffer from the effects of uncertainty as described by Howell and Ballard in their 1996 report entitled *Managing Uncertainty in the Piping Function*. The EZStrobe model developed to represent the existing piping supply chain was broken into two parts. The first part of the model depicts the segments of the piping supply chain which relate to the fabrication process. The second part of the EZStrobe model depicts the segments which relate to on-site installation. The first part of the model is composed of those activities which are directly related to the fabrication of pipe spools and associated activities which are based offsite. These activities include the generation of design specifications, the design process, the overall pipe spool fabrication process, and the transfer of material to the site. The second part of the developed model is composed of those activities that are directly related to the installation of the pipe spools and other associated on site activities. The activities in this part of the

model include the material receiving process, the completion of install area preparation, pre-installation work, and final installation. There is little to no supply network visibility assumed to exist within this model.

Modified Supply Chain Model

AMLTT, specifically RFID, employed in conjunction with a comprehensive data management system, offers the potential to drastically improve the ability to transfer information within the construction supply network. This in turn influences the potential to increase supply network visibility and subsequently decrease the level of uncertainty held at the site level concerning the status of material and equipment yet to be delivered. It is theorized that with decreased levels of uncertainty concerning material and equipment deliveries that site based project managers will be able to take advantage of work opportunities that would have otherwise been considered too risky. Accordingly, the requirement to build up costly stockpiles of material and equipment in project lay down yards and warehouses, prior to beginning specific construction tasks is expected to be mitigated. This theory is explored using the modified piping supply chain model presented in this section. In this model, however, it is assumed that AMLTT, in the form of RFID transponders, associated readers, and data management and communication systems, is incorporated into the piping supply chain at the earliest possibly phase. The start of the fabrication process was considered to be the earliest point in which AMLTT could be integrated into the piping supply chain, as this is the first point in which a physical entity exists that a RFID transponder can be affixed to. With the increased use of information technology based tools such as Building Information Models (BIM), the ability to automatically convey information regarding the status of specific items to a central project database may also be extended into the engineering and design phase in the future.

Figure 1 represents about a 10% sample of the complete model. We are sorry we could not present the full model which incorporated 40 “combi’s,” 32 normals, and dozens of probability branches and queues. These cannot be presented in this paper. The modified EZStrobe model is divided into three parts. Part 1 focuses on the segments of the supply chain related to the pipe spool fabrication process. Part 2, is focused on the pipe spool installation process. Part 3, is comprised of the majority of the additional modeling elements required to incorporate the conceptual flow of AMLTT derived information and the mechanism by which possible work opportunities are generated.

In the modified model, the install area preparation, pre-installation work, and installation activities are not constrained by the quantity of loads received on site; rather they depend on the availability of potential work opportunities that are generated as a result of information conveyed from various stages of the supply chain. It should be noted that a 50 day delay period to account for the completion of site work was applied to the install area preparation activity in this model. Dynamic based probabilities were assigned to the decision nodes associated with on site data collection points to account for the occasions when materials arrive on-site early or out of sequence with installation. The probability that a data signal originating from

one of these data collection points will be converted into a work opportunity is dependent on the number of occurrences of that activity up to that point in the simulation. The probability that a work opportunity will be generated increases as the number of occurrences of an activity increases. A feedback loop was also incorporated with these decision nodes to ensure that sufficient work opportunities are generated to eventually complete the specific work task in question. These work opportunities had the effect of reducing the need for a site stockpile. The stockpile was not in fact arbitrarily or directly reduced.

Simulation Results

The ability to meet or exceed a construction schedule is often a primary measure of project success in the construction industry. Accordingly, schedule performance was used as the gauge by which the theory that an increased level of supply network visibility via an AMLTT based system can beneficially impact site operations was tested. A baseline for comparison purposes was first established using the existing supply chain model. As stated earlier, piping constructors typically utilize a 60 to 80% material buffer (Howell & Ballard 1996). Therefore, the output generated using the existing model subjected to a 60% install buffer was used for comparison purposes. Subsequent analysis of the simulation output associated with other buffer sizes confirmed that the highest level of schedule performance, given other model parameters, was attained with a 60% install buffer in combination with a 55% buffer constraint on the remaining site based activities. For both the existing and modified supply chain models, the output associated with six principal activities has been reported. These activities are divided evenly between the off-site fabrication and on-site installation phases of the overall supply chain. The fabrication based activities

include the design of pipe spools, the overall fabrication of pipe spools, and the delivery of pipe spools to the site. The installation based activities include the install area preparation, pre-installation pipe spool work, and installation activities. A summary of the simulation results is provided in the next two sub-sections.

Summary of Existing Supply Chain Model Output

The existing model output for the case of a 60% install buffer is presented. Figure 2, shows the percent complete of each activity over time. The "Install Area Ready" and "Pipe Ready for Install" activities commence operations 124 days after the simulated project kick off. The last area is subsequently made ready for installation at day 222. This finish date corresponds to a rate of production of approximately 1 area prepared every 10 days. This rate of production is in line with the assumed overall rate for this activity. The final set of pipe spools is made ready for installation on approximately day 226. The corresponding rate of production is therefore 3.9 pipe spools per day. Installation is subsequently able to commence on day 131. Installation was recorded as being complete on day 246. This translates into a rate of production of approximately 0.9 areas per 10 days. This rate of production is slightly less than anticipated; however, it can most likely be attributed to the accumulation of incremental delays incurred in upstream activities. Overall, based on a combination of 60% install buffer and 55% precedent activity buffer, the estimated optimum schedule duration for the existing model was recorded to be 246 days. This is the result for which the corresponding output of the modified model will be compared to.

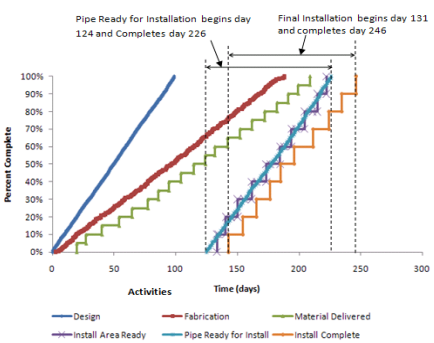

Figure 2: Percent Complete vs. Time (Existing Model)

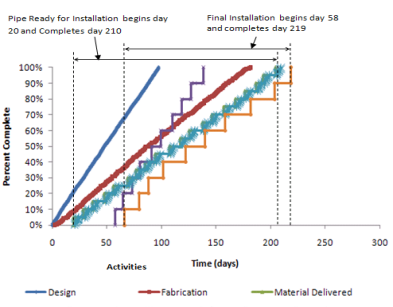

Figure 3: Percent Complete vs. Time Modified Model (Work Opportunities)

Summary of Modified Supply Chain Model Output

The simulation output for the modified model output is presented in the same format as the previous model. Figure 3 provides the percent complete profiles for each activity. Relatively constant rates of production are able to be achieved for each of the three on-site activities under the modified model. Sufficient work opportunities were generated to allow for the pipe spool pre-installation work activity to commence

immediately following the delivery of the first load of pipe spools on day 20. This activity reached 100% completion 190 days later on day 210. This corresponds to an overall rate of production of 2.1 pipe spools per day. Sufficient work opportunities were also generated to allow the preparation of install areas to commence immediately after the 50 day delay period to account for site work. This activity reached 100% completion on day 139. This translates into a rate of production of 1.1 areas every 10 days. Finally, installation was able to begin on day 58 and was subsequently completed on day 219. The resulting rate of production for this activity was calculated to be 0.6 areas completed every 10 days.

Comparison of Schedule Performance

To compare the performance of the modified model to that of the existing model in terms of schedule, three parameters were examined for each site based activity. The parameters examined include the start and end time of each activity and the ensuing rate of production. Each activity is compared separately in the following sub-sections.

Comparing the Rate of Install Area Preparation

The corresponding percent complete profiles for the install area preparation activity for both the existing and modified models from the previous sections are displayed together in Figure 4 (a) below. The transparent overlays correspond to the resource allocation profiles for each instance of this activity. The elimination of the material buffer and the subsequent change over to a reliance on work opportunities generated via AMLTT has the effect of moving ahead the start time of the install area preparation activity. The resulting difference between the start times is 73 days in favor of the modified model. The overall length of time to complete the preparation of all 10 install areas was also reduced from 99 to 89 days; however, this reduction can be attributed to randomness in the simulation engine and would not be expected to occur on average. The subsequent rate of production of each instance of this activity is relatively the same. Accordingly, the resource allocation profile is the same for each case at 1 full crew for 100% of the activity duration.

Comparing the Rate of Pre-Install Pipe Work

The percent complete profiles for the pre-install pipe work activity for both the existing and modified models are displayed together in Figure 4 (b). The resource allocation profiles for each instance of this activity are overlaid in the corresponding transparent colour. The effect of eliminating the reliance on material buffers as a primary constraint on operations is more evident when comparing the percent complete profile for the pre-install pipe work activity for each model. In the case of the existing model the pre-install work is completed over a relatively short period of time of 102 days as previously reported. In the case of the modified model, the start time of the pre-install work is able to be pushed forward by just over 100 days. The overall duration, however, is increased by a factor of two. This is caused in part due to increased crew idle time, which is manifested in the form of disjoints in the percent complete profile for the modified model. Accordingly, the rate of production between the existing and modified model is decreased by a factor of 2. However, this

can be compensated for by reducing the crew size by a half as indicated by the corresponding resource allocation profile. While the overall activity duration is increased, most project managers should appreciate the greater flexibility that this alternative provides and improved productivity.

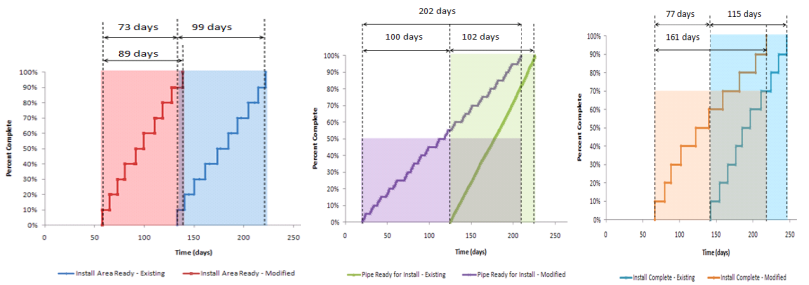

Figure 4 (a) **Figure 4 (b)** **Figure 4 (c)**

Figure 4: Comparing Rates of Productivity – (a) Install Area Preparation Activity; (b): Pre-Install Pipe Work Activity; (c): Installation Activity

Comparing the Rate of Installation

The percent complete profiles for the installation activity for both the existing and modified models are displayed together in Figure 4 (c). The resource allocation profiles for each instance of this activity are overlaid in the corresponding transparent colour. Similar differences in the percent complete profiles for the installation activity between the existing and modified models can be seen here as compared to the previous activity. The elimination of the material buffer allows for the start time of the activity to be shifted forward, in this case by 77 days. The overall activity duration under the modified model is increased by a factor of 1.4 from 115 to 161 days, which in turn decreases the overall rate of production. However, like the previous case, this can be compensated for by reducing the overall crew size by slightly less than 30%.

Conclusions

Based on the completed comparison it is evident that the integration of AMLTT into the construction supply chain has the potential to improve or at least maintain construction schedule performance, while reducing the dependency on costly material stockpiles. It is recognized that under the AMLTT based model the rate of production of two thirds of the site based activities was reduced significantly and crew idle time increased. However, as was shown, this can be compensated for by reducing the applicable crew size. The ability to start work tasks earlier in the construction schedule as a result of an increased state of knowledge of the supply situation should also provide project managers with a greater flexibility to account for other unexpected events that may hinder project performance. In addition, the overall duration of the theoretical piping operation was reduced from 246 to 219 days in favor of the AMLTT based model; a reduction in schedule duration of approximately

11%. An improvement in schedule performance of even 2 to 4% would translate into significant cost savings on any typical industrial construction project. While completely hypothetical, the results presented here serve to demonstrate the beneficial impact on schedule performance that could potentially be achieved via the integration of AMLTT within a single construction supply chain such as piping, let alone the greater construction supply network as a whole.

Abstract

Accurate and efficient tracking, analysis and visualization of the as-built status of projects are critical components of a successful project monitoring. Such information directly supports control decision-making and if automated, can significantly impact management of a project. In this paper, we describe an innovative automated approach for recognition of physical progress from unordered daily construction photologs and Building Information Models (BIMs). First, we describe an automated approach to photo-realistically reconstruct the as-built in 4D and label scene for occupancy. The IFC-based BIM is subsequently fused into the as-built scene by a registration-step and is traversed and labeled for visibility. Finally a machine learning scheme built upon a Bayesian probabilistic model is introduced that automatically detects physical progress in presence of occlusions and demonstrates that progress tracking at schedule activity-level could be fully automated. We present results on automated tracking, analysis and visualization of two ongoing building projects.

Introduction

Accurate and efficient tracking of the as-built status of buildings under construction has been repeatedly reported as a critical factor for success of project monitoring (e.g., Bosché 2009, Bosché et al. 2009, Zhang et al. 2009 and Navon 2007). Such information directly supports progress control and if automated can significantly impact the management of a project. Current monitoring methods (1) require manual data collection and extensive as-planned and as-built data extraction from construction drawings and schedules; (2) and due to extensive workload are sometimes measured non-systematically and (3) are visually complex (Golparvar-Fard et al. 2009a, Navon and Sacks 2007). There is a need for effective techniques allowing data to be collected easily and at almost no cost, processing automatically and reporting back in a format useful for all project participants. In the meantime, cheap and high resolution digital cameras, low cost memory and increasing bandwidth capacity have enabled capturing and sharing of construction photographs

on a truly massive scale. For example, on a 200,000 SF building project an average of 500 photos/day is being collected by AEC professionals. Such a large and diverse set of imagery enables the as-built scene to be fully observed from almost every conceivable viewing position and angle during construction of a project. The availability of such rich imagery with minimal cost may enable reconstruction and visualization of as-built site geometry at high resolution. In the meantime, Building Information Models (BIMs) are also increasingly turning into binding components of AEC contracts. If linked with project schedules, BIM can form detailed chronological models that allow 4D clash detection and schedule quality control to be conducted. Furthermore they can serve as powerful baselines for progress tracking as well as visualization of discrepancies. Application of BIM during construction phase will be increased if further added-values from integrating BIM with as-built are investigated.

To date, application of unordered daily photologs for monitoring progress is unexploited by researchers. A major reason is such imagery has traditionally been in a form that is not easily adaptable for image processing; i.e., site photologs are usually unordered, un-calibrated, with widely uncontrolled lighting conditions. Developing computer vision techniques that can effectively work with such imagery to track as-built is a major challenge. In this paper, we introduce an innovative approach for tracking as-built elements from daily photographs based on *a priori* information (4D as-planned models). First using structure-from-motion (SfM) techniques, an as-built point cloud is generated and images are automatically registered. Subsequently the as-built point cloud is registered over the as-planned model. At this stage a combination of Multi-View Stereo (MVS) as well as voxel labeling-coloring algorithm is used to generate a volumetric reconstruction of the site, labeling different areas based on occupancy. Same labeling process is conducted on the as-planned model to identify occupied and visible areas for monitoring. Finally a Bayesian probabilistic model is introduced to automatically recognize progress by comparing it with dynamic thresholds learned through a Support Vector Machine (SVM) classifier. This makes our model to be the first *probabilistic model for progress tracking and visualization of deviations that incorporates both as-planned models and unordered daily photographs in a principled way.* Unlike other methods that focus on application of laser scanners or time-lapse photography (Bosché 2009, Bosché et al. 2009, Ibrahim et al. 2009, Zhang et al. 2009, Golparvar-Fard et al. 2009b, El-Omari and Moselhi 2008), our model is able to use existing information without adding burden of explicit data collection on project management and reports competitive accuracies compared to (Bosché 2009, Ibrahim et al. 2009) especially in presence of occlusions.

Overview on the D^{4}AR progress visualization and detection engine

As shown in Fig. 1 our work is based on the application of daily construction photographs, Industry Foundation Class (IFC) as-planned models as well as construction schedule to generate the D^{4}AR model and automatically measure progress. First we combine schedule with the IFC as-planned model to generate a 4D baseline for monitoring. Next using SfM, we generate an underlying 3D geometry for the as-built and set a baseline for visual navigation based on automatic registration of photographs in the scene. This is done by calculating camera pose (i.e., location, orientation, and field of view) and sparse 3D coordinate information of the as-built scene (Golparvar-Fard et al. 2009a). Subsequently the IFC model is superimposed

over the as-built point cloud. The Euclidean point cloud as well as the camera parameters is fed into MVS algorithm (Furukawa and Ponce 2009). The results are subsequently placed into an as-built voxel coloring and labeling algorithm developed in this research to get a dense reconstruction of the as-built and label scene for occupancy. Using a similarly structured algorithm, as-planned is also labeled for occupancy and visibility. The labeled scenes are fed into a novel Bayesian model and monitored by dynamically classifying the results through an SVM classifier. Finally, detected as-built, camera configurations, plus 4D as-planned model are fed into the D^4AR viewer to visualize as-built, as-planned and progress deviations in an integrated fashion. In the following, these steps are presented.

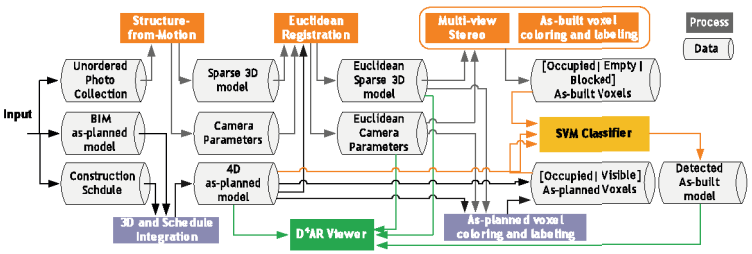

Figure 1. An overview of data and processes in our proposed system.

Reconstructing the underlying as-built representation

Recently Golparvar-Fard et al. (2009a) sparsely reconstructed and visualized the as-built scene from unordered daily photographs. The work is based on SfM similar to (Snavely et al. 2008) to fully automatically reconstruct an as-built point cloud from a set of images. This module consists of the following steps: (1) Analyzing and extracting SIFT feature points (Lowe 2004) from images; (2) Matching image features across image set; (3) Find an initial solution for the 3D locations of features points, calibrating cameras for an initial image pair and reconstructing the rest of the scene plus estimating motion of the cameras based on bundle adjustment (Nistér 2004; Triggs et al. 1999) and finally (4) Registering point clouds that are generated for each day to build a 4D as-built model (new concept in this paper). To present how these steps are formed, we choose two sets of 112 and 160 images that are taken on 8/20 and 8/272008 at Residence Hall (RH) project in Champaign, IL. In both cases, field engineer causally walked along the sidewalk of the project and took images within a few minutes.

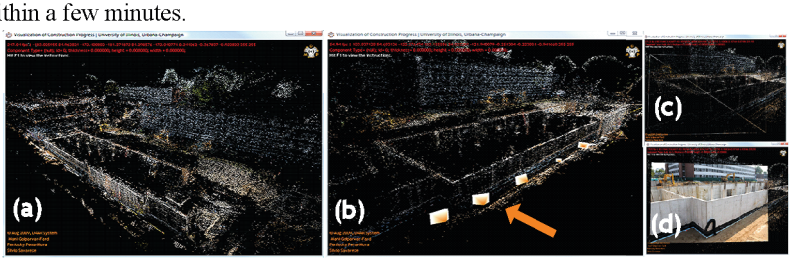

Figure 2. As-built point cloud reconstruction for RH project using 160 images taken on 8/27/2008.

Fig. 2a and b represents reconstructed scene from the same image subset and illustrate five registered cameras in the D^{4}AR environment. Once a camera is visited, the frustum is texture-mapped with a full resolution of the image so user can interactively zoom-in and visually acquire information on progress, quality, safety and productivity details as well as workspace logistics (Fig. 2c and d).

Aligning the as-built model to the as-planned model

To align the as-built point cloud with the as-planned model, transformation between these two Cartesian coordinate systems needs to be found. In this case, given an as-built point cloud that is reconstructed from photos collected at a time (t), we use the as-planned model that is updated up to time (t_0) ($t_0 < t$); i.e., the as-planned model shows progress up to time (t_0). The alignment transformation can be formed as a rigid-body motion and hence can be decomposed into rotation and translation. However in SfM, the scale may not be known. To solve this transformation with uniform scale (7 DOF) we need at least 3 corresponding points. These points could be surveying control points or a set of points that represent geospatial location of the foundation walls and columns as their detection and correspondence is visually easier. Let there be n corresponding points from as-planned and as-built models for registration. We denote the two coordinate system points by $r_{b,i}$ and $r_{p,i}$ respectively, where i is the number of corresponding points which ranges from 1 to n, $r_{b,i}$ and $r_{p,i}$ be the Cartesian coordinates of as-planned and as-built models respectively. We are looking for transformation of the form:

$$r_{b,i} = sR(r_{p,i}) + T \tag{1}$$

where s is a uniform scale factor, T is the translational offset and $R(r_p)$ is the rotated version of the as-planned model. This can be formulated as:

$$\sum_{i=1}^{n} \left\| e_i \right\|^2 = \sum_{i=1}^{n} \left\| r_{b,i} - sR(r_{p,i}) - T \right\|^2 \tag{2}$$

We follow Horn (1987) to get a closed-form solution to the least square problem of absolute orientation. In our system, this procedure needs to be done only once to have the initial point cloud registered to the 3D model. From then after, we only need to register the point clouds that are generated from new photographs to the underlying point cloud. For this purpose, we use a set of photographs that are showing part of the scene which is not significantly changed from one-day to another. For this dataset we use an Iterative Closest Point (ICP) algorithm that solves for scale as well (Du et al. 2007). This method automatically finds a random set of points from each point cloud and automatically aligns the new point cloud to the former one, in turn having the new point cloud registered with the as-planned model. This allows 4D as-built point clouds to be generated wherein user can navigate the as-built scene both spatially and chronologically. The 4D as-built registered with the 4D as-planned model allows expected and the actual schedule of the project to be compared as well. Fig. 3 shows 4 snapshots from the RH project. In Fig. 3a and b two separately reconstructed point clouds are shown while in Fig. 3c the two point clouds are registered and mutually visualized. In cases (a) and (b), reconstructions are based on 112 and 160 photographs collected from outside of the basement along the side-walk. In Fig 3d, registration of as-planned and as-built models is visualized. Table 1 reports the accuracy of registration. As observed high accuracies are achieved, though the accuracy is not

sensitive to how the control points are selected. Since usually more than the minimum number of control points (three) is selected, such error is minimized.

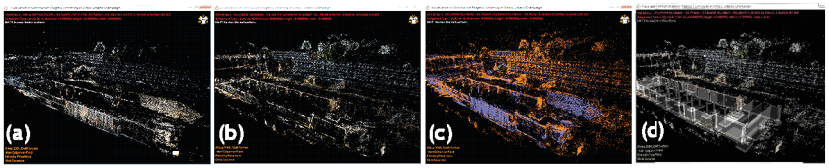

Figure 3. Registration of as-built point clouds for 112 and 160 images taken on 8/20 and 8/27.

Table 1. Registration error measured on reconstructions shown in Figure 3.

Automated progress monitoring problem setup and notation

In order to detect progress, we first discretize the integrated as-built and as-planned scene Ω into a finite set of opaque voxels (volume element in space) along dominant Euclidean axes wherein each voxel (v) occupies a finite homogeneous volume of the scene and has a consistent visual appearance. This approach allows us to reason about progress in small elements of space. In our model, voxels are equilateral; therefore resolution of the voxel grid is determined by δ. Given an image II_i, $proj_i(v)$ is used to denote the reprojection of the voxel over image i and is measured as:

$$\ni k = 1,2,...,8 \rightarrow [u,v,1]_k' = K_i[R_i \mid T_i][x,y,z,1]_k' \quad (3)$$

wherein k is the index of the voxel corners, K_i is the intrinsic camera parameters, R_i and T_i represent camera rotation and translation. Since we analyze all images within the SfM step, intrinsic and extrinsic camera parameters are known at this stage. The next step is to traverse the scene and assign as-built and as-planned labels as well as a color to each voxel. This step allows expected and actual progress in each voxel to be sensed. It is critical to traverse voxels in a certain order otherwise the reconstruction results will not be unique. In order to address this issue, we introduce an ordinal visibility constraint similar to that of Seitz and Dyer (1999) allowing certain invariant voxels whose colorings is uniquely defined to be found. Rather than only using this constraint to address uniqueness of the solution, in our approach we find areas within the space that are occupied and visible (progress). First we transform the integrated scene to a new coordinate system wherein the axes are aligned with the dominant axes of the as-planned site. This will minimize search space, since we can only reason about areas in which progress is expected to be observed. Then we start traversing the scene from the closest voxel to the convex hull of the cameras in a plane normal to the convex hull and in a front-to-back order (See Fig. 4- axis 1 to 3 directions). As we march through voxels, we verify visibility constraint and label scene as follows:

(1) *As-built labeling:* We first check if a voxel contains 3D SIFT or MVS points. In this case, we label that voxel as Occupied (O_b), have that voxel reprojected back on all images that observe it (3) and mask the reprojected pixels. Next, we keep depth of the voxel as another masking layer for each image. This allows us to automatically generate segmented images while accounting for complete and partial occlusions. If a voxel does not contain SIFT or MVS points (which is more often the case), we check

for visual consistency. In such cases if voxel reprojections on the image-set do not overlap with masked pixels i.e., is not fully occluded from all images, and it happens to contain part of the as-built scene (without considering noise or quantization effects), it needs to have equal radiance reprojections. In presence of these effects, we evaluate correlation of pixel colors to quantify voxel consistency:

$$\lambda_v = \frac{(n-1)SD^2}{\sigma^2} \leq thresh \qquad (4)$$

where SD is the standard deviation of color values, and σ^2 is the sensor color measurement error, and finally n is number of all images that observe the voxel. If λ_v is less than allowable correlation error ($thresh$), we label that voxel as visually consistent (O_b) and have that reprojected on all observing images and mark their reprojections. In our experiments there is a minimum allowable number of reprojected pixels for each voxel from all images (20 pixels). If consistency is not satisfied, we label the voxel as Empty (E_b) and finally if the minimum allowable number of pixels is not satisfied, the voxel is occluded from all views and we denote that voxel as Blocked (B_b). In our experiments we chose $thresh$ by analyzing completeness vs. accuracy for as-built reconstruction. This process has two significant outputs: (1) Labeling all as-built voxels [O_b| E_b| B_b], allowing reasoning to be made in presence of both static and dynamic occlusions; and (2) creating as-built range images.

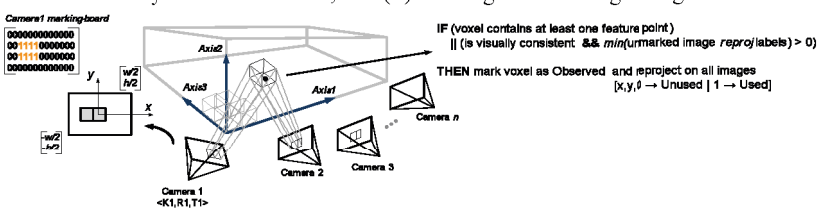

Figure 4. An illustration of coloring and labeling voxels and reprojecting labels on the image dataset.

(1) *As-planned labeling:* The as-planned model by itself accounts of static occlusions, though by placing the non overlapping areas of the as-built scene (e.g., reconstruction of excavators, temporary structures) over the as-planned, we induce dynamic occlusions. Now we march the scene in a similar fashion to that of the as-built. This time, if a voxel has at least one of its corners inside an as-planned element, we label that as Occupied [O_p]. Subsequently we reproject voxel on all images that observe it and mask reprojected pixels. In case of non-overlapping as-planned and as-built areas, we check the consistency from the as-built masking and have visually consistent voxels reprojected back on all images for masking pixels. This allows us to count for occlusions since if the reprojections contain the minimum unmasked pixels, we can label the voxel as Visible [V_p]. In our model, all labels are independent from one another and are marked with 1 or 0. Image pixels are also marked so that if a pixel is observed, the pixel is labeled with 1 and if not observed remains as 0 (See Fig. 4 left side). Such labeling allows us to reliably reason about progress in partial visible areas.

Probabilistic model for progress detection and discriminative learning

Once the scene is labeled, we can formulate progress as observation per expected as-planned element (i) with a binary value (E^i): E^i=1 if progress is detected and E^i = 0 if not. First we need to check for observation of expected columns attached to an

activity (all Elements i as E^i). Let's assume that each element E^i attached to the activity consists of n voxels. We introduce a set of probability events: Within a given volume in the scene (ω_i): Let η be the event of observing an occupied as-built element (any tangible physical element), θ_p be the event of observing as-planned element, θ_T be the event that an as-planned element is occupied and finally s the expected level of progress queried from the 4D as-planned model. We define probability of observing progress for element E^i associated with a given schedule activity (duration = n days) as a conditional probability of the form:

$$P(\eta^i \mid \theta_T^i) = \frac{P(\theta_T^i \mid \eta^i) P(\eta^i)}{P(\theta_T^i)} \tag{5}$$

Where $P(\theta^i_T|\eta^i)$ is the probability of observing as-planned element given evidence of occupancy; $P(\eta^i)$ probability of the expected as-built element observation and $P(\theta^i_T)$ probability of observing expected progress. Each element can be computed as:

For the as-built:
$$P(\theta^i{}_T \mid \eta^i) = [\frac{\sum O_b}{\sum O_b + \sum E_b}]_{\theta_p} \tag{6}$$

For the as-planned:
$$P(\theta^i{}_P) = [\frac{\sum V_p}{\sum O_p}]_{\theta^i{}_P} \tag{7}$$ and $$P(\theta_T^i) = (t/d)V \tag{8}$$

where $P(\theta^i_T)$ is the expectation of observable progress, d is the total duration of construction activity, and t represents the t_{th} day within d and finally V is the volume of expected as-built element. We use $P(\eta^i|\theta^i_T)$ to estimate progress with a threshold Γ^i. Choosing an optimal value for the threshold for each element is problematic. For example given a 10% visibility [$P(\theta^i_P)$] and 25% accuracy of reconstruction $P(\theta^i_T)$, the $P(\eta^i|\theta^i_T)$ may be susceptible to noise and inaccuracy in reconstruction. Therefore it may not be reported as detected. This selection is particularly difficult, because (1) to achieve a desired accuracy, for different element types with different materials, different *thresh* needs to be used; (2) Progress monitoring task with partial visibility is subjective by nature and needs a field expert's opinion as to whether it has taken place or not. Thus we use a machine learning model to estimate such dynamic thresholds in a principled way. We can express the threshold (Γ^i) as:

$$\Gamma^i = f(\theta_p(t), P(\eta \mid \theta_T), t/d, T, \Psi(t), \delta, thresh, \varepsilon) \tag{9}$$

Where t is construction activity duration from t=0 to d, T_i is element type (e.g., column, beam, foundation), $\Psi(t)$ is the surface visual appearance of the element i (e.g., concrete, formwork, steel), δ voxel resolution, *thresh* consistency threshold and finally ε is accuracy in registration and the underlying SfM and MVS algorithms. As shown in Table 1, we assume there is minimal error in registration and as-built reconstruction. Γ^i can be learned by casting the problem into linear classification problem. That is by learning the hyper-plane that separates the two classes in a multi-dimensional feature space, as shown in Eq.(9). The two classes are *progress*=1 and *no-progress*= 0. The optimal hyper-plane that separates the two classes can be learned in a supervised fashion using a linear support vector machine (SVM) (Fan et al. 2008). Once the classifier is learned given a new observation along with the measured features, we can establish whether progress has occurred or not by feeding observation into the classifier and retaining the output.

Experiments and results

In order to verify effectiveness and robustness of our proposed reconstruction pipeline as well as automated progress detection over arbitrary set of daily photographs and in presence of occlusions, we performed experiments on three different image datasets. These datasets were collected under different viewpoints and lighting conditions and were used for evaluating this task. These datasets are two photologs of 112 and 160 images from RH project and a 288 image dataset from a Student Dining (SD) construction project. The images are all taken at the basement level of project with significant amount of occlusion observed in both RH cases as the images were not taken from inside the basement area. Rather they were all taken along a side walk of the project (See locations of the camera frusta in Fig. 3-b). We synthetically reduced the resolution of these images to about 2MPixels and initially set voxel resolution to $0.06m$. Fig. 5 illustrates the dense reconstructions presented in Fig. 3b.

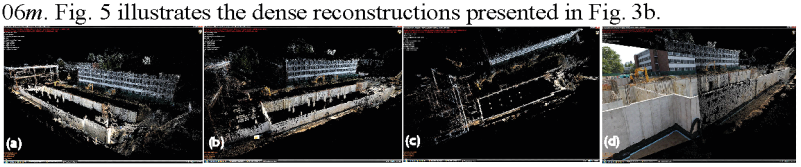

Figure 5. Illustration of dense as-built reconstruction for the same dataset presented in Fig. 3-b.

Comparison of detection accuracy

In our experiments, we analyze performance by (1) *Recall*: The fraction of truly recognized IFC-model elements relevant to the total number of model elements that are used for our SVM classifier. This will show *sensitivity* of our detection engine. (2) *Precision*: The fraction of truly recognized IFC-model elements relevant to the total number of elements that are recognized with progress in our detection engine. This will show the *accuracy* of our SVM classifier. In our approach, the SVM model classifies progress with a binary value (progress/ no progress). We train the SVM model over an initial set of categories that are fed into the machine (Cross-checked by two field engineers and a superintendant). The hyper-plane is dynamically learned though it can be roughly reported (from experiments) that if the expected observable area is less than 20% of the observable surfaces of the IFC element and the volumetric reconstruction has only been able to reconstruct the expected areas up to 50%, this element should not be recognized by the detection. The results of average accuracy for our experimental datasets are presented in Table 2. Although our approach is the first of its kind to take advantage of existing daily photographs, yet even in presence of sever occlusions, high accuracies are reported.

Table 2. Average accuracy of SVM binary detection for training and testing samples.

# of training elements	# of IFC elements	Training accuracy	Detection accuracy
112	152	87.50%	82.89%

To further examine accuracy and sensitivity of our detection engine, we studied precision-recall and true-positive/false-positive. Fig. 6 illustrates our experimental results. These graphs are only drawn for the elements that were expected to be detected and not for those elements that are fully occluded. Given the formation of this approach for the first time, the results seem very promising, yet it shows our approach is not sensitive to formation of the hyper-plane. Finally to represent progress, we use the D^4AR model platform reported and the color-coding scheme

presented in (Golparvar-Fard et al. 2009b). Fig. 7a to c show the result of our progress detection engine. In this case, IFC elements that are behind and on-schedule are color-coded with red and green accordingly. For those elements that progress is not reported, we color them in gray. Such color-coding scheme makes it easy to observe accuracy of progress detection, yet allows corrections to be made on a case-by-case basis. Fig. 7d to g illustrate examples of false positive and false negative in our detection. As observed, since our model does not contain operational details (e.g., forming stages), the formwork is falsely detected as finish of a concrete element construction. In Fig. 6d the wall highlighted should be detected, but due to occlusions it is not properly reconstructed and consequently not detected.

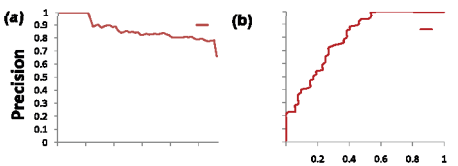

Figure 6. (a) Precision-Recall graph and (b) the TP/FP graph for our progress detection engine.

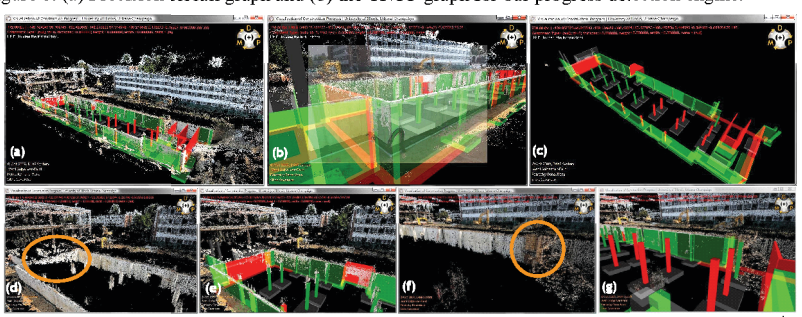

Figure 7. (a - c) Progress detection results color-coded over the IFC model and visualized in the D^4AR environment. (d, e) False Negative – the wall should be detected for progress although it is severely occluded (f, g) False Positive – the formwork should not be detected as evidence of progress.

Conclusions and summary

An automated approach for tracking, analysis and visualization of progress using daily site photographs and IFC-based 4D models is presented. In our approach, images can have low qualities, yet robustly generate dense point clouds. Subsequently the underlying point cloud is registered with other point clouds as well as the as-planned model, generating an integrated 4D as-built and as-planned model for progress visualization. Our as-built and as-planned voxel traversing demonstrates high accuracy in labeling for occupancy and visibility. The SVM model shows promising results in detecting progress. This overall marks our approach to be the first of its kind to fully take advantage of daily site photographs and IFC-based 4D models for progress tracking and analysis. Application of our system is perceived to minimize the time required for as-built data collection and as-planned data extraction; removing subjectivity of progress detection through an automated systematic detection; and finally interactive visualization to minimize the time required for coordination of

progress possibly leading to a better decision-making for project control. We need to conduct more conclusive experiments and research on reconstruction and progress detection especially at interiors and for MEP components, incorporating visual appearance detectors [$P(\eta^i)$] as well as introducing sequence knowledge to our system to enhance progress tracking and reporting abilities.

Abstract

Measuring and controlling productivity of critical activities will have a significant impact on the cost and time performance of a project. The current practice of acquiring productivity data is heavily dependant on manual collection and data entry; hence it is time consuming, costly and difficult. The objective of the present work is to investigate the automation of the activity sampling method for rapid and real time collection of productivity data. Activity recognition or classification is identified as the major challenge in activity sampling. The proposed method uses accelerometers for activity recognition and a framework was developed for construction activity classification using accelerometers. This paper discusses the preliminary investigation phase in lab environment with a single wired triaxial accelerometer attached to the body of the subject performing typical repetitive movements of a mason. The data patterns were distinct for different movements and hence the features extracted can be used in training for classifying various activity categories.

1 Introduction

The importance for measuring and controlling productivity is based strongly on the fact that construction labor costs are generally known to be 33-50% of the total project budget (Hanna 2001). The need to go back to the basics of measuring productivity at the project site level is strongly recommended as site is recognized as the defining locus of production for construction (Chan and Kaka 2004).The literature shows that there is inertia towards measuring productivity at the project level. Time and expertise needed in handling productivity data are identified as the major practical issues faced in the implementation of on-site productivity measurement system. The results of a survey indicated that 31% of the respondents stated that they did not have formal process to measure, monitor and

document construction productivity as it is time consuming, costly and was too difficult (Motwani et al. 1995).

The effectiveness of work sampling as a productivity indicator has been verified and work sampling information has shown close relationship to labor productivity (Liou and Borcherding 1986).Work sampling is a method that evaluates the amount of productive, supportive and non-productive time spent by the workers in performing the work activities. Time utilization studies are important as the meta-analysis study by Horman and Kenley (2005) reveals that 49.6% of time in construction is devoted to wasteful activity. Work sampling is a useful method for analyzing site productivity and helps in providing solutions for existing productivity problems (Orth et al. 2006). But one of the major constraints with activity sampling has been the amount of data that the observer can record and analyze during a sampling assignment. Manual methods of recording activity are both time consuming and pose difficulties in analysis. A computerized activity sampling tool, 'CALIBRE' as an application in Microsoft Access was developed (Winch and Carr 2001), but still it relies on onsite observations for monitoring the site.

Some studies have explored the benefits of image based techniques for activity classification. Peddi et al. (2009) developed an automated on-site productivity measurement system employing the concepts of computer vision and artificial intelligence where the system wirelessly acquires a sequence of images of construction activities. Gong and Caldas (2009) used intelligent video imaging method for analyzing productivity data for cyclic operations in construction. But vision based recognition has several disadvantages-computationally intensive, difficulty with moving backgrounds and varying light conditions. Gonsalves and Teizer (2009) attempted human motion analysis using range image cameras. Here a star skeleton structure was used for human activity recognition for application in health and safety. This method may be considered for automated activity recognition in activity sampling but the dynamic change in construction environment with higher levels of noise will severely affect the accuracy.

As activity recognition has been identified as the major challenge in activity sampling, a novel method, construction activity classification using accelerometers is investigated in this study. There has been research, utilizing accelerometers in health care and sports, and section 2 gives a review on both accelerometers and activity recognition using accelerometers. Section 3 discusses the frame work developed for activity classification in construction. The description of pilot study on classification in a labor intensive activity like masonry is presented in section 4, followed by conclusions in section 5.

2 Review on activity recognition using accelerometers

An accelerometer is a sensor that returns a real value of acceleration along the x, y or z-axis and so it can be any of the three types, uniaxial, biaxial or triaxial accelerometer. Accelerometers are objective and reliable for assessing physical activity levels as the signal magnitude area of acceleration signal gives very good correlation (r=0.89) with metabolic energy expenditure for various activities

(Bouten et al. 1997).The data from the accelerometer can be stored locally for offline processing or wirelessly transmitted to a data logging unit.

2.1 Advantages

The advances in micro electromechanical systems (MEMS) have greatly reduced the cost and size of these devices. These belong to the category of wearable sensors as easy attachment to the human body is possible with elastic straps. Accelerometers are currently among the most widely studied wearable sensor for activity recognition not only because of small size but also of accuracy and reasonable power consumption. They can be embedded in devices like wrist bands, cell phone, belts, etc. Sony-Ericson mobile phone with in-built 3D accelerometer (Prekopcsak 2008**),** EWatch multi sensor platform with a dual axes accelerometer (Maurer et al. 2006) and 3-axis accelerometer with embedded image sensor in a belt buckle (Cho et al. 2008) are some good instances showing integration of accelerometers with commonly used devices. Accelerometers have the advantage of being resilient and robust in trying conditions as opposed to image sensors.

2.2 Number of sensors and Position

Recognition accuracy increases with the number of sensors, but more sensors may be uncomfortable for the subject and could interfere with normal or spontaneous physical activity**.** So the main focus of research has been to recognize activity with one or two sensors. In general it is difficult to recognize activities using only one accelerometer, but the work by (Yang et al. 2008) reports an overall recognition of eight daily activities with an accuracy of 95% by keeping the sensor module on the dominant wrist. Comparing the classification accuracy with different configuration of accelerometer placements on human body helps in arriving at the optimum location. Positioning at the waist was chosen in many studies because this location provides the most useful information on the subject movements being close to the centre of the body. The waist is also a location that has been found to be comfortable to wear and convenient to the user.

2.3 Accelerometer specifications

Triaxial accelerometers are preferred as majority of activities performed involve movement in the three directions. Past studies have shown that the acceleration at body limbs and extremities can exhibit a 12g range, where as torso and hip experience 6g range in acceleration (Bouten et al. 1997). Hence the specification for ‘g’ range required for study depends on the location assigned for the accelerometer. The band width of mobility of interest of activities normally encountered lies below 20Hz and a sampling frequency of 40Hz is sufficient to meet the Nyquist criterion (Lyons et al. 2005).

2.4 Areas of application of activity recognition using accelerometers

A fertile domain for activity recognition is health care. Recent developments in communication and sensor technologies have paved the way for creating a smart health care environment. It is possible that patients can stay at home and their

movements can be remotely monitored using accelerometers. Assessing abnormal movements resulting from poor health is essential for monitoring patients' health status. Accelerometers also have been used for unsupervised home monitoring for house bound elderly and fall detection has been the primary subject for researchers in this area. Jonathan et al. (2006) have reported developing a cell-phone embedded activity recognition system for a variety of health-care related applications ranging from personal fitness to elder care. The field of sports is another area where it has found promising applications like recognition of movement patterns of a player. It helps in improvement to enhance skill and prevent injury. The prototype developed by Namal et al. (2006) can be used to select players based on their abilities and performance during the training. In another work triaxial wireless accelerometers were placed at chest and back to understand the stance and posture in lawn bowling (Gopalai et al. 2008). The study by Ermes et al. (2008) was aimed to assess the feasibility of activity recognition in out of laboratory settings that included cycling, rowing and playing football. But only a few works have been reported utilizing accelerometers in industrial settings. Uiterwal et al. (1998) have used accelerometers for measuring time utilization in various activities for assigning the right job for an injured worker under the rehabilitation program. In another work the accelerometer and acoustic data were used for indentifying different activities happening in a wood shop (Lukowicz et al. 2003). Zappi et al. (2007) have tried to recognize set of ten activities in the quality assurance checkpoint of a car assembly line.

2.5 Classification methods

Activity recognition is essentially a data analysis task in which the input accelerometer data is processed and analyzed to give output in the form of classification categories or labels. Hence activity recognition can be formulated as a classification problem. The real world activity recognition can rely on classifiers that are pre-trained on large activity data sets to recognize relevant activities as per Bao and Intille (2004). Human activity recognition traditionally has been performed by statistical methods like the Hidden Markov Model. Currently classifiers like Decision Trees, Artificial Neural Network and Support Vector Machines have become popular for delivering accurate results.

3. Construction activity classification frame work using accelerometers

Figure 1 shows the framework that was developed for activity classification in construction based on the available literature. This can be used for arriving at the best classifier and the best location of the accelerometer. Step wise explanation of the frame work is given below.

i. An activity is selected on the basis of its critical nature with regard to cost and timely completion of the project. .
ii. The activity categories of the workers can be obtained from the work sampling sheet if available or by conducting an observation study.
iii. The selection of the accelerometer depends on the range of measurement required and the sampling rate.
iv. The position of the accelerometer depends on the integration possibility and subject comfort. Initially more than one location may be chosen and the frame work helps in determining the best location.

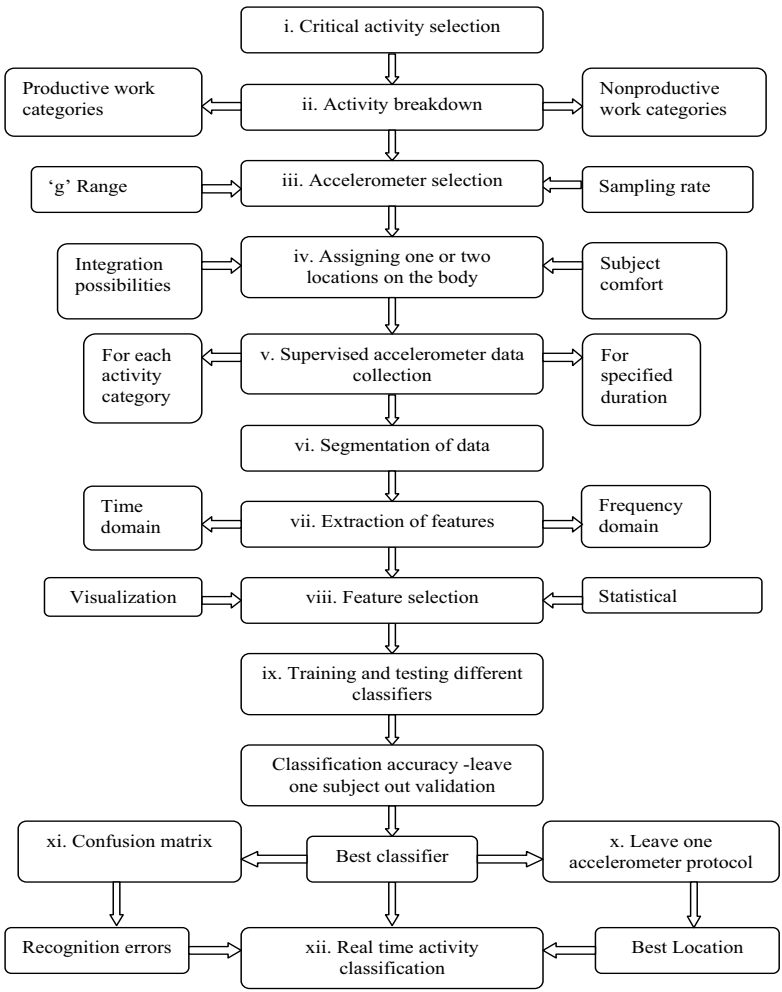

Figure 1 Construction activity classification framework

v. Data collection is taken for assigned tasks for fixed duration for different subjects in a supervised environment.
vi. The accelerometer data is broken into windows or segments. Human activity recognition employs typical overlapping window sizes of 1s or 2s.
vii. Time domain and frequency domain features are extracted from the segments.

viii. The highly discriminating features are selected using visual bar graphs or statistical techniques.
ix. Different classifiers are trained and tested , best classifier is identified
x. For the best classifier, the best location can be identified if more than one location was selected in the initial stage
xi. Confusion matrix helps in detecting the limitation of the accelerometer in recognizing any activity with the best classifier
xii. Real time classification is possible now using best classifier at the best location

4. Pilot study on activity recognition in masonry

Masonry or bricklaying is a critical labor intensive activity in building construction and the literature is rich with productivity studies in masonry.

4.1 Brief review on productivity studies in masonry

Sanders and Thomas (1991) have used data from multiple projects and have identified work type, building element, construction methods, design requirements and weather as the project related factors that significantly affect masonry productivity. As a continuation to this work they have used an additive regression model to forecast masonry productivity (Sanders and Thomas 1993). Sixteen field factors affecting masonry labor productivity were analyzed in a study by Ovararin and Popescu (2001). Enhassi et al. (2007) have used benchmarking approach to measure, analyze and compare masonry labor productivity across nine different projects. Olomolaiye et al. (1987) measured the amount of productive and unproductive times for masonry work in seven sites, using activity sampling. In another work, six critical productive activities were identified for bricklaying using step wise regression and these are fetch mortar, fetch brick, cut brick, lay brick, setting and checking, and measuring (Olomolaiye et al. 1996).

4.2 Selection of accelerometer

Low cost MEMS (micro electromechanical systems) inertial measurement unit Motion Node Accel was selected for the initial investigation. It provides measurement of linear acceleration along the three axes with USB interface output (2009, GLI Interactive LLC) and the Table 1 gives a few technical details.

Table 1 Technical details of Motion Node Accel

Weight	14 grams
Enclosure	ABS plastic
Sampling rate	50 to100Hz by 10 Hz
Physical size	59 mm x 36 mm x 15 mm
Power requirement	Powered by USB host
Range	Range ± 2g or ± 6g (user selectable)

The data acquisition is performed using Motion node software through a USB communication port, whose protocol is a GLI Interactive LLC proprietary format. A wired accelerometer was selected to ensure good quality of data for the initial investigation.

4.3 Position of the accelerometer

Activity recognition is investigated using single triaxial accelerometer at the mason's hip as it is a comfortable location and there is a possibility of integrating with belt and personal digital assistant. The sensor is firmly attached to the human body using velcro tape in order to avoid rotational noise caused by imperfect adherence. The 'g' range of ± 6g is appropriate for measurements at hip.

4.4 Data collection

Data was collected from one subject posing as a mason performing the repetitive movements like fetch brick, twist laying, fetch mortar, spread mortar and cut brick. These activities are typically cyclic, but for training the classifier, data need to be collected continuously for a particular movement for a specified time interval. Hence the data was taken continuously for five minutes for each activity and this corresponds to 18,000 samples as the sampling frequency selected was 60 Hz. The wired accelerometer is connected at the hip as shown in Figure 2 and the descriptions of each activity are given in Table 2

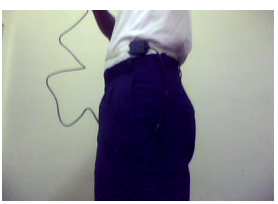

Figure 2 Location of sensor at hip

Table 2 Description of activities

Activity	Description
Fetch brick	Stooping down and fetch a brick with single hand by bending back
Twist laying	Turning towards the wall after a fetch with twisted action at the back for laying
Fetch mortar	Scooping mortar using trowel in one hand and placing on the wall with a bend and twisted action at the back
Spread mortar	Forward and backward action of arm and shoulder to spread mortar with trowel at a horizontal level
Cut brick	Performed with a trowel, to and fro motion of the arm along a vertical plane

4.5 Data analysis and Discussions

The acceleration data was stored in comma separated value format and then imported to Microsoft Excel for further analysis. The acceleration values for duration of one minute were then plotted. The acceleration values for all the activities follow a distinctive repetitive pattern. Figures 3a and 3b shows the patterns of acceleration for spread mortar and fetch brick respectively along the three axes. Hence the data segments are rich in information related to a particular

activity and this justifies the classification method utilizing the segments rather than instantaneous values. It can be also seen that the acceleration along the Z axis is more or less near to '-1g' value, due to the gravitational acceleration.

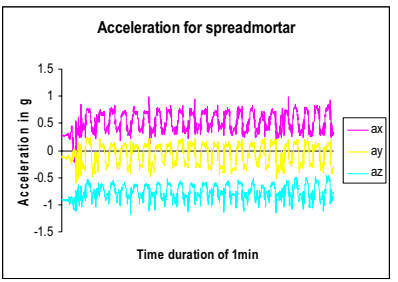

Figure 3a

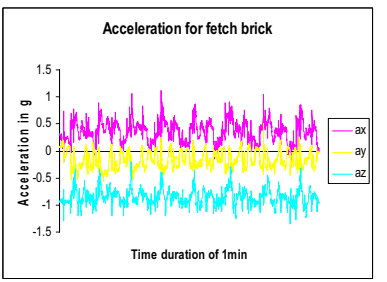

Figure 3b

A few popular time-domain features like arithmetic mean, median, mean absolute deviation, standard deviation and variance were calculated along the three directions. The features were obtained for the entire data set of 18000 samples for each activity category. Charts for mean and variance are shown in figures 4a and 4b respectively.

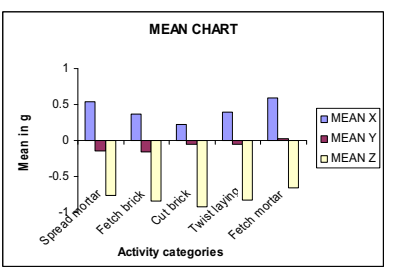

Figure 4a

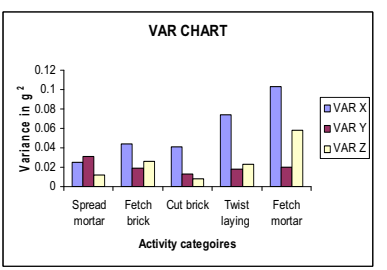

Figure 4b

It can be seen in figure 4b that the bar lengths are distinct for each activity. Hence 'variance' in prima facie is a discriminating feature and it may be used for training the classifier to recognize activities. However further statistical analysis and experiment based investigations are essential to evaluate the accuracy of the system to classify activities.

A few challenges of using wearable accelerometers in similar applications are discussed here in brief. It is difficult to ensure proper contact between the sensor and the body part for longer periods of time. The position of the accelerometer must be decided judiciously so that it will not interfere with the natural movements of the labor. Careful handling of wearable sensor with out damage can pose challenge in tough construction environment. Wireless accelerometers are necessary for real world application, but interference of other signals can affect the data quality. The labor must be educated regarding the objectives of the study to guarantee hearty cooperation.

5. Conclusions

A framework was developed for automating the activity classification process utilizing low cost accelerometers. A pilot study on activity classification in bricklaying was performed in lab environment and the preliminary results are highly encouraging. As discussed in the previous section, this framework relies on acceleration data segments and hence its optimum length and amount of overlap are decisive factors in correct classification. It was also shown how basic statistical parameters are relevant to select features for the training process. This work has opened an avenue for detailed studies with more subjects, different classifiers, out-of-lab settings and multiple sensor locations.

Abstract

As the construction industry transitions towards green buildings, and the number of LEED certified facilities continues to increase, the question of how to evaluate as-built energy performance becomes more important. Most homeowners rely on a monthly bill to determine their electric consumption, which is not an effective way to understand the results of most energy-saving strategies. Real-time feedback and appliance-level information is necessary, but most solutions require extensive hardware sub-metering, with a high price due to the hardware and installation costs. We argue that, in order to achieve wide adoption, the solutions need to be simple, easy to install, inexpensive and be able to return the investment in a reasonable time.

In this paper we first analyze and compare the different types of technologies that are currently available for allowing homeowners to monitor their energy expenditure. Then we discuss new approaches that balance the trade-off between information and cost, and present preliminary results from a prototype Non-Intrusive Load Monitoring (NILM) system we have installed in a building.

1. Introduction

Conserving energy has become a pervasive goal across many different fields in recent years. The construction industry has been slowly embracing the concept of sustainability, partly through the application of certifications and standards for "green" buildings. It is rarely the case, however, that these sustainable buildings continue to be monitored after their construction, to assess their energy footprint. How do we know that these new facilities are in fact continuing to achieve the desired efficiency levels? How can building managers ensure this? For comparison, the

automotive industry, one whose products are hundreds of times less expensive than buildings, has been providing consumers with figures like instantaneous miles per gallon (MPG) for newer cars, helping the driver adjust their behavior accordingly.

The importance of buildings in the global energy consumption is hard to overestimate. Out of the 102 quadrillion BTU (quads) of total annual primary energy consumption in the United States, 40% is used to generate electricity. Of this number, 36% is consumed by commercial buildings and 37% by the residential sector (Energy Information Administration 2005). The remaining 27% is used, mainly, in manufacturing and transportation. Hence, reducing the consumption on any or both of these two types of facilities can have a significant effect on the total energy savings.

Facility managers (including residential homeowners), are interested in lowering their energy consumption, as it is becoming an increasingly expensive resource. But while there exist methods and tools for assessing the consumption of the various energy sources in a house, selecting the right approach in terms of costs and benefits, is not a simple task. Furthermore, most of the available solutions report static and/or aggregate information, such as monthly consumption, making it difficult to base energy-efficiency decisions on that type of data.

1.1 Motivation

As researchers in the intersecting field of information and building/construction technology, we believe it is our responsibility to shed some light on the different aspects of the problem of continuously evaluating the electric consumption of residential buildings. Specifically, we would like with this paper to (a) provide a brief summary of the different considerations that need to be taken when designing a measurement system for monitoring electricity consumption in residential buildings; (b) provide some insights into the type of data that homeowners may need in order to effectively reduce their electric consumption, based largely on literature findings; (c) survey some of the currently available solutions that exist in the market and analyze their similarities and differences; and (d) describe what some of the future technologies, currently being researched, could bring about.

A key motivation in the building industry is the Leadership in Energy and Environmental Design (LEED) family of certified facilities by the US Green Building Council. The LEED criteria have spawned a generation of high-performance buildings, yet they were devised for the design and construction of facilities. The bronze/silver/gold level achievements are awarded soon after buildings are occupied. In the future we expect that amendments to such standards will require life cycle monitoring of the facilities and/or require continuous energy improvements to maintain the ratings. To continuously improve energy use, significant improvements will need to be made in either user behavior and/or energy efficient technologies.

The behavioral impacts of providing users with real-time energy use feedback, even at the aggregate level (e.g., overall consumption of the building) can produce savings of up to 10-15% according to some studies (Fischer 2008; Parker et al. 2006). Larger savings are potentially achievable if more detailed data were available to the user, to automated building control systems or to electricity suppliers (allowing them to reward peak-shifting loads or subsidize equipment upgrades). We believe that if

decision makers had real-time access to the operational schedule and energy consumption of all the appliances in the building, better decisions could be made towards managing the building's electrical consumption. Furthermore, access to such fine-grained data would also benefit the building industry in many ways: informing designers about the effect of their choices on the energy consumption, supporting electricity audits and building commissioning processes, etc.

In principle, one way to obtain detailed appliance usage information would be through extensive hardware sub-metering. However, such an approach would have a high price due to the hardware and installation costs, as will be seen in later sections of this paper. Utilities provide their customers with monthly reports of their consumption, but automated meter reading (AMR) systems are starting to provide more frequent updates. Additionally, there are a growing number of commercially available power meters that can provide traditional power metrics in real-time at varying degrees of detail: the building's main electrical feed, circuit panels, individual circuits or individual outlets. These latter solutions range from hundreds to tens of thousands of dollars, their cost increasing with the level of detail obtained. The challenge, then, is to find a technology that balances this tradeoff.

In light of this, when discussing future technologies, we are going to give special attention to a technique called Non-Intrusive Load Monitoring (NILM), which attempts to deduce the energy consumption of each individual appliance in a building by matching their "*fingerprints*" on the overall voltage and current coming into the facility as measured by a single measurement system installed at the main electrical feed of the building.

1.2 Paper Organization

We will start by giving a brief overview of the different hardware and software considerations that we believe are important for effectively designing a system to continuously measure electricity consumption in buildings. These recommendations are based, primarily, on our past experience installing commercially available systems in different buildings around the city of Pittsburgh, PA. As an example, we have installed circuit-level power meters in two separate buildings in Carnegie Mellon University's (CMU) campus; collected data from 7 other previously installed panel-level meters; designed and built 3 custom panel-level systems for residential buildings; and evaluated a number of other commercial meters in our laboratory.

We then provide a brief survey of the currently available technologies, putting special attention to the average costs of installation and the information that can obtained from each of them. Following this, sections 4 and 5 are devoted to what we believe are possible future technologies. Section 5, in particular, focuses on NILM, and provides early results from a prototype system installed in a residential building in Pittsburgh. Finally, we present our conclusions and discuss possible future work.

2. Measuring Electricity Consumption in Buildings

To understand what, where and how we need to measure electricity consumption in residential buildings, it is important to first understand some basic principles of power systems. Energy, the physical quantity we are interested in, is computed by

integrating power over time. Electric power, in turn, is a function of voltage and current. Hence, by measuring these last two phenomena we can then use some basic mathematics to obtain energy measurements. The question then is: where should the voltage and current be measured? The electric distribution system in each housing unit can be thought of as having a tree-like structure where the leaves would be the individual loads (i.e. appliances), and the trunk would be the main feed coming from the utility. In between these two extremes, there are electrical circuits branching out of distribution panels. Thus, measuring energy at different points in this distribution system yields different levels of aggregation.

2.1 Hardware Considerations

As discussed earlier, there exist a wide variety of commercially available tools for measuring the electricity consumption of buildings. They can be differentiated, primarily, in two dimensions: (1) their time resolution (i.e., how frequently they sample the waveforms and compute measurements); and (2) what we will call their space resolution or, in other words, which points in the power distribution system they are measuring. Therefore, to properly select the appropriate hardware for the task, one needs to match these resolutions to the requirements of the application.

2.1.1 Time Resolution

The speed at which the voltage and current signals are sampled generally depends on the type of information that needs to be extracted from them, as well as the accuracy that is sought for the measurements. If the meters are designed for power quality analysis/control purposes, then higher sampling rates (in the kHz order) are necessary. This rate does not correspond to the rate at which the power-metrics are reported to the user.

2.1.2 Space Resolution

Meters are typically designed for measuring specific points in the distribution system: the main feed, the distribution/circuit panels, the individual circuits in those panels, in between the outlets and the appliances, etc. The choice of any of these depends mainly on the information that is being sought. If the user is simply interested in the overall energy consumption, then measuring the main feed would suffice.

As installing meters in the panel must be done by certified electricians, the cost for their installation scales with the number of circuits measured. The total installed cost, then, can be more than twice the price of the hardware. Such was the case for one of our installations in a 100-year old building at CMU.

3. Current Practices

Now that we have described some of the main considerations, we turn our attention to the different commercially available solutions. Table 1 shows the different devices that we considered in our analysis. Far from being a complete list of commercial products, this sample was obtained by making use of an on-line store specialized in power meters (www.powermeterstore.com), as well as a traditional web search engine (www.google.com). A more thorough review can be found in (EPRI 2009).

We needed to make some assumptions in order to perform an equitable comparison between devices of different types. To start, we did not consider those meters which did not have a data link for communicating with a computer and uploading the measurements. An asterisk is used in Table 1 to indicate such cases. Secondly, for circuit- and plug-level devices, we needed to assume the number of measurement points that would be required in order to provide an estimate of the whole-building consumption. For circuit-level meters the number we used was 18, which corresponded to the number of circuits of the device with the least number of inputs from our list. Similarly for plug-level devices, we chose 20 as the number of required measurement points since according to (Energy Information Administration 2005), that number of appliances accounts for approximately 85% of the electricity consumption of residential buildings in the U.S..

Table 1: List of commercially available residential power meters considered for this paper. An asterisk (*) is used to indicate that the meter does not provide a computer data port.

As shown in Figure 1, the least expensive solutions we found for continuous monitoring of the overall consumption of a residential building were in the $50-150 (US Dollars) range without considering the installation costs. For more detailed data as can be obtained by measuring each individual circuit, the least expensive solutions were in the ten to twenty times more expensive. The price increases even more when considering the plug-level meters, which have a minimum cost of approximately

$3,000, without considering the networking costs and assuming that only 20 different loads in the house will be monitored.

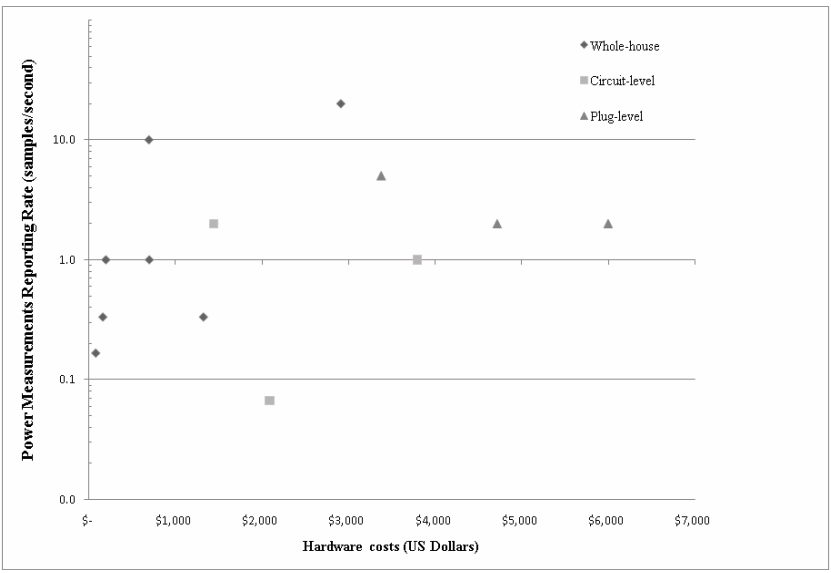

Figure 1: Cost of hardware versus update rate (logarithmic scale) for different types of power meters, all of which have a data port for uploading the measurements to a computer.

This last consideration is based on the idea that it is possible to limit the number of loads being continuously monitored in a house and still obtain valuable feedback that can guarantee savings. According to the Residential Energy Consumption Survey, just 5 end-uses account for roughly 50% of U.S. household electric consumption: refrigeration, air conditioning, space heating, water heating, and lighting (Energy Information Administration 2005). However, even if we know which appliances are responsible for the greatest portion of the energy consumption, many of these loads may offer very little room for modification. For example, besides changing the thermostat configuration in an old and inefficient refrigerator, the only other options left to reduce its consumption would be to repair it or replace it. This alternative may not be cost-efficient when compared to the energy savings it would bring about, even if it would greatly reduce the total consumption of the building.

Clearly, information has its price in this context. The more details homeowners want to know about their energy consumption, the more they would have to pay to obtain them. The real challenge, however, is that potential savings based on these different feedback mechanisms extend the payback period of these investments to unacceptable figures: decades in some cases.

3.1 Measuring green buildings

In the case of verifying the as-built energy performance of a residential building, the energy consumption of air conditioning, space heating, water heating, and lighting are

of particular interest. Since appliance choice and usage can be responsible for a great deal of variation in a home's total energy use, it is informative to separate these loads from the total consumption reflected by utility bills. Of course, not every home has all-electric space heating, cooling, and water heating, but according to the 2001 US census, approximately 40% of the space and water heaters in residential buildings are fueled by electricity (Energy Information Administration 2005). Table 2 notes some of the pros and cons of using different metering techniques to measure each type of load, with color shades indicating the difficulty, darker meaning more challenging. This analysis might suggest that a hybrid approach is best for achieving accurate measurements for each category.

4. Future Prospects

In recent years, there has been an increase in the number of product offerings that are targeting the residential and/or commercial building energy monitoring sectors. Many companies are focusing on creating better interfaces, specifically designed to appeal to the homeowner. Big names in the information technology industry, such as Google (Google) and Microsoft (Microsoft), have recently revealed their free products that make use of the energy-related data that is currently available, to manage and efficiently display electricity consumption information for building managers or owners. These products are implicitly assuming that more data will become available.

Table 2: Comparison of metering solutions for four major load-types. Shading indicates level of difficulty, with darker shades being more difficult.

	air conditioning	space heating	water heating	lighting
Whole-house	Measure spring/fall baseline and correlate cooling degree days (CDD) with elec. consumption.	Measure spring/fall baseline and correlate cooling degree days (CDD) with elec. consumption.	Measure watts of single off-on change and multiply by typical duty cycle.	Observe change in power when switching each light on or off.
Circuit-level	Central air conditioning can be easily measured; window units may share circuits with other plug loads.	Most likely isolated on one or more dedicated circuits.	Most likely isolated on a dedicated circuit.	Loads spread across many circuits; often on shared circuits and can even change circuits.
Plug-level	Central air inaccessible (hard-wired); window units usually require specialized outlets.	Central or baseboard is hard-wired (no plug). Portable space heaters overload some plug-load meters.	Hard-wired; impossible to metter.	Plug-in fixtures are easily measured. Hard-wired fixtures cannot be measured.
NILM	Easily recognized, but power varies during cycle, complicating energy calculation.	Easily recognized; if heat pump, power varies during cycle, complicating energy calculation.	Easily recognized, but hard to train on sample transitions without user controls.	Lights are often confused with other lights. Category-level recognition may help.

However, even though hardware costs may decrease with time due to technological improvements and economies of scale, labor costs for installing these solutions in

homes will likely not, thus maintaining the total price for intensive sub-metering solutions at a high level. It follows, then, that many of the near future prospects for residential energy monitoring will likely be utilizing easy-to-obtain aggregate consumption data. The advent of the so-called "Smart Meters" (meters that establish a two-way communication with the utility company) could also support this vision by providing energy readings that are closer to real-time.

Of particular importance is one technology that tries to extract as much valuable information as possible from these aggregate data streams: Non-Intrusive Load Monitoring. First investigated more than twenty years ago (Hart 1992), this approach aims at identifying patterns in the total voltage and current signals which it can relate to the operation of individual appliances in the building. The technology has yet to reach the consumer market, probably due to hardware costs and the challenges posed by having to train the system (Smith, Leslie Norford, and Steven Leeb 2003). We believe that technological improvements in recent years have decreased the costs of hardware enough to overcome the first barrier, and ongoing research is now tackling the human-computer interaction problems posed by training.

Given the promising outcomes that NILM could provide, we devote the following section of this paper to share our experience implementing a simple prototype system based largely on the techniques described in the literature.

5. The Case for Non-Intrusive Load Monitoring

To test the effectiveness and analyze the potential of NILM, we developed a prototype system and installed it in an apartment unit. The system measured voltage and current on the two voltage sources (phases) coming into the apartment from the utility's transformer. A computer with a data acquisition card sampled these signals at a rate of 10kHz, and computed estimates of the spectral envelope as described in (S.R. Shaw et al. 2008). Using an event detection algorithm inspired by (Luo et al. 2002), the system could identify the precise moments when an appliance in the house had changed its state. Following this, we applied kernel regression on a fixed window of samples of the power signals around the event, and used the coefficients of this regression as a "signature" for the given state-transition. These signatures were stored during the training phase, and used during regular operation to compare new, unknown state-transitions against them and provide proper labels. More details on the system can be found in (Berges et al. 2009).

Our tests in the laboratory, before deploying the system in the apartment unit, showed that after events were detected, it was capable of assigning the correct label, out of 34 possible ones (e.g. toaster turning on, fan going from low to high, etc.) with an average 10-fold cross validation accuracy of approximately 80%. Additionally the detector gave very few false positives in our lab tests, and virtually no false negatives.

The situation proved to be different in the apartment unit. Because we did not implement the multi-resolution techniques for the event detector described in (Luo et al. 2002), some slow start-up transients triggered many false positive predictions. The electric heating system of the building especially contributed to this type of error. Nonetheless, these start-up transients did not occur very frequently, and we were able to reduce the number of false positives by fine-tuning the parameters of the detector.

Validating the NILM system requires hardware sub-metering (either plug-level or circuit-level if on a dedicated circuit). To test the accuracy of the energy estimates, we installed a plug-through power meter in the top-consuming appliance: the refrigerator. Using these isolated measurements we could compare the estimates of the NILM system and evaluate the performance. Figure 2 shows the result of this experiment. The difference between the energy usage as computed by NILM and the plug-meter was less than 0.5 kW-h (15%) for a 1 day period partly shown in Figure 2.

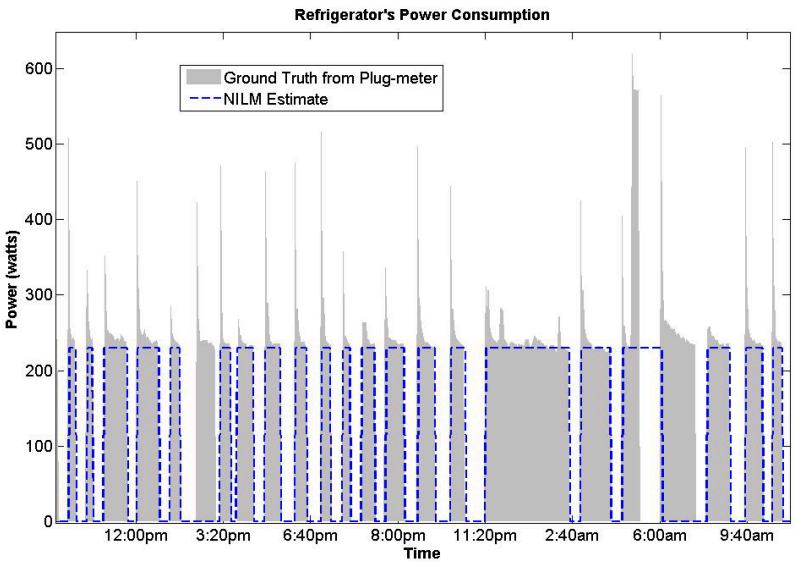

Figure 2: Power consumption of the refrigerator during a 12 hour period as estimated by NILM (dashed line) and the plug-meter attached to the appliance (solid line).

6. Conclusions and Discussion

Future technologies for continuous, detailed measurement of the electricity consumption of buildings will likely rely on a hybrid approach combining advanced techniques for extracting useful information out of low-cost data sources present in buildings, as well as direct measurements of the consumption of individual appliances. We have shown some examples of currently available technologies and provided a brief comparison which indicated that the level of information provided by them is proportional to their cost.

Detailed feedback on electricity consumption can benefit many facets of the building industry. It may facilitate the implementation of LEED standards that go beyond the design and construction of facilities, inform building designers on how buildings really operate, and provide support for building commissioning and energy audits.

NILM techniques show promising results to provide detailed information at a low cost. However, more research is needed to bring this technology to market. We believe that ways of achieving this include a combination of better training processes and interfaces, more generalized appliance signatures that can be shared across buildings, and the integration of other sources of information (e.g., motion sensors, temperature sensors, etc.) into the framework. As lower-cost sources of detailed consumption data become available, we anticipate the growth of more sophisticated software for analyzing those data, as well as more reliance on such analysis for investment planning and verification.

Abstract:

Tunnel Boring Machine (TBM) has been extensively implemented in microtunneling and pipe jacking projects for constructing subsurface pipeline infrastructure. Commonly used laser systems for TBM guidance tend to suffer from instable performance and low accuracy, while the high complexity in the system design of some advanced solutions compromises the system reliability while driving up the technology's cost. This paper presents an in-house developed automated and cost-effective TBM guidance system. The TBM's positions are automatically surveyed by a robotic total station and real-time line and level deviations from as-designed tunnel alignment are derived instantaneously. Given the coordinates of three observation points on the TBM, the TBM's three rotation angles in the underground space are determined by a "point-to-angle" computing algorithm. The automated system was assembled in house and tested at a pipe jacking site in Hong Kong. Practical constraints and considerations associated with the system setup and field testing are discussed. The performances of the automated system are evaluated in terms of accuracy and timeliness by comparing the testing results against data sourced from current control practices.

Introduction

Microtunneling and pipe jacking are commonly employed in urban areas for the installation of small to medium diameter underground pipelines, such as sewers, drains and water mains (Mok et al. 2007). In contrast with the conventional open-trench method, microtunneling provides an environmentally friendly and sustainable urbanization technology thanks to its "trenchless" nature. Tunnel boring machine (TBM) is a steerable and remotely controlled tunneling machine

that has been extensively applied in microtunneling to excavate subsurface tunnels (Kramer et al. 1992). How to steer the advancement of a TBM along the as-designed tunnel alignment is a crucial factor to the success of every microtunneling project (Thomson 1993). Tolerances of deviations on line and level are generally specified in orders of ± 50 mm and ± 75 mm respectively for pipe jacking projects (PJA 1995). However, unforeseen underground obstacles and variable geological conditions present uncertainties and challenges to tunnel alignment control.

An effective TBM guidance system plays a significant role for closely controlling the subsurface tunnel alignment. At present, laser targeting systems predominate in straight drive microtunneling and pipe jacking applications (Geoffrey 2004). However, problems in practical applications include (1) the displacement of the laser beam due mainly to the theodolite standpoint being destabilized during the pipe jacking process; (2) the dispersion and refraction of the laser beam over a long travel distance in the tunnel; and (3) the difficulty in receiving laser's projection over a long distance on target boards having restricted screen size (Thomson 1993). Additionally, some sophisticated gyro-compass systems or motorized laser targeting systems have been developed for TBM guidance, especially for installing pipeline along curved alignments (Seilert and Nod 2007; Tacs 2009; VMT 2003). On the other hand, the high complexity in the system design compromises system's reliability while driving up technology's cost, including system maintenance and technical service. In practice, many operators are guided by conventional laser systems while heavily counting on experiences to steer the TBM. It is not unusual that TBM operators and site managers are caught by surprise with out-of-tolerance tunnel alignment errors (Mok et al. 2007).

The research aims to investigate automated and cost-effective alternatives to guide TBM's advance during microtunneling and pipe jacking operations. We proposed a simplified TBM guidance system through integrating automated TBM tracking with on-line computing (Shen et al. 2009a; Shen et al. 2009b). A robotic total station is remotely controlled to automatically survey the TBM's position in terms of point coordinates. The coordinates are then processed to derive the line and level deviations from as-designed tunnel alignment. Further, based on the coordinates of three observation points on the TBM, the TBM's three rotation angles, namely yawing (TBM's head turning "left-right"), pitching (TBM's head turning "up-down") and rolling (TBM's body rotating around its own central axis), can be determined by innovative "point-to-angle" computing algorithms, without the use of instrumentation (inclinometers and gyro-compasses). As a continuous effort, the present research focuses on the evaluation of the system performance in practical settings by conducting field testing. A local pipe jacking site for constructing one cross-river tunnel with a length of 220 m and an inner diameter of 1200 mm was selected as the test bed. In this paper, practical constraints and considerations associated with the system setup are discussed. The performances of the automated system are evaluated by comparing the testing results against data sourced from current practices in terms of accuracy and

timeliness.

The remainder of this paper is organized as follows: first, the design and the functionality of the proposed automated TBM guidance system are described. Next presented is the implementation and field testing of the system in a pipe jacking site, followed by analysis of testing results. Discussions on practical performances and applicability of the research are made before drawing conclusions.

Automated and Simplified Solution to TBM Guidance

To address the limitations identified in current TBM guidance systems, we developed an automated and cost-effective TBM guidance system based on robotic total station and on-line computing. Figure 1 gives a depiction of the system design. A robotic total station is linked with a control laptop computer to automatically fix three tracking points on the TBM. Thus, the TBM position in the underground space can be accurately mapped and line and level deviations derived in real time. In addition, with the coordinates of three tracking points known at two consecutive time events, three rotation angles of the TBM (yaw, pitch, and roll) can be deduced through on-line computing by a "point-to-angle" algorithm. To counter the likely destabilization of the total station by ground vibration during the tunneling and pipe jacking operations, a reference benchmark, which is a fixed point in the shaft or above the ground, serves as the fourth tracking point for periodically calibrating the offsets of the total station's standpoint.

TBM Positioning and Deviations Calculation

Suppose the coordinates of the total station are $[x_0, y_0, z_0]$. The total station automatically surveys one specific tracking point i by measuring three parameters relative to the total station: (1) the slope distance d; (2) the horizontal angle α; and (3) the vertical angle β. Note, all the coordinates are given in the local geodetic frame (East-North-Zenith). The coordinates of point i is calculated by

$$\begin{cases} x_i = d \times \cos\beta \times \sin\alpha + x_0 \\ y_i = d \times \cos\beta \times \cos\alpha + y_0 \\ z_i = d \times \sin\beta + z_0 \end{cases} \quad (1)$$

Given the ideal coordinates for point i are $[x_i', y_i', z_i']$ as per the as-designed

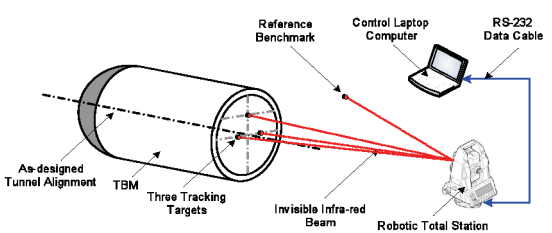

Figure 1. System design of the automated TBM guidance system

tunnel alignment, the deviations in line and level can be determined by

$$\begin{cases} DevLine = \pm\sqrt{(x_i - x_i')^2 + (y_i - y_i')^2} \\ DevLevel = z_i - z_i' \end{cases} \quad (2)$$

Computation of Three Rotation Angles

The majority of currently available TBM guidance systems utilize inertial instrumentation, such as gravity-referenced inclinometers and magnetic compasses, to gauge rotation angles of the TBM. By contrast, this research implements an innovative "point-to-angle" computing algorithm to calculate the TBM's orientations. It provides a cost-effective alternative to current methods by eliminating the use of any inertial instrument.

Theoretically, two non-zero and non-collinear vectors form a unique rigid plane to describe the position and orientation of a solid object in space. In the proposed TBM guidance system, three tracking points mounted on the TBM form the two vectors. Shown in Figure 2, the TBM together with the three tracking points (P1, P2 and P3) undergo orientation changes from t1 to t2. Mathematically, the changes can be represented by three sequential rotations, namely (1) a yawing angle $\Delta\psi$ about the z-axis; (2) a pitching angle $\Delta\theta$ about the x-axis; and (3) a rolling angle $\Delta\Phi$ about the y-axis, as illustrated in Figure 2.

The coordinates of P1, P2 and P3 are determined at two consecutive time events t1 to t2, and further processed to form two vectors V_{t1} and V_{t2}. The TBM's three rotation angles can be calculated by solving

$$\begin{bmatrix} \Delta\psi \\ \Delta\theta \\ \Delta\phi \end{bmatrix} = f\begin{bmatrix} V_{t2} & V_{t1} \end{bmatrix} = f\begin{bmatrix} P1_{t2} & P1_{t1} \\ P2_{t2} & P2_{t1} \\ P3_{t2} & P3_{t1} \end{bmatrix} \quad (3)$$

The "point-to-angle" computation has been comprehensively investigated in aeronautics and astronautics disciplines in the past four decades. In order to maintain a balance between computing time, accuracy and minimal tracking points, the classic TRIAD (Tri-Axial Attitude Determination) algorithm was implemented in this research (Black 1964; Wertz 1978; Shuster and Oh 1981).

Monte Carlo simulations have been conducted to assess the errors in point positioning and angular measurement by the proposed solution. The resulting

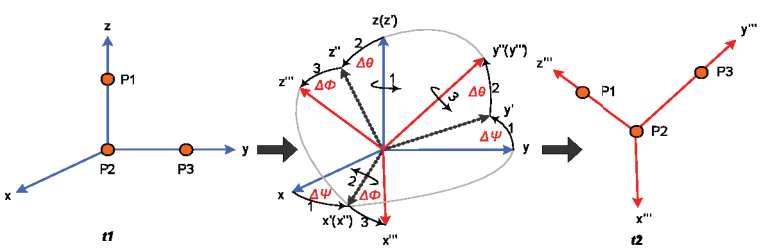

Figure 2. Rotations of a solid frame represented by three sequential rotations

position errors were found to be in the order of 3-4 mm, while the angular errors in the three rotation angles in the order of 0.8-0.9 degree in terms of the standard deviations (Shen et al 2009b). The performance of the system is validated through field testing in the following section.

Field Testing Validation

The proposed TBM guidance system was assembled in house and underwent extensive lab testing from October 2008 to August 2009 at the Hong Kong Polytechnic University. The prototype system mainly consists of a robotic total station linked with a laptop computer via a RS232 serial cable. A computer program was coded by graphic user interface (GUI) programming in MATLAB (Marchand and Holland 2003), to enable total station control, automated data collection and on-line computing. The field testing commenced in late August 2009 at a pipe jacking site in Hong Kong with close collaboration with local industry partners. The project constructed a concrete tunnel with a length of 220 m and an inner diameter of 1200 mm across a 40 m-wide river situated in the New Territories of Hong Kong. Site operations commenced in October 2008 and were completed by December 2009. Figure 3 shows the layout of the jacking shaft. A laser theodolite was deployed for guiding TBM steering, complemented with periodic independent surveying for cross-checking the deviations of the as-built tunnel.

System Setup and Practical Constraints

Before conducting the field testing, system setup at the site was deliberately designed, in order to ensure the functionality of the automated system while minimizing disruptions to ongoing site operations. In particular, practical spatial constraints presented challenges to the installation of (1) three tracking targets on the TBM and (2) one robotic total station in the jacking shaft. After coordination with site engineers, three tracking targets were finally mounted around the laser target board on the TBM, while a custom-built stand of the total station was firmly attached to the stand of the laser theodolite, as shown in Figure 4 and Figure 5 respectively. Notably, the length and height of the total station's stand were well considered so as to maintain the line of sight to the three tracking

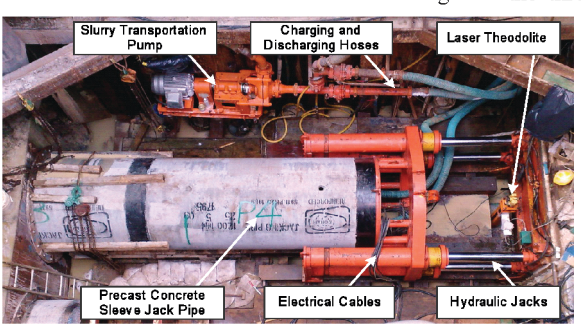

Figure 3. Layout of the jacking shaft with pipe jacking equipment

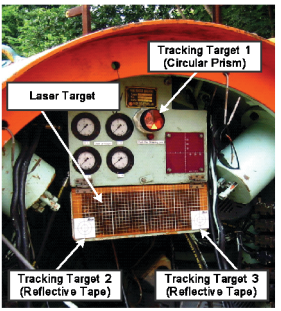

Figure 4. Three tracking targets mounted on the TBM

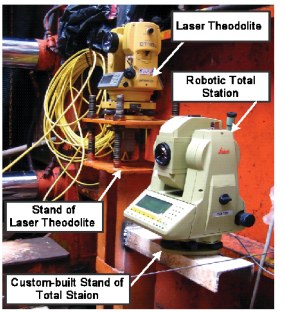

Figure 5. Installation of the total station on a custom-built stand

targets on the TBM.

Evaluation of On-Site Performance

After all instruments were properly initialized on site, the robotic total station was controlled by the program running on the laptop computer, shown in Figure 6. Coordinates of three target points on the TBM were automatically tracked and surveyed. Three rotation angles of the TBM were determined by on-line computing in real time. The resulting surveying and computing data were recorded in a database for further analysis.

The automated system functioned well for continuous tracking and real-time computation of the TBM positions in the 3D underground space. With the well-thought system setup on site, the line of sight between the total station and tracking targets proved to be available, even with the intermediate jacking stations and intermediate pumps installed within the pipe strings. The frequency for updating the TBM position and the rotation angles was once per minute. Table 1 gives the automated surveying results recorded in the database, including target point surveying results and calculated coordinates with time stamped. In addition, two different types of tracking targets were tested under practical settings: the glass prism functioned well to track the working TBM in the dark underground

tunnel over the entire drive length (220 m); while two reflective tape stickers could be automatically recognized and tracked within 55m. In the following section, the minute-by-minute positions and orientations of TBM over the first 55 m are checked against on-site manual records and independent surveying results provided by the contractor.

Data Analysis and Comparison

Site trials were carried out during the course of microtunneling operations. Figure 7-11 illustrate continuous two-hour testing results on September 10, 2009 with the tunnel chainages (or jacking distances) ranging from 36.68 m to 37.44 m. Figure 7 and Figure 8 present the line and level deviations of the TBM alignment determined by the automated system. It was found that the alignment was well controlled during the testing period. In particular, the line deviations varied between ± 10 mm while the level deviations were less than 35 mm. Besides, Figure 9, 10 and 11 give the resulting three rotation angles in the testing. As the TBM operator adjusted TBM's orientations cautiously and infrequently, the rotation angles were found to be relatively steady. For instance, the majority of yawing data lay between 198 deg and 199 deg.

The testing results were further compared against actual site records. The TBM operator recorded the TBM's deviations and inclinations upon the start and completion of the jacking process of every pipe section. In addition, the alignment and deviations of the as-built tunnel were checked by independent surveyors hired by the contractor on a weekly basis. Table 2 compares the alignment results by different methods on three tunnel locations (with close chainages). Data obtained from the automated system were found to closely match manual records resulting from the other two methods. The differences in deviations from the three methods are less than 18 mm, while the differences of the pitching and rolling angles are less than 1.7 deg. Note the yawing angles are unavailable by use of the current laser system and the independent surveyors only check line and level deviations. The automated system, therefore, provides real time TBM positioning and tunnel alignment surveying with reasonable accuracy while significantly increasing the frequency of data updating.

Conclusions

A TBM is the leading resource employed in microtunneling and pipe jacking operations for constructing underground utility pipeline. Accurate TBM positioning in the underground space is crucial to guiding the TBM's advance and controlling the subsurface tunnel alignment. To address the limitations identified in current TBM guidance systems, we propose a simplified TBM guidance system: accurate TBM positions can be automatically measured by a robotic total station so as to derive the line and level deviations in real time; Additionally, with the coordinates of three fixed points on the TBM tracked, three rotation angles of the TBM are computed by a "point-to-angle" algorithm, without the need of instrumentation such as inclinometers and compasses.

Field testing of the prototype automated TBM guidance system was conducted at a pipe jacking site in Hong Kong. The system was deliberately set up at the site against practical challenges, especially the tight spatial constraints for mounting three tracking targets on the TBM and installing the total station in the jacking shaft. As a result, the automated system functioned well for continuous and real-time tracking and computation of the TBM positions and its three axes orientations. The frequency for updating TBM's position was once per minute. The tunnel alignment deviations and the rotation angles of TBM over the first 55 m were collected by the automated system, and further compared against TBM operator's manual records and independent surveyors' results, indicating a close match.

In short, the research has contributed to the state of the practice in TBM guidance and tunnel alignment control for microtunneling and pipe jacking operations through integrating automated data collection and on-line computing. By deploying an off-the-shelf robotic total station and eliminating the use of inclinometers and gyro-compasses, the resulting TBM guidance solution can potentially provide a quick, cost-effective alternative to tackling a critical engineering task.

Automated/Real-Time Systems
Information Technology and Computer Applications

Abstract: The U.S. has more than 14 million miles of buried pipelines and utilities, many of which are in congested urban environments where several lines share the underground space. Errors in locating excavations for new installation or for repair/rehabilitation of existing utilities can result in significant costs, delays, loss of life, and damage to property (Sterling 2000). There is thus a clear need for new solutions to accurately locate buried infrastructure and improve excavation safety. This paper presents ongoing research being collaboratively conducted by the University of Michigan and DTE Energy (Michigan's largest electric and gas utility company) that is investigating the use of Real-Time Kinematic GPS, combined with Geospatial Databases of subsurface utilities to design a new visual excavator-utility collision avoidance technology. 3D models of buried utilities are created from available geospatial data, and then superimposed over an excavator's work space using geo-referenced Augmented Reality (AR) to provide the operator and the spotter(s) with visual information on the location and type of utilities that exist in the excavator's vicinity. This paper describes the overall methodology and the first results of the research.

1. Introduction: The underground space in urban environments is a spider's web of electric lines, gas lines, cable TV lines, fiber optics, telephone cables, traffic signals, street lighting circuits, drainage and flood control facilities, water mains and waste water pipes. In some locations, major oil and gas pipelines, national defense communication lines and mass transit rail/road tunnels, all compete for place underground (Sterling 2000). The U.S. has more than 14 million miles of buried pipelines and utilities, many of which are in congested urban environments where several lines share the underground space. Hits to utility lines cause interruption to daily life and commerce, and physical danger to workers, bystanders and nearby buildings. These costs are borne by the Contractor, Locating Company, Utility

Providers, Insurance Companies, Affected Public and Business Owners. Thus it is a cost borne by all parties, including tax payers and society at large either directly or indirectly.

The period from 2004 to 2007 saw a total of 52 fatalities, 132 injuries and over 600 million dollars loss in damage to property. Additionally, of all incidents related to buried utilities, excavation related accidents accounted for nearly one-third (PHMSA 2009). Thus it is apparent that increased attention needs to be paid to utility locating technologies that aid in accurate and safe excavation. A Federal study on buried utility detection technology identified the following two goals: firstly, avoiding third-party damage to existing underground utilities that is caused by the presence of unknown or mislocated utilities; and secondly, developing utility location capabilities independent of size, depth and utility materials, that can detect even in presence of utility congestion. The overarching goal of our ongoing research project is to address this critical state of affairs and propose new integrated technological solutions to prevent excavator-utility hits, and thereby improve safety and accuracy in urban excavation projects.

2. Problem Description: Locating underground pipes and other infrastructure prior to excavation has long been a problem area due to complexity involved and the large number of variables over which accurate control is not possible. This section deals with the current state of affairs in terms of locating utility lines and limitations in them.

2.1 Current Locating Technologies: Geophysical technologies are those technologies that assist in investigating the earth's sub-surface. While tremendous development has taken place in the field of locating technologies over the past decade, no one method has emerged as being complete and without flaws. The following is a brief description of the most commonly used methods in locating underground utilities.

Ground Penetrating Radar (GPR): Ground Penetrating Radar (also known as Ground Probing Radar) is a technique that uses short duration, high frequency electromagnetic wave pulses. These pulses are transmitted from an antenna into the ground. Materials such as rocks, water, or pipes buried below the surface reflect the waves which are returned as an echo. While GPR is widely used with good results, when used with conductive soils (clays, saturated soils, etc.) and in congested environments (presence of rocks etc), it gives below par results. (Read and Vickridge 1997)

Electromagnetic Techniques: Electromagnetic methods detect the field generated by the buried network and not the buried pipe itself. Electromagnetic techniques can be Active or Passive. Active systems depend on current being applied to the pipe and detecting the field thus generated. While in passive systems, the location is based on receiving natural signals transmitted from the underground assets themselves as would be the case of an electric conduit that has current flowing through it naturally.

Electromagnetic methods are low cost, simple and quick but cannot locate non-metallic pipes except if tracer wires or Sondes are used (Read and Vickridge 1997).

Magnetometer Technique: This method works on the fact that the earth's magnetic field varies over a particular distance which is caused by underground features such as metallic pipes, large voids and ore bodies. The setup uses two coils to evaluate the difference in intensity and/or direction of the vertical component of magnetic flux which maybe caused by a ferromagnetic object. The advantage of this method is that it is relatively cheap. However, presence of buildings, cables, fences, etc affect the output considerably and thus this method cannot be relied upon entirely (Read and Vickridge 1997).

Resistivity Methods: The setup for this method uses 4 electrode probes placed in a line in the ground and a current passed through the outer pair. The inner pair measures the potential drop between them, giving an estimate of ground resistivity. However this method is quite slow. The electrodes need to be coupled very well with the ground making surveying beneath roads for buried assets difficult (Read and Vickridge 1997).

Acoustic Detection Systems: Although acoustic detection methods are primarily used for locating leaks in water mains, they can also be employed for detecting and mapping water distribution pipe networks. However the system requires easy access to the pipelines like a hydrant or a water meter. Passing traffic can also lead to sources of errors. Thus it is limited to small and shallow networks. No depth value can be obtained as well. (Read and Vickridge 1997)

Infrared Thermography: This method is based on measuring very slight variations in temperature, and producing a thermographic image, where objects are represented by their thermal rather than their optical values. An infra-red scanner head and detector are used to capture the thermal data. The equipment is relatively expensive. Ground moisture content drastically affects the readings and depth values cannot be measured. Thus it needs a supplementary system to measure depth values (Read and Vickridge 1997)

Subsurface Utility Tracing: In this method a signal is induced in a subsurface utility and the signal's position is tracked as it moves along the utility. It is also referred to as Direct Induced Signal Emission as the electric field formed as a result of the signal passed is used to detect the buried pipe.

Vacuum Extraction: Another method often used is Vacuum Extraction (Vacuum Excavation) or Potholing. This method offers the option of safely and economically excavating in areas inaccessible to conventional digging equipment. The air excavation method however cannot be used on hard surfaces like pavements and has a higher initial cost. The water vacuum excavation systems can cut pipes or electrical conduits due to the force of the water (Read and Vickridge 1997).

Each of the described techniques is effective in certain scenarios and less effective in others. However given the wide range of variables that one has to deal with in underground utility location, no single technology emerges as being comprehensive in locating underground utilities of all types in a range of soil conditions. Thus it is generally accepted in the industry that a multi-sensory approach that would utilize a combination of such technologies is likely to give more accurate results.

2.2 One-Call Utility Notification Organizations: A study of various One-Call Utility pre-marking systems/organizations reveal that most states within USA require by law for excavators to have the utilities pre-marked by the identification service before actual excavation is carried out. Michigan's statute, Act 53 of Public Act 1974, requires anyone who engages in or is responsible for the planning or performance of any type of excavation e.g.; grading, demolition, cultivating, auguring, blasting, or boring to provide advance notice of at least three full working days to MISS DIG (MISS DIG Systems Inc. 2009). In the state of Michigan, MISS DIG SYSTEMS is the One-Call Utility Notification Organization. The MISS DIG system and other similar One-Call systems have reduced utility line hits to a great extent. However such systems still have 2 limitations in their current form (DTE Energy 2009, Personal Communication). The first being that location of a buried utility is marked approximately on the surface within a 3 feet wide band rather than its exact location, and once the excavator has removed the top soil/surface, the operator once again depends more on judgment than on visible information. Secondly, MISS DIG system does not provide any information regarding depth of a buried utility (MISS DIG Systems Inc 2009). Furthermore, as noted above, the markings are made as a strip of potential area which is 18 inches wide on either side of the utility line's expected location. This equates to a zone that is 3 feet wide. Thus it is not as exact as an excavator operator would like and current One-Call systems would need additional improvements to make them more useful for excavators.

2.3 As Built versus Actual: The single largest cause for utility line hits is the discrepancy between as-built drawings and actual location of utility lines and incomplete as-built drawings (Hammond and Weintraut 2001). This issue leads to negating the positive effect of the MISS DIG System. Most utility owners including our collaborator DTE Energy concede that often times the as-built drawings show a completely different picture from what actually exists beneath (DTE Energy 2009, Personal Communication). Part of the problem lies in the method of laying utility lines. In extremely crowded urban environments, contractors are left with no choice but to shift utility alignments by a few inches to a few feet to account for existing utility lines occupying the same space. As-Built drawings thus do not actually represent the reality of what lies beneath (Hill 2006). Since existing As-Built data solely does not accurately serve the purpose of underground utility locations, an alternate method of location, based on a combination of recorded as-built data, and active real-time sensing is proposed in the following section.

3. Importance of the Research: The importance of research in the area of underground utility location can be exemplified by incidents of stray hits to utility

lines that look innocuous at first but have consequences that are dire. An example of such a hit was a case in January 1995 when a construction crew driving piles for a new garage accidently crushed a high voltage underground electric cable serving Newark International Airport's three passenger terminals. As a result, hundreds of flights were cancelled and thousands of passengers were left stranded (Minneapolis Star Tribune 1995). Also with utility companies spending millions of dollars every year on locating their buried assets and accident recovery (Sterling 2000), it is clear that the area is in need of urgent attention.

3.1 Federal Interest in Utility Locating Technologies: A Federal Study on Utility Locating Technologies suggested that that multi-sensor technology (GPR, Acoustic plus Electromagnetic) and multi-frequency approaches offer the greatest potential for stand-alone utility location in the future (Sterling 2000). The use of this multi-sensor technology together with a 3D model view of the buried infrastructure is one of the responses to the Statement of Need. The view would be of such quality so as to allow identification of material of pipe and other essential details. Section 15 of the Pipeline Safety Improvement Act of 2002 discusses the National Pipeline Mapping System which requires operators of pipeline facilities to provide to the Secretary of Transportation geospatial data appropriate for use in the National Mapping System, the name and address of the person with primary operational control, and a means for a member of the public to contact the operator for additional information about the facilities. There is a requirement to update the information as necessary. Such information can then be used by a system to create 3D models of the buried pipes and be projected onto the real world view. Thus there is all-round effort, guided by a federal agenda, to convert buried utility data into a format that is interoperable, accessible, and always current.

3.2 Introduction to the Proposed Collision Avoidance Framework: It is evident that all the existing techniques in the field of underground utility detection have limitations. A consequence of these limitations is the hits to underground utility lines that lead to large values of loss to surrounding facilities, residents and other utilities in the network. Thus an approach that combines these existing technologies by building upon their capabilities offers the most promise to help mitigate the extent of the accidental damage caused.

In particular, a technology that gives the excavator the location of the pipes at all times (i.e. even after the top surface has been excavated away) as well as the depth and other attribute information of the pipes can help alleviate most of the problems not addressed by using current technologies. To achieve this, our proposed approach involves the creation of 3D models of the buried pipes from existing databases owned by utility companies and superimposing these models over the normal real-world view (captured in Real Time) of an excavator or backhoe operator using Augmented Reality (AR). This can be better understood by referring to the Figure 1 below.

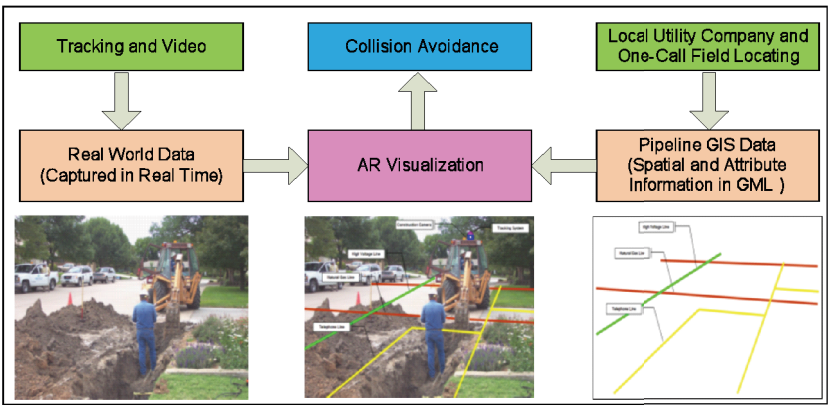

Figure 1: Data Flow for Collision Avoidance System Using Augmented Reality

The advantage of such a technology over using spray paint, stakes or flags to mark the approximate location of the utility is that unlike the existing methods, the location indicators remain in the operator's view even after the top layer has been excavated away. Furthermore, the superimposed 3D pipe models can be color coded allowing the operator to easily identify the pipe(s) the crew is interested in. As can be seen in Figure 1 above, other attribute information such as depth, material of pipes, etc. can be annotated over the pipes thus giving the excavator additional information. The following section describes our Technical Approach in detail.

4. Technical Approach: The excavator-utility collision avoidance framework being developed by our group is based on the use of Augmented Reality (AR) visualization technology. Data on the underground pipes is obtained from the databases of utility companies. The data from these databases can be transported and encoded in an XML based format called Geography Markup Language (GML). A combination of GML and wireless fidelity make such an operation of transporting data over the internet extremely feasible today unlike a few years ago. Such a view of 3D pipe models on the real world view of a user has been attempted in the past (e.g., Mendez et al. 2008). Utility information has also been visualized as vector based graphics in AR before (e.g., Roberts et al. 2002). In each of these cases, the goal of the study has been to demonstrate the feasibility of AR technology to visualize GIS information. This research builds upon the success of these prior studies and incorporates AR visualization as a key component into a multi-sensory excavator-utility collision avoidance framework.

Figure 2 graphically depicts the major components of the developed framework. The major components of the framework are: 1) Accessibility and conversion of accurate as-built graphical information on buried utilities; 2) Visualization of annotated graphical information in excavator operator's view in georeferenced AR; 3) Real-time tracking of excavator's kinematic articulation and position of digging implement; 4) Proximity querying and interference detection between digging implement's current location and buried utilities; and 5) Rapid reality capture of buried utilities using

geophysical technologies to supplement accuracy achieved by geometric interference analysis.

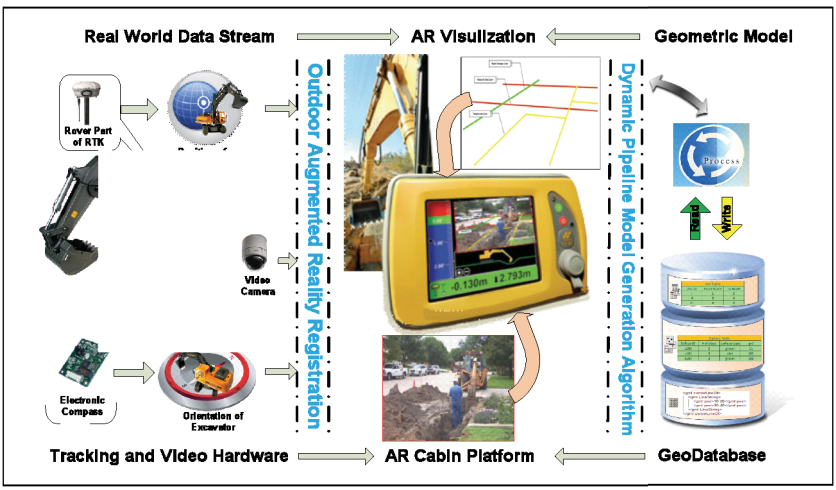

Figure 2: The architecture of visual excavator-utility collision avoidance framework

4.1 Underground Utility Data Classification: The research team has first begun addressing challenges in the utility data accessibility and conversion component of the proposed framework. We have classified the data into 4 cases such that every owner of utilities whether public or private would fit into one of these 4 cases. A flowchart of this classification is shown in Figure 3.

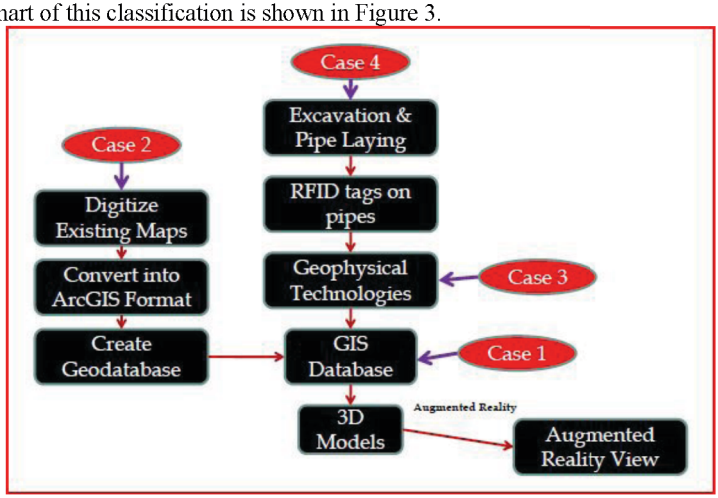

Figure 3: Buried infrastructure data classification cases 1- 4.

Case 1 is the best case scenario where utility owners have all their assets stored in a GIS database. Case 2 refers to those owners who have the asset information stored in the form of maps and drawings either in paper or digital form but not in the form of an intelligent database. These maps then need to be converted into GIS format from which a database can be built. When utility owners already have pipes buried underground but are unsure about their exact location, it is classified as Case 3 in our classification. This case will require the use of Geophysical Technologies to get the exact location of the underground utilities. After the location is obtained, a database would be constructed using the geophysical test results. These steps would then bring the data up to the level of Case 1. Case 4 refers to the case when new pipes need to be laid and thus along with documenting the location of pipelines, the use of new technologies such as Radio Frequency Identification (RFID) tags and Sensors mounted on pipes is also envisaged. Thus Case 4 is the all encompassing case. The eventual goal for any case is to produce 3D models of the underground pipes and project them in AR (framework component 2).

As a test case, our group worked on a sample dataset provided to us by the University of Michigan Architecture, Engineering & Construction (AEC) division. The data provided to us was in the form of a digital AutoCAD drawing (.dwg file). Thus it was a Case 2 classification. We performed a series of operations to convert this AutoCAD drawing into a GIS shapefile. Our group used ArcGIS 9.3 for this initial test case. The ESRI Shapefile or simply a Shapefile is a popular geospatial vector data format for geographic information systems software. It is developed and regulated by ESRI as a (mostly) open specification for data interoperability among ESRI and other software products. We created 3D models of the pipes in Google SketchUp. Even though this algorithm involved several manual steps, our overall goal is to create 3D models for AR visualization in real-time. Figure 4 below shows the conversion of data from the initial AutoCAD drawing to a Google SketchUp 3D model. The middle drawing has selected utility lines highlighted in red as a feature of being converted into GIS shapefile unlike an AutoCAD drawing.

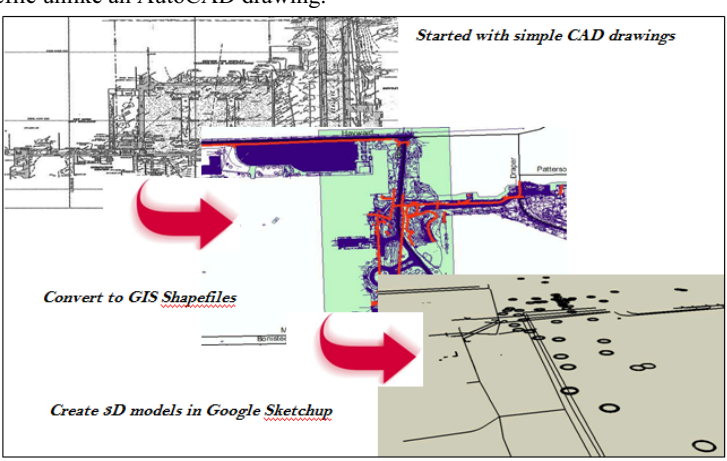

Figure 4: Conversion of data from one format to the other.

4.2 Augmented Reality (AR): As Figure 1 shows, to implement the AR view of pipelines on the excavation site, two data resources are needed: the pipeline GIS data and the real world data. The two data resources are retrieved independently and integrated by AR software in real time to render the augmented view. Many local utility companies establish Geodatabases (GIS Databases) for their underground assets. The GIS data is transported via GML. In the GML schema, geographical coordinates, geometric characteristics and other attribute information of the pipelines are represented. At the same time, the real world data contains the real time tracking data and video stream of the real excavation scene. The tracking data supplies the AR system with position and orientation of backhoe, which is used for establishing the camera reference coordinate system with the origin at the video camera. The CAD models of pipelines, which are originally represented under the geographical coordinate system, can thus be aligned with the new camera reference system, calibrated and superimposed on the video sequence representing the real world.

4.3 Working of the System: The framework is based on the data flow chart in Figure 2, . Mounted on the rear of the backhoe is the rover component of a RTK (Real Time Kinematic) GPS system, which transmits the geographical coordinate at the frequency of 1Hz. Considering the chassis of backhoe is stationary at a short time slot during operation, The frequency of 1Hz is enough for updating the position of backhoe. Also the electronic compass is attached to the front of the backhoe close to the boom, and transmits the orientation of boom in the form of yaw, pitch and roll with the maximum sampling speed of 30 times per second. Since the boom of backhoe swinging continuously during excavation, high frequency of orientation sampling is necessary for updating the gaze direction of video camera so as to maintain the correctness of the viewing frustum (Khoury and Kamat 2009). Video stream captured by video camera is put at the background of the augmented view. Eventually, the mixed view of pipelines and real excavation site can be displayed to the excavator operator through a cabin monitor. A prototype simulation of such a system was created in the virtual environment of Google Earth. This prototype simulation is shown in Figure 5 below. Figure 5.a shows the third-person view of the excavation site. Figure 5.b is the augmented view which is displayed on the cabin monitor. Straight colored lines indicate the location of underground utilities, the strip buffer warns the excavator of the uncertainty in the location displayed. The pop-up annotations let the excavator be aware of the attribute information of the buried pipelines.

5. Conclusions and Future Research: The framework described in this paper, by building upon the existing technologies has the potential to transform underground utility locating methods. The simulation in the virtual world of Google Earth shows that having the utility lines pre-marked using AR would be an extremely useful aid to excavators. As mentioned above, the registration process of superimposing pipeline models on the real scene can be divided into two steps: First using the location and orientation of the backhoe to set up the camera reference system; second aligning the pipeline's geographic coordinate with the camera reference system. Therefore obtaining the accurate location of the excavator and the pipelines are the deciding elements for the registration accuracy.

The American Society of Civil Engineers (ASCE) estimates that a total of nearly $2.2 trillion is needed to overhaul the entire United States infrastructure over the next several years. Water and waste water pipelines were given a grade D- in the 2009 ASCE report (ASCE 2009). Laying new pipelines and replacing decades old sewer lines would all be required as part of the expected rehabilitation work. The presented research is thus very timely and critical, as the proposed framework would allow excavating teams to observe buried utilities while on the surface, and could help reduce time and cost over-runs while significantly improving safety. As noted earlier, viewing 3D models of pipes in AR is an initial step of our research. Our eventual goals are to develop an integrated collision avoidance system and a comprehensive utility maintenance system. Ongoing research is addressing technical challenges defined by this overall technical agenda.

6. Acknowledgments: The presented work is partially supported by the National Science Foundation (NSF) through grants CMMI-0448762 and CMMI-0825818. The authors gratefully acknowledge NSF's support. The authors thank Mr. Ronnie May, Mr. William Terrasi, Mr. James DeKimpe, Mr. John Squires, and Mr. Steven Facine from DTE Energy for their enthusiastic ongoing collaboration in this project. The authors are also grateful to Mr. Dharmesh Joshi from UM AEC for providing datasets used in the initial experiments of this research. Any opinions, findings, conclusions, and recommendations expressed in this paper are those of the authors and do not necessarily reflect the views of the NSF or the individuals mentioned here.

ABSTRACT
Information has the best value when it is delivered to the correct place at the correct time in the required format. Many scholars have noted information and communication chaos in the construction industry. The "*i - Booth*©" is a real time information management system, which functions as the hub of the real time information integration system, is a novel technology developed at the University of Calgary in 2006. The concept was tested in commercial building construction settings with positive improvements in terms of tool time, productivity, and worker satisfaction. The content of this paper includes the conceptual framework, Graphical User Interface (GUI) development, and system building & verification process of the "*i - Booth*©*."* The challenges under worker, management, technological, automation, and external issues during the development of the interface of the "i-Booth" are also explained in the paper. The multi-point capability of the system is expected to enhance the integration of the design office, the construction office, and the site staff as well as improve tool time, construction productivity, worker satisfaction, and communication.

Introduction

The present status of the technology usage in the construction industry and current communication practices were recently investigated in Alberta, Canada to develop innovative solutions to improve communication and productivity (Hewage and

Ruwanpura, 2009). One of the main findings in this investigation was the justification of "inadequate communication" between the various parties involved in construction projects. Almost all workers blamed the managers for the insufficient "information flow" from the site/main office to the operational (site) levels (Hewage and Ruwanpura, 2006a). Wachira (2001) too mentioned that 50% of construction workers usually complain about inadequacy in communication. Bowden et al. (2006) and Mohamed and Stewart (2003) found that only 20% of the information passed down to the operational (worker) level in a construction site. This also confirms FIATECH (2008)'s remarks on the field-level automation and the wireless and display technologies by comparing lack of use in the construction industry compared to manufacturing and transportation industries in terms.

Further, Hewage and Ruwanpura (2006b) found that the "inadequate communication" between the stakeholders in construction projects; especially at the site level leads to productivity losses and inefficiencies. This was validated by interviewing 101 workers from four construction sites of four general contractors. Hewage and Ruwanpura (2006a) also proposed and pilot tested a novel concept called "Information Booth" to address communication issues in the construction site environment. "Information Booth" is an automated information outpost designed to aid lead workers and foremen during the daily tool box meeting and site operations. The key information elements stored in the 'Information Booth" were daily and weekly targets, technical specifications, 2D or 3D drawings, 3D construction details, and safety information (Hewage and Ruwanpura, 2009).

Communication involves the flow of material, information, perceptions, and understanding through a variety of sources. To be able to contribute to the success of a project, a worker must be told exactly what tasks are expected of him (Dozzi and Abourizk, 1993). Clear explanations of tasks and expectations are required to achieve optimum productivity levels. Employees must also know where their instructions come from: there must be a visible communication chain on the job. It is likely that the instructions from an unknown source will be disregarded by most of the people. Moreover, to be totally successful, the communications should flow both ways. The "bottom-up" management system practiced in Japan improved productivity substantially; the system works because it nurtures the idea of communicating ideas both upward and downward (Dozzi and AbouRizk, 1993).

The main purpose of this paper is to discuss the real-time information integration using the latest version of the Information Booth called "*i-Booth*" to improve communication between various entities in a project. The challenges faced during the development of the interface of the "*i-Booth*" are also explained in the paper.

Present Status of Information Integration in Commercial Construction

The construction industry has an increased recognition of the need to implement innovative information and communication technologies and its potential benefits on projects (Weippert et al. 2003). Magdic et al. (2002) concluded that some important experience has already been gained and the main building blocks for mobile computing in the construction industry are already available in the market. Their final test showed that the efficiency of information interchanged with and at a building site can be improved significantly even by using current mobile computing components

unmodified (PDA's, mobile phones and web services). Despite the barriers to implement IT at site level, Daito Trust Construction Company, a Japanese construction firm, developed a large-scale mobile computing system called the DK Network. The company reports that the system made the process of construction easier and greatly increased productivity (Daito, 2003).

As projects become more complex, the amount and detail of the information required increases. This increase in turn makes the process of storing, retrieving and analyzing the control information more complicated. One commonly cited means to overcome labor shortages and improving productivity, cost effectiveness, and competitiveness is through the use of advanced technologies (Tatum, 1986, Johnson and Tatum, 1993).

It has been reported that the tool time of the construction projects is approximately 45 to 60 % with a mode of approximately 50% (Ruwanpura et al. 2006, Hewage and Ruwanpura, 2006a, Hewage and Ruwanpura 2009). The inefficiency in materials management, equipment management and communication issues lead to non-tool time (Hewage and Ruwanpura, 2006a). The researchers have found that the morning tool box meeting in which foremen communicate the day's planned activities to workers lacks effectiveness and enthusiasm. It was also noted that supervisors do not deliver the information in a format that is easily understood by the workers. As a solution, the researchers have come up with a novel communication tool that may serve many purposes. A computerized information kiosk equipped with important jobsite information called the "Information Booth". The "Information Booth" was successfully tested in an active hospital construction project in Calgary by using it in the toolbox meeting on a daily basis. The focus was to improve communication between the foreman and workers. Foreman used the "Information Booth" to explain the work targets, expectations and work assignments while showing other additional information such as the technical information and safety to improve communication. Hewage and Ruwanpura (2009) explained in detail the use of the "Information Booth" in the hospital project, which increased the tool time by 10% and productivity by 17%.The "Information Booth" was further developed as the "*i-Booth*©" (Figure 1) with several additional functions. The additional functions include Short Message Service (SMS) alerts for communicating new uploads (drawings, approved change orders) to the system by linking remotely accessed camera system for "Virtual Supervision" (Silva et. al., 2009) and integrating handheld electronics for information transfer between site and office. These updates were included in the *i-Booth* based on the input received from workers and the managers of the construction sites documented in Hewage et al (2009).

Real-Time Information Integration System using *i- Booth*©

Construction companies use several internal systems for information management between the head and site offices; however, the systems used for on-site information management are relatively fragile (Hewage and Ruwanpura 2006a). Integration of existing company systems with the proposed system is a critical factor for success. The link between these systems must be integrated and automated so that the current data from the company system can be retrieved from the "*i-Booth*©". At the same time, the company system can access the data from the site level in real time. Construction companies utilize various web portals for document management.

Figure 1. "*i-Booth*©" and Graphical User Interface (GUI)

These systems fall in to two categories i.e.; in house systems and commercial systems such as "e-Builder" (trademark of e-Builder Corporation). The main challenge researchers encountered during development stage is to find a uniform data structure to facilitate the integration process. FIATECH (2008) has developed an ISO standard (ISO 15926) for process plant information exchange, though such a standard has not been developed for commercial construction until now.

Research team designed a link between the "*i-Booth*©" and in-house document management system to facilitate integration process. This linkage prevents information double handling and increase user acceptance of the proposed system. The primary reason behind the selection of in-house document management system was the accessibility to the information (software architecture).

Research team has identified three main data types i.e.: primary data, secondary data and supporting data for "*i-Booth*©". The main focus of the primary information category is drawings and its related documents such as specifications and change orders. The design and engineering staff at the engineers' office has the ability to edit the contents of the drawings whereas the site staff can only read/view the drawings. Site staff (end users) with editing privileges could add additional details for each category such as description, index, and version. Timely delivery and notification of approved change orders is a critical to ensure smooth operations in construction sites. When a change order is issued from the system (through architect's office or engineer's office) the end-users (construction manager, superintendent) in site level will be notified with a SMS message.

The secondary information of the "*i-Booth*©" system consists of technical information, safety, 3D-views, schedule and productivity toolbox. Information/data loaded in this section consists of technical documents, training/safety videos, site manuals, Material Safety Data (MSD) sheets, 3D or isometric drawings and training handouts. The schedule section includes the master schedule, look-ahead schedule (2 or 3 week), marked working drawings and handheld synchronization. Site supervision and management personnel have the ability to upload working or marked drawings to working drawings sub sections. Schedule sub-section contains the construction master schedule, look-ahead schedule, and work assignments. Project

manager/construction managers have the ability to export MS-Project and Primavera schedule directly to the system to share with site personnel (supervision staff and lead workers).

The supporting information provides valuable inputs to better plan and manage construction projects. Supporting data section consists of "Virtual Supervision" and weather information. Remotely accessible wireless cameras enhanced the potential of site supervisory capabilities; emerge the term "Virtual Supervision" (Silva et. al., 2009). "Virtual Supervision" is added to the "*i-Booth©*" system to enhance the supervision quality of building construction. Weather information will be useful for the workers in the workface to prepare for weather variations throughout the day as the researchers found that the workers spent significant amount of time moving between the site trailers and the workface (Hewage and Ruwanpura, 2006b, Hewage and Ruwanpura 2009). The weather variations can also be used to proactively plan the work of the day if the prediction shows negative impacts to the projected plan of the day.

Figure 2 illustrates the fundamental relationship between main data types and construction process. Arrow styles represent the importance of the data (solid; high priority, dash; medium priority and dots; low priority) and arrow heads mark the information flow. The network diagrams in the right side of figure 2 represent the conceptual information flow in the proposed system. System data management processes make use of hybrid (server and local terminal) solution. Primary data will be handled by a server solution. Primary data will be stored in Network Attached Storage (NAS) or Storage Area Network (SAN). Servers and the network were designed with redundancy to improve data reliability. Server loads will be managed by a special system administration team (initially University of Calgary IT administration will provide assistance) to maintain the speed and accessibility of the system. Secondary data in the system will be managed similarly. However large capacity files associated with safety and 3D-views is an exception and majority of these files are static. These files will be manually uploaded to the system in the job site. This synchronisation process will be carryout though high speed USB port of the local "*i-Booth©"* terminal. Supporting data management is relatively simple since two external websites were embedded to the proposed system.

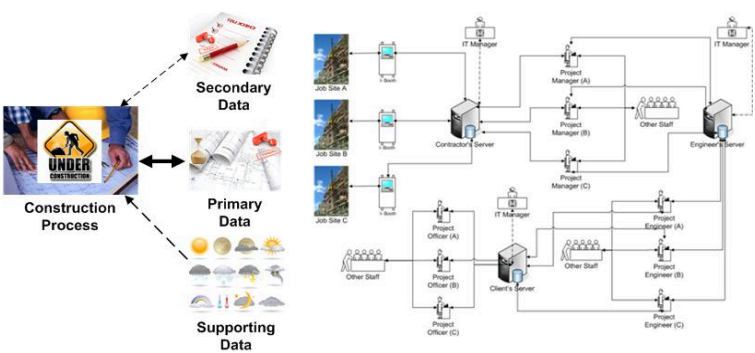

Figure 2. Relationship between the Data Types and Construction Process

System Design and User Behavior

Graphical User Interface (GUI) and Human Interface Device (HID) selection was an important issue encountered by the research team during system design stage. The main screen of the system was designed to enable touch screen functions. As work force in Alberta commercial construction include significant number of foreign workers with limited English literacy, icons were selected to enhance the identification without much difficulty. The data structure and browsing mechanisms were kept uniform and simple to improve usability. Construction personnel's' behavior modification (manage the resistance to change) and adult education were important factors considered when deciding on GUI and HID's.

HID's were selected carefully based on the results from Hewage and Ruwanpura (2008). Initially, the research team identified mechanisms such as trackballs, joysticks, pointing devices, keyboards, and touch screen for interaction between the system and site personals. After many interviews and discussions with construction professionals, touch screen was selected as the main interactive media. Construction workers were more comfortable with touch screen rather than keyboard and pointing device (Hewage and Ruwanpura, 2008). Screen selection was based on factors such as screen size, anti-reflective (sunlight readability without back light enhancement) (Vartech, 2009), resistance to dust, resistance to construction chemicals and weather resistance. 32" and 42" LCD screens were selected for the system based on opinion from construction professionals.

When the system is idling, screensaver function is utilized to convey safety tips and proper work practices to educate the operational level (workers). Research team is developing safety and work practice screen savers with the aid of industrial research partners. Screen savers will be changed every two weeks based on the work activities carried out in job site (research team and site staff will decide the suitable screen savers). Every 10min screen saver will change based on identified main activities (in two weeks time frame discuss above).

Expected Problems and Intended Solutions

Problems may be encountered in the early stages of implementation of the real time information integration process in construction projects. The researcher team expects problems in five major categories: worker, management, technological, automation and external issues. The researchers carried out a brainstorming session with the construction professionals and project team to mitigate the impact of the following issues.

Worker Issues: Worker issues have been identified as the most influential area. Human issues will be the most influential factor in the success of the integration system. The majority of human issues are expected to be with the "*i - Booth*©" and integration system. Issues related to the "*i - Booth*©" will be coping with the technology, any changes in workload, and the associated benefits. The problems related to the "*i - Booth*©" are being tackled by the researchers from its inception because of the knowledge gain during the actual test of the Information Booth (Hewage and Ruwanpura 2009). The "*i - Booth*©" is designed in such a way that anybody with a general understanding of a computer or an automated teller machine

(ATM) will be able to operate this device. Site management may raise concerns about the using system as a toy by the workforce in the workface. Research team has introduced user authentication protocol to prevent this. In the workface foremen and lead workers will have the full access information (according to the trade) such as drawings, change orders, etc. The workers do not have direct access to the "*i-Booth*" without the assistance of the foreman or the assigned lead workers (in the absence of the foreman).

Management Issues: In general, the construction sector offers stiff resistance to IT solutions (Mak, 2001). The majority of these problems are initiated by management. Researchers may encounter strong resistance from management with the proposal to change internal systems with IT for better efficiency. The success of the integration system will depend on management comfort and trust to the system. Researchers will carry out awareness sessions with management to convince and educate them on IT tools, which are available to assist, and not intended to replace the human brain. The other main challenge will be to convince construction industry to use e-format instead of paper version. Both electronic version and paper format will be used during the early stages of the implementation to measure the effectiveness of both versions. The construction sector is slow moving towards to e-format from paper version but there are positive signs of emerging such as e-bidding (Coolnet, 2009).

Technological Issues: Researchers encountered a few technological difficulties in the inspection of the project to provide connectivity and power for the "*i-Booth*©". In site level getting a hardwire connection to workface will lead to many other problems (such as wiring and disturbance). Therefore connectivity issue was settled by cellular modem and portable internet connection. In site level getting a hardwire connection to workface will lead to many other problems (such as wiring and disturbance).

Automation Issues: Automation issues will arise during the early stages of the implementation of the integration system. An internal IT department (of construction companies) should be able to handle these issues. If not, the research team and the IT division of the University of Calgary will have to resolve the issues with the internal IT department of the contractor (research partners). The main issue will be managing the loads in the file servers. Finding a uniform data structure to integrate in-house/commercial document manage system with proposed system (this aspect was explain in detail in real time information integration section) is another concern. Solution to this concern is explained in details in the real time information integration section.

External Issues: Weather conditions in Alberta can be critical during both late Fall and winter seasons. The system is designed to withstand up to -40C temperature. In case of unidentified problems, the researchers have been advised to follow a four step procedure to resolve the problems (Silva et al. 2008). The four step procedure is (figure 3.):

- The worker or identifier of the problem should immediately inform their supervisor.

- The supervisor should inform the issue to the information manager (IT Manager), which a new position suggested by the Information Booth, or his assistant on the construction project.
- The information manager will discuss the issue and its resolution with the researchers/developers.
- Changes will be made, and a pilot test will be conducted by the researchers/developers in the actual site environment.

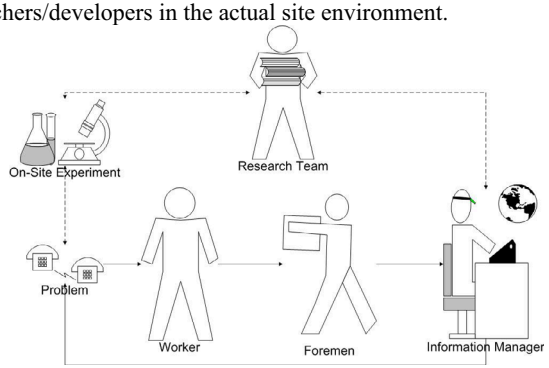

Figure 3. Resolution Mechanism of Unidentified Problems at the Front-end

Conclusion

"*i-Booth*©" system is a novel concept currently being implemented in Alberta, Canada. The main contribution expected from this system is to enhance efficiency and effectiveness of the work force in the site environment through improved communication between site management and workers. The authors strongly believe that the worker and supervisory staff satisfaction will be increased due to the real time information integration and improved communication, as in the case of the actual test of the first version of the Information Booth documented in Hewage and Ruwanpura (2009). It is noted that the sustainability of the system depends on the worker and supervisory staff satisfaction, increase in efficiency and communication, and the significant savings to project schedule and cost.

Accuracy of construction planning and estimation may improve considerably due to the real-time connectivity between construction site and head office (Silva et al. 2008). On site implementation of "*i-Booth*©" may revolutionize 3D and 4D CAD application such as BIM in field level because of the simplicity in implementation and utilization. These 3D visualizations will aid foreign/local workforce in Alberta to better understand the work to be performed. "i-Booth©" system is easily applicable to Oil and Gas industry to disseminate information at workface. Tool such as SMART Plant 2010 can be effortlessly integrated with the propose system to enhance the productivity and effectiveness of the workforce. Authors strongly believe "i-Booth©" may persuade positive outcomes in construction industry such as improvement in direct tool time, productivity, improvement in worker satisfaction and better information integration and information management. The comments made by the industry professionals after seeing the features of the i-Booth and the results of the first version of the Information Booth have increased the opportunity to test it in few

construction projects from the end of 2009 until mid of 2010. According to Constructor 2010 Magazine "i-Booth©" will revolutionize the construction industry in Alberta (Contractor, 2010). It is noted as a limitation that the proposed frame work will focus the issues and necessities of the participated research companies in building construction in Alberta, Canada.

Acknowledgement
The researchers wish to acknowledge the support and funding for this research project by Ellis Don, Graham, PCL, and Ledcor companies, Construction Research Institute of Canada, Canadian Construction Research Board, Calgary Construction Association, and the Natural Sciences Engineering Research Council (NSERC) for their Collaborative Research and Development (CRD) Grant # CRDPJ 299392 – 03. The researchers also wish to thank the commitment given by Cana, PCL, Ellis Don, Graham, Ledcor, Stuart Olson, Revay & Associates, Canadian Construction Research Board, and Calgary Construction Association and NSERC for their commitment for the second phase of the research through the CRD Grant # CRDPJ 341047 – 06. Further, the research acknowledges the continued support of the same organizations and the new research partners of Lafarge Canada Inc. and the City of Edmonton Design, Construction and Drainage Services to develop the integrated framework outlined in the paper through the new grant # CRD 385591-09 (pending NSERC funding approval) for 2010 and 2011.

Abstract

Emerging wireless remote sensing technologies offer significant potential to improve the management of construction resources in lay down yards by tracking the location of personnel, yard vehicles, and materials in real-time. This paper presents a theoretical concept for real-time lay down yard asset management. A field trial using Ultra Wideband (UWB) positioning technology is presented to track spatial and temporal location of resources (workforce, equipment, material) that are present in lay down yards. The benefits and limitations of the technological approach which were applied in this research will be explained in detail and recommendations for its use in field tracking applications in large and open construction environments will be given. A particular focus of the paper is on the comparison of the accuracy of real-time location data from a commercial UWB system with ground truth measurements from a robotic total station.

Keywords: Automation, Data collection, Sensors, Tracking, Ultra Wideband.

1. Introduction

Compared to manufacturing and production, the dynamic environment in which construction activities take place presents a challenge in automating its work tasks. Nevertheless, sensing technologies and automated data collection techniques promise to have large benefits compared to the current materials management and control procedures in construction industry, which are mostly manual, labor intensive and

error prone (Navon and Berkovich 2006). They often are not applied in the field for various reasons, e.g. due to the high implementation cost and risk of failure during the initial implementation phase. Recent developments in the field of asset location and tracking may represent an opportunity for research in the construction industry. These include technologies designed to help workers and managers to locate equipment, hazard areas or tools anywhere on the construction premises. Among other advancements, wireless, non-destructive, and reflector-less construction technologies have been identified as key breakthroughs for both practitioners and researchers in the construction industry. Such envisioned technologies focus on reducing non-value-added activities while monitoring and tracking the position of a particular resource on site from a remote and safe location. A combination of the advantages of several technologies formulates a system that ultimately operates near real-time (1Hz or higher) and will expedite material delivery, track the location of workers, equipment and hazardous areas, and increase process, productivity, and facility quality.

Measuring the aggregate productivity is a difficult task in construction. A number of studies point towards a possible decline in onsite construction productivity (Eastman and Sacks 2008). By using technology during the construction and life cycle of the built environment, it is beneficial to track resources to improve the efficiency and effectiveness of the supply chain in construction. Moreover, as the construction industry has been moving towards prefabrication and preassembly in recent times, the industry and society as a whole can benefit by studying the improvements made in manufacturing and other industries and by tracking, locating, finding, and distributing the right material to the right location at the right time (Haas et al. 2000). Supply chain management involves all the activities associated with the transportation of goods from the raw material to the end user. In a construction industry supply chain, lay down yards play an important role to facilitate both quick information and material flow (Barriga et al. 2005), thereby transforming the control from a “push” system to a “pull” system.

This paper focuses on material handling in construction lay down yards, which forms an integral part in this “pull” system and on technology that has the potential to speed up processes, saving cost and time. In addition, this paper explains the concept of using technology to pro-actively monitor workers and operators in real-time which could be used in the near future to reduce incidents rates and idle times in lay down yards. Potential applications are elsewhere on a construction site.

2. Current State of Knowledge

There is immense interest and potential in systems that provide users the location of project critical resources (workforce, equipment, material), which is also called “context awareness” in robotics and telecommunications. Localization is the technique that is used to achieve such measurements and is mostly solved by proximity, angle, or distance to a reference location (time of flight or signal strength of transmitted and received signals). Knowing the location of construction resources (workers, equipment and material) and identifying and measuring the status of work tasks helps to improve the project performance. Sensors and sensing technology can be used in construction and infrastructure projects (Akinci and Anumba 2008) to achieve automated tracking ability. Selection of a particular technology for tracking

depends on the principle of localization techniques such as line-of-sight (LOS), required signal strength and calibration required for implementing the technology. The prevailing legal framework regarding the permitted bandwidth and associated availability and implementation costs also adds constraints in the selection of technology (Khoury and Kamat 2009). Radio Frequency Identification (RFID) technology has found uses in identification and localization in various industries including the retail and medical industry. In the construction industry, RFID was successfully used to automate the task of tracking the delivery and receipt of fabricated pipe spools in industrial projects (Song et al. 2006a). Results showed that RFID technology can function effectively in a construction environment involving large metal objects, but at the same time issues regarding the optimum speeds at which the reader can be moved (<2 mph) so that tags can be read with 100% accuracy remain a concern. Global Positioning Systems (GPS) are capable of providing position information but the high cost of equipment makes it unfeasible for tracking every piece of material in a construction lay down yard. Combining RFID with GPS technology, where mobile RFID readers are equipped with GPS (Song et al. 2006b) reduce the implementation cost, but concerns with read range and the number of passes required to identify the location are still present (Grau and Caldas 2009). Other approaches focus on RFID in combination with ultrasound signals in a wireless sensor network (Skibniewski and Jang 2009). However, low power ultrasound devices with a measuring range of up to 100 m and multi-path effects limit the application of this methodology to smaller work areas. Existing technologies like RFID, RFID +GPS, RFID+ultrasound are found to have limitations in terms of reliability, scalability, and interoperability. Hence a low cost sensor system, which is robust in cluttered environment and provides real-time location information is desired.

3. Construction Resource Location Tracking Using Ultra Wideband Technology

Ultra-wideband (UWB) was initially developed for military use in the 1960's. FCC approval lead to UWB being explored for monitoring of construction site activities (Teizer et al. 2007b). Use of UWB for target imaging and identification was explained by Taylor in his studies of Ultra Wideband radar (Taylor 1991). UWB is a short pulse radio frequency (RF) waveform which is based on the time-domain principles of electromagnetic theory (Fontana et al. 2002). Compared to other technologies like RFID or ultrasound, UWB has shown to possess unique advantages like high temporal resolution along with a high bandwidth, which are ideal for precision localization applications. Higher range, measurement accuracy and immunity to interference from rain, fog or clutter makes it ideal for use in construction environments. Research has shown the feasibility of a commercial UWB system for precision asset location for tracking of high valued assets in hospitals and military facilities (Fontana et al. 2003). Unlike GPS, UWB provides a means for indoor positioning systems which are helpful in the case of emergencies (Ingram et al. 2004). UWB signals are considered to be immune to multipath interference, and hence have an edge over other technologies in a cluttered and dense communication environment. Testing is underway to use UWB localization in mining environments and several challenges like presence of physical obstacles,

communications constraints and other environmental factors have been identified (Chehri et al. 2009).

Personnel, equipment, and materials inside a lay down yard can be tagged with UWB tags to track the location of each of these resources in real-time. A typical UWB localization system comprises of (i) a central hub processor and computer interface with (ii) receivers that are capable of instantaneous ultra wideband field detection while being connected to the hub using CAT-5e shielded cables, and (iii) tags that are attached to the resources which are to be tracked. The location of each tag is calculated based on synchronizing the arrival signal using the time-of-flight principle. Signals between receiver and a tag can then generate real-time two-dimensional positioning data if at least three receivers are used. Real-time 3D location sensing requires at least four receivers, preferably at locations with significant difference in elevation. The accuracy of the distance measurements will depend on the geometric configuration of the reference point and the receivers on the field. Studies are being done to determine if a larger overlapping region is advantageous in terms of accuracy as compared to a smaller overlapping region or vice-versa. The materials and equipment operators are tagged and the operators are provided with a visual display of their own location and the location of the material to be picked up in a plan layout.

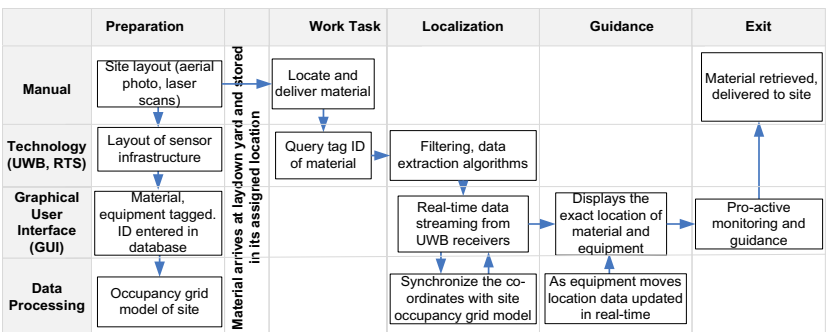

FIGURE 1 A methodology of lay down yard tracking using Ultra Wideband technology

4. Methodology for Real-time Location Tracking using Ultra Wideband

This paper explores the possibilities of UWB technology to locate the precise co-ordinates of resources and the application in a construction lay down yard for real-time tracking and proactive monitoring to guide equipment operators to the exact location with high accuracy. This paper extends the laboratory work already conducted at RAPIDS Lab at Georgia Tech for real-time three dimensional location sensing for workforce, equipment, and material positioning and tracking and provides a methodology for on-site implementation on the basis of field trials (see Figure 1).

The methodology involved tagging each material that arrives at the lay down yard gate and entering the data into an inventory management system database (see Figure 2). The key here is to match the piece mark of the material with the ID (identification) of the UWB tag. Pieces of equipment in operation and in motion in the yard are also tagged. Once an operator receives the instructions to pick-up and deliver a particular item(s), the corresponding tag ID can be looked up in the computer interface. A data

processing and graphical user interface (GUI) is developed that analyzes the RF signals inside the hub and displays the location of receivers and UWB tags in real-time. The data can be filtered to display only the locations of the equipment and the required items for pick-up in a plan layout. Additional data processing algorithms and visualization tools were developed to display the position data in a MATLAB environment and to predict the shortest path, using path-planning algorithms. This can be used for pro-actively guiding the equipment operators. More details about the GUI is given in next section.

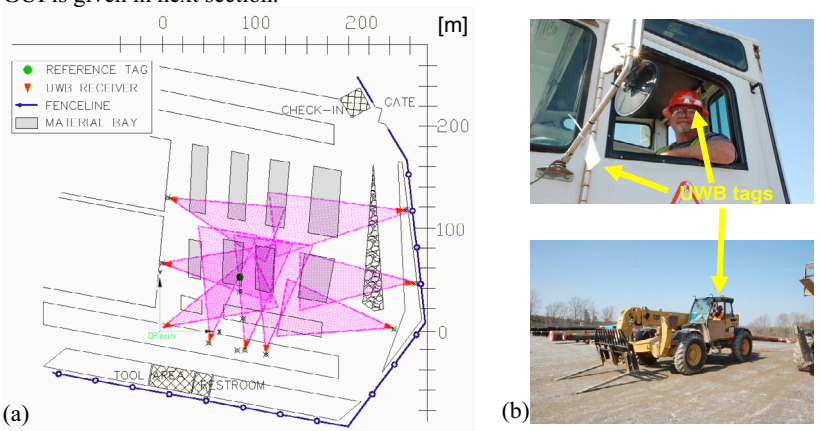

FIGURE 2 (a) Triangulation of UWB tags using receivers that overlap the area of coverage, and (b) UWB tags applied to construction resources inside the lay down yard.

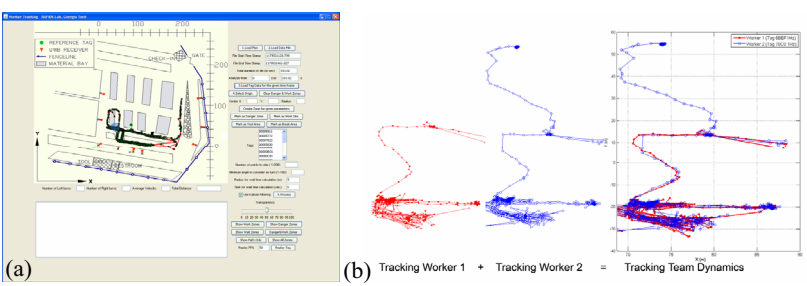

FIGURE 3 (a) Visualization of a resource trajectory inside the graphical user interface (GUI), and (b) paths of two workers on the same work task assignment.

5. Developing a Graphical User Interface (GUI) for Pro-active Guidance

A graphical user interface was developed which uses the CAD model or site layout plan to provide the information of current site conditions. Robotic Total Station (RTS), laser scan, or GIS information can be integrated to provide the spatial characteristics of the lay down yard. Sensing data is geospatially registered with these models to provide a rich data set as input for planning and execution of activities. These models can be fully utilized by including the schedule information for resource

monitoring and allocation and also measurement of work hour utilization of activities. Such a model is envisioned for the construction site and was experimentally tested in lay down yards.

A data fusion model based plan layout of the laydown yard and path planning algorithms like modified Dikjstra's algorithms were used for pro-active resource monitoring and equipment and worker guidance. A RTS was used to locate the maximum co-ordinates of the laydown yard. These are plotted onto a CAD drawing and divided into suitable sized grids, usually 1m x 1m. The occupancy grid model, which is used in robot navigation (Moravec and Elfes 1984), has been adapted for detection and tracking of construction resources (Teizer 2008; Teizer et al. 2007a). The principle of occupancy grid model is to represent a multidimensional tessellation of space into cells, where each cell stores a probabilistic estimate of its state (Elfes 1989). The methodology to embed 3-dimensional construction sites into a 2-dimensional surface and to decompose it into cells are explained in the literature (Lee and Adams 2004).

In this research, these cells have two sets of information for static and dynamic objects. The static objects such as the boundaries of the lay down yard, the approximate alignment of all the materials, the tool area and break and rest rooms are located by RTS, laser scans, camera or a combination of any of these technologies. They are then integrated in the CAD drawing. Developing this static model completes the first step, which is followed by locating dynamic objects. All dynamic objects in the lay down yard were tagged. The initial locations of materials are also marked in the model and were again tagged and whenever moved, their location was updated automatically and in real-time. The static and dynamic models are then combined to obtain a complete data fusion model, which has all the details of the lay down yard.

6. Field Experiments and Data Collection

Experiments were conducted at the lay down yard site for new coal power plant near Cliffside, SC. The lay down yard under consideration had an overall area of 16 acres, which provided ample opportunity to test the maximum ranges and feasibility of employing an UWB system over a large area. The major material bays comprised mostly of custom fabricated steel pieces, which were well laid out for workers and equipment to move around. There was only one entry point to the yard, which was guarded, and a tool and restroom area for workers. All experiments were conducted under the supervision of a safety manager at all times and with consent of the workers and equipment operators. The site layout and sensor infrastructure deployed is illustrated using Figure 2a.and 3a.

UWB receivers were set-up at the boundaries of the lay down yard at suitable locations based on prior experiences. These receivers were connected to the central hub using shielded cables. The cables were buried in soil whenever crossing the vehicle paths to avoid damage. A reference tag was placed, which was in the line of sight of all the receivers. Laser scan data of the environment was not available for this experiment. The plan view of the lay down yard that can be seen in Figure 2a was established through the data collected from a robotic total station.

The location of important control points such as material bays, fence, road and other installments on the field were recorded. These were used to develop a plan of the lay down yard. The lay down yard, access and work areas, the tool area and other facilities, and sensor locations can be identified. Real-time x, y, and z data from the UWB sensors were then merged with readings from the RTS. Both data sources were calibrated to have the same Cartesian coordinate system.
The origin was set to be one of the UWB receivers and the y-axis was oriented to be in line with another receiver. The red triangles in Figure 2a represent the location and orientation of UWB mid gain receivers (60 degree field of view) and the green circle show the location of the reference tag that is necessary to triangulate the radio frequency signals of the UWB system based on time-of-flight (TOF). The shaded areas are the bays that were tracked for material pick-up and delivery. Figure 3a shows the plan with the experimental layout of receivers and the material bays.

6.1 Tracking equipment and material in lay down yard
An UWB tag of 1Hz frequency was attached to a yard dog (the truck without the trailer) as shown in figure 2b. The driver was instructed to drive around the yard to simulate the process of picking up material and delivery. Data in this preliminary experiment was collected for duration of 45 minutes and the position of the equipment was tracked successfully in real-time. Figure 3a shows the path followed by the equipment during the test. The figure shows the movement of the equipment and features such as the exact location for a given time, turning radius, start and end points of the path etc. can be extracted. The plan layout was embedded in the GUI and the UWB data was analyzed in this background. Figure 3a also shows the GUI with this test data. The GUI can be used to analyze the data within a particular time range and the path of the equipment can also be simulated (replayed). Based on these simulations, it was possible to conclude that the equipment data collected stayed within the actual paths on the plan. The experiment was repeated with different pieces of equipment to ensure that the type, size and functionality of the equipment do not affect the data collection.

6.2 Tracking Workers and Team Dynamics in Lay Down Yard
UWB tags of different frequencies were used for a second experiment. This test included 60Hz, 30Hz and 1Hz UWB tags. These tags were attached to the hard-hats of workers. Data was collected while the workers were involved in their daily activities. Figure 3b shows the paths of the workers tracked during a particular work tasks (searching for a material piece). The visualized trajectory data shows that it is possible to pro-actively monitor the workers and their location in a very large lay down yard using UWB technology.
Figure 3b shows the path of a worker who had a 1 Hz tag attached to his hard-hat. The path runs from the material bay towards the tool area. The tool area was outside the experimental set-up and hence, was not very well captured by UWB receivers thus causing some considerable noise measurements. However, within the experimental area, all UWB paths were very well defined. The experiment shows the feasibility of using UWB in tracking and that UWB technology can be used to study the productivity of construction resources, including workers. For example, it can be

measured how much time workers spent to get tools from a tool box (a task that is considered to be non-value adding task by many field practioners). The paths of two different workers on a same task were monitored using 1Hz UWB tags (IDs: 6BEF, 70C0). From the data log that was recorded at the same time, it was evident that both of workers were riggers and consequently need to work together to hoist steel members. This is evident from the UWB data as well.

6.3 Comparing UWB data with RTS data to Validate Error Measurements

Data was collected simultaneously using RTS and UWB technologies. A 1 Hz tag was attached to a special hard-hat developed for measuring the error rate of UWB technology. The top of the helmet carries a miniature RTS prism. The RTS was calibrated to follow the prism and collect highly accurate data (less than 3 mm per data point). This was compared with the data received from UWB for the same duration. Initial results show almost negligible differences (see Figure 4a). Plotting the error measurements (deviation between RTS and UWB) on a time based scale resulted in Figure 4b. Overall error measurements can include instrument reading error, field observation and recording errors. Another reason for larger deviations is the data output of UWB and RTS as they were collected in two different time scales (up to 60Hz vs. 4Hz, respectively).

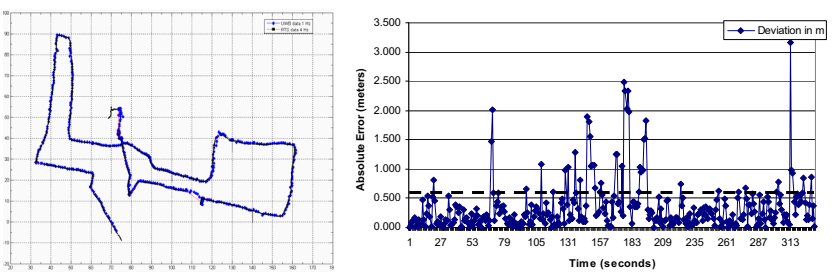

FIGURE 4 (a) Comparison of paths measured by UWB and RTS (Distance in meters) and (b) error rate of UWB data in comparison to ground truth measured with RTS

An algorithm was developed to synchronize the frequency using interpolation of data points. The absolute deviation of the data points was computed. After analyzing the data, a suitable range for the deviations are fixed and the results were plotted. Figure 4b shows preliminary results of comparing UWB to RTS data for the duration of about 300 seconds using a 1Hz UWB tag which equates to roughly 300 data points. It is observed that nearly 95% of all recorded points show a deviation of less than 0.6 m, which is suitable for construction activities.

7. Results and Discussion

Application of lean principles in material management and delivery in a lay down yard can help optimize the entire process by avoiding or reducing the time spent in performing activities. All tasks in work processes can be classified as value-adding or non-value-adding activities. Some examples of non-value-adding activities that are common in lay down yards are redundant search functions and unnecessary

transportation. Inefficient means used in identification the location of material and errors in retrieving the correct material are the major reasons for loss of time and resources. Use of an automated localization system based on UWB can minimize this loss and thereby help streamline the operational processes in lay down yards. In addition to tracking, proactive monitoring has immense potential to reduce the incidents and near-misses that occur on construction sites. The application for safety purposes needs to be explored in more detail as part of future research.

Moreover, a detailed study on cost vs. benefit, in particular on cost saving by using UWB technology may provide construction practitioners with enough confidence to embrace this technology. Along with improved data acquisition techniques, UWB may provides easy integration with other management and scheduling systems providing prompt updates to changing field information and to any kind of project stakeholders that are interested in such data.

The ease of use coupled with enhanced information sharing will increase the responsibility of ownership within a group of practitioners. These, along with an improved resource utilization and cost savings on document handling and storage space, are some of the major advantages of UWB tracking systems. UWB's main limitation at this point is a necessary measurement infrastructure, which once set in place can be effective for at least the project duration.

8. Conclusions

Rapid technological advances have made it possible to implement cost-effective UWB radar and UWB communication and tracking systems in construction tracking applications. As demonstrated in a field trial, UWB system can provide robust real-time tracking of multiple construction resources at the same time giving decision makers tools in their hands that were not available before. Preliminary experimental results to locate and track materials and pieces of equipment were presented. In addition to some successful field trials that tested a commercially available UWB system, some limitations and benefits of the technology applied were highlighted. Technological challenges remain and are on the side multipath interference. Additional research was identified to investigate UWB systems and its applicability in construction further.

Semi-Automated As-Built Modeling of Light Rail System Guide Beams

Pingbo Tang[1], Burcu Akinci[1], Daniel Huber[2]

[1]Civil and Environmental Engineering Department, Carnegie Mellon University

[2]Robotics Institute, Carnegie Mellon University

Abstract

For a light rail system, smooth contact between the vehicle and the guide beam is critical for reducing the friction and the vibration of an operating vehicle. Therefore, the shape of guide beams needs to be controlled with mm-level accuracy during the construction. Currently, most methods for detecting shape defects of guide beams, such as experimental run of vehicles, are costly and tedious, and can only identify defects after the completion of the construction, causing reworks and delays.

From dense point clouds collected by laser scanners, inspectors can manually extract geometric features and conduct virtual inspections of guide beams. However, the manual geometric feature extraction process impedes effective utilization of point clouds for the shape analysis of guide beams. This research developed a semi-automatic approach for simultaneously extracting the axis parameters (e.g., radius) and cross-section features (e.g., width) of a guide beam using a Hough-Transform based approach, and discusses factors (e.g., data density) influencing the performance of this approach.

Keywords: Laser Scanning; Geometric Feature Extraction; Information Retrieval; Quality Control; Surveying; 3D Modeling;

Introduction

The precise installation of a guide beam for a light rail system is critical for both the riding quality and the maintenance costs. Smooth contact between the guide wheels of a vehicle and the guide beam are important for reducing the vehicle frictions and hence reducing the vibration of an operating vehicle and the maintenance costs of the vehicle and the guide beam. Therefore, the quality control of the shape of a guide beam is important for the performance of a light rail system and the cash flow of the project. Currently, two approaches for detecting shape defects of guide beams are mainly used: 1) Visual inspection; 2) Experimental run of vehicles. The former requires inspectors to walk along the track and manually identify shape defects (e.g., distortions of the flanges). This method requires highly-skilled

inspectors to make decisions based on their experiences, and is subjective and time-consuming. Experimental runs of vehicles expose a constructed light rail system to real working conditions. During experimental runs, engineers can observe the vibrations of the vehicle to identify sections of problematic guide beams. Such real-scale experiments could be expensive. Moreover, both the visual inspection and the experimental run methods are conducted after the construction, when it might be too late or too expensive to fix those detected defects.

Laser scanning is a promising method for capturing geometric details of guide beams during the construction. A laser scanner can densely sample the surfaces of a guide beam in minutes (1 cm step size within 50 m for the scanner used in this research), and generate dense point clouds. With such dense data, inspectors can reconstruct 3D as-built models of guide beams using commercial 3D modeling tools, and manually conduct virtual inspections on these models. One major issue is that this manual approach requires inspectors to manually extract axis (e.g., radius) and cross section features (e.g., width) from point clouds. This becomes a tedious approach considering the fact that guide beams can run for miles resulting in a very large amount of 3D data.

For improving the efficiency of utilizing laser scanners for more effective quality control of guide beams, this paper presents a semi-automated approach for simultaneously extracting the axis and cross-section features of an I-beam.

Related Studies

Previous research studies have investigated various methods for extracting geometric features and object poses from 3D data. Kwon *et al.* developed algorithms for extracting parameters of cuboids and cylinders from flash LADAR scanned point clouds (Kwon et al. 2004). Vosselman *et. al* showed the effectiveness of a set of Hough transform-Based algorithms for extracting planes, cylinders and spheres from laser-scanned data (Vosselman *et al.* 2004). Based on Gauss-Newton least square fitting method, Barker developed a MATLAB library for extracting 2D and 3D lines, circles, planes, cylinders, cones and spheres (Barker 2004). Using the Generalized Gauss-Markoff model, Gruen and Akca proposed a framework for extracting arbitrarily posed parametric surfaces by comparing data patches against a library of predefined surface templates and determining the most probable surface model for a given data patch (Gruen and Akca 2005). Gilsinn *et al.* used Principal Component Analysis (PCA) to estimate the pose of an I-beam (Gilsinn *et al.* 2005). Results of these research studies show the feasibility of automatic extraction the geometric features of light rail guide beams from dense point clouds.

One major difficulty of applying these previously developed geometric feature extraction algorithms for automatic extraction of guide beam features is that most algorithms can only handle simple 3D scenes (e.g., horizontal beam on flat ground in an open space). Many construction sites have more complicated geometric conditions (e.g., moving objects, and occlusions) than those in these simplified scenarios. To overcome this issue, we decided to develop a semi-automated approach, which requires inspectors to manually localize a number of axis points of the guide beam, and then the algorithm can refine such rough axis information to obtain accurate geometric features of the guide beam.

Guide Beam Features

Generally, a guide beam has two categories of geometric features to be inspected for their shape quality control. The first category of features includes the parameters of the axis curve (axis curve features), while the second category of features are the features of the guide beam's cross sections (cross section features).

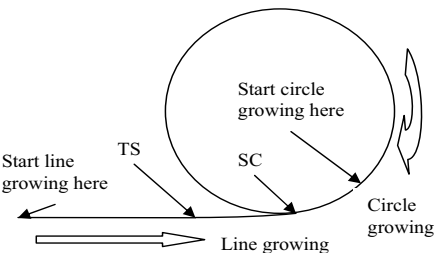

Figure 1 Line and circle fitting and growing for finding TS and SC points

For most light rail systems, to ensure the smooth turning of the vehicle, the curvature variation should be continuous: from straight line (infinite radius), to a spiral curve (a curve the radius of which continuously changing from infinity to a specific radius value), and to a circle with the specific radius value at the end of the spiral curve (Figure 1). Such curve shape has continuous curvature changes. In this research, we call the boundary point between the straight line and the spiral curve a "TS" point, and the boundary point between the spiral and the circular sections a "SC" point. This research focused on recognizing the parameter of the straight line, the spiral curve length between "TS" and "SC", and the radius of the circular section, because these parameters are controlled parameters having explicit as-designed values to be compared with the ones in the design drawings.

For such a cross-section of a guide beam, the critical features to be recognized are the web and two flanges, which could be simplified as three lines on the cross-section. With these three lines, it is possible to derive two geometric properties of the cross section: the width of the guide beam, and the angle between the flange and the web. This research focused on obtaining the width of the guide beam, but did not look into angles between web and flanges, since the former is usually a controlled property of the guide beam according to several interviews with domain experts. Table 1 lists the parameters focused on in this paper.

Table 1 Targeted features of a guide beam

Category	Feature Details (Symbol for Representing It)
Axis Feature	• Line parameters of the straight section • Spiral curve length (L): curve length between TS and SC • Circular section radius (R)
Cross-section Feature	• Flanges (F1 and F2) and Web (W) • Intersection points of W and F1/F2 (P1, P2) • Width (w): distance between P1 and P2

Overview of the Guide Beam Feature Extraction Approach

In most cases, guide beam axes are straight, or curves with small curvature (with radius larger than 100 m), so that the axis of a small guide beam segment (e.g., 1 m in length) can be approximated by a straight line linking the two ends of the segment. That line is called the "approximate axis" of a segment in this paper. For point clouds of a straight or approximately straight beam segment, projecting all points along its approximate axis results in 2D points profiling the cross section of the beam (Figure 2). The diagonal lines shown in this figure are formed by "mixed pixels" (Tang et al. 2007), which are data artifacts caused by laser spots spanning over spatial discontinuities (object edges). Figure 2 shows the location of the scanner to indicate that these diagonal lines are along the viewing directions of the scanner for guide beam edges.

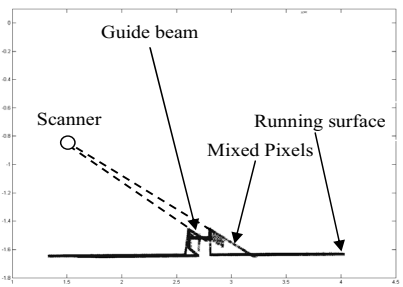

Figure 2 A segment of guide beam point cloud projected along the beam axis to form a cross section profile

In this research, we found that if a user can manually select a number of points roughly on the axis of a guide beam, these manually selected points were accurate enough to generate approximate axes of guide beam segments for generating their cross-section profiles. This observation motivates the development of an approach, which requires users to pick the rough locations of a number of guide beam axis points from point clouds, and then the algorithm uses these inputs to extract and refine cross-section and axis features of the guide beam (Figure 3).

Given the manually selected axis points, the semi-automated approach for guide beam feature extraction consists of six major steps: 1) Interpolating the manually selected axis points with a user-defined interpolation step size; 2) Identifying the locations of TS and SC points by fitting and growing straight lines and circular curves based on the interpolated axis points; 3) Generating a segment of point clouds for each line segment that link each pair of neighboring interpolated axis points; 4) Projecting points along its approximate axis and extracting cross-section features (lines representing the flanges and the web, and the intersection points between them) for each point cloud segment; 5) Using the extracted intersection points as refined axis points; 6) Using the updated axis points as input and starting the whole process to generate another set of cross section feature points along the axis. Once the updated points have no substantial deviations from the results of the

last iteration, then the algorithm concludes that the curve updating process converged, and reports the latest results of curve fitting and cross section feature extraction.

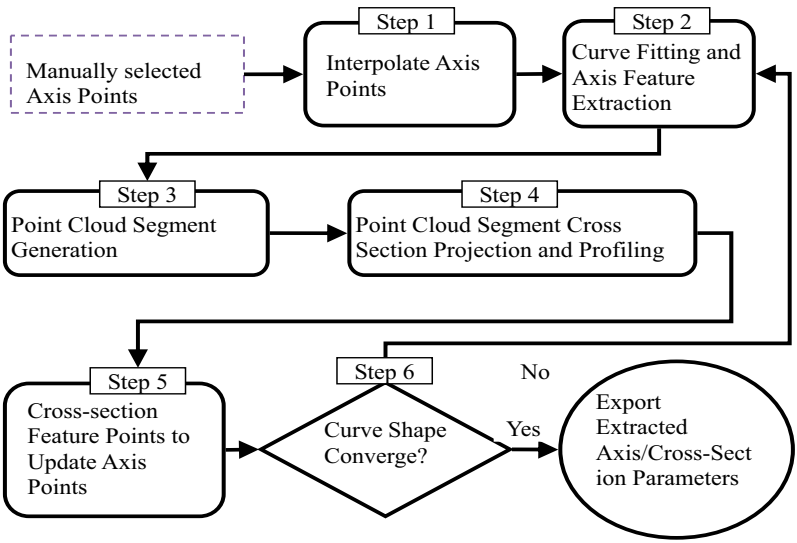

Figure 3 Overview of the developed approach for guide beam feature extraction

Detailed Feature Extraction Process

In Step 1, the algorithm utilizes the spline interpolation method to generate interpolated points along the x-axis (which we define as the direction of the straight section of the guide beam, toward the spiral section) with a fixed step size of 1cm. In other words, using the manually picked axis points, the algorithm generates a sequence of x values with 1 cm intervals, and interpolates corresponding y values.

In Step 2, the algorithm fits and grows straight lines and circles on the interpolated points for identifying TS and SC points through the following semi-automated steps. This step requires an inspector to visually inspect all interpolated points, and manually identify a point on the straight section and a point on the circular section. Then, starting from the manually picked straight section point and circular section point, the algorithm iteratively fits and grows a straight line (starting from the straight line point) or a circle (starting from the circular section point) toward the spiral section. These fitting processes use least-squares fitting. While growing straight/circular sections, the algorithm uses an "average deviation" metric to measure the fitting quality. Average deviation is defined as the sum of the deviation values of all axis points from the fitting line/circle divided by the total number of points. The algorithm will check through all possible TS and SC point locations, identify the locations achieving the minimum average deviation, and labels them as TS and SC. The concept is that since the two sections bounding a

spiral section are known to be a straight line and a circular section, it would be possible to find the TS and SC points by growing two parametric models and finding the best fit (Figure 1). This step generates the parameters of the linear (line parameters) and the circular sections (radius), and the TS and SC points for getting the length of the spiral section.

In Step 3, the algorithm splits the point clouds of a guide beam into segments of point clouds. With a sequence of interpolated axis points, the algorithm generates lines linking pairs of neighboring axis points. These line segments are linear pieces approximating the shape of the axis curve. Then, for each line segment, the algorithm identifies the x coordinates of the points in the point cloud that are falling into the x value range formed by the x coordinates of the end points of the line segment. Points for one line segment forms a slice of a point cloud capturing the shape of a beam segment.

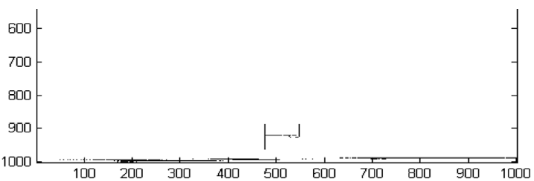

Figure 4 A binary cross-section occupancy image

In Step 4, for each point cloud segment, the algorithm processes the data in the following three sub-steps: 1) Projecting all the points along the direction of the corresponding line segment; 2) Generating a binary cross-section occupancy image depicting the cross-section profile of the guide beam (Figure 4); 3) Applying a series of Hough transforms to the binary cross-section profile to detect lines in it. In sub-step 2, noticing that the cross section profile parts generated from data artifacts (e.g., mixed pixels that form a sloping line in Figure 2) have lower data densities, the algorithm generates 2D rectangular cells with fixed 2D dimensions on the cross section plane, computes the number of points falling into each cell, and only label cells with more than a fixed number of points as "occupied" in order to ignore the lines formed by data artifacts. Based on large number of experiments on the data sets used in this research, the implementation in this research uses 3 mm by 3 mm as the cell size, and 20 points as the occupancy threshold, because these values were found to be able to distinguish lines formed by data points falling on actual object surfaces and diagonal lines formed by mixed pixels. The binary occupancy image generated in this sub-step serves as the input of sub-step 3.

In sub-step 3 of Step 4, the algorithm utilizes the Hough transform for detecting lines on cross sections (Vosselman et al. 2004). Hough transform is a feature extraction technique to find imperfect instances of objects within a certain class of shapes by a voting procedure. This voting procedure is carried out in a parameter space, from which object candidates (e.g., straight lines) are obtained as the local maxima in a so-called accumulator space explicitly constructed by the algorithm for computing the Hough transform (Vosselman et al. 2004). In this research, in order to improve the sensitivity of the line detection, the algorithm runs the Hough

transform multiple times. Each time, the algorithm extracts the longest line detected (the largest peak in the parameter space), and removes all occupied pixels on that line in the occupancy image. The next run of the Hough transform will be based on the updated occupancy image with the most obvious line removed. We found that this multiple-run Hough transform approach can detect more lines (especially short lines) in an occupancy image compared with the conventional approach of running the Hough transform once and report all the lines. Figure 5 shows five groups of points labeled by different colors, which are corresponding to five lines identified by five runs of the Hough transform on the occupancy image of a segment of point cloud. This figure shows that points on the flanges, the web, and the running surface are separated. The reason that the algorithm detected two planes in data points on the running surface is that the projection direction is not exactly parallel to the running surface, such that the projected points are not forming a line but a wide stripe. The algorithm detected that wide stripe as two lines.

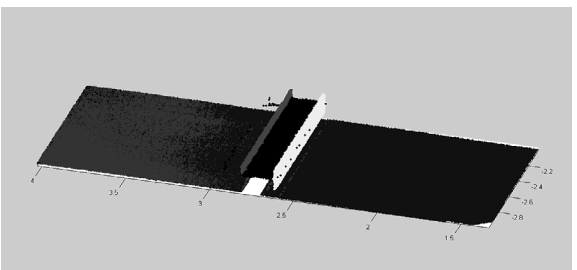

Figure 5 Five groups of data points corresponding to five lines detected on the cross section of a guide beam segment

In Step 5, with the detected lines on a cross-section, the algorithm computes the intersection points between the detected horizontal lines (the web and the running surface) and the vertical lines (the flanges). These feature points can be used to generate the width of the guide beam: the distance between two flange-web intersection points is roughly the width of the web. The only issue is that the flange is about 1 cm thick, and the detected flange line is actually the centerline of the flange cross-section. Using that flange center-line for calculating the guide beam width will generate values slightly smaller than the actual width of the guide beam, as will be shown in the following section.

In Step 6, the developed approach calculates the distances between the detected flange-web intersection points and the interpolated axis points used in Step 2 on each guide beam cross-section. If these distances are larger than a specific threshold, then the whole iterative guide beam feature extraction process will be repeated until the extracted parameters converge.

Evaluation Results and Discussion

The evaluation of the developed approach uses point clouds collected on a site for experimental run of metro vehicles. The laser scanner used in this study was a phase-based scanner, which is capable of collecting 3D point clouds with angular

resolution of 0.018 degree (20,000 pixels for a row in a collected panoramic range image), and with an accuracy of about 5 mm for every point within 50 m from the scanning location. After importing such dense and accurate point clouds into a commercially available reverse engineering environment, we manually selected a number of axis points, exported them as the input of our approach, and tested three critical components of the approach: 1) Axis feature extraction; 2) Cross-section feature extraction; 3) Axis updating using the extracted cross-section feature points.

Table 2 lists the results of axis feature extraction. This table indicates that for the straight section, the error of the generated axis is about 0.1 mm, which is very small. However, the extraction results of the length of the spiral curve and the radius of the circular curve are less accurate. These observations indicate that the developed approach needs to be improved for extracting axis features of curved guide beams, especially for spiral sections. More specifically, we found that the boundary point between the straight line and the spiral curve is difficult to be located accurately, and even large variations of the possible TS point (end point of the growing straight line) would not have substantial impact on the average deviation value of the straight line section. As a result, the generated TS locations have large uncertainties. This fact implies the necessity of developing a better fitting quality measure other than the average deviation used in this research for accurately locating the TS point.

Table 2 Guide beam feature extraction results analysis

Axis section	Recognized feature values	Errors
Straight line	A point on line: (-0.2099 m, 1.001 m) Line direction vector: (0.5042 m, 0.8036 m)	0.001 m (the average deviation of points on the generated line from the as-designed line)
Spiral curve	Length of spiral: 3.45 m (as-designed: 5.76 m)	2.31 m (difference from the as-designed spiral curve length)
Circular curve	Circle radius: 35.15 m (as-designed: 38.10 m)	2.95 m (difference from the as-designed circular section length)

For cross-section feature extraction, the algorithm extracted flange/web and flange/running-surface intersection points on all cross-sections for a straight guide beam (for curved guide beam, the exploration is on-going). Figure 6 shows (a) the extracted feature points of twelve cross-sections of that beam segment; and (b) the calculated guide beam width based on these feature points on those twelve cross-sections. An interesting observation is that, for cross sections closer to the scanning location, more feature points can be extracted (Figure 6a). The non-uniformity of the data density causes this phenomenon: point clouds closer to the scanning location are denser, so that in the sub-step 2 of step 4 of our approach (occupancy image generation), more cells will be recognized as “occupied” with the constant occupancy threshold 20 (any 3 mm by 3 mm cells with more than 20 points in them are labeled as “occupied”). As a result, more lines will be detected for cross-sections with higher data density (sections 5 to 12 in Figure 6); while for cross-sections further away from the scanning location (sections 1 to 4 in Figure 6), the algorithm could not extract enough lines for detecting all four feature points (two flange-web intersection points, two flange-running surface intersection

points). That's why in Figure 6 (b), for cross-sections 1 to 4, the generated width is 0 m (there were not enough feature points to compute the width).

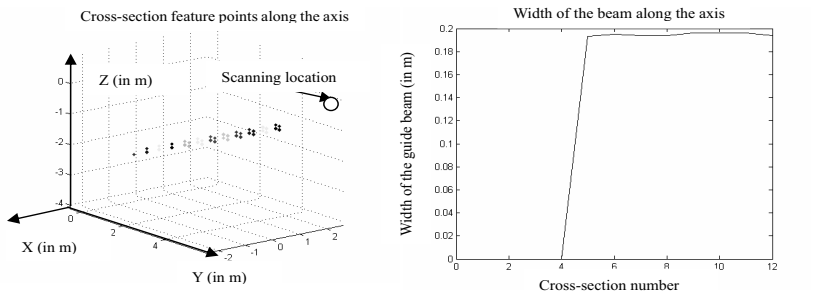

Figure 6 (a) Extracted feature points on 12 cross-sections along a straight guide beam; (b) Automatically extracted guide beam widths of the 12 guide beam cross-sections

For cross-sections 5 to 12, the obtained guide beam widths vary from 0.193 to 0.196 m; while the as-designed guide-beam width is 0.2 m. In-depth analyses indicate that the algorithm only extracts one line locating at the center of flanges, which are slabs of about 1 cm thick. The distance between two center lines of flanges should be slightly smaller than the actual width of the guide beam, which is defined as the outer-outer distance between two flanges. Therefore, the automatically generated guide beam widths are expected to be smaller than the as-designed value, and the testing results are consistent with this expectation: adding 5 mm (half of the flange thickness) back to the generated widths results in accurate results, the errors of which are equal or less than 2 mm.

For updating of the guide beam axis, several preliminary analyses and visual inspections indicate that utilizing the feature points can roughly adjust the selected axis points to particular cross-section feature points (e.g., cross-section center) for more accurate axis feature extraction. Due to the space limit of this paper, these results are not presented.

Conclusions and Future Research

This paper presents an integrated approach for combining the two aspects of guide beam feature extraction from 3D laser-scanned point clouds: axis feature extraction and cross-section feature extraction. The evaluation results of this approach on point clouds collected by a phase-based scanner indicate the potential value of this approach. The major findings of this research are two-fold. First, it has been showed that a fitting-and-growing approach can extract parameters of the straight section, spiral section, and circular section of a curved guide beam, and the primary difficulties of accurately extracting these parameters occur in the fitting of the curved sections and localizing the connection point between the straight section and the spiral section. Second, a multiple-run Hough-transform-based line detection

approach can accurately extract cross-section lines of a straight guide beam, and can automatically generate widths of the beam with 2 mm accuracy. The major difficulties occur in the non-uniform data densities of the point clouds, which require different parameter settings to achieve the best line detection results for different parts of the point clouds. Instead of setting constant parameter values of the algorithms, in the future, we plan to explore an approach which can automatically adjust the algorithm parameter settings according to the data density variations of point clouds.

Future studies should target at improving the axis feature extraction and cross-section feature extraction algorithms to overcome the difficulties mentioned above. In addition, in order to achieve an integration of axis extraction and cross-section feature extraction algorithms to get an iterative guide beam feature extraction approach for obtaining accurate axis and cross-section feature through several circles of the "axis fitting – cross section feature recognition" process, we plan to further test the mechanism of using recognized cross-section features to update axis points for converging to an accurate axis.

Abstract
Equipment related fatalities account for about 25% of all construction fatalities in the United States. One leading indicator for equipment related incidents are blind spots that are prevalent around most construction equipment, inhibiting the operator's visibility of personnel and vital materials on jobsites. Incidents such as injuries and fatalities do occur because operators or ground personnel fail to identify that other objects can be in too close proximity to the work envelope they are operating in. This paper presents a new and unparalleled research approach to help identify the blind spots of equipment in order to quantify and protect the required safety zone(s) for such equipment. An automated blind spot detection tool is presented that determines the equipment blind spots rapidly and in 3D through analyzing the point cloud data from a laser scan inside the equipment cab. Terminology of planar and spatial blind spot measurements are defined and explained. Results to numerous vehicle types that were studied in the construction environment are presented and compared to existing manual and semi-automated methods for similarities. Future work and the applicability of automating the blind spot detection with alert technology in the construction industry are presented.

Keywords: Blind Spots, Construction Equipment, Laser Scan, Ray Tracing, Safety.

1. Introduction
Blind spots on construction equipment resulting in poor operator visibility are one of the leading causes of contact collisions in the construction industry (Fullerton et al. 2009). Blind spots create problems for operators by restricting their line-of-sight and eliminating their view of personnel, materials on the ground, and other equipment being close to their own work envelope (area of operation).
Safety statistics published in the 2009 Census of Fatal Occupational Injuries (CFOI) safety demonstrate that the construction industry accounts for about 21% of all

occupational fatalities or 1,204 of 5,657 total workplace related fatalities in 2007. Within the construction industry, most worker fatalities relate to being struck-by objects in heavy construction (10% of all construction related fatalities) and to specialty contractors (13% respectively). Other statistics indicate that 6% of all occupational injuries were from workers being struck-by vehicles (BLS 2009). Between the years 1992 and 1998, the CFOI reported that out of 465 vehicle related construction fatalities 318 involved workers-on-foot (BLS 2009). The most common vehicle types that were involved in struck-by incidents were trucks (60%), followed by other construction machinery (30%). 110 of the 465 fatalities occurred to equipment operators; and of these fatalities more than half occurred to an equipment operator who was operating a type of construction vehicle (53%) that was not a truck. The remainder of the 465-recorded fatalities occurred to supervisors and other personnel. The Bureau of Labor Statistics (BLS 2009) further reported that the majority of these fatalities (51%) occurred when a vehicle was in reverse mode; which was attributed to the large amount of blind spots that are prevalent in the backside of a vehicle (Pratt 2001).

The presented safety records indicate that a need exists for improving the situational awareness of workers-on-foot and vehicle operators, in particular in the construction environment where workers are often nearby or too close in proximity to heavy construction equipment. The Occupational Safety and Health Administration (OSHA) sets forth minimum guidelines to protect the health and safety of those working in the construction industry and other occupational fields. Construction safety can be found in 29 CFR 1926 OSHA Construction Industry Regulations.

This paper focuses on demonstrating the importance of several key aspects: (1) Understanding the impact blind spots have on construction safety through reviewing relevant safety statistics that have been reported, (2) Explaining existing standards, rules, and practical approaches that are currently applied in preventing injuries and fatalities related to construction equipment blind spots, and (3) Providing new approaches that have the potential to solve limitations in (1) and (2), and demonstrating and discussing results of the developed new approach. The following sections of the paper include a background review of existing blind spot detection and measurement approaches, introduction of the research objective and methodology, and experimental results and discussion. The conclusion includes a discussion of potential next steps and future research.

2. Background

Every construction work site is unique and the work tasks for construction equipment vary from job to job, therefore modifications to equipment are often necessary to get the job done. Even if modifications are not performed, equipment operators are typically little aware of the blind spots surrounding them. To overcome this limitation, heavy equipment manufacturers and researchers have conducted time consuming manual blind spot measurements on equipment in the design stage, on original manufactured and used equipment. Blind spot measurements and demonstrations also can become a useful tool in automated object detection and warning systems, and in construction equipment safety training and education for equipment operators and other workers. This section reviews existing blind spot

measurement and warning techniques and finalizes with a needs statement.

2.1 Current Methods for Measuring Blind Spots

The National Institute of Occupational Safety and Health (NIOSH) released a report in 2007 on potential systems that could aid in the issue of low visibility in heavy equipment operation. This report by Ruff (2008) focused on fatal accidents where victims were in the blind spot area of heavy (construction and mining) equipment. Ruff (2001) proposed also on methods of eliminating blind spots. A first step was to determine the blind spots of the equipment that caused equipment to struck personnel and materials or equipment that came into contact with other equipment and materials. Overall, four different methods to determine blind spots were found in the literature, two manual and two computer-aided blind sport detection techniques.

To study the performance to each of these techniques, Ruff (2008) examined five large pieces of surface mining equipment during this experiment using four measurement techniques: (a) the light bar method, (b) operator guidance, (c) computer-aided virtual reality, and (d) high quality photographs. A library of blind spot diagrams was published by Hefner (2004).

2.2 Warning Systems Addressing Blind Spots

Several commercially available warning systems are available to operators when objects appear in blind spots or for vehicles that are in reverse mode operation (Fullerton et al. 2009). These systems rely on accurate measurement of blind spots beforehand their use. Vision or radar based detection and warning systems for backing-up vehicles are the most commonly used pro-active approaches in the construction industry (next to the acoustic back-up signal alerts). Several automobile makers utilize camera or sonar sensors that are reliable in use, but require manual input or offer alerts only to shorter distances.

2.3 Need for Advanced Blind Spot Measurement for Construction Equipment

A combination of several blind spot measurement, distance ranging and alert techniques would benefit operators in the use of construction equipment. The advantages, limitations, and applications in the construction industry are identified in some more detail in Fullerton et al. (2009). Since OSHA allows for adjustments to be made to construction vehicles such that they can be used for the needs of the equipment owner, it is eventually important to check the blind spots of vehicles as they are on the work site frequently. To optimize any warning systems, however, precise and up-front measurements of the space that blind spots occupy and obstruct the operator's field-of-view are necessary. The true blind spots of the equipment as seen by the operators on a daily basis need to be measured as an accurate representation of the potential adverse conditions present in the workplace, such as low visibility due to dust or cracked glass. Therefore, blind spot measurements presented in this paper have been measured on heavy construction equipment and in the construction environment. Preference should also be given to a measurement technique that allows rapid, automated, and spatial blind spot measurement rather than providing 2-D blind spot measurements only. This becomes particularly important in heavy industrial construction operations where many lifts and equipment

movements are performed.

3. Research Objectives and Methodology

This research aims to collect more realistic and more accurate data on blind spots than any previous study before. This research uses a laser scanner to measure the geometrical properties of construction vehicles-in-use in an obstruction free environment in less than 2 hours per piece of equipment. Computational algorithms were developed to automatically identify spatial (and 2-D) blind spots from heavy construction equipment in field environments. Knowing the detailed location of blind spots, this research strives to identify and quantify the necessary (or minimum) safety zone required for all equipment analyzed. A sample 3D library of equipment blind spots is developed through experimental studies. the following research tasks are explained in more detail: Design of experiments for blind spot measurements utilizing a laser scanner; design of the developed automated blind spot measurement tool using a ray tracing algorithm; experimental data collection; validation of blind spot measurement tool, results and analysis; and identification of potential applications, research recommendations and future work.

4. Execution of Research Tasks

4.1 Laser Scan Data as Input for Automated Blind Spot Measurement Tool

Instead of using one of the previously discussed research approaches performed by other researchers, laser scans of heavy construction vehicles like excavators, dump trucks, motor graders, rollers, wheel loaders, and smaller heavy equipment were taken from outside the vehicle and by mounting the laser scanner on the driver's seat inside the equipment cab. A commercially available high-definition three-dimensional (3-D) laser scanner performed the automated distance measurement to all objects that were in the field-of-view of its laser beam. All recorded points (around 1.5 million per scan; varies per scan) were registered and stored in a point cloud file. The point cloud file was converted to a comma separated variable (CSV) file that has x, y, and z-coordinate representation of each distance point. This CSV file became the input to the developed blind spot calculation and analysis tool.

4.2 Ray-Tracing Algorithm

The developed automated blind spot calculation tool uses a ray tracing approach to calculate blind spots of any of the selected construction machines. Ray tracing is similar to the idea of using a perfect light source from the driver's perspective. Traced is the imaginary path of light emanating from the light source. Should rays from this imaginary light source hit a distance point the laser scanner measured, the further part of the ray would be considered a blind spot line. Blind spots can be identified once this process is repeated for all distance measurements. Blind spots are typically spaces that are not visible to the operator. Blind spots are typically visualized as areas and illustrated in plan view. Their nature, however, is volume. Thus, the (automated) measurement and analysis of blind spot spaces of construction vehicles is an important addition to existing blind spot research.

4.3 Grid Representation of Equipment

Since the laser scanner provides a dense cloud of distance points, a flexible 3-D cube system was designed to handle error measurements of the laser scanner as well as to reduce the computational power required for analyzing for blind spot volumes. The number of cubes and their size are variable and set by the user; for example X,Y,Z=300,300,300 with a single dimension of 0.1m per cube. A similar technique for personnel tracking has been applied before by Teizer (2007). Cubes that are in line-of-sight (LOS) to the operator are visible; the combination of all other cubes that are hidden behind the filled cubes creates the blind spot volume (space).

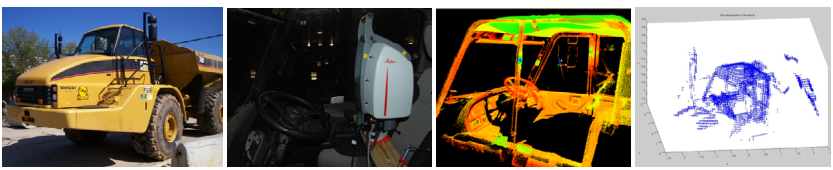

Figure 1: Laser scan within the cabin of an articulated dump truck and the resulting grid model representation.

4.4 Automated Blind Spot Measurement Tool

To limit the computational burden of the blind spot calculation algorithm further, the developed tool allows the user to select radius *R* and origin *O* of the field-of-view at any point in the range point cloud. The tool user is given a choice setting the origin and size of the radius of the sphere inside or outside the equipment, with preference placing *O* inside the cab (at the operator's eye position). Placing the sphere at the origin (X,Y,Z) = (0,0,0) (which equals the position of the laser beam of the laser scanner inside the equipment cabin) with a radius of R = 10 m, results in a cube size of 6.66 cm.

A ray tracing algorithm is then applied and a grid model of the equipment results. The grid model for an articulated dump truck is shown in Figure 1. Since the dense range point cloud is collected for each equipment type, the blind spot measurement tool itself can be applied in remote offices, reducing the down time of the actual equipment. The developed approach also allows adjusting for operators with different body heights or selecting different viewpoints (location and orientation of head).

4.5 Blind Spot Location Detection, Recording and Analysis

The goal of the automated blind spot location detection, recording, and analysis tool is to gain detailed blind spot information, for example, the ratio of blind spots vs. visible space, or when workers-on-foot are visible and when not.

To calculate the percentage of blind spots in the 3-D grid, the number of cubes that are labeled as part of "blind" spots, and number of cubes that are labeled "visible" are counted. According to ISO 5006's "Operator Field of Vision", generally a radius of 12m is evaluated for the ratio of blind spots. The ratio of the space that belongs to blind spots can then be defined as:

$$\text{Spatial Blind Spot Ratio [\%]} = \frac{\text{Sum of the Number of 'Blind' Cubes} * 100}{\text{Sum of the Number of ('Blind' + 'Visible' cubes)}} \quad (1)$$

The developed tool can also compute percentage of blind spots in a particular cross section of the space. For a constant 'k' ($-r \leq k \leq r$; r = sphere radius), the tool can be used to compute blind spots in XY plane for any Z=k, YZ plane for any X=k, and XZ plane for any Y=k. Therefore, the plane parallel to the ground level and at the level of equipment operator's eyes, would be XY plane at Z=0m. Figure 1 shows the laser scanner mounted inside the cab of the equipment; the level of the "laser" was defined to be always at the Z=0m reference location.
To calculate blind spots in a XY, YZ or ZX plane, the number of cubes labeled as "blind spots" and cubes labeled as "visible" in each of these planes are counted. Therefore, the ratio of blind spots in a user defined plane (or area) can be defined as:

$$\text{Ratio of Blind Spots in Plane [\%]} = \frac{\text{Sum of the Number of 'Blind' Cubes in Plane} * 100}{\text{Sum of the Number of ('Blind' + 'Visible' cubes) in Plane}} \quad (2)$$

Distinguishing from other research approaches (Fosbroke 2004, Ruff 2008), the developed automated blind spot calculation and analysis tool allows accurate blind spot measurements from a: (1) Cross-sectional view (planar view), and 2) Spatial representation. In addition, any experiment in this study was conducted in the construction environment.

4.6 Visibility of Personnel on Ground from Operator's Perspective

Because of the blind spots of any equipment, a person or construction worker standing on the ground may or may not be visible to the operator. In some situations, the person might be partially visible to the equipment operator. The developed blind spot measurement tool can compute the percentage of visibility of a person standing anywhere around the equipment. The tool user can define the location and dimension of the person. Decision can be made whether a person is standing too close to heavy equipment during operation.

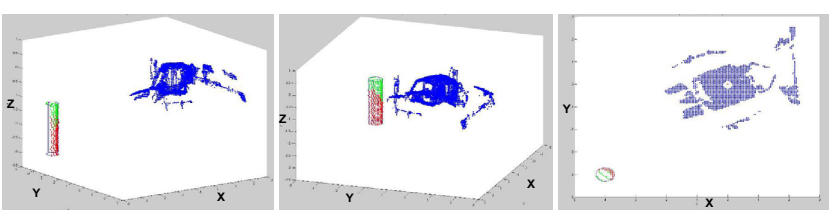

Figure 2: Visibility of a person standing on ground at X=-4m, Y=-4m, Z=-3.29m.

The developed tool applies a user-defined cylinder model to represent a construction worker. Height and radius of cylinder can be adjusted in the tool. For general understanding, a person 1.8 m tall with a diameter of 0.6 m is considered for the experiments explained in the following sections. The portion of a person (cylinder)

that is visible to an operator (laser beam origin) can be defined as:

$$Visibility\ of\ a\ Person\ [\%] = \frac{Sum\ of\ the\ Number\ of\ 'Blind'\ Cubes\ on\ Cylinder\ Surface\ *\ 100}{Sum\ of\ the\ Number\ of\ ('Blind'\ +\ 'Visible'\ cubes)\ on\ Cylinder\ Surface} \quad (3)$$

Different isometric and planar views of the cylinder's surface that were analyzed for blind spots can be seen in Figure 2. The area in green marks the parts of the person that would be visible to the equipment operator, and the area in red is marked as part of the blind spots.

5. Experimental Validation of Blind Spot Measurement Tool

The developed blind spot tool was designed to automatically compute the: (1) Percentage of blind spots in the work envelope (plane) of construction equipment, and (2) Visibility of a person when standing in proximity to equipment (calculation based on planar blind spot measurement). Experiments and results to each of these experiments are explained in the following subsections.

5.1 First Experiment (Blind Spot Measurement)

In the first experiment the ratio of blind spots in plane view is calculated by varying the radius of a circle encompassing the vehicle. This ratio of blind spots is the percentage of the area that is invisible to the driver of the machine. The illustration in Figure 3 shows manual and automated blind spot measurement for a bulldozer at a visible radius of 10 meters. The areas in blue are the invisible areas and the white areas are visible to the operator. The red points belong to the equipment cabin and are an overlay of the laser scan data points used in the computer tool on top of the blind spots. Differences in the blind spot measurements can be seen.

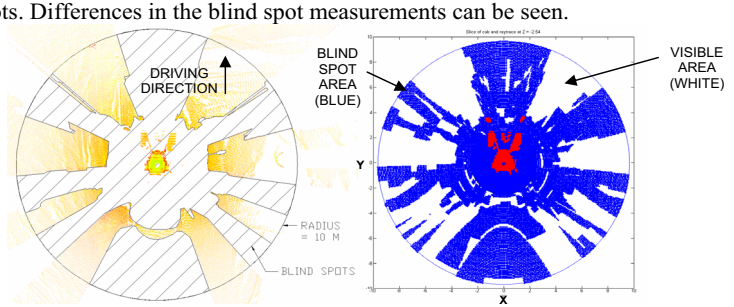

Figure 3: Manually vs. automatically drawn blind spots of a bulldozer (10 m radius)

Although the diagrams are similar to Hefner's (2003) and Ruff's (2008) experimental results, the automated method provides an efficient way for multi-view analysis at multiple planar comparisons without performing manual measurements (even after laser scanning). Similar to the argumentation in Ruff (2008), the ground plane, the 1.5m and1.8m-high planes (with respect to ground plane) were analyzed and compared to depict the differences in the blind areas for objects and people.

The default origin of the point file is the location of the scanner, but the location of the ray trace may be modified in the developed blind spot measurement tool. All

results included were calculated with the default origin established in the blind spot measurement tool. Reasons for creating such functionality in the program may be to account for the operator's ability to translate his/her head in the x-, y-, or z- within the cab of the equipment.

Table 1: Automated (a) vs. manual (b) blind spot measurement; worker visibility (c)

(a)

	z-value	Description	% Blind Spot
Bulldozer	0	Eye-level	36.97
	-0.74	1.8 m Tall	44.24
	-1.04	1.5 m Tall	46.60
	-2.54	Ground	61.06
Pick-up Truck	0	Eye-level	37.91
	0.34	1.8 m Tall	33.08
	0.04	1.5 m Tall	37.93
	-1.46	Ground	53.63
Art. Dump Truck	0	Eye-level	28.45
	-1.49	1.8 m Tall	48.82
	-1.79	1.5 m Tall	52.06
	-3.29	Ground	71.08
Roller	0	Eye-level	20.43
	-0.79	1.8 m Tall	25.17
	-1.09	1.5 m Tall	28.47
	-2.59	Ground	48.73
Excavator	0	Eye-level	40.71
	-0.77	1.8 m Tall	46.74
	-1.07	1.5 m Tall	48.74
	-2.57	Ground	63.77
Motor Grader	0	Eye-level	27.22
	-0.88	1.8 m Tall	46.32
	-1.18	1.5 m Tall	48.55
	-2.68	Ground	68.45

(b)

At ground level	% Blind Spot
Bulldozer	58.42
Pick-up Truck	63.69
Dump Truck	62.98

(c)

Position	Path	Distance [m]	Visibility [%]
A	1	2.5	43.1
B	1	5.0	98.2
C	1	10.0	87.1
E	2	2.5	5.2
F	2	5.0	3.9
G	2	10.0	0.0
I	3	2.5	23.6
J	3	5.0	23.5
K	3	10.0	0.0

Table 1a shows the ratio of blind spots to selected equipment types in the construction field environment. One radius was chosen (10 m) to provide comparative results. Since the experiments were conducted in the construction environment, site layout and existing obstructions had measureable impact on blind spots. The measurement of blind spots preferably uses smaller radii. It is interesting to note (and surprising to the common believe that dump trucks have the largest blinds spots) that the selected (standard) excavator had a larger blind spot (about 41%) than the selected (standard) articulated dump truck (29%) (at the operator eye-level). A reason for this observation is the boom of the excavator that is blocking the FOV of the operator.
Table 1b shows the results to the manual calculations that were completed for three types of equipment. Since the actual scan data is analyzed in a CAD program and by hand, only the ground level plane was assessed. From these few measurements it can be noted that the manual procedure includes generally blind spots that are larger than the automated measurements.

5.2 Second Experiment (Worker Visibility)

In the second experiment the visibility of a person standing on the ground was calculated while varying the distance from the person to the construction equipment. This component of the developed blind spot measurement tool allows the opportunity to effectively visualize which locations around equipment are more dangerous than others. This infers a new method for detecting any hazardous work areas around equipment. The next steps explain how the visibility of a worker-on-foot from the operator's perspective was measured.
The plan view of the laser scan for a bulldozer is shown in Figure 4. The same figure also displays a cross sectional view (point A-C). Concentric distance circles are centered in the origin (eye of operator). The white areas illustrate blind spots and the visible areas are in color. The three radii for the circles are 2.5 m, 5 m, and 10 m, respectively. The three straight lines drawn represent the selected paths to measure the visibility of a person that is 1.8 m tall and 0.6 m wide (defined by a person's shoulder width). Noticeable become the positions A through C, E-G, and I-K. These letters represent the positions chosen for the worker in "standing" mode.

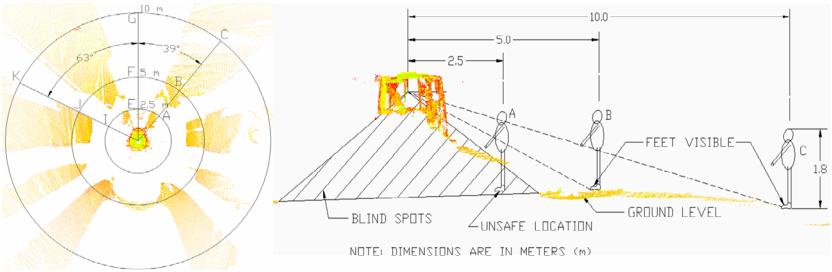

Figure 4: Worker visibility at different locations (A, B, and C) close to equipment.

Table 1c shows the percentage a person is visible at locations A through K. Notice that position B has many visible data points (visibility close to 100%) therefore a person at location "B" is most likely very well visible from the cabin of the dozer. Going from location B to C the percentage decreases from 98% to 87% visibility. This decrease is due to uneven ground conditions in the field. However, these results demonstrate that the developed blind spot measurement and analysis tool works in realistic construction environments.

On path 1, the decrease from B to C may also be due to objects on the construction site, or mounted objects inside or outside the dozer cab (e.g., mirrors), and a variety of other possibilities. Path 2 corresponds to locations E, F, and G (see Figure 4). The visibility of a person on path 2 is slim (less than 6% of a person's body is visible until reaching a distance of 10 m from the machine). This poor visibility is mainly the result of the operator's limited visibility due to obstructions on the front portion of the bulldozer (including the motor compartment, exhaust pipe, and front blade). Path 3 corresponds to locations I, J, and K, and runs parallel to a border between visible and invisible regions. Based on the initial hypothesis, parts of the worker-on-foot should be visible, while the other part may not be invisible. The results agree with the initial hypothesis, because approximately 23.5% of the person is visible at locations I and J, and 0% is visible at location K.

6. Limitations of Developed Approach and Future Work

Blind spot measurements, analysis, and results depend on equipment type and environment the measurements are conducted in. Several assumptions and limitations of the developed approach have been discussed in the sections of the paper where it the developed approach is most useful in. Future research is necessary to address its current limitations. Future research could focus on: (1) Expanding the current tool with more functionalities; (2) Build a spatial 3-D blind spot library (as it already exists for 2-D blind spot measurements); (3) Experimenting with safety zones and alert devices for operators and workers to protect their individual work envelopes; (4) Calibrating the developed blind spot tool to account for certain equipment characteristics; and (5) Developing a dynamic blind spot measurement and alert system that accounts for real-time tracking of the operator's FOV.

7. Conclusions

Equipment related incidents account for a large number of injuries and fatalities in

construction. Construction equipment blind spots are identified to be the cause for poor operator visibility. Existing practices have been developed for measuring blind spots but have limitations in the measurement approach as well as functionality. A novel blind spot measurement tool was developed. The terminology and a methodology that was used to determine blind spots were explained in detail. The use of a ray tracing algorithm to automatically measure the blind spots was demonstrated and results to experiments were presented. The functionality of the developed blind spot measurement tool was demonstrated under real construction conditions. It is envisioned that fully automated blind spot detection, worker-on-foot detection, real-time pro-active alert devices can be integrated in the operation of heavy equipment on construction sites and elsewhere. Safer and injury- and fatality-free work sites are a realistic goal.

8. Acknowledgment

This research was supported by the National Science Foundation (NSF) under grant #0800858, the Construction Industry Institute (CII) Research Team 269, Leica Geosystems Inc. and CW Matthews Inc. Their support is gratefully acknowledged. The views and opinions stated in this paper are the ones of the authors. Certain trade names and company products are mentioned in the text or identified in an illustration in order to adequately specify the experimental procedure and equipment used. In no case does such an identification imply recommendation or endorsement by the Georgia Institute of Technology, nor does it imply that the products are necessarily the best available for the purpose.

Abstract

Perhaps the greatest challenge facing the cost estimating community over the next decade is the loss of knowledge and experience of highly experienced estimators as a high percentage of them are retiring and a shortage of qualified cost estimators is evident in the construction industry. This study identified 23 core estimating competencies classified into skills, knowledge, and personal attributes and also identified the gaps between the current and desired level of the estimating competencies. In total, 228 completed questionnaires were collected through the Construction Industry Institute (CII) member companies, and the Association for the Advancement of Cost Engineering –International (AACE-I) and American Society of Professional Estimators (ASPE) workshops. A criticality matrix was developed to prioritize competencies based on the combined effects of the level of importance of each competency and its associated gap. The factor analysis technique has been applied to investigate the correlation effects of the 23 estimating competencies. An implementation tool which assesses the current level of competencies of an estimator or an estimating team and recommends appropriate training tools has also been developed. The findings of this study will help engineering and construction companies design and develop appropriate educational and training programs to enhance estimating functions.

1. Introduction

The cost estimate for a capital project is critically important to both owners and engineering/construction companies. Owners rely on cost estimates to perform

economic analyses for return on the investment from their capital expenditures. Engineering/construction companies rely on the cost estimate for bidding and negotiating work, which is the basis for securing future work and ensuring profitability of their companies. Most efforts to promote good estimating have focused on developing cost information, adjustments for time/size/location, and estimating tools, in particular automation of the estimating process by computer methods. However, those tools that aid the estimating process cannot replace the judgment and experience of a competent cost estimator. A recent article by the President of the AACE-I described a court case to illustrate that the sound judgment of estimators, based on their experience, is equal to and perhaps more important than the cost data information (Zack 2007). As a high percentage of experienced cost estimators are retiring, the construction industry is facing greater challenge of losing the knowledge and experience those estimators acquired through their career in the estimating profession. This study was conducted to identify and prioritize estimating skills, knowledge, and personal attributes required to develop qualified cost estimators and quantified the gaps between the current and desired level of the estimating competencies based on 228 completed questionnaires collected from estimating experts. This study grouped 23 competencies into seven major factors using the factor analysis technique and developed an implementation tool based on the findings of this study.

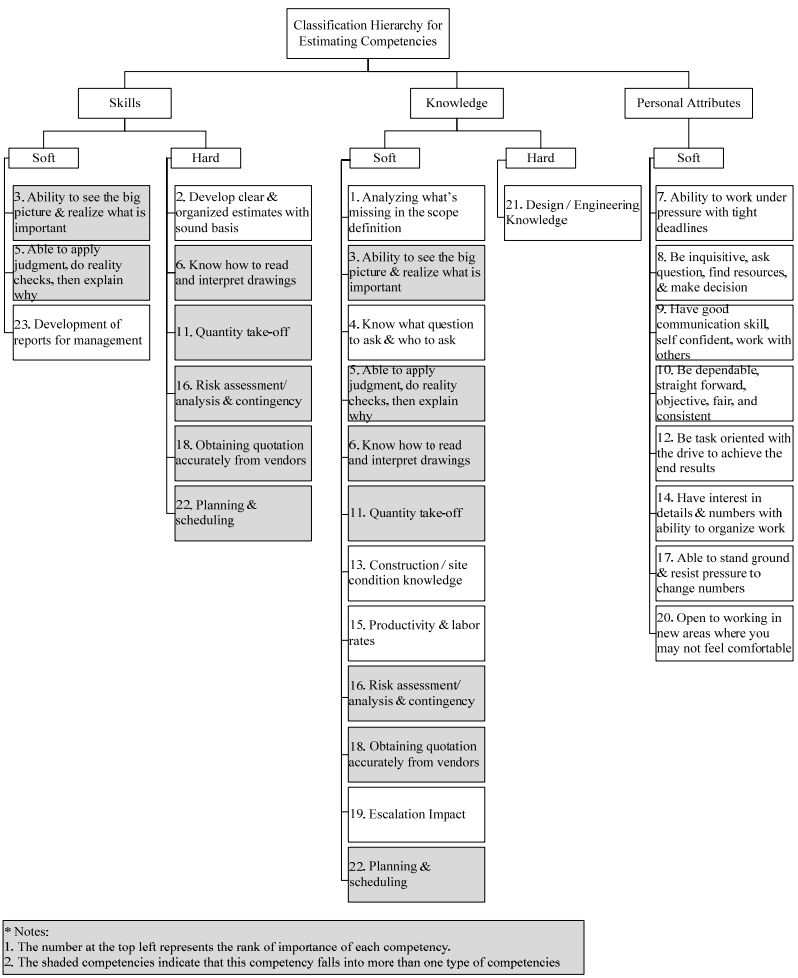
2. Data Collection

During spring and summer 2008, a questionnaire survey was conducted to obtain expert opinions on various issues in the estimating profession such as estimating functions, required estimating competencies, the gaps between the ideal and the current level of competencies, and current practices in recruiting, attracting, retaining, and training estimators. For this survey, a questionnaire of four sections with 37 questions was developed through a two day workshop with 22 expert estimators. The questionnaire was sent to all CII member companies, and also was distributed at the AACE-I and ASPE national workshops in 2008. A total of 228 completed questionnaires were collected. 79% of the respondents were from CII member companies, and 21% were from AACE-I and ASPE members. 31% of the survey participants were from owner companies and 69% were from non-owner companies. The data collected represented a total of approximately 3,500 years of experience in the estimating profession and 52% of the respondents had at least 15 years of experience in the estimating profession.

3. Core Estimating Competencies

Estimating competencies can be defined as a cluster of interrelated skills, knowledge and personal attributes required to properly perform an estimating job. In this study, 23 core estimating competencies were identified as important competencies required for developing good cost estimators. The identified 23 estimating competencies are

classified into skills, knowledge, and personal attributes. Skill is the ability to perform a certain estimating task, while knowledge is information an estimator has attained related to estimating, and personal attributes represent personal attitudes, traits or behaviors required to do good cost estimating. Furthermore, skills and knowledge are divided into soft and hard subcategories. Soft skills or soft knowledge is difficult to be taught or developed and requires more experience and training, while hard skills or hard knowledge is relatively easy to be taught, developed, and learned. Figure 1 shows the hierarchy of estimating competencies identified in this study.



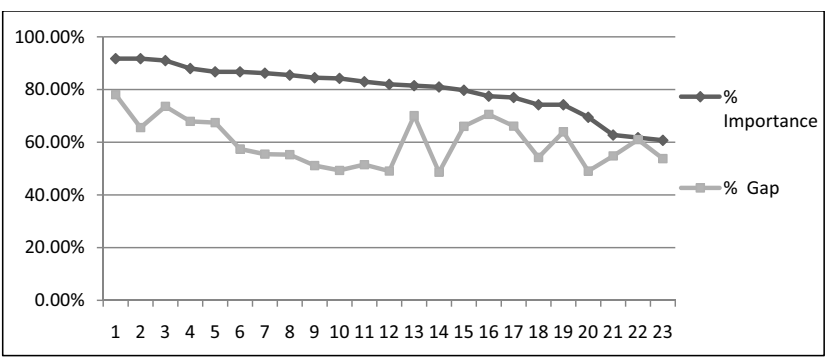


Figure 1. Classification Hierarchy of Estimating Competencies

4. Assessment of Estimating Competencies

In the survey, the importance of each of the 23 estimating competencies and the degree to which junior estimators typically lack in each competency were assessed using a 5-point likert scale. Figure 2 shows the assessment results of the survey data. The results are the average values after the 5-point likert scale was converted into a "0-100" percentage scale. The competencies are sorted in descending order on X-axis in terms of their importance values. The number of each competency matches with the number of competencies in Figure 1.

The top five most important estimating competencies are "1) analyzing what's missing in the scope definition", "2) develop clear and organized estimates with sound basis", "3) ability to see the big picture, realize what is important", "4) know what question to ask and who to ask", and "5) know how to read and interpret drawings". The top five biggest gaps exist in the competencies including "1) analyzing what's missing in the scope definition", "3) ability to see the big picture, realize what is important", "16) risk assessment/analysis and contingency", "13) construction/site condition knowledge", and "4) know what question to ask and who to ask". It is noteworthy that the largest gaps exist in competencies that are mainly classified as soft skills or soft knowledge. The nature of these competencies makes them very hard to be captured or learned.

X-Axis Legend	
1.Analyzing what's missing in the scope definition	12.Be task oriented with the drive to achieve the end results
2.Develop clear and organized estimates with sound basis	13.Construction/ Site condition knowledge
3.Ability to see the big picture, realize what is important	14. Have interest in details and numbers with ability to organize work
4.Know what questions to ask and who to ask	15.Productivity and labor rates
5.Able to apply judgment, do reality checks, then explain why	16.Risk assessment/ Analysis & contingency
6.Know how to read & interpret drawings	17.Able to stand ground and resist pressure to change numbers
7.Ability to work under pressure with tight deadlines	18.Obtaining quotations accurately from vendors
8.Be inquisitive, ask questions, find resources, and make decisions	19.Escalation impact
9.Have good communication skills, self confident, work with others	20.Open to working in new areas where you may not feel comfortable
10.Be dependable, straight forward, objective, fair, and consistent	21.Design/Engineering Skill
11.Quantity take-off	22.Planning and scheduling
	23.Development of reports for management

Figure 2. Assessment of Estimating Competencies

5. Criticality Matrix of Estimating Competencies

A criticality matrix was developed to prioritize the competencies based on the scores which are calculated using the importance value of each competency and the value of the associated gap with the competency. In calculating the criticality score of each competency, both the importance and the gap values of each competency are equally weighed. The criticality score of each competency measures the Euclidian distance from the point where an imaginary competency has the highest importance (100%) and the widest gap (100%) to a point where the competency is located in Figure 3 (see Equation 2). The criticality matrix classifies the competencies based on their criticality scores into five zones; most critical, more critical, critical, less critical and least critical zones. The criticality matrix provides an idea about which competencies should be given more efforts and time in training and educating estimators in order to improve the overall performance in estimating.

$$\text{Criticality Score} = \sqrt{(100\% - \%\ \text{Gap})^2 + (100\% - \%\ \text{Importance})^2} \quad \text{(Equation 2)}$$

Criticality Score	
0.00 – 28.28	Most Critical
28.28 – 56.57	More Critical
56.57 – 84.85	Critical
84.85 – 113.14	Less Critical
113.14 – 141.42	Least Critical

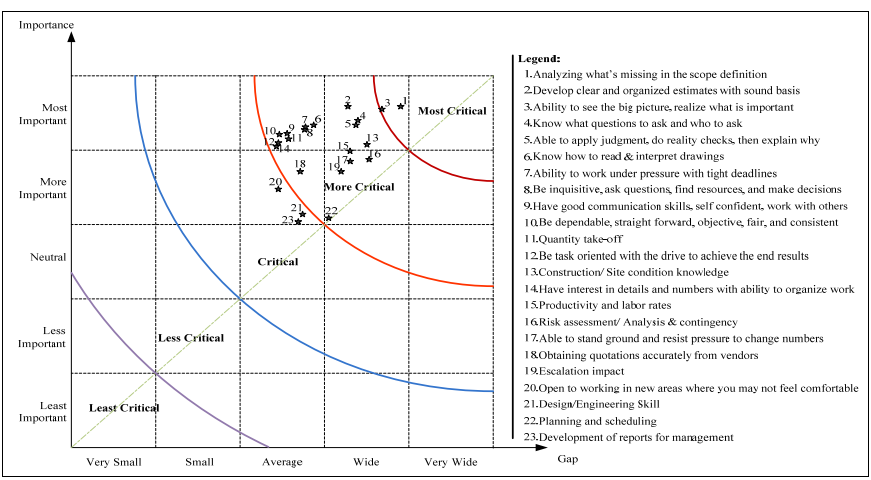

Figure 3. Criticality Matrix of Estimating Competencies

The criticality matrix (Figure 3) shows that all estimating competencies fall on three zones; most critical, more critical and critical zones. The two most critical

competencies are “1) analyzing what’s missing in the scope definition” and “3) ability to see the big picture, realize what is important”. These competencies are determined to be most critical because i) they are most important competencies for high quality estimating and also ii) they are the competencies that most estimators are significantly lacking (their gaps are very wide between the current level and the ideal level).

6. Factor Analysis

The factor analysis technique was applied to the identified 23 competencies in order to determine whether these competencies can be grouped under different factors and to categorize them into a manageable number of factors. The factor analysis investigates the correlation relationships between the estimating competencies. In order to use the factor analysis technique, the reliability of the scale used in the collected data and the appropriateness of using the factor analysis method on the data must be assessed first. The Cronbach alpha coefficient was used to test the reliability of the scale used in the collected data. The tests used for assessing the appropriateness of factor analysis include; Kaiser-Meyer-Olkin (KMO) for measuring the accuracy of the sample, Anti-image correlation for measuring the sample adequacy (MSA) for each variable, and the Bartlett test of sphericity (Akintoye and Fitzgerald 2000 and Field 2005).

The Cronbach alpha coefficient determines the internal consistency between the variables that measures particular characteristics, and the scale is determined to be reliable with cronbach alpha higher than 0.8 (Cramer 1994). The cronbach alpha coefficient on the 5-point likert scale used in studying the importance of the estimating competencies is 0.86, which indicates the scale is reliable. After testing the reliability of the scale used, the appropriateness of factor analysis was tested. The Kaiser-Meyer-Olkin statistic is 0.82 which means that the correlation pattern between variables is compact and thus makes the factor analysis appropriate. The Anti-image correlation matrix test shows that the MSA for all variables ranges between 0.68 to 0.91 and greater than 0.5 (Field 2005) which indicates that none of the variables needs to be eliminated and the factor analysis is appropriate. Finally, the bartlett test of sphericity was conducted to test whether the correlation matrix is an identity matrix or not. The result of the sphericity test is 1238.49 and its associated p-value is 0.000, which indicate that the correlation matrix of the variables is not an identity matrix and the factor analysis is an appropriate method.

After validating the appropriateness of using the factor analysis, the 23 estimating competencies were subjected to the factor analysis, with principal component analysis and varimax rotation. The principal component analysis uses the correlation between the variables to produce a smaller set of uncorrelated components, where the first component accounts for the greater variability in the data and the second component accounts for less variability and so on. The principal component analysis resulted in seven competency groups (factors) with eigenvalue greater than 1 and explaining 60.34% of the total variance in the data. Since the initial set of factors was difficult to interpret due to the unclear pattern of the factor matrix, the varimax rotation was used

to transform the principal component matrix into a new matrix for easy interpretation. The varimax rotation is an orthogonal rotation used to maximize the high correlations and minimize the low correlations. Table 1 shows the final seven factors resulted from the factor analysis along with the percentage of the variance that each factor explains. Each factor is a linear representation of the variables (competencies) and their loading on the factor.

Table 1. Seven Factors of Estimating Competencies

Factor 1 **(25.5%)** (Estimator's communication and work behavior)	Factor 2 **(8.70%)** (Basic knowledge required by an estimator)	Factor 3 **(6.79%)** (Preliminary tasks for developing quantity of work)	Factor 4 **(5.22%)** (Estimator's ability to analyze project scope and deal with the profession pressure)	Factor 5 **(5.02%)** (Ability to put together the project pieces and make decision)	Factor 6 **(4.68%)** (Construction process knowledge and judgment skill)	Factor 7 **(4.40%)** (Ability to produce a reliable estimate)
Be task oriented with the drive to achieve the end results	Escalation impact	Know how to read and interpret drawings	Analyzing what's missing in the scope definition	Ability to see the big picture, realize what is important	Construction/ site condition knowledge	develop clear and organized estimates with sound basis
Open to working in new areas where you may feel not comfortable	Risk assessment/ analysis and contingency	Quantity take-off	Know what question to ask and who to ask	Be inquisitive, ask questions, find resources, and make decisions	Able to apply judgment, do reality checks, then explain why	
Be dependable, straight forward, objective, fair, and consistent	Productivity and labor rates	Obtaining quotations accurately from vendors	Able to stand ground and resist pressure to change numbers			
Have good communication skills, self confident, work with others	Planning and scheduling		Ability to work under pressure with tight deadlines			
Have interest in details and numbers with ability to organize work	Design/ engineering knowledge					
Ability to work under pressure with tight deadlines	Obtaining quotations accurately from vendors					

For example, the third factor "preliminary tasks for developing quantity of work" includes competencies "know how to read and interpret drawing", "quantity take-off", and "obtaining quotations accurately from vendors" These competencies were grouped together because they represent the basic skills and knowledge required for developing quantity of estimating items. Another example is the sixth factor "construction knowledge and judgment skill" which consists of "construction/site condition knowledge" and "able to apply judgment, do reality checks, then explains why" competencies. These competencies are grouped together because for an estimator to make good judgments and justify his/her decisions, the estimator needs an extensive amount of experience in the construction field in order to familiarize himself/herself with different construction techniques, project execution methods, and different site conditions.

7. Implementation Tool

As a result of this study, an implementation tool was developed to help companies quantitatively evaluate estimating competencies, identify gaps and prioritize critical competencies, and design appropriate training programs for estimators. The implementation tool - Estimating Competency Assessment and Training Recommendations (EsCATR) is an independent excel based computer software program developed using Microsoft visual basic programming language. This tool is a user-friendly tool in which a user rates an estimator or an estimating team's performance for each of the 23 competencies and then, the EsCATR automatically generates five different reports including a competency assessment result, a competency assessment summary chart, a criticality matrix, a competency assessment result per factor, and training recommendations. The EsCATR tool provides companies with a means to evaluate their estimating workforce's capabilities and identify which competencies are most critical and require immediate attention in order to improve the estimating performance. The EsCATR can help companies in designing customized training programs for each individual or the estimating team based on the performance assessment results.

8. Conclusions

This study has addressed a growing concern about the loss of knowledge, skills and experience of cost estimators while the cost estimating profession is not fully prepared to solve this problem. This study has identified 23 core estimating competencies for developing qualified cost estimators. The competencies were classified into skills, knowledge, and personal attributes and were further classified into soft and hard subcategories. The criticality of each competency was assessed based on the importance of the competency and the associated gap of the competency between the current level and the ideal level. The study has found that most critical competencies are soft skills or knowledge which are difficult to be transferred. The study has grouped the 23 competencies into seven different factors using the factor analysis technique. A tool was developed to help and guide companies in evaluating the capabilities of their estimating department workforce, and gaps in each

individual's skills, knowledge, and personal attributes. The tool also identifies the most critical areas that require immediate attention to improve the estimating performance and the most appropriate training programs. This tool (EsCATR) is available at the CII website for download and use.

Future research in this domain should be geared toward identifying currently available education and training programs for cost estimators and assessing the coverage of the programs related to the core estimating competencies and the efficiencies of the programs. It will also be equally important to develop new methods and techniques to successfully capture soft and intangible estimating competencies and transfer them to the young generation of estimators.

ABSTRACT

The Project Health Indicator (PHI).was developed because traditional measures and tools used during project design and construction to track project progress often do not identify potential problems in a timely manner. The PHI tool is based on the identification and assessment of "leading indicators." Leading indicators are fundamental project characteristics and/or events that reflect or predict project health. Revealed in a timely manner, these indicators allow for proactive management to influence project outcomes. The PHI tool contains 43 weighted leading indicators based on survey methodologies and ranking analysis. The PHI tool quantifies non quantifiable measures, that is, "Gut Feelings," and provides an early warning of potential problems. The tool was validated using completed projects by checking statistical correlations between tool output scores and cost and schedule performance indices. Industry users of the PHI tool have successfully applied it in practice. The objective of this paper is to describe the research methodology for tool development and how it is being successfully applied by industry.

INTRODUCTION AND MOTIVATION

A typical construction project life cycle begins with planning where the project concept is developed and minimal scope definition is achieved. Projects proceed through different phases of development including design, construction and startup. Once a project budget is developed, traditional project control methods are used to monitor cost growth and keep actual costs as close to the initial budget as possible. Project cost increases are often an unfavorable project outcome that owners and contractors strive to avoid.

Project teams monitor the status of projects using traditional methods such as cost variance, schedule variance, performance ratios, milestone variances and earned value. These methods provide a measure of a project's current status relative to planned progress but may lack the ability to identify warning signs and project issues

that may indicate the degree to which the project is on the right track (Choi et al., 2006). Identification of issues as they emerge can draw the attention of the project team to potential problem areas that may require more attention. Using non-traditional methods such as the leading indicators (LI) identified in this research, project teams can identify issues that impact project outcomes significantly.

Past research indicates that managers have often not been satisfied with the use of traditional performance measures like return on investment and earnings per share in measuring organizational performance and have expressed concerns that the use of such methods could misrepresent a project's or an organization's performance (Kaplan and Norton, 1992). Kaplan and Norton (1992) developed a strategic performance assessment tool for use with traditional methods to measure project performance in terms of objectives.

To address concerns about the inadequacies of traditional methods to measure project performance, the Construction Industry Institute (CII) funded a research study involving industry professionals from CII member organizations. The research team developed leading indicators which could have significant impacts on project outcomes; these leading indicators are the basis for the development of the project health indicator (PHI) tool. The PHI tool was developed for use by project teams as an assessment tool that can forecast potential risk of not meeting specific project outcomes.

RESEARCH OBJECTIVES AND METHODOLOGY

The research team involved in the development of the PHI tool consisted of nine owners and ten contractors from CII member companies representing construction, petroleum, chemical, pharmaceutical, and manufacturing industries.

The team was formed with the main aim of achieving four research objectives (Choi et al, 2006):

- Identify leading indicators that impact project outcomes during project execution
- Determine the leading indicators which have the greatest impact on project outcomes
- Develop a tool for performing project reviews periodically based on the assessment of the leading indicators
- Validate the tool

The research team members established criteria that define a leading indicator. Some of the key characteristics of a leading indicator are that a LI must predict potential risks to future project outcomes and must correlate to project outcomes (Choi et al., 2006). The following definition of a leading indicator was established by the team members: *Leading indicators are fundamental project characteristics and/or events that reflect or predict project health. Revealed in a timely manner, these indicators allow for proactive management to influence project outcomes.*

The definition of a LI implies a relationship between LIs and project outcomes. This research therefore defined six project outcomes/factors critical to project success and

commonly used in industry as a measure of project success: 1) cost; 2) schedule; 3) quality/operability; 4) safety; 5) stakeholder satisfaction; 6) benefit attainment by research members. These outcomes were viewed against the planned objectives relating to that outcome. For instance, according to Choi et al. (2006) cost performance was viewed in terms of overall actual final cost versus the authorized project budget.

Initially, 181 potential leading indicators were identified by industry experts. The 181 identified LIs were then screened to determine those with the greatest impact on project outcomes. The industry experts reviewed the LIs using the following criteria:

- Did each leading indicator statement agree with the formal definition of an LI?
- What potential problem does each leading indicator address?
- What categories of project health does each leading indicator affect?
- Is there a tangible measure for each of the leading indicators?
- Is the leading indicator unique to the owner, the contractor or to both?

Of the 181 LIs reviewed by the project team, 66 similar LIs were screened out and eleven new ones were added bringing the total number of LIs remaining to 126. Three surveys were conducted to provide rationale for reducing the number of leading indicators and ensure consistency in the assessments. The first survey required that team members score the LIs based on their negative impact on project outcomes and further evaluate the 126 LIs by comparing owner, contractor and aggregate responses for each LI with the aim of eventually reducing the number of LIs further. Fifteen members responded to this survey (9 owners and 6 contractors) A four-point scale was used (Table 1) with a score of 3 indicating a high negative impact on the six project outcomes and 0 indicating minimal or no impact on these project outcomes.

Table 1. Four-point scale based on negative outcomes

Score	Impact on project outcomes
3	High negative impact on project outcomes
2	Medium negative impact on project outcomes
1	Low negative impact on project outcomes
0	Minimal or no impact on project outcomes

For the team member assessments, the LIs with the highest aggregate scores have the highest negative impact on project outcomes while the LIs with the lowest scores have the lowest negative impact on project outcomes. The maximum negative score for each LI was 45 (3 x 15 members) and assessments were performed for each of the six project outcomes making a maximum possible aggregate score of 270 (45 x 6 project outcomes) for each LI. Table 2 shows a sample of the overall assessments and ranking of the leading indicators for each outcome. For instance LI 148 was ranked number 1 by project outcome with a total score of 200 out of a possible 270.

Table 2. Overall Ranking of LIs by Total Scores for each Outcome (IR220-2)

LI No.	Cost	Schedule	Quality/ Operability	Safety	Stakeholder Satisfaction	Benefit Attainment	Total (max score: 270)	Ranking
148	36	38	34	27	34	31	200	1
79	36	40	35	22	32	30	195	2
43	40	39	25	19	36	33	192	3
123	37	37	36	17	30	31	188	4

There were significant variations in the results of the comparison of the overall rankings with the owner and contractor rankings. For instance LI number 148 which was ranked first in the group of owners was ranked 13 in the contractors group (Table 3). According to Choi et al. (2006) the variation may be attributed to differences in understanding, perception or interpretation of the LIs. This clearly shows that the understanding of an LI may be influenced by the nature of the project work, by the individual performing the assessment and the company perspective from which the assessment was performed.

Table 3. Ranking of LIs by Owners, Contractors, and Overall (RS220-11)

LI No.	Owners	Contractors	Overall
148	1	13	1
79	3	4	2
43	2	7	3
123	7	2	4

To reduce the number of LIs, the top 50 were chosen based on a comparison between the overall rankings, owners rankings and contractor rankings (Table 3) providing a list of 66 LIs because some LIs in the top 50 were selected by one group and not by the other. The top 10 LIs based on the project outcomes (ranked as shown in Table 2) were also included because the team determined that some key LIs may be left out otherwise if they were not included in the top 50 based on the comparisons. A total of 79 LIs were selected. Some new LIs were proposed by members and eight more were added to the list. The LI statements were then rephrased negatively to have more meaning since they represent potential future problems on a project.

A second survey was conducted to further reduce LIs that had the least impact on project outcomes. Thirty-three professionals from the industry participated in this survey. The team included 17 owners and 16 contractors. LIs were ranked as in the first survey using the four point scale (Table 1) based on their negative impact on project outcomes. The number of LIs was reduced to 53. At the end of the survey the 6^{th} project outcome (benefit attainment by research members) was dropped from the list of outcomes/factors because for owners it can only be assessed after a period of operation of a completed facility.

A third and largest of the three surveys was performed with a total of 84 respondents from CII member organizations, including 26 owners and 58 contractors/engineers/designers. They assessed the LIs and reduced the list to 43 LIs using a six point scale with the following options: no, very low, low, moderate, high and very high negative impact on five project outcomes. This scale was modified from the four point scale used in the first survey to improve the accuracy of assessments in reducing the LIs to 43. The 43 final leading indicators chosen were arranged in order of decreasing negative impact on project outcomes implying that the LI with the highest impact on project outcomes was first on the list. The same analysis and ranking was used for the third survey as used on the first and second surveys. The third survey formed the basis for the weighting of LIs based on the extent of their negative impact on project outcomes.

LIs were sorted into new categories called project practices to make it easier to analyze the final survey results, review the final list of LIs and build the project health indicator (PHI) tool. For this study, a project practice was defined as a process or method that, when executed effectively, leads to enhanced project performance. Eight project practices were identified from CII knowledge areas and used in this study. They are: 1) alignment; 2) change management; 3) constructability; 4) contracting; 5) quality management; 6) safety practices; 7) project control; 8) team building. Each of the 43 LIs was included in a project practice where it was most relevant. The eight categories can help users identify potential sources of risks to project outcomes and guide users towards developing potential mitigation strategies (Choi et al, 2006).

THE PROJECT HEALTH INDICATOR TOOL

The main idea behind the development of the PHI tool is that it should have the ability to measure project health and forecast the potential for meeting specific project outcomes. It should be a tool that can quantify a project evaluator's perception of current status based on weights assigned to each of 43 leading indicators identified by the research team (Choi et al, 2006).

The 43 LIs identified from the third survey form the basis of assessment the project health indicator (PHI) tool provides. Initial weights were determined based on survey responses for each of the LIs using:

$$Weighted\ score = \frac{Aggregated\ score\ of\ LI}{Standard\ deviation\ of\ the\ aggregated\ score\ for\ that\ LI}$$

Different weights were applied to each LI depending on how negative an impact it had on project outcomes and on the variation in the responses for each LI based on the 84 survey responses. Dividing by the LI standard deviation increased the weight for LIs with small standard deviations due to consistent survey responses for that LI. For tool development, different weights had to be applied to the LIs for use in assessing the project health.

To be able the fully understanding the meaning of the raw weighted scores and appreciate the extent of the negative impact on project outcomes, the weighted scores

were normalized to a total of 1000. The maximum of 1000 would only be attained if all the 43 LIs indicate that project is not experiencing any problems. On the other hand, a score less than 1000 indicates that the project is showing warning signs of potential problems. A lower the score reflects a higher risk of potential poor performance.

Measurement of Leading Indicators

Users of the PHI tool must assess leading indicators to be able to determine an aggregate score which would indicate how healthy a project is at that point in time. The PHI tool is designed for use at any point during project execution. Leading indicators are measured using a five point scale (Table 4) with a score of 1 indicating that the project may be experiencing serious problems or at the other extreme, a score of 5 indicating that the project is not experiencing any problems relative to the description of that LI.

Table 4: Five-point scale for measuring leading indicators

Scale	Focus
1	Serious problem
2	Major problem
3	Moderate problem
4	Minor problem
5	No problem

LIs are worded in a negative form to indicate potential problems achieving the desired project outcomes. The following is an example of a leading indicator stated negatively and showing the measurement considerations of each rating on the five point scale relative to that LI. An example of one LI with the scoring assessment scale is shown below (IR220-2):

Leading Indicator 37
Actual schedule activities are lagging behind planned scheduled activities over several reporting periods.
Measurement Considerations on a five-point scale

1. *The entire critical path has shifted beyond its planned dates, and previous non-critical activities are now becoming critical.*
2. *Critical path activities have slipped beyond their planned dates, but float remains on sub-critical activities.*
3. *A significant number of non-critical activities are being delayed, but the critical path is stable.*
4. *Some activities have lagged behind their planned dates, but they are non-critical and can be completed without becoming critical to the project.*
5. *Actual progress is tracking in accordance with planned schedule progress, and there are no delays.*

The ratings 1 to 5 on the scale focus on different measurement considerations for each of the leading indicators depending on the context in which it is used, that is a

rating of 1 on one LI may mean something totally different for another LI. For instance LI 27 is "The project manager (or team leader) is lacking in the required level of experience and skills" and rating 1 on the scale which implies a serious problem has the following measurement consideration: *Project manager is inexperienced and lacks many of the skills needed to lead the project to success.* The measurement considerations for LI 27 are different from that of LI 37. However, measurement considerations with the same rating express the same level of negativity on the five point scale for the LI measurement. All 43 LIs are described using a similar approach to LI 37.

LI Impacts on Project Outcomes and Project Practices

The impacts of the LIs are measurable and different for each of the five identified project outcomes: 1) cost; 2) schedule; 3) quality/operability; 4) safety; 5) stakeholder satisfaction. The LI with the most negative impact on a particular project outcome is the LI with the highest score for that particular outcome. The use of individual project outcomes can help focus a team's attention on general project areas that may need special attention, for example cost related versus schedule related outcomes. The different impacts of the 43 LIs on eight identified project practices can also be determined and can draw a project team's attention to potential or actual problem areas.

Using the PHI Tool

The PHI tool is a Microsoft excel based tool consisting of six tabs the first of which is the introduction tab that clearly details instructions for using the tool. The other five tabs are: Tab 2 - a user guide; Tab 3 - input tab; Tab 4 - an output-outcomes; Tab 5 - output-project practices; and Tab 6 - customization tab. The input tab (Figure 1) is where the user assesses each of the 43 LIs using the five-point scale as previously described. For each LI, the measurement considerations can be viewed by moving the pointer over the measurement scale (red comment indicator).

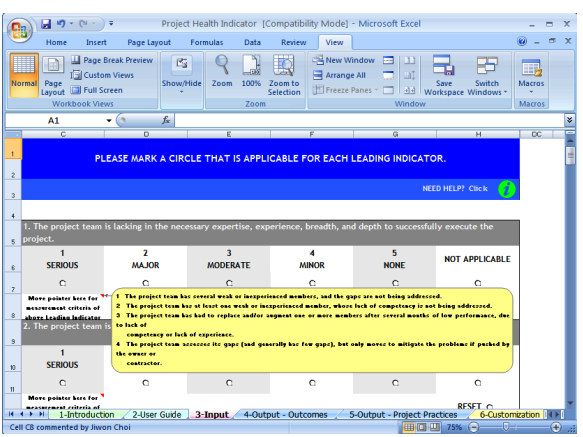

Figure 1: Screen Capture of the Input tab

Outputs of the assessments are shown on tabs 4 and 5 using calibrated speedometer-like gauges. Each gauge has three colors: red which is considered as high risk, yellow considered as moderate or medium risk and green considered as low risk of poor performance. The default ranges for the three colors are 70 percent, 15 percent and 15 percent respectively. The default ranges were set based on the results of the tool validation which indicated that a score below 700 (70%-red) was considered high risk (Choi et al. 2006). A score of 700 to 850 (yellow) was considered moderate risk and a score of 850 to 1000 (green) was considered low risk. Examples of the output outcome dials are shown in Figure 2. Similar gauges are used for the eight output-practices and can be customized according to user preferences.

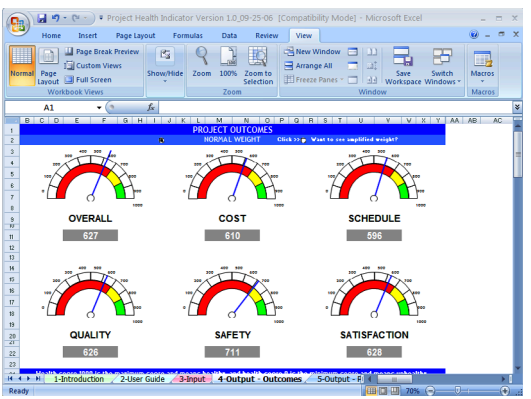

Figure 2: Screen Capture of the Output-Outcomes tab

Since riskiness is viewed in various ways by different organizations and levels of risk tolerance may vary, the dials can be adjusted based on user preferences.

PHI Validation

The PHI tool was developed using the 43 LIs as a basis for measuring the health of a project. The tool was tested and validated by industry professionals. Participants were asked to complete a questionnaire and provide performance data (such as planned versus actual cost and schedule) for past projects whether successful and unsuccessful. The actual performance data was required for comparison with the tool outputs for the same projects to determine if any correlations exist between the two. Past projects were evaluated in hindsight by one evaluator and current projects by a few different evaluators. An analysis of the data by regression indicated a high negative correlation between cost and schedule health scores and cost and schedule performance data (see Figure 3). This implies that projects that had higher health scores in the assessment were mostly projects that were completed on schedule or ahead of schedule, on budget or below budget. The tool was then finalized after the validation.

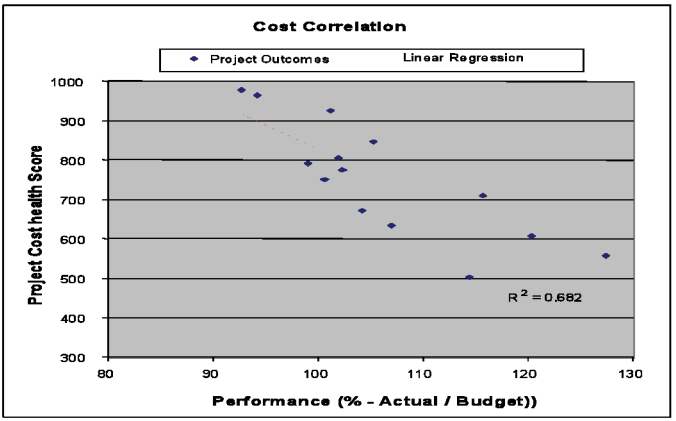

Figure 3. Cost Correlation Results

Use of PHI Tool

The tool is designed for use during the project execution phases. Prior to project execution, tools like the CII project definition rating index (PDRI) and the alignment thermometer can be used to assess the level of scope definition and team alignment with project objectives. The tool is most effective when used right after the completion front end planning and first use is recommended early in the detailed design phase. Tool effectiveness decreases as the project moves through the project development phases up until the end of construction as shown in Figure 4. The PHI Tool is not a replacement for traditional measures and its use is recommended to supplement traditional measures. Generally, LIs should as much as possible be evaluated through face-to-face meetings with project participants. Participation should include project participants from the various disciplines such as engineering, construction, safety, and procurement. All scores should be recorded even in cases when disagreements exist. Any disagreements will help draw attention of the project participants to areas where potential difficulties exist. Results can be communicated to and reviewed by the project team members to generate discussions and improve team focus.

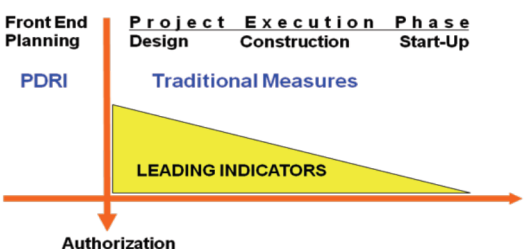

Figure 4: Change in Effectiveness of Leading Indicators

INDUSTRY APPLICATIONS OF THE PHI TOOL

When the tool was developed, its successful use was confirmed through case studies (IR220-2). One of the case studies was a schedule driven $3.2 million industrial revamp project. The scope of this project was to replace several aging refrigeration machines used to chill feeds to batch reactors. Initially, the main objective of the project was replacement of process machines without increasing the process capacity. The engineering contractor suggested a change in the process flow which would ultimately increase production rates without incurring any substantial additional costs. The suggestion was taken by the owner and the scope was revised to include the increase in process capacity. Some configuration changes and tie-ins posed difficulties as a result of the short notice of the process scope change. In addition the construction area was congested, a few key construction crafts fell ill and were replaced by new ones who were less experienced. Project forecasts indicated potential cost overruns and schedule slippage. One accident was recorded when a worker was injured by a loose piece of insulation sheathing.

The PHI tool was used by the owner and contractor project managers to evaluate project performance at 98 percent engineering completion and 35 percent construction completion. The assessments were discussed and combined. The results showed consistency with the project situation. It indicated a warning for potential cost overruns (red zone), and even greater potential problems with meeting the schedule (red zone) (Figure 5). Individual assessments of the LIs and reconciliation of the project managers' responses is useful for gap identification to focus the project team's attention on issues that may be critical.

A large engineering-contractor organization has used the PHI tool to evaluate project health. Practices were assigned to appropriate functional expert reviewers and the results were reconciled and analyzed by members of the review team. PHI Tool outcomes ranged from as low as 300 to 400 and as high as 800 to 900. Analysis of practices indicated few problems with alignment, safety, and contracting. On the other hand, constructability, quality management and change management were areas where poor performance was occurring. Gaps were identified for company-wide action based on low scores for specific LIs in the latter three practice areas.

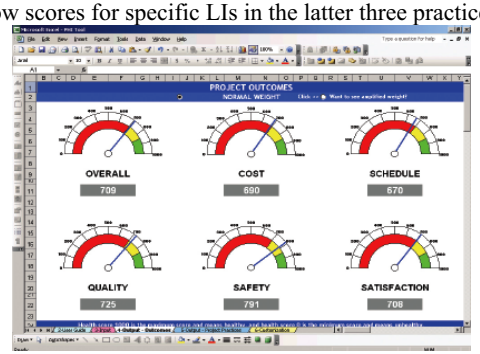

Figure 5: Case Study Project Outcome Gauges

A government agency and their consultant have utilized the PHI tool on the $12 billion waste treatment and immobilization plant project scheduled for completion over a 20-year horizon. The scope of this project involves the treatment of radioactive waste. The project has experienced technical uncertainties and cost growth which continued even after the project baseline was reviewed in 2006. Since 2007, the use of the PHI tool has provided early warning signs of problem areas that initiated corrective actions. Each year, PHI scores are compared with the previous year. Improvements shown in all measures are reflected in increasing PHI scores.

CONCLUSIONS

The research team identified 43 leading indicators that have a substantial impact on project outcomes and can effectively measure project health. The tool is most effective when used from the beginning of detailed engineering through construction. It can be used by project managers, directors of multiple projects and auditors for team evaluations, global project reporting and for review of project performance data respectively. The tool is designed to supplement traditional methods. The PHI tool was validated using actual projects and it was observed that there were high statistical correlations between the tool output scores and the actual project outcomes. Appropriate use of this tool will enable project teams identify early warning signs of project problems and take appropriate preventive action as suggested by industry applications.

Abstract

Quality Management Systems in the capital facilities delivery industry were examined to identify best practices. The research surveyed 118 owner, contractor and supplier firms, performed statistical analysis of the responses, and conducted targeted structured interviews with 17 firms. The survey revealed several statistically significant areas where organizations with self-reported highly successful quality management systems differed from those organizations with self-reported less successful systems. Structured interviews were conducted to examine the practices of successful companies in greater depth. Through a synthesis of the results of the survey, the structured interviews, and a literature review, the research found that organizations with highly effective quality management systems had demonstrable management commitment with adequate resources for effective quality management; capable and consistent quality procedures across the organization; integrated and aligned quality management and project execution processes; effective training; strong partnerships with suppliers and contractors across the project life cycle; metrics that met organizational and project needs; and quality metrics used during all stages of engineering, procurement, construction, and start-up and commissioning. The survey results for leadership and third-party certification are presented here.

Introduction

The quality management boom took place over 25 years ago, resulting in the development of a discipline known as Total Quality Management (TQM). There were many players and developments in this era, but the mark made by the so-called "gurus" including Shewhart (1931) for plan, do, study, act; Deming (1986) for his 14 Points for Management; Juran along with Gryna (1980) for their Economics of Quality Conformance; Crosby (1979) for his zero defects, do it right the first time, and the Quality Management Maturity grid; Ishikawa (1990) for his fish bone diagram; and Taguchi (1993) for his quality loss function were profound and still remain significant today. However, advancements in technologies, tools, and processes have changed the quality management systems (QMS) used for capital facilities project management. QMS and the associated knowledge base have evolved and expanded. Practices once thought to be valuable have lost some of their effectiveness. Consequently, there is a need to identify and analyze the QMS, programs, and continuous improvement activities being used in the construction industry today.

The Construction Industry Institute (CII), established in 1983, is a consortium of leading owners, engineering and construction contractors, and suppliers who have a singular mission: to improve the cost effectiveness of the capital facility project life cycle, from pre-project planning through completion and commissioning. Over the past 25 years, CII has sponsored research in the quality management domain within the following broad areas: quality management, risk reward, total quality management, quality performance measurement, and do it right the first time. Reports / documents culminating from these research efforts are categorized as Body of Knowledge (BOK) 8.01 on the CII website (see https://www.construction-institute.org/scriptcontent/index.cfm.) In total, there were 21 research documents developed (17 which are currently active) in five CII-sponsored Task Forces (TF) and Research Teams (RT). Table 1 shows the historical development and relationships of these 17 active documents in or related to the 8.01 BOK.

One of the first CII task forces was the Quality Management Task Force (QMTF), commissioned in the summer of 1985. The mission of this initial effort was to identify, develop and disseminate information to improve the effectiveness of quality management in the construction industry. During its four-year life, the task force undertook three research studies and published seven CII Publications (only three of which are still active CII documents and thus depicted in Table 1). It became readily apparent to this task force and CII that the topic of quality in the construction industry would need additional attention and focus long after they completed their work. One of the major recommendations of this first task force was for CII to continue research in this important area.

In the spring of 1990, CII formed two additional task forces focused on quality, the Total Quality Management Task Force (TQMTF) and the Quality Performance Measurement Task Force (QPMTF). The purpose of the TQMTF was to further investigate the implementation of TQM in the construction industry. One of the main products of this task force was a roadmap for implementing TQM from a broad,

company-wide perspective. The QPMTF focused its attention on measurement at the project level.

Additional research was conducted by CII over the next 15 years and documents were published in 1992 by the Risk Reward Task Force, in 2001 by the Cause and Effects of Field Rework Research Team, and finally in 2005 by the Do It Right the First Time Research Team.

Methodology

A survey of the CII membership was used as a data gathering instrument. The survey consisted of 31 questions and was divided into four areas relevant to quality management in the capital facilities industry. The Demographics/Respondent Data category included five questions about the organization such as the respondent's role in the organization, the title of highest-ranking management representative responsible for implementing quality procedures, the number of employees in the organization, and the number of employees in the organization with quality as a key responsibility. The QMS for capital projects category included ten questions regarding the standards and guidelines used by the organization, certification policies, training, documentation procedures, and audit procedures. Metrics used by the organization and its suppliers were determined in seven questions in the Metrics used in QMS for capital projects category. The Incentives, Methods and Programs used in QMS for capital projects category covered data regarding the organization's QMS processes in nine questions.

The CII membership served as the sample frame and in all, 148 surveys were sent to 118 organizations. It was left to the discretion of the organization to select the company personnel that would complete the survey. It was requested that the respondent should have the best perspective on the organization's QMS. After the survey was distributed, two reminders were sent to the organizations. Thirty three responses were received by the initial deadline and after reminders were sent, a total of 53 responses from 47 distinct organizations were received. The response rate based on distinct organization and total number of responses was 36% and 40% respectively. In order to maintain the confidentiality of the respondents, the surveys were coded by removing the respondent organization's personal information, i.e., company name, personnel name, title, location, contact information.

As a first step, the responses for the 31 survey questions were analyzed to obtain the descriptive statistics. For this analysis, the surveys that were submitted by the same organization were treated as a unique response, since the perspectives of respondents from the same organization may be quite different from one another.

The survey questions consisted of three types of questions: Yes/No questions, five-point Likert scale questions, and open-ended questions. The descriptive statistics for the Yes/No questions and Likert scale questions were straight forward. The open-ended question responses were categorized and classified based on their similarity in order to obtain the descriptive statistics. The purpose was to organize a large amount of data into a smaller number of categories such that statistical analysis of the question could be done. Categories were defined and iteratively refined into a final list of categories.

The survey responses were also analyzed by the following groups.

Organization type: The majority of the participant organizations are owners and contractors (49% and 32%, respectively). The descriptive statistics of the survey responses for "owners" and "contractors" were created to compare these two groups.

Organization size: By grouping the organizations into "large" and "small" categories, differences between these two groups were examined for certain questions.

Effectiveness of QMS: The descriptive statistics were split into organizations whose QMS was self-reported as "extremely effective" and organizations who did not self-report that their QMS was extremely effective.

QMS certification: Separate groups of descriptive statistics were created for organizations who certified their QMS by a third party or parties and those organizations who do not certify their QMS.

Several other combinations of organizational attributes were created and compared such as owner organizations that self reported that their QMS was extremely effective compared to contractor organizations that self reported that their QMS was extremely effective.

In the analysis of the data categorized and classified as described above, the research team focused on the differences among the descriptive statistics of the comparable categories such as "owners" vs. "contractors" and "extremely effective" vs. "others." Hypothesis testing and statistical analysis was used in order to determine whether there was a significant difference between any two categories. In the hypothesis tests, four statistical tools were used: the Chi-square, Two Proportions, and Fisher's Exact tests, and one-way Analysis of Variance (ANOVA).

Results

Leadership

The survey question "In your organization, what is the title of the highest-ranking management representative responsible for implementing quality procedures for capital facilities delivery?" was asked in order to determine where responsibility for quality management rested in the organization's management structure. This was a multiple choice question with an open ended option. Choices given were "Director," "Vice President," "Manager," or "Other."

Fisher's Exact Test was used to analyze whether the titles of the highest level individual responsible for quality procedures was significantly different for owners vs. contractors and for respondents that self-reported that their QMS was extremely effective compared to those respondents that did not. The following two groups had a statistically significant difference:

1. Respondents that self-reported that their QMS was extremely effective vs. those that did not when testing the number of responses of "President" and "Vice President" combined as the title of the highest-ranking management representative responsible for implementing quality procedures for capital facilities delivery; and

2. Owners that self-reported that their QMS was extremely effective vs. owners that did not when testing the number of responses of "President" and "Vice President" combined as the title of the highest-ranking management representative responsible for implementing quality procedures for capital facilities delivery.

There was a statistically significant difference at the 90% confidence interval (CI) ($p = 0.106$) between organizations that self-rated their QMS as extremely effective compared to organizations that did not self-rate their QMS as extremely effective when testing the number of responses of "President" and "Vice President" combined as the title of the highest-ranking management representative responsible for implementing quality procedures for capital delivery. Responsibility for implementing quality procedures were at a higher management level for organizations who self-rated their QMS as extremely effective compared to organizations that did not self-rate their QMS as extremely effective. Organizations that self-rated their QMS as extremely effective had more Vice Presidents and Presidents responsible for implementing quality procedures for capital projects compared to organizations that did not self-rate their QMS as extremely effective (see Figures 1a and 1b).

The research also found that in these organizations, management actively participates in quality management both at the project manager and the vice-president level. Participation is usually through ISO 9001 and monthly executive meetings. QMS implementation is seen as the primary responsibility of management. High rated organizations usually have a corporate vice-president for quality and have disciplined and standardized processes.

The research found that organizations with self-rated highly effective QMS had management that was highly committed, provided a great deal of support, and allocated budget for quality at the corporate level in addition to the business line level. In high rated organizations, quality managers are visible and in place. They make use of scorecards to measure effectiveness and their consistent leadership throughout the organization ensures that the QMS is applied.

There was also a statistically significant difference at the 95% CI ($p = 0.010$) between owners that self-rated their QMS as extremely effective compared to owners that did not self-rate their QMS as extremely effective when testing the number of responses of "President" and "Vice President" combined as the title of the highest-ranking management representative responsible for implementing quality procedures for capital delivery. Fifty-three percent of owners that self-rated their QMS as extremely effective had Vice Presidents and Presidents responsible for implementing quality procedures for capital delivery compared to 26% of owners that did not self-rate their QMSs as extremely effective.

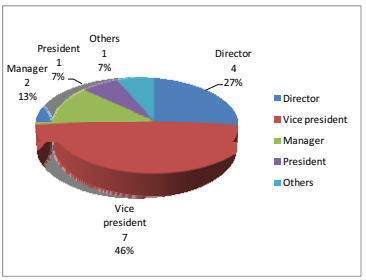

Figure 1a: Distribution for the title of the highest-ranking management representative responsible for implementing quality procedures for capital projects for organizations with self-reported extremely effective QMS (N=15)

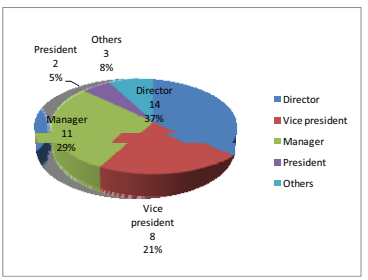

Figure 1b: Distribution for the title of the highest-ranking management representative responsible for implementing quality procedures for capital projects for organizations that self-reported their QMS other than extremely effective (N=38)

QMS Certification

The question "Is some, or all of your organization's QMS certified by a third party or parties?" was asked in order to determine the frequency and importance of third party certification. This was a yes/no type question. The "yes" response contained multiple choice options as well as an open ended option. Multiple choice categories were "ISO 9000," "Nuclear," "ASME," "API," "AWS," and "Others." Descriptive statistics for an organization's QMS certification by a third party or parties for all respondents reported 55% (29 respondents) indicating "no," 43% (23 respondents) indicating "yes," and 2% (1 respondent) who did not respond.

Fisher's Exact Test was used to compare third party QMS certification for owners vs. contractors and for organizations that self-reported extremely effective vs. not extremely effective QMSs.

There was a statistically significant difference at the 95% CI ($p = 0.000$) between owners compared to contractors when testing for "yes" as the response for third party certification of the QMS. Seventy-six percent of contractors had third party certification of their QMS versus 19% of owners.

There was also a statistically significant difference at the 95% CI ($p = 0.002$) between organizations that self reported their QMS as extremely effective compared to organizations that did not when testing for "yes" as the response for third party certification of QMS. Eighty percent of organizations that self reported their QMS as extremely effective had third party certification compared to 29% for organizations that did not self report an extremely effective QMS.

Finally, there was also a statistically significant difference at the 95% CI (p = 0.036) between owners that self reported their QMS as extremely effective compared to

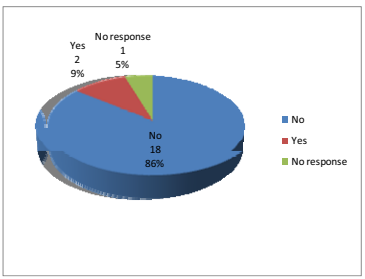

Figure 2a: Distribution for an organization's QMS certification by a third party or parties for owners that self-reported their QMS other than extremely effective (N=20)

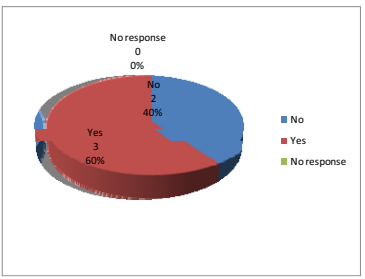

Figure 2b: Distribution for an organization's QMS certification by a third party or parties for owners that self-reported their QMS as extremely effective (N=5)

owners that did not self report their QMS as extremely effective when testing for "yes" as the response for third party certification of QMS. Owners that self reported their QMS as extremely effective had third party certification of their QMS more frequently compared to owners that did not self report their QMS as extremely effective (see Figures 2a and 2b).

For organizations with self-rated highly effective QMS, certification provides an external perspective and review of the QMS. These organizations reviewed their QMS anywhere from biannually to every 2 or 3 years, and these reviews were done by external reviewers. Management uses the results of the review to improve the QMS and the reviews are considered to be valuable for improving the QMS as well as the strategic alignment of the organization.

Conclusions

The research determined that there were differences in quality management practices regarding leadership and third-party certification between organizations. The following is a summary of the overall key quality management practices of effective organizations in terms of leadership and certification. These practices have generally been integrated into the organization's business management system and processes. This is not to say that other less effective organizations do not follow some of these practices, but what has been observed in organizations with highly effective quality management is a consistent commitment by top management with strong visible leadership and accountability.

Organizations that self-reported an extremely effective QMS had the following differences with respect to leadership and third-party certification as compared to organizations that did not self report an extremely effective QMS:

1. Leadership: Responsibility for quality rests higher in the organizational hierarchy.

Responsibility for implementing quality procedures were at a higher management level for organizations who self-rated their QMS as extremely effective compared to organizations that did not self-rate their QMS as extremely effective. Organizations with extremely effective QMS more frequently responded that the responsibility for their QMS was at the President and Vice President levels compared to other organizations. There is consistent, visible leadership that is more extensive throughout the organization, and at the highest level such as Vice President of Quality. Furthermore, highly effective owner organizations lead by example, not simply by delegating responsibility for quality to contractors including providing training to contractors that enhances their understanding of requirements and arranging meetings and work sessions with contractors to ensure alignment of project deliverables.

2. Certification: More frequently certify their QMS.

Organizations that self-rate their QMS as extremely effective are more likely to have third party certification compared to organizations that did not self-rate their QMS as extremely effective. Some or all of a highly effective organization's QMS is regularly reviewed (every 6 months to 3 years), adding value through the external audit by improving and validating the QMS and by improved project satisfaction and quality. The organization's top management reviews the results of the audit and uses them to improve the QMS and align certification with its strategic business interests. When owners and contractors are compared, contractors are more likely to have third party certification than owners, regardless of whether they self-rate their QMS as extremely effective or not. Contractors are also audited by owners in addition to 3rd party auditors, making it likely that contractors are more frequently externally audited than owners.

In conclusion, quality management is a broad term and there is a great deal of diversity in QMS interpretation and implementation across organizations. Further research is needed to define the appropriate elements and characteristics of a range of quality management criteria for capital facilities delivery by organization type, project type and for different business units.

Acknowledgements

The authors acknowledge the support from the Construction Industry Institute (CII) for their generous support of this research effort. They are particularly indebted to the Research Team 254 – Quality Management Refreshment.

An IDP-BIM Framework for Reshaping Professional Design Practices

D. Forgues and I. Iordanova

Department of Construction Engineering, Ecole de technologie superieure, 1100 Notre-Dame West Street, Montreal, Quebec, H3C1K3; (514)396-8668); FAX (514)396-8854; daniel.forgues@etsmtl.ca, ivanka.iordanova@videotron.ca

Abstract
Integrated design process (IDP) and Building Information Modeling (BIM) have been recognized as two approaches to address the problem of fragmentation in the construction industry. Adopting these processes and tools nonetheless requires drastic changes in design practices. There is a need for generating and formalizing new knowledge practices, and discarding obsolete ones. However, traditional approaches to create and transfer this new knowledge cannot cope with this need. This research builds on social learning theories, such as activity theory, to propose a situated learning environment in which BIM-related technologies are structured in an IDP framework. This learning environment is designed as a laboratory where traditional practices in planning, managing and designing construction projects can be challenged. BIM and simulation models, together with collaboration tools are used as boundary objects to break barriers between professional practices. Design teams, by adapting to this new environment, generate new practice knowledge. This knowledge is captured using ethnographic methods to enhance and consolidate the IDP framework. The proposed approach contributes to accelerating the co-generation of new knowledge practices within the proposed environment.

Introduction

The problem of fragmentation has been widely recognized, both by the research community and in industry, as a core problem related to the industries loss of productivity (Allmon et al. 2000, Goodrum and Haas 2002), lack of or unreliability in meeting project constraints of cost, schedule and quality (Egan 1998), and/or the loss of value (Koskela 2000). Some large clients (the UK and the US governments) have taken stiff measures to induce changes in current practices, promoting the integration of design and construction processes or improving the management of information. The use of Integrated Design Processes (IDP), Integrated Project Delivery (IPD) or Building Information Modeling (BIM) is now part of the clients' requirements to the supply chain for the definition or realization of a building project. These new requirements have not, however, brought the expected improvements in existing practices. Authors argue (Moore and Dainty 2001, Forgues et al. 2009) that resistance

to changes, especially by design professionals, seems to hinder integrated team performance or the adoption of BIM. However, the construction management literature does not provide a convincing explanation about the source of the problem, nor its solution.

Research on practices suggests that the problem is related to the nature of the organization of work in construction. As opposed to disciplines in similar industries – in which collaborative work is built on task-discontinuous status structures with highly fragmented divisions of labor and diverse bodies of knowledge – design practices are built on a guild organization of work, in which relationships are defined around a structure of power and influence based on their members' skills, knowledge, experience, and mastery (Clegg and Hardy 1996, Forgues 2008). This actually hinders problem-solving and knowledge creation across functions, due to compartmentalization (Carlile 2002, Engeström et al. 1995, Janis 1982) and a lack of knowledge articulation among experts (Blackler et al. 1999, Boland and Tenkasi 1999).

We argue that the change from fragmented to integrated processes and management of information is a change of paradigm. The standard organization of work and bodies of knowledge or codes of practices are becoming more or less obsolete in this new context; and the generally-recognized theories and research paradigms in engineering may not be appropriate to address this problem. There is thus a need to build on a new set of theories and related empirical research related to the generation and transfer of new knowledge in construction; and to devise a research approach for generating new knowledge of practice. The research goal is to develop a new IDP-BIM body of knowledge integrating planning and design practices at the definition phase of a project. The amount of new knowledge of practice to be generated is significant. It is our view that this challenge requires breaking boundaries within research disciplines and between research and industry. One of the aims of this paper is to encourage and motivate the academic research community into preparing a first version of an IDP-BIM body of knowledge. We present here the first version of an IDP-BIM framework, and the preliminary results of a pilot project in which students were involved in a design simulation based on this framework. Some of the expected contributions from this work are to theory, regarding new methods for generating knowledge of practice, and to industry, by proposing ways to address socio-cognitive barriers that hinder the performance of integrated teams.

Background

In information technology research, it is acknowledged that to fully reap the benefits of technology, the organization of work, processes and methods often have to be redesigned. Pundits in IDP agree that integrated design is irrelevant without the validation of design solutions using simulation tools (Eastman 2009). These tools have now been related to BIM technologies. We put forward that the rethinking of design practices to meet new client requirements has to occur and will occur around IDP and BIM. The challenges, therefore, are to generate a new body of knowledge of practices to cope with these changes in the environment of construction projects, and to accelerate the knowledge transfer to practitioners.

Koskela (2000) posits that the problem with the existing professional practice codes is that there is a lack of adequate theory supporting the understanding of the construction process. He suggests that the design and construction process should not

be based on project management but on production theory. According to his theory, production in construction should balance three "views": transformation, flow and value (TFV). He asserts that the problem with existing practices is that they are built around only the transformation view: this Taylorist model of work organization is weak at managing the interdependencies between work packages and inefficient in generating value for the customer. Winch (2002) emphasizes the problem of information processing within this view. The sequential and fragmented design and delivery process creates information gaps between phases, resulting in a building product that is sub-optimal and not up to client needs and expectations. To address the flow and value problems, research and studies have suggested integrating project information within one product model through interoperability; or reorganizing the project definition and delivery around an integrated design or construction process (Larsson 2002, Löhnert et al. 2002). These concepts present two different perspectives: linking distributed work within an integrated virtual environment, or organizing work around multidisciplinary teams. In the former, project teams replicate traditional interactions in a virtual world; in the latter, client and supply chain representatives actively collaborate within a new, iterative framework in which the team members are co-located, a process that encourages learning and innovation.

Research on initiatives to "rethink construction" or to adopt integrated design and BIM technologies indicate that there are three socio-cognitive factors that hinder the implementation of the required changes to existing design practices (Forgues 2008). First, professional associations in construction are based on what could be qualified as a guild structure. The traditional role of a guild is not to endorse the evolution of existing bodies of knowledge but to preserve the status quo (Lawson 2006). Second, research in construction reflects the fragmentation of the industry – researchers work in isolation and there is little integration of knowledge, even within engineering. Third, the market value of a design professional is based on their specialized knowledge. Changing roles and methods put this unique knowledge at risk (Carlile 2002). Dominating actors may use their power and influence to create barriers to developing shared meanings by refusing to modify the knowledge and interests from their own domain (Brown and Duguid 2001, Carlile 2004).

Emerging theories and empirical research in design science and social learning shed new light on how to address the socio-cognitive problems obstructing the evolution of design practices. For example, researchers in social learning have done empirical studies in the military and chemical industries in an effort to pinpoint the origin of conflicts between management and engineering in the process of changing the configuration of work to fit a new logic of value centered on innovative products (Blackler et al. 1999, Vinck 2003, Vinck and Laureillard 1996). It was observed that engineering groups resisted the changes in roles and relationships required by management – specifically, moving the leadership of product definition from engineering to marketing or business units and involving users in the design process – with the aim of offering innovative products that were based more on user needs. These researchers posited that such a change demands an evolution of the engineers' practice frameworks and of the way they conduct design activity. The proposed changes to the framework included: greater involvement during shorter amounts of time; moving from a prescriptive to an adaptive approach to requirements, from

sequential contributions to a collective process, and from specialized expertise to devoted individuals.

These changes demand not only reconfiguring existing bodies of knowledge, but also breaking the fragmented mental models and work structures that define roles and relationships in the traditional project design and delivery process.

A theoretical foundation for evolving design practices

In the field of construction, there is almost no literature related to how to address the problems, the socio-cognitive barriers hindering the generation and adoption of a new body of knowledge for integrating design practices. The problem is not limited to the construction industry. According to Vinck (2003), there is little ethnographic research that addresses the problems related to barriers created by specialized knowledge. One of the obstacles is the fragmentation in research work. Engineering is concentrated on developing working rules (*règles de l'art*) and tools; management on increasing performance by changing delivery models from sequential to concurrent or integrated; psychology on defining cognitive processes; and sociology on shaping these cognitive processes. Not much is said about how people interact during the design process. It is still difficult to identify all the actors, activities and roles: the sharing of activities remains ambiguous within the new organization of work for integrated design (Vinck and Laureillard 1996).

Nonetheless, there have been some breakthroughs from studies in social learning (activity theory and situated action theories). These theories suggest that learning and knowledge generation occurs mainly within a social process defined as an activity. "The activity itself is the context. What takes place in an activity system composed of object, actions, and operation, is the context. Context is constituted through the enactment of an activity involving people and artifacts" (Kaptelinin and Nardi 2006). Hatchuel (2002) argues that the design activity is regulated by the final object, which is absent until it is achieved. The conceptualization of this "*objet absent*" is realized through the representation of intermediary objects, also called "objects-in-use." Design professionals are surrounded by these objects-in-use: tools for designing, validating and exchanging. For example, even if new technologies are used in design, the collaborative process within building design workshops is still paper-based and dominated by architects.

As asserted by Lawson (2006), the perception that design is the result of one individual creative act is rooted in architecture training and is deeply embedded in architects' practice knowledge and tools. To be effective, multidisciplinary teams in design workshops need to break the power and knowledge barriers and build a shared mental model. This means that all participants need to be able to develop a shared ownership of a project, and engage in a mutual learning process. This also demands retooling, i.e. redefining the collective objects and artifacts around which the integrated design process can be articulated. Changes will be required not only in practices, but also in the way that design science is researched and taught.

Research and teaching in engineering is built on the paradigm of natural science. In contrast to the natural or social sciences, social learning theories (activity and situated action) regarding design are not just about explaining but also about intervening in phenomena with the aim of transforming its reality Niiniluoto (1993). Simon (1996) argues that the "raison d'être" for research regarding design is to advance both

science and practices. But this role remains elusive, hence the justification of design science as a new science paradigm aimed at creating "practice knowledge". From design science we adopt the concept of developing a set of rules, namely a body of knowledge; and from the social learning theories the concepts of situated learning (Lave and Wenger 1991), boundary objects (Carlile 2002, 2004) and expansive learning (Engeström 2002). According to these theories knowledge is created through interactions between the individual and the collective (situated learning) and between individuals, tools and the collective (activity theory, distributed cognition). The integrated design activity is viewed as a mutual learning process in which people interact through mediating objects to achieve a common goal.

In summary, Koskela's TFV theory provides a theoretical foundation for the technical aspects in devising a new body of knowledge. Social learning theories, taken from a design science perspective, offer a fertile ground in which to devise a research approach for addressing the socio-technical issues.

The research design and method

Other disciplines have developed evolving bodies of knowledge. For example, there are two international organizations (the Association of Project Management and the Project Management Institute) that are producing and updating a project management body of knowledge on a regular basis. Our first design strategy for an adaptive process to evolve an IDP-BIM body of knowledge is to borrow from the experience of IEEE in the development of the Software Engineering Body of Knowledge (SWeBoK). This body of knowledge started as a research project. It was developed in three successive iterations (straw man, stone man and iron man). The straw man version was produced by the researchers and included the development of the ontology of knowledge and a first draft of the content, which was based on relevant literature. The stone man version was then evolved by practitioners that were recognized as experts in one or more of the themes. Finally, the iron man version was the result of an overall review of the proposed practices by the broad base of the community. This review is now conducted every four years to update the content of the body of knowledge.

These bodies of knowledge are nevertheless built on existing knowledge, focusing on developing consensus on recognized practices. IDP and BIM are new approaches to design for which it is required to learn "what is not yet there". It is creation of new knowledge and new practices for a new emerging activity. The second strategy is derived from the work development methodology proposed in activity theory for expansive learning, i.e. a method aimed at generating, mediating and routinizing new knowledge for design practices. It combines three approaches. First, there is the *learning laboratory*, in which new technology is introduced to destabilize existing practices. According to Engeström's (2002) activity theory, collective learning can be accelerated by acting on the objects used in an activity within a laboratory (in this case BIM technology), inducing the creation of new knowledge within the IDP. New knowledge is mainly generated during unique activities involving multiple disciplines (Leonard-Barton 1995). Second, *communities of practice* are to be created for mediating and routinizing this new knowledge. According to Blackler's (1999) theory on knowledge and innovation, organizations are networks of knowledge and sense-making activities systems, grouped around communities of practices. A proper

context has to be set at the beginning, to stimulate the production of this new knowledge (perspective shaping), and then each community, through consensus, has to review, mediate and incorporate this new knowledge within their own body of knowledge (perspective shaping). Third, BIM and collaborative technologies are used as *boundary objects,* a specific type of mediating object for representing, learning about, and transforming knowledge to resolve the contradictions that exist at a given boundary between two or more of these communities (Carlile, 2002). Several authors (Engestrom 1995, Carlile 2002, 2004) suggest that boundary objects could play a key role in generating and mediating learning in the context of an activity involving representatives from different practices.

A *learning laboratory* was first set up, into which the design team is placed in an unfamiliar context that challenges their traditional work patterns and power structure. Engeström's Development Work Methodology is used to facilitate the co-production of new knowledge. The laboratory consists of a large room equipped with a new set of *boundary objects*: collaborative tools: intelligent boards and wireless technology that allows files or URLs to move between screens (thereby saving digital drawings from a whiteboard) and thus allow collective web browsing and file sharing with the whole group, BIM technology (parametric software for 3D, 4D, 5D and energy simulation) and a 3D projector. The researcher then approached a 3D software user group and helped them develop a *community of practices* for IDP-BIM. Next, a *pilot project* was devised. A pilot project is a good approach to validate a research strategy and to calibrate the instruments to be used in the core of the research. The pilot consisted of an experiment with an early version of the IDP-BIM framework. It involved a group of 38 students, comprising 12 graduate students in architecture, 14 students in construction engineering (structure and cost estimating) and 12 students in mechanical engineering. One of the teams worked in the learning laboratory; four other rooms were equipped with similar technology, for a total of 5 teams.

Identifying relevant research methods was a challenge, since the research community in construction and engineering is not familiar with most of the methods used in research on social learning. Nardi (1996) advocates the use of a varied set of traditional data collection techniques including interviews, observations, video, and historical materials, without undue reliance on any one method (such as video) and recommends paying attention to broad patterns of activity rather than narrow episodic fragments that fail to reveal the overall direction and import of an activity. Interactions using technology as boundary objects for collaboration, planning, design and management are captured through audio and video and coded using Nvivo 8. Data from the observations are triangulated with interviews, questionnaires, and the review of the electronic documents and data exchange through the virtual network. The result is then framed using cross-comparisons within the ontology of patterns devised by researchers for task analysis and that of the team members' level of maturity in collaborative work (Fruchter 1999). All of the design sessions were videotaped. Students also filled out two types of questionnaires, one to identify conflicts and contradictions in the team interactions, one to measure the evolution of team members' perceptions of their ability to share knowledge with other disciplines.

Devising the IDP-BIM framework

This first draft of an IDP-BIM framework is derived from two sources: best practices in system and software engineering for conducting collaborative design work; and findings from previous research in the experimentation of a requirement-based approach to integrated design (Forgues and Eugenie 2009). The framework focuses on the project definition, i.e. the development phases preceding the preparation of the working drawings. It is well-recognized that opportunities to maximize value occur at the early phases of a project. This is the reason why proponents of IDP suggest moving the core of design efforts from the detailed design stage to the project definition, which encompasses planning, program, concept and preliminary design.

The core of the framework is the combination of a gating process derived from configuration management and an agile process derived from software engineering. Integrated Design Processes (IDP) was first used in product and system development after World War II (Ziemke and Spann 1993). With the development of complex software-intensive products in aerospace, software engineering evolved these processes-combining agile development methods with the configuration management process from system engineering. Agile methods are based on short and intense collaborative design phases that deliver successive versions of a complete solution. Configuration management is a rigorous requirement-based validation and verification process conducted at the end of an iteration (identified in industry as a gate) to measure the level of compliance of the solution (at this point) to the functional and technical requirements. The combination of these methods has permitted the defects, development time and cost of complex products to be drastically reduced.

The framework is divided into three successive iterations, the first to validate the users' requirements, develop the sustainability strategy and devise the model of reference, the second to analyze the options and generate a concept, and the third to refine the concept that proved to be effective to design, and to do it within the constraints, each closed by a gate. At the outset of the process, the integrated team receives a set of targets and requirements to meet at each gate. They collect feedback from the gating reviews as inputs to improve their design within the next iteration.

The technologies are divided into three groups within the framework: automating the verification and validation of the design outputs in the gating process; facilitating visualization using 3D design software; and supporting options or constructability analysis and collaborative design with simulation tools.

Conducting the pilot study

The project is a future building that will be dedicated to the student community of a university in Montreal. The future users wanted to be involved the in the design process. It was proposed to develop a special course using a situated learning approach. Three universities and two departments in engineering participated in the project. The program was rich and complex from a sustainability perspective. It encompassed diverse functions such as a hockey rink, a swimming pool, commercial space and offices for students' clubs and associations. A coffee shop was included in the project. Soil conditions were a challenge as the site had been a landfill over an ancient river bed. At each stage, the teams had to demonstrate the financial and technical feasibility of the project.

The *learning laboratory* was duplicated in four other spaces to accommodate the five teams. Each team had access to an intelligent board or Sympodium**,** collaborative software**,** 3D parametric software for architectural design, cost-estimation and energy simulation. The process followed the IDP-BIM framework with the exception that no technology was used for validation or verification of the design outputs. An electronic version of the 3D model of the site and its surroundings was provided to the students. The teams worked over three two-day intervals, separated by two-week intervals. Iterations were closed by a three-step verification and validation process. For the verification process, the teams had to comply, for each step, with a set of requirements to demonstrate the value of their strategy in regard to sustainability, financial and technical feasibility, and compliance to budget and program constraints. This verification was conducted by professors in the related disciplines. The validation process was realized through a public presentation in two stages. In the first stage, experts from industry and representatives from the administration and student associations were invited to provide comments regarding the design, sustainable construction or the management of the future facility, and their perceptions about the suitability of the solution. In the second stage, the public was invited to give their evaluation on three criteria using an electronic voting device.

The results were quite impressive considering the fact that most of the students were unfamiliar with the technologies and had never worked with other disciplines in a collaborative environment. The simulation also allowed interrogation of the hypotheses found in the literature regarding the concept of interoperability. Integration is not only a matter of exchange protocols, but also of rules to be developed on the conduct of the design process. For example, the way that 'rooms' are defined in 3D software will determine if the energy simulation software will be able to extract or analyze the design data that were transferred. Therefore, within an IDP-BIM environment, it is not only necessary that the disciplines develop a common language for sharing knowledge, but also that they share a common understanding on how each BIM technology works and how they communicate with each other.

Discussion and conclusion

The aim of a pilot study is first, to validate the value of the theories to be verified through an empirical investigation, and second, to select and calibrate the research instruments to be used for the core of the research. One of the key contributions of the here defined first version of the framework is to propose a process in which technologies are used as accelerators for innovation and knowledge generation in the project definition process. In current IDP frameworks, little has been written on how technology is integrated in the process, whereas it is recognized that IDP is almost worthless without the use of simulation tools. Literature on BIM focuses on how to increase productivity by facilitating coordination during detailed design and construction. Thus far, there is almost nothing in the literature about how technology can contribute to improve the project definition process. Another contribution is the integration of multiple feedback loops within and between design iterations to accelerate collective learning and knowledge generation. The proposed theoretical foundation and its application for this empirical research proved to be convincing and to justify the acceleration of collective learning between disciplines and the capture, mediation and routinization of knowledge.

The pilot project also helped to identify knowledge gaps in both architectural and engineering teaching that could be addressed in future work. Architectural teaching is focused on developing a student's ability to resolve wicked problems through design; engineering teaching concentrates on the procedural problem-resolution of 'tamed' problems. Unsurprisingly, at the conceptual phase of the project, engineering students did not demonstrate the same level of reflexive skills in devising solutions to complex design problems as the students in architecture. Both replicated the traditional pattern of power and influence conveyed by industry, in which the architect designs before the engineer specifies his/her solutions for making the building work. This fragmentation was also reflected in the way teachers in architecture and engineering assisted the students in solving design or technical problems.

The core concept of activity theory – as opposed to situated action theory – is the ability of the researcher to help the members of the activity to pinpoint the conflicts and contradictions that affect their collaborative work and to resolve them. This means that the researcher has to be able to first capture and analyze patterns, and then provide feedback to the team within a very short time. However, this proved to be a difficult task to manage. Too many quantitative and qualitative tools were used. They permitted the capture of a large set of data for research, but hindered the researchers' ability to provide feedback to the team in a timely or effective manner. For example, a quantitative method using a questionnaire to assess the members and team's ability to resolve conflicts was used. The students had to fill in the questionnaire at the end of an iteration. They received the results of the analysis before the next iteration. The aim of the tool was to help the team to become aware of the conflicts and resolve them. However, the students were too preoccupied to realize the deliverable within the short timeframe and did not use this feedback to improve their efficacy.

This research is exploratory. The contributions to knowledge or practice may be limited at this stage. However, as asserted by Van de Ven (2007), understanding how research can advance scientific and practical knowledge is an ongoing challenge for scholars researching professional practices, and developing such an approach could be considered as a contribution in itself, at both the theoretical and empirical levels. The pilot project helped to test and asses various methods and instruments and to develop a more robust research protocol.

The next step will be the building of the knowledge base to complete the first version of the framework. Ontology was developed as a canvas for the framework with relevant information regarding the organization of work, process, methods and tools, based on the literature and on experimentation conducted in the laboratory (Forgues et al. 2009). Preliminary results from this experiment will be added to this knowledge base and shared with the BIM community of practices. A group of early adopters from industry (client, architects, engineers and contractors) will participate in workshops for sharing their own experience in IDP and BIM. A pilot project is in negotiation with a major public client to test an updated version of the framework derived from these workshops. In parallel, a more focused effort will concentrate on a unique boundary object, 3D energy simulation software, for mediating the interactions between architects and mechanical engineers for the development of holistic solutions to the design of high-performance buildings.

ABSTRACT

Market demands for improved infrastructure and a more sustainable built environment are increasing the importance and scope of construction engineering throughout the project development process. Despite this, many construction programs face pressures to increase coverage of construction management topics, lessening time for construction engineering. These two opposing trends form the background for this paper.

The goal of the paper is to provide compelling reasons and useful guidance to restore the balance between engineering and management in construction education. The method of analysis is to identify the priority fundamental elements of construction engineering knowledge and to describe the learning approaches applicable to each. The main contributions are a structure and methods for learning about construction engineering that are applicable to all types of construction.

The paper also includes recommendations for educators to increase coverage of construction engineering using new learning approaches, for industry to assist in offering relevant courses, and for researchers to further develop construction process models and other tools with potential benefits for construction engineering education.

INTRODUCTION

Many characteristics of current construction markets and firms create a need for increased attention to construction engineering education. Increasing priority for certain project objectives and criteria, such as life cycle performance of the facility, is increasing the technical scope of buildings and infrastructure. New technologies with significant potential to help increase project performance, such as increased integration and modeling, are requiring new technical capability in

firms and on projects. However, other drivers are increasing emphasis of construction management topics in many graduate and undergraduate construction programs. Both engineering and management topics are important for young engineers seeking successful careers related to the built environment; a balanced approach is needed.

The purpose of this paper is to help restore the balance between the engineering and management in construction education. The major sections highlight the importance of construction engineering education, describe what it includes, and suggest use of proven and encouraging new ways to help young engineers learn about it. The conclusions highlight actions by all stakeholders in construction to advance construction engineering education.

NEED FOR CONSTRUCTION ENGINEERING EDUCATION

Several key new features of constructed projects and rapid technological advancement create a strong need for young engineers to bring a solid technical background to their initial positions in design and construction firms. This section reviews trends in requirements and new technology. It argues that a technical foundation can also provide major advantages for diverse types of careers related to the built environment.

Trends in market and project requirements

Leading owners, now even more than in the past, want constructed products with increased performance, sustainability, and life cycle value. As a result, many parts of the built environment are increasing in scope and technical complexity. In addition to wanting an improved product, leading owners are seeking significantly improved performance of all project activities required to meet each type of objective: cost, schedule, quality, safety, and sustainability. These increasing demands on projects prompt the involvement of many types of specialists during design, construction, and commissioning. This requires broader technical understanding by the project managers, project engineers, and construction engineers who engage, coordinate, and manage these specialists in performing activities such as environmental compliance.

New technology

Rapidly advancing information technology creates major opportunities and challenges for increased project performance and needs for construction engineering. Research to develop new tools for construction process modeling encourages greater creative breadth and technical depth in evaluating alternatives for construction methods and other parts of field planning (Kunz 2009). This will increase the effectiveness of design-construction integration, construction planning, and construction engineering activities to support field operations (Tatum 2005). However, taking full advantage of the potential offered by these tools will require background in construction engineering.

Increased offsite work and mechanization or automation of specific fabrication and limited erection operations require understanding manufacturing operations and detailed planning for assembly operations at the site. Realizing each of these opportunities for project performance improvement requires a basic technical understanding of design processes and products along with construction resources and field operations.

Students' background and career opportunities

Many young engineers are very comfortable with information technology and attracted to modeling tools and activities to support planning and analysis. Real estate development, facility management, and other possible careers related to the built environment are potentially interesting to a growing number of students and graduates. These and other career paths related to constructed facilities benefit from construction engineering knowledge. Using this knowledge to get very good at performing an important task can provide significant benefits for the start of careers in design or construction. Construction engineering knowledge can also provide a major career advantage by increasing communication and rapport with all professionals, disciplines, and trades involved over the full lifecycle of the project.

CONSTRUCTION ENGINEERING ACTIVITIES, EDUCATIONAL GOALS

For this paper we will define construction engineering as the application of technical fundamentals and knowledge from experience to integrate design and construction, foster innovation in both, provide technical information and physical resources for field operations, avoid and solve field problems, and transfer experience between projects. Technical input to planning and estimating is a key construction engineering activity early in the project.

The activities mentioned in the definition lead to two broad goals for construction engineering education. First, students completing a set of construction engineering courses will be able to apply technical fundamentals and knowledge related to resources and operations to provide construction engineering support to meet all project objectives, to learn quickly from doing this, and to gain increased capability and responsibility. Second, they will continue learning from experience and gaining career advantages based on superior performance of construction engineering.

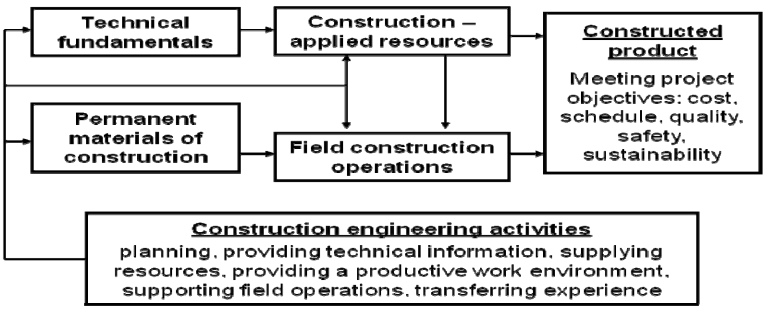

Figure 1. Knowledge elements and activities for construction engineering

PRIORITY CONTENT

Construction engineering knowledge consists of four elements: technical fundamentals, materials, construction resources, and field operations (Figure 1).

Technical fundamentals

Technical fundamentals provide a foundation or context to understand design and construction products and processes. They are the engineering basis for the performance of both the constructed facility and the resources and construction operations needed to build it. Including fundamentals from multiple disciplines as a main topic in construction engineering education recognizes the interdisciplinary nature and provides a generalizable foundation for experiential and lifelong learning.

The major engineering disciplines involved in most types of constructed facilities include: materials science and engineering; mechanics and dynamics; geotechnical engineering; structural engineering; fluid mechanics; thermodynamics, psychometrics, and heat transfer; electric power, and process control and instrumentation. Design engineers apply engineering fundamentals to define the function and performance of systems and for analysis and design. Construction engineers need to understand the fundamentals for each discipline and how they are applied in the design of the permanent facility and temporary works.

Materials of construction

The basic bulk materials of construction are soil, concrete, steel, other metals, and architectural materials. Engineered materials included permanent equipment and fabricated portions of distribution trees in systems. Design properties of materials include chemical, physical, performance requirements, and special restrictions such as toxicity. Construction properties include: cost, availability, potential for substitution, interdependency with construction operations, and toxicity.

Knowledge of the basic materials properties and of the standards that define them, such as ASTM, is necessary to understand design intent and avoid and solve field problems. Design and construction properties of materials are often a key consideration in establishing many types of design requirements and in evaluating alternate construction methods. Materials properties are a major part of the shared knowledge required for effective design-construction integration. Materials of construction and field operations are highly reciprocally related; they influence and constrain each other. This means that selecting materials of construction requires knowledge of field operations and planning construction operations requires knowledge of materials properties.

Construction-applied resources

To build the work, construction forces use many types of materials and equipment that do not remain with the completed facility. These include consumable materials, salvageable materials, tools, and construction equipment. The capabilities and limitations of these resources are often the major consideration in selecting construction methods. Criteria to select types of construction-applied resources described in construction engineering courses include: widely used, influence on project objectives, young engineers involved, and includes an IT component.

Important construction engineering knowledge related to resources includes: technical requirements and performance for typical uses, how it works, capabilities and limitations, best applications, degree of mechanization and potential for automation, major risks of use, implications for all types of project objectives, and examples of evaluation and selection. For more complex and critical construction resources, such as large cranes and construction equipment, full understanding of capabilities and applications will require analysis at a systems level, such as traction or power train systems for earthmoving equipment (Tatum et.al 2006).

Field construction operations

Completing any part of a constructed facility requires a series of field operations. These activities required to complete a specific type of work follow a sequence:

Earthwork: erosion control, clearing and grubbing, stripping topsoil; excavating, hauling, placing, compacting, and testing soil; finishing surfaces, grade checking.

Concrete: fabricating and erecting formwork; placing reinforcing steel and other embedded items; batching, transporting, placing, finishing, curing, testing, and repairing concrete. Concrete work may also include special methods and operations such as precasting, shotcrete, underwater concrete, slurry wall construction, and roller compacted concrete.

Structural steel: ordering and detailing steel shapes; fabricating, coating, transporting, and shaking out fabricated steel members; raising, plumbing, connecting, and testing portions of steel structures.

Permanent equipment for building or plant systems: specifying performance requirements, reviewing technical information from suppliers; fabricating and testing equipment; transporting, receiving and storing equipment items; installing, connecting, and testing equipment.

Piping and ductwork: detailing, coordinating, and fabricating pipe spools or duct pieces; transporting, erecting, supporting, connecting, and testing pipe or duct branches.

Electrical systems: detailing, coordinating, fabricating, transporting, and installing raceway; transporting, positioning, pulling, terminating, and testing electrical cable.

Priority learning for each type of operation is determined by the knowledge required to complete construction engineering activities.

LEARNING APPROACHES FOR CONSTRUCTION ENGINEERING

Felder and Brent (2009) developed a model of learning styles that contrasts four activities: perception, input modality, processing, and understanding. *Perception* contrasts sensing learners who focus on external input and practical and concrete thinking with intuitive learners who focus on internal input and imaginative and abstract thinking. *Input* contrasts visual learners who focus on images with verbal learners who focus on spoken or written words. *Processing* contrasts active learners who learn best doing something and thinking out loud with reflective learners who think about presented material and work introspectively. *Understanding* contrasts sequential learners who learn by logical sequential steps with global learners who want to view the big picture, absorb information randomly, and synthesize it.

Felder and Brent report that most students are sensors and most faculty are intuitors and encourage using a varied approaches to appeal to all types of learners. They advocate active learning approaches, often linked with inductive methods, involve the students in inductive processes to increase their understanding. They define and solve problems and receive instruction and assistance during the process.

Building on these learning styles, possible methods for teaching and learning the elements of construction engineering knowledge identified above include the three approaches described in this section: traditional, active, and integrated.

Traditional learning approaches

The classroom portion of traditional learning is often mostly passive and deductive in nature. Teachers communicate the fundamentals using one of the methods described below and students then deduct increased understanding through derivations, examples, and applications in assignments Felder and Brent (2009).

Lecture with examples. Class description of selected topics from each element of construction engineering knowledge can provide a useful starting point. The broad scope of the discipline and the potential depth of each topic create a major challenge for the instructor. Even devoting the majority of class sessions to this approach, and missing the opportunity offered by the active and integrated approaches described below, does not allow adequate coverage in most programs. Focusing on lecturing also does not give the students the experience of application. Traditional problem sets can provide part of this if focused at the correct level of analysis.

Reading, analysis, and application. Guided by questions that require critical analysis and application, students can gain valuable understanding of construction engineering topics from course notes, textbooks, or handbooks. Some form of input from the students prior to the applicable class session, such as a response to a query or a set of questions on the reading, increases their learning. If reviewed in advance of the session, this input also helps the instructor structure the class to further develop the topics that were especially interesting or difficult to understand.

Find, analyze, and apply. The vast amount of information available on the Internet supports learning through discovery and application. Many of the types of information used in construction engineering activities, such as the technical aspects of materials or construction equipment, is easier to find, more complete, and more current when obtained from the Internet rather than hard copy. Learning to use this resource in the most effective way also provides background for continued learning. Assignments involving this approach need to include requirements for comparison and analysis of results, along with specific findings related to the construction engineering topics.

Active and cooperative learning approaches

Brief pair discussions. Each of the four elements of construction engineering knowledge is a good candidate for brief discussion between pairs during class sessions, as strongly advocated by Felder and Brent (2009). Examples include: use fundamentals to analyze a site condition or a resource; forecast the implications of materials properties such as plastic concrete; speculate on the most likely failure mode of a crane making a specified lift; or develop a recommended sequence of installation for plant systems.

Extended group class exercises. Group exercises to select a construction method and forecast production rates are a very effective learning approach for all the elements of construction engineering. Completed during class sessions, these exercises typically require prior analysis of project conditions and alternates for resources and operations. The student groups then receive the detailed questions at the start of the class session, complete the analysis to respond to the questions, and submit a summary report by the end of the session. Student feedback indicates that this is an effective learning method for construction engineering

topics and also provides valuable experience concerning task organization for effective group processes.

Structured visits and field trips. Visiting firms and active construction projects provides a very valuable learning opportunity. Progressive design and construction firms welcome student visits and willingly share information that contributes to learning about construction engineering. Realizing the full potential value of this learning opportunity requires a structured approach. This can include prior research and questions by the students, assignments to collect and analyze specific types of information, and reports to summarize what they learned.

Group projects to analyze resources or construction operations. The overall objective of group assignments is to increase learning through analysis and application of construction engineering knowledge. Possible activities include modeling operations, forecasting production rates for alternate construction methods, and analyzing different types of risk. A course project for groups to focus on a construction operation and its analysis and application on a project or in a firm can also provide an excellent learning experience. This learning method requires student groups to investigate a field operation in a firm, ideally on a project.

Integrated learning approaches.

Context-sensitive learning approaches provide many benefits. Related to construction engineering topics, they require some background but can potentially add breadth and depth of understanding by providing a situation and requiring application of the four elements of construction engineering knowledge.

Design-construction integration and design build. A Stanford degree program focusing on design-construction integration provides a very valuable opportunity for learning construction engineering topics with emphasis on those that involve linkage with design. The purpose of the program is to prepare students for multidisciplinary collaborative teamwork in an integrated design and construction process. It extends background with courses that emphasize integration decision making related to the design and construction of concrete and steel structures.

Virtual design and construction. Researchers seeking to improve work processes in design and construction, manufacturing, and other fields have developed modeling and other tools with potential applications in construction engineering education. These tools allow individual, group, or class exercises to evaluate multiple alternatives for design approaches and construction methods.

A Stanford course focused on virtual design and construction illustrates this learning approach (Fischer, Kunz 2009). It includes product, process, and organization modeling. The course project applies construction engineering knowledge to visualize, integrate, and automate design and construction work processes. Examples of construction engineering activities in student course

projects include: analyzing construction access and workspace, avoiding conflicts between collateral work activities, obviating safety problems, and considering alternatives for temporary ground support.

Project-based learning. These group activities to develop a design that fully considers the methods to build the facility can provide excellent learning opportunities related to each phase of a project. The members of the group who provide construction input can apply construction engineering knowledge to develop plans and estimates for alternate design approaches. This increases learning for the team regarding the benefits of considering construction methods early in the project.

A long-term course at Stanford illustrates the benefits of this approach (Fruchter 2001). Structured by global project teams, it requires an integrated process with team members in the roles of owner, architect, structural engineer, and construction manager. The collaborative process requires analyzing construction requirements and constraints, along with developing a cost estimate and a schedule. Examples of construction engineering activities in the projects include: construction input to the architectural and structural design, construction site and logistics planning, erection planning for precast concrete or steel structures, and planning and estimating to evaluate design alternatives.

CONCLUSIONS, IMPLICATIONS, AND RECOMMENDATIONS

The analysis of construction engineering education in this paper leads to conclusions regarding the critical need, a helpful structure for the contents, and effective learning methods in the classroom and on the jobsite. These conclusions highlight implications for all the stakeholders in construction engineering education.

Need, elements, and learning methods for construction engineering education

Need. Challenging projects, new requirements for field operations, new materials, and new IT-enabled resources for construction increase the need for attention to construction engineering. The combination of opportunity in specific market segments, new uses of information technology, and the interests of young engineers prompt opportunities for rewarding career paths related to the built environment.

Construction engineering activities are critical for project success in meeting all types of objectives. Completing many of these activities early in the project increases the alternatives available for design, construction, and the value chain, along with the potential for integration and innovation. Absent this, construction crafts complete the activities most directly related to construction operations in the field, making the best they can of the constraints they inherit.

Construction engineering knowledge, diligently pursued and carefully applied, will provide a major career advantage. It will foster critical analytical thinking to increase performance of current activities and keep learning. A foundational

understanding of the four elements will help to select and excel in an early-career activity, bringing increased visibility and responsibility. It will also create a motivating preview of the satisfaction that comes from contributing to the built environment. Finally, related to restoring the balance between construction engineering and construction management, an increased scope of construction engineering education can strengthen the construction management portion of programs by providing technical understanding for more effective use of management techniques and tools.

Elements. The structure of construction engineering knowledge described in this paper includes two fundamental and two applied elements. Technical fundamentals are an essential basis for gaining other types of construction engineering knowledge and for the evaluation of alternatives for construction methods. Materials properties are basic to the performance of temporary and permanent facilities and components.

Construction-applied resources, used to complete construction operations, transform permanent materials into a constructed facility. Coverage of construction operations captures how to build the work, including field challenges. The full scope of construction engineering includes other specialized topics, but these four can provide an effective foundation for continued learning throughout careers in design, construction, or other parts of the project lifecycle.

Learning methods. A combination of traditional, active, and integrated methods provides an effective approach for learning the diverse elements of construction engineering knowledge. As with appealing to different learning styles, a mix is best. Many faculty and students rely on traditional learning methods because they are familiar. Active methods get both more engaged and increase learning by inductive thinking. Integrated methods offer significant potential to increase the effectiveness of learning each element of construction engineering knowledge through application.

Implications and recommendations for stakeholders

Young engineers. A beneficial approach for continued learning involves alternating between two types of construction engineering knowledge and learning methods. The first step is experience-based or empirical. The second step is self study to gain deeper understanding of the technical fundamentals that are most applicable to the empirical knowledge gained in the first step. The Internet provides an increasingly valuable resource for this second step. An iterative process between fundamental and empirical knowledge provides a deeper and broader basis for continued learning from experience.

Regular and adjunct construction faculty. Considering possible coverage of the knowledge elements identified in this paper will encourage increased attention to construction engineering in construction education. This should include analyzing linkages with construction management topics in the program to leverage both parts. Developing a shared approach that includes the fundamentals

along with examples described by industry professional can increase both learning and interaction with industry. Using alternate methods of learning will increase the students' understanding and potential for an increased rate of learning from experience.

A core of basic teaching materials for each of the elements would help additional faculty offer construction engineering courses. The author is developing parts of these materials, including notes and class presentations, to make available for the construction education community. They will complement the many excellent textbooks available to describe some of the elements of construction engineering knowledge and help direct students to these sources for increased depth. Taking full advantage of different learning methods for construction engineering education will also require assignments and case studies using active and integrated learning approaches. Professor Michael Vorster is developing these key ingredients.

Construction researchers. Many construction researchers are now focused on developing model-based tools to assist in analyzing design alternatives and selecting construction methods that best meet all project objectives. These new tools can provide major benefits for construction engineering education by helping to bring the jobsite into the classroom. The four types of construction engineering knowledge identified in this paper can also provide assistance in selecting the scope of representation and reasoning for the models. This can assist in tailoring the models to the owner's priorities for project objectives, the type of construction, and the special challenges of the site.

Identifying Competencies for Baccalaureate Level Construction Education:
Enhancing employability of young professionals in the construction industry

Faisal Manzoor Arain

ABSTRACT

The competence of a construction program in the core area of construction project management is in imparting to its students the necessary expertise in order to practice professionally in the construction industry. The study identifies the competencies for baccalaureate level construction education in Alberta, Canada. To achieve the study objectives, a questionnaire survey was carried out to collect information on industry's perspective on construction professional competences. Responses from 32 construction industry professionals were analyzed. The results suggest that the construction acumen, project management and leadership, business acumen, professionalism, and communications were considered as the most important (top five) and desirable competencies for baccalaureate level construction education. Other important competencies include building techniques, international project management, research, cost management, conflict resolution, ability to learn, contracts management, risk management, teamwork, and technological competency, procurement management. It is recommended that the breadth and depth of the core's syllabi ensures sufficient coverage of fundamental and extended topics on construction project management. Construction programs should help to equip our students better to participate in the local and global construction industries that await them. The findings from this study would also be valuable for all academicians and researchers involved in the area of academic development in general.

INTRODUCTION

As the Canadian population grows, so does the demand for residential and commercial property. Construction is and always has been a major player in Canada's economy. The construction industry employs close to 1 million Canadian men and women and chalks up volumes of $123 billion annually (Arain, 2009). The construction industry also has been accounting for about 12 percent of Canada's GDP. The construction industry has a growing need for management professionals and effective project management, which are crucial for major building or renovation projects, especially given the growing complexity of large construction projects and construction-related law (Ling and Leow, 2008). For these reasons, positions in construction management

increasingly require a specialized degree. Construction management requires a broad skill set in a variety of areas, and construction project managers are ultimately responsible for every aspect of their projects, including planning and scheduling project activities; managing employees, contractors, equipment and materials; project design; and budgeting.

Construction project management is the study of how the principles of scientific management are applied to construction projects (Kramer, 2005). It also covers maintenance of existing buildings and management of construction companies. Various management tools and theories are used to solve problems relating to the planning and control of construction projects. The core establishes the professional basis for successful operations in development projects as well as a strong basis for advanced studies in related areas (Arain, 2007).

Construction projects are complex because they involve many human and non-human factors and variables (Arain *et al*., 2004). The construction process can be influenced by changing variables and unpredictable factors that could derive from different sources. These sources include the performance of the parties, resources availability, environmental conditions, involvement of other parties and contractual relations (Arain and Low, 2003). As a consequence, the projects may face problems possibly causing delay in the project completion time.

It is commonly accepted that the construction industry has for many years been criticized for not developing consistent projects that are on time, within budget and with high quality standard (Arain, 2007; Ling and Leow, 2008). Generally, failure to deliver successful projects has been considered in relation to schism between design and construction, lack of integration, lack of effective communication, uncertainty, changing environment, and increasing project complexity (Arain and Low, 2003; Arain *et al.*, 2004; Arain, 2005a). Turner and Muller (2003) pointed out that committed people with high team spirit are essential for effective project management. Successful implementation of projects has always been a critical factor to the success of organization (Conrad and Sireli, 2005).

The rapid trend of globalization and technological changes have made difficult for construction organizations to survive in the competitive world (Babcock and Morse, 2002; Arain, 2007). Consequently, the importance of construction project management has been increased many folds. It is difficult to face the challenges of present international business arena without being more agile, adaptive and efficient. To develop the required expertise and resource, construction project management education is the key. In order to effectively operate in such competitive environment, the construction professionals should have project management knowledge and essential skills and competencies (Arain, 2007). The objective of this study is to identify the graduate competencies for baccalaureate level construction education in Alberta, Canada.

COMPETENCIES FOR BACCALAUREATE LEVEL CONSTRUCTION EDUCATION

The construction industry is becoming increasingly global and the role of construction management professional now includes many front-end services, which increases the required skill set of new construction graduates (Choudhury, 2000; Kay 2001). Alternate contractual delivery systems, collaborative partnerships, new management initiatives, and global product markets require students to have a broader awareness of construction methods and project management issues (Kramer, 2005).

Due to the complex nature of present construction business environment, the organizations often undertake multiple projects which are varied in nature and call for more specialized expertise in project management (Arain and Low, 2005). The engineers are often assigned management responsibilities as a result of promotion to higher level or due to the nature of work. Therefore, the engineering managers must have project management skills and ability to have the holistic view of the project from initiation till closing. The engineering managers have to work in an organizational setting that demands high degree of cross-functional integration. In order to effectively operate in such environment, the engineering managers should have required skill set and project management knowledge (Babcock and Morse, 2002).

Leading companies want and need construction professionals with solid foundations in both construction and project management, specific training in complex and challenging management problems, and sufficient workplace experience to assume leadership roles quickly. Construction Project Management program is a management-based course of study that prepares students for leadership roles in the construction industry. The program aims to provide participants with structured management and leadership techniques that will provide the basis for broader management decisions as well as on-site leadership in construction operations.

Graduates competencies of the construction project management program should be determined based on advice from leading regional industries, professional bodies, and the experience of other local and international for improving graduate's educational preparation for the construction industry (Arain, 2009). Program curriculum should be designed using a learner-centered model that provides choice, project based learning, opportunities for student interaction and active learning. Current best-practices in education, which encourage problem solving and critical thinking as key components of the learning process, should be employed.

Due to the technological advances in the IT industry around the world, the need for better project management skills is becoming more evident. Hartenian *et al.* (2001) pointed out that there is need that construction schools strive to improve the course offerings that incorporate the issues of complex dynamic environment. They particularly pointed out that the graduate students do not possess required knowledge of project management related skills. Arain and Tipu (2009) wrote that the issue of lack of project management skills has been realized by many technical schools and

there is encouraging sign that schools are considering developing a complete project management curriculum addressing key competencies sought by the industry.

Management decides and implements the ways and means to effectively and efficiently utilize human and non human resources to reach predetermined objectives (Bryde, 2003). Project managers are expected to marshal resources to complete a fixed-life project on time, on budget, and within specifications. Project managers are the direct link to the customer and must manage the interface between customer expectations and what is feasible and reasonable (Arain, 2005a). They provide direction, coordination, and integration to the project team, which is often made up of part time participants loyal to their functional departments. Project managers must ensure that appropriate trade-offs are made between the time, cost and performance requirements of the project (Arain and Low, 2003; Arain, 2007). At the same time, project managers, unlike their counterparts, generally enjoy only rudimentary technical knowledge to make such decisions. Instead, they must orchestrate the completion of the project by inducing the right people and resources, at the right time, to address the right issues and make the right decisions (Arain, 2005b). Certainly, resource optimization for successful project management is a unique and challenging task. Choudhury (2000) pointed out that the underlying reasons of the issues, such as time delays and high cost, could be lack of knowledge of the project management skills.

Many researches indentified the competencies for construction education that assist in increasing employability of construction professionals. The competencies include project management, leadership, business skills, professionalism, construction acumen, contracts management, research, communication skills, conflict resolution skills, cost management, procurement management, risk management, building techniques, technological skills, teamwork, ability to learn and global project management (Choudhury, 2000; Kay, 2001; Hartenian *et al.,* 2001; Babcock and Morse, 2002; Turner and Muller, 2003; Arain *et al.,* 2004; Conrad and Sireli, 2005; Karmer, 2005; Arain, 2007; Arain, 2009; Arain and Tipu, 2009).

The studies above discussed many competencies for construction education for enhancing employability of young professionals in the construction industry. The literature study assists in compiling a list of competencies for undergraduate construction education, as shown in Table 1.

Table1: Competencies for baccalaureate level construction education for enhancing employability of young professionals in the construction industry

SNo.	Competencies for Baccalaureate Level Construction Education
1.	Project Management: *Apply principles of project management to plan, scope, schedule, cost, resource, complete and evaluate construction projects*.
2.	Leadership: *Assume leadership role within teams to achieve the intended outcome.*
3.	Business Acumen: *Apply knowledge of business processes, organizational structure, management principles and financial requirements to core business*

SNo.	Competencies for Baccalaureate Level Construction Education
	practices such as human resources, business operations, financial management, information systems, organizational behavior, business negotiations and law.
4.	Professionalism: *Integrate professional and ethical responsibilities that contribute to a safe and positive working environment*.
5.	Construction Acumen: *Interpret plans, drawings, shop drawings and materials information documents for different types of construction projects*.
6.	Contracts Management: *Prepare and negotiate contracts common to construction projects and the construction industry*.
7.	Research: *Apply research and analytical skills to solve problems within construction projects*.
8.	Communications: *Communicate effectively in both written and oral forms to a variety of audiences in a professional and ethical manner*.
9.	Conflict Resolution: *Apply conflict resolution strategies to resolve current and emerging conflict*.
10.	Cost Management: *Utilize current technologies and established practices to plan and manage construction budgets*.
11.	Procurement Management: *Incorporate procurement management skills to evaluate and select bids for materials and skills needed to complete construction projects.*
12.	Risk Management: *Incorporate risk management skills to evaluate and select construction projects*
13.	Building Techniques: *Demonstrate a robust knowledge of building techniques and construction methods*.
14.	International Project Management: *Differentiate and apply the management strategies and requirements for local versus international projects*.
15.	Technological competency: *Apply recent technological knowledge to manage projects.*
16.	Teamwork: *Assume various roles within teams to achieve an intended outcome in a professional and ethical manner.*
17.	Ability to Learn: *Demonstrate a capacity to learn through formal and informal methods, in order to confirm and extend their knowledge and skills when addressing new or emerging challenges.*

The literature study forms the basis for the questionnaire survey to collect information on industry's perspective on construction professional competences. The study is a unique research that identifies the competencies for baccalaureate level construction education for enhancing employability of young professionals in Canadian construction industry for the first time. The study sets the foundation for future larger research study on identifying competencies for baccalaureate and graduate level construction education on a larger scale.

RESEARCH METHODOLOGY

Through the above literature review, the 17 competencies for construction education for enhancing employability of young professionals in construction industry were identified. These provided the basis for the formulation of a questionnaire.

A survey of 32 professionals from the Albertan construction industry was carried out. They included vice-presidents, directors, senior managers, project managers, construction managers and project engineers. A total of 32 questionnaires were distributed personally to the respondents, together with an explanation on the purpose of the study and assuring them of anonymity.

In addition to collecting information via the questionnaires, face-to-face discussions using the questionnaires were also carried out to ensure that all questions were answered and the respondents have a chance to clarify any doubts with the research team. A 5-point Likert scale was used in the questionnaire to gauge the most important competencies for baccalaureate level construction education for enhancing employability of young professionals in the industry.

BACKGROUND OF RESPONDENTS

A total of 32 professionals were asked to gauge the importance of the competencies using a 5-point Likert scale. They included 14 professional from contractor side, 11 from consultant side, 3 from academia, 2 from governmental organization, and 2 from professional association. Table 2 shows the details of the responses.

Table 2 Survey response rates

Respondents	Responses received	Interviewed	Percentage
Contractors	14	14	43.76%
Consultants	11	11	34.37%
Academia	3	3	9.37%
Governmental organization	2	2	6.25%
Professional Association	2	2	6.25%
Total	32	32	100%

As shown in Table 3, of the 32 professionals interviewed, 5.25% were vice presidents, 21.87% were directors and 34.38% were senior managers. 18.75% of the interviewees were project managers, 12.50% were construction managers, and 6.25% of the interviewees were project engineers. Professionals were involved with the construction industry for more than 10 years; therefore, they were likely to be better able to assess the employability issues and graduate competencies sought by the construction industry. As a majority of the interviewees were professionally positioned at management level or higher, a certain level of accuracy in the data collected was assured.

Table 3 Professional interviewees' statistics

Respondents	Appointments	Responses received	Percentage
Professionals	Vice Presidents	2	6.25%
	Directors	7	21.87%
	Senior Managers	11	34.38%
	Project Managers	6	18.75%
	Construction Managers	4	12.50
	Project Engineers	2	6.25%
Total		32	100

ANALYSIS OF RESULTS

The data collected from the 32 questionnaires was analyzed statistically. As shown in the Table 1, the 17 competencies for baccalaureate level construction education for enhancing employability of construction professionals were identified from the literature review and feedbacks from the professionals in the construction industry. The questionnaires containing 17 graduate competencies and section for feedback (additional competencies) were provided to the professionals involved in the construction industry. The competencies for construction education for enhancing employability of construction professionals were analyzed and ranked according to their responses. As shown in Table 4, the 17 competencies for baccalaureate level construction education were tabulated according to their means and standard deviations.

Table4: Competencies for baccalaureate level construction education for enhancing employability of young professionals in Canadian construction industry

S No.	Competencies for Baccalaureate Level Construction Education	Mean	Std. Dev.
1.	Project Management	3.62	0.64
2.	Leadership	3.62	0.58
3.	Business Acumen	3.56	0.64
4.	Professionalism	3.48	0.75
5.	Construction Acumen	3.64	0.73
6.	Contracts Management	3.14	0.59
7.	Research	3.22	0.64
8.	Communications	3.39	0.83
9.	Conflict Resolution	3.18	0.67
10.	Cost Management	3.21	0.92
11.	Procurement Management	3.07	0.58
12.	Risk Management	3.11	0.70
13.	Building Techniques	3.32	0.77
14.	International Project Management	3.25	0.65
15.	Technological competency	3.07	0.73
16.	Teamwork	3.11	0.70
17.	Ability to Learn	3.18	0.64

Furthermore, the competencies for baccalaureate level construction education for enhancing employability of young professionals in the construction industry were categorized into the most important ones as shown in Table 5. The results suggest that the construction acumen, project management, leadership, business acumen, professionalism and communications were considered to be the top five most important competencies for baccalaureate construction education for the construction industry in Canada.

Table5: Top five competencies for baccalaureate level construction education for enhancing employability of young professionals in Canadian construction industry

S No.	Competencies for Baccalaureate Level Construction Education	Mean	Std. Dev.	RANK
5.	Construction Acumen	3.64	0.73	1.
1.	Project Management	3.62	0.64	2.
2.	Leadership	3.62	0.58	2.
3.	Business Acumen	3.56	0.64	3.
4.	Professionalism	3.48	0.75	4.
8.	Communications	3.39	0.83	5.

DISCUSSION AND CONCLUSIONS

The study results showed that all program competencies were considered important by the respondents. It is revealed through in-depth interviews that employers expect construction graduates (young professionals) to possess the key competencies to be beneficial part and prosper in the construction industry. The construction acumen was ranked as the most important competency for enhancing employability in the construction industry. Considering the technical nature of the construction project management discipline, this was not unexpected. Many research studies have suggested that the construction acumen is the foremost skill that is sought by the construction industry. It was revealed through in-depth discussions with the professionals that ability to interpret plans, drawings, shop drawings and materials information documents for different types of construction projects is an integral skill that construction graduates should possess to be a beneficial part of the construction industry.

Project management and leadership were jointly considered as the second most important competency for baccalaureate level construction education. The graduates of the construction project management baccalaureate program are expected to demonstrate sufficient knowledge of principles of project management application to plan, scope, schedule, cost, resource, complete and evaluate construction projects. Project management is all about providing efficient leadership at every level of the

construction projects. Young construction professionals should be able to assume leadership role within teams to achieve the intended outcome.

The results revealed that business acumen was perceived as the third most important competency for young construction professionals. Business acumen would help construction professionals to participate in the construction organization beyond the implementation and management of construction projects. It was acknowledged by the professionals interviewed that construction graduates should be able to apply knowledge of business processes, organizational structure, management principles and financial requirements to core business practices such as human resources, business operations, financial management, information systems, organizational behavior, business negotiations and law.

Professionalism and communication were considered fourth and fifth most important competencies for construction graduates respectively. It is evident that the construction industry requires professionalism as an integral component to encourage a conducive and professional environment. Construction graduates are expected to have ability to integrate professional and ethical responsibilities that contribute to a safe and positive working environment. Effective communication is an important attribute of project leadership, construction graduates should be able to communicate effectively in both written and oral forms to a variety of audiences in a professional and ethical manner. Construction education should address to these required competency to produce career ready professionals for the local and global construction industry.

In the face of this changing economic environment, existing and upcoming professionals in the construction industry must be adequately trained to adapt to different markets and cater to regional demands in a more internationalized market. The skills needed to be successful in the international market such as project management skills, construction acumen, professionalism, business acumen, construction laws and regulations, communication, and cultural knowledge will become increasingly vital for construction industry professionals who wish to compete in the global arena. Present student generation in construction-related disciplines is well aware of the changing market conditions ahead and realizes that they need to reach out to developing regions to expand and build their careers.

Academic institutions now realize the need for courses in global project management, language skills development as well as working environments, laws and regulations in emerging markets. Nevertheless, additional efforts are required for further adjustments to their curricula in response to this emerging need. Incessant pace in education development to train students in construction-related disciplines for working in local and global, emerging markets can help add a degree of flexibility to their arsenal, enabling them to have fewer restrictions, thus opening a wider venue of opportunities for them. This added flexibility can reduce the chances of construction professionals leaving the field for other professions, thus ensuring a more constant and stable supply of human resources. Overall, these combined advantages will ultimately lead to a healthier industry and promote a better image for the entire profession. It is recommended that the breadth and depth of the core's syllabi ensures sufficient

coverage of fundamental and extended topics on construction project management. Construction programs should help to equip our students better to participate in the local and global construction industries that await them. The findings from this study would also be valuable for all professionals, academicians and researchers involved in the area of construction education in general.

Abstract: Scientific literature and practical experience point out fragmentation of the building design process as one of the reasons for ineffective design and construction processes. This paper proposes interdisciplinary team learning in the context of an integrated design studio as a successful approach for both: achieving sustainable design solutions and transforming disciplinary cultures into integrated practices. In a rather unique collaborative experience based on strategies from situated learning and activity theory, students with different design and construction backgrounds were placed in multidisciplinary (co-located) teams to work on a real architectural project with specific requirements for sustainability. This integrated design studio was timed in three intensive 2-day *charrettes*. A coherent digital environment for integrated design was proposed in order to meet the needs of the multidisciplinary teams. The results from this experience were very positive in respect to both individual and team learning.

1. Introduction

Scientific literature and professional experience point out one of the reasons for ineffectiveness in construction is due to a bi-directional fragmentation of the building design process: horizontally (between disciplines contributing to the project) and vertically (along the time axis, between different phases of the project). Environmental design requires the participation of a number of experts early on, thus adding complexity to the process. According to a recent bibliography authored by Sanguinetti (2009), Building Information Modeling (BIM) aims to provide an integrated model (common & unique) of a projected object which is meant to optimize the design process and facilitate the interactions between specialists by concentrating them around one (digital) object. Thus, the purpose of integrated design process is to increase productivity (Eastman et al. 2008) and to stimulate innovative solutions (Egan 1998).

This transformational process is essentially lead from within design and construction practices. Pedagogical strategies remain limited by traditional methodologies which do not address the unique expertise and requirements of

integrated design demands. The respective expertise of students combined with effective and collaborative tools are essential to engage in an integrative approach to design. In this paper, the authors discuss the main findings of an experimental and environmental design studio that intertwined architecture and civil engineering. More specifically, this study asks the following research questions:

- How does a multidisciplinary design studio influence team learning in terms of team organization, collaboration, (individual) design strategies and project definition?
- How commercially available software maps to the needs of a multidisciplinary team in a context of co-situated design?
- How "integrated" was the design experience of the *Maison des étudiants* (MDE)-project studio? What was integrated and what was not?

The design proposals were presented publically and (according to the voting results), were well received by the student community and were well evaluated by the instructors. For the purposes of this research, though, the importance is put on the process rather than on the result. The best indicator of the success of this teaching experience is considered the learning that has occurred on individual and on team levels. First, scientific work related to the research is presented. Second, the context and the methods of the study are described. Third, data is discussed in the light of each research question. Finally, some conclusions and proposals for future research and pedagogy are put forward.

2. Related work

The studied phenomena are complex and therefore require a variety of complementary viewpoints. The following section focuses on some of them, namely: learning, collaborative design, transformational learning and technological environment.

On learning

Design studios are the traditional form of teaching architectural design at universities. Trying to recreate the environment of an architectural office, they exploit the method of "learning by doing" (Schön 1983). Studios are traditionally uni-disciplinary (with some rare exceptions). Conversely, engineering students do not go through the same type of education and thus, do not build a 'studio' culture. This leads them to different methods of work (compared to architects) from a cognitive point of view (Cross 2006, Lawson 1980). For the purposes of designing a sustainable building, multidisciplinary teams have the greatest potential for optimisation and innovation of a design solution (Blackler and Crump 2000). Even more, according to the socio-constructivist theory of the historico-cultural nature of learning (Vygotsky 1978), such a context creates a fertile context for learning. That is why this teaching approach was chosen for the MDE-project design discussed in this article.

On collaboration during design

Much research has been undertaken on collaborative design, especially on remote collaboration. Recently, interest in co-situated and technologically-assisted collaboration has gained prominence because multidisciplinarity is essential to achieve a successful integrated design process and because multinational teams require that spatially dispersed designers contribute to a specific project.

As sustainable building design is one which combines efficiency in building performance, economy and socio-cultural impact, it requires the implication of

various specialists. As the most important decisions for a project are made in the initial conceptualization phase (and errors at this moment are the most costly), multidisciplinary teams are summoned to work together from the very early stages of the design project. This process of integrated design is successfully applied in other domains of production for a long time now (Forgues and Eugenie 2009). Some avant-garde AEC companies integrate in their design teams various specialists at the conceptual phase of the project. Such a collaboration requires considerable transformation in the professional traditions of the AEC professions (Backler and Crump 2000, Carlile 2004).

In a large qualitative research (ethnological enquiry) on a co-situated multidisciplinary design team of professionals, Tory et al. (2008) study the role of physical and digital design artifacts during the design-collaboration process. The authors analyze the interactions between team members, find various bottlenecks in the communication via digital technology and propose some simplifications for better use.

In a co-situated collaborative learning environment, Fruchter (1999) proposes a new metric for cross-disciplinary learning as a "journey from the state of island of knowledge (discipline-centric) to a state of understanding of the goals, language, and representations of the other disciplines". This approach helped establish the basis for the evaluation of our multidisciplinary design studio learning.

On boundary objects and transformational learning

Multidisciplinary design sessions immerse students in a context of knowledge sharing and situated learning around their project while manipulating various kinds of representations of the building-to-be. The concept of *boundary object* identifies a specific mediating artefact that will help represent, learn about, and transform knowledge to resolve the existing contradictions at a given juncture between two or more disciplinary 'communities' (Star and Griesemer 1989). Authors of this paper have previously reported on the augmented role of digital boundary objects compared to physical ones in the framework of multidisciplinary design processes (Forgues and Eugenie 2009).

Activity theory, a social learning theory that uses mediating artefacts to systemically study the role and influence of boundary objects on practices and organisations. It has its roots in Vygotsky's theory of social learning. An *activity* is viewed as a mutual learning process in which people interact through mediating objects to achieve a common outcome.

Transformational learning occurs when teams successfully achieve a shared mental model. According to Engeström's (2002) theory of expansive learning, joint design activity is characterised by a community of multiple points of view, traditions and interests. When participants join a team, they bring their own diverse histories, and the activity system itself carries multiple layers and strands of history engraved in its artefacts, rules, and conventions. Conflicts and contradictions between various perspectives are sources of change and development that trigger transformational learning. They accumulate and hence, create structural tensions within the system. As the contradictions of an activity system are aggravated, some individual participants begin to question and deviate from the established norms. Expansive transformation occurs when the members of the activity system embrace a radically wider horizon of possibilities than in the previous mode of the activity. Boundary objects can serve as enablers or drivers of this transformation by facilitating generative learning at a given

boundary. Simulation tools are an example of an innovative technology that encourages the creation of new knowledge between novices and specialists by graphically expressing complex problems (Dodgson et al. 2005). Engeström (2002) suggests the introduction of new boundary objects – a new technology for example – in order to destabilise existing practices and push them to radically explore new ways of achieving the expected outcome. Building Information Modeling (Eastman et al. 2008) provides technological basis for the creation of project representations functioning as a boundary object to bridge information and knowledge between practices in construction. This approach is put into practice in the context of the current integrated design studio.

On technological environment

Technological environments represent a strong avenue for design learning and practice (Jabi 2004). As a concept, BIM has the potential to revolutionize construction and help environmental design become easily accessible (Krygiel 2008). Some governments require the use of BIM for public projects. Nevertheless, its implementation is rather heavy and demands greater technical resources (in terms of information and calculating power), which renders its access difficult for small practices. In addition, the interoperability of the different modules or software remains fragile and time consuming. Energy, cost and life-cycle simulations are mostly separated from the main modeling software (Eastman et al. 2008). Architects state that it is difficult to nurture creativity in such an environment (Yessios 2006). Yet, it offers new integrating and simulation functions, inaccessible through other forms of representations by now. That is why the use of BIM-enabled software for the purposes of integrated design was encouraged. Other modeling programs (SketchUp, Rhino 3D and 3D-Max) were used during the ideation process or for representation of the project.

3. Design studio context

The research project was conducted in the context of a multidisciplinary design studio combining students in architecture (from McGill University's School of Architecture) and students in civil engineering (from the ETS-Montreal) to work on a real design project. The proportion of work expected from students in the different disciplines, and the number of interested students in taking the course (13 students in their first year of a master's level in architecture and 24 undergraduate students, usually in their final year of engineering) lead to the following composition of each of the 5 teams: 2 or 3 architects, 2 or 3 engineers in building mechanical systems, 1 or 2 cost estimation engineers and 1 structural engineer, for a total number of 7 or 8 (which is the limit for a self-managed team). Their motivation was clearly expressed before the beginning of the studio and their engagement in the project was evident. Each team was allocated an individual space equipped with a PC, Internet and a local network access, a projector and a printer. Additionally, students brought their personal computers (mainly laptops). A communication board was provided in the form of either a vertically standing interactive (smart) board, an interactive tablet or a white board.

The cluster organization of the tables provided an optimal configuration for teamwork, especially successful in the collaboratory of the ETS. The work-area of the other spaces was more flexible and the organization depended on the available furniture. Some configurations (big round table) were more favorable to teamwork than others (two or more clusters) and had an impact on the frequency

of the discussions in which all the team participated (one cluster favors the higher frequency).

The work was organized into three intensive *charrettes* of two days with two-week pauses between them. Information sessions and software capsules were offered in-between the *charrettes*. As the workload was quite heavy, students were not required to work between the sessions. Nonetheless, instructors expected them to practice and familiarize themselves with the presented software but this did not happen. The three-stage organization helped provide substantial feedback to the students and encouraged them to propose new solutions at each stage, thus inciting innovation and creativity (as reported in another paper on the ID-framework of this studio (Forgues et al. 2010). In terms of input from the tutors, it was limited to a minimal frequency feedback in order to allow the students to self-organize and learn from the other disciplines. This organization was pertinent, but somewhat insufficient for some of the disciplines. Inputs from specialists in sustainable technologies and techniques were highly appreciated.

The students had access to technology that helped: (1) facilitate collaboration through the use of TeamSpot and interactive-board or tablet software, and (2) assist knowledge sharing and the evolution of the building design through AutoCAD 2010, Revit Architecture 2010, SketchUp, Ecotect Analysis, Design Builder and D-Profiler. While the architecture students had good knowledge of CAD and digital modeling (but were less familiar with Revit and Ecotect), most of the students in engineering were novices to software tools. This is an important difference, because previous research has shown that often, who 'possesses the tools' leads the team (Forgues 2009).

The project, a student centre for the ETS is an actual project with a complex program including: a soccer field, a hockey arena, a swimming pool and an underground parking, in addition to the administrative, health and leisure services for the students. A variety of structural, systems-organisation and spatial challenges compose this building. The requirements for sustainable building were fundamental.

4. Methods

According to the specialized literature, quantitative research methods are inappropriate for research on design processes and especially on collaborative design (Fruchter and Emery 1999, Backler and Crump 2003, Cross 2006). Due to the complexity of the studied processes, this research relies on qualitative methods inspired by grounded theory and case study (Creswell 2007, Glaser and Strauss 1967, Yin 2004). Rich and extensive data was gathered by: 1) camera recordings of the *charrettes* and the public presentations, 2) semi-directive interviews and 3) questionnaires. As this is a participative research, the observations of the instructors are taken into consideration.

Mainly based on the interviews and on the questionnaires, inspired by the methodology used to evaluate collaborative learning (Fruchter and Emery 1999), after the first and last *charrette*, the students were asked the question: *How do you estimate (at this moment) your level of knowledge of the work of your colleagues from the other disciplines?* Four levels were defined and proposed as answers: (1: islands of knowledge): *I master my discipline, but do not have experience in the other disciplines represented in our team.* (2: awareness): *I am aware of other disciplines' goals and constraints.* (3: appreciation): *I am interested to understand and support the other disciplines' goals and concepts and know what questions to*

ask. (4: understanding): *I can negotiate and I am proactive in the discussion with other disciplines, I provide input before the input is requested, and begin to use the language of another discipline.* The students were asked to justify their answers. A final question was asked: *After this experience, do you plan to take any courses in any of the other disciplines? Which topics?*

5. On situated learning

Judging from the general attitude and from the interviews, the students have shown a very high overall satisfaction from the multidisciplinary studio experience. All of them have stated having learned a lot from their colleagues: on their working habits, on the aspects treated by each discipline and on the way to collaborate. Answers on the level of knowledge of the work of the other disciplines showed a manifest but not drastic increase of the 'level' after the third *charrette*, compared to the first one (average values: 2.47 to 3.31). We speculate that this is due to (at least) two factors:

(1) the fact that the first questionnaire (Q1) was given after the first two days of intensive design sessions, and not at the very beginning, so there was already some learning even before it (here is an example form Q1: *I am **now** aware of the dynamics of the other disciplines **and was able to learn** new ways of thinking and attitudes from them.*) The researchers were aware of the shortcomings of the questionnaire' timing but wanted to present it together with another one meant for a different research in order to minimally disturb the students.

(2) the effect of 'learning' during the studio: at the end of the third *charrette* the students know more about the work of the others, but have a better understanding of the large quantity of knowledge manipulated by their colleagues (i.e., they know of what they are ignorant).

The diagrams on Figure-1 present the distribution of the four levels of knowledge as reported in Q1 (in blue) and in Q2 (in red). The diagrams in the center and to the right show different patterns for architects and for engineers. The fact that a large number of students in engineering have stated having an "understanding" since the very beginning, in our opinion, demonstrates that they were not prepared enough for conceptual design.

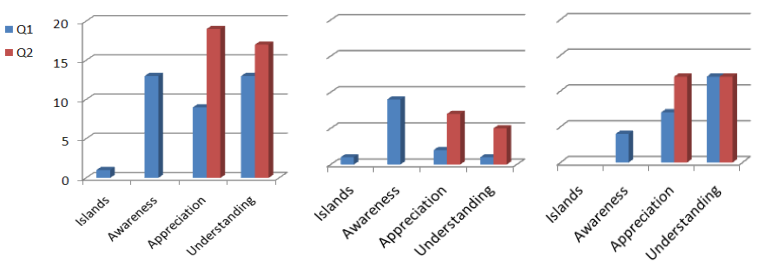

Figure 1: Levels of knowledge of the work of the other disciplines: (left): general for all disciplines; (center): students in architecture; (right): students in civil engineering.

The differences observed between the teams are negligent. The distribution per disciplines shows a more important increase of the level for engineers (2.57 to 3.46) than for architects (2.28 to 3.04).

Here are some examples of the justifications given by the students: architect, showing awareness (2) at the beginning and proactive participation and comprehension (4) at the end:

- Q1: *I have a good understanding of their work without necessarily understanding the material processed by these specialists*
- Q2: *I am interested to understand and to learn this language and the technical concepts behind mechanical and structural systems. I learned a lot with this project. The team was very well integrated.*

The interest in taking additional courses slightly decreased after the end of the multidisciplinary experience. In our opinion, this demonstrates that what has been learned throughout the project has filled in gaps of knowledge for several team members. Many students have answered this question as such: «*Not necessarily, but I wish to do integrated design projects»,* which means that the multidisciplinary studio experience gives them valuable knowledge and can replace a course in another discipline. In general, students expressed an interest in taking courses in the following areas: sustainability, BIM, and simulation software.

The justifications given by the students witness for some other aspects of their experience too. For many engineering students, this was a first contact with a design process and they showed special interest (even fascination) to architectural design and its creative aspects: (1) *I would like to learn about architectural trends. If I was younger, I would take up studies in architecture;* (2) *Architecture is a fascinating domain* ...Another testimony: *My knowledge of the work of my colleagues from their disciplines has improved over the course of this project, and as such I have become more interested in their work. It also helped me communicate with them in a more efficient manner.* On developing common language and project strategies: *The hard work of structuring and organizing ideas forces me (in a positive way) to use a common language, and gives me a (general but improved) understanding of the topics.*

The subject of the differences in the way of working for engineers and architects reoccurred consistently during the *charrettes.* Here is very significant statement coming from an architectural student: *I am aware of what they are doing but I wish they would suggest directions for development (related to their interests) more often.* The fact that engineers are used to (maybe even taught to) "make (a design decision) work" and to simply analyze and dimension elements, does not fit onto an integrated strategy of design. That is why, at the beginning of the design sessions, the engineers were "waiting" for the architects to give them a design to analyze and "make work". The different cognitive models of study and work of engineers and architects (verbal & analytic *versus* visual & holistic) are pointed out by Lawson (1996) and Roberts (Roberts 2006). The integrated design studio proves to be an appropriate experience for decreasing these differences or at least make them explicit.

6. On the use of digital means and its present limits

Throughout the duration of the integrated studio, instructors encouraged the use of digital technology and especially BIM software with the objectives to facilitate team work and the workflow of multidisciplinary information. It is necessary to mention that the technological setting of team #3 was more stable because it is permanently installed. Other teams occasionally encountered technical problems that were repaired in a short amount of time, nonetheless the interruption in the

collaborative design process prompted students to turn back to some "good old" ways of doing.

Technology for facilitating team work. Interacting through a SmartBoard was surprising and motivating for the students. Judging from the partial data analysis, this way of communication was mainly used during the first *charrette* after its use was demonstrated, but referring to the interactive functions increasingly became seldom. Projecting and writing on the white board was especially appreciated by the students.

TeamSpot, a collaboration program with various possibilities to communicate, show content, and exchange files, can enable a team member to "take possession" of the computer of another member (upon his agreement), to use his programs, and to project the files on one's screen, annotate them and keep traces of the discussions held, etc. Some limitations of this program were found, mainly due to the rather high number of participants trying to access the projected screen at the same time, or because of the intensive memory and processor requirements of the CAD and BIM software used simultaneously.

BIM and simulation software. Prior to the integrated studio, a special effort was made to put together a BIM environment in order to facilitate the project data workflow. As the commercial software are yet far from offering an unified and fluid environment for integrated design, it was proposed (1) to begin the project by creating schematic models in different specialized software (Rhino, SketchUp or Revit-massing for the architectural design; D-profiler for the cost estimation and Design builder or Ecotect for energy simulation); (2) to continue the project in Revit Architecture; and (3) to export this model to D-profiler, DesignBuilder and Ecotect for iterative analyses following the design modifications (and proposing such modifications based on obtained simulation data). We encouraged the students to repeat these cycles, to a greater or lesser extent, during each *charrette.* This scenario was conceived with the purpose to give consistent and continual project feedback after each iteration and to encourage a reconsidering of the building design, thus stimulating creativity and incorporating innovation.

It seems though, that, experiencing time pressure, the students (1) progressively abandoned the use of different technologies because they were not familiar enough with them, and (2) preferred to stick to the design idea (*parti*) from the very first *charrette* in order to have time to develop it and to represent it in greater detail.

Two other factors created difficulties: (1) the software were briefly introduced to the students shortly before their use was required. This did not give them the possibility to acquire an appropriate ease of use during design. (2) the interoperability between Revit and the other modeling and simulating tools is both incomplete and very fragile. Simulation calculations are quite time-consuming, especially for heavy models.

Another shortcoming is that simulating software tools rarely have an output to modeling software, and almost never have generative abilities (i.e. cannot propose a more optimal solution or a new form, but can only analyze a given design model). This means that interdisciplinary learning can occur based on the technological environment, but new knowledge creation would occur mostly outside these software programs.

7. Integrative aspects of the multidisciplinary design studio

A major objective of the multidisciplinary studio was to provide an appropriate context for situated learning of integrated design process. The organization of the design process was new to the students. Judging from partial results from the interviews, from the direct observations of the researchers, as well as from the results presented by the students, 'horizontal' integration was considerably successful. The disciplines of all team members influenced the design proposition, thus proposing sustainable design solutions.

The design tasks were relatively well planned at the beginning of each *charrette* during a 'brainstorming' discussion. Then, periods of working in discipline-specific groups were followed by general discussions. In most of the cases communication was fluid and direct. Team #3 tried a temporary organization into 3 mini-multidisciplinary teams which worked in parallel for several hours. The results from this experience were of great value to the team.

Most of the teams continued to communicate between the *charrettes*, mainly via Internet. Communications intensified as the final *charrette* approached. Team #3 physically met for a discussion during this period.

Different kinds of representations of the design object were used. BIM models were partially used, sometimes with difficulties due to inadequate interoperability or lack of knowledge and limited software practice. Free hand sketches were mainly used by the architects to explain their ideas to students in the other disciplines. In developed stages of the project, models were built (sometimes 3 different models were made: for photorealistic renderings, for simulations and for the layout of the building). The lack of time was given as an explanation for not working on a main and unifying Revit model. They had to choose to deliver a reasonably good result, or to learn to work with BIM.

8. Conclusion and proposals

Through this research we could answer the questions asked at the beginning of the paper. Findings reveal a very satisfactory level of collaborative learning during a multidisciplinary design studio. Cross-cultural influences and interdisciplinary understanding helped creating a fruitful experience for the students.

As for the technological framework, an additional effort is necessary by software industry and by instructors in order to combine creativity and building performance under the same digital environment. As simulation software tools do not generate design proposals, they are limited to analytical aspects of the project, whereas designs create spaces (Iordanova 2007). In consequence, a future integrated design studio could envisage the integration of a collaborative environment as developed by (Muramoto et al. 2009). These researchers aimed to define a collaborative digital environment which can meet the conditions of "possibility for a creative design process". The ability of this environment to cohabit together with BIM-enabled models could be evaluated then. The level of collaborative learning and creativity could be assessed.

Design proposals elaborated by the teams were well received by potential future end-users. Based on this, as well as on the sustainable strategies used, this experience can be considered a successful "integrated design process". Hence, future research can lead to defining the outline of other similar design studios, and to expending this experience to the professional practice and the industry.

Repositioning the Faculty Internship Experience in Construction Management

Ken-Yu Lin[1], Yong-Woo Kim[2], and Carrie Dossick[3]

Assistant Prof., Dept. of Construction Management, U. of Washington
120 Architecture Hall, Box 351610, Seattle, WA 98195
([1] kenyulin@uw.edu, [2]yongkim@washington.edu, [3]cdossick@washington.edu)

Abstract:
Previous studies have confirmed that industry internships help young faculty sharpen their teaching portfolios. Few studies, however, have explored the potential of research enhancement and the benefit that industry sponsors gain from the internship experience. This paper discusses how industry internships impact: (1) junior faculty's scholarship, and (2) industry sponsors' work. The paper presents an analysis of the authors' internship experiences through case studies with supporting data obtained from interviews involving industry personnel. The analysis suggests that an industry internship can, besides improve teaching methods, enhance the richness, quality, and scope of scholarly research and support industry sponsors. The paper also discusses a successful internship strategy and how the internship experience can be tailored to different faculty research areas. In the end, recommendations to guide future faculty internship programs are presented.

1. Introduction

In the practice of construction engineering and management (CEM), professionals cultivate clients, execute technical and managerial tasks, and juggle the demands of fast-paced project schedules and questions from and for colleagues, contractors, suppliers, designers, owners and users. Although some parallels can be made, the varied demands of full-time tenure--track faculty members in CEM are quite different than those in the industry. Faculty are expected to achieve proficiency in teaching and to learn pedagogical methods through self-study and in-classroom trial by fire. Faculty are also expected to develop and execute research agendas while guiding graduate students through the processes of independent thinking and research methods. Lastly, faculty are expected to give their time and energy to the department, the college, the university, and the community.

For faculty in the professional disciplines such as CEM, there is an additional expectation – they are expected to have had some work experience in the field and then continue to remain current while teaching, conducting research and doing service. Industry experience ranges from an informal expectation to a formal requirement in CEM programs. The accreditation boards insist on and support a balance between

academic research and industry practice. According to the Accreditation Board for Engineering and Technology (ABET), a construction program must have at least one faculty member who has had full-time experience and decision- making responsibilities in the construction industry (ABET, 2006). For the American Council for Construction Education (ACCE) accreditation, the council states that, "Evaluation of faculty competence must recognize appropriate professional experience as being equally as important as formal educational background." (ACCE, 2009)

Although in each department, there are faculty who have extensive industry experience, there are a growing number of faculty members who have little–to-no field experience. A study done by McCuen (2007) pointed out that only 21% of tenure-track faculty job announcements in the area of CEM in 2006 required any industry experience in addition to a Ph.D. degree. This is striking when compared to the period between 1992 and 1994 where 71% of faculty job announcements in CEM required industry experience but not a Ph.D.(McCuen, 2007).

While a handful of previous studies (see Section 2) have confirmed the educational impact of faculty internships in professional disciplines, it is not clear what strategies could be used to launch, embolden or even enhance research agendas through faculty internships for a discipline such as CEM that is very much an applied science. Models from the disciplines of medicine and law, where most faculty have practiced and continue to practice as a medical doctor or as an attorney (Gunderson & Gloeckner, 2006), might not be applicable to CEM as fewer construction programs are making industry experience a job requirement (McCuen, 2007). Schools of Architecture, Art and Design also often have faculty who are actively practicing their profession, and those activities constitute scholarly work that takes the place or complement research in the Teaching-Scholarship-Service triad. For junior faculty in CEM, for whom many faculty internship programs are focused, it is a dilemma whether they should pursue professional practices since the associated benefits in research enhancement are not self-evident and professional practices can distract the faculty from other activities more closely associated with tenure and promotion.

Incentives for the industry sponsors present another issue. With student interns, companies seek to cultivate future employees, and have a business motive for investing time and effort in on-the-job training and education. This same motivation is not there for faculty because the benefits are one step removed from the host firm who seeks to gain some value from a faculty's presence in their company. At the end of the faculty internship, the company cannot hire the faculty member as a full time employee (or at least that is not the goal of the program), so the benefits of training the faculty member are not as clear and immediate. One can argue that the internship experiences will be brought into the classroom and improve the education for all students, some of whom will then be hired by the company. However, for the company to support a faculty internship project, academia often needs to be able to present a more immediate value to the company above and beyond educational service.

The challenge then is to align the faculty member's research interests and industry experience goals, and the needs of the hosting company.

The authors participated in the faculty internship program at the Department of Construction Management (CM), University of Washington (UW) and were interested in addressing the following two questions associated with the faculty internship experience:
(1) How does the experience impact the faculty member's scholarship and research?
(2) How does the experience impact industry sponsors?

The authors have research expertise in three different areas including, (1) building information modeling, (2) supply chain management, and (3) document management and information searching, which provided a good spectrum of insights to explore the two questions. The authors used case study observation and analysis supported by interviews with industry internship hosts as the research methodology. In this paper, the authors present the case study analysis and discuss how the internship experience impacts industry sponsors and CEM junior faculty, not only in teaching, but also in their scholarship.

2. Faculty Internship Significance

There is a proven need for faculty internships in CEM. Benefits include improved classroom instruction, enriched relationships between academia and industry, and enhanced career counseling and networking (Tener, 1996). Hynds (2000) also called faculty internships a win-win opportunity for construction faculty.

Improved Classroom Instruction
Previous studies have confirmed that internship experience helps junior faculty sharpen teaching portfolio and improve their classroom instruction in many professional disciplines, including computer science (Hartman and White 1990), accounting (Hendricks, 1993), construction engineering (Tener 1996), and business (Griffin and Homkes, 1999). "Through internships faculty can gain a better understanding of the workplace [into] which students enter when they leave the college or university environment and the skills which are essential to survival." (Hartman and White 1990) The internship experiences help faculty connect academic concepts to current practice (Hartman and White 1990), improve the practice with students experiencing practical, up-to-date classroom instruction (Hendricks 1993), and enhance the credibility of the faculty in the eyes of the students, who are looking for 'real world' knowledge they can use when they graduate (Griffin and Homkes 1999).

Enriched Relationships between Academia and Industry
Many CM programs have industry advisory councils whose companies often participate in the faculty internship program. Faculty internship opportunities enable the academic faculty to work directly with these industry professionals and enrich the connection between academics and industry (Griffin and Homkes 1999). Mutual

appreciation and understanding can lead to a stronger industry connection to the academics to support not only education but research as well. Through working with the faculty member, practitioners will be exposed to research and, hopefully this exposure will increase their awareness of research and subsequently increase the perceived value of research. The connection to industry can also develop into an ongoing resource for the faculty to draw upon for guest speakers, advice from industry as questions about current practice arise, and potentially research sponsorship.

Career Counseling and Networking
A better understanding of local industry practice and companies enables faculty to counsel students about career opportunities (Hendricks 1993), particularly those in the local job market. Furthermore, recommendations for students to industry contacts improve both the reputation of the program and the faculty's ability to advise our students about career options.

Research Opportunities and Enhancement – Where is the Niche?
"Problems identified during the internship usually are related to practical problems as opposed to theoretical projects…" (Hendricks 1993). On the one hand, CEM is very much an applied science and research questions often necessitate observations of or data collection from the industry's day-to-day operations or practices. Therefore, at the very least, working embedded in an industry setting provides an opportunity for the CEM faculty to enrich their frames of reference for research. On the other hand, faculty are trained to challenges themselves with the research topics which exhibit "intellectual merits" and can make "broader impacts", two of the main funding criteria of National Science Foundation. Therefore, the research topics rooted in the practicum of the construction industry have to be meticulously selected to avoid projects that are job-specific or business applications.

Benefits to the Industry Sponsors – Are They Larger than the Drawbacks?
According to Griffin and Homkes (1999), industry sponsors of internship programs can benefit from leveraging existing university-based centers and research outputs while the cost is shared by the university and the corporation. Hendricks (1993) also identifies three specific key ways internship sponsors benefit: 1) "providing well-educated capable employees", 2) "adding unbiased perspective to the company", and 3) "suggesting new approaches and constructive comments". In some situations, the faculty intern can host a corporate training session or sessions during residence (Griffin and Homkes 1999). However for the hosting companies, there could also be drawbacks such as time reallocation of the involved professionals, resource diversion (e.g. office space, parking, computer equipment), confidentiality concerns, and an altered work environment (e.g. complicated working culture with the presence of an outsider) (Gibson, 2001).

3. Methodology

The research relies on the soundness of using qualitative research methods, interviews and case studies in order to know how the internship experience impacts faculty's

scholarship and research as well as the industry sponsors' work. Structured interviews with participating industry sponsors were designed to obtain feedback from the hosting companies (particularly from the internship coordinators) and to see how the sponsors perceived the resulting benefits (or drawbacks) of the internship program. The data presented here includes three case studies which are built upon faculty observations and interviews of industry hosts. This enables us to reflect on how and to what extent the internship experiences launch, embolden or even enhance faculty research agendas and further industry-academia relationships through research activities.

Interview questions were initially prepared based on post-internship reviews reported in the literature (Lantos, 1994) and then subsequently refined by the authors to remove unrelated or ambiguous questions. Two additional rating questions using a 5-point Liker scale were included to identify and measure specific impacts that the industry sponsors perceived throughout the internship experience. The questions are listed in Figure 1 below. Each of the authors interviewed the internship coordinator from his or her industry sponsors in a face-to-face meeting that took approximately 20 to 30 minutes in the summer of 2009, although Dr. Dossick and Dr. Kim had their internships in Year 2007 and Year 2008 respectively. Each interviewee was given a list of the questions prior to the interview and the transcripts were taken during the interviews. All three interviewees had more than 20 years of construction experiences and held decision-making, managerial to executive level of positions at times of the interviews. The authors then assessed the feedback from interview transcripts to identify the industry perspectives.

Open-ended Questions:

1. Why did you invite faculty to do an internship with your company?
2. Before the faculty internship, what were your expectations?
3. What did your organization learn from the experience?
4. How did the faculty influence the company activities and practices?
5. How has your opinion or understanding of research and the role of research in professional practice changed?
6. What are the drawbacks to hosting a faculty member?
7. What recommendations do you have for other companies hosting a faculty internship?

Rating Questions:

1. How did the faculty influence the company?
   Individual rating criteria include "meetings", "talking to employees (informal)", "working as member of team", "conducting seminars", and "individual work output".
2. What did the faculty influence?
   Individual rating criteria include "educational/training programs", "work processes", "culture – leadership", "culture – teamwork", "creativity", and "attitude toward UW".

Figure 1 - Questions for Personal Interviews with Coordinators from Industry Sponsors

4. Case Analysis

Case A

Background: The faculty's goal for an internship was to expand her knowledge in the areas where the author had least experience – "cost control", while the industry sponsor hosting the faculty hired her for her strengths and experience in BIM research. The faculty and the internship coordinator were able to design a summer internship that both allowed the faculty to explore cost control practices while adding immediate value to the firm through research activities related to BIM. The faculty used her expertise in research to discover and study current practices in cost control and then applied them to BIM methods that provided the internship host company insights as to how they could and should adopt BIM tools for cost control as well as other applications.

Impacts on the Industry Sponsor: The hosting company had been motivated to be the leader in 3D applications in construction and was able to bridge that motivation with the faculty's expertise for its own benefit. Over the course of the summer, based on their collaboration and experience the faculty and industry host developed theory, coined here as "it's-not-one-model", and presentation graphics to describe the theory. The internship coordinator confirmed that "the interactions and the discussion have been really helpful." "… going through all the graphics and everything of IT'S-NOT-ONE-MODEL is holding so true. We are finding more and more reasons that our estimating models are just not the same as your coordination model. We are not going to share the estimating model with the field guys…somebody to go through that thought process and say 'is this model good for that purpose?'" It is clear that the faculty's presence in the hosting company has impacted the way BIM was thought of within the organization. This has also resulted in changes of philosophy in adopting the technology within the hosting company because the coordinator mentioned that "It wasn't just a matter of putting the technology in place and reviewing what needs to be done with the person (i.e. the GC MEP [General contractor mechanical electrical plumbing] coordinator), but really having a step back and saying, 'is this the right person'" After the internship program, the hosting company also made a very conscious decision to have internal critics where employees review and discuss the applications of the technology. From this end, the internship experience instituted the hosting company's internal reflection.

Impacts on the Faculty's Research Agenda: The faculty and the company employees together developed a theoretical basis to explain how the use of BIM is evolving in industry. In the interview, it became clear that this theory provided a basis for the company's BIM program. Likewise, the theory has been fundamental to the faculty's research exploration. During the internship, the faculty had the opportunity to collect data through interviews with field personnel, project managers, superintendents, as well as the home office managers. After the internship, the faculty was able to build upon the internship experience with the theory as a foundation and continued her

research along the developed theory, explored more opportunities in the BIM domain, brainstormed research questions about the way people work and the way that the technology either challenges or reorganizes the ways that people work, and obtained research funding to support her data analysis on the theory.

Case B

Background: The faculty's goal for an internship was to expand his knowledge on lean construction to the domain of lean design or pre-project planning while the industry sponsor hired him for his expertise in lean construction. The sponsor was involved in its very first lean construction project, which necessitated the need to get assistance in its lean journey from experts. The faculty joined a new lean delivery project for approximately six weeks and participated in the pre-construction process including design coordination, management coordination, and target costing. He used his internship experience to discover current practices and identify areas to be improved.

Impacts onthe Industry Sponsor: The industry sponsor launched its lean implementation in its very first lean construction project. Over a six-week period, the faculty worked as an internal member in the pre-construction group of the industry. Together with the pre-construction group, the faculty developed a lean production plan, and attended coordination meetings and target cost meetings. He also informally assessed the company's opportunities and challenges in lean implementation. Additionally, the faculty contributed to two lean construction seminars hosted by the sponsoring company and its subcontractors. The broader impact is that the lean pre-construction model has affected other projects within the company in the way pre-construction planning is managed using the lean principles.

Impacts on the Faculty's Research Agenda: The benefits to the faculty member included exposure to industry and an opportunity to update his knowledge and to extend his research area to pre-construction. Even though the faculty had more than 10 years of experience in lean implementation , his area was limited to the lean implementation during the construction phase. Only a limited number of projects have adopted lean in their pre-construction phase. The internship project was the first lean construction project where lean is applied throughout the project including pre-construction phase in the Northwest area. Therefore, the internship experience expanded his research area to the pre-construction phase and enabled him to consider the mechanics and challenges of lean principles when applied to the pre-construction phase.

Case C

Background: The faculty had the goal to observe active examples and best practices in construction safety, estimating, and project management for her teaching and student advising duties at UW. Although the faculty has the expertise and technical skills in "document management" and "information searching", the original scope of the internship arrangement did not include activities where she could specifically apply her information technology background and knowledge. The industry sponsor has a

long standing relationship with the construction management program at UW and offered to host the faculty intern as a way to improve the quality of its future employees, many of whom were educated in the CM program at UW. Therefore the internship was very education-oriented as it commenced.

Impact on the Industry Sponsor: As the internship coordinator stated "We didn't have very high expectations since it was the first time the company took a faculty as its summer intern. The original idea was that it's going to be a one-way conversation with the faculty observing most of our practices. However, it turned out to be a two-way conversation and we were able to obtain different perspectives about the industry from the faculty". The faculty had several individual assignments during her internship and some, although they were in the contexts of "bidding" and "safety violation tracking" but not document management, provided opportunities for her to exercise her research expertise in IT. One of the work products was to compile a list of sub-contractors that were certified as small, female-owned, veteran-owned, or disabled-veteran-owned businesses. The faculty demonstrated to the hosting company how her knowledge in data cleaning and enhancing could add value to delivering the work product more efficiently and effectively and how the existing method, i.e. manual compilation, could be improved. The industry sponsor was involved in the internship with the main purpose of participating in construction's future. However, the coordinator also reflected that there is a place for research in that "Construction management is a very practical business. However, the internship experience allows us to be removed from our daily practices and have an unbiased look for possible improvement."

Impacts onthe Faculty's Research Agenda: The faculty has benefited from the internship not only in teaching but also in her research development. The faculty observed how the construction industry adopted technology in its day-to-day operations and the potential opportunities for IT-based research in construction. The faculty also noticed that an abundant amount of data, which could be analyzed for useful knowledge, was not being studied or utilized. For example, one of the faculty's research interests (and challenges) is to identify ways to generate and represent construction knowledge in order to support applications such as information searching in construction. To her surprise, during the internship, the faculty discovered an existing practice within the hosting company that naturally generated and organized a specific type of data that can be converted into useful construction knowledge. This could significantly reduce the level of laborious efforts that are traditionally-deemed as necessary during knowledge compilation. The discovery has a high potential to fundamentally support a range of knowledge-oriented IT research in construction and is added to the faculty's future research agenda for experiment and validation. Last but not least, the internship provided the faculty with rich construction contexts as a foundation for her research expertise.

Ratings for All Three Cases

Table 1 summarizes the data obtained from the rating questions for the criteria that were applicable to all three cases. Criteria which received one or more "N/A" in rating

responses are removed from the summary table because they were too specific and only applicable to some cases. From the data, it is clear that all three intern faculty influenced the industry sponsors by working as member of a team and all three sponsors held constructive attitudes toward UW after the internship. These reflections also suggest that a promising faculty internship strategy is for the participating faculty to seek opportunities in which he or she could team up with employees in the hosting company, as opposed to working individually.

Table 1 Result of the Rating Questions

	Case A	Case B	Case C	Average
1. How did the faculty influence the company?				
Meetings	4	4	3	3.67
Talking to employees (informal)	4	2	4	3.33
Working as member of team	4	4	5	4.33
2. What did the faculty influence?				
Attitude toward U. of Washington	5	4	4	4.33

5. Discussion

In cases A and B, the faculty interns have research interests set in particular "construction contexts", which provide explicit opportunities to match the faculty's expertise with industry sponsor needs. For example in Case B, the faculty was involved in a specific project where the faculty expertise on lean construction was greatly appreciated. The industry sponsor obtained assistance from the expert (i.e., the faculty intern) in its very first lean construction project throughout the internship. On the other hand, the faculty achieved his research objectives through implementing his knowledge and expanding the domains of the "lean construction" knowledge to the pre-construction stage. In both cases, the faculty intern worked with a specific department or team within the hosting company and explored new issues collaboratively with his or her colleagues at the company. The impacts of the internship experiences were bi-lateral and bi-directional in both cases. In case C, the faculty intern's research area, although broadly applicable, does not fall into a specific "construction context". The industry sponsor hosted the faculty intern because of its relationship with the university. Eventually, the faculty benefited from the practices she observed, and the hosting company learned about the faculty's expertise and although it was unanticipated the company benefited from her expertise. The impacts of the internship experiences were bi-lateral but unidirectional in case C. Therefore, there are different models in which successful faculty internships can be molded and one of the model determinants is the nature of a faculty's research expertise and the goals of the host company.

6. Conclusion

Faculty internships can be a great way to add real-world experience to the classroom setting. We have found that they also enrich faculty's research experiences and thereby impact industry sponsors. Our analysis suggests that a promising internship

strategy is for the participating faculty to seek opportunities in which he or she could team up with other employees in the hosting company, as opposed to working individually. Our analysis also indicates that there are different models in which successful faculty internships can be molded and one of the influential factors is the nature of a participating faculty's research areas and the industry host's goals.

Our study helps both the CM academic and professional communities comprehend the often under-looked perspectives of faculty internships:

1. The study enhances our understanding of the faculty internship dynamics and how that leads to impacts upon academic scholarship and the industry sponsors' work.
2. The study provides a spectrum of CM faculty internship experiences to identify common and promising strategies for successful internships.
3. The study shows how internships could be designed with the faculty's research focus in mind and that it's not one model.

Consider treating the faculty internship as a research project. Just as a research proposal, the internship should be planned with a specific timeline and goals and objectives. Then, as the internship is executed, the plan evolves as discoveries are made. In the end, all parties should document and discuss the impact of the experience - perhaps resulting in internal or external publications or presentations. The authors would like to encourage all involved - faculty and industry personnel- to have an open mind about the internship and allow the researcher to explore the goals and objectives and, through dialog and work product, the discoveries of the internship unfold. Particularly for faculty, we recommend they explore their learning objectives as well as their research interests. We all found very compelling and unanticipated things at this intersection.

7. Acknowledgements

The authors would like to thank John Schaufelberger, the Department Chair of Construction Management, and industry sponsors for their support of this work.

Abstract:

Interdisciplinary collaboration is becoming standard practice in the Architecture/Engineering/and Construction (AEC) industry. However, educational models in AEC have been slow to adjust to this rapid shift in project organization and execution. In recent years, industry leaders have expressed an increasing need for interdisciplinary professionals in the AEC industry. AEC education has great challenges ahead in order to address these needs.

This paper explores the needs and challenges for interdisciplinary education in AEC and introduces initial efforts at the Georgia Institute of Technology to meet this need. The results of a survey of students, alumni and other groups are presented as well as the analysis of data from an on-line petition. Analysis of the data collected shows that there are conflicting views of the benefits of such an initiative. However, the results also highlight opportunities for enhanced collaboration through digital tools and greater inclusion of engineering departments in the process.

Introduction:

Collaboration between multidisciplinary teams is becoming standard practice in the Architecture/Engineering/and Construction (AEC) industry. However, educational models in AEC have been slow to adjust to this rapid shift in project organization and execution. Most students in these fields spend the majority of their college years working on individual projects that do not build interdisciplinary teamwork or communication skills. When these students confront the intensively collaborative reality of today's AEC practice, the inadequacies of their education suddenly become clear. For example, a survey of architecture alumni revealed that only 46% felt their school did a good job fostering their ability to work cooperatively in interdisciplinary teams (Boyer and Mitgang, 1996). Therefore, opportunities for improvement of AEC education must be pursued.

Engineering education, as well as AEC education, has great challenges ahead. The 14 Engineering Grand Challenges proposed by the National Academy of Engineering involve energy, sustainability, medicine and health care, reducing our vulnerability to natural and human threats, and advancing our human capabilities and understanding our world and ourselves (Vest, 2008). In particular, AEC education can address many if not all of these challenges by adapting to provide learning experiences that incorporate creativity, sustainability, and interdisciplinary interactions on a greater scale.

Industry has also expressed the need for changes in curriculum to address present and future challenges for the engineering profession, such as the need for skills in an increasing global and virtual workplace, as well as the aptitude and attitude required in sustainable development, discipline-mixing, and experience-based innovation (Fouger, 2008). It is no longer acceptable for engineers to just analyze problems or mathematically derive models of problems; they must experience design, creativity, and innovation (Almgren, 2008). In order to empower the next generation of engineers, it is necessary for education systems to focus on "green engineering" for sustainable growth (Gopalakrishnan, 2008).

The National Academy of Engineering has identified the need to expand current messages about engineering beyond the need for math and science skills. These messages ignore other vital characteristics of engineering, such as creativity, teamwork, and communication (National Academy of Engineering, 2008). These last three are part of the focus of the study of the need for interdisciplinary education in AEC. Therefore, the significance of the findings discussed in this paper is the contribution to the understanding of this need, and the challenges in embarking in such an endeavor. Finally, the paper will share The Georgia Institute of Technology's experience in the pursuit of a new undergraduate education model that integrates various disciplines within the College of Architecture.

Interdisciplinary education in architecture, engineering, and construction (AEC): The concept of integrated curriculum has been discussed as early as 1937 (Hopkins, 1937). The exploration of interdisciplinary education in AEC was recommended as one of the seven goals outlined in the Boyer Report (1996). The special report by the Carnegie Foundation for the Advancement of Teaching points to the need for a "full exploration of the interdisciplinary potential for architectural education and practice", and "interdisciplinary connections to better serve society's needs"(Boyer and Mitgang, 1996). The desire and importance for reforms in engineering education has resulted in significant efforts, such as the Synthesis Coalition and Project Succeed, which emphasize reforms in multidisciplinary content, teamwork and communications, hands-on and laboratory experiences, and open-ended problem formulation and solving. Through the years, various academic institutions have experimented in interdisciplinary collaboration. Researchers in construction education have studied the integration of disciplines in their academic programs by developing a range of learning experiences. A summary of relevant examples is shown in Table 1.

Table 1. Studies on Interdisciplinary Education in AEC

Authors	Institution(s)	Description
Fenves, 1995	Carnegie Mellon University	First year graduate level course intended to foster an interdisciplinary setting for domain-independent problem solving for engineering students.
Mills et al., 1996	Virginia Tech	Vertical and horizontal integration at the undergraduate level.
Mills and Beliveau, 1999	Virginia Tech	Capstone course across academic levels in the Building Construction Department
Robson et al., 1996	University of Oklahoma	Architecture, interior design, landscape architecture, and construction science students worked in teams.
Fruchter, 1999	Six universities from Europe, Japan, and the United States	Developed a distributed learning environment.
Hussein and Peña-Mora, 1999	MIT and CICESE in Mexico	Developed Framework for the development of a distributed engineering laboratory.
Graham and Geva, 2001	Texas A&M	Interdisciplinary studio between architecture and construction science students.
O'Brien et al., 2003	University of Florida and the University of Illinois at Urbana-Champaign	Master's level capstone design course which involved architecture, structural engineering, and construction management students.
Breit et al., 2006	Various universities in Europe	The concept of Project Oriented Learning Environment (POLE) was used to conduct a collaborative course
Leicht and Messner, 2009	Penn State	Interactive workspaces for improving learning in the engineering and construction context.

As past and current research shows, collaborative and interdisciplinary education models in AEC education have been explored with positive results. In spite of this, interdisciplinary education in AEC has not gone beyond test courses and limited application.

Case Study: Interdisciplinary Education at Georgia Tech's College of Architecture

In the Spring of 2007, the Construction Resource Center at Georgia Tech held a workshop to gain understanding from industry practitioners and academics about AEC Integration. The workshop resulted in ideas that would help the College of Architecture (CoA) at Georgia Tech to develop a curriculum centered on AEC integration (Construction Resource Center Report, 2007).

Experts from different sectors of the AEC industry, representing the private and public sector, as well as academia, were invited to participate in the event. Faculty from Georgia Tech's College of Architecture (CoA) also attended, and included representatives from the Architecture; Building Construction; City and Regional Planning; and PhD Program departments as well as from the Dean's Office.

The workshop was organized in four parts: In the first part, each member of the panel was asked to provide a definition of AEC integration. Definitions varied greatly depending on the professional background and perspective of the panelist. Panelists defined integration as: a 'Team Approach' to project execution; leadership and project/program management; either a 'Renaissance Man' master builder or a shared sense of empathy among disciplines; relationship-building; technology-based

Building Information Modeling (BIM); and a reflection of industry trends toward consolidation.

In the second part, panelists provided both driving and preventing factors toward integration. Among the driving factors included: demands of market; client expectations; increasingly complex project; litigation; technology; and re-conceptualization of the meaning of 'value.' Some of the factors preventing the industry from achieving integration included: lack of trained personnel; attitudes of professionals; fragmentation of disciplines in university setting; lack of unifying standards; and fear of technology.

Panelists discussed the general tools that can be utilized to enhance integration in the third part of the workshop. Some of the items discussed included: innovations in procurement and project delivery systems; development of standardized processes; gathering industry feedback on their needs and concerns; and creating an educational environment in which integration is central to learning.

The fourth part included a discussion of the role of Georgia Tech, and other universities, in promoting AEC integration at the college level. Panelists discussed some of the core competencies which were critical for future graduates, including: financial and business skills; problem-solving skills; technical expertise; and more exposure to the various disciplines. Panelists also discussed some of the specific ways Georgia Tech can move toward a more integrated curriculum, including: development of jointly-taught courses; joint lecture series with College of Engineering; open dialogue with the College of Engineering on strategies for closer cooperation; and development of the first graduate degree for Professionals in the Built Environment (MBA, in partnership with College of Management).

After the workshop in the Spring of 2007, the CoA conducted a review process that culminated in a strategic emphasis on interdisciplinarity. This emphasis would allow expanded focus on areas such as green buildings, alternative energy, healthcare, digital design and information technology. It was envisioned that the graduates of the resulting programs would have leadership and problem-solving skills of great value to industry and that faculty would have the resources to pursue interdisciplinary research areas. The changes under consideration would create an undergraduate experience that integrates core requirements with new content areas and modes of teaching and learning (Atlanta Journal Constitution, 2009; College of Architecture News Release, 2009a).

Initially, the CoA planned for the creation of a Bachelor of Science in Design degree with designations in core areas in the CoA such as Building Construction, Architecture, Industrial Design, and others. After the strategic plans were announced, a petition was posted on-line to collect signatures of those in disagreement with the vision of the College (On-line petition, 2009).

On August 19, 2009 the CoA announced the creation of a steering committee to oversee the incremental changes to the curriculum. The steering committee would be tasked with conducting market research including job placement statistics and alumni focus groups; assessing and preserving core disciplinary skills; and assessing options, including an integrated curriculum that is complementary to current academic offerings in the CoA (College of Architecture News Release, 2009b). One month later the CoA expressed that the changes to the undergraduate program would not include

the elimination of any of the existing degrees as pointed out by the on-line petition circulated since the month of July, 2009 (College of Architecture News Release, 2009c).

In order to understand the reasons for the reaction to the CoA's plans for the undergraduate program, an analysis of data collected from the On-line petition is presented in subsequent sections. The need and challenges of such an endeavor are studied through an analysis of data collected from various sources. A survey of students and Alumni at Georgia Tech, industry groups, and students at a close-by university with similar programs to the ones involved at Georgia Tech was conducted.

Methodology:

In order to explore the challenges and opportunities for interdisciplinary AEC education, data was collected from a survey among students and alumni of the Georgia Institute of Technology, Southern Polytechnic State University, and Georgia Southern University in the state of Georgia (these three Universities represent all the AEC programs in the state). Data was also collected from an informal web-based petition pursuing reconsideration of the CoA plans.

The Survey Instrument: The survey instrument was distributed via the Survey Monkey website to a target population of approximately 3448 subjects as shown in Table 2. The response rate is estimated to be 6.64% not including a few faculty and alumni who responded to the survey.

Table 2. Approximate respondent population (estimated from enrollment at respective institutions)

Institution	Enrollment
Southern Polytechnic State University (Spring 2009) (SPSU, 2009)	
Civil Engineering Technology, Construction Engineering, Construction Mgt/Construction Dev., Architecture/Pre Arch./Pre Design Arch.	1442
Georgia Southern University (Fall 2008) (GSU, 2009)	
BSCET in Civil Engineering Technology, BSCONS in Construction Management	617
Georgia Institute of Technology (Fall 2008) (GT, 2009)	
Architecture, Building Construction, Industrial Design, Civil Engineering	1389
Total	**3448**
Response Rate	**6.64%**

The survey was divided in two sections, respondent's demographic information and respondent's perceptions. The questions in the second section included statement for the respondent to indicate level of agreement using the provided five-level Likert scale. The next sections describe the results of the survey.

Survey Responses: The following sections describe the results obtained from the survey. As shown in Figure 1, students were the largest group of survey respondents with 94.6% of the total respondent sample. Although, there was an interest in exploring the perceptions of faculty and alumni, the low response from these groups did not allow for extensive analysis of this group.

Academic Rank: The academic ranking of participants was mainly in the upper levels

of undergraduate degrees and graduate students at the master's degree level as shown in Figure 2. This may be an indication that issues related to interdisciplinary education may be of interest to more experienced students.

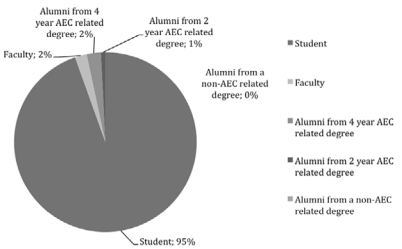

Figure 1. Distribution of Survey Respondents

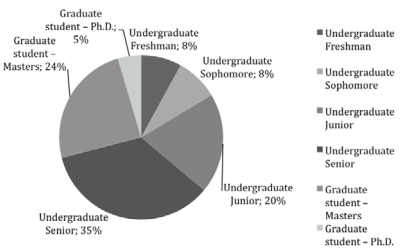

Figure 2. Academic Rank of Respondents

Respondent Age: Over half of respondents (56.8%, n=241) were between the ages of 18 and 24 years. This is representative of the student population who responded to the survey.

Industry Experience: The industry experience of respondents was an average of 3.43 years (n=234).

Work Experience while attending College: The results of the survey showed that a large number of respondents (80.7%, n=202) had some kind of work experience in the AEC industry while being students with 62.4% of those having internship or full-time positions.

Student Competition Experience: A significant number of respondents did not have student competition experience (79.1%, n=215). Of those who did participate in student competitions, the largest number participated in the ASC student competition (7.9%, n=215).

Perceptions about Interdisciplinary Education, Sustainability, Creativity and Technology Use in AEC Education: When presented with the statement; "I feel that my current or past academic training prepared me or is preparing me to work in an interdisciplinary environment", over half of the respondents (69.36%, n=173) agreed or highly agreed with the statement. Over half of the respondents (64.5%, n=173) agreed or highly agreed that their current or past academic training provided them with knowledge about the functions of team members from a professional background different from their own.

Regarding the importance of sustainability in their coursework, 64.16% (n=174) agreed or highly agreed that was important. In addition, 69% (n=174) of respondents expressed to have a deep understanding of the benefits of an interdisciplinary work environment for the sustainability of a project.

A significant number of respondents agreed or highly agreed with the statement "Creative problem solving was or is an important part of my coursework" (79.53%, n=172). Also, a significant number of respondents agreed or highly agreed in that interdisciplinary work environments can enhance creativity of design solutions (92.26%, n=172), as well as solutions to construction related problems (91.07%,

n=172). Over half of respondents indicated that educational information technology was extensively used during their academic preparation (60.46%, n=173).

Regarding the use of educational information technology, a significant number of respondents (75.59%, n=173) expressed that they agreed or highly agree that its use enhances collaboration in a team environment. Over half of respondents (54.6%, n=173) also expressed that they agreed or highly agreed that they felt their academic training is preparing them well to use information technology for information exchange in the workplace.

About the respondent's familiarity with the interdisciplinary education initiatives at Georgia Tech's CoA, the results showed that respondents were not very familiar with almost 30% expressing neither agreement or disagreement and 35.93% expressing disagreement or high disagreement (n=168). Without providing any specific information about the CoA's interdisciplinary education initiatives and considering only the information that respondents may have access through the local media, about half of the respondents (50.6%, n=168) agreed or highly agreed with the interdisciplinary education initiative at GT's CoA.

Respondents agreed or highly agreed (61.58%, n=168) that inclusion of engineering programs in the interdisciplinary education initiatives at GT's CoA would enhance them. More than half of respondents (54.55%, n=168) also agreed or highly agreed that a graduate of an interdisciplinary program from GT's CoA would have good employment opportunities.

The Web-Based Petition

The greatest number of respondents to the on-line petition was from the United Sates (n=546) with 18 being from 12 other countries. The US respondents were distributed among 32 States as shown in Figure 3. Respondents represented a total of 24 disciplines. The disciplines with the largest number of respondents are shown in Figure 4.

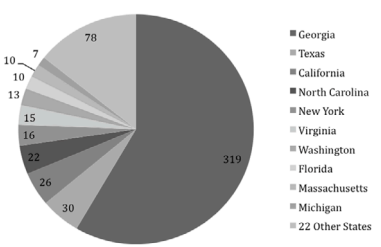

Figure 3. Respondents by US State

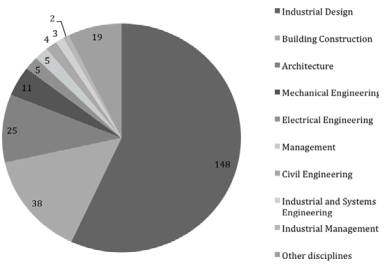

Figure 4. Respondents by Dicipline

The main concerns expressed by respondents to the on-line petition about the interdisciplinary education initiatives at Georgia Tech's CoA included (extracted from the comments posted by respondents on the petition website):

- Graduates will be ***less competitive***, ***less specialized*** for the job market. ***Focus is needed***, CFY (this is the Common First Year, a unique program to GT where students from various disciplines in the CoA take several studio based courses

together) is not good and its more than enough integrated coursework. We ***need professionals***. There are ***no jobs for generalists***.

- ***It weakens all three disciplines*** (lowering the value of undergraduate degrees)
- The three disciplines (Architecture, Building Construction (BC), and Industrial Design (ID)) are ***extremely dissimilar*** (use of different techniques).
- Not at the ***benefit of the student***, but at the benefit of the college tuition profits (Use design thinking rather than accounting thinking).
- The transition ***will surely damage the integrity and the value (discrediting) of the already awarded Building Construction, Arch, and ID degrees***, and will decrease interest in the construction industry.
- We will ***lose the students*** who are interested in the actual disciplines.
- ***4 years is enough to work***, most students want to work after BS.
- It will ***damage their reputation.***
- The fact that ***ID is offered at so few schools*** already really helps keep GT on the map for out of state students.
- More ***management focus for BC.*** A BC student would be better served studying material that is relevant to their field of choice. They should not be forced to spend many hours on studio tasks (mainly charcoal drawings) and being evaluated with arbitrary grading requirements.

Conclusions:

Multidisciplinary collaboration plays a vital role for successful completion of projects in the AEC industry. To meet the growing demands and challenges of AEC industry, an interdisciplinary approach to AEC curriculum design is becoming increasingly relevant. For over ten years, various institutions have experimented with different modes of interdisciplinary learning, but there is still no interdisciplinary curriculum in the AEC education in the US. The recent initiative of Georgia Tech's College of Architecture for an interdisciplinary curriculum was presented as a case study of interdisciplinary education in AEC. A survey was conducted to explore the perceptions about interdisciplinary education, sustainability, creativity and technology use in AEC education by students, alumni and practitioners in the state of Georgia. In addition, an analysis of an on-line petition was performed in order to understand some of the reactions to the CoA's interdisciplinary education initiative.

The results of the survey reinforce the conclusion that interdisciplinary work environments that significantly use information technology have the potential to enhance creativity of design solutions. These work environments also have the potential to enhance solutions to construction related problems as well as sustainability. They also show that use of information technology enhances collaboration and information exchange. It was also observed that the majority of students perceived that their current or past academic training have prepared or will prepare them to work in an interdisciplinary environment. Most of the respondents expressed that including engineering in an interdisciplinary education initiative at GT's CoA would enhance it and that such an initiative could provide them with good employment opportunities.

However the on-line petition of those in disagreement with GT's CoA interdisciplinary education initiative presented a different perspective. There were

many respondents who expressed concerns with lack of specialization, weakening of existing degrees at GT's CoA, the amount of time needed for employment vs. graduate education, and the fundamental differences between the degrees currently offered and that would be integrated.

There is clearly more work to be done to address the needs and challenges of interdisciplinary education in AEC. Georgia Tech's CoA will continue to evaluate ways in which to address those and a continued and in-depth analysis of the process and results will be necessary.

ABSTRACT

J. E. Dunn Construction Group and Iowa State University have collaborated in an innovative distance education program. By utilizing a micro-PC, digital camera and hands-free headset and microphone; jobsite personnel at the J. E. Dunn headquarters building construction site transmitted, via wireless technology, video imagery and voice information of real-time construction events to students in Iowa State University's Construction Engineering Program. Remote students seated in a high technology classroom were able to observe and discuss actual jobsite activity as it occurred 225 miles away. A series of "virtual" field trips were conducted covering several phases of the project, including site work, foundations, building structure and interior finishes. One of the virtual tours was led by J.D. Dunn's LEED specialist. In this tour, the guide specifically identified those building components earning LEED points for the project. Students, by and large, were pleased with the virtual site tours as the remote tours were less disruptive to their schedules and accomplished the same educational objective. Although this approach incurred certain technical difficulties, the information technology system performed satisfactorily and demonstrated promise for increased application of virtual construction site tours for many project stakeholders such as owners, architects, engineers, and lender representatives.

INTRODUCTION

No longer must an individual physically travel to a construction project site to observe construction operations. It has been generally believed that only by walking the project could an individual judge the status of the project's schedule, evaluate conformance with safety requirements or understand the unique physical characteristics of a particular construction site or building project. Now with modern communication technologies, virtual visits can be utilized to augment traditional on-site visits and reduce travel costs.

The Construction Engineering Program at Iowa State University in Ames, Iowa has teamed with J. E. Dunn Construction Group of Kansas City, Missouri to leverage information technology to benefit student learning. Construction Engineering students have virtually visited a building under construction to see, first hand, the process of construction. And they never had to leave the classroom! The subject project was the recently completed headquarters building for J. E. Dunn Construction Group located in downtown Kansas City, Missouri. The project includes a 6-story office building of approximately 205,000 gross square feet and an attached multi-level parking garage. This project was specifically selected as it was designed and built to achieve LEED Gold certification through US Green Building Council. When certified, it will be the first commercial office building in the Kansas City metropolitan area to achieve that status (Setzer, 2008).

LITERATURE REVIEW

The most fundamental and widely used wireless communication device is the cellular phone. This common device offers advanced technology beyond simple voice transmission. For example, researchers at the Massachusetts Institute of Technology have collaborated with medical practitioners in the Philippines to transmit X-rays using a cellular phone platform (Denison, 2009). This wireless technology allows experts in distant metropolitan areas to review X-rays taken in remote, rural areas. Without this application of cellular technology, rural patients could not be provided the high level of medical care common to metropolitan areas.

The construction industry has wide application of cellular phone technology, most commonly for verbal communication. But in addition to cellular voice transmission, many construction researchers propose to use wireless technologies, including digital cameras and wireless computers, to observe, review and monitor construction projects. Digital camera technologies and wireless communication infrastructures have proven to increase the efficiency of completing many common project management processes.

Fixed, remote-controlled project site cameras, also referred to as web-cams and surveillance cameras, have become prevalent over the last ten years (Hannon, 2007). Digital cameras are an increasingly common tool for observation, monitoring and

management of construction site operations. The ability to transmit live video images from fixed locations at the project site to a construction company's central office was identified as an application of Internet-based project management systems for the construction industry by Deng et. al in 2001. Their research indicated that at the time of the research the limits of data transmission speed in the available Internet infrastructure did not "generate video-like quality images" (Deng, 2001). These researchers also identified the benefit of improving productivity by analysis of the images recorded through site cameras.

Early research regarding collection of field data using digital cameras was also performed by Liu at the University of Illinois at Urbana-Campaign. Liu developed a prototype information collection device, termed a "Digital Hardhat" (Liu, 1997). This innovative, information technology device included a standard hardhat outfitted with a digital camera mounted above the brim. This hand-free camera allowed transmission of real-time images, audio and video from the project site to remote office. In this experimental model, Wi-Fi technology was employed to transmit data from the hardhat to a server located in the project site trailer. From the site trailer, data traveled off-site via a cabled Internet service.

Researchers at Carnegie Mellon University in Pittsburg, Pennsylvania have also investigated the application of mobile technology on construction projects (Burgy, 2002). They studied certain mobile technologies termed "wearable computers," including lap-top computers, Personal Digital Assistants (PDAs) and Pocket PCs. The proposed application of these IT devices is to collect construction project data by recording information relayed by embedded or attached sensors.

Applications of "active data collection" (Trupp, 2004) has been further explored through research by Trupp et. al. at the University of Illinois. Active data collection is performed when on-site construction personnel manually operate the recording devices. These researchers also envision automated data collection which would not require user interaction, including fixed digital cameras, 3-D laser scanners and RFID-tags. These researchers have suggested that "3D Laser scanning, digital close-range photogrammetry and mobile computing are among the promising data collection technologies" to advance the effectiveness of construction management (Trupp, 2004).

Research by the National Cooperative Highway Research Program (NCHRP) in 2007 reported the advancement of fixed camera systems from either a single camera per project location or independent multiple cameras per project site to the development of "a networked robotic camera system" in which cameras have robotic features and improved image resolution capability (Hannon, 2007).

Silva, et. al. (2008) reported that declining construction productivity is resulting from inadequate supervision. This team researched improvement of project management with a "Virtual Supervision" model using project information obtained by video cameras mounted on tower cranes. The model allows project supervisors to watch construction activities remotely. The anticipated result of this convenient manner to provide construction supervision is improvement of operational efficiency, quality of communication and construction worker satisfaction. These and numerous other research efforts strongly support the continued use of wireless technologies to advance construction.

METHODOLOGY OF VIRTUAL PROJECT TOURS

Off-campus field trips are time consuming and often inefficient uses of students' limited time resources. Field trips may not only result in absenteeism in other classes, but may also cause significant challenges for students with mobility disabilities. Yet, visiting construction projects offers educational experiences for construction engineering students not able to be taught with photographs in textbooks or one-directional filmed media. Virtual project field trips solve the previously noted disadvantages of traditional project tours, and maintain many of the advantages of a real, live construction observation.

Execution of the virtual tour pilot program required the research, selection and integration of information technology devices including a digital camera, voice recorder, and wireless mobile computer. Secondly, software and communication services were researched and initiated to allow voice and videographic information to flow from each mobile device, through a Wi-Fi network and the Internet to its destination of large television screens and speaker system in the high technology classroom. Furthermore, this information network was designed for two-way interaction, allowing students to query the project tour guide and achieving real-time dialogue.

The methodology for this experiment included multiple tours so that "bugs" in the system could be worked out. A series of seven project tours where designated. Following the completion of experimental tours, the tour guides and students were asked to provide feedback on the quality of educational experience, advantages and disadvantages of virtual tours compared to typical on-site field trips, and improvements that could be made to the IT application. This participant feedback provided qualitative data through a sample of convenience.

TECHNOLOGY ELABORATION

Using a handheld camera and head-set microphone, project personnel walk a designated jobsite, narrate, and beam live action back to the classroom in real-time via wireless internet technology. Figure 1 depicts the equipment used for this experiment. Students are able to view the project conditions and converse with jobsite personnel as the action happens, experiencing project management situations as they occur.

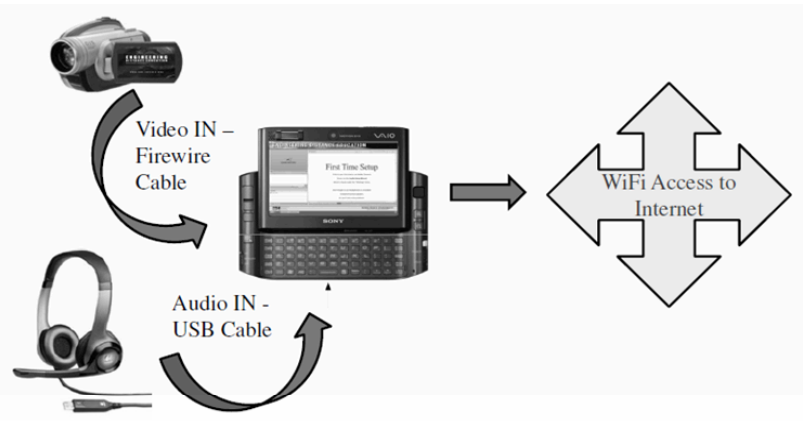

Figure 1: Information Flow Chart and Videography Devices

The remote classroom technology is hand-held and wearable to enable walking, talking work-site lectures over the Internet. The tour guide used a Sony Vaio® UX-390n computer which is similar in size to a portable DVD movie player and designed to be mobile with built-in wireless and cellular broadband capabilities. This micro computer has two built-in cameras for providing live video feeds of the narrator's face or a point-of-view shot of the construction site. The other essential component is a headset/microphone system worn by the construction professional under a hard hat. The headset plugs into the micro computer to enable the two-way audio communication with the remote students attending via Iowa State University's Engineering Distance Education (EDE) online learning system.

At the J. E. Dunn construction site, a wireless LAN system from Trapeze Smart Mobile was deployed to blanket the work-site with Wi-Fi coverage. The last piece of mobile technology is the ubiquitous Sony Handycam camcorder which can be connected to the micro computer to provide long distance shots when heavy equipment and other hazards prevent the instructor from getting close to the construction work zone.

In the classroom, students view a large screen split into sections (refer to Figure 2). On the left, is the live video feed divided between the classroom and job site. On the right, project documents, Building Information Modeling (BIM), drawings, details, specifications and the independent, fixed job-cam can be viewed to illustrate or explain the audio/video portion. An operator monitors the screen from within the classroom.

As demonstrated in Figure 2, in addition to students being able to view actual in situ construction, they can also view at the same time a Building Information Model (BIM) of the subject project. Having both a live image and a BIM model facilitates enhanced understanding and offers easy side-by-side comparison by the students.

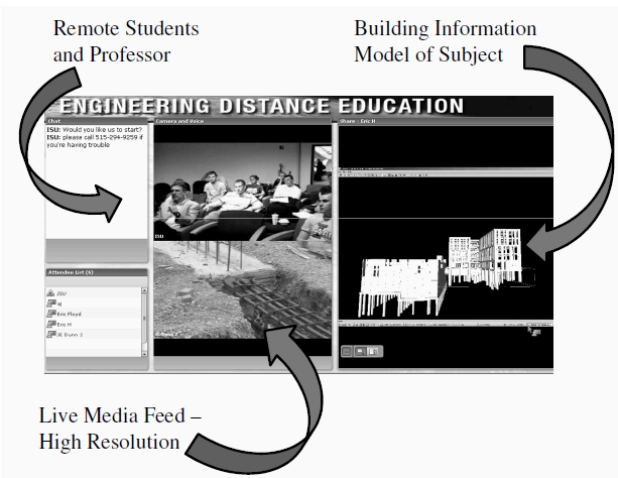

Figure 2: Representative Screen Images comprising the Virtual Tour

The research team's goal from the beginning was to use off-the-shelf technology familiar to the online learning community. Using the *AdobeConnect* web conferencing system as the common platform required that the remote classroom computer be mobile. In the Iowa State University classroom, the equipment included a basic desktop computer, speakers, video projector to enlarge the images coming from the digital camera, and several conference style microphones to capture the student questions. The advantage of using a web-based conferencing platform is that anyone with a computer and Internet connection can join the online class session. For example, architects sitting in offices anywhere could be invited to join the live discussion and display drawings for the live virtual classroom. These web sessions

are captured and archived for later viewing from servers supported by Iowa State University's Extension Information Systems Department.

LESSONS LEARNED

Virtual tours were conducted for students that included five to ten minute segments of audio and video with gaps of similar amounts of time that occurred while the tour guide navigated around the job-site in search of a location that both had Wi-Fi coverage and a construction operation that was of interest for the students. The students were enthusiastic about the opportunity to participate in the experiment and enjoyed the segments of the tour that were transmitted. The consensus was that the concept should be further developed and that virtual tours such as these would be a worthwhile experience, especially if a nearly continuous audio and video feed could be maintained. Positive feedback suggests that students will accept a certain amount of short interruptions in the audio and video feed and some harsh audio in order to have the opportunity of a remote construction tour.

Maintaining a Wi-Fi signal proved more difficult as the building enclosure became partially complete. Strategically placing Wi-Fi antennas to provide complete job site coverage was challenging. This problem was mitigated when the antennas were moved to higher locations, such as the tower crane mast. Even when antenna were placed in the best locations, constant vigilance was necessary to ensure that construction activity did not block the signal or that the antenna was moved to be better location. During virtual tours, when signal was lost, a frustrating amount of time was expended to reconnect the communication link between project site and classroom. These interruptions detracted from the educational experience and lengthened the time required to complete a project tour. This experiment demonstrated that proper antenna placement is a key element to the success of virtual tours if a local area, Wi-Fi infrastructure is used.

At times, a high volume of noise caused by background construction operations and wind caused difficulty for the tour narrator to hear questions from the classroom and also reduced the clarity of audio delivered to the classroom. Unexpectedly for the research team, wind noise detracted greatly from many of the virtual tours. Efforts to protect the microphone from wind somewhat mitigated the problem, but never provided a complete solution. In addition, voice over internet protocol (VOIP) at times delivered harsh audio and latency problems that detracted from the learning experience.

A standard cellular phone was used as an alternate to the head-set microphone and often provided considerable improvement to communication clarity. It also offered the benefit of a separate voice connection to the classroom from the mobile computer connected through the Internet. At times when the Wi-Fi connection failed and the video feed dropped, the use of an independent cellular phone connection allowed the

tour to continue with audio-only delivery until the digital feed could be re-established. Also, the length of time to re-establish the live video link was lessened when the head-set audio device was not used as the total number of devices to be "re-booted" was reduced by one device. While the video feed was interrupted, the cell phone connection offered the opportunity for both the audience and the tour guide to cooperatively engage in trouble shooting. This was especially helpful when it was necessary to establish the Wi-Fi coverage limits of where the video feed could or could not be maintained. When VOIP was used the tour guide often was unaware when the connection to the classroom was lost, much to the frustration of the audience. Based on the experience gained from these test tours, it is recommended to have a back-up audio connection that allows the tour guide to communicate with the audience at those times when the primary connection is lost.

The selected camcorder required operation by hand. At times, however, the tour guide required use of his hands to safely walk the construction site and avoid construction hazards. A hands-free camera, such as hard-hat mounted, would be preferred to hand-held. In such a case, however, the narrator still requires an option to adjust camera settings, such as zooming in on the details of a specific construction activity or as-built condition. In the future, voice activated technologies may offer a solution to this human-equipment interface.

Developing a planned route for the tour is challenging. The tour guide usually knew about the site in detail, has a 3-D 360 degree view of the job site, is geographically-oriented to the surroundings and knows the history of the project. Meanwhile, the students may be suddenly confronted with a narrow angle video view of the details of assembling a constructed facility, possibly before they understand the context within which the details lay. This issue was mitigated by providing students with a map showing the location of the project within its surroundings, a computer-generated rendering of the building, a site plan and a one-page, double-spaced narrative description of the project. Furthermore, it was helpful to begin the tour with wide angle views of the project and its surroundings with frequent references to cardinal directions, the location of nearby landmarks and an orientation regarding the major features of the construction project and their actual location in wide angle views. Subsequent more detailed views were kept in context by occasionally referencing landmarks during the virtual tour. Based on the research team's experience, learning might be further enhanced by giving a brief overview presentation that might include aerial photos of the site, 3-D models, renderings, site plans and floor plans and building elevations.

CURRICULUM DEVELOPMENT

Based upon the success of this pilot program, the construction engineering program at Iowa State University will increasingly implement virtual project tours into its curriculum. Virtual project tours are appropriate components of numerous

construction engineering classes, specifically including construction methods and materials, construction estimating and design/build. In addition to these established classes, a new class on international construction will be offered in the fall of 2010. Virtual project tours, likely predominantly asynchronous, will provide much of the subject matter for the class. These tours filmed in countries around the globe provide access to international construction projects otherwise unavailable to engineering students.

NEXT STEPS

Research and experiment with digital cameras and wireless communication, including this work in virtual project tours, has demonstrated the feasibility of using this concept for construction education. The challenge for construction researchers is to refine the technology with regard to field connectivity, audio quality and virtual tour planning. In addition, it is desirable to develop new practical applications that are consistent with availability of new equipment and advancements in communication infrastructure.

3G cellular coverage is one example of newly available communication infrastructure. This research team is currently modifying the hand-held computer in order to access an AT&T 3G cellular service area directly from the project site in lieu of connection via a project-located Wi-Fi network. We plan to test the transmission speed of media data directly from the hand-held computer to the Internet by cellular service. If the transmission speed is sufficient to support real-time delivery of the audio and video feed, then projects located within any 3G coverage area could offer virtual tours as well.

Background noise reduction is a technology with direct application to virtual tours of construction projects. By the nature of construction projects being both outdoors and involving loud equipment, background construction noises can easily interfere and potentially even inhibit the comprehension of the tour guide's audio information by the classroom audience. Reduction of background noise has an application in hearing aids and hands-free cellular phone devices (such as noise canceling Blue tooth ear-mounted devices). Future research could include incorporation of "smart" noise reduction technology into the apparatus used by the on-site tour guide. It is hypothesized that automatic elimination of background construction and wind noise will significantly improve the clarity of audio transmitted to the classroom and greatly improve the learning experience.

This research group is also testing the benefits of synchronous vs. asynchronous delivery of media from construction projects. Synchronous media is provided live, real-time as demonstrated by the pilot project of the J. E. Dunn headquarters building. With asynchronous delivery of media, the tour is pre-recorded prior to presentation to

the classroom, similar to a traditional film. An asynchronous delivery could offer benefits that are not available with synchronous delivery, such as editing, fast-forwarding, and pausing of the video for discussion and questions. Asynchronous tours could be enhanced by presentation of the pre-recorded tour video by the tour guide. Researchers suggest that the tour guide travel to the classroom to present the pre-recorded video to the students. Although not fully virtual, this solution limits travel to one individual from the project site to the classroom in lieu of an entire classroom of students from classroom to project site.

CONCLUSION

The virtual project tours described in this paper were developed with the purpose of educating construction engineering students who could not easily take a day off from classes and travel to a distant job site. These tours constituted a pilot program through which various information technology equipment and communication options were explored. This experience has proven that modern videography equipment and communication technology allow, in concept, for onsite construction professionals to conduct real-time, virtual construction project tours. These results provide the basis to explore further applications for virtual tours that may be useful to other construction project participants.

Abstract:
Various attempts have been made to apply Radio Frequency IDentification (RFID) technologies to current construction operations and processes; however, RFID applications have still required considerable investments and efforts to be successfully applied in the real construction projects. This paper examines the RFID technology applied to construction projects. A simulation model is developed to quantitatively evaluate the possible productivity benefits of RFID in construction. The model is based on the case study of a real construction project where the critical points of economically feasible solution for RFID application can be searched variable depending on the costs of RFID tags and RFID readers The simulation model also compares performances to apply RFID applications before and after. The results of simulation showed that RFID technology is effective for enhancing the project performances improvement at the operation and process level by reducing cycle time, decreasing queuing time, and improving other benefits including reliability of construction operations compared to invested costs. The results, however, also indicated that RFID application needs for further analysis in view of assessing qualitative aspects as well as implementation obstacles, based on more broaden case studies.

Introduction

Construction productivity has declined and project performance has recently been a major issue in the construction industry. Productivity measurement has focused on

efficiency, which is the ratio of the effective or useful output to the total input in a project (Klanac and Nelson, 2004). In contrast, little has been done to hence the reliability of a process performance, which is the controlled defect rate to maintain a high-standard quality level through six sigma principle (Han et al 2008). Therefore, it is necessary to consider both quantitative and qualitative aspects and to optimize the work conditions improve performance, and build strategies to improve productivity in a construction work. In particular, the qualitative level of material management is a critical factor influencing total project productivity; in other words, the performance of a construction process can be enhanced when both the efficiency and the reliability of material management are insured.

To achieve this objective, many researchers and project managers have sought to improve project performance by applying emerging technologies to current construction operations and processes. In particular, Radio Frequency Identification (RFID) is a branch of automatic identification technologies using radio frequencies, which uses read/write transponders that are able to capture and transmit data in harsh work spaces (Jaselskis et al. 1995). In construction projects, lots of materials and components are confined in a limited space, and construction work processes are complex and operated concurrently. Therefore, tracking the location of materials on a construction site has a direct impact on project performance (Song et al 2006). By improving the resource tracking process, RFID technology is able to provide efficient communication between work processes and to improve the integration of functions in material management. However, construction work sites are complex to formalize and construction operations and processes are various according to a project. Therefore, the RFID application should be customized to a construction work site respectively. The purpose of this research is to establish a systematical framework, in which both quantitative and qualitative aspects are considered when integrating lean six sigma approach and RFID applications in construction industry. Through this framework, this study analyzes the benefits of RFID applications when integrating lean six sigma approach to improve performance of construction operation process.

Recent Applications of RFID Technology in Construction Industry

In the mid 1990s, research on RFID technology in the construction industry began. Jaselskis et al. (1995) first proposed its potential applications in the construction industry. They discussed three potential construction applications for RFID technology including concrete processing and handling, cost coding for labor and equipment, and material control. Jaselskis et al. (2003) proposed a RFID application idea and conducted pilot tests in a refinery project to learn more about RFID and its applicability to the material procurement process on a construction site based on the information gathered from a construction industry-RFID supplier workshop. They derived potential applications from four groups in the workshop: engineering/design, material management, maintenance, and field operations. Recently, the ERABUILD (European Research Area on Sustainable Construction and Operation of Buildings) (2006) conducted research to identify the applications of RFID technology in the current and future construction industry. This research was based on interviews and workshop surveys, and suggested SWOT (Strength/Weakness/Opportunity/Threat) analysis and strategies, and RFID roadmap in the construction industry. Most recently, Chin et al. (2008) proposed the strategy and information system to manage the

logistics and progress control of structural steel works under the integrated environments of RFID and 4D CAD (four-dimensional computer-aided design) technology. They provided the three critical factors for RFID applications in the construction process such as technological availability, domain applicability, and information management strategy. In spite of intensive and hard efforts of researchers during past decade, however, most RFID studies have mainly focused on the technical applicability of RFID on the construction industry. Therefore, the studies have been limited to the assessment of RFID benefits when integrating lean construction principles and six sigma approaches on construction processes.

Lean Six-Sigma Approach for Improving Performance in Construction Process

The concept on combining of the lean manufacturing principle and six sigma approach has been addressed in manufacturing industry for both productivity improvement and quality improvement at the same time. The previous studies in manufacturing industry examined that performance can be improved through incorporating lean manufacturing system and statistical tool (DFSS 2002) and that integration of both lean and six sigma principle application can lead better performance (Kroslid 2002). In construction industry, there also have been limited attempts on the combination of the lean construction and six sigma principle. Abdelhamid (2003) proposed the conceptual six sigma approach in lean construction using the lean project delivery system developed by Ballard (2000). On the other hand, although the lean construction considering production as a flow has been adapted to eliminate waste in workflow (Howell and Ballard 1994; Howell 1999), it has not been obvious that the veiled procedure of how to measure the level of defects in work process. In addition, the concept of near zero inventory in JIT (Just In Time) philosophy has been confront with the questions of many researchers about the size of inventory buffers to achieve the best performance in a volatile and uncertain construction environments (Han et al., 2008). In particular, it has been known as productivity can be deteriorated when inventory size and time lag became zero (Horman and Thomas, 2005). Based on previous studies, Han et al. (2008) suggested an approach for combining lean and six sigma principle based on evaluating the quality of the current operation and quantifying the definite goals of improvements for the targeted operation so as to control the critical sources of variability in construction operation. They proofed the benefits of combined lean six sigma approach using simulation tool. To achieve the goals, they adopted the process capability index (C_p) as the six sigma principle performance indicators using critical total quality (CTQ). The process capability index (C_p) can be calculated as the difference between upper specification limit (*USL*) and mean of the data (*MEAN*) divided by 3 times of standard deviation of the data (*STDEV*).

$$C_p = \frac{USL - MEAN}{3 \times STDEV}$$

If only *USL* given, the sigma can be defined by 3 times of C_p.

$$\sigma = 3 \times C_p$$

Using this indicator, Han et al. (2008) developed the basic framework for the six sigma application to construction projects. They applied the six sigma principle concept to the construction process control through CTQ input, DMAIC (Define-Measure-Analyze-Improve-Control) procedures, and output measures. They

considered the six sigma principle's statistical definition associated with minimizing the defect rates through a control of CTQ. Based on this consideration, the modified DMAIC in a six sigma principle was provided to fit in the construction operations. In addition, the input indices and subsequently measures the sigma level of CTQ was defined. This basic framework for combining the lean construction and six sigma principle became a meta-framework of this research.

Systematic Framework for Integrating Lean Six-Sigma and RFID Applications

This paper presents a systematic framework to the guidelines for implementation of RFID application integrating lean six-sigma. To take an advantage of the lean six-sigma principle, the RFID application can be applied to the construction process on the lean construction environments within basic framework of CTQ inputs as performance indicators, six-sigma application procedure based on DMAIC procedure, and indices of performance improvement as output measures. Thus, this research adopts the basic framework for integrating lean construction and six-sigma principle to construction projects developed by Han et al. (2008). The framework is appropriately modified to fit in a construction process using RFID technology under the lean six-sigma environment. As shown in Figure 1, the systematic framework for integrating lean six-sigma and RFID applications in the construction process is developed.

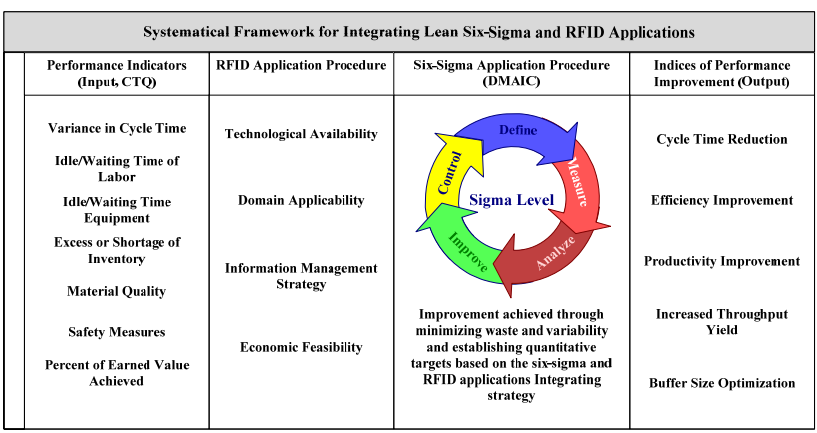

Figure 1. Systematic Framework for Integrating Lean Six Sigma and RFID Applications

The RFID application procedure requires four main considerations for applying RFID application to the construction process: technical availability, domain applicability, information management strategy, and economical feasibility. Technological availability, domain applicability, and information management strategy have been addressed as a critical factors in RFID applications in previous studies (Jaselkis and El-Misalami, 2003; Chin et al. 2008). In particular, economic feasibility of RFID applications should be defined to verify the cost effectiveness of RFID technology in construction process.

Case Study: Simulation of Iron-Reinforced Bar Assembling Process

To show the benefits of RFID application with integrating lean six-sigma approach, this study simulated the iron-reinforced bar assembling process for analyzing the effects of RFID applications under lean six sigma environments when RFID applications are applied or not. This assembling process is the building process of 765kV power transmission lines including site mobilization, foundation, steel tower assembly and erection, and attaching a power line to a tower. In this research, the assembly process of iron tower is focused for case study. This process was committed by 13 crews including tower assembling engineers, tower erecting engineers, helpers, and crane operators. In particular, the maximum size of the storage for iron bars was less than 20t due to the limited site accessibility in the harsh environment. The field data of the target process was collected during 10 working days as shown as Table 1.

Table 1. Field Data of the Target Process

Field data	Values
Committed workforce	13 crews
Current storage weight of iron bars	8.4t
Maximum of the field space to store iron bars	less than 20t
Cost to store 1t of iron bar	$25/day
Delivery and other process cost for iron bars	$6/t
Cost for extending storage space exceeding current capacity	$365/t

Based on this field data, the discrete event simulation models was developed through Extend® based on the simulation model proposed by Han et al. (2009). This simulation model is designed to examine the combination effect of RFID and lean six sigma principle, and to explore the optimal economically feasible solutions to apply RFID applications to a construction process under lean six sigma environment. Thus, the simulated main work process if iron bar assembly consists of delivery of iron bars to the storage area, classifying steel member, moving steel member to the specific location, and assembling each part. Figure 2 shows a part of the Extend model for this process.

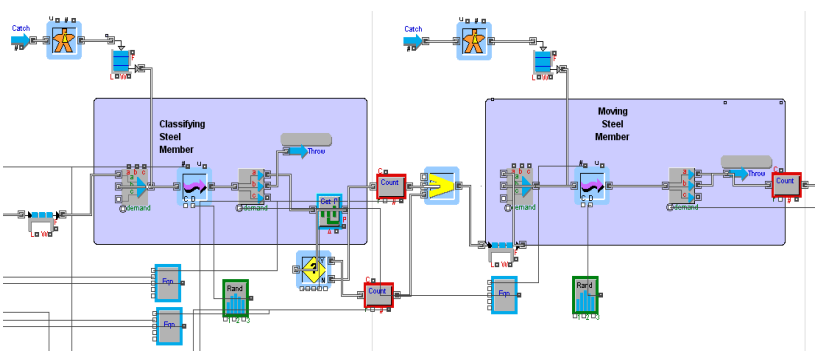

Figure 2. Part of Extend model for the iron bar assembly process

Assumptions for RFID application procedure

The RFID application procedure identified technical availability, domain applicability, information management strategy, and economical feasibility and assumed to develop adequate simulation model based on the previous study (Chin et al. 2008).

1) *Technological availability*: RFID tags are assumed as general 125 kHz passive type and RFID reader is assumed as CF slot and stationary reader which has reading distance with 3 cm.
2) *Domain applicability*: Tracking targets are iron-reinforced bar with metal and magnetic substance and read-only tag and portable and fixed reader is used.
3) *Information management strategy*: Material management of iron bars in the inventory committed by crews of the contractor.
4) *Economical feasibility:* Regarding economical feasibility of RFID application, four input components are assumed such as unit cost of RFID tag, quantity of RFID tags, and effects of RFID application in the activity level. The target quantity of iron bars to be installed in this process is assumed as 500t. In addition, the unit price of RFID tag with chip is $5 per card and the unit price reader is $800 per reader. The time saving of RFID application is assumed as 28% in the process time. Thus, this process is deemed to require 3 RFID readers and one RFID tags per 1t of iron bars.

Simulation Results of Case Study

The simulation results show that the productivity and sigma level of cycle time can be improved in the RFID applied process rather than RFID not applied as shown in Table 2. When comparing the impacts of RFID applications in the As-Is process, the productivity increases from 0.049 to 0.052 (6.1% increases). On the other hand, the cycle time of the process is almost no change and the sigma level of cycle time (CTQ) decreases by RFID applications without any process improvement. That is, the RFID applications without any lean construction treatment are difficult to improve the reliability of work process.

Table 2. Performance by applying Lean Six Sigma and RFID

		Lean Six Sigma Applications		
			To-Be process	
RFID Applications	Performance Indices	As-Is Process	Process Modified	Buffer Size Modified
RFID Not Applied	Buffer Size	8.4	8.4	11.5
	Productivity (t/min)	0.049	0.052	0.055
	Cycle time (min)	162	150	154
	Sigma level of cycle time (CTQ)	1.41	1.72	2.58
RFID Applied	Buffer Size	8.4	8.4	11.5
	Productivity (t/min)	0.052	0.057	0.058
	Cycle time (min)	162	145	153
	Sigma level of cycle time (CTQ)	1.17	1.77	1.84

When comparing the impacts of RFID applications in the process-modified To-Be process, the productivity increases from 0.052 to 0.057 (9.6% increases) and the CTQ increases from 1.75 to 1.77 (2.9%). Moreover, when comparing with simulation results between RFID applied and process-modified To-Be process and basic As-Is process, the productivity drastically increases from 0.049 to 0.057 (16.3% increases)

and the CTQ increases from 1.41 to 1.77 (25.5%). These results imply that both the productivity and reliability of the process can be enhanced by RFID applications under lean construction environments as shown in Figure 3.

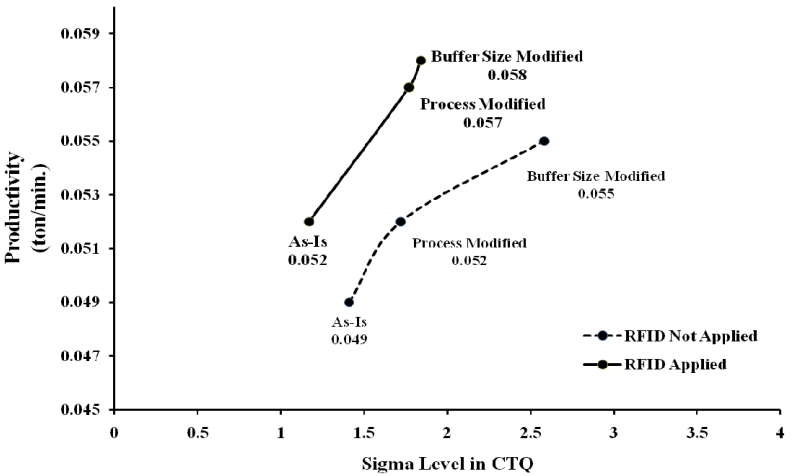

Figure 3. Productivity Improvement by Sigma Level in CTQ

When comparing the impacts of RFID applications in the buffer size-modified To-Be process, both the productivity and the CTQ in the process with both the lean six sigma and RFID applications increase little more than that with only lean six sigma applications. That is, the impact of RFID applications under the inventory management through the control of buffer size is not too much. Thus, it is necessary to search the optimal buffer size to maximize both productivity and reliability of the work process.

Table 3. Process Cost by Lean Six Sigma and RFID applications

		Lean Six Sigma Applications		
			To-Be process	
RFID Applications	Performance Indices	As-Is Process	Process Modified	Buffer Size Modified
RFID Not Applied	Production Cost (US$/10days)	9,400	9,900	11,900
	Additional Storage Cost (US$/10days)	3,500	3,600	5,600
	Throughput (t/10days)	236	252	268
RFID Applied	Production Cost (US$/10days)	9,800	10,400	12,005
	Additional Storage Cost (US$/10days)	3,596	3,740	5,657[a]
	RFID Installed Cost(US$/10days)	3,660	3,780	3,790[b]
	Throughput (t/10days)	252	276	278

[a] Additional cost of US $2,157 for increasing buffer size from 8.4t to 11.5t (3.1t) consists of: (1) storage cost for additional buffer = 3.1t × $25/day × 10days = $775; (2) the cost for extending a storage area = 3.1t × $365 = 1,130, and (3) delivering and other processing cost for producing more throughput (278 - 236 = 42t) = 42t × $6/t = $252 (all in US dollars)

[b] RFID installed cost of US $3,790 for installing 3 readers and one tag per 1t consists of: (1) the cost of 3 RFID reader = 3 × $800 = $2,400; (2) the cost of RFID tags installed during 10days = 278t × $5/t = $1,390 (all in US dollars)

Table 3 shows the process cost that are the sum of the production cost and the additional cost, including the additional storage cost and RFID installed cost in each condition: (1) RFID-applied As-Is process increases 32%, (2) RFID-applied and process-modified process increases 38%, (3) RFID-applied and buffer size-modified process after process-modified increases 66%. Thus, the cost effectiveness of RFID applications needs to be verified for economical feasibility.

Critical points of economically feasible solution for RFID applications

For taking advantage of RFID applications under lean six sigma environments, the economical feasibility of RFID applications needs to be verified on the basis of the simulation results of the work process. Table 4 shows the comparison of total process cost by each application case on the process. The goal of the process is defined as the installation iron bars of 500t for assembly of the transmission tower. To reach this goal, the basic As-Is process requires the total process cost of 28,380 US dollars and 22 days of the estimated duration. The only lean six-sigma applied process requires 27,000 US dollars of total process cost and 20 days of estimated duration. The only RFID applied process requires 31,692 US dollars of total process cost and 20 days of estimated duration are required. Finally, the process integrating lean six-sigma and RFID applications requires 30,352 US dollars and 18 days of estimated duration. For the economical feasibility of RFID applications, however, the critical points of economically feasible solution needs to be identified.

Table 4. Comparison of Total Process Cost by Applications

Items	As-Is process	Lean six sigma applied	RFID applied	Lean six sigma + RFID applied
Target quantity to be installed (t)	500	500	500	500
Available throughput (t/day)	23.6	25.2	25.2	27.6
Estimated Duration (days)	22	20	20	18
Production cost (US$)	20,680	19,800	19,600	18,720
Additional storage cost (US$)	7,700	7,200	7,192	6,732
RFID installed cost (US$)	0	0	4,900	4,900
Total process cost	28,380	27,000	31,692	30,352

To be economically feasible of RFID application under lean six sigma environments in this process, the RFID installed cost should be less than 2,928 US dollars (= US $30,352 – US $28,380). The following formula on the relationship between the unit price of reader and tag of RFID can be obtained.

$$3x + 500y \leq 2928$$

The unit price of RFID reader is presented by x and the unit price of RFID tag is presented by y. The constrains of unit price of RFID reader and RFID tag should be less than current unit price of those RFID applications.

$$0 \leq x \leq 800\,,\ 0 \leq y \leq 5$$

Figure 4 shows the critical points for economically feasible solution for RFID applications and the area of possible combination of unit price of RFID applications. The points on the area resented by the formula mean the possible combination of unit price of RFID reader and tag to obtain the economical feasibility of this process. From the relationship of unit price of reader and tag, the following implications can be known. The unit price of reader needs to lower to 143 US dollars when the unit price of tag is fixed, while the unit price of tag need to lower 1.06 US dollar when the

unit price of reader is fixed. If the reduction rate of the unit price of RFID reader and tag is same under bulk manufacturing environments, the possible unit price of reader and tag can be 478 and 2.98 US dollars. This means that the unit price of RFID reader and tag should be less 40% than the current unit price to obtain the economical feasibility.

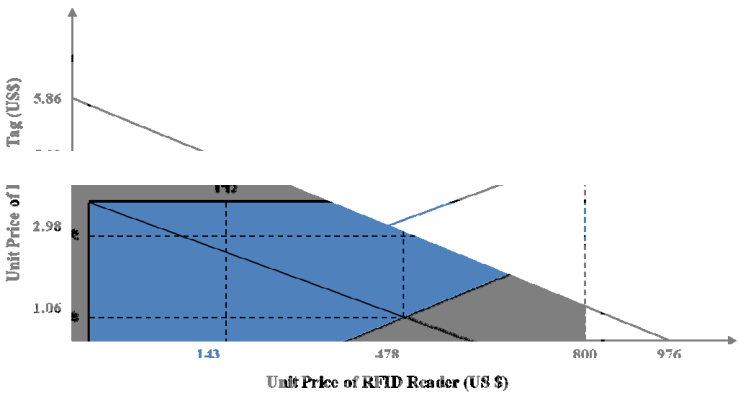

Figure 4. Critical Point of Economically Feasible Solutions for RFID Applications

Conclusions

This research proposes the systematic framework for integrating lean six sigma principle and RFID applications and simulates the construction process to examine the combination effects of those applications. Lean six-sigma principle and RFID technology have been shown to improve performance of a construction process by researchers. When these principles are integrated and applied together, it is shown by process simulation models based on the systematic framework that these principles can have drastic effects on improving performance of the construction process both quantitatively and qualitatively. In the quantitative aspect, the productivity can increase and cycle time can be reduced. In qualitative aspect, the reliability of process capability variation within six sigma level can be controlled and assured. Finally, it is examined that the unit price of RFID applications should be lower than the current unit price to gain the economical feasibility of RFID applications. This research gives the guideline to improve performance of the construction process through integration of lean construction, six sigma, and RFID application. Many researchers and practitioners can be allowed to understand the integration effects of lean six sigma and RFID applications. In spite of merits of this research, there are some limitations. First, this study mainly considered unit price of RFID tag and reader; however, indirect costs and other possible extra costs associated with RFID applications need to be identified and considered to get more realistic optimal solution. Second, field experiment needs to be conducted based on this systematic framework and the simulation results in order to verify the benefits of integrating lean six sigma and RFID applications, the simulation models. Lastly, the impact of buffer size is not significant in the process integrating lean six sigma and RFID applications. Thus, the

buffer size needs to be optimized to maximize both productivity and reliability of the process capacity variability. Based on these limitations, future research will focus the analysis of another construction work process using the systematic framework based on the real data of field experiments and conduct the optimization of the buffer size when RFID technology is applied under lean six sigma environments.

Abstract
Simulation is a relatively new area of engineering research, whose implementation in day-to-day construction industry activities continues to lag behind research efforts. It is widely viewed that the lack of a visualization component in construction operations simulation contributes to this low level of adoption within the industry. This paper discusses the development of a framework for simulation visualization and the implementation of this framework in modeling a real pipe spools assembly yard and pipe modules site installations. The framework can be used to better represent spatial data in simulation. The framework is developed through a distributed simulation based approach using High Level Architecture (HLA) standards. The paper demonstrates how this research can benefit construction through a real case study.

Introduction

Visualization in general, and particularly in construction projects, is a convenient and intuitive way of conveying project information among various project parties. Recently, construction management researchers have been trying to add a visualization component to construction operations simulation models in order to make these models more intuitive and to enhance decision making in construction projects. These researchers argue that the construction industry has not made optimum use of simulation techniques. Current construction operation simulation models are limited in terms of representing construction sites' spatial data and layouts. This paper explains the development of a framework for construction operations simulation visualization, based on the HLA standards for distributed simulation.

The HLA based Simulation Visualization for Construction Operations framework (HSV) aims at facilitating and improving decision making in construction projects by providing a better representation of construction sites' spatial data among other factors in construction operations environment, that are poorly depicted by mere simulation techniques inside the construction operation simulation models. This indirectly enhances the utilization of simulation models and techniques during decision making in real day to day construction operations.

The paper starts by giving a quick review of the simulation visualization research in the construction research literature. This will be followed by an explanation of the framework, the way it is developed and its components. The features which make this framework distinctive among other simulation driven visualization mechanisms or frameworks will also be emphasized. An experiment in which the HSV framework was implemented to visualize some of the simulated industrial construction processes of pipe modules' assembly and field installations in a real module yard and construction site respectively is demonstrated to assess the capabilities of the framework. Future developments of the framework and the way it is expected to benefit the construction industry will be discussed. Finally, an evaluation of the HSV and its potential will conclude this paper.

Simulation Visualization Mechanisms & Limitations

Simulation is defined as the process of designing a model of a real system and conducting experiments with this model for the purpose of either understanding the behaviour of the system or evaluating various strategies for the operation of the system (Shannon, 1975). The strength of simulation is that it can be used to test the outcomes of various scenarios on the simulated system rather than giving an optimum mathematical result, as it is the case in mathematical optimizations. Most studies stress the fact that simulation is not used to its maximum potential in the construction industry (Ioannou and Martinez, 1996; Kamat and Martinez, 2001; Huang & Halpin, 1994; Tucker et. al., 1998).The reasons behind that are:

- Most simulation models show results in statistical and text format, which has caused simulation to be perceived in the construction industry as a "black box" where statistical text and graphics are outputted based on certain input.
- The current simulation models do not consider the transformation of space that results from the evolution of the constructed product (Kamat and Martinez, 2001).

In order to overcome the limitations of current simulation and to encourage its application in the construction industry, SDV (Simulation Driven Visualization) evolved as a way of incorporating animation with simulation to provide better understanding to the end user and to represent construction site spaces in simulation. Also, SDV mutually addresses the limitations of using standalone animation or simulation systems. There are "commercial off the shelf" (COTS) SDV packages in the market, including AutoMod® and Quest®; however these SDV COTS packages concentrate on manufacturing operations only, not construction ones. These COTS

are generally unable to effectively handle the additional complications introduced by the changes in the geometry of the construction site as work progresses and using them to model and animate construction operations requires a radical change in the model conceptualization and the thought process followed by construction model developers (Oloufa, 1993; Tucker et al., 1998; Kamat and Martinez, 2008). Another visualization and CAD package commonly used in the construction industry is CATIA®. Although powerful on the CAD side, it has limitations on the simulation side of processes. CATIA offers a better solution for 4D modeling—final product development modeling—but not for construction processes simulation. It is fair to say that products like CATIA inherit the pros and cons for standalone animation systems that are not based on simulation engines.

The first construction simulation tools to adopt graphics were introduced in the early 1980s (Rohrer, 2000). This was done by linking construction simulation packages to animation, to achieve a post-process playback of the simulation (Halpin and Woodhead, 1976; Kalk and Douglas, 1980; Paulson et al., 1983). The "Utopian Framework" for earth movement operations was a good example of this graphic animation (Oloufa and Crandall, 1992). Another attempt was to extract product information from CAD design into simulation through the PSE (Product-oriented Simulation Environment) (Xu and AbouRizk, 1999). This was followed by attempts to display simulation results in statistical graphics as a form of visualization (Huang and Halpin, 1994; Hajjar and AbouRizk, 1999). This category of simulation visualization had its own disadvantages: construction planners and analysts, who are typically well-versed in actual construction operations, are reluctant to base their decisions solely on the statistical text and graphical chart output provided by most simulation systems (Ioannou and Martinez 1996).

Recent research in construction operations SDV involved the use of construction operations simulations' resulting trace files to invoke a post-simulation animation (replay) of the simulation. This included the Dynamic Construction Visualizer (DCV) and Visualization of Simulated Construction Operations (VITASCOPE) by Kamat and Martinez in 2001 and 2004, respectively. Since then, all work in Construction Operations SDV has been contributing to the development of VITASCOPE. This mechanism using simulation trace files is a post-processing SDV mechanism and depends on tightly coupled simulation and visualization engines. Also, the information in these mechanisms flow one way from the simulation to visualization component.

HSV Framework

The proposed HLA based Simulation Visualization for Construction Operations (HSV) framework is based on distributed simulation HLA standards. Distributed simulation is a technology that enables models to be linked together over computer networks so that they work together (or interoperate) during a simulation run. High Level Architecture (HLA) (IEEE 1516.2000) is a set of standards that regulates distributed simulation development (Taylor et al., 2003). In HLA, each simulation is connected to the other through a Runtime Infrastructure (RTI) software. The simulations or models connected to the RTI are called Federates. A federate is not

necessarily only a simulation model, but it can be any software, hardware or even a human player (user-in-the-loop as referred to by HLA distributed simulation terminology, Rycerz et al., 2007). RTI facilitates communication between federates and performs time management of the simulation. Another important component of a Federation (collection of federates) is the FOM (Federation Object Model) which defines all the entities produced by the various simulation federates during the simulation run, state attributes for those entities and most significantly records which federates will update those entities' attributes (publish them) and which federates will merely read them (subscribe to them). For example, in the HSV, federates responsible for the visualization only subscribe to certain attributes of certain entities, while simulation responsible federates can write and read (publish and subscribe) these attributes. On the other hand, for future developments of the HSV, the visualization components (federates) will also publish certain simulation objects' attributes when it starts communicating back with the simulation.
Figure 1 shows the HSV concept, typical components and communications between the visualization federate(s) on one hand and other functional/simulation federates on the other hand.

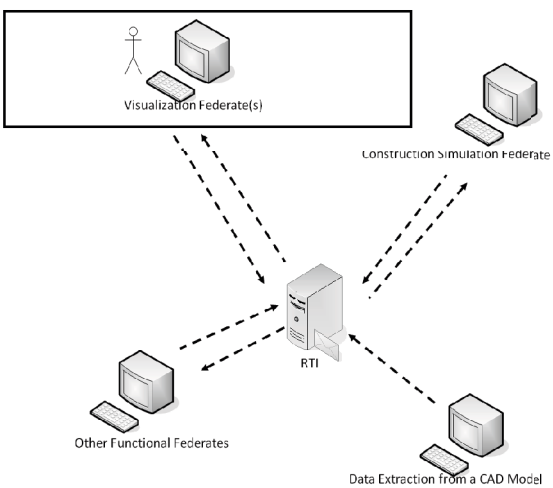

Fig. 1 HSV framework typical components and communication

As it is shown in figure 1, the framework is made up of the following components:

Visualization Federate(s) and its/their User Interface(s): Communicates with the source simulation or any other federate. It depicts the construction operation simulation concurrently as the simulation time advances to reflect what is going on in the simulation instantly. Developments are underway to allow the user to update the simulation during its run through the visualization component.

Source Simulation Federate(s): That is where the simulation of the various construction processes takes place. Also, simulation time advances in these federates. They connect to their respective viewer federate through the RTI.
Other Functional Federates: For example a Databases Federate or a CAD Model federate used to extract the simulated objects' attributes values to update them during the simulation run.

As it is shown in figure 1, all communications between the various federates go through the RTI using predefined HLA protocols. Federates simulating various construction processes can be added/removed to/from the federation. Visualization federate(s) can be connected to allow simultaneous visualization of various simulated construction operations. This visualization is concurrent with the simulation and not post-simulation, which allows the decision maker to see the simulation as it is happening and make more educated decisions by understanding spatial related aspects and logic of the simulation process through the visualization component. Figure 2 below explains- at the conceptual level- the difference between post-run visualization mechanisms and the developed HSV.

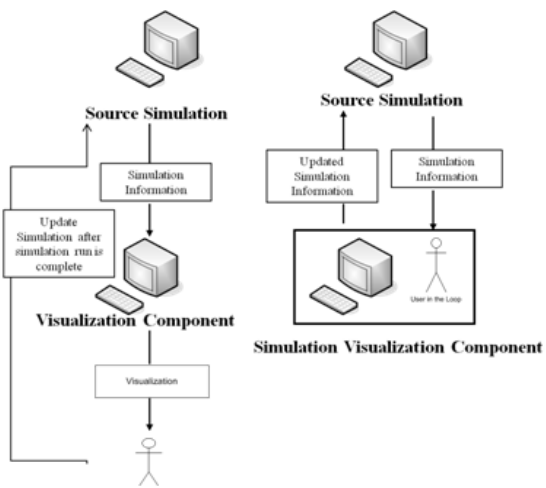

Fig 2. Conceptual differences between post-run visualization mechanisms (left) and the developed HSV framework (right)

In the post-run construction simulation visualization mechanisms (shown in figure 2-left), the decision maker simply watches a post-simulation recording of the simulation events. Also, the tight coupling between the simulation and the visualization components requires more effort for developing both. On the other hand, the HSV

framework (figure 2-right), gives more freedom in choosing the visualization component to connect to the source simulation. For example, three different experiments were carried out using three different platforms as visualization components inside the HSV framework; AutoCAD Civil 2009® for data extraction into the simulation, TrueVision® 3D engine to visualize a simulation of bidding processes in the construction industry and finally Blender® gaming engine as the visualization component in an industrial construction simulation federation. These experiments demonstrated the flexibility that is inherited in this framework. Inside the HSV, the developer can choose the visualization engine that would fit his/her needs either by using an engineering application such as AutoCAD to extract data into the simulation component, or by opting to visualize the construction operations that will take place through more flexible 3d engines or having both at the same time. The framework has this flexibility inherited in it due to the underlying HLA distributed simulation standards. The following sections describe one of the experiments mentioned earlier in more details.

Visualization of industrial construction simulation

The simulation mimics the process of pipe modules manufacturing, starting from the pipe spools fabrication process going through the various stages of the modules assembly at the module yard up to the final stage of installing these completed modules on site. The spools fabrication involves the processes of pipe cutting, fitting, welding and testing. The completed spool is then passed to module yard. In the module yard, each module is assembled at a predefined bay. The pipe spools that compose this module are moved to this bay where the assembly of the spools into the module takes place. Once the module is complete it is transported to site. Site construction sequence depends on the modules installation program (schedule) and if its predecessor has already been installed in its final location at site or no. In this simulation, each of these phases is represented by a certain federate. Visualization of processes in two of these phases is achieved through two separate federates. The architecture of these federates in relation to the whole federation is represented in figure 3. Communication between visualization federate and the federation is enabled through a number of layers.

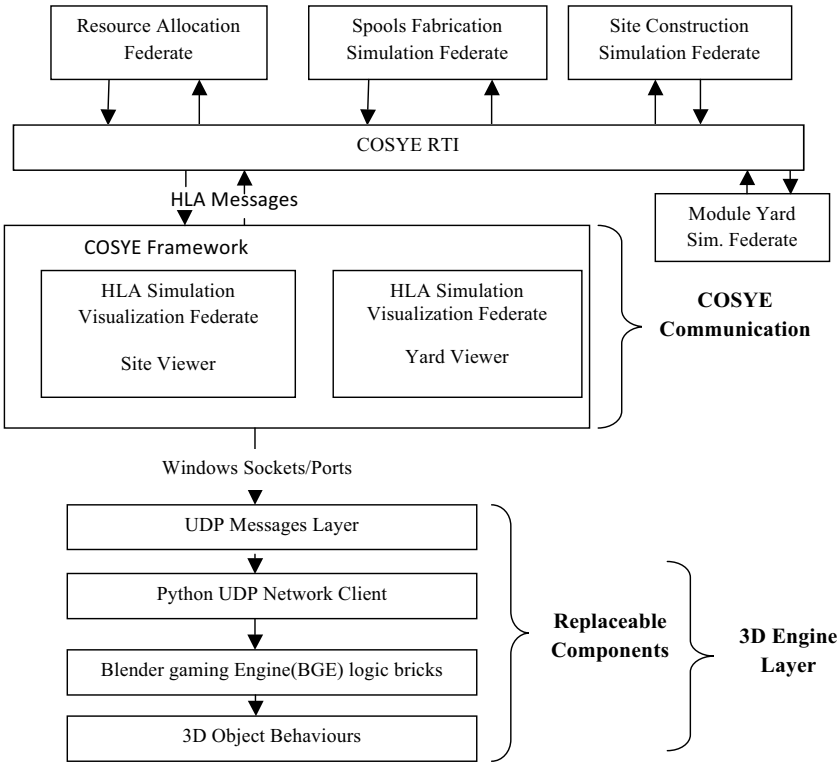

Figure 3 Framework used in simulation/visualization of pipe modules assembly and their site installation

The first layer consists of the following:

- Simulation Federates: Where all the simulation of the various spool fabrications and spools assembly takes place. These federates produce the statistics needed by decision maker. Spool Fabrication Federate, Site Construction Processes Simulation Federate and Module Yard Simulation Federate are shown in figure 3.
- Other Federates: Resource Allocation Federate is responsible for allocating the various cranes to lift/move certain modules to their final location on site. Cranes are assigned to modules based on the cranes availability and their fitness to handle that module.
- Visualization Federates: Federates that read (subscribe to) the objects' (cranes and Modules) attributes and detect changes in these attribute values and communicate these attribute values with a secondary layer of the framework that contains the visualization engines.

The second layer consists of the visualization engines, which were based on Blender Gaming Engine® in this experiment. Two screens are provided for the user to interact with; one showing installation of modules at their final location on site and the other showing modules assembly progress with simulation time in module yard before transporting it to the site.

The two visualization federates subscribe to the attributes related to modules' locations and percentage completion in the FOM of the framework. These attributes are published by the simulation federates. Once the attributes are published, the viewer federates read them and send a message containing the module unique identifier (module ID), module state and its percentage completion to the Blender Gaming Engine (BGE). The communication between the Viewer Federates and the BGE takes place through a User Datagram Protocol (UDP) similar to a client-server connection that is used to send messages between various systems on a network. The server part on the Blender' side is based on a Python API. This API controls the 3D movement and displays it on the screen as the simulation proceeds.

The visualization federate provides the following:

- The logical sequence of modules installation on site (for example the top module can't be installed without the bottom installed first or the middle module cannot be installed before the left/right module's installation). This can't be understood by merely looking at the simulation results.
- The progress of modules assembly together with the bay it is assigned to, so the user can know the bay occupancy schedule during the course of the assembly process.
- A check for the logical flaws in the processes simulation. For example if a module appears in the visualization to be installed before its predecessor is in place, then there is a delay in the assembly/installation of the predecessor module, this means that there is something wrong in the manufacturing schedule of the modules in this case.

Figures 4-1 & 4-2 show some screenshots from the visualization engines and viewer federates implemented in the industrial construction simulation visualization using HSV framework:

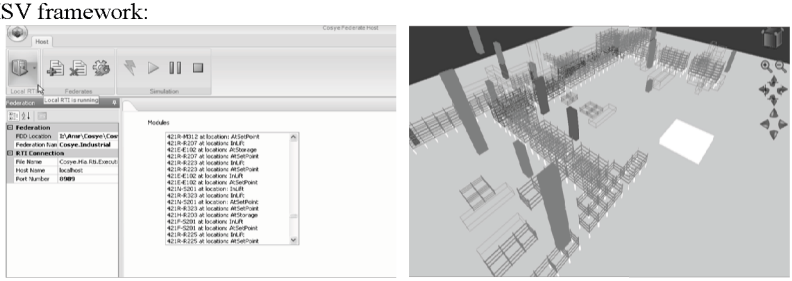

Figure 4-1 Site Viewer Federate and Site Visualization using Blender®

Figure 4-1(left) shows the message in the list box which is sent to the Blender, it simply tells the BGE® (Blender Gaming Engine) to recall a certain module using its module unique identifier, followed by its location on site. Once a module is "At Set Point" then it appears in its predefined location based on the design drawings.

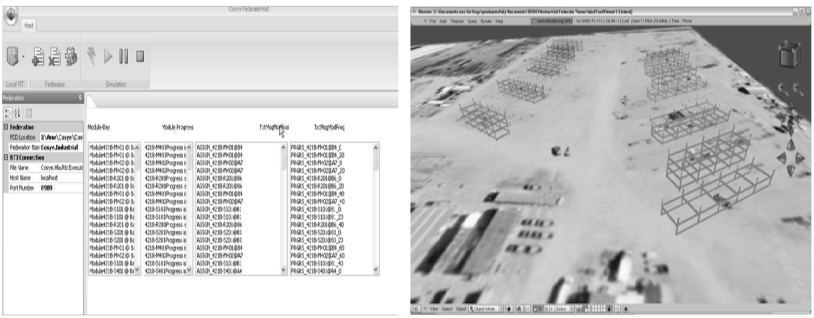

Figure 4-2: Yard Viewer Federate and Yard Visualization using Blender®

Figure 4-2 (left) shows the message sent to the visualization BGE. One message which is in the list box called "Module-Bay" which tells the visualization engine which module goes to which bay based on the simulation. The other message contains the changes in percentage completion of a module during the simulation run

Future Developments:

Currently, development is in progress to make the visualization engine on the second layer of the framework communicate back with the simulation federates, so that a user can update the simulation during its run through the 3D visualization engine. Also, work is in progress to utilize this framework to assist in dynamic site layout planning by defining the logical obstacles on site and deciding on crane paths.

Conclusion:

This paper presented a prototype framework (HSV) for construction operations simulation visualization using distributed simulation approach. The framework is characterized by a loose coupling between the simulation algorithm and the visualization mechanisms. It separates the simulation and visualization components from each other, which removes any compromises on the strengths of any of them. This separation also provides more flexibility and allows the framework to be used to view a wider spectrum of construction operations by enabling the addition or replacement of the simulation/viewer federates or the 3d engine. The HSV framework's potential has been put to test in experiments. A sample case for visualizing industrial construction simulation is presented, and shows the ability of using the proposed framework to harness the power of existing 3D engines.

Abstract

Determining feasible mobile crane configurations and positions on a complex industrial construction projects that are free of spatial conflicts and the subsequent scheduling of the lifts is important to the productivity and safety of a project. This paper focuses on the integration of a crane dimensional and capacity database with a project's lifted object information to select and position the cranes and then utilize expert knowledge to simulate the heavy lift plan. The system uses dimensional and coordinate data instead of CAD software for computation of crane position areas amongst known obstructions and boundary limits. The crane position area is specific to a crane model and identifies where the center of rotation of the crane can be placed without having any part of the crane body contact the known obstructions and boundary limits. This analysis is performed for multiple cranes and lifted object scenarios to develop a list of possible options. Schedule date constraints and logic are used to simulate and optimize the schedule and crane selection. This provides the practitioner with an effective planning tool to select, position and schedule cranes.

Keywords

Mobile crane; site layout; Heavy lift planning; simulation

Introduction

Construction of a heavy industrial project utilizes expensive mobile cranes to lift

large and heavy pieces of equipment and modules. Due to the magnitude of such large projects and the fast tracked nature of the project, the analysis and selection of mobile cranes is often performed during the pre-construction phase where limited data is available. Plot plans, usually in 2D CAD format are available along with a list of equipment including their weights and dimensions. Some preliminary elevation views of the project may add the third dimension to the project. Historical knowledge of similar projects is sometimes used to assist in the analysis. Complete 3D models are not available until later in the detailed design phase of the project.

To perform the analysis, the experienced lift engineer identifies the piece or pieces of equipment or module that will likely establish the size and configuration of the crane. As is common in the industry, the minimum and maximum radius circles area placed around the center of the object on a plot plan using the object weight and crane capacity as the criteria. The overlapping areas between the crane radius circles for various objects represent is analyzed for optimum crane location based on various criteria [Lin et al. 1996]. The crane position is normally chosen manually by the lift engineer, and a preliminary lift study is developed. This preliminary lift study contains information such as the crane configuration data, crane capacity, load information, percent of crane capacity, layout drawing of the crane on the project, and usually a 2D elevation view where the boom clearance is checked against the object and obstructions. Custom spreadsheets may also be used as a quick method of determining boom clearances.

Use of 3D project models and insertion of crane models to check for clashes have become more common recently due to technological advancements. Some authors have developed a database to house crane dimensions and load capacity information [Al-Hussein et al. 2000] and have developed an algorithm to determine the most suitable crane configuration [Al-Hussein et al. 2001]. Software has also been developed by manufacturers as well as crane and construction companies that access dimensional and crane capacity data to select a crane for insertion into a 3D model but requires user defined crane positions and object trajectory paths. Developing the proper position of the crane body and analyzing the movement of the crane boom is a challenging process that some professionals dealt with for two crane lifts [Smith 2006] using a heuristic search solving three problems with increasing levels of complexity or using a digital plan and simulating the construction operation. Time animation of crane lifts is also achievable through programs in the market with some customization.

These developed programs are typically performed for a single crane lift of one object. Schedule and crane cost optimization, if performed, and cost analyses are usually done separately and manually. Automation and optimization of the schedule, crane selection logic, and crane location are not integrated into these programs.

Few experienced lift engineers have sufficient knowledge or time to integrate the functions of lift analysis into an automated crane positioning, clash detection, logic of crane selection, construction simulation, and schedule and cost optimization program.

Without this functionality, the analysis for all objects and possible crane configuration and locations would be time consuming, thus are not analyzed in entirety.

Researchers employed various mathematical representation techniques to optimize the layout planning methods, namely hybrid artificial intelligence components where a knowledge based database or a fuzzy quantifier played a critical role [Beltagi and Hegazy 2001] and such recent developments in lean theory [El-Ganainy et al. 2007] allowed for better planning in space optimization. Computation based on symbolic model formulation used the input condition that is governed by the positions of facilities relative to the crane [Choi and Harris 2001]. In the construction industry, mathematical algorithms are recognized as a powerful tool for optimization process operations. They are well known and recognized but not easy to develop like in other industry field such as in electrical works. Multi-tasking operations, complex spatial movement of the all construction equipment and materials are complicated to model and analyze. Despite the difficulties, some authors try to model and solve decentralization design problems for a satellite system [Murase et al. 2005]. They show mathematically the challenges created by having multi-objective subsystems, where a method based on set-based design alleviate some of these challenging issues. Others determine possible locations of mobile cranes based on discrete-event simulation incorporating dynamic behaviors of cranes [Tantisevi and Akinci 2008] or concentrate on crane/space scheduling issues [Zhu and Lim 2005; Zouein and Tommelein 2001]. Solutions to spatial collision or interferences problems evolve where the collision detection algorithm is developed for virtual reality applications [Takemura et al. 1998].

Research objectives

This paper focuses on integrating a mobile crane selection and positioning with simulation to plan and schedule the various lifts based on knowledge based heuristic rules. The approach uses data centric mathematical computation of the crane position areas. The crane position area is specific to a crane model and identifies where the center of rotation of the crane can be placed without having the crane body contact the known obstructions and boundary limits. This analysis will be performed on multiple crane and lifted object scenarios. The crane positions areas are partially optimized to points to develop a list of possible crane configurations and their positions. The lifted object delivery dates, resource and schedule constraints, and the list of crane options are used to simulate and optimize the heavy lift program. Post analysis animation is used to visualize the results.

Methodology

In order to develop the framework to support computational analysis of lifting multiple objects for multiple crane configurations, data must be made readily available. There has been considerable effort in entering crane dimensional and capacity data into the industry company database (see figure 1). It currently contains 312 cranes, 25735 crane configurations, and 390,000 capacity entries. Along with the crane data, project specific information is needed to identify the lifted object

information such as dimensions, coordinates, weights, elevations, dates, and crane selection logic. This data is entered manually into the database or through a customized interface within AutoCad that links to the project database (see figure 1).

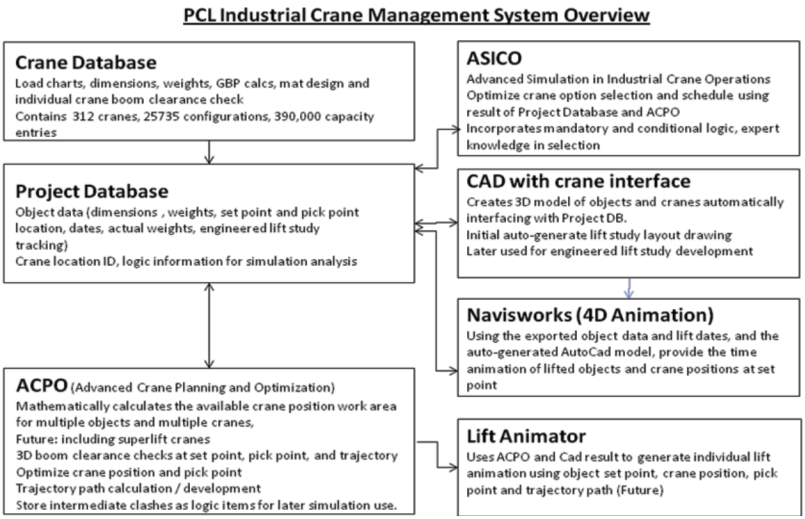

Figure 1 PCL Industrial Crane Management System Overview

The Advanced Crane Planning and Optimization (ACPO) research project noted in figure 1 encapsulates the field operation and engineering expert knowledge with the company's crane database to provide lift engineers with an automated project crane selection, positioning, and 3D trajectory analysis. This decision support system employs advanced mathematical theorems to solve static and dynamic spatial tasks. It lists all available crane options providing the crane configuration, crane location, and pick point that meet the required spatial and capacity constraints. The first part of this process will be described in this paper.

The resulting crane options developed by ACPO are accessed directly by ASICO (Advanced Simulation in Industrial Crane Operations) to use expert knowledge in selecting the best crane configuration and location based on given schedule and logic constraints. The result of this second decision support system will provide the best suitable crane and respective lift date for each object as calculated by the simulation model. The post simulation schedule is then visually presented using the CAD model of the project. This CAD model can be auto generated from the database or obtained directly from the engineering company. The project 3D model and developed crane models are imported into an off-the-shelf animation software (Navisworks) using the dates from the simulation to provide a 4D animation of the project heavy lift schedule.

Development of the Crane Position Area

A 3D model of the project is usually not available during the preconstruction phase of a project. Utilizing the available two dimensional plot plan of a project, the object and boundary data is entered either manually into the project database or through a custom CAD interface that is linked to the project database. The object and obstruction dimensions, 3D coordinates, object type, and weight are entered in the CAD interface as shown in figure 2 below:

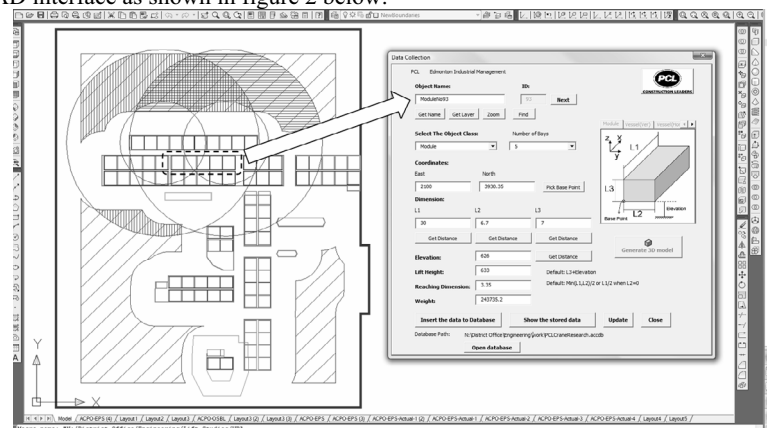

Figure 2 CAD Interface for entering Object Data into the Project Database

The project database contains lifted object data, list of desired cranes, date constraints, lift study tracking, scheduling logic criteria, transport and storage data, and activation of the simulation engine. A screenshot of the project database interface is shown in figure 3:

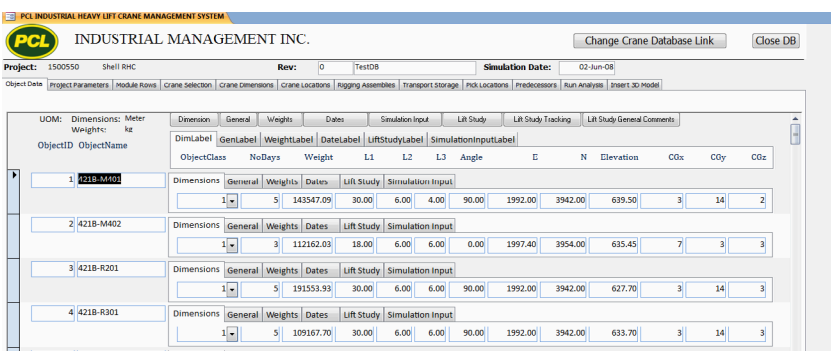

Figure 3 Project Database Interface Screen

To develop a 3D model, these objects are auto-generated through code programmed in AutoCad using information from the project database. This 3D model is also used for developing lift studies.

To further define the first part of ACPO, the crane body work area is calculated by a series of algorithms using data residing in the databases. The project plot plan is divided into several areas. The first is to define the outside boundary limit/s representing the physical outside boundary of the available project construction area. The area occupied by existing obstructions or other construction activities inside the boundary limits are determined next. The area between these two represent where the physical body of the crane can reside. An offset dimension is required from the crane's center of rotation in order to define the crane body work area. This offset is the mobile crane's tail swing or the outrigger diagonal dimension plus an additional safety buffer clearance dimension (see Figure 4 and 5).

Figure 4: Crawler Crane Tailswing

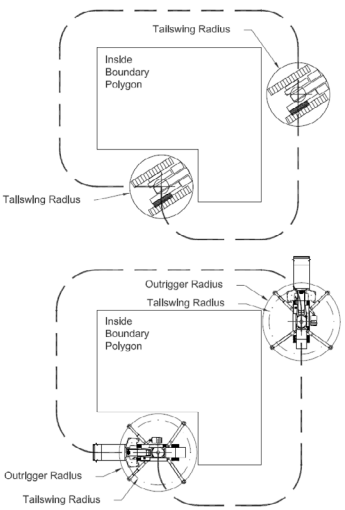

Figure 5: Offset from Crane's Centre of Rotation

The issue of using a crane with superlift will be dealt with in a future paper. This method of determining the offset can be used for any 2D geometrical shape and stores the data for further analysis. The following Figure 6 describes this phase.

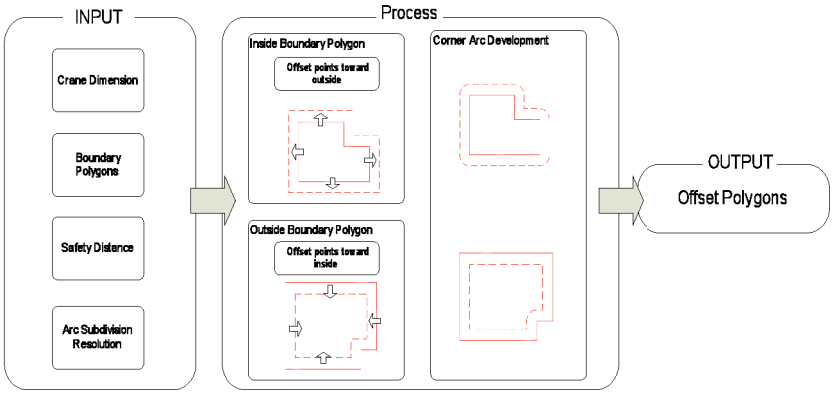

Figure 6 Crane Body Work Area Development Flowchart

An example of a project where this methodology was implemented is shown in figure 7. The crane body work area is clearly seen, and represents where the centre of the crane can be placed knowing that the tailswing rotation of the crane will not come into contact with either the interior or exterior boundary limits.

The crane body work area noted above does not take into consideration the weight of the lifted object and the corresponding minimum and maximum radius that the specific crane configuration can handle. As is common in the industry, the minimum and maximum radius circles area placed around the center of the object. The overlapping areas between the crane body work area and these radius circles represents where the crane can make the lift based on capacity. The crane capacity data and minimum and maximum radius is obtained electronically from the crane database for the corresponding crane configuration selected in the project database. The boom clearance and trajectory check is also performed at specified intervals around the perimeter of the crane position work area and is reduced accordingly to reflect the specified criteria. These calculations, though not described in detail in this paper, are performed using algorithms without the use of CAD software. The crane position area analysis is done for every lifted object entered in the project database. The result is exported into CAD for visualization and shown in figure 8. Area 'A' is the crane position area for object 1 whereas area 'B' is for object 2. Area 'C' is the area where both objects can be lifted with the same crane.

It is important to note that the chosen methodology is based on areas, and not on a grid system. Defining the crane position area is useful in various stages of development to show the available crane position area for specific objects, for overlapping areas for crane position optimization, and to validate the final chosen crane positions. It is also useful when meeting with site personnel to visually represent the feasible crane options.

Determining the best specific crane locations within the areas can utilize methodologies similar to [Lin 1996] that uses various criteria to evaluate the options. When multiple crane configurations, crane locations, and objects areas are analyzed, several thousand options are generated. This would be hard to achieve without integration of the various system and the automation described above. The resulting crane options are then analyzed by ASICO, a simulation based program which determines schedule the cranes and objects using the best option based on date and heuristic expert knowledge criteria. The schedule data result of the simulation is passed to a software program (Navisworks) that creates a 4D animation of the project using the auto generated 3D model developed from the object data in the project database. A time snapshot of this animation is shown in figure 9:

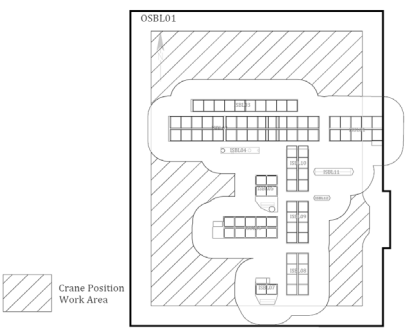

Figure 7 Project Crane Body Work Areas

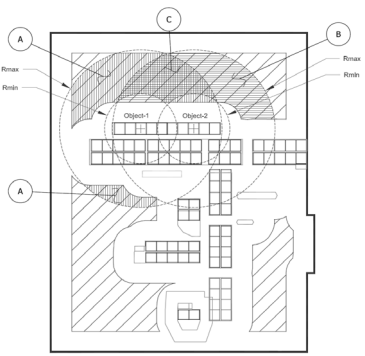

Figure 8 Crane Position Area for given objects

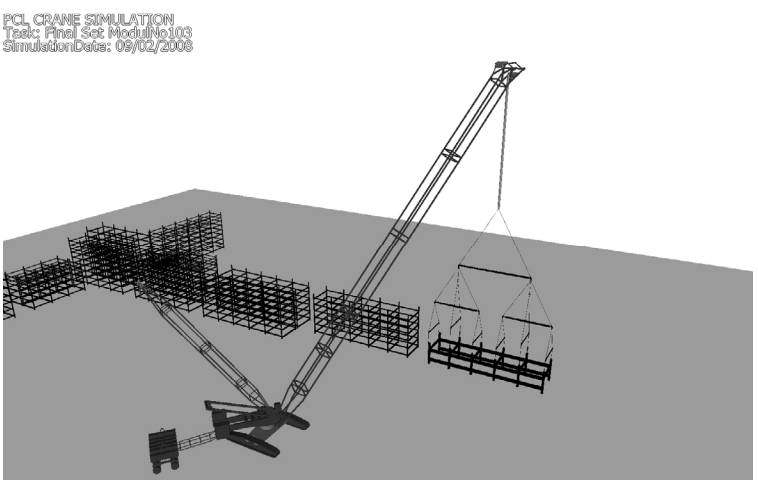

Figure 9 4D Animation Snapshot of Crane Heavy Lift Analysis

Conclusion

Heavy industrial projects involve complex analyses to determine the crane selection, the positioning of the crane, and the scheduling of lifts. Without automation and integration, this analysis is heavily dependent on experienced lift engineers who choose the crane and position based on intuition and experience, and do not check every possible alternative. To overcome these limitations, a methodology and program was developed to integrate the crane data, project information, CAD model, expert knowledge, and simulation to provide all the possible crane and location options based on given criteria, and subsequently optimize the selection and heavy lift schedule.

The developed crane database contains dimensional and capacity information, and the project database provides object dimension, coordinate, weight and date information. This information is accessed by the ACPO (Advanced Crane Planning and Optimization) program to calculate the crane position areas specific to a crane model and identifies where the center of rotation of the crane can be placed without having the crane body contact the known obstructions and boundary limits. The overlapped areas are then optimized to provide a crane position point. The result is a list of crane options (configuration and location) for each lifted object that takes into account all the spatial and capacity constraints. Such an extensive list of crane options could not be practically developed using traditional methods that rely heavily on the practitioners' intuition and experience. The list of crane options is analyzed by ASICO (Advanced Simulation in Industrial Crane Operations), is a simulation based model to optimize the schedule of cranes and object placements based on heuristic expert knowledge logic. Its output together with the auto-generated 3D model is then visually represented in a 4D animation for an easily understandable project execution plan. This integrated system is a useful decision support system for lift engineers and project personnel to effectively manage the heavy lift program of a complex industrial project.

Abstract
This paper introduces a mathematical model and an optimizer to optimize dynamic variables of construction operations in multi-project environment. Vulnerable nature of construction schedules, resource limitations, multiple objectives, project uncertainties, business priorities and other inevitable constraints make the operations very challenging. The ultimate outcome of the model is to improve construction business efficiency and productivity in terms of profitability and resource management. The model consists of two main components; theoretical model and an optimizer. The first part is the formulation of the theoretical model considering all the multi-objective variables using mathematical descriptions, assumptions and equations. The second part is the solution using special purpose discrete-event simulation and genetic algorithms (GA). An example with real life project data is presented to demonstrate the application of the proposed model. The results offer the best solution for conflicting objectives of minimizing multi-project schedules, maximizing resource utilization and maximizing the profit while satisfying all the imposed constraints.

Introduction

Research study shows that 90% of all projects, by value, are carried out in multi-project context (Turner 1993). In contrast, the vast majority of practical and theoretical developments on project management have been related to single projects considered in isolation (Evaristo & Fenema 1999). The current demand for higher quality of living and greater technological development has meant that large construction projects are increasing in number and complexity year by year. Many problems and issues associated with multi-project environment (MPE) are documented in literature. Some of the very common issues are as follows:

- Getting attention from senior management (Olford 94; Lycett et al 2004)
- Resource management (Dumond&Dumond 93; Olford 94; Payne 95; Eskerod 96)
- Establishing a good and dynamic scheduling (Olford 94; Payne 95; Wang 2005)
- Effective communication and coordination (Olford 1984; Ferns 1991)
- Risk management (Eskerod 1996)
- Management structure for MPE (Merwe 1997)

In a MPE, the management of engineering and construction companies are interested in (1) taking care of all the projects in different phases (e.g. a number of projects are under construction, some of them are waiting for start, while others are in bidding stage and quite a lot of projects are in conceptual stage); (2) having a structured approach for taking "go" or "no go" decisions during project selection; (3) looking for an optimum (better solution within the feasible zone) program schedule that incorporates major decision variables of the company, project delivery system, individual project objectives, driven factor and priority; (4) dealing with uncertainties; and (5) monitoring the projects by preparing checklists and reports regularly related to site and management issues for improvement. They also want simultaneous solution or optimum solution for multi-objectives problems e.g. timely completion of all the projects on one hand and effective utilization of available resources on the other hand.

The goal of the study explained in the paper is to develop an integrated optimization model based on simulation and genetic algorithm (GA) with an aim to address and answer the questions as mentioned above. The paper demonstrates the optimization methodology with an illustrative example of ten building construction projects. The model can be applied to any construction projects with minor modifications of the parameters and constraints as suitable to.

Previous Studies

The previous studies related to MPE are explained under the following four categories.

(a) Multi-project management critique

Table 1 illustrates relevant past researches on the multi-project environment and respective management issue addressed by them. It is readily apparent that a few attempts were made for solving optimization problem. Most of the researcher considered one or two issues in isolation for managing multiple projects. Kandil (2005) developed an advanced multi-objective optimization model for highway construction. The problem was to minimize construction time & cost, while maximizing its quality. In their study, Wang & Schonfeld (2005) introduced a methodology for evaluating waterway systems and optimizing the selection and scheduling of interdependent projects by using simulation model (for assessing waterway system performance) and genetic probabilistic model, in which, its application is limited to interdependent projects in large waterway networks. The optimization model developed by Wiley et al. (1998) focused to the initial design and development of multi-project programs. Their intention was to provide the program

manger with a vast array of alternatives to investigate different options in designing and initiating multi-project programs.

(b) Mathematical model for construction operations of MPE

There is lack of evidence that any mathematical model developed for solving multi-objective optimization problem in construction. However, mathematical modeling technique has been applied in many areas for resolving various real life problems for many years. Alattar (2003) developed a mathematical model to optimize for container terminal operation. The approach was to develop an integer program using set theory and partitions. He considered two objective functions, the waiting time for vessels and the waiting costs for container. The ultimate goal was to minimize for these objective functions. Maji (2008) developed a GA based multi-objective algorithms for highway alignment design optimization.

(c)Advancement of simulation in construction

Construction simulation was first introduced by Halpin in 1973 with the development of CYCLONE modeling methodology. It was a construction-specific process simulation technique with a small abstract set of modeling elements. There have been a few significant developments in this area since CYCLONE. They include: simulation model for earthwork operation, tower crane operation, concrete pouring, PERT scheduling, etc using Simphony environment (Hajjar & AbouRizk 1999). Most of the templates focus a specific area of construction operation rather than overall optimization. Another study by Lee and Miller (2004) for multi-project management focused on developing a simulation model using system dynamics principles. Their model was designed and applicable only for the software industry. A little evidence

was found in the literature where researchers attempted to develop simulation model for analyzing multi-project schedules of construction in MPE.
(d) Genetic algorithms based optimization models
A number of research efforts have developed genetic algorithms that search for optimal solution. Li & Love (1997) formulated time-cost trade-off problem as a single objective optimization problem. Zheng et al. (2004) developed a genetic algorithms-based approach for time-cost optimization. The objective functions were minimizing duration and project cost. Hegazy and Kassab (2003) presented a new approach for minimizing cost applying flowchart based simulation tool and GA. The model was used to determine the least costly, and most productive amount of resources that achieve the highest benefit/cost ratio. Marzouk and Moselhi (2004) developed a framework using computer simulation and genetic algorithms for minimizing time and cost of earthmoving operations. All of these models were mainly intended and applicable for single project environment.

The simplified objectives of the study current study are:

1. develop an influence diagram for MPE
2. identify and prioritize the factors related to optimization of schedules, resources and business decisions in the MPE
3. develop an optimization framework and methodology
4. develop a theoretical model to formulate multi-objective problem in terms of mathematical equations and algorithms
5. develop a simulation model for analyzing multi-project schedules, and
6. develop a GA-based optimization model for solving multi-objective problems.

Optimization Methodology
The optimization model was developed on the basis of conceptual framework as shown in Figure 1. The model has two main parts: (1) the "theoretical model", and (2) "solution procedures" or optimizer. Again the theoretical model can be divided into three components such as (i) problem definition, (ii) algorithms formulation, and (iii) mathematical solution. On the other hand, the solution procedures consist of seven components such as (i) input database, (ii) the simulation model, (iii) simulation output, (iv) the genetic optimization model, (v) integration of GA model and the simulation model, (vi) the GA model output (optimal solution), and (vii) model validation.

Part 1: The Theoretical Model
The purpose of the theoretical model is to define a construction multi-objective problem in terms of algorithms and find mathematical solution. Due to page constraints of the paper, detail discussion will be limited to deriving relationship equation between two key decision variables (project duration and resource requirement) of the theoretical model. The word "project duration" means here the time required (in months) to complete the construction work of a project and "resource" means the manpower resource required (in number) for a project and directly deployed by the general contractor.

a) Objective – mathematical modeling of a multi-objective problem in construction including defining the research question, identifying and quantifying factors/variables, setting mathematical assumptions and developing mathematical relationships for objective functions, variables (e.g. time-resource relationship, project cost break down), and constraints.
b) Approach – multi-objective optimization using set theory, series expanding (Binomial theorem), derivatives (Calculus) and discrete algebraic equations.
c) Deliverables – a mathematical model for constr. multi-objective problem.
d) Results/outcome – mathematical optimum solution to the problem.

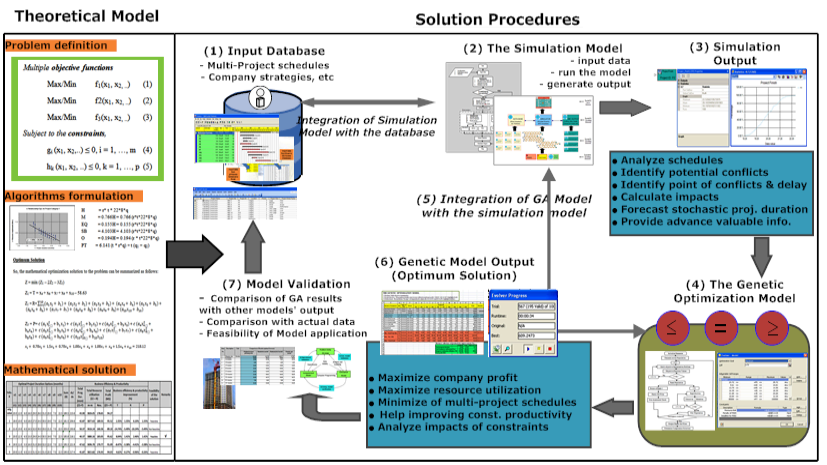

Figure 1: Conceptual framework of the study

Deriving relationship between project duration and resource requirement

Project duration (t) and resource requirement (r) are the two key ingredients of the proposed optimization model. These two variables are very critical for the success of any project. There is lack of evidence in the literature where mathematical relationship was derived between t and r for a typical high-rise building construction. Following is the brief description of formulating this relationship.

"Work" can be defined as the time required for completing a task or assignment.

So, Work = Resource assignment * Time required = Or, $W = r * t$

Assuming that W is constant for a specific project/work package.

i.e. $r * t = \text{Constant}$ i.e. **$r = \text{Constant} * 1/t$**

That means if duration of a project decreases then resource required normally increases and vice versa. However, the rate of change for increase or decrease will not be the same for all type and size of project. A number of similar nature and type of projects were investigated to derive a suitable relationship between time and manpower resource requirement. Necessary data were collected from three leading

construction companies as mentioned in the acknowledgement section using the questionnaire survey form shown in Table 2. The data were then analyzed and graphed for developing the t-r equation. Figure 2 illustrates the time-resource graphs for one of the five categories of high rise building construction projects with duration of 9 months. The nature of graph was found close to linear although not totally linear. From practical point of view, a linear regression line was considered that builds the equation for that particular category. The x and y-axes represent the duration and resource requirement for completing the project respectively. It is noticed that time and resources are inversely proportional to each other i.e. if the value of one variable decreases then the value of other variable increases.

Table 2: Questionnaire survey form for collecting project data

Project Resource Allocation Data (only for building construction projects):

Project No.	Project Info					Manpower (GC's own staffs)	Remarks
	Brief Description	Duration (Months)	Year of completion	Value (M$)	Self-Perform Trades (Tick as apply)	(Nos.)	
					• Concrete • Formwork • .....?	3-5 6-10 11-15 16-20 21-25 26-35 36-45	

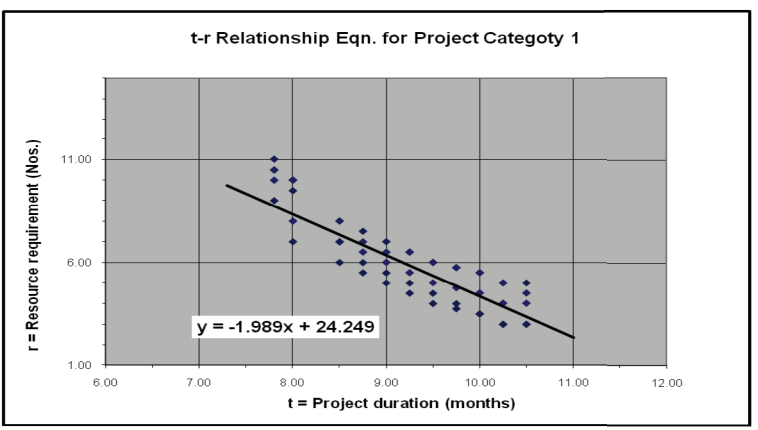

Figure 2: t-r relationship equation for project category 1 (duration ~ 9 months)

Using the graph (Figure 2) and equation, one can find the corresponding value of t and r. For example, if x (project duration) = 9 in the equation then the y (resource requirement) value = 6.348. This information is very important for adjusting the t-r values of projects in searching of optimum solution to business objectives. The building construction projects were divided into five categories. The t-r equations for categories 2, 3, 4 & 5 were derived in the same way as summarized in Table 3.

Table 3: The t-r equations for five categories of building construction projects

Category	Project dur. (months)	t-r equation	Type of project
1	~ 9	**y = -1.989x +24.25**	High-rise building construction
2	~15	**y = -1.034x +26.20**	High-rise building construction
3	~24	**y = -1.318x +47.64**	High-rise building construction
4	~36	**y = -1.436x + 72.40**	High-rise building construction
5	~48	**y = -1.202x + 86.00**	High-rise building construction

Part 2: The Solution Procedures or Optimizer

The solution procedures can be divided into seven components as follows. The outcome of the mathematical model has triggered the road map for finding the practical optimum solution to real life problems, which are described below.

1) Input database – this is basically creating a database collecting all the necessary information e.g. project info, multi-project schedules, resource allocation plan, constraints, and project risks. MS Access® was used for creating this database.

2) Simulation model – this is to develop a discrete-event simulation model and integrating using Simphony.NET environment for analyzing the multi-project schedules. It was designed to simulate the progress of construction work. It has total 16 modeling elements in four levels such as level 1 (root element), level 2 (database, program and simulation output), level 3 (database portfolio, project start, link, work package, project finish, report 1, report 2, report 3 and report 4), and level 4 (risks, constraints and capture duration), as shown in Figure 3.

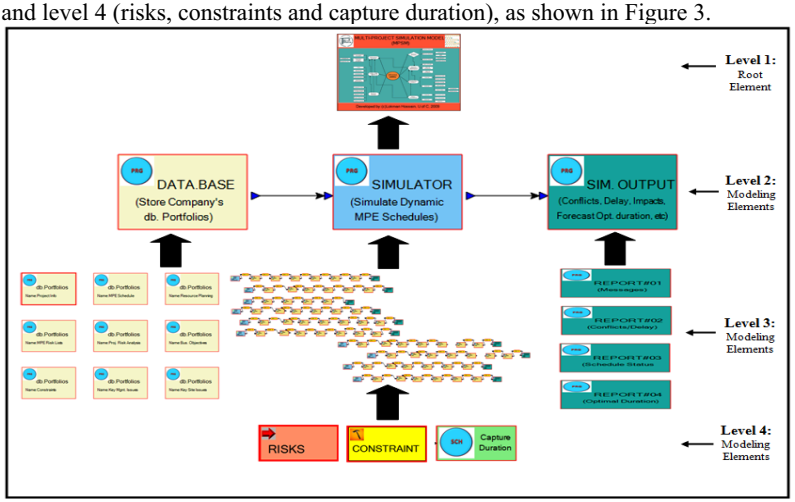

Figure 3: Hierarchical structure with modeling elements of the simulation model

The model was integrated with the database such that many of data can be retrieved automatically from the database into the model. Key input parameters for the simulation model include project info (e.g. project priority, project delivery system, etc), info about project level schedule or bid schedule (e.g. project start, logical relationships among work package, etc), manpower resource required, uncertainty (e.g. description, probability, impact, etc). Some of the uncertainty variables that were considered in the model are a) urgent change order, b) sub-trade's performance, c) shortage of resources, and d) unexpected events. Also these variables were modeled as the sub-model of "project start" modeling element. Interested readers may refer to the paper Hossain & Ruwanpura (2008) for further detail information about the simulation model.

3) Simulation output – The simulation model is designed to generate four different kinds of output – messages for the decision makers, project conflicts or delay, schedule status and optimal duration forecast for projects. Figure 4 shows an example of one of the key output of the sim. model i.e. forecasting stochastic duration for projects given the conditions and uncertainties. Table 4 illustrates the summary of forecast duration (min., most likely, max.) of all individual project.

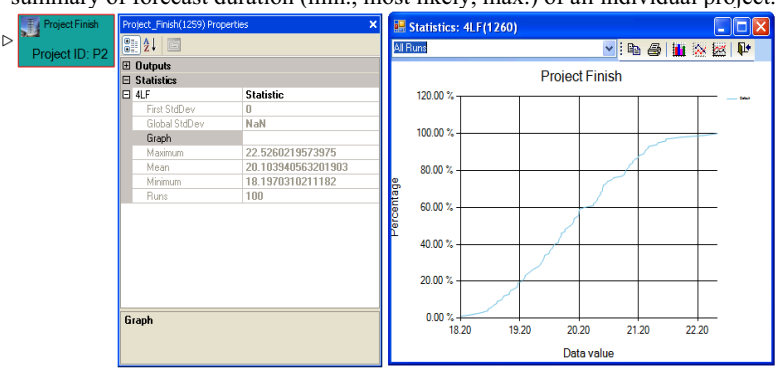

Figure 4: Forecast of stochastic duration for project P2 (statistics and CDF graph)

Table 4: Simulation output – summary of forecast duration for all projects

Project No.	Project ID	STATISTICS Optimal duration (months)		
		Min.	Most likely	Max
1	P2	18.20	**20.10**	22.53
2	P3	10.65	**11.78**	13.21
3	P4	4.22	**6.31**	8.49
4	P5	12.71	**13.94**	15.24
5	P6	21.03	**30.90**	38.09
6	P7	18.37	**24.99**	30.96
7	P10	20.86	**28.81**	34.50
8	P11	12.59	**18.73**	26.18
9	P15	7.77	**8.63**	9.71
10	P17	20.63	**22.68**	25.29

4) Genetic optimization model – the genetic optimization model was designed considering a number of parameters, mathematical equations and constraints for solving multi-objective problem. Mainly company level data and some of the project level data were required to drive this model. The performance of the

model has been demonstrated by solving a problem with three conflicting objectives - (i) minimizing schedules (Z_1), (ii) maximizing resource utilization (Z_2), and (iii) maximizing profit (Z_3). The relative weight for Z_1, Z_2 and Z_3 were considered as 1, 2 & 3 respectively. So the weighted average of objective functions were defined as $Z = \min (Z_1 - 2Z_2 - 3Z_3)$. Input variables considered – project duration (t), resource required (r), cost of manpower, cost of materials, cost of equipment, cost of sub-contracts and cost of overhead. Also in this optimization model, five constraints were considered namely – company resource limit (max = 190 nos.), minimum target profit ($90M), penalty for project P5 if delays more than 16 months, and deadline for project P15 and P17. It has the capability of solving for near optimal solution to any complex problem.

5) Integration of GA model and the simulation model – The GA model was integrated with the simulation model for using the output data shown in Table 4.

6) GA Output – once the problem was defined, the GA model was ready to search for near optimal solution. The results show the optimum values for each of the objective function. It will also indicate the improvement in business efficiency and productivity in terms of schedule, resource utilization and profitability.

Table 5 illustrates the optimum solution for the example problem with ten projects. The compromise optimum values for the objectives functions are T (program duration) = 37.87 months, R (total resource utilization) = 185 nos. and P (overall profit) = $97.29M compared to the original values of 43.90 months, 178.65 nos. and $94.27M respectively. The solutions indicated an improvement in business efficiency by 13.74%, 3.43%, and 3.20% in terms of time, resource utilization and profitability (Please see bottom right hand corner of Table 5).

7) Model validation – The optimization model were validated using the validation techniques of a) data validation, b) conceptual model validation, c) computerized model verification, d) operational validation, and e) comparisons of results with actual project data. Detail discussion is out of scope of the paper.

Table 5: Output of the GA model

Conclusions

This paper presents a methodology and tools for optimization of dynamic multi-project environment in construction. First, a theoretical model was developed to formulate the problem in terms of mathematical equations and algorithms. Secondly, a discrete-event simulation model was developed for analyzing the vulnerable multi-project schedules, identifying potential problems, calculating cumulative impacts on project and overall program, and forecasting optimal duration for project completion. The simulation model can be used for any number of projects regardless of project size, type of resources, project delivery system and other business strategies and constraints. Thirdly, a GA-based multi-objective optimization model was developed for solving complex construction multi-objective problem with conflicting objectives subject to a number of constraints. While the theoretical model provided necessary optimization concept and algorithms, the simulation output data provided the basis for optimizing project schedule and resources, the GA-model performed the final part of the optimization to find the compromise optimum solution of the problem.

ABSTRACT

The primary goal of the research is to investigate the discontinuities between current energy modeling tools and the implementation of sustainable features within the models they produce for better envelope design and construction material selection. From previous research efforts, it was discovered that energy modeling has made advances within their integration to early and mid level design phases, particularly through the use of Building Information Model (BIM) and the Green Build eXtensible Markup Language (gbXML) file type. However, it was also discovered that BIM-integrated energy modeling tools are often lacking in their ability to incorporate renewable energy sources such as photovoltaic panels, wind turbine, and geothermal wells. This paper introduces strategies to include such sustainable fixtures to predict energy generation with a case study of Zero Net Energy Test Home(ZNETH). In addition, this paper introduces parametric analyses for better envelope design and construction material selection by analyzing simulated energy consumptions with various parametric inputs, e.g., material types, location, and size.

KEY WORDS

Energy Modeling, Energy Analysis, BIM, Zero Net Energy

1. INTRODUCTION

The University of Nebraska-Lincoln has started an innovative research project to build a Zero Net Energy Test House (ZNETH). The project was started in June of 2008 and is expected to be completed by the summer of 2010. The main objective of the test bed home is to address the best method of designing and constructing houses that has a negligible effect on the environment. Engineering students and faculty from the construction and architecture departments are engaged in the research to address the required specifications and appropriate materials that should allow for a zero net energy scenario. Some of these specifications and materials have been chosen while others are currently under examination. ZNETH has been designed to comply with the frame work of the Leadership in Energy and Environmental Design (LEED) Platinum certification rating from the US Green Building Council's LEED for home requirements.

The ZNETH project has been used to investigate several research objectives. For this paper, the main objective is to address the discontinuities between current energy modeling tools and the implementation of renewable energy features within the models they produce for better envelope design and construction material selection.

2. BACKGROUND

2.1 The Zero Net Energy Test Home (ZNETH)

ZNETH consists of two floors and a basement (Figure 1). Several sustainable systems have been proposed and implemented with this project. Insulated concrete forms (ICF) were installed for the basement walls and the walls at the north, east, and west of the first floor. 2x6 framing with closed cell, soy based spray foam is planned to be used for the south wall of the first floor and all second floor walls. The home is clad with an Exterior Insulation Finishing System (EIFS). In addition, various high efficiency window types were selected to reduce solar heat gains during summer months and heat losses during winter months. Horizontal and vertical geothermal wells were also incorporated into the house's design. The horizontal well was looped at 8 ft deep, and the two vertical wells were drilled to 150 ft. In addition, to lower the energy consumption of heating system, a radiant floor system will be used in the first and second floors to eliminate the use of a furnace for heating the house.

Figure1 Zero Net Energy Test House (ZNETH)

To make the house more efficient and sustainable, a wind turbine and solar panels have been selected as the energy producing resources for this project. It was assumed that the total produced energy from the wind turbine and solar panels would be more than the house consumes. If successful, the unused energy can be sold back to a

power company using a net metering system. The maximum assumed energy produced from the wind turbine is 2 kilowatts-hour (kWh). kWh is a rate of power consumption equal to 1000 watts for one hour. Likewise, a maximum of 2 kWh rate is expected to be produced by the solar panels that were installed on the roof.

2.2 Building Information Model (BIM)

In this study, two different BIM processes were conducted for the ZNETH energy modeling: object-oriented geometric information modeling (e.g., envelop, doors, windows, walls, zones, etc.) with a BIM tool and 3D building energy modeling (e.g., materials, heat resistance, location, weather data, etc.) with an energy simulation tool. The main advantage of using this approach is that the 3D geometric building information is transferred to the energy simulation tool rather than recreating 3D geometric information again from the energy simulation tool.

2.2.1 Energy Simulation Modeling

After examining several energy programs, Autodesk's Ecotect v5.6 was selected for the energy simulation. Ecotect has a variety of energy analysis functions. In 2005, the US Department of Energy examined 20 energy programs to provide an overview of their features and capabilities. Ecotect was defined as a complete building design and analysis software (Crawley et al. 2005). One of the most powerful features that Ecotect offers is its ability to view analysis results in various formats such as graphs, tables, and 3D objects (Riether and Butler 2008). Ecotect is a stand-alone energy analysis program capable of applying energy analyses such as thermal, solar, acoustics, and lighting throughout early design phases. Moreover, Ecotect allows results to be mapped directly over 3D objects, creating a more intuitive design process (Crawley et al. 2005). Ecotect can import and export a number of file formats such as IFC, gbXML, 3DS, DXF, and VRML.

2.2.2 Geometric Information Modeling

ZNETH was modeled using Constructor 2008, which was developed by Vico Software. From the previous study (Cho et al. 2009), gbXML was identified as the most accurate interoperable file format between BIM and energy programs. Figure 2 shows the BIM models before and after the exporting process from Constructor to Ecotect.

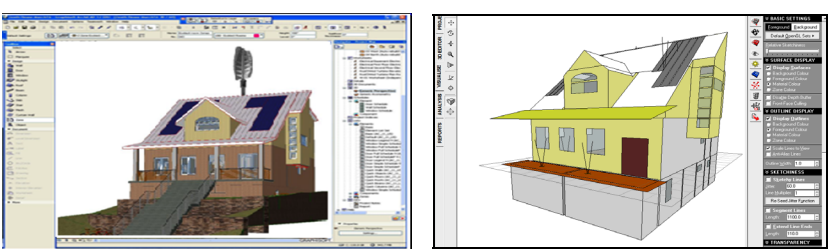

Figure 2 Geometric BIM in Constructor (left) and Exported BIM in Ecotect (right)

3 APPLYING THE RENEWABLE ENERGY SOURCES INTO THE ENERGY MODEL

Ecotect has a variety of tools and functions to perform the required analyses however, there are limitations of modeling the renewable energy resources within the model. For example Ecotect has 1) a limited solar panel tool, 2) no wind turbine tool, and 3) no geothermal system function. The strategies that have been taken in this research to solve those limitations are discussed in the sections that follow.

3.1 Photovoltaic Panels

To calculate the produced energy from the photovoltaic panels (PVs), two data sets have to be available: the electrical efficiency percentage which is unknown in this study, and the available solar radiation for different seasons. Ecotect has a specific tool that operates as a PV where some specifications can be entered manually like the electrical efficiency percentage and space heating. However, the tool does not have an option to calculate or enter the available solar radiation for different seasons. Therefore, the electrical efficiency percentage was calculated using the trial and error method to find the required percentage that would produce the expected energy amount using the average available solar radiation for Omaha Nebraska. That solar radiation was found to be 4.6 hour / day (Radarsign 2008).

3.2 Wind Turbine

The inclusion of a residential wind turbine was difficult to implement into the energy model due to Ecotect's inability to directly incorporate one. To solve this issue, some appliances available in Ecotect have an option of adding daily produced energy. To calculate the daily produced energy of the turbine, the mean annual wind speed of Omaha was assumed as 5.5 miles (8.85 kilometers) per second based on the official Nebraska Wind Resources Record. Then the mean wind speed was used to extrapolate the expected annual amount of produced energy from the wind turbine (Figure 3) (Helixwind 2007). Next, the annual produced energy (1000 kWh/year) was divided by 365 days to produce the theoretical daily energy output of the turbine (2.74 kWh/day). Finally, the obtained theoretical output was tagged to the appliances in Ecotect.

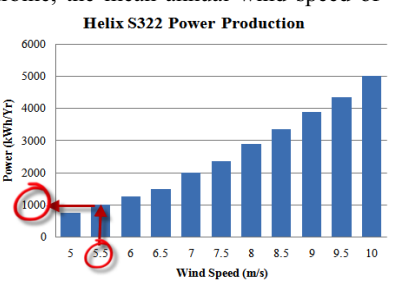

Figure 3 Wind Turbine's Stated Energy Production (Helixwind, 2007)

3.3 Geothermal System

The geothermal system affects two aspects of the energy analysis: the thermal analysis and the energy consumption analysis. Ecotect does not have a function to

calculate the thermal effect or the expected energy consumption of HVAC systems affected by a geothermal loop. To solve these issues, two steps were taken. First, for the thermal analysis, a natural ventilation system was added to each room to mimic the effect of the geothermal and radiant floor systems. Second, TRACE 700, another commercially available software which has a specific tool for the geothermal system, was adopted to calculate the total consumed energy of ZNETH. TRACE 700 can be used to design and analyze building's energy consumption. Extensive information, such as a room's area, volume, location, appliances specifications, schedule, as well as their structural components need to be available to build a model in TRACE 700. The calculation procedures are based on the American Society of Heating, Refrigerating and Air-Conditioning Engineers manual (ASHRAE 1997).

4 ANALYSIS RESULTS

The cumulative energy generated by the PVs and the wind turbine were 2,219 kW/year and 1,000 kW/year respectively. Thus 3,219 kW were estimated as the total generated energy in a year.

By using TRACE 700, the total consumed energy of ZNETH was estimated at12,189 kW/year. Figure 4 demonstrates a comparison between the total cumulative energy consumption (brown line), total cumulative energy production (yellow line) and the total cumulative energy consumption after subtracting the energy production (red line). The graph shows the produced energies from the solar panels and the wind turbine as not being enough to cover the total electrical consumption of ZNETH.

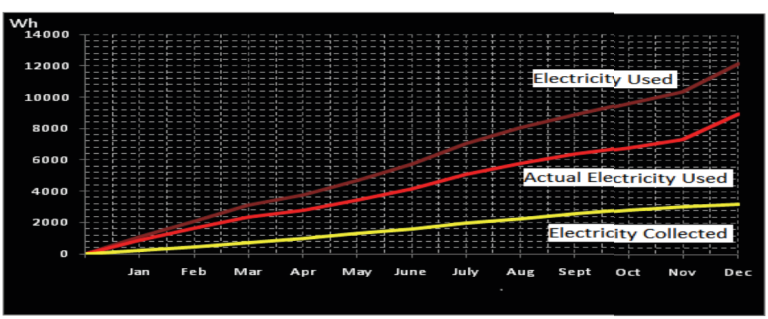

Figure 4 ZNETH's Calculated Energy Production vs. Energy Consumption

5 PARAMETRIC ANALYSES

Examining a number of different design alternatives, especially from an economic perspective, throughout initial design phases help design teams attain a more concise perception of what the most economically and environmentally efficient strategy should be taken. Therefore, theoretical changes have been made to ZNETH's energy model and tested to investigate what the most efficient design of the home could have produced.

First, the overhang width was tested to find the most efficient width that would block the sun radiation during the summer months only. Additionally, some windows have been resized and relocated to increase natural light levels. Second, a model was built similar to the ZNETH, but with the newly proposed design changes. This new model was notated as ZNETH-NEW. A comparison was conducted between the ZNETH-current, which is the as designed model with no changes, and ZNETH-NEW using four different wall material scenarios.

5.1 Resizing the Overhang

A 2.4m width overhang was built atop of ZNETH's front porch as shown in Figure 5. Using Ecotect, a solar analysis was conducted to calculate the total monthly solar radiation transmitted through the front windows of the living room throughout the year, and found to be 139.95 kW/year. The low value indicates that the as-built porch overhang is overdesigned, minimizing the sun's radiation to the front windows during all seasons

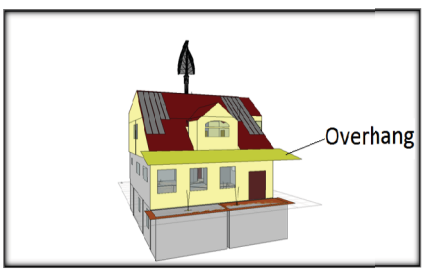

Figure 5 The Transmitted Solar Radiation After Resizing the Overhang

To promote a more practical approach to the amount of solar radiation entering from the main floor's front windows, the overhang width has been analyzed. Through simulations with various sizes of overhang widths, 1.1m was identified as the most efficient overhang size to provide the highest shading percent during the summer months while allowing for a larger amount of solar radiation to enter during the winter, spring and fall months. The simulated total transmitted radiation was 390.10 kW/year. As shown in Figure 6, there is a smaller amount of transmitted radiance through the summer months when using the newly designed overhang. However, there is more radiation during the spring, fall and winter seasons, that helping to increase the heat sources available to this room. Also, the design would reduce the required heating loads, in turn decreasing the total energy consumption of the house.

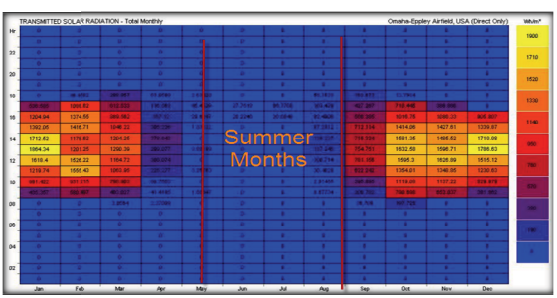

Figure 6 Transmitted Solar Radiation of Optimal Overhang (lighter color shows higher radiation)

Using TRACE 700™, a consumption analysis was conducted to calculate the expected heating load and the total consumed energy of the whole year for the

ZNETH model before and after redesigning the overhang. The heating load needed to regulate the house's temperature has been reduced by 204 kWh/yr. This is because there is more solar radiation entering the living room during winter, fall and spring months. Also, this heating reduction would further minimize the total energy consumption of the house by 189 kWh/yr. Table 1 shows a summary of the analyses that were conducted by Ecotect and TRACE 700 on ZNETH before and after optimizing the overhang.

Table 1 Results of the Overhang Analysis from Ecotect and TRACE (kWh/year)

Analysis type	Before	Suggested design	after	Improvements
Ecotect Transmitted radiations	139.95	Optimizing the overhang for the living room	390.10	250
TRACE Total heating load	2,430		2,226	204
TRACE Total consumed energy	12,189		12,000	189

kWh: Kilowatt-hours

5.2 Resizing Windows

To improve lighting levels on the second floor, three windows in the second floor were enlarged and relocated to allow for more natural light into the house. These windows were selected because they did not have any obstruction that would block the sun light. By using Ecotect, the effect of the day lighting levels was tested before and after resizing the windows (Figure 7). Based on the as-built design, rooms (1), (2) and (3) have an average of 160 Lux, 110 Lux, and 45.5 Lux (lumens per square meter) respectively. By resizing the windows in rooms (1), (2) and (3), the available

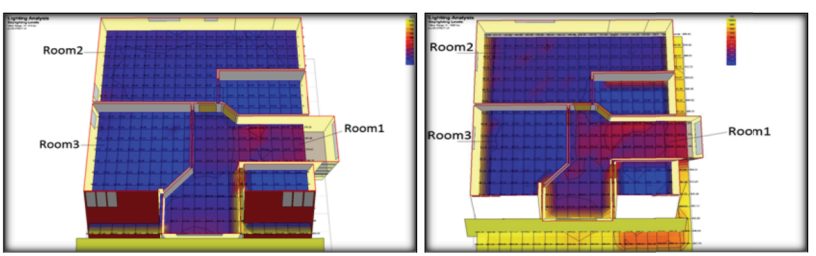

Figure 7 The Daylight Levels as Designed (left) and After Window Resizing

daylight was increased over the previous results by 88.33 Lux.

5.3 Material Selection

After investigating the most efficient overhang size and second floor window size and location, a parametric analysis of materials already being used in the house was conducted using Ecotect and TRACE 700.

The first scenario analyzed was that of the as-built external walls of ZNETH. In the basement Insulated Concrete Forms (ICFs) with an R-Value of 26.34 h.ft^2.^{o}F/Btu was used. While 2x6 stick framing filled with closed cell soy based spray foam with an R-value of 34.55h.ft^2.^{o}F/Btu was used. The second scenario incorporated the use of ICFs in all external walls with the concrete core thicknesses at 4", 6", and 8". The third scenario mirrored that of a typical 2x6 framed home with traditional batt insulation and 8" concrete foundation walls. The last scenario replaces the batt insulation of the framed walls in the third scenario with the closed cell soy based spray foam. The table below summarizes each setup.

Table 2 Summary of the Four Scenarios and Their R-values

	Description	**Floors**	**R-value (ft^2.^{o}F h/Btu)***
Scenario 1	As designed	basement	26.34
		first and second	34.55
Scenario 2	ICF-4"	basement, first and second	26.17
	ICF-6"		26.34
	ICF-8"		26.5
Scenario 3	Typical home insulation (2x6)	basement	12.19
		first and second	21.65
Scenario 4	Closed cell soy based spray foam	basement	22.22
		first and second	34.55

*1 ft² F° h/Btu = approx. 0.1761 K.m²/W

Using the setups above, parameters were loaded into the two energy models and a thermal analysis was conducted using Ecotect, while a total consumed energy analysis was conducted using TRACE 700.

5.3.1 Thermal Analysis

Hourly thermal analyses were conducted to compare the heat gains between the two models. The hourly thermal analysis calculates how much heat is obtained through the wall material on the hottest day in the area, which is July 26th. Table 3 shows the heat gain through the wall materials, in kilowatt-hour (kWh) for ZNETH-current and ZNETH-NEW, under the four scenarios. As can be seen, the ZNETH-current under the first scenario has the lowest heat gain because this scenario has a higher thermal resistance value (R-value). On the other hand, the ZNETH-NEW under all the four scenarios showed a high heat gain because enlarging the windows reduced the thermal resistance (R-value) of the second floor's walls.

Table 3 The Heat Gain Through the Materials in Kilowatt-Hour (kWh)

	Description	ZNETH- current	ZNETH-NEW
Scenario 1	As designed	16.370	26.403
Scenario 2	ICF-4"	17.587	24.778
	ICF-6"	17.257	24.488
	ICF-8"	17.224	24.457

Scenario 3	Typical house	24.755	33.822
Scenario 4	Closed cell soy based spray foam	17.055	26.692

5.3.2 Consumption Analysis

Using TRACE 700, the total consumed energy analysis was conducted to compare the total consumed energy between the two models. Table 4 shows the total consumed energy for the whole year in kilowatt-hour (kWh/year) for the four scenarios. Enlarging the windows of ZNETH-NEW would decrease the R-value of the walls, which would in turn increase the total consumed energy. On the other hand, applying blinds to the windows have a greater effect at reducing the total energy consumption. Additionally, the use of closed cell soy based spray foam in all external walls was found to be the most energy efficient alternative for both energy models.

Table 4 Total Consumed Energy for a Year in Kilowatt-Hour (kWh/year)

	Description			
		ZNETH - current	ZNETH-NEW	Difference
Scenario 1	As designed	12,189	12,478	-289
Scenario 2	ICF-4”	12,325	12,506	-181
	ICF-6”	12,253	12,487	-234
	ICF-8”	12,179	12,439	-260
Scenario 3	Typical house	15,336	15,494	-158
Scenario 4	Closed cell soy based spray foam	12,079	12,417	-338

6 CONCLUSIONS

The ZNETH project has been used as a case study to address the main objective of this paper, which is to investigate the discontinuities between current energy modeling software tools, and to investigate the implementation of sustainable features within the models they produce. While several energy software packages were examined for possible inclusion in this research, Ecotect was selected as fulfilling the research's parameters. Based on research outcomes, the following conclusions were drawn:

1) Ecotect has a variety of capabilities to perform different energy analyses. However, it lacks tools or functions to simulate renewable energy resources. Other programs such as Trace700 or EnergyPlus are required to simulate energy consumption to supplement Ecotect’s limited functions.
2) A wind turbine can be indirectly added to Ecotect models using appliances, which have an option of adding daily produced energy.
3) The geothermal system can be applied only as a natural ventilation system to simulate thermal effects.

For the parametric analysis, two changes were made: resizing the windows and reducing the overhang size. After analyzing all the changes, thermal and energy consumption were compared between ZNETH-NEW and ZNETH-current. The following conclusions were drawn from thermal analysis comparison:

1) For ZNETH-current, the as-designed materials of the exterior walls were sufficient enough to reduce the heat gains during the hottest day.
2) Enlarging the windows would reduce the thermal resistance (R-value) of the walls which increases heat gains.

The energy consumption comparison has shown the following conclusions:

1) Closed cell soy based spray foam as an insulation material for all walls was found as being the best alternative for both the energy models.
2) Enlarging the windows decreases R-value and increases consumed energy.

ACKNOWLEDGEMENTS

A special thanks to Dr. Avery Schwer at the University Nebraska-Lincoln for the use of ZNETH as a test bed for this investigation.

EXPLORING THE EFFECTS OF CONTEXT LEVEL FACTORS ON THE STRUCTURAL STEEL FABRICATION SHOP OPERATION

[3]Professor, Hole School of Construction, Department of Civil and Environmental Engineering, University of Alberta, Edmonton, Alberta, Canada Email: abourizk@ualberta.ca

Abstract

Structural steel fabrication is influenced by both operation and context level effective factors. Usually the mechanisms through which operation level effective factors (e.g. capacity of equipment and operation sequences) affect the fabrication shop are properly documented within a variety of methods such as equipment manuals, job instructions, standards, quality control charts and ISO documents. However, while context level effective factors (e.g. operators' fatigue level and organizational policies) originate from human behavior, usually their enforcing paths are not well understood like operation based effective factors. This issue usually limits decision makers at steel fabrication shops to accept more inaccuracy by ignoring the effects of context level factors during their analyses. In an effort to address this issue, this research attempts to explore the effects of fatigue (as a context level effective factor) and its affecting dynamics within a steel fabrication shop. A hybrid model of system Dynamics and Discrete Event Simulation modeling approaches has been employed as the main tool for the research.

1. Introduction

Structural steel construction is a major part at many construction projects, ranging from industrial projects, such as refinery, petrochemical complex, and power plant, to the infrastructure and municipal projects, such as bridge, stadium, residential building, hotel, and office building. In order to reduce the total duration and cost of the structural steel construction projects, most of structural steel constructors have

either owned the structural steel fabrication shops or established joint partnerships with them. Because of the mobilization restrictions involved in the project job sites, these well equipped fabrication shops carry out many operations for the steel using specialized and more productive stationary equipment. The fabricated steels, then, are shipped to the job sites to get erected in the form of the designed structure.

In addition to the benefits that use of fabrication shops can put in the structural steel construction, it increases the complexity of the structural steel construction projects by introducing an extra phase, i.e. steel fabrication. Furthermore, to be cost effective, most steel fabrication shops concurrently provide fabricated steel pieces for different projects. These all require further managerial efforts for planning and controlling the assigned projects to the fabrication shop.

In order to come up with more accurate planning and control methods for the shop, in this research we are going to explore some feedback loops between operation (or physical) and context (or nonphysical) level of the fabrication phase, which affect the operators' productivities (see [Lee et al. 2007] for more information). Our focus at this part of the research will be more on the feedback loops related to the operators' fatigue and productivity rate at the fabrication shop. We will link these feedbacks to some control policies that fabrication shop managers have, e.g. adjusting the working hour schedule.

A hybrid simulation modeling approach based on System Dynamics (SD) and Discrete Event Simulation (DES) has been proposed for following the effects of made changes to the policies in the fabrication shop operations. This is a modeling approach which utilizes SD for capturing the system behavior at the context level and employs DES for modeling the operation level behavior of the fabrication shop (refer to [Alvanchi et al. 2009] for more information). This hybrid model will make us capable of applying different alternative policies to the fabrication shop and testing the effects of them on the fabrication shop productivity.

2. Problem Statement

In addition to the direct costs of material, equipment and operators, charged to the steel fabrication shop, holding a fabrication shop will add many indirect costs to the fabrication process. These indirect costs load relatively constant amount of money to the fabrication shops. Meanwhile it should be considered that there is always an easy replaceable alternative option to the fabrication shop that is onsite structural steel assembly. As a result, it is very critical for every fabrication shop to keep its capacities busy as much as it can and to maintain its productivity rate at the highest possible level to stay at a competitive price. Therefore, despite onsite construction works, usually fabrication shops run the night shifts as well as day shifts. The prevalent use of overtime in the fabrication shops is also in accordance with such condition. However, the shop managers should also obey the labor codes enforced by the authorities which defines the main bottom lines regarding the working hours (e.g. Canada Labour Code [is accessible at http://laws.justice.gc.ca /en/L-2/FullText.html] limits the total standard and overtime hours to 48 hour per week).

On the other hand, the nature of the work in the fabrication shop requires considerable physical involvement in the work which creates fatigue in the operators

and reduces their productivity. Furthermore, work safety tools, such as boots, glasses, helmets, masks and gloves, amplify the created fatigue and reduce the productivity. These all generate a situation in which the way that shop managers distribute the standard and overtime working hours during the week can play a significant role at the final achieved productivity. Moreover, there are some parameters such as timing and durations of the coffee breaks during the day and the amount of assigned workloads to the stations which can affect the level of the fatigue and productivity at the stations.

In this research we are trying to model the dynamics of the fatigue and productivity in the working stations which also involves fabrication shop managers control policies regarding the operators' working hours. This model will give shop managers the capability of examining the effects of changes to their set working hour policies and making their final decisions based on that. Although this research mainly gets focused on the mutual effects between fatigue and productivity, the fabrication shop operators can also get their benefits since a minimized fatigue level will be another result of this research.

3. Dynamics of the Fatigue in a Station

Reviewing the research efforts on the relationship between human fatigue and productivity, main effective parameters in this relationship can be listed as in below:

- Overtime
- Length of the continuous work and shift
- Time of the work during the day
- Difficulty and special conditions of the work

In this section we are going to portray the dynamics through which these effective parameters affect the human fatigue and productivity in a fabrication shop station. We will first depict the *basic* dynamic model of a typical fabrication shop station and then each effective parameter will be added as a complementary dynamic mechanism.

3.1. Basic Dynamic Model of a Fabrication Shop Station

Figure 1 presents the basic dynamic model of a typical fabrication shop station using stock and flow diagram (see [Sterman 2000] for more information). According to the *committed work* and *fabrication start schedule*, new works are released to the station. These new works are going to be added to the list or backlog of *fabrication to be done* at the station. Existence of any *fabrications to be done* at the station will make the station status busy during the scheduled working hours. The plus sign (+) at the head of the arrow between the *fabrication to be done* backlog and the *station busy status* resembles a positive relation between them, i.e. the more works on the station's *fabrication to be done* list, the busier station will get kept. A busy station will do the work at the *fabrication finish rate* which is calculated based on the station's productivity rate and *number of operators*. As soon as station does the fabrication jobs, the *fabrication to be done* backlog is depleted and it will be added to the *fabrication done* backlog.

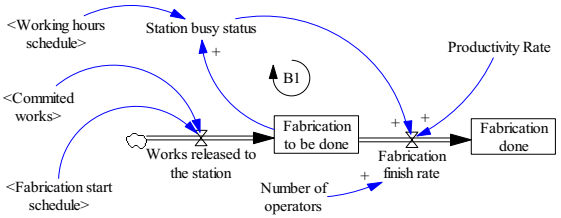

Figure 1. Basic dynamic model of a fabrication shop station

The feedback loop B1 refers to the balancing feedback loop formed by *fabrication to be done*, *station busy status*, and *fabrication finish rate*. The balancing term here refers to the fact that an increase in the value of a variable on this loop would cause a decrease in that variable later on, through the active cause and effect dynamics of the loop. For example on the feedback loop B1, by an increase in the level of the *fabrication to be done,* the *station busy status* will be increased and as a result of that the *fabrication finish rate* will get increased which will result in a reduction at the *fabrication to be done*.

3.2. Dynamics of the Overtime Fatigue

Compared to the standard working hours, overtime working hours during the week will produce more fatigue for the operators. According to the results presented by Sterman (2000), the effects of this overtime fatigue are mainly revealed during the next working week. Feedback loop R1 in Figure 2 represents a simplified reinforcing loop through which the effects of overtime fatigue is conveyed to the productivity rate of the station.

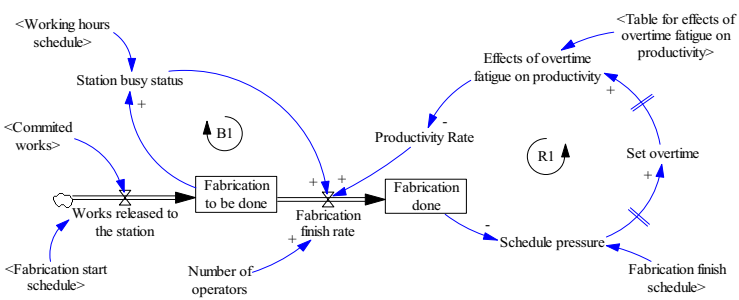

Figure 2. Effect of the set overtime on the work fatigue and productivity rate

In the reinforcing feedback loop an increase in the variables on the loop is a cause for an ensuing increase to that variable in the future. In the feedback loop R1 the schedule pressure is determined as the result of the difference between level of the *fabrication done* and the *fabrication finish schedule*. The minus sign (-) at the head of the arrow between *fabrication done* and *schedule pressure* in the Figure 2 resembles a negative relationship between them, i.e. an increase in the level of the *fabrication done* backlog will result in a decrease at the schedule pressure. An increased schedule pressure may cause the shop managers to increase the *set overtime* for the station.

The *set overtime* hours should be announced to the operators a while in advance to the workers. The double slash on the arrow between the schedule pressure and set overtime in the Figure 2 represents this delay. Based on the set value for the overtime in the previous week and the overtime effects table, *the effects of the overtime fatigue on the productivity* and in the next step the *productivity rate* are determined.

3.3. Dynamics of the Continuous Work Fatigue

Since early 1960's many researchers in the area of ergonomics and occupational medicine have driven various research efforts for deriving the relationship between the human endurance and different levels of workloads (e.g. Rohmert 1973a; Rohmert 1973b; Koparadekar and Mital 1994; Vøllestad 1997; Rosa at al. 1998; Folkard and Tucker 2003; Shih 2007). The results of these research efforts mainly have been used as guidelines or regulations to the work managers to adjust the assigned workloads to their workers. However, in this part of the research we will use these results to investigate the dynamic effects of the continuous work fatigue on the productivity rate at fabrication shop stations.

The reinforcing feedback loop R2 in the Figure 3 depicts a simplified dynamic model for the effects of the continuous work and shift length on the fatigue and productivity rate. Loop R2 starts with a positive relationship between *fabrication to be done* and *station busy status* (which is also in common with the base dynamic model). The value of the *station busy status* (0 or 1) during every period of the time determines the value of *busy time rate* and *idle time rate* flows which adjust the *total busy hours in shift* and *total idle hours in shift* backlogs. At the end of each working shift the total accumulated values at these backlogs gets discharged since the operators in the new shift will receive no effects from the accumulated fatigue at the previous shift. The *effects of continuous work on productivity* can be determined at each period of the time according to its related table and current values of the *total busy time in the shift* and *total idle time in the shift*. At the final step the *effects of continuous work on productivity* will be applied to the *productivity rate* which adjusts the level of *fabrication to be done* and *fabrication done* backlogs.

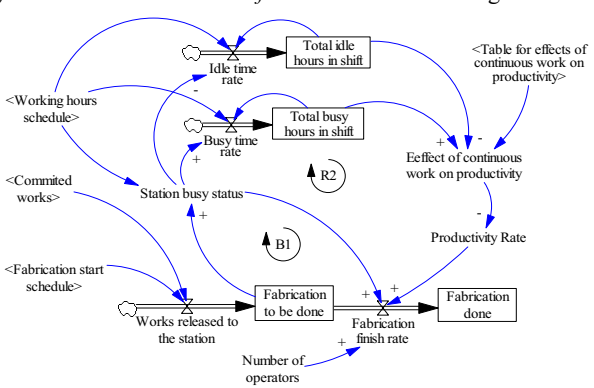

Figure 3. Effect of the continuous work and shift length on the work fatigue and productivity rate

3.4. Dynamics of the Time in the Day and Fatigue

The physiological characteristics of the human force him to not keep an evenly distributed attitude during the day. This issue has been investigated by the researchers in the area of ergonomics and occupational medicine (e.g. Rosa at al. 1998; Folkard and Tucker 2003). In our research we are going to incorporate the achieved results from these research efforts for developing the fabrication shop stations' dynamic model. The effective chain related to the time of the day fatigue has been presented in the Figure 4. Despite the previously mentioned dynamic mechanisms, the *effect of time in the day on productivity* follows a straight line of causes and effects to affect the productivity rate, instead of a feedback loop.

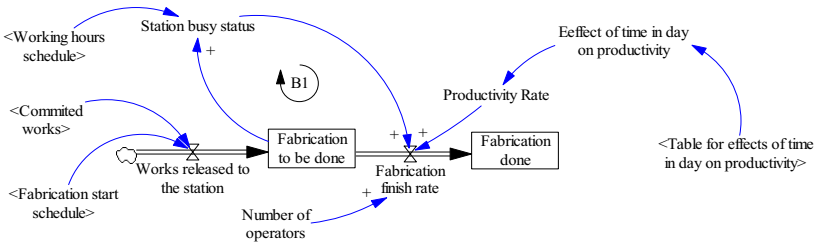

Figure 4. Effect of the time of the day on the work fatigue and productivity rate

3.5. Difficulty and Special Conditions

The presented dynamic mechanisms for the fatigue and productivity rate in the previous sections follow a generic approach which can be applied to different types of fabrication shop stations, e.g. cutting, fitting, welding, and painting. However, it should be taken into account that, depended on the level of physical and mental involvements at each station, the occurred fatigue and productivity rate varies from one station to the other. Furthermore, usually quantified values and curves provided by the researchers have been sampled from special types of works and do not necessarily represent fabrication shop stations' behaviors.

The mentioned issue, more or less, is extendable to many other types of the work for utilizing the provided fatigue data. Though, many research efforts (e.g. Rohmert 1973a; Rohmert 1973b; Vøllestad 1997; Rosa at al. 1998; Shih 2007) have considered different levels of work difficulties in their samplings and have published their results based on these levels. It is significant to know that most of research works have defined the work difficulty level as a percent of Maximal Voluntary Contraction (MVC) which returns to "a maximal exertion of force reported as force (e.g., lb, kg, Newtons) or as a moment around a joint (e.g., Newton-meters, foot-pounds, kilogram-meters)." (Bernard 2006). Thus, one easy way for tuning the provided data to the specific station of fabrication shop (or any other type of work) is to estimate the level of MVC at every station and to develop its related reference tables. In this perspective, every fabrication shop station will have its specified dynamic mechanism and will follow its own behavior as reactions to the applied workload. For example, while, presumably, welding operation requires more level of physical involvement than painting, the estimated MVC level at welding station will

be higher than painting station and the fatigue at the welding station will occur in shorter period of time during its busy status.

4. Fabrication Shop Model

Going one step higher than the station level, a set of corresponding stations constitute the fabrication shop. Within the fabrication shop a station receives steel pieces from previous stations, performs its assigned operation and then sends the pieces to the next stations. Therefore, an appropriate fabrication shop model should be able of concurrently tracking both the interactions at the shop floor and the ongoing dynamics of every single station. In this research we are going to follow the hybrid SD-DES modeling architecture proposed by Alvanchi et al. (2009) for the structural steel fabrication shop model development.

4.1. Hybrid Model Development

The SD modeling approach is the commonly used modeling tool for capturing the dynamics and feedback loops within the systems. As such, the SD modeling approach is going to be utilized as the main modeling approach for capturing the dynamics of the fatigue and productivity rate within every single fabrication shop station. On the other hand, the DES modeling approach is the proper modeling tool that can capture the flow of materials from one station to the other at the fabrication shop floor.

Figure 5 depicts a simplified structure of the hybrid SD-DES model for the fabrication shop. The rounded rectangles at the bottom of the figure linked to each other with straight arrows represent the fabrication shop stations and the flow of material among them. A DES model will capture this part of the fabrication shop. As well, the presented stock and flow diagram at the top of welding station represents an inclusive SD model of the single dynamic models explained in the section 3 which describes the dynamics of the fatigue and productivity rate inside the welding station. This dynamic mechanism works in every station within the fabrication shop.

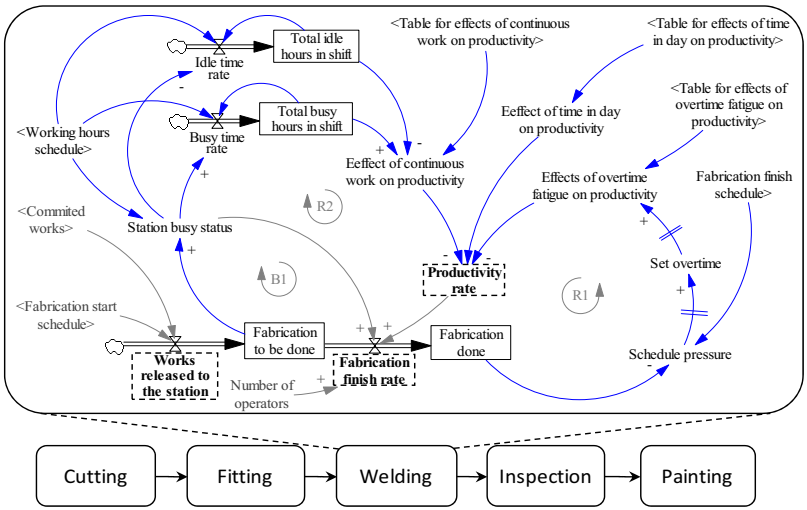

Figure 5. Hybrid SD-DES model of fabrication shop

Three main contact points between SD and DES models have been highlighted in a dashed rectangle with a bold font in SD part at Figure 5 (i.e. *productivity rate*, *works released to the station*, and *fabrication finish rate*). These are the points in which SD models update DES model (for *productivity rate* contact point) and receive updates from DES model (for *works released to the station* and *fabrication finish rate* contact points). On the one hand the contact points which send updates from DES model to the SD model form disconnections in SD modeling parts and might cut off the previously recognized feedback loops in the model. For example, as shown in Figure 5, the SD model receives the updates of the *fabrication finish rate* from the DES model. This means that regardless of previously recognized relationship between *productivity rate*, *station busy status*, and *number of operators*, as the causes, and *fabrication finish rate*, as the effect of them, in the SD model (see section 3.1) *fabrication finish rate* will not get calculated in the SD model and feedback loops B1, R1 and R2 will look uncompleted. All faded variables and relations in Figure 5 refer to this disconnection.

On the other hand, there are also other types of contact points which send updates from the SD model to the DES model, e.g. *productivity rate*. These points are the points which complete the feedback loops and form the hybrid feedbacks between operation and context level of the system. For example, as shown in Figure 5, *productivity rate* is calculated in the SD model and its values are sent to the DES model and the DES model will use these values to come up with the *fabrication finish rate*. But, what really has caused us to not calculate the *fabrication finish rate* directly in the SD model? The answer is: besides the recognized and captured causes in the SD model there are more causes mainly originated from the operational issues, such as station breakdown, crane unavailability and limited working capacities of the next stations, which affect the *fabrication finish rate* of the station. Compared to the SD

modeling approach, these effective factors usually are captured more properly in DES models.

4.2. Model Analysis

The main purpose of developing this hybrid model of fabrication shop is due to investigate the most appropriate combination of the set working hours and time break schedules at the fabrication shop. The key point is that according to the explained dynamics of the fabrication shop, the fatigue level and its consequent productivity rate at each station can dynamically get changed based on the assigned workloads to the stations and the working hours schedule.

Suppose a situation in which shop managers are using a constant working schedule all around the year. Suddenly the fabrication shop becomes committed to a big project. So, fabrication shop will face a tight fabrication finish schedule, the schedule pressure will go up and shop managers are going to set additional overtime for the shop (see the feedback loop R1 in Figure 5). This additional overtime will exert its fatigue effect on the productivity rate and will cause a reduction in fabrication finish rate which will add the schedule pressure. On the other hand, further committed works will result in more work released to the stations (Figure 5). This will increase the busy portion of the time in the stations, the result of which is increased effect of continuous work fatigue on productivity and additional decrease in the productivity rate. In such situations the reinforcing mechanism at both feedback loops R1 and R2 (Figure 5) gets active and can have significant effects on the fabrication shop process. One of corrective actions, which can moderate the mal-effects of this situation, is to shorten the duration between two consequent time breaks, especially when it reaches to the end of the shift. However, it should be taken into account that a real steel fabrication shop is usually a complex combination of different types of stations. Depended on different stations' capacities and volume and types of contracted structural steel projects, the concentration of the workloads at the stations dynamically gets changed within the fabrication shop. In this perspective, without using a robust modeling approach, tracking the effects of any made changes to the work schedule on the productivity will be impossible in a real steel fabrication shops.

The developed model of fabrication shop will enable the fabrication shop managers to test resulting effects of alternative arrangements for the working hour schedule. The model automatically will consider the expected changes to different stations' workloads and will directly reflect the effects of the made changes to the final throughput of the fabrication shop. The schedule arrangement with the best achieved result can be set as the based schedule for the shop. This schedule adjustment process can be done several times during the year, especially for the periods of the year in which there are considerable amount of changes to the types of the committed works for the shop.

5. Conclusion

In this article we introduced a new approach to the way that structural steel fabrication shop manager can adjust the fabrication shop working hours for enhancing the total throughput of the fabrication shop. A hybrid SD-DES model has

been developed for this purpose which captures the mutual effects of the fatigue level, as a context level variable, on the productivity rate, as an operation level variable, at the fabrication shop operations and allows shop managers to examine alternative work schedules for choosing the most appropriate option. While the adjusted schedule, as the main output for our developed model, requires no special investment in the fabrication shop (i.e. no changes to the shop equipment or no additional facilities required), it is expected that the achieved result can be easily enforceable to the fabrication shop. As future research work, we are going to implement the model for a real fabrication shop. As well, we will attempt to explore and add new feedbacks between context level and operation level effective factors to our hybrid SD-DES model.

Abstract

The Korean government has announced new policies to regulate mortgage lending, which aim to decrease both the Loan to Value ratio (LTV) and the Debt to Income ratio (DTI); this is due to the recent upturn in house prices and the increase in the number of mortgage loans that have been the result of deregulation policies such as increasing both the LTV and DTI, adopted in the second half of 2008. The government expects mortgage lending policies related in both the LTV and DTI to control housing demand and to stabilize house prices in the influence of market status. However, it is difficult to analyze how effective is these kind of policies on price and demand through an empirical approach. Also, because mortgage loan is a key element of real estate financial market, impact on secondary market in charge of mortgage securitization should be conducted. Consequently, a comprehensive and systematical method is necessary to analyze the effects of new government policies. This paper, therefore, utilizes an integrated perspective and applies a system dynamics methodology to develop Korean real estate market dynamics models. Using these system dynamics analysis, this research understands changes in housing market and mortgage lending agencies, as well as secondary financial market. In addition, the authors use system dynamics simulations to examine the interplay between mortgage loan variations, housing prices, and demand. This research found the missing links of empirical policy analysis and connected these links in order to expose the hidden side effects of these policies, as well as proposed comprehensive solutions and systematic approaches of dynamic systems.

Introduction

The Korean real estate market currently is experiencing an upturn in housing demand and an increase in house price. This is due to policies adopted by the Korean

government in the second half of 2008, which boosted mortgage lending in an effort to increase housing demand. In response to present conditions, however, the government has announced a comprehensive real estate program which will regulate mortgage lending by commercial banks; the program mandates a decrease in both the Loan to Value ratio (LTV: the amount of a first mortgage lien as a percentage of the total appraised value of a real property) and the Debt to Income ratio (DTI: the percentage of a consumer's monthly gross income that goes toward paying debt) in an attempt to control housing demand and to stabilize house prices. However, neither house prices nor consumer demand are expected to exhibit much change due to the existence of secondary lending agencies (e.g., mutual savings banks and credit unions), which can issue mortgage loans and that are unaffected by the new government policies. Consequently, the Korean housing market could fall into deep confusion; an empirical approach to the analysis of the housing market for forecasting is difficult but necessary.

Several analytical studies of real estate policy exist. Shiller and Weiss (1999) proposed a framework for comparing real estate valuation systems through the simulation of mortgage lenders' profits and density estimation. Park et al. (2008) demonstrated the effectiveness of bank lending restrictions and analyzed the relationship between bank lending and apartment prices using real data. However, these studies utilized empirical approaches encompassing only a few factors and did not consider diverse perspectives. Instead, a comprehensive and systematic method is required to analyze the real estate financial market and the causal relationships between market influence factors. Kim (2007) has been the only study that has understood and analyzed the basic mechanisms of the real estate market and market policies in a macro perspective; to do so, Kim used system thinking.

The current paper uses Korean real estate and mortgage market dynamics models developed with an integrated perspective and system dynamics methodology; these models are based on the fundamental principles of and the causal loops found in housing markets and emerge out of the economic activities both of consumers and financial agencies. Dynamics models provide information to decision makers through a comprehensive approach elucidated by diagrams representing feedback loops. This study estimates the effects of current policies upon LTV and DTI ratios using these simulation models.

The policy models employed were constructed by concentrating on the law of supply and demand and the price expectations of consumers.

Previous Research

System Dynamics

System Dynamics (SD) is a modeling tool that provides an understanding of strategic problems in complex dynamic systems. An SD model provides system users with insight into the feedback processes and dynamic behavior of a system. Table 1 shows the legends in SD models.

Table 1. Legends in the Causal Loop Diagrams (Sterman 2000)

Legends	Explanation	
	When other conditions are the same	When Factor A increases (decreases), Factor B increases (decreases)
		When Factor A increases (decreases), Factor B decreases (increases)
	Including weighted delayed time between two factors	
	Positive feedback or self-reinforcing loop	
	Negative feedback or self-balancing loop	
	Stocks : Define the state of a system and represent stored quantities, also called 'Levels'	
	Flows : Define the rate of change in system states and control quantities flowing into and out of stocks	

Influence Factors in Models and their Relations

Evidence of a relationship between factors within the real estate market is shown in Table 2. The dynamics models used in this research are based on fundamental economic theories and expert views of market states.

Table 2. Influence Factors in Models and Correlations

Factor A	Factor B	+/-	Sources
credit rating for lending	mortgage loan borrowers ratio	+	Fischer 2005
default probability	borrowers' repayment	+	Fischer 2005
demand	perceived price change	+	Baumol & Blinder 2003
demand response to expected profit	potential demand	+	DiPasquale & Wheaton 2004
expected profit from trading	potential demand	+	Fischer 2005
expected profit of primary agencies	credit rating for lending	-	The Bank of Korea, Lander 2008
expected profit of primary agencies	mortgage loan ratio	+	Lander 2008
Fund of primary agencies	mortgage loan	+	Saunders & Cornett 2005
House Price	default probability	-	The Bank of Korea
House price	demand	-	Baumol & Blinder 2003

House price	expected profit from trading	-	Kim & Kim 1999
Perceived house price	expected profit from trading	+	Kim & Kim 1999
price elasticity of demand	potential demand	+	E. Jung 2005

Policy Models

Price Model

In the housing market, house prices are determined through the acknowledged market principle of supply and demand. However, this study assumes that housing demand generally plays the leading role; supply has been static, with the exception of new town developments which have had only a temporary ripple effect on the market. Since the policy models used are constructed to analyze the policies' effect on areas of over-demand, such as capital regions, the authors ignore supply in this study. Housing price models thus focus on the relationship between house prices and demand in the following manner.

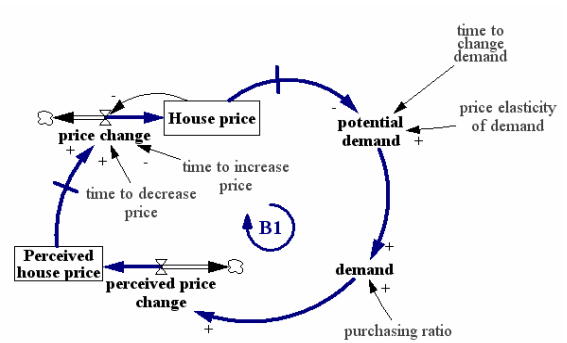

Figure 1. Demand and Price Self-control

Figure 1 shows how house price self-control through demand changes in accord with general market principles. In this model, *perceived house price*—which is defined as the consumer's perception of the possibility of price volatility before the house price is determined—is influenced by *demand* change. When *perceived house price* is transformed into *house price* as a result of housing transactions, housing *demand* is controlled as a balancing feedback process of demand and price in Loop B1.

However, in the housing market, a reinforcing feedback relation of expected demand, price, and profit contrary to general market principles is in play. As illustrated in Figure 2, the *expected profit from trading* is an essential factor in this relationship. The *expected profit from trading* is defined as the householder's expectation that a profit will be produced through a future trade in houses. Further, the *expected profit from*

trading is affected by time variables between the perceived house price and the actual house price.

In the housing market, when housing *demand* is high, consumers expect future house prices to increase (i.e., perceived house price increases). This reinforcing loop shows that *house price* and housing *demand* are caused by mutual rising tendencies.

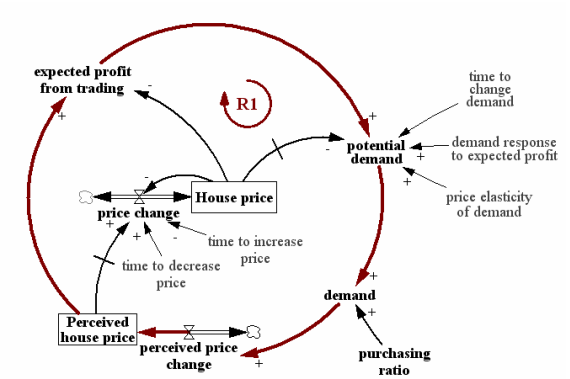

Figure 2. Consumers' Expectancy of Marginal Profits.

Figure 3 shows the result of the price model simulation of consumer marginal profit expectation. House prices are simulated in accord with changing demand and in response to expected profit. The *demand response to expected profit* is defined as a coefficient of demand variation by expected profit change, which has a unit of Won per person. When consumers do not expect a profit, house prices will be stationary and the *demand response to expected profit* will be zero. When consumers do expect a marginal profit, house prices will either fluctuate widely or tend toward a long term upward swing. Previous research, which examined the Boston real estate market from 1961 to 1992 (DiPasquale and Wheaton 2004), revealed a *demand response to expected profit* of 0.00038 [$/Person]. However, this coefficient cannot be applied to the current Korean housing market. Instead, this study assumes a *demand response to expected profit* of 0.000012 (Won/Person), obtained through an analysis of house price tendency in relation to the changing effect of consumer expectations. Applying this value results in a house price tendency in accord with current Korean house prices.

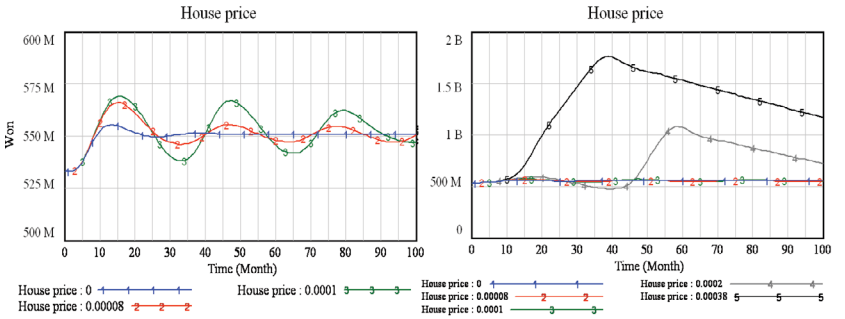

Figure 3. Simulation: House Price Tendencies by Consumers' Expected Marginal Profit

Mortgage Market model

This study describes the general real estate financial market structure, with a focus on mortgage lending, using System Dynamics (SD) modeling (illustrated in Figure 4). The *fund of primary agencies* refers to the cash liquidity of primary mortgage agencies; *mortgage loaned money* refers to the cash liquidity that has been lent to mortgage borrowers and has not yet been repaid. The financial market lends to the borrower at the *mortgage rate*. The more financial agencies lend, the higher their profits; primary agencies expect to maximize their earnings and thus either increase the amount of loans or lower the credit rating (*expected profit of primary agencies* → *mortgage loan ratio; credit rating for lending*). Financial agencies therefore continue to lend *mortgage loans* until their fund liquidity disappears (Loop B2). However, if financial agencies issue *mortgage bonds* to ensure fund liquidity and investors buy these bonds, they will lend *mortgage loans* and issue *mortgage bonds* much more frequently.

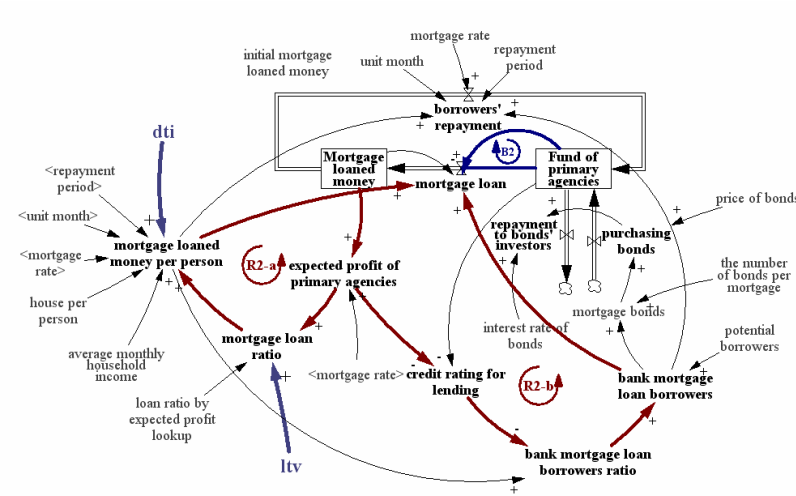

Figure 4. Mortgage Lending in Real Estate Financial Market

Based on the these causal loop diagrams, this study has attempted to construct a simulation model using correlations between influence factors as shown in Table 2 and national data, as shown in Table 3.

Table 3. Data in Simulation Models

Independent Factors	Sources	Value	Unit
initial house price	The bank of Korea 2008, KB Bank 2008	533,000,000	Won
initial demand	http://www.cisr.co.kr/	76,000	Person
price elasticity of demand	Korean Housing Institute	-0.37	dmnl
purchasing ratio using loan	KB Bank 2008	65.4%	%
loan ratio of primary agencies	The bank of Korea 2008	28.76%	%
base rate	The bank of Korea 2008	4.93%	%
mortgage rate	The bank of Korea 2008	6.92%	%

In these models, the ratio of mortgage loan to mortgage worth (*mortgage loan ratio*) of primary agencies is decided as the minimum value between the maximum LTV ratio permitted by government policy and the loan ratio of lending agencies. Also, the mortgage loan amount (*mortgage loaned money per person*) is decided as the minimum value obtained between the maximum DTI ratio permitted by government policy and monthly repayments calculated by lending agencies.

Policy Analysis

This study simulates future house price tendencies and demand effects by changing LTV and DTI ratios. Figure 5 shows the changes in house price and demand when diverse LTV and DTI values are applied, following the assumption that 50% of potential borrowers will transfer their mortgage loans from banks to secondary agencies. Simulation results reveal that the regulation of LTV and DTI ratios will stabilize both house prices and demand in the short term. Further, the more that government lowers DTI and LTV ratios, the greater the tendencies for house prices and demand either to stabilize or fall in the long term.

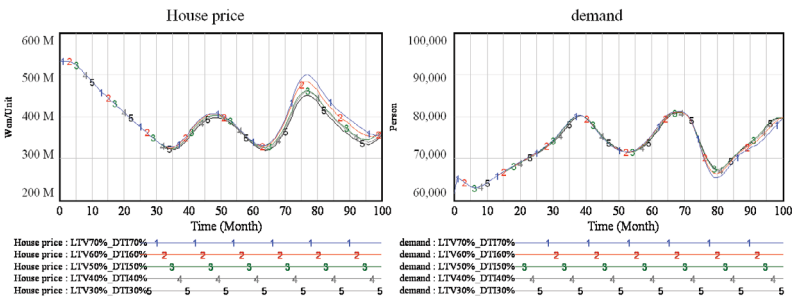

Figure 5. House Price and Demand Changes by LTV, DTI Regulations

On the other hand, the regulation of LTV and DTI ratios can result in the transfer of potential borrowers from primary banks to secondary agencies, such as mutual saving banks or credit unions, which have lower fund liquidity. When potential borrowers choose secondary mortgage loans in response to regulations, house prices will be unaffected (as shown in Figure 6). Assuming that 75% of borrowers shift to the secondary market, a short term fall in house prices can be expected. However, if 90% of borrowers move to the secondary market, house prices will remain consistent with prices in an unregulated market. That is, if potential mortgage borrowers transfer to the secondary market after the implementation of mortgage lending regulation, the effectiveness of government policies on house prices could be offset by an increase in demand caused by an increase in secondary mortgage loans.

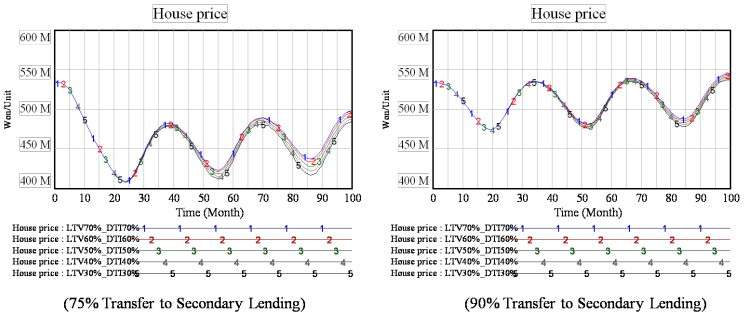

Figure 6. House Price Changes by Transfer Rates to Secondary Lending Agencies

Conclusions

Utilizing system dynamics simulations, this study attempted to analyze the Korean government's regulation policies regarding LTV and DTI ratios. In these policy models, house price and demand are placed in balancing loops, such as demand controlling loops. Further, a reinforcing loop that incorporates the expectation of future marginal profit is shown to have a great effect on house prices by increasing price volatility and upward tendencies. The regulation of excessive demand through mortgage lending policies can help to control these upward tendencies on a pertinent level. However, the same regulations may cause potential mortgage borrowers to shift to the secondary market and thus offset the intended effect of regulations on house prices. Consequently, secondary lending agencies need to be regulated equally with primary agencies to maximize the effectiveness of government policies.

Through considering various perspectives using system dynamics simulation, this research can provide decision-makers with more evidence to support both their policy regulation and deregulation.

Future research needs to expand simulation models to include the behavior of primary agencies. Also, the financial behavior of a construction company related to housing supply should be examined; this will more effectively examine the impact of mortgage lending policies.

Abstract

The research presented in this paper focuses on understanding areas in which BIM is being utilized in general contracting companies and what these companies have as lessons learned from utilizing BIM. The authors conducted extended interviews with professionals (such as BIM managers, project managers, planners) from two different general contracting companies over various projects. The discussions were held such that each participant provided his/her experience over a project, where BIM was used for at least one phase of a construction project. The results of the discussions and interviews provided a wide range of case studies (in overall eight cases) on BIM utilization and lessons learned by project members related to BIM usage on these case projects. This paper provides an overview of each case project, introduces the phases of projects where BIM was helpful, and provides findings on lessons learned by project members with BIM usage. Practically, the lessons learned from these contracting companies can be helpful for construction professionals to improve their practices of BIM usage.

Keywords: case studies, building information models, construction scheduling, estimating and coordination

1. Introduction

Generation and sharing of construction project information based on building information modeling (BIM) have been a widely accepted practice within the architectural, engineering, construction and facilities management domain (AEC/FM). Companies operating within the AEC/FM industry have been

benefiting from using BIM in order to improve the efficiency of information sharing among various actors of construction projects. Among these companies, general contracting companies utilize BIM for streamlining efficiency in construction management tasks, such as estimating, scheduling and coordination. Still in the AEC/FM industry, the impact of utilizing BIM on the construction companies' projects performance and business processes is not understood in details. In order to measure the impact and benefits of utilization of BIM in construction management tasks, there is a need to understand how BIM is currently utilized in different companies. Before measuring the impact of BIM usage, the phases of construction projects in which BIM is incorporated and the business process changes due to BIM usage need to be understood.

The authors focused on the need stated above and started to conduct a research with the participation of general contracting companies in USA to understand first the changes in the business processes related to construction management tasks in the AEC/FM industry with BIM usage. In this paper, the authors provide findings of this research that was conducted with an initial set of general contracting companies. Findings include changes observed in the business processes that are executed at different phases of a construction project with BIM usage, and lessons learned from the perspective of professionals working in these processes.

Various studies in literature mentioned the importance of measuring tangible benefits of BIM in construction projects (e.g., Boryslawski 2006, Leicht and Messner 2007, Heller and Bebee 2007, Smilow 2007, Hartmann et al. 2008). These efforts not only led by research institutions but also by industry participants, such as BIM tool providers (e.g., Solibri 2005, Graphisoft 2004). Among these studies, some even measured the benefits of BIM corresponding to a phase of a project and for a given task (such as during cost estimating, planning and coordination). For example, Alder (2006) identified that with BIM, cost estimating can be 44% faster as compared to traditional quantity take offs. CIFE (2007) showed also that cost estimating accuracy improves 3% and estimating can be even faster (80%) as compared to traditional methods. Savings project plans are measured to be around 19% (Matta and Kam 2005). During coordination of subcontractors work, around 25% faster and 20-30% cost savings are measured (Khanzode et al. 2008). Software providers mainly looked at BIM benefits in terms of savings from BIM usage from total project costs. However, these studies are limited in number, focus only to a specific construction management task (i.e., cost estimating, coordination, planning). In addition, measured benefits change in wide ranges (e.g., estimating 40 % to 80% faster), and business process changes are not detailed. In the research presented in this paper, the aim is to understand the changes in the business processes that would lead to such variations in benefits and help general contracting companies to understand these processes for executing various construction management tasks.

2. Research method

In order to understand changes in processes related to construction management tasks and lessons learned from these changes, the authors conducted extended face to face interviews with professionals (such as BIM managers, project managers, designers, estimators and schedulers) so far from two different general contracting companies. The discussions were held such that each participant provided his/her

experience over the projects, where BIM was used for at least one phase of a construction project.

During the face to face interviews, a questionnaire, designed by the authors, was used to guide the interviews. This questionnaire incorporated five sections, incorporating demographics, too. Each section was specific to a group of participants and incorporated questions specific to that group. The groups included subcontractors, software vendors, owners, and general contractors. Questions directed to each group were mainly related to BIM usage on specific past projects completed/handled by the participating companies. In addition, for each project that was provided as an example by the participant, the authors asked about further questions to learn the project characteristics and the benefits of using BIM as compared to using traditional business processes.

3. An overview of the participants of the research study

So far, the authors had access to seven participants from two general contracting companies and six subcontractors, each from a different discipline (plumbing, fire protection, mechanical, piping, electrical, sheet metal). An overview of these participants is provided in Table 1. Table 1 introduces the number of participants from each company, participants' role in the company, and their experience in the construction industry in years. Average experience of participants in the AEC/FM industry was around fourteen years, where the minimum experience level was five years and the maximum experience level was twenty-five years. Company I was a general contracting company that operated locally in Pennsylvania and was experienced in commercial projects. The other participating company (Company II) was a global contractor and was experienced in housing and commercial projects.

Table 1. Participants of the research study.

	Company I		Company II	
Role	Number of participants	Years of experience	Number of participants	Years of experience
Project manager	1	25	1	20
BIM manager	1	17	2	6-7
Project planner	0	NA	2	5-14
Subcontractors	0	NA	6	10-25

4. Utilization of building information modeling (BIM) over case projects and lessons learned

Based on the detailed interviews with the participants, the authors combined the results and summarized them in this section. The results are overviewed in Table 2, which shows business process changes with BIM use and lessons learned from the cases. Participants provided eight case projects where BIM was used for construction management tasks. These case projects included a variety of facility constructions, such as a museum, hospital renovations and expansions,

construction of a resort, office towers, government buildings and research centers with costs ranging between $ 95 and $ 500 million.

Table 2. An overview of the case projects where BIM was utilized during and before the construction phase.

Project characteristics	**Construction management task that BIM was used**	**Traditional business process**	**Lesson learned**
Case Project 1 *Type:* Museum *Cost:* $ 450 million *Completion:* 2008	Coordination of MEP*, plumbing, fire protection subs	2D shop drawings over light tables	• Reduction in the number of iterations per floor • Clear visualization of clashes
Case Project 2 *Type:* Hospital *Cost:* $ 320 million *Completion:* 2011	Scheduling and phasing of construction works	2D documents and hand sketches	• Expedition in planning • Reduction in construction time • Trust of owner to the reliability of plans
Case Project 3 *Type:* Hospital renovation *Cost:* $ 150 million *Completion:* 2009	Constructability analysis and design check Vision to use for cost estimating	2D drawings On screen quantity take off	• Reduction in cost & rework during construction • Accurate and faster cost estimates
Case Project 4 *Type:* Office tower construction *Cost:* $ 500 million *Completion:* 2006	Phasing of demolition work	2D documents and hand sketches	• Reduction in planning time • Trust of owner to the reliability of plans • Less waiting/idle time between trades
Case Project 5 *Type:* Hospital renovation *Cost:* $ 222 million *Completion:* 2009	Scheduling and phasing of construction works	2D documents and hand sketches	• Expedition in planning • Reduction in construction time • Trust of owner to the reliability of plans
Case Project 6 *Type:* Resort construction *Cost:* $ 135 million *Completion:* 2011	Scheduling and phasing of construction works	2D documents and hand sketches	• Expedition in planning • Reduction in construction time • Trust of owner to the reliability of plans
Case Project 7 *Type:* Research center for health services *Cost:* $ 400 million *Completion:* 2008	Coordination of MEP*, plumbing, fire protection subs	2D shop drawings over light tables	• Reduction in number of iterations per floor • Clear visualization of clashes
Case Project 8 *Type:* Government building *Cost:* $ 95 million *Completion:* 2008	Coordination of MEP*, plumbing, fire protection subs	2D shop drawings over light tables	• Reduction in number of iterations per floor • Clear visualization of clashes

*MEP: mechanical, electrical and piping. The new business process in each of the projects incorporated BIM and/or 4D.

As detailed in Table 2, in the case projects BIM was mainly used during the construction phase for (a) the coordination of works to be executed by the subcontractors, (b) the phasing/scheduling of construction works (c) the constructability analyses and design checks before construction. Construction companies had also a vision of using BIM for cost estimating before construction, and for tracking and maintaining operation and maintenance items during facilities management phase of construction projects. As the last two uses were vision at the time the research was conducted, these uses are not detailed in this paper.

The following subsections provide details of each case project, the construction management task that BIM was used, a summary of the traditional business process, and potential benefits obtained by the companies with BIM use in these construction management tasks.

4.1 Using BIM for coordination of work and lessons learned from museum, research center and government building projects

Project 1 was a museum project that was composed of 250, 000 square-foot, twelve residence floors and 14 exhibition spaces. It was mainly a steel structure worth of around 450 million USD, and was completed in 2008. Projects 7 and 8 were a research center and a government building, having costs of 400 and 95 million USD. In these projects, the company that participated in this research study was the general contractor.

BIM was mainly used in coordination of mechanical, electrical, plumbing (MEP) works in these projects for extended periods. For example, in Project 1 BIM was used during construction between February 2006 and December 2006 for 10 months for every week. The traditional process included 2D drawings and light tables to coordinate spaces and installation of components for MEP and iterate this process many times to eliminate clashes. In this traditional process, there were around 10-12 iterations to coordinate the works in one floor.

In the new process, with utilization of BIM, the parties develop detailed models for the components that they were responsible to install from 2D shop drawings approved by the architects and engineers. The entire work is divided into coordination zones and for each zone, the responsible subcontractor adds its components to the base model provided by the general contractor. While modeling of the components to be installed, each subcontractor models both hard and soft/access dimensions for better coordination. Hard dimensions are those that are required by manufacturer or codes (e.g., handicap clearances, door widths, wall heights). Soft (access) dimensions are those required to access a piece of equipment or install a piece of equipment. For example, there may be 92 cm clear space between the ceiling and deck above and there may be a lateral access required to service an equipment of height 61 cm. If the access door or equipment is located at 46 cm, then there is a potential issue, and soft dimensions are modeled to see these potential problems beforehand. While modeling hard dimensions, subcontractors can put a simple solid that represents a group of objects (e.g., a wall with a thickness that incorporates metal studs and insulation layers), or can put multiple layers of objects composed of different object types (e.g., a wall, an insulation layer and a metal stud layer objects). While modeling soft dimensions, subcontractor can put a separate element to show the required

access space or embed the dimensions of the required space within the main element (i.e., increase the size of the main elements by the required space dimensions).

After the models are ready, these models are then submitted to the general contractor before coordination meetings. The person, who is responsible for detecting clashes on BIM, overlays these models on each other using specific tools for identifying clashes on the zone that will be discussed in an upcoming coordination meeting. These clashes are analyzed and if they are really clashes they are listed to be discussed in the coordination meeting. During the meeting, each clash is shown in BIM to the clashing parties (i.e., the parties who are responsible for the installation of clashed components) using smart boards and a solution is generated. If the project has a work station at that job site, BIM is updated to reflect the final solution by the general contractor on the fly; if not, the responsible party updates the model and uploads to the server to be used by the other parties.

With BIM based coordination, the number of iterations for coordination is generally reduced and the coordination is faster. Specifically, it was down to 5-6 iterations per floor in the museum project (Project 1). In addition to having faster coordination of work, users have cost savings and reduced rework at the job site. For instance, in Project 1 with BIM usage, users discovered that there were major conflicts with the duct work, some structural members and the electric works. The slabs were at fixed elevations and the duct work was a tight work with no flexibility of change in the design. They realized the problem before the installation started at the job site, and changed the electrical works with a redesign, which was according to the fixed conditions of slabs and duct works.

Another example that was large in scale was related to ductwork. In 2D, the ductwork looked like a step wise duct both from top and bottom of the ducts. While developing the building information model, the ductwork subcontractor realized that the continuous duct did not have a step like shape from its bottom. If this problem was missed until the job started at the job site, there would be rework, liquidate damages to be paid to owner due to late completion, time of request for information resolving, and trade waiting times for the affected trades (such as lighting, ceiling work).

In addition, the participants stated that they identified more clashes as compared to 2D drawings, which eliminates false positives (i.e., not identifying a real clash). As shown in these projects, general contractors benefited from BIM use during coordination of works with reduced surprises at the site.

4.2 Using BIM in scheduling and phasing and lessons learned from new hospital, hospital renovation and resort construction projects

Project 2 was a hospital project with a total of around 700, 000 square-foot facility including eight story inpatient pavilion, and a five-story support services building. The project was worth 320 million USD, and would be completed in 2011. Projects 5 and 6 were 222 million USD hospital renovation and 135 million USD resort construction projects. In these projects, the company that participated in this research study was the construction management company.

BIM was mainly used in planning, scheduling and phasing of construction works. The traditional process included 2D documents to sequence work and

simulate coordination of equipment and cranes used in construction operations. The problem in the traditional processes was that the project planners had difficulty in visualizing overlapping activities and operations at the job site.

The new business process for the construction phasing and scheduling processes included developing construction phases, generation of zones and sequencing of activities based on the BIM of the project. In these three projects, BIM was developed before the construction management company started using BIM in phasing. For example, in Project 2 BIM was first developed by the steel manufacturer including steel frames, detailed by the gypsum board manufacturer for the interior walls and augmented by the construction management company with exterior enclosure and construction equipment and cranes.

With BIM, it was easier to visualize the project execution over time and see possible time and space conflicts between the operations. For example, in Project 2, construction management company gained 2 months of time in construction period with the utilization of BIM during scheduling and phasing of construction works. In addition to these, the construction management company had reduction of cost in 'general conditions' due to less staff being employed.

4.3 Using BIM in constructability analyses and lessons learned from a hospital renovation and expansion project

Project 3 was a hospital renovation and expansion project including a new seven story acute care tower and new patient care space. It also included demolition of some of the existing buildings and renovation of some others. The project was worth 150 million USD and would be completed in 2009. In this project, the company that participated in this research was the general contractor.

At the time the professionals from the general contractor company participated in this research, Project 3 was just awarded to the general contractor and BIM was at that time being used for constructability analysis and keep track of design coordination and design changes as a requirement of the owner. The objective in the future phases of the project was to use BIM for clash detection and phasing of construction works. The traditional process of constructability analysis and design checks included the utilization of 2D drawings and documents and having meetings using the information changed on these drawings and documents. The problem in the traditional process was that the task was error prone in terms of identification of problems/errors before construction, or design conflicts before it was too late at the job site.

In this project, a BIM tool was used by the general contracting company and by the architect to develop BIM of the facilities that will be newly constructed and renovated. The purpose was to identify design problems and conflicts while developing the building information model and to fix them before the construction process began. General contractor was expecting to select construction methods while BIM was being developed and identify constructability problems with the given design, contact to the owner and the architect if problems were observed. For the renovation parts, the 3D model would be generated using a laser scanner and then would be mapped to the final (i.e., required) to-be version of the project BIM and clashes would be identified before installation of new components started. Related to constructability analysis, the general contractor expected to have 1200- 5000$/day of gained revenue from BIM use in this process. Due to

unexpected problems, lost revenues could be expected up to 10, 000 $/day depending on the problem.

In addition to constructability analysis and design consistency check, the general contractor wanted to use this project as a pilot project to start benefiting from model based estimating process. Their vision was to obtain quantities from the building information model of project automatically to reduce human errors experienced during traditional methods of estimating (currently, on screen take off was utilized in the company). With the model based estimating, they expect to obtain faster and more accurate cost estimates.

4.4 Using BIM in managing demolition work and lessons learned from an office tower construction project

Project 4 was a 42 story steel tower construction project to be used as office space with around 860, 000 square foot of construction over functioning railroad tracks. The project was worth 500 million USD and completed in 2006. The participants of the research study were from the construction management company of this project.

BIM was mainly used in planning and phasing of construction works. The traditional process included 2D documents to sequence work and simulate coordination of construction operations. The problem in the traditional processes was that the project planners had difficulty in visualizing and sequencing operations at the job site. For this particular project, phasing of the project also included moving and demolition of existing railroad tracks and moving the tracks to another location. So, in addition to construction phasing, the construction management company had to incorporate demolition of old subs and stations and building of new subs and stations, putting sheet metal protective shielding around the existing retaining wall, taking down that retaining wall and building structural steel. With 2D documents and sketches, it would be hard to track the sequence of demolition and reconstruction tasks.

The new business process for construction phasing and scheduling included generation of zones and sequencing of activities based on the BIM and visualizing the construction simulation over its 4D model. The steel structure members were modeled by the architect and provided to the construction management company. Then, the schedulers added additional components of wires for trains, existing tracks and stations, retaining wall and protective sheet metal shielding, scaffolding for the retaining wall, a platform for steel structure and new tracks and stations to the model. They created a 4D model by working with the schedulers. For example, demolition of the retaining wall was originally 50 days and in the 4D simulation they visualized it at 5 steps.

Via utilizing BIM and 4D model, the construction management company could sequence the work with realistic durations and sequences, and could convey that information to owner and subcontractors in an effective and visual way. The 4D simulation helped them to create zones and sequence demolition of existing structures and moving of tracks to their final location without a problem. It resulted in time savings and gain of owner's trust to the work-plan generated by the construction management company. With the 4D simulation, faster construction was observed with also 15-20 percent cost savings from BIM.

5. Conclusions

This paper detailed a set of initial findings related to an ongoing research. Initial findings revealed that general contractors in USA have benefited from BIM usage with their own lessons learned. Lessons learned from BIM usage in these companies can be grouped in three categories, as (a) lessons learned from BIM use before construction starts, (b) lessons learned from BIM use during construction, and (c) lessons learned from BIM use after construction phases.

Before a construction project starts, the companies mainly used BIM as an effective and visual communication tool between the owner and subcontractors. In addition, during preconstruction, general contractors used BIM mainly for constructability analysis and design consistency check to eliminate unexpected problems and reworks during construction phase. With less reworks, they had reductions in total project costs, from 1200- 5000$/day from BIM use in this process.

During construction, BIM was mainly used in the companies that participated in this study for coordination of subcontractors' works (e.g., plumbing, fire protection, MEP) and eliminate clashes of components way before installation of those components starts. With BIM implementation in coordination phase, companies had reduction in number of iterations per floor. For instance, the number of iterations was reduced to 5-6 iterations per floor in a particular project from 10-12 iterations per floor. They also identified clashes that could be missed in traditional way of coordination (i.e., 2D shop drawings overlaid on light tables). In addition, during construction, companies used BIM for construction phasing and planning with faster planning phases, and reduced construction times (e.g., around 2 months of time gain in a particular project).

After a construction project is complete, the general contracting companies have a vision to use BIM for facilities management. Among various tasks to be performed after a construction is complete, companies would like to use it for punch-list administration, keeping up to date manufacturing and installation information about maintenance items, which are needed during repair and replacements.

To summarize, general contractors benefited from BIM use and would like to benefit from BIM use by developing visions to deploy BIM use over various construction project phases. With more deployment of BIM use in traditional way of executing construction management tasks, challenges such as defining levels of details in BIM, privacy rights and defining responsible parties in developing a building information model of projects are expected to be resolved in a shorter time.

Abstract

The management of equipment allocation for earthmoving operations is a complex dynamic series of discrete events. This paper presents a common and flexible Petri net model for the optimization of equipment allocation for a given construction period, cost and labor. A case study was conducted on a real construction project involving earthmoving operations. The data required by the research was collected on-site. A Petri net model was used to represent the dynamic constraint relationships among various types of equipment and their assigned tasks. The model describes the process workflow and equipment utilization for an earthmoving operation. The model was tested and sensitivity analysis carried out. Based on simulation results, and the given conditions, a minimum cost solution to the equipment allocation problem is obtained. This paper provides both practitioners and decision makers with a real study, a simulation model, and a useful approach to the equipment allocation problem in construction.

Keywords: earthmoving operations; simulation; equipment allocation; multi-objectives optimization; Petri net

Introduction

Earth moving operations can be represented as Discrete Events Systems. It refers to all the operations involving the cut, loading, haulage, unloading, grading, humidifying and compaction of materials in a civil engineering building, aiming to adequately shape the natural field to the specifications of the project (Prata 2008). The management for equipment scheduling is a dynamic discrete event which is affected by a large number of uncertainties and random factors.

The main goals of simulation-optimization for earthmoving operations are to improve productivity, equipment efficiency and construction safety. According to the specific construction project, the suitable equipment is selected to maximize productivity and consequently maximize profit of contractors, and projects are completed with the

least cost and within the given targeted project duration (Reda, 1990). In an earth moving process, contractors tend to use the equipment available instead of allocating the ideal number of machines. In these situations, given the available equipment, equipment characteristics and parameters, main factors and cost information, a simulation model can predict the construction situation of earthwork operation, estimated time of completion and cost to provide a reliable basis for earthmoving organization and management.

Considerable work has been carried out to develop models for planning earthmoving operations so as to achieve the previous stated goals. Halpin and Woodhead (1976) used queuing theory. Halpin and Riggs (1992) evaluated different fleet scenarios by MicroCYCLONE. Marzouk and Moselhi (2000, 2004) optimized the earth moving operations using an object-oriented simulation approach and Genetic Algorithm (GA). Hegazy and Kassab (2003), Cheng and Feng (2003) and Cheng et al. (2005) proposed simulation–optimization by combining GA with CYCLONE or other simulation techniques. Bargstädt and Blickling (2005) proposed an IT system which realizes earth moving teams, permitting the user to establish scenarios in real time. The system has a graphical user interface which provides for visualization of the established scenarios. Moselhi and Alshibani (2007) presented a robust system for planning, tracking and control of earth moving operations combining a module of spatial technologies. Zhang (2008) presented a particle swarm optimization algorithm to search for the potential equipment-configurations. Prata et al. (2005, 2007) suggested the Petri nets as a method for loader and truck teams dimensioning via simulation. Prata et al. (2008) proposed a model using Stochastic Colored Petri Nets to represent the operational dynamics of earth moving work.

Most of these simulation optimization algorithms focused on optimization of simulation results rather than dynamic processes of earthmoving work. Prata et al. (2008) considered the operational dynamics of earthmoving work for taking local operations as objects of simulation-optimization, including loading earth and truck hauling in order to determine the quantity of haulage units to be used conjointly with a loader. But the proposed Petri net model could not simulate the whole operation process. Moreover, the model did not respond to the dynamic random events during the construction.

In the field of scheduling research, one of the important problems is to show the scheduling process dynamically and visually. Color Petri net combines the advantages of Petri net and high level programming languages. The concurrency of Petri net makes it suitable to describe the system characteristics of concurrency, resource competition and synchronism. Compared to other modeling methodologies, Petri net is based on strict mathematical theory. It supports the designer to validate the rationality of the system from the view of formalization and graphically simulate the distributed system (Liu 2007). Modeling earthmoving operations with Petri net can not only express the static characteristics of the earthmoving operations but simulate the dynamic behavior in the construction process. The information collected is used for both qualitative and quantitative analysis of earthmoving processes.

In this study a general extensible Petri net for optimizing earthmoving equipment configurations is proposed by integrating colored Petri net and ML high level

programming language, which is capable of expressing dynamic constraint relationships among various equipment. The Petri net model considers multiple criteria and the preference of decision-makers. The reasonable plans for different optimization goals can be generated on the analysis of the model.

Colored Timed Petri nets

The Petri Nets theory was born from the thesis defended by Carl Adam Petri in the Faculty of Mathematics and Physics of the Technical University of Darmstadt (Germany) in 1962, entitled "Communication with autonomata". Petri net has the characteristics of strict mathematical foundations and understandable graphical representation. At the end of the 60s and beginning of the 70s, researchers from MIT in the USA developed the foundations of the concept of the Petri nets.

An ordinary Petri net is a 4-tuple *PN = (P, T , Pre post)*, formed by a finite set of places *P* of dimension *n*, a finite set of transitions *T* of dimension *m*, an input condition *Pre: P x T → N,* and an output condition *Post: P x T → N*. To each place an integer non-negative number denominated token is associated.

According to Jensen (1992), a more compact representation of a Petri net is obtained via the association of a data set (denominated token colors) to each token. A colored Petri net is a 9-tuple: $CPN = (\Gamma, P, T, A, N, C, G, E, I)$. The concept of color is analogous to the concept of type, common among the programming languages. In the colored Petri nets, the quantity of places, transitions and arcs is, generally, sensibly reduced via the addition of data to the structure of the net.

CPN Model of Earthmoving Operation

CPN Model

The simulation model of an earthmoving operation based on Petri net is defined on the basis of a colored timed Petri net. The correctness of structure and operation for the model can be validated by liveness and safety of a Petri net. The formulism for the modes is expressed as follows:

Definition 1 CPN Simulation model of an earthmoving operation

CPN Simulation model of an earthmoving operation (CPNSMEO) is a 9-tuple:

$$CPNSMEO = (R, P, T, F, M_0, C, G, I, S) \quad (1)$$

Where:

(1) R is a finite, non empty multi-set of types, denominated colors set, see definition 2;

(2) P is a finite set of places of dimension n;

(3) T is a finite set of transitions of dimension m;

(4) F is a finite set of arcs so that $P \cap T = P \cap F = T \cap F = \varnothing$;

(5) M_0 is an initiation status marking.

(6) C is a color function, defined from P on R;

(7) G is a guard function,

$\forall t \in T : [Type(G(t)) = Boolean \wedge Type(Var(G(t))) \subseteq R]$, defined from T;

(8) I is an initiation function, $\forall p \in P : [Type(I(p)) = C(p(a))_{MS}]$, defined from P.

(9) $S(S \in [0, 1])$ is the firing possibility of transition T when it conflicts with other transitions. S=1 when there is no conflict.

Definition 2 Token color multi-set

R is a multi-set based on an object oriented, denominated colors set. $R = \{ID, OR, B, i, e, A\}$,

Where:
ID is the only identification of token in the system
OR is the activity type of token. The value is *ON* or *OFF* decided by a predecessor activity for expressing the synchronousness or asynchronousness of the activity;
B is the Boolean value of tokens, $B \in BOOL$;
i is the number of an iteration;
e is the Timestamp;
A is the subset of the resource characteristics.

Definition 3 Status Marking

M is the status marking. M_0 is the initial marking. In the case of natural numbers ($i \in N$), $M_i(p)$ is the number of colored token of place p. Transition t is binded and enabled if and only if
(1) $G(t) < b > = \text{True}$;
(2) $E(p, t) < b > : M_i(p) \mid \forall p \in \bullet t$;
(3) The timestamp of any binding token exceeds the time limit

If transition t fires, the marking is changed from M_i to M_{i+1} in a legitimate firing time. The firing result is as follows:

$$M_{i+1}(p) = M_i(p) - E(p, t) < b > + E(t, p) < b >, \forall p \in P \quad (2)$$

$$M_{i+1}(p) = (M_i(p) - E(p, t)\langle b \rangle + E(t, p)\langle b \rangle, \forall p \in P \quad (3)$$

CPNSMEO is different from the general colored Petri net. The token colors in CPNSMEO are determined by execution environment and influenced by other token colors.

Model Analysis

Application Example

The example, Zijin City high-rise residential project located in Harbin of China, is chosen as the subject of this research. The total building area is 320000m^2. The project involves excavating construction foundation with 300m long, 200m width and 6m deep, and moving 360,000m^3 (bank volume) of moraine (loose density = 1.2t/m^3, loose density = 1.53t/m^3) from construction site to an soil placement pit located at a distance of approximately 15km from the project site. The teams include excavator, dozer, loader and truck.

A maximum of eight excavation sites can be set on construction surface within the construction site. Each excavation site can include a maximum of two excavators working simultaneously. Loading area contain up to five loading sites. Each site permits a maximum of two loaders to load one truck at the same time. In the dumping

area, there is a maximum capacity of 3600m^3 for temporary earth storage. In addition, because the construction site is located in the city, the transportation is restricted to traffic situation. The traffic has a great impact on truck transportation between 6a.m. to 10p.m. The impact is relatively small during other times. Table 1 shows the detailed data.

The available equipment includes 14 excavators, six dozers, seven loaders and 35 trucks. The equipment is rented daily. Each type of equipment runs 24 hours with an eight-hour shift. The rental price (including driver cost and other cost) is shown in Table 2. The rental price for an excavator is 1,200RMB per 8 hours, for an excavator is 1,200RMB per 8 hours, for a dozer is 600RMB per 8 hours, for a loader is 800RMB per 8 hours and for a truck is 300RMB per day.

Table 1 Earthmoving operation time and parameters

	Excavators	**Dozers**	**Loaders**	**Trucks**
Type	WY160	T3-100	ZL20	EXQ153
Volume of soil	1.6m^3/time	100m/min	1.0 m^3/time	13 m^3
Triangle function of volume of soil	(1.5, 1.6, 1.7)	(1.7, 2.0, 2.2)	(0.9, 1.0, 1.1)	See Table 2
Triangle function of time (min)	Excavation (1.4, 1.6, 1.7) Load (0.6, 0.8, 1.0)	(0.9, 1.0, 1.2)	(0.5, 0.6, 0.7)	See Table 2

Table 2 Triangle function of truck operation time (min)

	Haul	**Dump**	**Return**
10 p.m.-6 a.m.	(13.0, 14.5, 15.0)	(1.1, 1.2, 1.4)	(10.5, 11.5, 12.0)
6 a.m. – 10 p.m.	(18.0, 20.5, 21)	(1.1, 1.2, 1.4)	(17.0, 18.0, 20.0)

Simulation Model of Earthmoving Operation

Based on the above theoretical foundations of the colored Petri nets, a simulation model CPNSMEO of earthmoving operation was constructed according to the practical characteristics of workflow (see Figure 1). Figure 2 shows the T5 sub layer of soil transportation. Figure 3 shows the T3_6 sub layer of soil load.

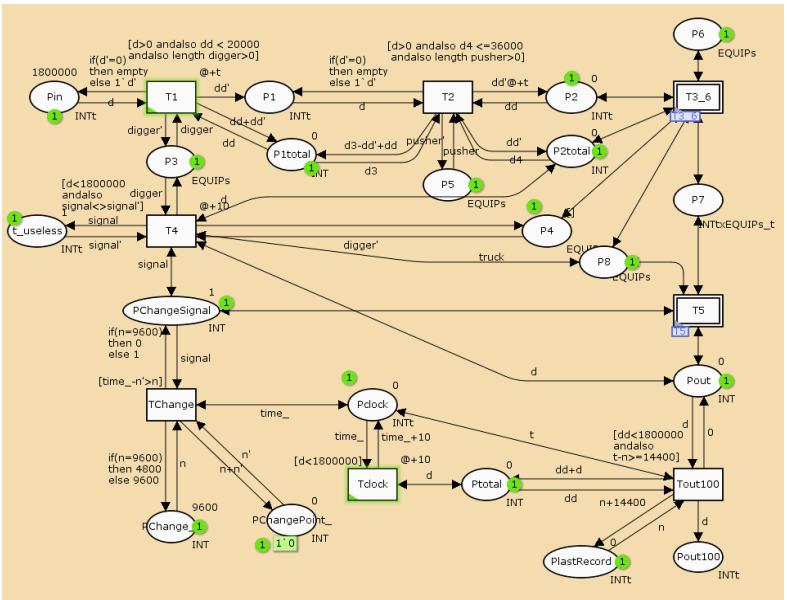

Figure 1 Colored timed Petri net model of earthmoving operation (top layer)

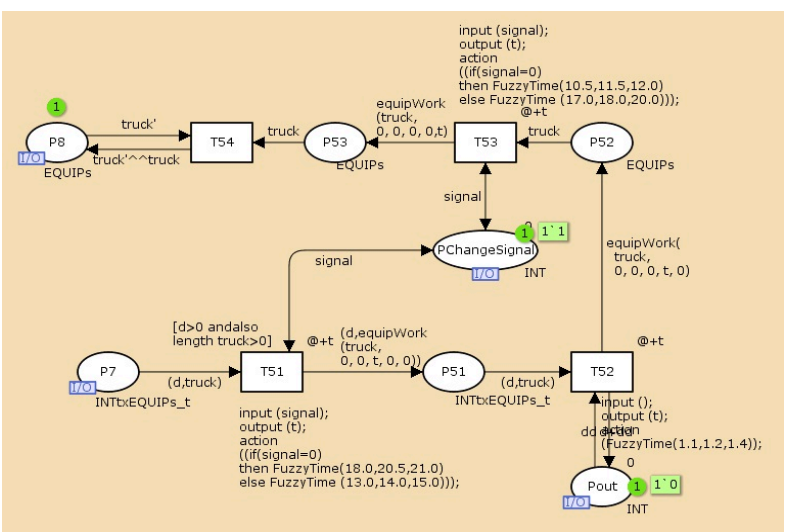

Figure 2 T5 sub layer of soil transportation of CPNSMEO

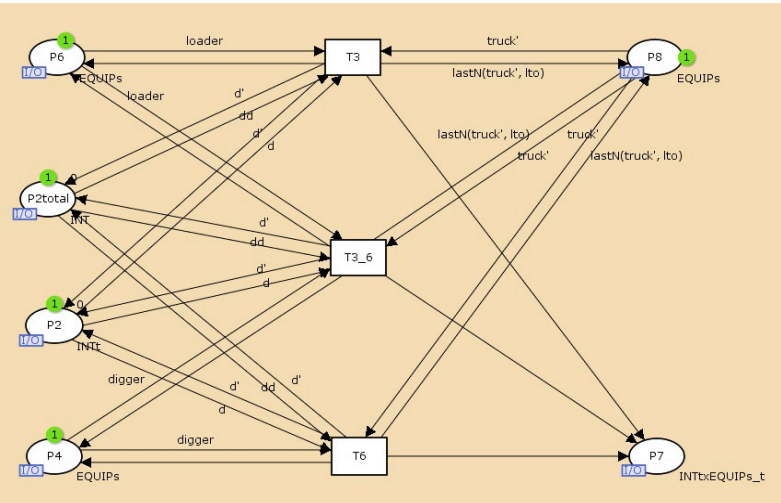

Figure 3 T3_6 sub layer of soil load of CPNSMEO

Table 3 introduces the captions of the places and the transitions of the proposed model. In this model, CPNSMEO uses *timed integer* variable to represent the volume of soil. *Timed integer list* variable is used to represent equipment. The equipment working hours are represented by triangle functions. The average value of 100 observations on site is used as parameters value.

Other transitions and places that cannot be noted in Table1 and 2 are auxiliary parts for model control and establishment.

Table 3 Definitions of the main transitions and places of the model

Transitions	Places
T1: soil excavation	Pin: soil to be excavated
T2: soil moving on construction site	P1: soil for temporary storage
T3: loader's loading	P2: soil to be loaded
T4: excavator's maneuver	P3: excavator ready to maneuver
T5: soil hauling by the truck (sub layer)	P4: excavator for loading
T3_6: excavator and loader's loading soil	P5: dozer ready to maneuver
T6: excavator's loading	P6: loader ready to maneuver
T51: truck's soil hauling	P7:truck with load ready for departure
T52: truck's unloading	P8: truck ready to load
T53: truck's return	P51: truck hauling
T54: truck's positioning	P52: truck returning
	P53: truck in loading site
	Pout: soil in dumping area

The soil in place Pin is excavated at transition T1 and stored temporarily in place P1.

The soil is moved at T2 to place P2 and ready for loading. The soil in place P2 is loaded to place P8 through the subnet T3_6 of soil loading. After the operation in transition subnet T5 of haul, the soil is moved to dumpling area. The empty truck returns. The transition structures like T4 realize the automatic allocation to the equipment on site: (1) Model can automatically regulate transportation capacity of trucks at different times; (2) If the soil volume in place P1 arrives at 2000m^3, which is the temporary storage upper limit, the excavator will stop work. If the soil volume in place P2 arrives at 3600m^3 which is the temporary storage lower limit, the excavator will stop work; (3) when the truck capacity enhances between 10p.m. and 6a.m. and the soil volume of temporary storage in place P2 is more than 3000 m^3, the model automatically transfers some of the excavators to loading area. When the truck capacity declines between 6a.m. and 10p.m., and the soil volume of temporary storage in place P1 is less than 3000 m^3, the model automatically transfers some of the excavators to excavation area. Therefore, the model can effectively reallocate the equipment according to the construction site situation.

Multi-objective Simulation Optimization

The model was implemented and simulated utilizing the software CPNTools, a public domain program developed by Aarhus University, dedicated to modeling, simulation and analysis of Colored Petri Nets. This software possesses an interface which allows easy handling by the user, facilitating the specification of scenarios. Table 4 shows the 28 equipment configuration plans which are the simulation results made by traditional equipment configuration management methods.

In this case, the cost of truck depends on the total volume of soil. Therefore, the number of truck does not affect the whole construction equipment rental costs. In order not to make too many trucks idle, the threshold value of truck number is needed for maximum volume of soil. Using the equipment configuration in scenario 28, the threshold value of truck number is 20 through model simulation only to adjust the number of trucks. More than 20 trucks will not be able to continue to improve the transportation capacity of soil. Meanwhile, less than 20 trucks will probably lead to deficiencies in soil transportation.

Table 4 Summary of the scenarios of earth moving

Scenario	Number of excavators	Number of dozers	Number of loaders	Number of trucks	Working time (d)	Scenario cost (RMB)
1	8	4	5	25	21	1165500
2	10	4	5	25	19	1191300
3	12	4	5	25	20	1398000
4	14	4	5	25	18	1387800
5	8	4	6	25	21	1215900
6	10	4	6	25	21	1367100
7	12	4	6	25	20	1446000
8	14	4	6	25	18	1431000
9	8	5	5	25	18	1031400
10	10	5	5	25	16	1032000
11	12	5	5	25	15	1075500

12	14	5	5	25	15	1183500
13	8	5	6	25	16	955200
14	10	5	6	25	16	1070400
15	12	5	6	25	16	1185600
16	14	5	6	25	16	1300800
17	8	5	7	25	17	1055700
18	10	5	7	25	17	1178100
19	12	5	7	25	16	1224000
20	14	5	7	25	16	1339200
21	8	6	6	25	15	922500
22	10	6	6	25	15	1030500
23	12	6	6	25	15	1138500
24	14	6	6	25	13	1080300
25	8	6	7	25	16	1022400
26	10	6	7	25	14	995400
27	12	6	7	25	14	1096200
28	14	6	7	25	13	1111500

The model has been tested in selecting equipment configuration to minimize project time, project cost, and project time and cost, as presented in Table 5 and Figure 4.

Table 5 Equipments for different optimization goals

Optimization	Excavator	Dozer	Loader	Truck	Time(d)	Cost(RMB)
	WY160	T3-100	ZL20	EXQ153		
Minimized Time	14	6	7	25	13	1111500
Minimized Cost	7	6	6	25	15	868500
Minimized Time & Cost	10	6	7	25	14	995400

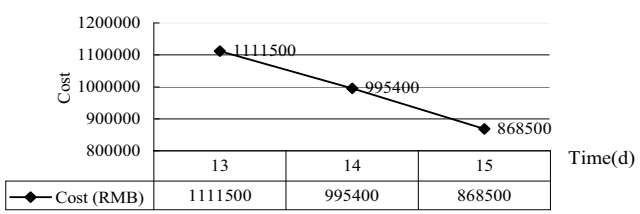

Figure 4 Optimization prototype for the application example

Conclusion

This study proposed a general and extensible Petri net for optimizing earthmoving equipment configurations. The developed model can express the dynamic constraint relationships among various equipment during the construction process. The model supports for: 1) dynamic and quantitative description of workflow and equipment resources in earthmoving operation, 2) visualization of dynamic management and optimization of equipment assignment, 3) an effective means for equipment configuration for planners and managers. The use and the capabilities of the developed model were analyzed through a construction project example.

Acknowledgments

This research was supported by the "11th-Five-Year Plan" National Key Technologies R&D Program of China (No. 2006BAJ03A10) and the Postdoctoral Foundation of Harbin Institute of Technology.

Abstract
Data on construction resources (personnel, equipment, materials) is vast and the effort to collect and analyze it automatically is a priority in the construction industry. Once remote sensing and intelligent data processing technology are applied to supplement manual data recording, however, very few data visualization tools in construction exist that allow visualizing dynamic resource data in a field realistic virtual reality environment and are at the same time able to perform this task in or near real-time. Moreover, technology to assist in real-time data visualization and situational awareness can have a significant impact on stakeholders' successful and safe completion of construction projects. This research addresses the need for real-time data collection and visualization technology in construction applications. It reviews state-of-the-art technology in this field and presents a new framework that implements real-time remote sensing and data visualization technology in two significant construction applications: (1) Real-time pro-active construction safety assessment and training, and (2) Real-time construction productivity and performance monitoring. Preliminary results to each of these scenarios are presented and discussed.

1. Introduction

The distributed nature of construction project information and the presence of multiple teams performing on site are well known characteristics of a typical construction project. Communication of essential information among project stakeholders is considered a key for successful construction engineering and management. Traditionally, an enormous amount of site information is available to

project team members. It is mostly communicated by means of paper documents including 2D drawings or verbal language. A significant deficiency in the traditional information delivery process has been that the project team is not always able to make rapid and correct decisions because of unavailable or insufficient data, or data that is hardly or badly presented.

This research focuses on developing a deeper understanding of construction information that should be provided in real-time and visually. A more effective use of the real-time information lies in its visualization; providing a visual understanding would allow project stakeholders to make fast decision and facilitate real-time remote control both on construction project level and operation level.

Thus, tracking and visualizing dynamic resource data in a field realistic virtual environment in real time offers several benefits to a project management team. For instance, workers' safety and health learning and education practices can be enhanced through real-time data collection and visualization approaches. Previous research efforts indicated that workers in the execution of their work often do not have good perception of the surrounding risks that are related directly or indirectly to their work task. According to Rasmussen's model, their motivation to achieve a high productivity pushes them to work 'near the edge' in terms of their exposure to risk (i.e. beyond the zone of control or recovery) (Mitropoulos et al. 2005). One such alternative to prevent similar work situations is training construction workers for safety through frontal teaching and instruction of hazards. Virtual reality learning and training offers an active learning experience where the user is in control and is required to deliberate proper actions.

This research integrated sensing and visualization technology of project critical resources (personnel, equipment, and material) in real-time. Realistic and rapid work status performance monitoring and worker training scenarios were built to investigate the procedure of enhancing decision making in construction project safety and task control management.

2. Background and Literature Review

In the past decades sensor technology has been widely applied to civil engineering and construction research problems and also for automated progress monitoring. Some location tracking technologies providing unique spatial-temporal information to resources are Radio Frequency Identification (RFID), Robotic Total Station (RTS), Global Positioning Systems (GPS), and Ultra Wideband (UWB). Each of these are candidate technologies to collect viable project related information on static and dynamic resources. However, some of the above technologies are constrained in their use by the complexity and layout of some construction sites. For instance, GPS can only be applied outdoor. Ultra Wideband, a more recent commercially available radio frequency technology, has been previously tested successfully in semi-open areas on construction sites (Teizer 2008). It suggests that multiple (other) technologies would be suitable for collecting data. As far as the information is extracted from the sensor data set, it must be visualized to the decision maker to provide relevant knowledge in an accessible manner.

There have been many efforts trying to implement virtual environments for visualization of architectural design and facilitating the building construction on

project level. Maldovan and Messner (2006) investigated the potential use of a virtual mockup to replace the existing physical mockups. Messner and Horman (2003) used an immersive Virtual Reality (VR) system consisting of a large scale immersive projection for students in the architectural engineering program at the Penn State Univ. in order to experience and experiment with three-dimensional (3D), full scale virtual models of construction projects.

Visualization technology has already been widely applied to the construction management and practice. Virtual construction allows all the stakeholders to indentify construction problems early in the design phase and enables contractors to manage the projects more efficiently. Most of the existing VR applications in construction management are aimed to visualize construction scheduling and quality control. Chau and Anson (2003) conducted a research on 4D graphics for construction planning and site utilization aiming to assist a planner who deals with daily activities and site management. Retik and Varszawski (1990) explored the potential application of computer graphics to construction scheduling and outlined the possible features of the tool. McKinney and Fischer (1998) presented and evaluated a 4D application integrating AutoCAD, Primavera, Jacobus Simulation Toolkit and Walkthru. Their work illustrated how feature extraction of 4D-CAD models can help identify construction problems. Koo and Fischer (2000) suggested that a 4D VR model increases the comprehensibility of project schedules and allows users to detect potential problems such as scheduling conflicts prior to the construction phase. More effective allocation of resources would results. At the same time easier evaluating of selecting alternative construction methods would allow to shrink construction schedules. Wand and Dunston (2009) also contributed in the area of the determining the benefits of mixed reality collaborative environments for design perception.

Despite much research in adoption of VR technologies on building design and construction project level, their application is not very common on everyday construction task level. One reason is that they can not represent and reproduce the immersive environment in real time. In addition, these tools are somewhat difficult to use and the visualization provided by them is not easy to customize with respect of intensive and dynamical characteristics of construction operations (Issa et al. 2003). On the construction operation level, Kamat and Martinez (2003) formalized a specific description to facilitate the automated communication between simulated dynamic construction scenarios and computer graphics facilities that depict the operations in 3D virtual worlds. Kamat and Martinez (2005) had also conducted a research on dynamic 3D visualization and simulation of articulated construction equipment, such as crane and excavator, by using principles of forward and inverse kinematics. Lai and Kang focused on collision detection strategies for virtual construction simulation (2009).

Apart from the implementation in engineering practice, many efforts have been invested in the application of information technology especially of advanced virtual reality (VR) and virtual environment (VE) technologies in building science education such as school teaching and learning (Bouchlaghem and Wilson 2002, Issa 1999).

However, these adoptions of VR in education used mostly simulated data in a made up environment. Very little effort has been made on implementing real-time immersive environment in construction training and education, even though a real-time training can enhance the memory retention and increase the learning gains of the trainees.

Apart from construction industry and construction education, VR has already been widely used in other fields. Santamaria and Op den Bosch (2002) introduced an application of tools that integrated near-real-time visualization with publish and subscribe mechanism to achieve remote monitoring and control of dynamic objects in an underwater scene for underwater operations. Fernandes and Raja (2003) modeled a virtual training system as an integrated system consisting of a training visualization suite, an interface model and instruction module. Its applicability in the manufacturing industry has been studied (Fernandes and Raja 2003).

3. Research Methodology

A major objective of implementing real-time data collection and visualization technology in construction is to increase the awareness of the project team so that it can make more informed decisions in less time and at lower cost. In order to accomplish this objective, the solution is consisted of four central phases: (1) data collection, (2) data processing and visualization, (3) decision making, and (4) learning and improving. Figure 1 illustrates a detailed workflow for implementing sensor data in construction safety engineering and management. Visualization is one key component to make information available in (3) and (4).

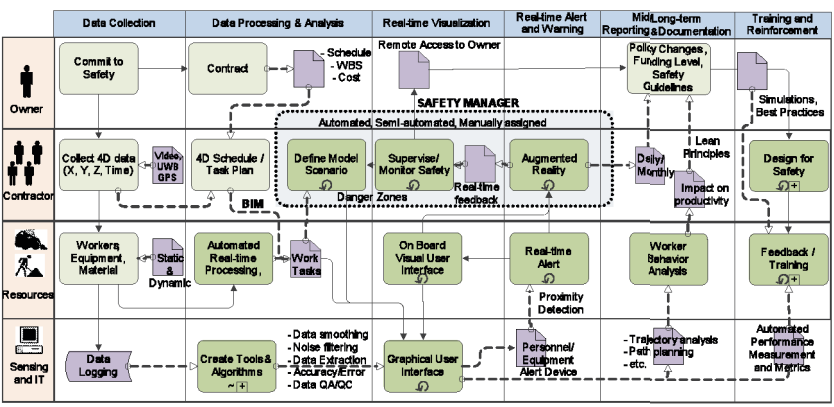

Figure 1: Framework for real-time data collection and visualization for safety

Different stakeholders require different information. A variety of sensing technology exists to collect relevant data for each stakeholder. Raw spatial and temporal data is collected by the sensor and must be processed to form relevant information before it is delivered to decision maker. Some construction applications including safety and health practices may require real-time feedback, which requires real-time data acquisition and processing. Data that is not used for real-time decision making can be

used for training and education purposes in near real-time or post real-time data processing data analysis. With the help of robust data distribution within this framework, stakeholders are able to make their decision with the help of interactive three-dimensional (3D) scenes.

3.1 Real-time Data Collection and Processing

In most construction tasks multiple objects exist that generate data. Such objects relate to construction resources (workforce, equipment, material). Data is generated from several of these objects and several systems on the job site, many of which are isolated from each other. Data transfer and consolidation becomes a challenge. One alternative is to apply a protocol for all data streams in order to uniform data reporting. For simplification, this approach focuses on a single data source from a specific tracking technology, providing location (X,Y,Z) and timestamp information.

3.2 Real-time Data Distribution and Visualization

To send relevant information to all project stakeholders that must have access to relevant data at the same time, a local data server was chosen that collects raw data. In addition a 3D online viewer was installed to visualize information to any project stakeholder regardless of the current location. The data server of the visualization system had the mechanism of data subscribing and publishing. It utilized existing internet and intranet infrastructure. Figure 2 shows the developed data collection, data distribution, data processing and information visualization architecture.

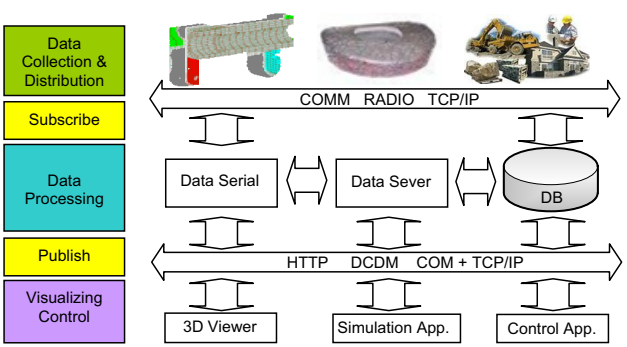

Figure 2: Architecture of data collection, data processing and visualization

4. Experiments and Results

Several experiments have been conducted to test the applicability of implementing real-time data collection and visualization technology in construction operations. The experiments are in particular concentrated on dynamic resources, as defined in the research scope. The first experiment illustrates a simulated scenario in which a worker is approaching heavy equipment and elevated loads. The second scenario presents an ironworker training procedure and includes real-time data collection and visualization

4.1 Simulation Scenarios of Close-calls (a.k.a. Near-misses)

Safety statistics indicate that workers may not communicate the majority of near-misses to existing site safety management. Lack of awareness of the incident type and fear of punishment of the workers are a few reasons why they are often not reported. An interactive 3D virtual environment can facilitate a more detailed inspection of construction operations. In particular, dynamic scenes can be viewed from multiple perspectives so that potential near misses can be studied. Combining this technology may even allow equipment operators to get a better spatial understanding of their location to other resources. Figure 3 (A-E) shows several scenarios of close calls (a.k.a. near misses) where limited perspectives of worker-on-foot or equipment operators (crane or dozer) cause recordable incidents.

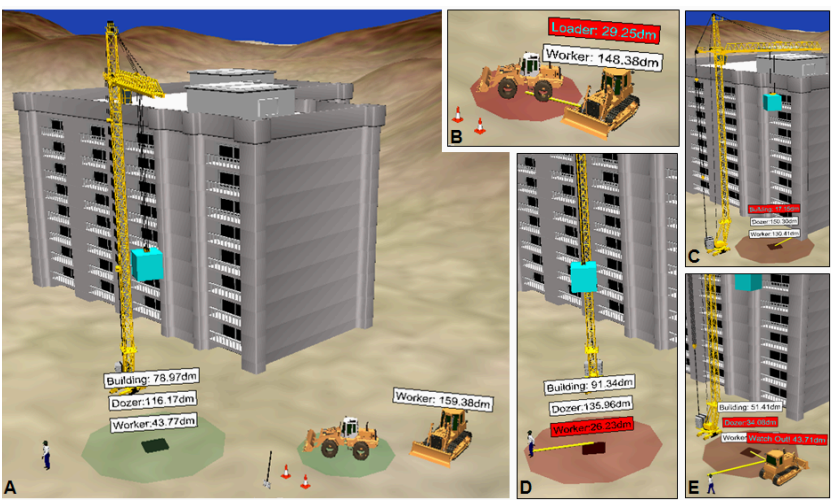

Figure 3: Visualization of close calls (a.k.a. near misses) using simulated data

The scene consists of five major objects (entities), a dozer, a loader, a worker, a crane with load and a building. Spatial data is subscribed to the server and the processed information is published to a 3D online viewer. Two preliminary defined dangerous zones are denoted by green circles to indicate the proximity to a static loader and the area projected from the load onto the ground. The distance between each pair of entities is computed automatically and in real-time from time-stamped trajectory data of the sensors. Both circular regions maintain in green when the center of its distance to all the other resources (worker, equipments, and material) is larger than minimum safety distance (proximity threshold). Regions switch to red (equivalent to the alert status) when the proximity threshold is smaller than the minimum recommended safety distance. In this virtual reality scenario, real-time calculation and visualization of the distance between several objects (see Figure 3) is indicated above each object. Real-time monitoring and recording of safety distances and thus automated near-miss data collection becomes feasible.

A particular strength of the developed virtual reality model is scene realistic field-of-views. For example, the activity of the crane involves the rotation of the crane arm along the base axis and translation of the elevated load. Since the sensor data can only provide absolute spatial information, same as the derivative of heading, multiple sensor data sources are necessary. The crane structure was broken down into three major subcomponents, crane base, crane boom and the pulley attached to the boom with a connection to the hook. In this experiment it is assumed that the crane cable that has the load attached does not swing the crane boom is rotating. Three sensors were attached on each subcomponent of the crane to collect absolute spatial information and the activity of the crane.

This experiment shows potential benefits. Risks can be easily detected by the decision maker (e.g., equipment operator) in advance and in real-time. A screen on board of the equipment knowing the color will change from green to red should another object violate the safety perimeter of the equipment. Workers on ground can be alerted of the situation of being too close to equipment or other objects (e.g., suspended loads during lifts). As the distance between machine and human is quantified automatically it also provides a visual update in real-time. The user can access the situation from any perspective in the virtual model and in an immersive manner, putting the viewer even inside the equipment cabin of crane or dozer. Realistic views of the field-of-view of worker-on-ground also become feasible. Detailed information of working activities can be performed form any preferred viewpoint in an interactive manner, for instance the view from the cabinets of crane and moving dozer can be displayed spontaneously and simultaneously. In addition, the user has the option to prioritize the visualization of relevant information over other less relevant information.

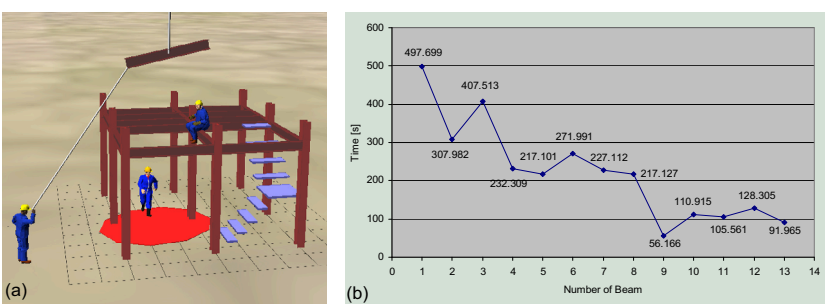

Figure 4: (a) Visualization of iron worker training facilities, and (b) time needed to connect steel members

4.2 Visualization of Trajectory Data from Union Iron Worker Training Facility

A second preliminary experiment focused on improving the safety performance and working efficiency of union ironworkers. Experiments were conducted at the Southeast Regional Ironworker Training Facility to test the applicability of the developed real-time data collection and visualization system. Spatial trajectory information of ironworkers and steel beams were collected by tagging the helmet of the ironworker and the steel members with UWB tags. Figure 4a presents a scenario

during the rigging and connecting of steel members. A suspended load above a worker on ground triggers an alert (red circle). The times to connect steel members in these particular training sessions were recorded.

Figure 4b indicates the learning curve of the same union ironworker connecting the steel members. Overall, five union ironworkers and one trainer were equipped with UWB tags. Their spatial movements in the training environments were recorded. The ironworkers were rigging, hoisting, and connecting on a two story mock-up structure that is located at the training facility. The beam was first rigged to the crane hook in the material deposit area. Then the steel beam was moved with the crane to the assembly zone where two connectors connected the steel beam to the vertical columns. The two connectors stayed on the steel structure all the time while two riggers and a crane operator walked on the ground level.

In the data processing phase, the velocity of the monitored tag was derived. A high speed is considered as a violation of preliminary defined safety rule since running is always prohibited on real construction site. Moving velocities of workers and materials are considered as an indicator of working efficiency. The speed range implies whether the worker is performing a work task or sits idle. This depends on the type of work task. Developed algorithms checked whether the location of any worker was within a pre-defined work zone or a hazardous zone. Productivity and safety performance data was computed and recorded.

Data recorded and visualized in the virtual reality tool in Figure 4a shows the only safety violation throughout the entire training period. A dangerous zone (3.5 meters radius) below the swinging load was defined prior to the experiment. This zone is represented by the red circle on the ground. Entering this area (cylinder or cone; from a spatial perspective) was defined to be a safety violation according to current best safety practices in erecting steel.

The automated data recording was later visualized and presented to the participating training crew. Within the visualization that was replayed, it can be recognized that the rigger stepped into the pre-defined dangerous zone from the left, and walked across the dangerous area (underneath the suspended load). Eventually, the rigger left this area towards the front of the virtual image. According to the recorded safety data, the rigger stayed within this dangerous area for about 8 second.

The productivity of a worker is represented by the time that is spent on a specific individual task. This experiment measured the time connecting 13 different steel beams to a column. For each connection, the time was recorded. Figure 4b visualizes the connecting time. Although it is eventually difficult to record the exact start and end time of the work task, measuring the time the worker spent in one particular connection location is feasible. The presented data shows a learning curve of the connecter. It took 497 to connect the first beam. The trainees then received an instructor lesson on how hoisting and connecting could be improved. After about 8 connections, the connection time leveled to roughly 100 seconds per bolted connection. Waiting times of the connector for the crane are included. As a whole, such data represents the crew effort rather than individualized information. However, information on crew productivity should be given priority unless objective individual measurements are possible.

5. Conclusions and Recommendations

A preliminary mechanism of implementing real-time data collection and visualization technology in construction industry was presented in this paper. Although virtual reality technology has already been widely used in construction research and development, and even in applications for and on high profile construction job sites, little research has been done on the problem of real-time data collection and visualization of construction operations. The presented research approach contains significant steps towards solving this problem. The concept of acquiring site relevant data to critical project resources (workforce, equipment, material) was presented. Real-time data collection of these resources, broadcasting its relevant information in real-time to the decision maker for real-time data processing, and embedding the resulting information in visual virtual 3D models has been demonstrated.

Future work is necessary to validate important research questions whether relevant information can be provided to decision makers and whether they are able to profit from the selected research approach. Initial experiments are few and limited. The entire framework for safety and productivity entails long term research projects and validation, including several experiments for site data collection and visualization. Studies need to be performed to measure tools that are required for advancing and whether construction information such as productivity and safety practice can be quantified and visualized in real-time. Ways need to be found to allow stakeholders to make fast decision on both operation and project level while the construction project is ongoing. By subscribing the data to multiple locations via internet and intranet infrastructure, distributed project teams can visualize the entire operation in 3D view as it takes place on a local site. Proving that such tools can be made available successfully will ultimately benefit in rapid decision making. The envisioned outcomes of this research can then enhance existing project and task based learning techniques by increasing job site safety and health planning and evaluation, improving task based performance measurements, and lower overall construction cost and schedule.

Abstract

Heavy lifting in industrial construction involves the installation of prefabricated modules and equipment weighing up to 1000 tons. Placing a prefabricated module requires a specific crane with a minimum capacity and specific configurations and riggings. Site construction process should follow a certain sequence. If the required cranes are not available or the predecessor modules or structures are not built yet, the module has to be stored in a storage area. Prior to lifting a module, several supporting tasks must take place including adjusting the location, configuration, and rigging of the crane and preparing the ground beneath the crane. Therefore, planning multiple heavy lifts is a complex process. However, it has a significant impact on the cost, schedule and safety of the project. This study employs a simulation-based approach to produce a heavy lifting planning system for mobile cranes. This system assists the project manager and lift engineer in decisions regarding the selection of mobile cranes and their locations and configurations for different lifts. It also produces a schedule that reduces the total cost and enhances the schedule of the project. This system is under implementation on an industrial plant in the province of Alberta, Canada.

Keywords: Heavy lift planning; Modular construction; Mobile crane; Simulation; Schedule

1. Introduction

Modular construction is a popular and cost-effective method for building remote industrial facilities (e.g. refineries, oil-processing plants), particularly in areas with harsh weather conditions. A module refers to a construction unit that is built off-site and transported to the work site for construction of the facility (Taghaddos et al. 2009). Prefabricated modules in industrial construction may weigh up to 1000 tons and are usually lifted with mobile cranes in North America (Hornaday et al. 1993; Lin and Haas 1996).

Planning multiple heavy lifts in congested industrial plants, particularly if the plant is built by modular construction (Figure 1), is a complicated and time consuming process. It includes determining the appropriate type, configuration, and rigging of the crane for each lift, preparing the prelift location of the module and the crane, verifying the lift capacity rating of the crane, and ensuring sufficient clearance during the lifting process (Lin and Haas 1996). Several activities may take place to prepare a crane to lift a module. These activities include mobilizing the crane to the site, changing the location, configuration and rigging of the crane, preparing the ground and putting mats underneath the crane's foundation. Each of these activities requires a different amount of time depending on the type of the crane (e.g. 1 day, 10 days).

Figure 1. A typical congested industrial plant

Developing reliable multiple heavy lift plans with minimum risk involved has a major impact on the cost, schedule and safety of the project. A good plan has to consider various aspects of the project to lift the modules on time, with the right sequence, with suitable cranes. An optimized plan minimizes the extra supporting activities such as storing the modules, mobilizing the cranes, relocating or reconfiguring the cranes. In a project that involves mobile cranes with several hundred dollars per hour (e.g. $1,500/hr) rental cost, some small modification in the

heavy lift plan may reduce or raise the project cost significantly. Moreover, any flaws in the lift plan or any accident during a lift may delay the schedule or result in injuries, equipment damages, and sometimes loss of life (Varghese et al. 1997).

This paper introduces a simulation-based approach to produce a multiple heavy lift planning system. This system is developed in collaboration with PCL Industrial Management Ltd. and is under implementation on a real industrial plant in Alberta. The produced model selects the mobile cranes, determines their locations and configurations for different lifts, and produces a lifting schedule for the entire duration of the project. It also reduces the total cost and enhances the schedule of the project by employing an optimization algorithm inside the simulation model.

2. Problem Statement

This study addresses the problem of multiple heavy lift planning in modular construction of the industrial plant. Field construction is the last ring of the supply chain of large-scale industrial construction, which also includes drafting, spool fabrication shop, and module assembly. Modules are made of pre-assembled components such as structural steel frames, racks of pipes, cables, equipment, or a combination of miscellaneous components (Taghaddos et al. 2008; Borrego 2004). Once all the required components of a module are built in the fabrication shop, the module is assembled in the assembly yard beside the spool fabrication facility and then transported to the field. Previous research in industrial construction at the University of Alberta studied the spool fabrication shop and module assembly yard in detail (Taghaddos et al. 2009; Sadeghi and Fayek 2008; Wang et al. 2009; Mohamed et al. 2007; Song et al. 2006).

Once a module arrives at the field from the assembly yard, if it can be lifted by the next day, it sits in the pick-point area. Otherwise, if the crane or the pick-point is not available or the predecessor modules and structures are not constructed yet, it goes to a storage area. This adds the daily rental cost of storage, transport cost, loading and offloading cost, and mobilizing cost of transport equipment to the project's budget.

A limited number of cranes (e.g. maximum three cranes) can mobilized to the site to carry all the modules in the project. These cranes have to be selected among the heavy cranes that are potentially available in a limited period for the rent. The first objective of this study is determining the cranes that are cost efficient and safe to be mobilized during the construction process of the plant.

Each mobile crane can be mobilized to predefined locations (Figure 2) by various configurations and rigging (e.g. 1 point, 2 points, 10 points). A crane can pick a module from different locations and with different configurations and riggings. Therefore, the below questions have to be addressed for each single lift:

a. Which crane should lift the module?
b. Which support activities (e.g. relocation) does the crane require?
c. Where should the crane pick up the module from?
d. Where should the crane sit to lift the module?
e. What configuration and rigging should the crane have to lift the module?
f. When should the required support activities of the crane start?
g. When should the crane lift the module?

This study aims to answer the above questions for all the lifts during the construction process (e.g. 2 years period) such that the total project cost is minimized and the modules are placed on time and in sequence. Minimizing the total cost implies minimizing relocation and reconfiguration of the crane, which enhances the safety of the project. Of course, the global optimum cannot be found for a scheduling problem, which is Non-deterministic Polynomial-time (NP) hard (Demeulemeester and Herroelen 2002). However, any improvement to the current traditional heavy lift planning methods is appreciated by the industry.

A lift schedule has to satisfy several logical constraints on the site. For example, modules should be assembled in sequence and a module cannot be placed between two adjacent modules. The bottom module must be assembled prior to its top module. Some of the predefined locations for the cranes are available for a limited period of time because of other construction activates on the site, and some locations may be available while a module is not yet installed.

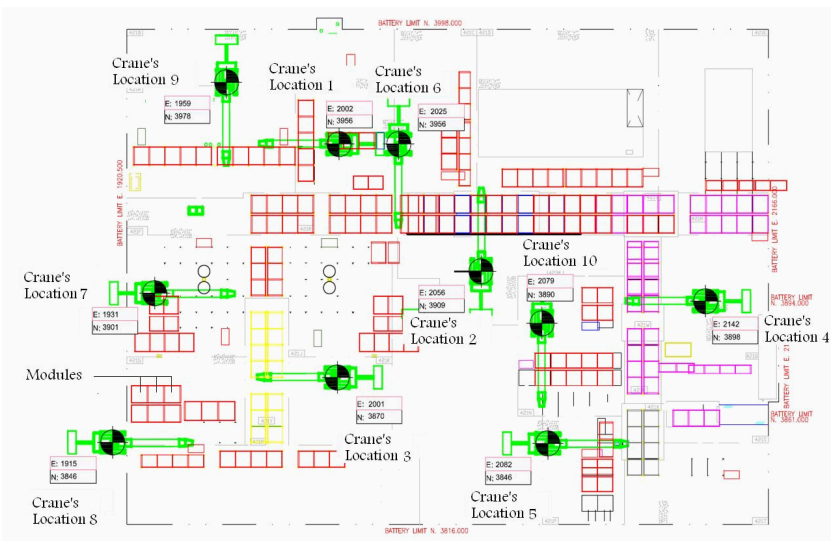

Figure 2. Plot plan with cranes' predefined locations

3. Related research studies

Heavy lift planning of mobile crane operations in the construction industry is mostly done intuitively by reliance on highly specialized planners and lift engineers. But the manual process of lift planning is very time-consuming and does not necessarily result in an optimum scenario. The fact that the pre-construction period of heavy planning is very constrained and cannot be performed without knowing the exact delivery dates of the modules, makes the problem more challenging. As a result, the need for a computer-aided heavy lift planning system has been identified by a number

of researchers and industrial practitioners since the early 1990s as a safe and cost-efficient tool (Hornaday et al. 1993; Varghese et al. 1997; Tantisevi and Akinci 2008; Shapira and Glascock 1996).

Research in computer-aided heavy lift planning began at the University of Texas about 20 years ago. Wolfhope (1991) recognized seven critical criteria to evaluate the feasibility of a lift, including availability of the crane, access to the site and lift area, location of the crane to execute lift, lift path clearances, safety, ground support during lift, and crane removal from the lift area. Hornaday et al. (1993) justified and developed architecture for computer-based heavy lift systems. Varghese et al. (1997) presented a computerized Heavy Lift Planning System (HELPS) to automate three of the above-identified tasks. In the last decade, some other commercial and industrial software have been developed to assist lift planners in selecting and scheduling the cranes (Bennett and Ditlinger 1994; William and Bennet 1996), and some researchers (Lin and Haas 1996; Tantisevi and Akinci 2008; Al-Hussein et al. 2005; Deen Ali et al. 2005; Moselhi et al. 2004; Mahalingam et al. 2000) have attempted to automate some other aspects of the heavy lift planning. However, no integrated planning system yet exists to consider different aspects of heavy lift planning for the multiple lifts throughout the project.

4. Research Approach

This paper introduces a system considering various aspects of heavy lift planning in industrial construction. Figure 3 shows the architecture of this system which is built upon previous research (Hornaday et al. 1993). This system reads the data from a database, runs a discrete event simulation model, and populates the results into the database. Therefore, the database includes some input information and some output tables filled by the simulation model. The input tables contain the information regarding the objects, cranes, site layout, and storage. The output tables contain the required data regarding the selected cranes, the status of the crane (location, configuration, and rigging) for each lift, the lifting schedule, the total cost and duration of the project, and the information to present a 4D animation of the entire construction process. The main feature of this system is that it considers different feasibility criteria recognized by Wolfhope (1991) as well as some extra factors:

a. It considers the arrival time of the modules to the site and early start data of the modules, which depends on the availability of structures on the site. It schedules a module to be lifted once the module is available at the site, the required structures or foundations in the site are built, the predecessor modules (e.g. module at the bottom) are installed, the required crane with enough capacity and boom length is available, the pick-point area to lift the module is available, and finally the lifting path of the module is not obstructed by any other module or structure.

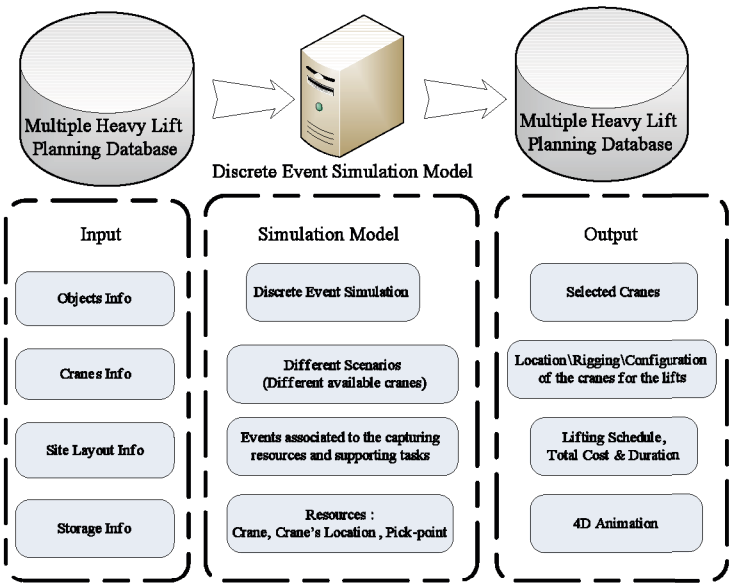

Figure 3. Architecture of multiple heavy lift planning system

b. This system proceeds by another preliminary study that associates a number of potential lifting options for placing the modules. This study takes into account a number of lift feasibility factors such as the capacity of the crane, boom length and configuration of the crane, crane's location and module's pick-point, and clearances. Each option introduces a crane with a particular configuration and location to lift a module from a pick-point.
c. This system can consider weekends and weekdays in the calendar as well as different shifts. These shifts include 4 day and 2-10 hr, 5 day and 2-10 hr, 6 day and 2-10 hr, 7 day and 2-10 hr, 4 day and 1-10 hr, 5 day and 1-10 hr, 6 day and 1-10 hr, 7 day and 1-10 hr, 5 day and 1-8 hr. Therefore, the planner can see the impact of different shifts on the cost and schedule.
d. One of the main outputs of this system is selecting suitable mobile cranes for all the lifts during the entire project. These cranes are selected among the potential cranes for the rent in certain periods of time. All the costs and durations associated with the supporting activities of each crane are also available.
e. The other output of this system is producing the lifting schedule, while considering availability of the cranes and accessibility to the site and lift areas. This schedule determines the lifting date and pick-points of the modules, the moving date and locations of cranes for different lifts, the date that a crane has to change its configuration or rigging and its new status. It also determines the cranes' mobilization and demobilization time, as well as their initial locations,

configurations and riggings. It also arranges to prepare or remove the ground and mats underneath the crane.

The multiple heavy lift planning system is developed based on a discrete event simulation model, which employs the core services of Simphony 3.5 simulation engine within Visual Studio 2008 programming environment. Simphony 3.5 is the new generation of Simphony.Net (Hajjar and AbouRizk 1999) targeted at the version 3.5 of the .NET.

In this project, different scenarios were generated to consider different combinations of the cranes to carry the lifts. If the combination of cranes cannot carry all the lifts in a scenario, the simulation engine stops and jumps to the next. The developed simulation model can run all possible scenarios or work with a developed Genetic Algorithm (GA) to run only a few. In practice, the total number of cranes is limited to a small number (e.g. maximum three cranes). So running all scenarios usually does not take more than a few minutes or a few hours (depending on the project). However, if the maximum number of cranes is not limited, running all the scenarios is not feasible and GA is the alternative solution. For each possible scenario, the following steps are performed:

1. Define resources (cranes, cranes' locations, modules' pick-points) based on the database information.
2. Define a waiting-file to capture resources and associate it with the defined resources.
3. Synchronize time of simulation engine with working hours based on the selected shift and weekdays.
4. Generate modules based on modules information and schedule their arrival at the site.
5. At every period of time (e.g. every day):
   - 5.1. Loop over all the arrived entities. For each entity:
     - 5.1.1. Check various constraints (e.g. if the required structures are built, the predecessor modules are installed, and the modules are built in a logical sequence).
     - 5.1.2. If the constraints are satisfied, loop over potential lifting options of the module. For each option (a combination of resources):
       - 5.1.2.1. Check the constraints regarding availability of required resources or maximum number of cranes.
       - 5.1.2.2. Check the other constraints (e.g. obstruction).
       - 5.1.2.3. If all constraints are satisfied, determine the bidding cost and required date to start crane's supporting activities and let the module bid for the resources in the option.
   - 5.2. Assign available resources (cranes, locations) among the bidding modules based on minimizing the total cost and on time delivery by employing a greedy optimization algorithm.
6. Run the simulation model based on the resource assignment results as follows:

6.1. Module waits in the waiting-file to capture the assigned crane and location.
6.2. Mobilize the crane, if it is not yet mobilized,.
6.3. Prepare the ground and put the mats underneath crane, if there is not any.
6.4. Reconfigure the crane, if the module needs a different crane's configuration.
6.5. Move the crane into new lift position, if the module needs a different crane's location.
6.6. Disassemble the precious rigging and assemble the new one, if the module needs a different crane's riggings.
6.7. Module waits in the waiting-file to capture the pick-point.
6.8. Lift and place the module, if the lifting process finishes at the same date. Otherwise, lift the module at the beginning of the next business day.
6.9. Release all the module's resources.
6.10. Populate the data into the database.

7. Finalize the scenario by the below steps:
7.1. Walk the cranes off the pads
7.2. Demobilize all the used cranes
7.3. Remove the ground preparations and the mats
7.4. Calculate the total cost and duration for the scenario

In the above-explained simulation model, the mobile cranes, locations of the cranes, and pick-points of the modules are modeled as the resources. In each scenario, an optimization algorithm (e.g. greedy algorithm) is employed to assign a specific set of resources (crane, location, and pick-point) to each module. The crane and location are captured at the start of supporting activities and the pick-point is captured at the start of lifting activity. All these resources are released at the end of lifting activity.

In each scenario, the total cost and the produced schedule have to be evaluated. At the end, the scenario with minimum total cost and the best schedule is proposed to the planner. Balancing between cost minimization and on time assembly of the modules is a time-cost trade-off and requires further research.

Another feature of this model is providing the required scheduling data to feed to a CAD application and illustrating the 4D animation of lifting and supporting activities during the entire construction process.

5. Limitations

The developed simulation-based system for multiple heavy lift planning has some limitations and should be advanced in the near future. Currently the optimization algorithm inside the simulation model is a greedy algorithm and the other optimization algorithms (e.g. dynamic programming) have to be experimented. Moreover, the mobile cranes, locations of cranes, and pick-points of the modules are the only resources inside the model, while several other resources can be incorporated in the simulation model including the mats, transport equipment, and storage area. Optimizing the best sequence to assemble the modules is another area for further research. The time-cost trade off is also an appealing research area, which has a key impact on the decision making process. Finally the construction process in the site

has to be connected with the other supply chains in the industrial constructions. For example, the modules arrive at the site from the module assembly yard. Linking the simulation model of the module assembly yard or fabrication shop to the simulation model of site construction is an important step to model the entire industrial constriction process. This large-scale simulation model assists the planner to decide about the best time to transport a module or spool from module assembly yard or fabrication shop to the site. It also results in a more realistic estimate of the arrival dates and the capacity of the entire system.

6. Conclusion

Multiple heavy lift planning of industrial projects is a critical and challenging issue, particularly if the plant is built by modular construction. Several cranes are involved in a congested site. Modules arrive on different dates and have to be lifted by a certain due date. The lifting process of the modules should follow certain sequences and should be synchronized by the construction of other structures. Moreover, limited resources (e.g. cranes, space) are available in the field.

There is some research toward automating some aspects of heavy lift planning. However, no research considers various lifting feasibility criteria for all the lifts. In this study, a simulation-based heavy lift planning system that automates different aspects of lift planning for all the lifts is introduced in industrial construction application. This system reads required data from a database, selects the suitable types of mobile cranes, and produces a lifting schedule. This schedule includes the lifting date and start time of cranes' support activities, as well as location, configuration, rigging of the crane, and associated cost for different lifts. This system reduces the total cost and enhances the project's schedule and safety significantly. This system is under implementation on a real case study.

7. Acknowledgements

The authors wish to acknowledge and thank PCL Industrial Management Ltd. for providing support and Mr. Ali Hendi for developing the multiple heavy lift planning database and the 4D animation.

Abstract

Managing the behaviour and trajectory of an object lifted by a crane is critical to a successful lift. This paper presents advancements in the development of mathematical algorithms for lifted object trajectory paths and analyses. The proposed methodology is divided into smaller manageable phases to control the process and at the same time to create independent modules. Each step of the lifted object movement was geometrically tracked, starting at the lifted object pick-point, through an optimum path development and completing at the object final position (set-point). Parameters such as the minimum distance between the lifted object and passing obstructions and minimum allowable clearance between the lifted object and the crane boom are some of the many predefined rules which were taken into account. The lifted object's spatial trajectory analysis and optimization is a part of the complex assignment relating to the crane selection process. A numerical example is presented to demonstrate the effectiveness of the proposed methodology and illustrate its essential value.

Keywords: mobile crane lifts, object trajectory, site layout, mathematical algorithm

Introduction

Computer advancement for the design of construction equipment has brought major changes to equipment functionality, productivity and construction practices. Mobile cranes, among other heavy industrial machinery, have increased in size, capacity, manoeuvrability and versatility inducing an increase in capacity.

The consequences of the misuse or improper planning of a crane lift can be severe. The preparation and planning of heavy lifts can be complex and involve challenging issues during lift analysis. Fast-tracked construction projects involve frequent changes to the construction plan thereby requiring many what-if scenarios and changes to the lift plan. The lift engineer extensively relies on computer technology to deliver solutions faster and safer than before.

Virtual reality combined with an interactive planning environment that explores human potential and computer advancement is an efficient alternative for spatial integration. A lead article introducing spatial integration in construction [Bernold 2002] presented the historical advancement and objectives of such technology. In other studies, authors found mathematical computations that helped identify configuration space and concepts to develop tools for creating lift paths [Raghunatha et al. 2002]. In addition, two levels of heuristic searches have been implemented for three-dimensional bin-packing problems [Raj and Srivastava 2007].

Trajectory and shortest-path developments are also of concern in this field. Ishigami et al (2005) encountered issues in the proper design of an all-wheel dynamic model during a steering trajectory analysis for planetary exploration rovers: the model's contact between the rigid wheel and loose soil was based on a terramechanical approach. A Makov-decision process with two algorithms addressed the problem of planning the shortest path for reliable landmark-based robot navigation strategies in the presence of significant sensor uncertainties [Briggs at al 2004].

Trajectory path analysis is also needed in applications such as tooling equipment, military rocket tracing, satellite space travel and even environmental disasters where oil spills must be traced. In the machine industry [Makhanov 2007], three algorithms for the tool path optimization of a numerically controlled five-axis milling machine were introduced. The focus of these algorithms is the development of a flexible geometric structure which adapts itself to a certain cost function as defined on the required part's surface. Algorithm 1 is based on the variation grid generation. Algorithm 2 is based on a modification of the space-filling curves technique. Algorithm 3 is based on the construction of vector fields composed of optimal cutting directions.

For military applications [Azimov 2005], the development of analytical, approximate analytical and numerical methods are used for solving variation when determining optimal rocket trajectories in gravitational fields and are also applied to study flight dynamics.

Yet the industry that stands most to benefit from this technology is the construction industry. A user customized database [Al-Hussein et al. 2005, Moselhi et al. 2004] integrated with mathematical algorithms for choosing a proper crane with respect to lift capacity while utilizing 3D animation for visualization techniques has been developed and is available on the market. Following this development, more complicated 3D analyses were evaluated. One analysis used a 3D optimization approach for construction using a tilt-up panel method [Manrique et al. 2007]. Another analysis used a combination of advanced visualization, the above-mentioned

crane selection process and detailed schedule optimization and interactive communication techniques [Olearczyk et al. 2009].

Proposed Methodology

The proposed methodology will be used for multiple crane configurations and positions and multiple lifted objects; thus, the use of commonly used CAD software for lift analysis is not practical. It will also be used in a more elaborate crane lift analysis program. Crane data, object data and obstruction data were entered into a database for mathematical analysis to determine the trajectory path. The process shown in Figure 1 is for one single lift with a given crane position, object pick-point location, and object set-point location.

The methodology consists of tasks and decisions. The input includes the information necessary for the system to run such as crane configuration data, the lifted object parameters, site configuration (slope or natural limitation areas) and obstruction data information for objects that could limit or impair the lift operation. During obstruction data input preparation special emphasis must be placed toward detailed and accurate obstruction positions since these items are critical to safe and smooth trajectory development.

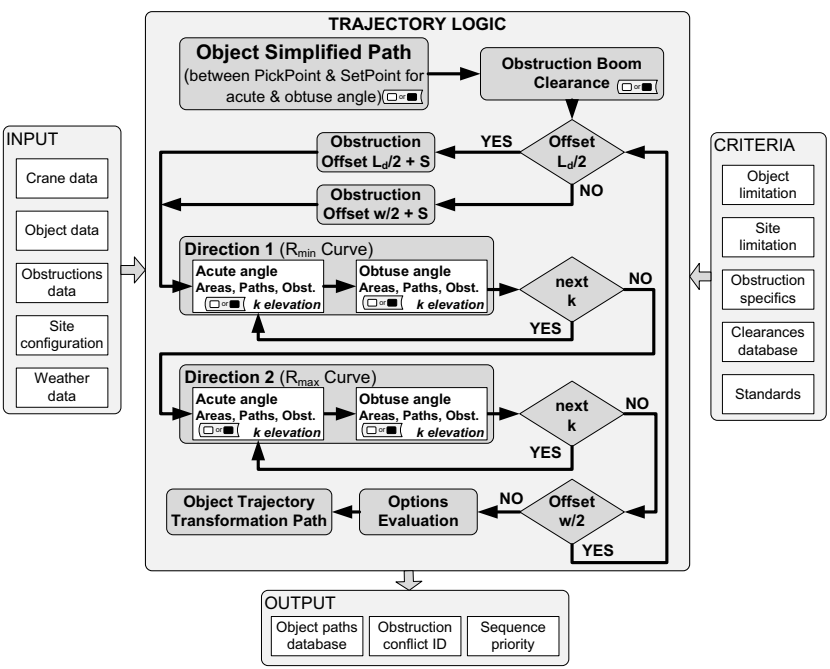

Figure 1. Methodology flowchart

The trajectory logic module is the center of the methodology with the most important components being the object shortest-path development and obstruction boom

clearance. The traffic light symbols represent a checkpoint where the task is completed either successfully or unsuccessfully. For example, after successful obstruction boom clearance, the algorithm then assigns the proper offset to the particular obstructions in the interested area. The trajectory path represents the hook position of the crane, and to clear the lifted object away from an obstruction, an offset to the obstruction dimension is required. This offset is the lifted object's geometric centre to either the diagonal half length (L_d) or half width (w) with an added minimum clearance distance (S) value (usually three feet).

In a simple trajectory following an arc from the object pick-point to its set-point, two radial directions are checked to modify the simplified path in acute and obtuse angles. Critical to this particular layout configuration is the k value (the distance from the top of an obstruction to the ground, see Figure 5). The expected amount of k elevation levels on a project is five. At the end of each system operation task, the resulting data is sequentially coded and stored for future trajectory optimization processes. Figure 2 shows an example of the number of analyzed path configurations for three different elevations.

3 elevations k_1,k_2,k_3 - all passed boom clearance

L_d/2+S - obstruction offset				w/2+S - obstruction offset			
Angle	**Elev**	**Direction**	**Status**	**Angle**	**Elev**	**Direction**	**Status**
acute	k_1	1	(failure) F	acute	k_1	1	P
"	k_1	2	P (passed)	"	k_1	2	P
"	k_2	1	F	"	k_2	1	P
"	k_2	2	P	"	k_2	2	P
"	k_3	1	F	"	k_3	1	P
"	k_3	2	P	"	k_3	2	P
obtuse	k_1	1	F	obtuse	k_1	1	F
"	k_1	2	P	"	k_1	2	P
"	k_2	1	F	"	k_2	1	F
"	k_2	2	P	"	k_2	2	P
"	k_3	1	F	"	k_3	1	F
"	k_3	2	P	"	k_3	2	P

Figure 2. Configuration example

Each elevation must pass an obstruction boom clearance check to be considered for object trajectory path development. The maximum and minimum offsets equations

$$\frac{L_d}{2} + S = Max\ Offset \qquad \frac{w}{2} + S = Min\ Offset$$

where:

L_d – lifted object's diagonal dimension (see Figure 3)
w – lifted object's width dimension
S – minimum clearance distance value (usually three feet)

are used to enlarge each obstruction area. When obstruction offset areas overlap, a union operation

$$\sum_{j=1}^{n} P_{kj} = M_{kj} \qquad \sum_{i=1}^{n} Q_{ki} = N_{kj}$$

where:

P_{kj} – intersected obstructions – crossing the CST (crane simplified object trajectory) line

Q_{ki} – intersected obstruction – non crossing CST line

M_{kj} – union region or P_{kj} crossing the CST line obstruction offset

N_{kj} – union region or Q_{ki} "floating" obstruction offset

is used to create one larger obstruction area, and this new area is given a new identifier (ex. M_{kj}). However, when the P_{kj} offset overlaps with the Q_{kj} offset, an M_{kj} region union is also created (see Figure 6 and 7). One or several obstruction areas may be analyzed at each k level in both radial directions (see Figure 4), and valid paths can be stored for further path optimization.

An optimization algorithm, used during the Option Evaluation task, will select valid solutions based on user-defined criteria. Limitation variables independent of the object and crane configuration are then put into the system.

Trajectory Path Logic Development

Object shortest path

To define the object shortest path from the pick-point (PP) to the final set-point (SP), an arc between the two points is created based on the radius distance from the closest point to the crane set-point (CS). Figure 3 shows a crane object simplified trajectory (CST) line developed in an acute angle section. There is a similar developed CST line between the pick-point and set-point covered in an obtuse angle section as well.

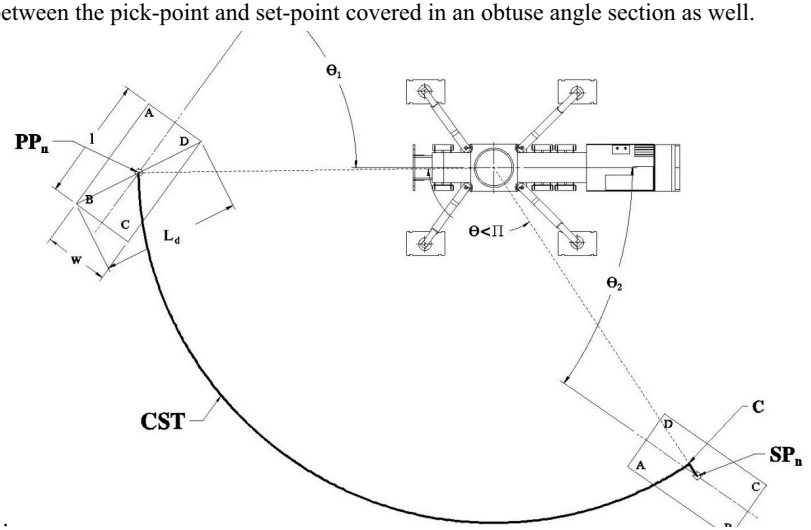

Figure 3. CST acute angle trajectory

At this point, the main objective for the crane object simplified trajectory evaluation is to ensure that the path is between the minimum and maximum crane radii values (R_{min} and R_{max}). This trajectory is the simplest and fastest for a crane operator to follow.

Obstruction boom clearance (Figure 4)

After the crane object simplified trajectory is calculated, the obstructions within the boundary established by the crane's maximum radius (R_{max}) are identified as well as the pick-point and set-point lines. The crane R_{max} is based on the crane's capacity to lift the object weight. Obstruction height and position information is available in the project database and is used to calculate and confirm clearances for the given crane configuration (P_{k1} and Q_{k1}).

Figure 4 shows an area based on the acute angle obstruction offset equation

$$\frac{B}{2} + S$$

where:

B – boom envelope width
S – minimum clearance distance value

There are two temporary obstructions (P_{k1} and Q_{k1}) in the area covered by the crane boom movement. These obstructions must be checked for crane boom clearance. If there is insufficient boom clearance, the trajectory path will be marked as a failure. If the radius has to be adjusted to obtain the required boom clearance, the maximum radius is modified to RQ_{k1} for the area behind the obstruction. Figure 5 shows a sectional view of Plane A and the adjusted radius RQ_{k1}.

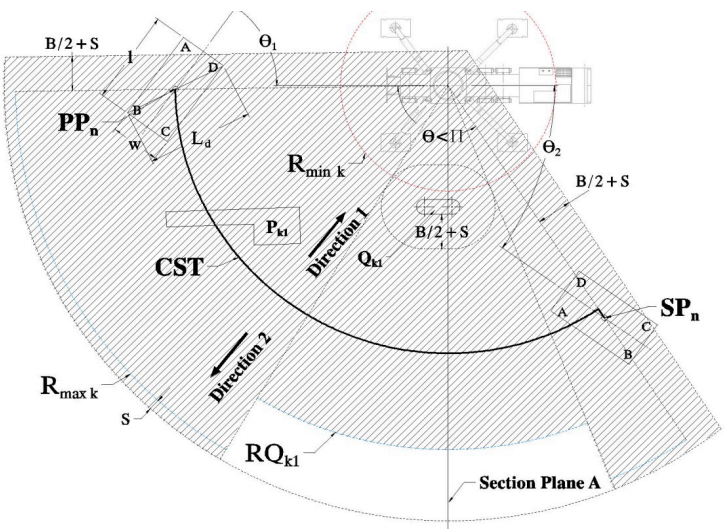

Figure 4. Acute lift angle obstruction offset on k_1 elevation

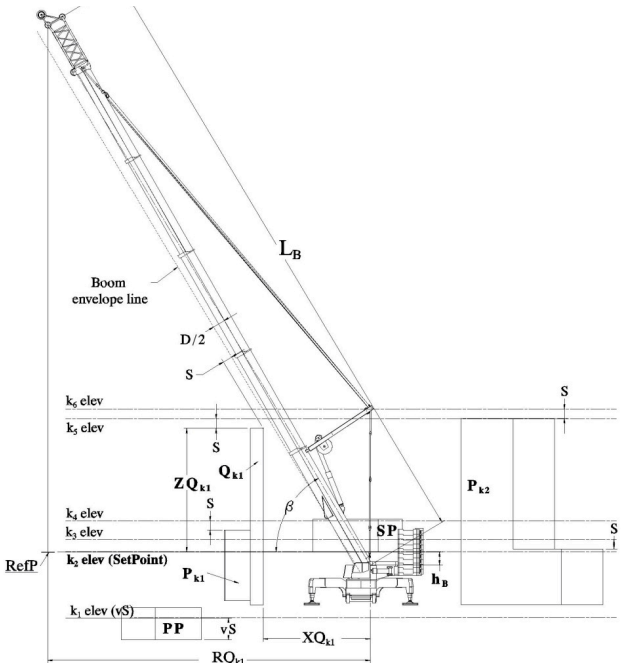

Figure 5. Section plane A elevation view

Figure 5 also shows the elevation set (k_n) for this particular setup. The acute-lift angle consists of only two obstructions; yet on the elevation view, a third obstruction (P_{k2}) exists in the obtuse section of the lift angle trajectory. Obstruction P_{k2} creates an elevation (k_6) which is analyzed only when the obtuse angle lift trajectory is analyzed. Elevations created from obstructions are vertically offset by the S value. The elevation created at the pick-point location is offset by vS (delivering equipment height), and the elevation at the set-point k_2 is the object's lowest resting point. For clarity and consistency, k_1 always refers to the pick-point position and k_2 to the set-point position. The next k value (i.e. k_3) starts from the lowest obstruction (or evaluation area height) and to the tallest obstruction.

Obstruction offsets

To identify a trajectory path and to maintain adequate clearance between the lifted object and the obstruction, the obstruction envelope must be increased accordingly. Distance

$$\frac{L_d}{2} + S$$

is analyzed first. This allows the object to rotate freely along the entire developed trajectory path at its optimum position (where the objects' long edge is perpendicular to the boom). If the distance between obstructions is too close and there is difficulty

finding an appropriate solution, the trajectory may be analyzed based on the minimum obstruction offset (w/2+S) value. A special envelope must be created to accommodate the smooth transfer of the object between obstructions (see Figure 6 shaded area). When the w/2 offset is introduced, the offset change applies only to the obstructions, and the perimeter of the object working area offset remains intact.

CST trajectory modification (R_{min} and R_{max} curve directions)

On each elevation plane, there may be different obstruction offset regions that must be considered. Union and subtraction operations on the obstruction polygons are the simplest options to consider in such configurations. Mathematically subtracting the unionized obstructions' offset areas from the entire object working area will define a suitable region for a particular lift. It will also determine whether the pick-point and set-point are in the same region, indicating a possible trajectory path solution. The concept of mathematical operations on region algorithms was previously developed and adopted for this application [Leonov and Nikitin 1997; Vatti 1992].

Figure 6 shows a united obstruction area (M_{k1}) in the acute-angle lift region that intersects the CST line at points Z_{11} and Z_{12}. All obstruction areas that do not intersect the CST line are called floating-area obstructions and are identified as N_{kj} (in this sample, N_{kj} does not exist). The main goal in the development of the object lift trajectory is to simplify the path even if obstructions are in its way. The intersection points between the obstruction offset area and CST line can support path development at either side of the CST curve (Z_{11} toward the R_{min} or Z_{12} toward R_{max}). To recognize the opposite side of the CST line, the obstruction offset maximum deviation is a tangent line to the obstruction offset area that crosses the CST line at point Z'_{11} and Z'12 (on corresponding sides of the main intersecting points).

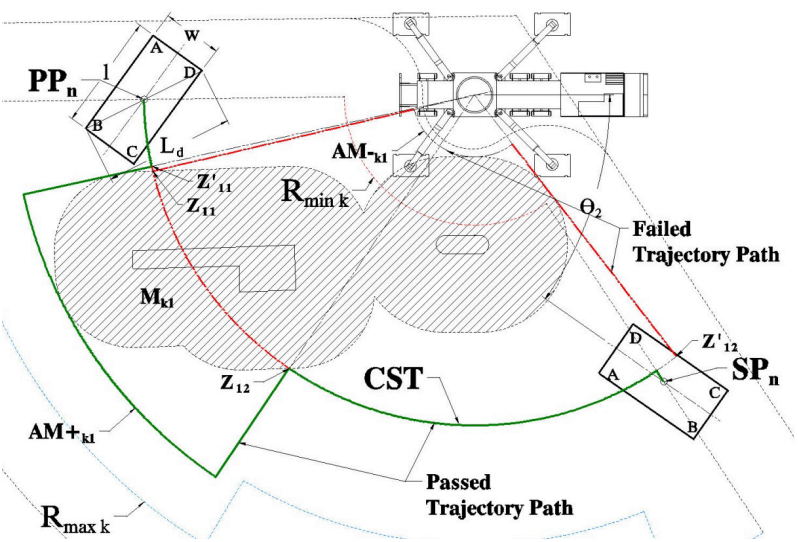

Figure 6. K elevation trajectory path development

Next, tangent arcs (AM_{-k1} and AM_{+k1}) to the M_{k1} obstruction area are constructed to bind the M_{k1} area to its minimum and maximum dimensions, respectively. These arcs must be located between $R_{min\ k}$ and $R_{max\ k}$ for the elevation being analyzed. In Figure 7, AM_{-k1} fails (Failed Trajectory Path) since its radius is less than $R_{min\ k}$; therefore, the entire object trajectory in the direction of R_{min} on k_1 elevation is marked in the database as a failure. When proceeding into the opposite side of the CST line, AM_{+k1} is perfectly positioned in the interested area, and the option for this side will follow this path: start at PP_n, Z'_{11}, radii transformation to AM_{+k1} arc, rotation as per AM_{+k1} arc, radii transformation to the CST line and end at SP_n.

The trajectory path developed with the w/2+S obstruction offset is optional and may depend on user criteria should the $L_d/2$+S offset path fail.

Option Evaluation

The path development algorithm will analyze all possible trajectories on each identified elevation for acute and obtuse angle lift options in both direction (toward R_{min} and R_{max}). Any full or partial path will be identified and stored for further analysis and then optimized for a final trajectory path movement. An option evaluation algorithm is customized by the user and will consider many options (such as staying as close as possible to the ground for heavy loads), the shortest path (for bulky but not heavy load), etc.) The developed final object lifted trajectory path is flexible insomuch that the algorithm can run indefinitely through code to permit the analyses of many obstructions, crane configurations and object scenarios. Furthermore, all of this can be done independent of CAD. This provides the user with a great tool to experiment with many possible scenarios that current graphical software cannot handle effectively.

Conclusion

This paper presents an algorithm that simplifies the complex process involving the selection of spatial trajectory path for lifted objects using mobile cranes. The proposed method calculates and optimizes the object lifted path for critical/heavy lift objects, and focuses on modular construction. Due to initial data preparation and complexity of the process a scenario base methodology was adopted in this study.

The recommended methodology analyzes all potential trajectory paths first for evaluation if the lift can be performed, and secondly determining the optimum trajectory path that the crane operator can use to lift the object from pick-point to its final location. The success of the presented technique provides a safe and cost effective solution for mobile crane lift of an object, and is expected to be used by planners, lift engineers and construction superintendents to run several user defined scenarios. A case study presented in this paper highlighted essential features of proposed methodology to illustrate its capability. The presented spatial object trajectory development path is one part of much larger crane application software being developed to assist in the crane selection process.

Abstract

Discrete-event simulation (DES) has long been used as a management tool to analyze and study construction processes. Project scheduling is one of its useful applications in construction domain. By simulating the behavior of a production system over time, the DES is able to reproduce the process of how jobs and resources interact with each other. A schedule can then be viewed a record of this artificial history. However, simulation-based scheduling is, more often than not, limited to create the initial schedules. The problem of how to update project schedule based on the current progress is rarely addressed in construction simulation research. This paper presents a state-based simulation approach that can facilitate project schedule updating by (1) reading the starting time (i.e. the point of time to update the schedule); (2) resuming the work load of production system at this time and running from there; and (3) updating the new schedule (from simulation) based on the As-Built project progress. An illustration example is used to illustrate how the new modeling approach is used to perform schedule updating and its benefits are discussed as well.

Introduction

Project planning and scheduling is one of the most important but also most challenging task in project management. Limitations of conventional scheduling tools (e.g. Critical Path Method (CPM))motivate researchers to adopt Discrete-Event Simulation (DES) as an alternative to solve scheduling problems in construction (Zhang et al 2002; Song and AbouRizk 2006; Hu and Mohamed 2009). This is due to its apparent advantages, such as explicitly accounting for resource interactions and handling dynamic and stochastic nature of construction operations.

Many research attempts have been made to develop simulation-based scheduling tools. This includes SimCon (Chehayeb and AbouRizk, 1998); Activity-based simulation model for project scheduling (Zhang et al 2002); simplified discrete-event simulation approach (SDESA) (Lu 2003); Virtual shop model (Song and AbouRizk 2006); Simulation-based scheduling for module yard assembly (Mohamed et al. 2007). However, a review of these tools indicates they are always limited at some point. These limitations can be summarized as following: 1) many of these tool requires users to have significant knowledge about the specific simulation tool before they can apply it to real construction processes ; 2) simulation models (developed by these tools) are usually tied up with one type of network logic (i.e. a set of distinct activities plus their sequences) or just able to allow few variations (e.g. variation in activity duration and etc.); and, more importantly, 3) most of them are not capable of performing schedule updating.

This paper introduces a new state-based simulation mechanism for structuring simulation models. It addresses the limitations described above and provides improvements in each. Particularly, it facilitates project schedule updating by (1) reading the starting time (i.e. the point of time to update the schedule); (2) resuming the work load of production system at this time and running from there; and (3) updating the new schedule (from simulation) based on the As-Built project progress. Scheduling requirements and the current simulation practice are described in the first section, followed by the introduction of the state-based simulation mechanism. The concept "state-based mechanism" and how it supports schedule updating is also explained afterwards. A prototype system is developed based on the proposed mechanism and a simplified case is used to illustrate how the schedule updating is achieved. At the end, both benefits and limitations about this tool are listed and its future improvements are pointed out.

Scheduling requirements

Contractors are often faced with scheduling projects that involves several similar work packages. These work packages usually refer to a construction product or an element that constitutes a part of a larger project. For example, a house unit in a residence project or a pipe spool in an industrial construction project. Each work package is defined with a number of physical features (e.g. identification, type, length, weight and etc.) as well as specific network logic. In a repetitive project or a job shop situation, work packages usually involve very similar or even identical operations. However, perfect repetition is a rare case in the real world. Instead, variations can often be found in work packages. For example, operations might vary in work quantity, production rate and duration. Some operations might not even be involved at some work packages. Moreover, the sequence or precedence relationship between operations might vary significantly as well. In a spool fabrication shop, for example, each spool tends to have a unique routing pattern (i.e. operation sequence) among machines, even though they all involve the same operations—cutting, fitting and welding. In a residential project, some houses might require that windows and roof installation should come before drywall erection; while, for others, the sequence could be reversed. These variations in similar work packages, coupled with

scheduling constraints (e.g. technological constraints, resource constraints and optimality constraints), need to be fully addressed during the scheduling process, which entails that an adequate scheduling tool has to be capable of both enforcing the constraints and, at the same time, having a high level of flexibility to account for variations.

Schedule updating is another major functionality that schedulers expect from a scheduling tool. This is because uncertainty is an inherent feature of construction projects. Bad weather, broken machines or missing materials all have the possibility of delaying the whole project and obsoleting the original schedule. Therefore, it is always necessary to update project schedules on regular basis.

Current simulation practice

The current simulation practice for modeling construction operations seems not fully support these two scheduling requirements. For network logic, it depends on mapping the logic into a flow of operations with duration associated with each and explicitly enumerating all the possible logics (required by different simulation entities) in the simulation model. These logics are usually represented by using a set of connectors and branching elements (as shown in Figure 1). Therefore, as the diversity of network logic increases, the simulation model will get exponentially complicated. As for schedule updating, most of current simulation-based scheduling tools do not support such function. This is because they often contain an implicit rule that scheduling has to start from the very beginning (i.e. no spools are being processed in the fabrication shop or no work packages have been performed by any working crew). Even for the few scheduling tools which do support schedule updating, they still follow this rule. To generate a sound schedule update, they have to manipulate the simulation and force it to 1) run in a way that exactly imitates the As-Built progress and then 2) start scheduling from that point. Although feasible, it is quite an unnatural way of updating schedules.

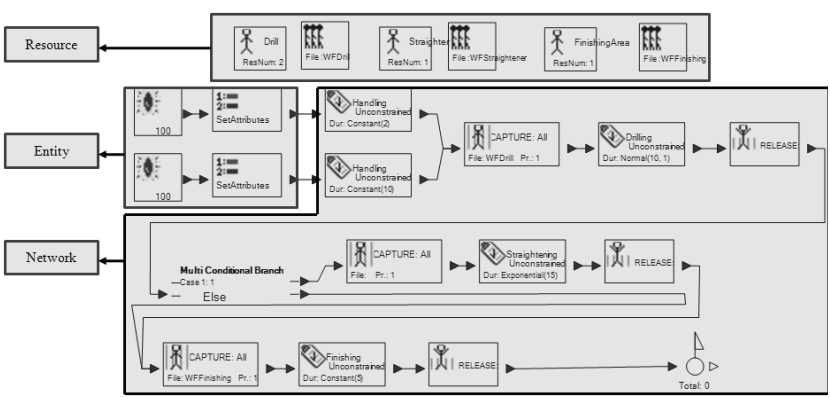

Figure 1 Three fundamental elements for a typical simulation model

State-based simulation mechanism

Declarative modeling approach suggests that a modeller looks at the world through a sequence of changes in state. Declarative models contain two primary components: states and events. They can be embedded within an object and are suitable for representing the dynamics within the object (Fishwick 1995). In the case of state-based simulation mechanism, objects specifically refer to simulation entities (i.e. work packages represented by entities). The state of an object focuses primarily on the completion status of a simulation entity (i.e. how much progress has been made in a work package). As previously stated, each entity is composed of distinct operations. The state of each operation can be simply described by its percent completion (completed portion divided by total work quantity). These states of individual operations, together with their sequence logic, at any point in time constitute the entity state (Figure 2). The state information is updated whenever a state-altering event occurs (e.g. an operation is just finished). These events trigger the transition of the entity state from one to another (until the final state is reached) and therefore drive the entire simulation forward.

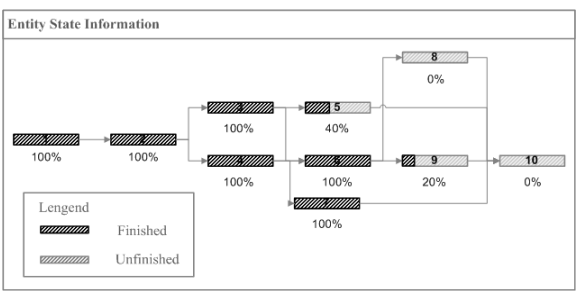

Figure 2 An example of entity state information

A state transition can be accomplished using different mechanisms. The basic types of state-based declarative models are: deterministic, nondeterministic, and production rule/logic (Fishwick 1995). The use of production rule/logic provides more general power, and it is the one chosen for implementation in the proposed framework. The inference rules or logic, which controls the transition of an entity from one state to another, can be expressed by operation constraints (e.g. the completion of all predecessors or the availability of required resources). The rules should have access to state information of its owner entity, so that it can 1) determine which operations can be started right away; 2) notify the entity to update this information when operations are performed. In the prototype system (will be described in later sections) a simulation element called "Dispatching Element" is developed to help entities to access their state information. This element also controls the dispatching of an entity according to the changes in the states of the entity.

Figure 3 shows the general algorithm for state transition in this framework, which is modified from state-based simulation algorithm (Fishwich 1995). Consider a

simulation entity which starts with the same state as in Figure 2. It will first take a look at its current state through the "Dispatching Element" and figure out which operations can be started immediately. In this example, they are operations 5 and 9 (instead of operation 1 again). The "Dispatching Element" will then send the entity to the corresponding operation elements for finishing these operations. After they are done, the state of the entity will be updated. Based on the new state, the entity will analyze which operation can be performed next again (i.e. it should be operation 8 in this case), and the loop will continue until the entity is completely finished.

```
Start simulation
    Set current time to zero
    Set Start state to any state in the automaton
    while not (final state) do
        Scanning current state information
        Identifying activities that can be started (based on activity constraints)
        dispatching entity to corresponding activities
        performing activities and updating current time by ΔT
        updating current state
    End while
End Simulation
```

Figure 3 Entity state transition algorithms

In order to implement the state-based simulation mechanism, simulation model needs to be structured in a different way. More specifically, the network logic will be extracted from the simulation model and carried directly by simulation entities themselves (as shown in Figure 4). This is because the network logic specifies operation constraints, which, in turn, define the state transition of an entity. A product-process integrated entity information model (Figure 5) is developed to help entities contain such information. It consists of four different types of information: 1) product information; 2) process information (i.e. network logic); 3) state information; and 4) schedule information. Equipped with such integrated information model, entities are enabled to route themselves through various operation elements without need of any connectors or branching elements. Therefore, the simulation model is reduced to resource modeling, which is simply a snapshot of the current production system (various workstations in Figure 4). Since each resource is associated with a specific type of operation, behaving as a workstation or a construction crew, it can be modeled by a 'Composite' element (AbouRizk and Mohamed 2000), which has a detailed child model that defines how many resources are available for this particular operation and how it will take place (in Figure 4).

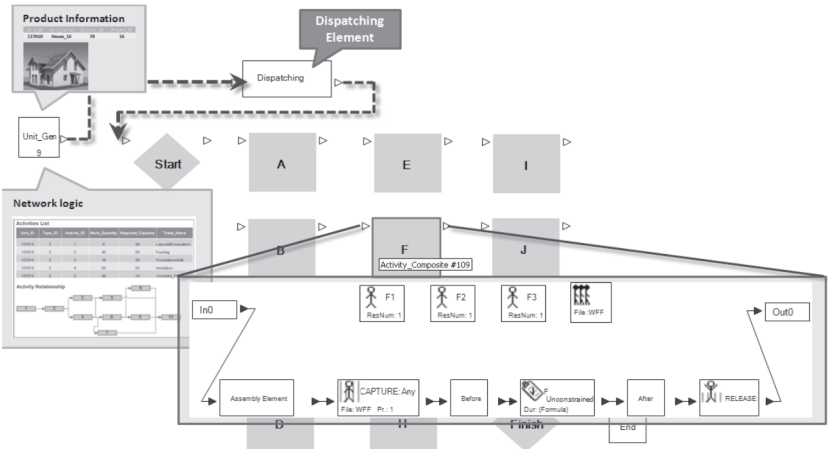

Figure 4 An example state-based simulation model

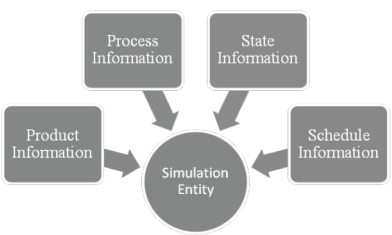

Figure 5 Product-process integrated entity information model

The state-based simulation mechanism allows entities to start simulation based on their current states. This means that if an entity enters the simulation model with a partially completed state, it will be processed precisely as what its state allows it to do, instead of having to start from the beginning again. This also means that the simulation is now able to schedule an entity (or a work package) from any point in its life span (i.e. from 0% to 100% completed). Therefore, if simulation users feed the simulation model with an as-built progress report (i.e. a group of entities with their completion status respectively) of any point of time during the project execution, the simulation can run directly from that point and produce a schedule update based on the report. In addition, the simulation is also endowed with the ability to reconstruct the current work load of a construction system (e.g. either a construction project or a job shop). It is particularly useful to model a situation where the construction system is already loaded with certain work, when work packages enter the system.

Another advantage of using the state-based simulation is that the simulation model becomes independent of entity network logics. No matter what specific sequence an entity choose to go through operations, it can always be simulated as long as all the

relevant operations are included in the model. This flexibility enables the simulation model to handle any type of variations in work packages.

The Prototype System

A prototype system was developed for scheduling construction projects (i.e. mainly refers to repetitive projects or job shops), which integrates with Microsoft Access® and Microsoft Project®. In this system, the simulation model extracts both product and process information (i.e. equal to job information and network logic) from a Microsoft Access® database and loads it onto entities. After running, it produces a schedule or schedule update and sends it back to the database. Meanwhile, a user-defined function was developed in the Microsoft Access® database which translates simulation times into real calendar dates. Finally, this table-format schedule is converted to Gantt chart style by integration between the Microsoft Access® and the Microsoft Project®.

The core component of the prototype system is a simulation model. This system adopts Simphony.Net (AbouRizk and Mohamed 2000) as its simulation platform and develops a special-purposed simulation template (Hu and Mohamed 2009) for simulation modeling. In order to reduce code-writing, the Hybrid Special Purpose Simulation (HSPS) development approach (Mohamed and AbouRizk 2006) is also used to build models.

Sample Application

To illustrate the schedule generating and updating of the prototype system, an example project is created. Assume there are three different types of product units to be constructed. The network logic to build each of them is shown in Figure 6. Variations in these networks should be noted. For example, type 2 differ from type 1 in that Activity E does not occur in it and durations vary in Activity D, G, I and J; while type 3, though involve all the same activities as in type 1, has a very distinct network from the first two types, with significant different sequences and durations in activities. For simplification purpose, all the activities have a deterministic duration. Assume 9 product units are to be processed, each with one of the types mentioned above. The start date of the project is 14/12/2009.

A simulation model is created for this project (Figure 4). After feeding both the product and process information of these product units to the model, it generates an initial schedule for the entire project (solid black bars in Figure 7). Assume that at the end of fifth day (18/12/2009) some progress deviations are found in the project. Table 1 listed all the activities that have progress deviations (i.e. for the activities or units that are not listed here, it means they are not started yet). When inputting this actual progress information (again from the database), the simulation automatically generates a schedule update. A comparison between the initial schedule and updated one is provided in Figure 7 (i.e. the black bars represent initial schedule; while the grey bars represent the updated schedule).

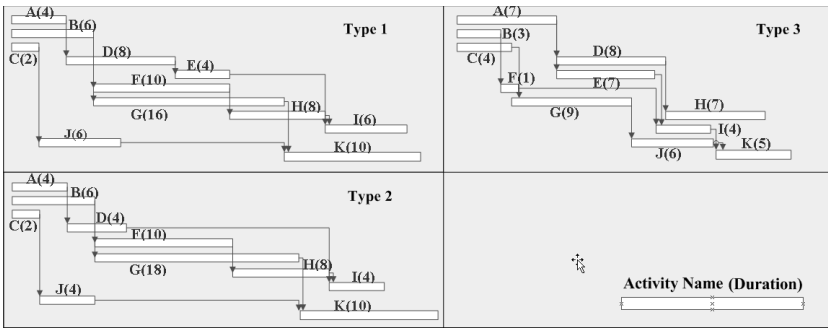

Figure 6 example networks logic for three product types

Table 1 Progress deviations at 28/07/2008

	Activity ID	Activity Name	Original Schedule	Actual Progress	Schedule deviations
Unit 1	1	A	100.0%	100.0%	on time
	2	B	83.3%	50.0%	2 days behind
	3	C	100.0%	100.0%	3 days behind
	4	D	12.5%	12.5%	on time
Unit2	1	A	100.0%	100.0%	on time
	2	B	83.3%	50.0%	2 days behind
	3	C	100.0%	100.0%	3 days behind
	4	D	25.0%	25.0%	on time
Unit 3	1	A	14.3%	14.3%	on time
	2	B	100.0%	100.0%	2 days behind
	3	C	75.0%	0.0%	3 days behind
Unit4	1	A	14.3%	14.3%	on time
	2	B	66.7%	0.0%	2 days behind
	3	C	75.0%	0.0%	3 days behind

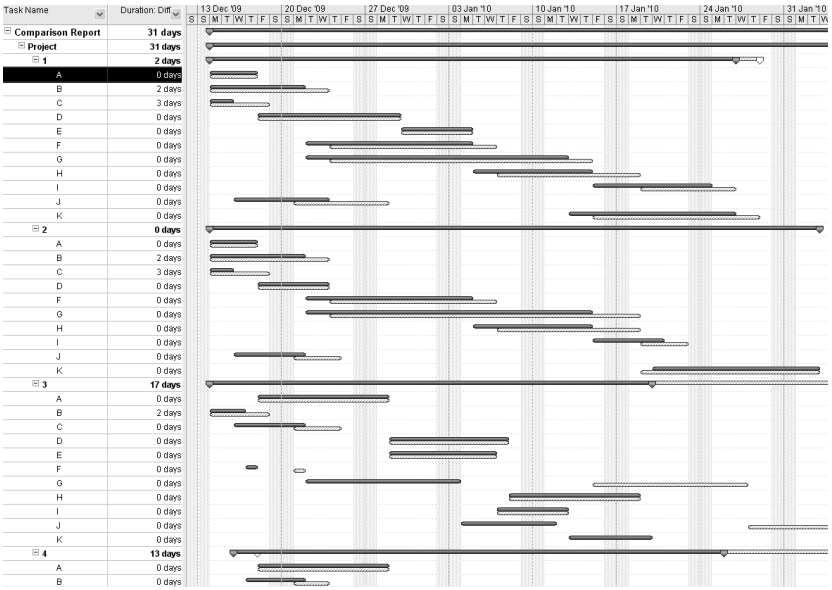

Figure 7 Initial schedule VS. Updated schedule

Conclusion

This paper presents a new way of structuring a simulation model. By providing simulation entities with an integrated product and process information model and a state-based simulation mechanism, the simulation model lends itself to an ideal scheduling and schedule updating tool. Meanwhile, it also obtains high level of flexibility in handling network logic variations, which is a limitation in most of current scheduling tools. The simplification of the simulation model, plus the opportunity of defining network logic outside simulation, makes this simulation-based scheduling approach user-friendly. Future development of this approach includes integration with other information systems and the optimality of schedules under work continuity or cost minimization.

Abstract:

Construction projects consist of multiple components such as on-site equipment resources, site layout, labor productivity, unexpected external events, and human decisions regarding resource allocation and activity rescheduling. Stochastic spatial and temporal interactions between those components result in dynamic complexity of construction projects. Decisions made in such dynamic task environments must consider both immediate impacts and long-term dynamic feedback. The objective of this research is to use the adaptive interactive simulation framework as an experimental test bed to study dynamics of decisions in construction scenarios. A simulation of a four story structural steel framed office building project was implemented within Interactive Construction Decision Making Aid (ICDMA) under five different decision strategies. Simulated construction performance data at each decision control point was collected and analyzed to compare the project dynamics resulting from five strategies, and those strategies were assessed as well. This research provides a perspective to study dynamics of decision making through interactive simulation while furthering the knowledge of effective decision making and the development of dynamic decision support systems in construction management.

Introduction

Decision-making in construction projects involves the management of multiple inter-related components such as site layout, critical equipment resources, labor productivity, unexpected events, resource allocation and rescheduling of activities. Uncertainty associated with each of these quantities, and the evolving relationships between them within the constraints of time and space are at the root of complexity in project management. Accounting for this complexity is critical to effectively plan for

contingencies and test the usefulness of alternative decision-making strategies. However, predicting the consequences resulting from such complex behavior is difficult as they are often emergent within dynamic contexts. We argue that interactive adaptive simulations provide experimental platforms to test and compare the sensitivity of the project plans and estimates to alternative decision strategies and dynamic project complexities (Watkins 2008, Mukherjee et al. 2009). In this paper we propose and illustrate a methodology for studying dynamic complexity in construction management using interactive simulations as an experimental testbed.

This research uses relevant research in construction decision-making using System Dynamics, interactive simulation, and Markov decision process as a point of departure. The Dynamic Planning Methodology (DPM) uses concepts and methods in System Dynamics (SD) to account for dynamic feedbacks in the planning and control of fast-track construction projects. (Park and Pena-Mora 2009, Pena-Mora and Park 2001, Lee et al. 2006). Interactive simulations such as RiverWare (Biddle 1999) have also been used to aid real-time optimization of water resource system operations, for developing training programs for system managers and technicians, and in demonstrating system management alternatives (Cunningham and Amend 1984; Cunningham and Amend 1986). Among other methods, Ioannou (1989) uses Markov decision process for the solution of the risk-sensitive dynamic decision problems.

Each of these methods studies decision-making as a choice between de-contextualized management strategies – accounting for uncertainties in long-term behavior, and models of cause-effect relationships. In this research we take the next step by developing a method that can be used to analyze and compare the evolution of outcomes associated with different decision-making strategies. A project specific implementation of a general-purpose interactive simulation environment the Interactive Construction Decision Making Aid (ICDMA) is used as an experimental platform to illustrate the method, specifically emphasizing the data collection and analysis process. The method is the contribution of this research – it can be used to gain insight into the behavior of specific simulated projects. The results of the analysis can be used to enhance the planning of contingencies during the pre-construction process – especially in the management of complex construction projects with limited historical precedence.

ICDMA Simulation and Methodology

ICDMA is a specific implementation of a general-purpose interactive simulation framework (Rojas and Mukherjee 2006, Watkins 2008). It simulates a construction project based on the as-planned schedule and costs as defined in a web-based database. The user of the simulation takes on the role of construction manager/ primary decision-maker whose goal is to complete the project on schedule and under budget. During the simulation run, the user is presented with random external events that force the simulated project to deviate from its original plan. The user has to respond to those events by making decisions on resource allocation. The consequences from the decisions result in new scenarios for the user to respond. This process continues until the completion of the simulated construction project.

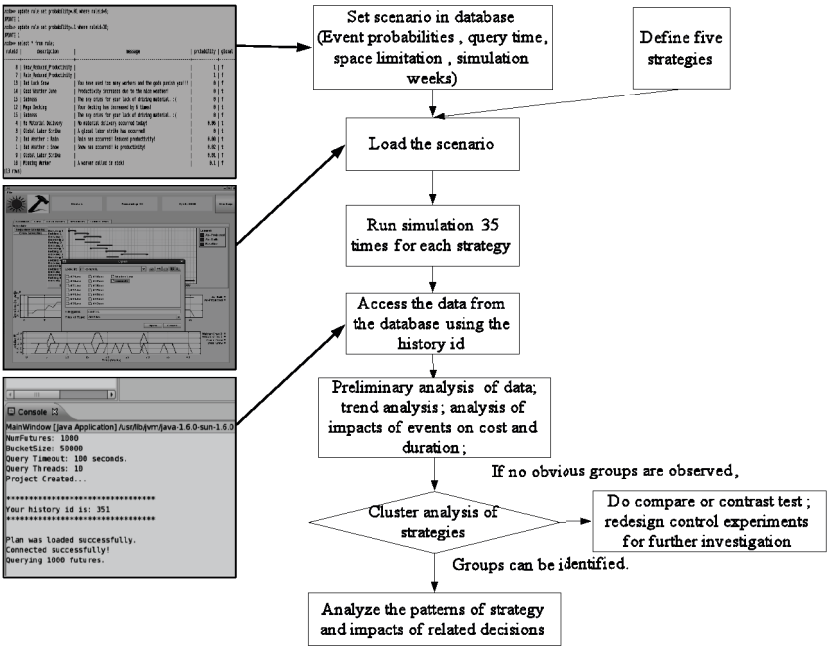

Figure 1 Flowchart of Methodology

ICDMA implements the construction of a four-storey structural steel framed office building that was built in real life. The simulation was based on the schedule and construction information documented by Daccarett and Mrozowski (1999). In previous work we have shown that the underlying construction models in ICDMA is capable of simulating the as-built performance of the actual project as described in Anderson et al. (2009). The research also illustrated the use of the querying algorithm, in ICDMA, to forecast likely project outcomes from any point in the project using current project information. A space of *possible* project outcomes consisting of future traces under varying conditions, constraints and decisions were generated and analyzed using a Monte Carlo sampling method. Each candidate in the future space is a complete simulation trace of the project. The *actual* project outcome was the most likely scenario in the space of possible outcomes.

In effect, the querying algorithm forecasts the likelihood of future scenarios and outcomes by *querying* a space of simulated project futures. In this paper, we take the next step in investigating the application of ICDMA and the querying algorithm to compare alternative decisions by statistically analyzing and clustering the simulated future outcome space. Specifically, a *potentially problematic* scenario is established and different control strategies to deal with its resolution are explored in an interactive simulation mode. The application of this research is during the pre-planning and planning phases of complex construction projects.

The scenario was set-up by simulating the office-building project to 14 days in the future. At this point, the project was behind schedule. External events expected in the project's future were rain (major weather), snow (extreme weather), labor strike, no material delivery, and worker sick. Their respective probabilities were set at 0.08, 0.02, 0.01, 0.06, and 0.10. Hence, the probability it will rain is 0.08 each time the simulator is advanced by one time unit. In addition, the space capacity was set to 3,000 units. If the space occupied by the material exceeds this limitation, a space conflict event occurs. These probabilities are specific to the project at hand and the investigators using the simulation can choose appropriate values to reflect the circumstances of their projects.

Once the scenario is set up, decision strategies are established and the simulation is run in the interactive mode using each of the strategies for a period of concern. During the simulation run, the decision-maker is required to manage the project by making decisions that specifically adhere to the strategy under investigation. In this research the window of concern was considered to be 6 days from day 15 to day 21. Hence, the decision-maker was allowed to implement control measures adhering to each strategy 6 times, once at the end of each day (details on strategies and data collection follow). Thirty-five such simulations were carried out for each of the decision strategies. During the simulation construction performance data at each decision control point was collected and stored in a database, organized by the history ID of each simulation run. The data is analyzed to compare the project dynamics resulting from five strategies. Figure 1 presents a flow chart of the methodology discussed.

A decision strategy is defined as the guideline and direction that provide the basis for a family of decisions towards achieving a project outcome. Five strategies are defined and implemented in ICDMA in this paper. Future studies using this method could choose a different set of strategies to reflect the reality of the project being simulated. A *control strategy* is used to reflect baseline conditions and the other four strategies are chosen as alternative approaches to managing the project at hand. In this case, the control strategy aims at completing the project by adhering closely to a baseline decision sequence. The *crash strategy* tries to crash the schedule to save time. The *reassign strategy* aims to optimize the project by prioritizing activities on the critical path. The *safety strategy* aims at reducing the risks due to delayed material delivery by ordering materials ahead. The *catch up* strategy tries to catch up with the schedule when it falls behind. It is important to note that the strategies make no direct adjustments for bad weather, global strike, and material delivery failure. The strategies were coded to respond to the consequences of the events rather than to the occurrences of the events. Detailed descriptions of the guidelines provided by each of the decision strategies are shown in Table 1.

Data Collection

Data was collected at the end of each simulation time point. The categories of data collected include: (i) Outputs of the querying algorithm including a set of simulated future spaces (set size = 1000) and a frequency distribution of final cost and duration outcomes of the simulated projects, and (ii) Metrics (as described below) defining the project status and specific decisions that were taken at the end of each decision control point. These data sets were collected after each of the 6 decision control

points for 35 runs per decision strategy. Hence a total of (6 x 5 x 35=) 1050 data sets were collected.

	Labor& material allocation	**Policy on Space Conflict**	**Material policy**	**Labor policy**
Control Strategy	Do not crash.	Reduce material inflow uniformly on all activities.	Do not order materials ahead.	Do not recruit workers if they call in sick.
Crash Strategy	Crash critical activity.	Allocate the space from non critical activities to the most critical activity.	Do not order materials ahead; Order more material on the most critical activity.	Recruit workers if they call in sick; Recruit more labor on the most critical activity; One crane operator must be ensured.
Reassign Strategy	Crash critical activities.	Reduce material inflow uniformly on noncritical activities; Do not reduce that on critical activities.	Reassign resources from noncritical to critical activities; Never order materials ahead.	Recruit workers if they call in sick.
Safety Strategy	Do not crash.	Reduce material inflow to 150% of normal on critical activities and uniformly on noncritical activities; Reduce uniformly if all are critical.	Order materials ahead on critical activities as a buffer.	Recruit workers if they call in sick.
Catch Up Strategy	Crash critical activities.	Reduce materials on non-critical activities uniformly, and never reduce material on critical activities.	Do not order materials ahead; Order more material on the most critical activities.	Recruit workers if they call in sick; Recruit more labor on the most critical activities; One crane operator must be ensured.

Table 1 Strategy Description

Description of the metrics collected from the simulation to describe the status of the project and the decisions taken at the end of each day are:

Labor data: (1) Number of laborers assigned per plan for each activity (unit=person); (2) number of workers who actually worked for each activity (unit=person).

Material data: (1) Number of materials assigned per plan to be installed (unit varies); (2) number of materials actually installed (unit varies); (3) number of materials not used and stored due to reduced productivity (unit varies).

Space data: (1) Space that has been used on site (unit=square yards).

Cost data: (1) As-planned labor cost (unit=$); (2) as-built labor cost (unit=$); (3) as-planned material cost (unit=$); (4) as-built material cost (unit=$); (5) as-

planned indirect cost (unit=$); (6) as-built indirect cost (unit=$); (7) predicted cost for entire project (unit=$).

Duration data: (1) Predicted duration for entire project (unit=day).

Activity data: (1) Activities that are being current – and schedule status.

Decision data: (1) Number of extra laborers recruited (unit=person); (2) actual number of materials that has been ordered (unit varies); (3) Percentage of schedule duration reduced; (4) Material and labor production rate in percentage - work schedule and increased labor budget in hours and percentage; (5) Activity priorities; (6) Decision time to judge the project condition (unit=second); (7) Decision time to response to the events (unit=second).

Events data: (1) list of external events that occurred.

Dynamic Decision Making Analysis

This part describes how the data collected from interactive simulation can be used to study the dynamics of decisions specifically how the decisions for each of the five strategies influence long term behavior of the construction project.

Preliminary Data Analysis: For each strategy, 35 simulation runs are carried out. The average costs and durations of those 35 simulation runs from day 15 to day 21 reflect how the system responds to the strategies. Since the costs and durations are represented by the frequency distribution, their expectations are calculated by approximating the frequency distribution into a probability distribution. The expected value of predicted costs and duration from day 15 to day 21 under five strategies are shown in Figures 2 and 3.

The horizontal axis in Figure 2 and 3 is the simulation time (unit=day), and the expected values of predicted duration and costs are on the vertical axis (unit=$ for cost and unit=day for duration). Figure 2, shows that as the simulator advances, the predicted costs and durations for the entire project decrease except for decisions made using the reassign strategy. Two explanations are offered for this general declining trend in cost and duration. One is that the temporal constraints (including activity relationships in the simulated project) are more complicated towards the beginning than towards the end of the project. As all decisions have a cascading impact on the schedule, the project status near the completion is less affected as, more activities are temporally connected earlier in the schedule. The sooner the decisions are made and events occur, the greater the impacts on the temporal constraints, resulting in a higher costs and longer durations. The second reason is that the occurrence of external events decreases as the project evolves. As the remaining duration is reduced, the probability of external events in future reduces, thus reducing the cost to mitigate the impacts.

Comparing cost data between control strategy and safety strategy indicates that ordering the materials ahead could help reduce both project cost and duration. From Figure 2, it can be seen that the control strategy is less cost efficient than the safety strategy. The difference between the two strategies is that material is ordered ahead under safety strategy. Without materials in stock, the project would be delayed in case of material delivery failure. Figure 3 also illustrates that predicted remaining durations after each day under safety strategy are shorter than that under control strategy.

Increasing resource input into more than one critical activity at one time seems to be more efficient in minimizing cost and duration. The differences in those two strategies are that only one critical activity could be crashed under crash strategy while more than one activity could be crashed under the catch up strategy. In Figures 2 and 3, the predicted cost and duration under catch up strategy is lower and shorter than that under crash strategy. However, the following cluster analysis shows that this assumption depends on how the non-critical activities are implemented.

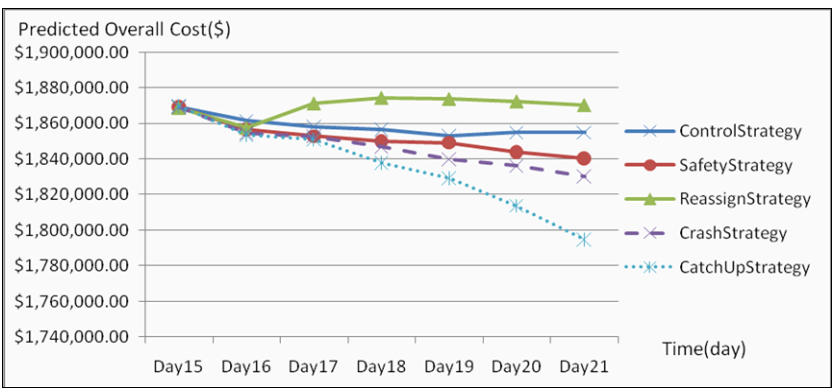

Figure 2 Predicted Project Cost from Day 15 to Day 21

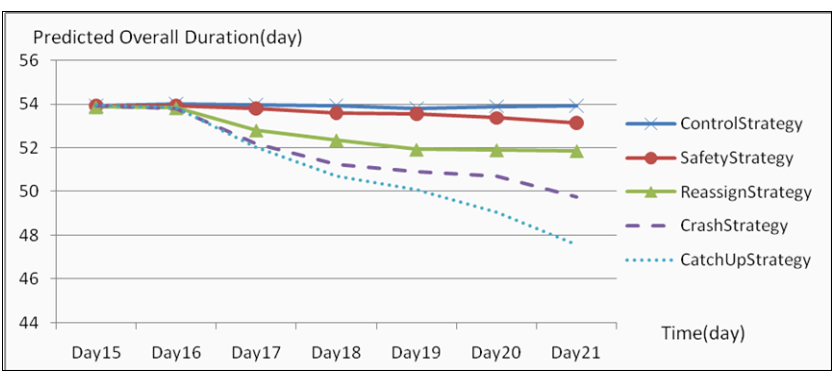

Figure 3 Predicted Project Duration from Day 15 to Day 21

Studying strategy groups might be meaningful because similar outcomes might have common behavior or mechanisms that drive them. From the project expenditures and durations under different strategies, we can see that control strategy, safety strategy, and crash strategy have similar outcomes and can be considered to be in the same group in Figure 2. Catch up strategy and reassign strategy offer distinctly different trends. In Figure 3, control strategy and safety strategy can be considered in

the same group. Catch up strategy and crash strategy offer different trends. It is difficult to classify the reassign strategy only based on Figure 3. Hence, the next step in the analysis is to conduct a cluster analysis to group strategies with similar outcomes.

Hierarchical Cluster Analysis: Cluster analysis is an exploratory data analysis tool aimed at sorting different objects into groups so that the degree of association between two objects is maximal if they belong to the same group (Aldenderfer and Blashfield, 1984). Cluster analysis is used to discover how outcomes from the simulation form associative groups. We used the Statistical Package for the Social Sciences (SPSS) to implement cluster analysis. The variables used on the cluster analysis were the expected values of the predicted cost and duration for the project from day 15 to day 21. The expected costs predicted in each day are chosen as variables and the cases are labeled by strategies.

A dendrogram was chosen to illustrate the forks between each of the simulation runs to indicate formation of coherent clusters. Ward's method was used to create clusters because it minimizes the sum of squares of any pair of clusters to be formed at a given step. (Aldenderfer and Blashfield, 1984). Z-score was chosen to standardize the data to eliminate the affects of the variance of variables.

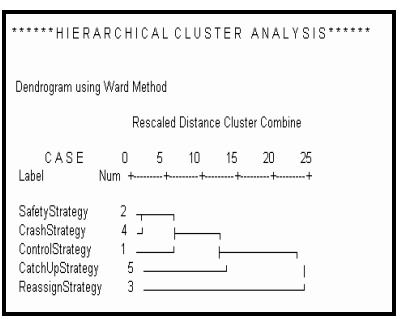

Figure 4: Cluster result with respect to cost

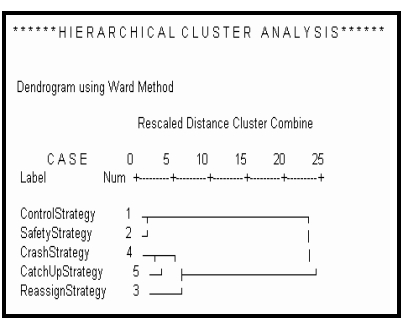

Figure 5: Cluster result with respect to duration

The dendrogram in Figure 4 was created using final project cost outcome. The safety and crash strategies are the most similar and are in one group. The control strategy is closer to that group than catch up strategy and the reassign strategy. Thus, the first group includes safety strategy, crash strategy, and control strategy while the catch up strategy and the reassign strategy are in the second and third group as what we have predicted from Figure 2. The dendrogram in Figure 5 was created using final project duration. The strategies can be grouped into two clusters. The first cluster includes control strategy and safety strategy, and the second cluster includes crash strategy, catch up strategy, and reassign strategy. Within the second cluster, two sub-clusters emerge. The first sub-cluster consists of the crash strategy and the catch up strategy, and the second sub-cluster consists of the reassign strategy. The sub-clusters provide a more nuanced perspective on the differences between the strategies.

Comparisons between those groups from duration data indicate that increasing labor and resource input on the critical activity reduces duration, even if its impacts on cost may vary. Critical variances between the first strategy group consisting of the control strategy and safety strategy, and the second strategy group consisting of the other three strategies, are that the later group has more labor and resource inputs on the critical activity. From Figure 2 and 3, the second group is more efficient in minimizing duration than group one.

However, whether a strategy is cost effective depends on how many non-critical activities are completed. The differences between the first strategy sub-cluster and the second strategy sub-cluster under the second strategy cluster in Figure 5 are that noncritical activities are impacted when resources are moved from noncritical to critical activities under the second strategy sub-cluster, while noncritical activities are hardly impacted under the first strategy sub-cluster. These differences show that increasing labor and resource inputs on critical activities is cost effective, as long as labor and material inputs into noncritical activities are not ignored. When the labor and material inputs are moved from noncritical activities to critical activities, critical activities are crashed while increasing the duration of noncritical activities. Beyond a threshold, the durations of the non-critical activities increase to the point where they become critical, incurring more indirect cost. This explains why the trend of cost under the reassign strategy is rising in Figure 2, and this is in the third strategy group in Figure 4.

Conclusions and Future Work

Preliminary data analysis together with cluster analysis indicates that it would be efficient to manage construction projects by (a) ordering the materials ahead; (b) increasing labor and material input on all the critical activities while ensuring the labor and material inputs into noncritical activities as well. While these results are specific to the project investigated, they reflect measures that contractors often use in practice, indicating the feasibility and usefulness of the proposed methods in studying the dynamics of decision-making. It is also indicated that it is important to study the overall project specific effects of fixed strategies and a good strategy will be a combination of the fixed strategies.

It is important to note that this paper provides only a preliminary investigation of the data. Further statistical analysis will need to be carried out to understand the time lags over which decisions have impacts. In addition, future research will provide enhancements to the simulation so that it can represent adaptive bottom-up influences resulting from labor and equipment interactions on site. These influences are critical to investigating and identifying dynamic feedbacks associated with alternative decision strategies. Future work also includes studying the similarities and differences between simulation results and the expectations according to general principles in construction management.

Finally, while this research is presented in the context of construction decision-making, the platform provided and the method proposed is extensible and can be applied to study decision-making in other temporally and spatially constrained dynamic task environments.

Abstract

One of the keys to successful safety management is establishing a strong safety culture within a company. Because workers' behavior is influenced by the workers themselves, by their supervisors, and even by the top managers, understanding the dynamics among them is beneficial for establishing and sustaining a culture of safety on a project. To model safety dynamics, we review the literature for the relationship between a worker's personal care for safety and a strong safety culture. We also investigate, from the perspective of resilience engineering, how an organization can perceive a change in the safety culture and restore safety to an acceptable state. As a result, a conceptual system dynamics model is established for qualitative analysis, and the analysis reveals that the model can be applied to establish a resilience system for safety management and used to predict organization's future risk. Thus, a practical application of theories on a safety culture is presented, and with the model, managers can monitor the safety culture as arising from an interaction among workers,

managers, and the organization, and can improve safety based on an organizational perspective.

Introduction

Because of the relatively high fatality rate in the construction industry (Bureau of Labor Statistics 2007), safety is a top priority on construction sites. In an effort to improve site safety, research on accident causation has been actively conducted, and accidents have been found to be strongly correlated with management actions during a project (Hinze 1997); that is, accidents can be reduced by consistent safety management (Sawacha et al. 1999, Heinrich et al. 1980). Although safety management implicates various aspects, such as site layout, inspection, communication, human factors, safety training, and education, recently a safety culture has been emphasized as one of the crucial factors that contribute to an improvement in safety (Choudhry et al. 2007).

In that respect, modeling a safety culture would help workers understand the concept of a safety culture and its impact on the occurrence of accidents. Because workers' behavior and attitudes toward safety can be either self-motivated or motivated by supervisors, site managers, or even top managers, understanding the interaction among them plays a key role in establishing a strong and positive safety culture. Therefore, safety culture modeling would contribute to an understanding of the interactive relationship among them and lead an organization to create and maintain a safety culture. Moreover, to control an organization's state of safety in a safety culture, the concept of resilience engineering can be modeled and then adopted because the approach enables an organization to respond to changes and recover a state of safety (Schafer et al. 2009). To measure an organization's state of safety and its safety performance, leading indicators available for a safety culture are reviewed and are then integrated into this model.

To develop a model of a safety culture, the definitions of a safety culture and a safety climate first need to be mentioned to distinguish between the two concepts. The term *safety culture* has been defined by many researchers, but in this paper, the definition provided by the Health and Safety Commission (1993) is used; "the product of individual and group values, attitudes, perceptions, competencies and patterns of behavior that determine the commitment to, and the style and proficiency of, an organization's health and safety management." In addition, the term *safety climate* is defined as "a summary of molar perceptions that employees share about their work environments" (Guldenmund 2000, as cited in Zohar 1980). Thus, the term *safety culture* is used in this paper to represent psychological as well as managerial factors, whereas the term *safety climate* emphasizes workers' perceptions of safety.

Leading Indicators

Measuring safety performance is important but challenging in construction safety management. Methods to measure safety have been studied and applied on construction sites, but most of the traditional methods have been based on retroactive data, referred to as *lagging indicators*. Lagging indicators, such as incident rate or EMR (Experience Modification Rate), are not appropriate measures to evaluate current performance and prevent future accidents (Herrera and Hovden 2008). Statistical data illustrate an organization's historical performance or an industrial trend so that the information can be reviewed as a reference. However, the data have limitations when used as indicators for proactive management because statistical data do not accurately reflect site conditions and the progress of projects on each site. Thus, *leading indicators* have recently been adopted to identify and control the risk involved in certain construction activities.

A leading indicator is "an observable characteristic of an operational unit, presumed to bear a positive correlation with the safety of the system," and it has specific, measurable, achievable, relevant, and timed characteristics (Herrera and Hovden 2008, as cited in Holmberg et al. 1994 and Blackmore 1997). To apply the concept in practice, it is necessary to identify which factors can be leading indicators and how they are to be measured. Research has recently been conducted to identify leading indicators. For example, the Office of the Federal Safety Commissioner (OFSC) (2008) studied indicators that contained such characteristics and classified them into five categories: planning and design, management processes, risk management, psychosocial working environment, and monitoring, and Halama et al. (2004) recommended a "top 10" list of practical leading indicators among 300 available indicators. The leading indicators related to a safety culture are presented in Table 1 along with their methods of measurement.

Resilience Engineering

Resilience engineering is a proactive management approach that allows future risk to be anticipated and the safety level in an organization to be maintained, based on perceptions of current and changing safety levels and recognition of acceptable limits.

Table 1 Leading indicators for a safety culture (extracted from OFSC 2008 and Halama et al. 2004)

Leading indicator	Measurement
Worker's behavior	Behavior-based observation
Employee's perception	Corporate culture survey, productivity survey, and safety survey
Schedule delay	Number of days behind schedule
Management participation	Number of tours, walkabouts, or written communications
Safety committee meetings	Number of safety committee meetings held for a minimum duration within a specified time frame
Toolbox talks	Number of toolbox talks conducted during a time period
Safety education	Percentage of employees who have received site-specific safety education
Supervisor inspection	Number of supervisor inspections completed
Worker's involvement	Near miss and near hit reporting
Workplace inspection	Number of inspections by managers and OSHA representatives
Hazard	Percentage of reported hazards rectified within the defined time frame
Competence	Prehire screening of employees
Safety training	Number of employees or managers that have completed OSHA training

Beyond the conventional perspective that human errors and unsafe physical conditions cause accidents, it is necessary to control safety by predicting hazards and planning for the organization to recover safety to an acceptable state, just as the load in a stress-strain curve should be in the elastic zone to prevent the deformation of materials (Sheridan 2008). This approach provides a new direction in safety management, and the concept of resilience has recently been adopted in the construction industry (Schafer et al. 2009).

To establish a resilience system, therefore, the following three attributes are required: situation awareness, management of keystone vulnerabilities, and adaptive capacity (McManus et al. 2008). Because situation awareness is a starting point for a resilience system, leading indicators have potential application to measure an organization's current state in a resilience safety system, and it was also studied by Herrera and Hovden (2008) that monitoring the indicators facilitate the recognition of normal performance. Therefore, the leading indicators shown in Table 1 can be implemented as inputs to establish a resilience system for safety culture management.

The management process of a resilience system is presented in Figure 1. Similar to other key controls, such as cost, schedule, and quality, safety management involves initiating a project target that determines safety priorities and acceptable risk levels. Leading indicators and their methods of measurement are then identified to measure safety performance, and the measured indicators are scaled to apply to a safety culture model. Through analysis of the model, an organization's state of safety is identified and compared with the initial project goal. If the state is unacceptable, corrective management actions should be taken, and the project target for the safety level is replaced, based on the current state of safety.

System Dynamics Modeling for a Safety Culture

A system modeling approach takes advantage of an efficient understanding of critical factors and their interactions in complex systems over time; hence, this modeling methodology has been applied for various construction systems, such as schedules and productivity (Peña-Mora and Park 2001), quality and change management (Lee et al. 2005), and accident causation modeling (Mitropoulos et al. 2005). Because a worker's personal care for safety influences other coworkers' attitudes, and the aggregated climate in turn affects each individual worker, the factors affecting workers and their interactive relationship could cause a hazardous situation.

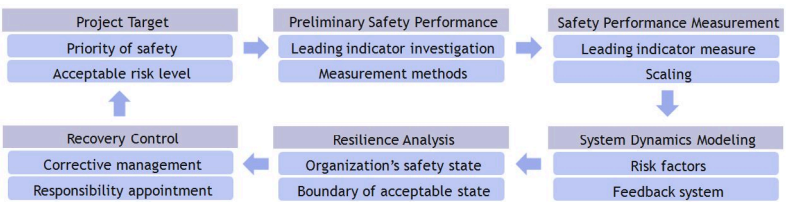

Figure 1 Resilience system management process

Moreover, the safety culture has an impact on a worker's behavior, and the attention top managers pay to safety may also increase when risk is perceived, or especially when an accident occurs. Therefore, it is hypothesized that a system model for a safety culture would contribute to understanding this complex correlation and be able to locate hazardous factors. The result is presented through a system dynamics model.

Cooper (2000) stated that a safety culture consists of three components—the person (safety climate), the behavior (safety behavior), and the situation (safety management system)—and that the three interact. Based on the model by Cooper (2000), the safety culture model proposed in this paper is divided into four components: (1) a person subsystem, which leads to participation in safety improvement; (2) a behavior subsystem, whereby the person subsystem affects the safety climate by participating in safety improvement; (3) a management subsystem, which represents factors affecting the efficiency of safety climate management; and (4) a measurement subsystem, which is used for performance evaluation (i.e., leading indicators).

First, the person model is based on the path model proposed by Goldberg et al. (1991), which illustrates the relationship between the safety climate and a worker's attitude. As shown in Figure 2, a positive safety climate increases a worker's motivation to engage in safe acts and promotes safety knowledge by disseminating instructions, which eventually lead the worker to participate in safety improvement. Furthermore, perceived risk increases anxiety and brings attention to safety issues, and this attention also increases the participation of the worker. This relationship was also adopted in the model by Choudhry et al. (2007). Second, the behavior model is based on the psychological courses of behaviors studied by Neal and Griffin (2009).

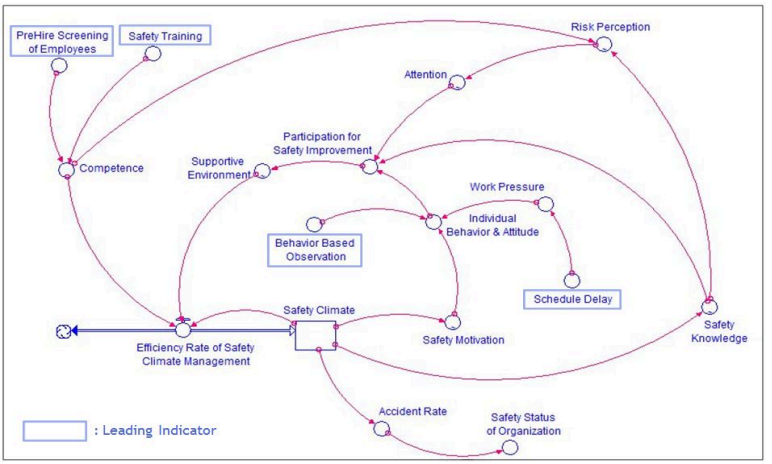

Figure 2 Simplified model of resilience system dynamics for a safety culture (based on the models of Cooper 2000, Choudhry et al. 2007, Goldberg et al. 1991, and Mohamed 2002).

An individual's motivation has a mutual relationship with safety participation, and increased motivation leads to an improvement in the individual's safety behavior and in the safety climate within a group. Third, the management model was extracted from a study by Mohamed (2002). In that study, factors affecting a safety culture were examined, and relationships among them were established. The last model shows how the leading indicators can be implemented for a system dynamics model. These indicators are used to measure the management factors and will be used as inputs for analysis.

Analysis

Through analysis of the system dynamics model, it was aimed to investigate (1) whether the leading indicators researched in the literature would work properly as leading indicators, (2) how the result from the simulation might provide insight into the relationships among components in the model, and (3) what impact the leading indicators would have on an organization's state. The first graph in Figure 3 shows the relationship among the variables *safety state of organization* (line 3), *safety climate* (line 2), and *individual behavior & attitude* (line 1), which were measured by the leading indicators *behavior based observation* and *schedule delay*. The result indicates that the variable *individual behavior & attitude* is strongly related to the variables, *safety culture* and *safety state of organization,* because the behavior of the variables has a similar shape in the graphs. Accordingly, although other factors, such as technical or environmental effects, were not considered in computing *accident rate* in this model, the result illustrates how these factors interact with each other.

Moreover, the variable *individual behavior & attitude* precedes the *safety state of organization* in terms of time; for example, line 1 (*individual behavior & attitude*) increases before line 3 (*safety state of organization*) begins to increase. Therefore, it may be presumed from this result that the leading indicators (i.e., *schedule delay* and *behavior based observation*), which were used to evaluate the variable *individual behavior & attitude*, can be used as leading indicators because the behavior in line 3 is predictable from the indicators. For example, if a leading indicator moves to follow an organization's safety state, this would mean that the leading indicator does not anticipate the state of the organization, so it is not a leading indicator.

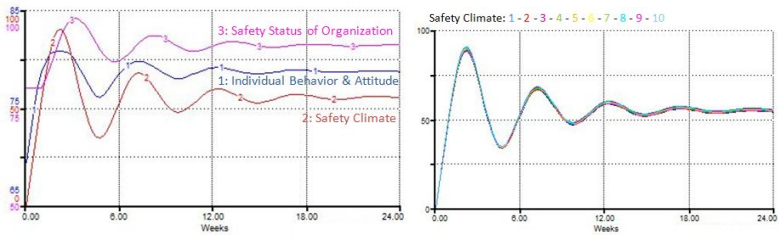

Figure 3 Simulation results: Relationships among leading indicator, safety culture, and organization's safety state (left) and Sensitivity analysis of behavior-based observation (0-100 with interval 10) to the safety climate (right).

Although the first diagram in Figure 3 shows the feasibility of using these leading indicators and their relationship, the second diagram illustrates the sensitivity of the *behavior based observation* indicator to the variable *safety climate*. The result is that *behavior based observation* does not have a significant influence on *safety climate*. This is because the model is based on the one proposed by Mohamed (2002), which consists of 10 factors affecting the safety climate, and the path coefficient of the behavior-related factor is not significant in the model. In this respect, a system dynamics model is a useful tool for a resilience system because it describes the correlation of factors and their effects on the organizational state as well as the feasibility of using the leading indicators identified previously.

Conclusion

This paper attempts to present that system dynamics modeling has the potential to be used to establish and maintain a resilience safety system. The concept of a leading indicator was introduced, and the leading indicators related to safety culture were presented through a literature review. Because the leading indicators can be used to evaluate the current safety performance, they would have synergy when combined with the concept of resilience engineering, which emphasizes proactive management. By integrating all the concepts into a system dynamics model, it was possible to analyze the feasibility of using the leading indicators identified previously, the factors related to a safety culture, and their impact on the safety state of an organization. In this paper, all the data were based on a literature review, so future work will focus on

validation to confirm that factors related to a safety culture work in the real world, as studied in this paper, and the time delay among factors will also be investigated thoroughly to identify the impact of the leading indicators on an organization's state of safety in terms of time. The model presented has such limitations, but this paper suggests that the system dynamics model has the potential to be applied for resilience engineering. With this model, it would be possible to identify the safety state of an organization and factors affecting that state. When an organization is not in an acceptable state, corrective management actions can be drawn from an analysis of those factors that expedite to increase the risk level of an organization. It is therefore expected that with this model, stakeholders would understand the concept of a safety culture in terms of the interaction among workers, managers, and the organization, and would make a decision for safety based on an organizational perspective.

ABSTRACT

Increasing performance pressure has forced modern construction enterprises to seek growth while dealing with inherent complexity of the construction business. Business complexity (fragmented business mode, organizational complexity, etc.) has been considered a major source of performance issues in the construction industry. Unfortunately, there has been no efficient way to estimate its effects on organizational or project performance. This paper proposes a simulation-based organizational analysis platform called "Virtual Organizational Imitation for Construction Enterprises" (VOICE) to assess and manage business complexity of construction enterprises. A series of Agent-Based Models (ABM) were built using Repast Simphony to explore the relationship between social behaviors, organizational factors, and emergent organizational and project performance. The platform allows decision makers to simulate individual social behaviors, organizational structures, and environmental aspects of construction enterprises. Initial findings show that these factors affect the final performance of construction enterprises to an extent. As a socio-technical system, business complexity should be understood, assessed, and managed well. Results indicate that VOICE is a reliable platform to capture patterns of business complexity.

1. INTRODUCTION

Construction enterprises are currently suffering serious performance issues: productivity keeps dropping (Teicholz et al. 2001); time/cost overruns are common (Flyvbjerg et al. 2003; Bordat et al. 2004); and the business failure rate ranks 2nd highest among 10 major American industries (Knaup and Piazza 2007). New technologies and sophisticated project plan/control approaches (CPM/PERT, etc.)

have been applied to improve project accountability and efficiency. However, there is evidence that Critical Success Factors (CSFs) of projects have moved from "purely technical system and traditional cost-time-quality constraints" to "a combination of social and technical systems" (Mengesha 2004). The literature has pointed to organizational factors as main drivers causing performance issues, such as "internal administrative and procedures factors" (Arditi et al. 2000), "fragmented business mode of construction industry" (Teicholz 2004), "business practices and procedures" (Ellis and Thomas 2003), "inefficient communication" (Majid and McCaffer 1998), "business strategy related issues" (Flyvbjerg et al. 2003) and etc.

As discussed above, it is necessary to study construction enterprises in order to address serious performance issues. Studies have already revealed some common problems with the nature of the construction enterprise and its business mode, including fragmentation (Ruikar et al. 2007), organizational complexity (Koskela 2000; Moavenzadeh and Marchini-Blanco 2004), and information problems (Bouchlaghem et al. 2004; Holness 2008). In addition, a number of new performance improvement practices have been proposed to address these problems, like Building Information Modeling (BIM) and Integrated Project Delivery (IPD). However, few analysis tools exist for a thorough understanding of construction organizations, as well as the impacts of individual new practices. Although some project organizational analysis models have been developed (Jin and Levitt 1996), none of them is an integral analysis platform for analyzing construction enterprises. Therefore, this paper proposes the use of Agent-Based Modeling and Simulation (ABMS) to develop an organizational analysis platform for construction enterprises, which is called Virtual Organizational Imitation for Construction Enterprises (VOICE). The sections are organized as follows: in Section 2, ABM as the simulation method will be briefly introduced; Section 3 outlines the way to represent construction enterprises; Section 4 presents the results of an initial model; and Section 5 summarizes the findings.

2. AGENT-BASED MODELING (ABM)

Agent-Based Modeling (ABM) is a computational modeling approach for studying the emergent property of complex systems by simulating the simultaneous behaviors and interactions of autonomous individuals in the system (Macal and North 2007). Different from top-down modeling approaches (e.g., System Dynamics, Discrete Event Simulation etc.), ABM is a bottom-up approach: system behavior emerges from individual agents who act based on what they perceive as their own interests. It has been widely used in sociology, economics, cognitive science, anthropology, physical sciences and biology (Epstein and Axtell 1996; Macy and Willer 2002).

Models specially designed for construction enterprises have been built using ABM, one of which is Virtual Design Team (VDT). By marrying an organizational structure with a project's task precedence diagram, VDT analyzes how interdependencies between sequential and parallel activities raise coordination needs, and how organization and communication tools may change the coordination capacity of project teams (Jin and Levitt 1996). Along the same track, various ABM models have been built to investigate project network dynamics, integrated technologies

impacts, and organizational alignment (Ortiz de Orue et al. 2009; Unsal and Taylor 2009). Current models, however, only focus on particular problems; as such, they are insufficient for an integral analysis platform to analyze organizational behavior and emerging performance of construction enterprises. VOICE is proposed to fill this gap.

3. REPRESENTING A CONSTRUCTION ENTERPRISE

A comprehensive, concise and accurate representation of construction enterprises forms the basis for a well performed simulation model. A model's proper level of detail is the level where decision makers can plan, execute and assess, and key success aspects are included. In this paper, this is called simulating "controllable and critical factors." Studies of Critical Success Factors (CSFs) and Organizational Behaviors (OB) have been employed to build the simulation framework and determine the key factors entering into VOICE. Critical Success Factors (CSFs) are critical to the success of an organization or project, and without the presence of these factors, the organization or the project will probably catastrophically fail (Huotari and Wilson 2001). Based on the framework of CSFs (Chua et al. 1999; Chan et al. 2004; Fortune and White 2006), the following elements are crucial for the success of construction projects and organizations, and should be modeled: organizational structure, business process, information flow, and project characteristics. On the other hand, under the framework of Organizational Behavior (OB), work performance is human output dependent on individual behaviors, group behaviors and organizational system, and affected by both change and stress (Robbins 2005). Thus, this paper represents a construction enterprise having the following three components: individuals, organization (including authority structure, work process structure and information flow structure), and work input/output (work characteristics and work performance).

3.1 Representing Work

Studies have revealed that "project characteristics" is an important component of CSFs (Walker 1995; Chua et al. 1999; Chan et al. 2004), and the most significant characteristics are "type," "nature," "number of floors," "complexity," and "size" (Chua et al. 1999; Dissanayaka and Kumaraswamy 1999; Chan et al. 2004). Therefore, we assign the following attributes to a project and tasks generated by it (Figure 1).

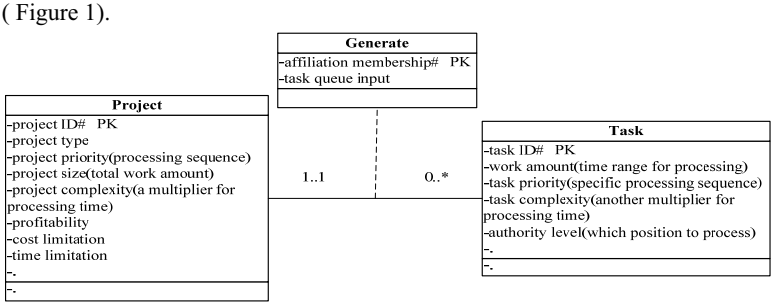

Fig. 1: UML diagram of agent project and agent task

3.2 Representing Individual Behaviors

Various individual behaviors are the basic determinants of work performance (Robbins 2005). Dependent on organizational behavior theory, this paper reproduces agents' behaviors with the following assumptions: (1) there are multiple roles inside one construction enterprise, and each role can be represented by one agent class that takes particular actions and makes decisions under particular rules; (2) each agent is imbued with bounded rationality, which means it does not follow the whole target of the organization. Instead, it moves toward more specific and particular work aims. For instance, one estimator aims to provide decision makers with a rational lump sum under given time without understanding other aspects of the project; (3) each agent occupies a particular position inside the organization which defines what task(s) the agent does, with whom the agent must communicate, to whom the agent reports, who reports to the agent, and so forth. As a result, the authority position, work arrangement and formal/informal network determine the agent's behaviors; and (4) each agent possesses specific knowledge, skills, and capabilities.

3.3 Representing Organizational Structures

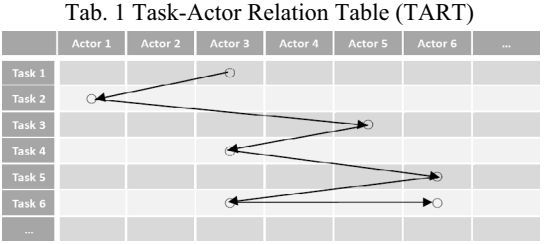
It has been well documented that organizational chart, work process and information flows are all very crucial for the success of construction projects and organizations (Majid and McCaffer 1998; Arditi et al. 2000; Ellis and Thomas 2003; Elwakil et al. 2009). For example, Elwakil et al. found that organizational structure is an important CSF for construction organizations (Elwakil et al. 2009). This paper proposes that multiple structures should be incorporated in VOICE. They are: (1) authority structure (A): the formal organizational chart which determines the arbitrary delegation pattern within an organization and reflects the report directions; (2) work process (W): the work processing sequence among different agents. Because construction enterprises are project-centered, work process structure in this paper is in terms of project-oriented work; and (3) information flow (I): the formal/informal communication connection that determines the coordination, message and knowledge movement, considered the most informal and intangible structure within an organization.

3.4 Representing Performance Indicators

Single aspect measures of performance (e.g., project Key Performance Indicators [KPIs]) capture only a limited perspective of a construction enterprise (Rouse et al. 1997). This paper utilizes a comprehensive performance assessment framework which balances principals of Balanced Score Card (BSC) and Excellence Model (Neely 2002). BSC allows the performance assessment from four important perspectives: customer, financial, internal business and learning (Norton and Kaplan 1992). The Excellence Model focuses on a broad range of measures, among them processes, people, partnership, learning and innovation (Nabitz et al. 2000). A comprehensive assessment framework built on these aspects allows managers to

evaluate performance on a company-wide basis, and thus has been increasingly accepted by construction enterprises in practice (Neely 2002).

4. INITIAL MODEL AND FINDINGS



4.1 Model specification

A working model constructed using Repast S (an open source agent based modeling toolkit with pure java implementation) forms the starting point for VOICE. Initially, two assumptions are made to strengthen conditions: (1) the simulated construction enterprises can obtain as many projects as they can, and (2) performance indicators are simplified, including project time, workers' work stress, contribution of each worker, error rate on projects and effectiveness of the work. The initial model is comprised of five agent types (projects, tasks, managers, staff and president), with all of them being connected by three association classes (authority structure, work process and information flow structure). Their behavioral rules are as follows:

Projects: Multiple project agents can enter into the model simultaneously with predefined attributes (e.g., size, complexity, type, etc.). The major behavior of project agents is to generate tasks according to the fixed sequence (obtained from the task queue input). In default, only one task can be generated at one time; however, multiple tasks can be generated at the same time by one project if the "multi-successor" indicator is bigger than one. If one task is dependent on previous tasks, it will not be generated until all dependent tasks are finished. After generation, the task attributes will be assigned to each task. These tasks are then delivered to its first processor, which is a staff member, manager or a president, based on the work process structure. Then, they will be passed through all relevant processors. Once finished, they will be removed from the model and their work amount will be subtracted from the corresponding projects. If all the tasks of one project are finished, then this project instance will be removed from the model.

Task queue: Task queue is an important input which connects people and work, or in this paper, "Task" agents and their actors ("President", "Manager" or "Staff"). This reflects the pattern of task sequence and work arrangement that involves two steps: first, drawing a Task-Actor Relation Table (TART), which reflects the task assignment for every actor as shown in the following table. Second, task instances are assigned to actors based on the zigzag lines in TART, as shown in Table 1.

Tab. 1 Task-Actor Relation Table (TART)

Managers: Multiple instances of manager agent can enter into the model simultaneously with predefined attributes (e.g., competence, process quality,

preferences etc.). The responsibilities of a manager are assigning or processing tasks, approving work, resolving exceptions (e.g. high work pressure of the staff), and checking the quality of submitted/delivered tasks. To assign tasks, a manager first checks for any meetings occurring at that time. If there is, then all other activities will be paused until the meeting is over. If not, the manager agent checks the priority of all the tasks at hand and processes the most urgent one (if the task is to be done by the managers), or assigns it (if the task is to be completed by the staff), based on three preferences: preference 1, speed oriented (assigning tasks to the staff agent who can finish the task in the shortest time); preference 2, quality oriented (assigning tasks to the staff agent who can finish the task with the best quality); and preference 3, pressure oriented (assigning tasks to the staff agent with the smallest work pressure). A manager either approves tasks that are beyond its staff's authority level or submits such tasks to the president. Also, it reassigns the tasks if the submitted tasks' qualities are not satisfied, if the staff complains of work overload, or if tasks are returned by subsequent managers because of quality issues. Once tasks are finished within the manager's scope, they are delivered to subsequent managers (if there are any) or removed from the model (if there are no subsequent managers).

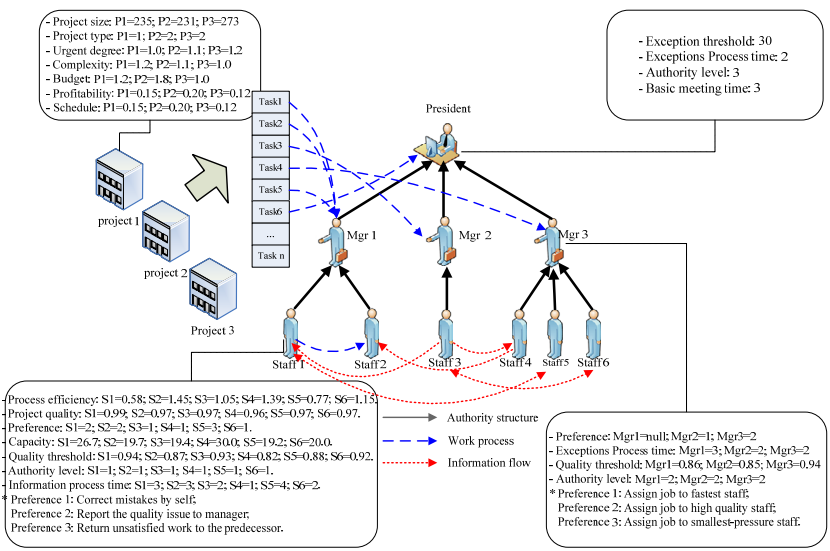
Staff: Based on the authority structure, there are a number of staff under one manager. To assess task needs, the staff agent first checks whether there is a meeting occurring. If there is, then all other activities are paused until the meeting is over. If not, it checks the priority of all tasks at hand and processes the most urgent one. As the first processing step, the staff agent will ask approval from its manager if the authority level of the task is beyond its level and if there is no approval with the processed task. Then the staff agent compares the total work time needed for all tasks at hand (work pressure) with available time (capacity) – if the work pressure is too great, then the staff will return the task to the manager for reassigning, whereby the manager will reassign the task to the staff with the smallest work pressure. After that, the staff agent will also check the task quality if it is a task delivered by other staff, and will return/report/correct the task based on its preferences (preferences 1, 2, and 3 stand for return, report and correct respectively), if the quality is not satisfactory. If information is needed for processing the task, the staff will ask for information from other staff, based on the information flow structure. It may also provide information to other staff based on the information flow structure. Once the staff agent starts to process the task, it will consume the amount of the processed task, and make mistakes. If the left amount of the task is equal to zero, then the staff will deliver the finished task to subsequent staff (if there are any) or submit the finished task to its manager (if there is no subsequent staff). After that, the competence and process quality of the staff agent will be improved according to the learning curve.

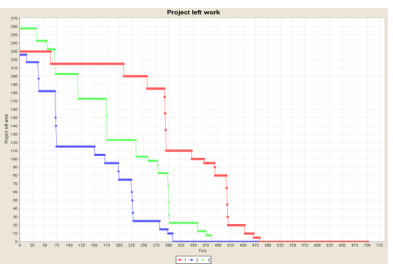
President: In the initial model, there is only one instance when the president agent enters into the model. Its responsibilities are selecting projects, approving the work, and setting up meetings. The president agent selects projects based on strategy and the president's preferences, while the selected projects will be triggered to generate tasks for the construction enterprise. The president agent also approves tasks

at the request of the manager; additionally, the president agent examines the exception indicator, which shows the frequency that agents ask for approvals/information/corrections on mistakes, etc. If there are too many exceptions, the president agent will hold a meeting based on the degree of the exceptions. During the meeting, all agents (president, managers and staff) must stop work. After the meeting, all current tasks will be approved, the work quality will be improved, and information will be shared thoroughly.

5.2 Initial Results

Figure 2 illustrates an initial scenario of a hypothetical construction enterprise comprised of six staff members, three managers and one president. Three different projects are awarded concurrently and will be processed. Tasks with different attributes will be generated by these three projects, based on a predefined TART table obtained from a case study. Behavioral rules of all individuals (the president, managers and staff) were described in above section. Parameters of the projects and every individual are shown in Figure 2. Also, organizational structures, including authority structure, work process and information flows, are illustrated.





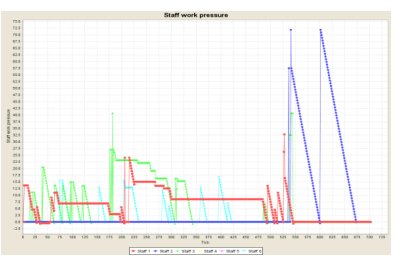


Fig. 2: A trial scenario

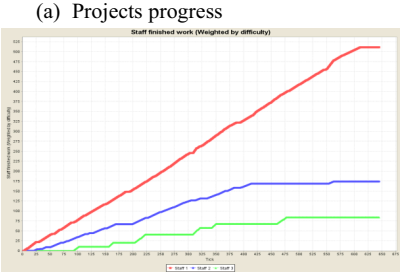
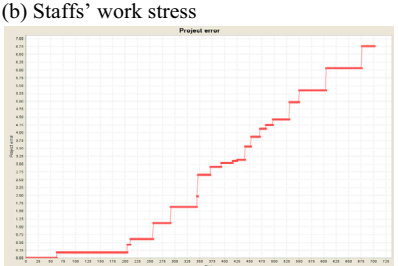
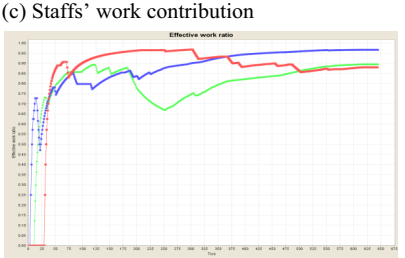
Figure 3 (a) illustrates unfinished work amount of the three projects along the time. This model can simulate the scenario where different projects are processed simultaneously, while former models could only simulate one project at one time. By comparing the simulation result and project deadline, decision makers can determine the maximum number of projects that the enterprise can afford. Figure 3 (b) illustrates the work pressure of every staff member during the projects. This indicator illustrates



the potential needed time for processing all the tasks on hand. If the work pressure is too big for one staff member, he/she will stop working and report this exception to his/her manager, which increases ineffective work time. This indicator is helpful for assessing the current work arrangement. Figure 3 (c) illustrates the contribution of each staff agent, where the slope means the accumulative finished work, and the level part shows the idle time of each one. This indicator can be used to assess work efficiency. Figure 3 (d) shows the work error amount of one of the three projects (project number 1). Figure 3 (e) illustrates the effectiveness of three projects. Effectiveness is measured in the ration of effective work time with total work time. Exceptions will happen when processing each project, such as the unsatisfactory quality of the delivered work, authority issue, lack of information and excessive work pressure. As a result, some amount of time will be consumed to resolve such exceptions. Compared to the time used for processing tasks directly (effective work time), such time is called ineffective time in this model. The effectiveness indicator shows the percentage of effective work time. The developed initial model can reflect the dynamic feature of this indicator of every project.



(a) Projects progress



(b) Staffs' work stress

(c) Staffs' work contribution

(d) Accumulated work mistake (project 1)

(e) Work effectiveness of projects

5. CONCLUSION

Increasingly, there is evidence that organizational factors are critical for the success of construction projects and organizations. However, few analysis tools exist for fully understanding construction enterprises. VOICE is proposed to fill this gap. Although not a substitute for field research, VOICE can help form hypotheses, sharpen theoretical relations, and set the agenda for more focused and productive empirical research. VOICE has the potential to have a transformative impact on our understanding of organizational natures of construction enterprises because it touches on several basic issues: (1) Providing a comprehensive micro-level analysis platform for understanding and managing the business complexity of construction enterprises; (2) Providing a user-friendly interface to practitioners, making the management more scientific, effective and efficient. With VOICE, decision makers can build their conclusions and decisions on reliable evidence and prediction so that mistakes can be avoided and better practices may be developed; (3) Providing a simulation tool to predict and validate the impacts of newly emerging business practices and innovative technologies, especially for construction enterprises that need to evaluate the risk to transform, to change strategy, to update technology and to reform business practices; and (4) "What-if" organizational design may be applied using the proposed platform.

Abstract

Disasters such as earthquakes and floods are sudden events that are difficult to predict, but have catastrophic consequences. A critical issue in disaster management is timely evacuation. University campuses face a unique challenge in developing effective emergency evacuation plans due to the complex site and high-dense buildings and population. This paper presents a method to optimize the placement of road barriers in emergency evacuation and assess the effectiveness via simulation. The main campus of the Western Michigan University (WMU) was chosen to implement and test the developed method. The placement of road barriers was optimized and the results were validated, using the Transportation Analysis and Simulation System (TRANSIMS). This system was also used to test the effectiveness of evacuation time to phased evacuation notification. It concluded that placing road barriers at appropriate locations could reduce the evacuation time by 20% or more.

Introduction

Disasters are sudden events that are difficult to predict and prevent, but have catastrophic consequences (Healy 1969). Disasters are categorized into natural disasters such as earthquakes, hurricanes, wildfires, severe storms, and floods, and manmade disasters including hazardous spills, terrorist attacks, and chemical explosions that are caused by human. Disasters cause the loss of lives and properties and have profound impact on our society. For example, the Tsunami occurred in 2004 killed over 225,000 people in eleven countries (Wikipedia 2009a). The hurricane Katrina in 2005 is among the deadliest disasters in the U.S. history. Over 1,800 people lost their lives and the damage was about $81.2 billion (Wikipedia 2009b).

Disaster management deals with a wide range of issues, focusing on maintaining control over disaster and emergency situations to help at-risk persons to avoid or recover from the impact of disasters (Disaster Management Center 1982). Among the many activities in disaster management, evacuation is a common strategy. In many

hazardous events the best option is to relocate threatened populations to safer areas (Cova and Johnson 2003). The key challenge in evacuation is to route evacuees to safety via optimal road paths under dynamic hazard and traffic conditions (MacGregor-Smith 1991, Southworth 1991).

Evacuation routing belongs to both the preparedness and response phases of the four emergency management phases defined by the Federal Emergency Management Agency (FEMA). Evacuation routes can be tested and evaluated via two approaches: mock exercises or drills, and simulation. Due to the nature of disasters and the cost or efforts involved, simulation is the preferred approach to conduct what-if analyses and assess various evacuation strategies. A number of simulation models have been developed to evaluate factors including routing, population distribution, road and intersection capacity, and human behavior, which contribute to road network clearance time (Han 1990, Southworth 1991, Tufekci and Kisko 1991, Urbanik and Jamison 1992, de Silva et al. 1993, Hobeika et al. 1994). These models are useful to model the evacuation of communities at risk to chemical stockpile sites, nuclear facilities, dams, and hurricanes. These macro-simulation models aggregate individual person and vehicle movement into macro-level parameters and consequently, lack the capabilities of incorporating detailed behavioral and management facets.

Emergency evacuations result in travel demand exceeding road network capacity, which causes traffic delays ranging from inconvenient to catastrophic (Cova and Johnson 2003). Strategies focusing on the optimal utilization of road network under extraordinary demand have emerged in recent years. Examples include counter flows, turn restrictions (Cova and Johnson 2003), traffic signal timing (Chen et al. 2006), and real time traffic guidance (Yue-Ming and De-Yun 2007). The basis for these strategies is the fact that most traffic delays occur at intersections (Southworth 1991) and therefore, reducing intersection conflicts will improve road network performance.

This paper presents a study that adopts the traffic control strategy of setting barriers at road intersections to control vehicle turns and to reduce intersection traffic conflicts, with the hope of improving the road network performance in emergency evacuation. In this study, a micro-simulation model was developed for vehicular traffic by using TRANSIMS to optimize the placement of barriers and to test the outcome. It is expected that using micro-simulation models can assess the road network performance more realistically and accurately. The developed methodology and models were tested in the context of university campuses in the United States, using the main campus of WMU as a representative case.

Significant Contributions

University campuses are among many communities that face dangers from disasters. A comprehensive literature review of emergency evacuation reveals that a university campus is treated as a “generic” community with their distinguishing characteristics neglected. Compared to industrial and residential communities, university campuses have certain key characteristics that cannot be sufficiently captured in the “generic” approach, but are critical to the success of evacuation routing: (1) highly dense population; (2) strong temporal variation in population distribution during school time (e.g. students move from one building to another to catch classes); (3) highly urbanized in terms of the density of buildings, parking lots and roads; and (4) the sparse distribution of hazardous materials. In addition, a road network on a university

campus is often one lane in each direction with many traffic calming devices. Traffic is mostly controlled via signs rather than signals. These distinguishing characteristics indicate the inappropriateness of treating university campuses as "generic" communities in evacuation routing. To our knowledge, there is very little research in this area. The study presented here has profound impacts by filling this gap.

This study also developed a method to optimize the placement of barriers via micro-level traffic simulation models (TRANSIMS models). The effectiveness was also evaluated using the same system to ensure the consistency. TRANSIMS is an agent-based traffic simulation tool developed by Los Alamos National Laboratory. It has the capability of capturing human behavior to certain extent and consequently, provides a more accurate and precise estimate of the road network performance under extraordinary travel demand. This study is among the first few studies to apply TRANSIMS in emergency evacuation routing and is believed to be the first one to apply TRANSIMS to university campus evacuation.

Methodology

The principal philosophy for this study was the utilization of TRANSIMS to simulate the network performance of road infrastructure under extraordinary travel demand that significantly exceeds the network capacity. Figure 1 provides a simplified version of the analysis flowchart. The overall procedure is described as below:

(1) Travel demand (number of vehicle trips) is determined based on individual building capacity and occupancy rate;
(2) Road network including physical road infrastructure and traffic control devices (signs and signals) are integrated to serve as the physical base for simulations;
(3) The travel demand and the road network resulted from the previous steps are combined to develop a TRANSIMS model and run simulation;
(4) Simulation results (network performance) are examined to identify problematic network links that face significant delays. Road barriers are set at appropriate locations to ease traffic that flows out of the problematic links. Information about the placement of road barriers feeds back to the original TRANSIMS model; and
(5) Steps (3) and (4) are repeated till either no further significant delays are detected or the placement of additional road barriers only leads to marginal improvement.

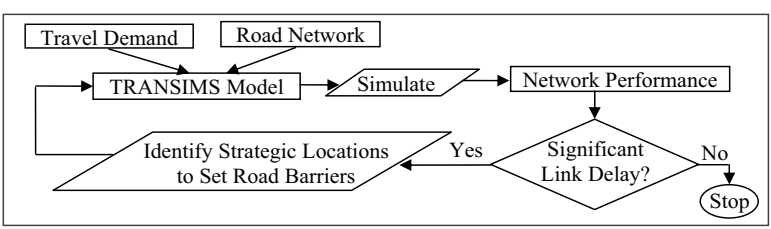

Figure 1. Flow Chart for Optimizing the Placement of Road Barrier

The method developed in this study helps to answer the following questions:

(1) How long does it take to evacuate the whole campus without any traffic guidance?
(2) Where to optimally place road barriers to shorten evacuation time?
(3) How efficient is the placement of road barriers in emergency evacuation?

In addition, the developed method can be used to conduct many what-if scenarios analyses in a sense that any traffic control/guidance measures are eventually reflected in the road network model and travel demand. For example, placing road barriers is treated as prohibiting certain turns. Also, phased notification can be incorporated by varying the time distribution of the vehicle trips in the travel demand.

TRANSIMS and Geographic Information System (GIS)

A key component in this study was the development of TRANSIMS models to simulate road network performance. TRANSIMS consists of a number of modules to accomplish all the tasks. An individual module can be viewed as an executable file and can be run with a control file that contains all the necessary information and parameters. Figure 2 illustrates a conceptual schema of the TRANSIMS framework. A TRANSIMS model can be developed using either the activity-based or trip-based approach. In this study, the trip-based approach was adopted. The embedded feedback mechanism indicates that the process is iterative.

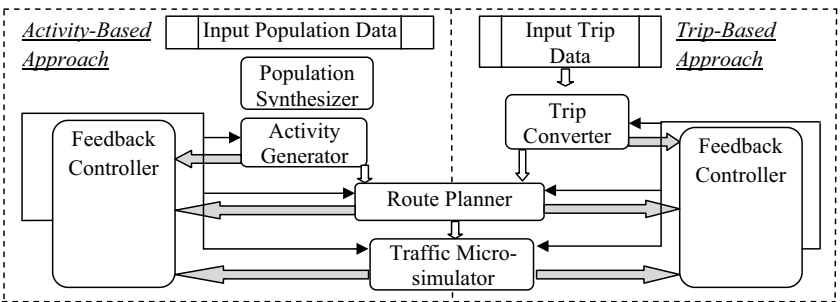

Figure 2. A Simplified Version of TRANSIMS Framework

WMU Case Study

In this study, the main campus of WMU was chosen to implement and test the developed method. This campus is representative of university campuses in U.S., most of which have complex infrastructure consisting of roads, parking lots, and buildings and a high-dense population that has a very strong temporal variation during the normal school time. Figure 3 provides an overview of the study area. The area above the major road running from southwest to the northeast is the main campus, on which this study focused.

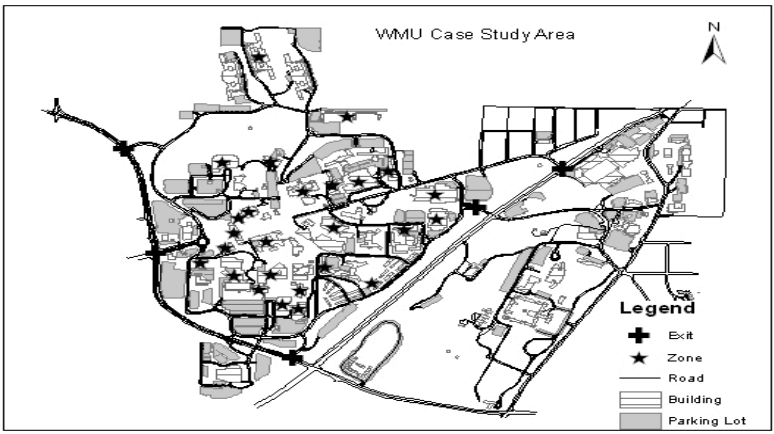

Figure 3. Overview of Case Study Area

Development of TRANSIMS Models

This section describes the development of TRANSIMS models for the WMU case study in detail. A total of six models were developed to evaluate the network performance in emergency evacuation when varying strategies were implemented, such as placing road barriers and phased notification. Figure 4 provides a detailed procedure in developing TRANSIMS models. Procedure details are described in the following subsections.

Travel Demand

The first step in developing a TRANSIMS model is to determine travel demand. In this study, the travel demand was determined by combining building capacity, class schedule, and parking capacity. Parking capacity was the constraining factor of travel demand of passenger cars. A number of buildings were visited during normal school time. It was determined that passenger car travel demand for each building is approximately 60 percent of the building capacity, which is the sum of capacities of rooms in that particular building.

TRANSIMS has its own mechanism of proportioning travel demand to activity locations and parking locations. For trip-based models, the travel demand shall be represented in the form of zone-to-zone trips. In this study, neighboring buildings sharing the same parking lot were combined to form an internal zone as illustrated in Figure 3. The travel demands of buildings in the same zone were summed to derive the number of trips that would originate from this particular zone. A total of 5 exits were also identified in Figure 3. These 5 exits, or external zones, are trip destinations. All trips originated in an internal zone were assigned to the closest exit. Table 1 lists the trip information in detail.

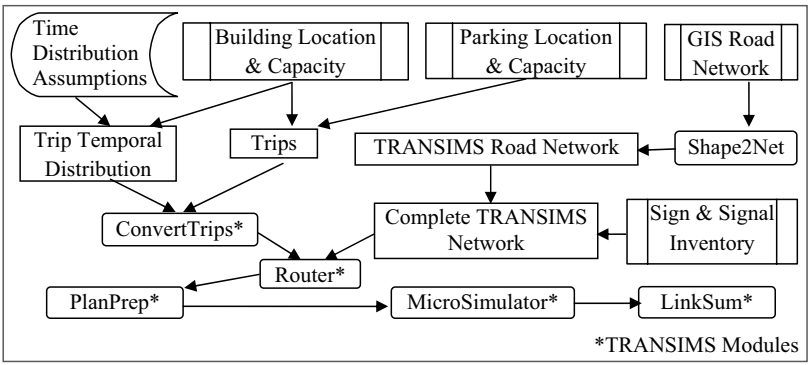

Figure 4. Detailed Procedure for the Development of TRANSIMS Models

Table 1. Travel Demand

Origin	Destination	Trips	Origin	Destination	Trips	Origin	Destination	Trips
1	28	73	10	29	567	19	30	108
2	28	56	11	29	70	20	28	900
3	28	774	12	29	1432	21	30	765
4	28	866	13	29	271	22	28	132
5	27	1289	14	31	27	23	30	210
6	28	681	15	27	122	24	27	49
7	28	112	16	27	81	25	30	62
8	28	14	17	31	493	26	30	30
9	29	882	18	29	240		**Total**	**10306**

The trips follow certain time distribution. The time it takes for a person to respond to an evacuation notification and to start the vehicle trip is affected by many factors. This study made a simplification by assuming that the time distribution of vehicle trips is determined by floor. It was assumed that (1) all vehicle trips of the first floor occupants occurred in the first ten minutes; (2) 25% of the vehicle trips of the second floor occupants occurred in the first ten minutes and the rest 75% occurred in the following ten minutes, or between ten and twenty minutes; (3) 25% of the vehicle trips for the third floor occupants occurred between ten and twenty minutes and the rest 75% occurred between twenty and thirty minutes; and (4) all vehicle trips of all forth and up floor occupants occurred between thirty and forty minutes. Table 2 lists the percentage of trips in four ten-minute time intervals.

Table 2. Temporal Trip Distribution

Start of Time Period	End of Time Period	Share/Percentage of Trips
12:00	12:10	0.57595
12:10	12:20	0.19900
12:20	12:30	0.16820
12:30	12:40	0.05685

Road Network

TRANSIMS needs a link-node road network. Having accurate road network data is critical to the development of valid TRANSIMS models. In this study, the road

network data were obtained from the physical plant of WMU and converted into a link-node structure via a GIS interfacing tool developed in another TRANSIMS study (TRANSIMS Manual 2007). Resulting text files were used as inputs to a TRANSIMS module entitled "TransimsNet", which converted textfile format link-node system into a network structure that was used in other TRANSIMS modules to complete traffic simulations.

Sign and Signal Locations

A field inventory of the locations of traffic signs, signals, and signal timing and phasing plans was collected. This field inventory was utilized to complete the construction of TRANSIMS network and verify and calibrate the resulting sign and signal data.

Route Planning, Micro-Simulation, and Network Performance

The TRANSIMS modules of Router, PlanPrep, MicroSimulator, and LinkSum were used to complete the development of TRANSIMS models. Router builds multi-modal travel plans with volume/capacity calculations to optimize the route selection. PlanPrep merges, sorts, and combines plan files when iterations are adopted. MicroSimulator simulates the vehicle movement on the TRANSIMS network based upon the travel plans. LinkSum summarizes and aggregates the network performance on a link-by-link basis so that network performance can be examined at both of the individual link and network levels.

Strategies for Setting Road Barriers

During emergency evacuation, a travel demand that greatly exceeds the network capacity is placed on the road, causing severe congestions. TRANSIMS reports such congestions by counting vehicle movement problems for each link. In our study, links with higher number of problem counts were given higher priority for placing road barriers to control traffic. Figure 5 illustrates the principle of placing barriers. A road barrier was placed to block left turns of the link with a severe congestion. Doing so forced the outgoing traffic to go straight or make right turn only and consequently, reduced traffic conflicts at the intersection. These left turn barriers were recorded in a turn prohibition table and fed into the Shape2Net step in the procedure outlined in Figure 4. The rest of that procedure was executed to test the effect. This step was repeated till the placement of additional road barriers either only marginally shortened or even increased the network clearance time.

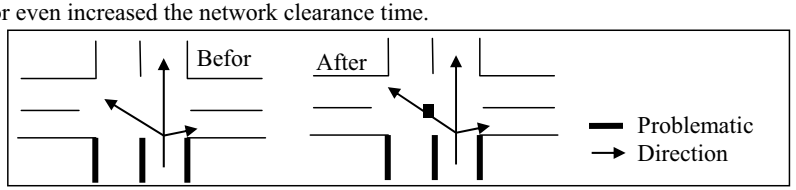

Figure 4. Placement of a Road Barrier to Control Traffic Flow

TRANSIMS Models

A total of six cases were investigated in this study.

(1) Case 1 assumed that trips went to the nearest exit (based on network distance) and no road barriers were in place.
(2) Case 2 was built upon Case 1 by following the procedure outlined in the section of Strategies for Setting Road Barriers. It could be viewed as having road barriers placed optimally. Table 3 lists the number of road barriers placed during the iterative procedure. Round 0 was the same as Case 1 and 10 most problematic links were identified. Placing 10 road barriers correspondingly lead to Round 1 model and so on so forth. Round 2 provided marginal benefit of adding additional 5 road barriers. Round 3 worsened the network clearance time. Round 2 was chosen to be the Case 2 model.

Table 3. Placing Road Barriers to Develop Case 2 Model

Iteration	# of Barriers	# of Problematic Links	Network Clearance Time
Round 0	0	55	2hr 14min
Round 1	10	51	1hr 16min
Round 2	15	36	1hr 8min
Round 3	20	56	2hr14min

(3) Case 3 was developed by incorporating a "virtual destination". This "virtual destination" was connected to all five exits by links that have a very large capacity, one-way traffic, and a long distance to remove the nearest distance assumption in Case 1 and Case 2. Having all trips destined at this "virtual destination", the bias of forcing trips going to the nearest exit was removed. A trip was considered to be complete as soon as it reached an exit. The network clearance time was determined by examining the link traffic volume for all links other than those links connecting exits to the "virtual destination".
(4) Case 4 was developed upon Case 3, following the road barrier set up strategies mentioned earlier. Case 4 can be viewed as having road barriers placed optimally.
(5) Case 5 was developed to evaluate the effects of phased notification. Phased notification could be building-based or floor-based. Building-based phased notification was determined to be of little help because (1) if the inner buildings (further away from exits) were notified earlier, then it caused more severe congestion to the portion of road network that is closer to exits; and (2) if the outer buildings were notified earlier, then the portion of road network that is further away from exits would be under-utilized. This thought was also validated in TRANSIMS models (not included herein). Case 5 evaluated the effects of floor-based phased notification: the first floor occupants were notified first, then the second floor occupants, the third floor occupants, and so forth. Table 4 lists the resulting temporal trip distribution.
(6) Case 6 was developed on Case 5 by placing road barriers at optimum locations.

Table 4. Temporal Trip Distribution

Start of Time Period	End of Time Period	Share/Percentage of Trips
12:00	12:10	0.5262
12:10	12:20	0.1990
12:20	12:30	0.1990
12:30	12:40	0.0758

Results

After developing six TRANSIMS models, traffic simulation was conducted for each case. Table 5 provides a summary of the distinguishing properties and the simulated network performance of each model. In addition to network clearance time, other performance measures including the total vehicle hours, total vehicle miles, total hours of delay, and total number of turns are included to provide a complete view.

Following is a summary of observations based upon Table 5 and Figure 5

(1) Comparing Cases 1 and 2 reveals that placing 15 road barriers to control the left turns of problematic links reduced network clearance time by 50%, reduced vehicle miles by 15%, reduced total vehicle hours by 30%, reduced hours of delay by 32%, and reduced number of turns by 29%.
(2) Comparing Cases 3 and 4 reveals that placing 10 road barriers reduced network clearance time by 20%, reduced vehicle miles by 26%, reduced total vehicle hours by 33%, reduced hours of delay by 34%, and reduced number of turns by 33%.
(3) Comparing Cases 1 and 3 reveals that after adopting the "virtual destination", network clearance time remained the same, but total vehicle miles were reduced by 20%. It indicates that travelers were intelligent in choosing exits to minimize the overall travel distance. However, this minimal travel distance did not affect the network clearance time. An increase in vehicle hours and hours of delays and a small decrease in number of turns were witnessed. This confirmed that total vehicle mile was not the only determining factor of network clearance time.
(4) Comparing Cases 2 and 4 reveals that adopting the "virtual destination" constrained the optimal set up of road barriers as indicated by the lesser number of road barriers in Case 4 and less significant improvement of the network clearance time. It was attempted to also set 15 road barriers in Case 4, but the resulting network evacuation time was 2hr 33 min (not shown in Table 5).
(5) Combining (3) and (4) leads to the suggestion of guiding evacuees to the closest exit based on the network distance.
(6) Comparing Cases 5 and 3 reveals that a floor-based, phased notification did not make improvement in network clearance time, even though it resulted in small decreases of vehicle miles, vehicle hours, hours of delay, and number of turns.
(7) Comparing Cases 6 and 5 reveals that by adopting the floor-based, phased notification, the benefit of placing ten road barriers was minimal.

Table 5. Simulation Results of TRANSIMS Models

Case	Virtual Destination	# of Road Barriers	Phased Notification	Network Clearance Time	Vehicle Miles	Vehicle Hours	Hours of Delay	Turns
1	No	0	No	2hr 14min	5090.97	730.07	654.22	16458
2	No	15	No	1hr 8min	4331.72	508.72	444.19	11705
3	Yes	0	No	2hr 16min	4064.83	841.18	780.61	14339
4	Yes	10	No	1hr 49min	3020.89	560.51	515.50	9590
5	Yes	0	Yes	2hr 19min	4013.12	782.25	722.45	14165
6	Yes	10	Yes	2hr 1min	2655.58	517.00	477.43	8089

Conclusions and Discussion

This study concludes that placing an optimal number of road barriers at strategic locations decreases the network clearance time significantly, as illustrated by the comparison of Case 2 to Case 1 and Case 4 to Case 2. If travelers are guided towards the nearest exit (based upon network distance), the developed methodology places 15

road barriers to block the left turns for the most problematic links. By doing so, the network clearance time is reduced by a significant percentage (50%). If travelers are given the option of choosing their own exits, the optimum placement of 10 road barriers reduces the network clearance time by 20%, which is still significant. In other words, these conclusions lead to the suggestion of assigning exits for travelers during emergency evacuation and placing road barriers at strategic locations.

It is also concluded that a floor-based, phased notification strategy does not work well either alone, or combined with the road barrier approach. The use of a single network performance measure might mislead our conclusions with regards of the network performance. For example, a minimum value of the total vehicle miles does not necessary means the shortest network clearance time.

It is realized that the study completed is very preliminary to address the campus evacuation routing problem. This study made many assumptions to simplify the problem. The authors recognize that campus evacuation is a very complex problem, involving not only the physical infrastructure, but also human behavior. There is a great room for further improvements and enhancements. This study simplified the building evacuation by developing a trip time distribution table to capture the outcomes of building evacuation. This simplification can be overcome by integrating TRANSIMS models with building evacuation models to acquire a more accurate temporal distribution of trips. This study focused only on vehicle evacuation. Yet in reality, not every person will bother to secure and drive his/her car. Rather, walking might be preferred. Many students come to school by bus. Focusing on a single transportation mode might not reflect the real scenario of campus evacuation. Rather, a multi-modal approach is more appropriate. Other limitations that provide future research directions include (1) the extent of reliance on TRANSIMS defaults such as activity locations and parking locations; (2) the more accurate incorporation of human response and behavior; and (3) the effects of not being able to put road barriers at the same time, i.e., ten road barriers might be placed in different orders.

ABSTRACT

There has been a significant increase in natural disasters that have negatively affected the U.S. economy in recent decades. The Government Accountability Office reported that the U.S. is not well prepared to manage large-scale natural disasters either through emergency response or financial relief. It is essential to develop integrated post-disaster investment strategies that avoid many of the pitfalls that have been observed following recent catastrophic events. This paper proposes a conceptual framework to build theoretical foundation and demonstrate technologies for creating a decision support system for optimizing stakeholders' resource allocation in natural hazards. The proposed framework will: (1) minimize the total costs associated with implementing such investment strategies and (2) maximize the uniformity of welfare distribution among all associated parties. This would provide broad members of the emergency management community as well as policy makers with easy-to-use preparedness and decision support tool, which would help in creating better societal financial resilience towards natural hazards.

KEYWORDS

Investment Strategies, Insurance, Post-Disaster Financial Relief, Multi-Agent Simulation, Multi-Objective Optimization.

INTRODUCTION

The development of this work is triggered through: (a) the increasing total costs associated with extreme natural events; (b) the challenges for effective natural hazards management; and (c) the urgent need for optimized hazard stakeholders' investment strategies. The Disaster Mitigation Act of 2000 now requires that to be eligible for Hazard Mitigation Grant Program (HMGP) funds, each state and local government must submit a mitigation plan to the Federal Emergency Management Agency (FEMA) describing how it is prioritizing mitigation actions so that its overall

mitigation strategy is cost-effective and maximizes overall wealth (FEMA 2003; Dodo *et al.* 2005). The development of optimized stakeholders' investment strategies can enhance the process of resource allocation prioritization in relation to natural hazard financial mitigation (Kunreuther *et al.* 2007).

BACKGROUND

A number of major impact assessment software systems have been developed to support disaster preparedness and recovery efforts. These systems include Hazards United States-Multihazard (HAZUS-MH) and MAEviz. HAZUS-MH is a hazard prediction software program developed by the Federal Emergency Management Agency (FEMA) under a contract with the National Institute of Building Sciences to estimate potential losses from earthquakes, hurricane winds, and floods (HAZUS-MH 2007; Pradhan *et al.* 2007). MAEviz is seismic risk assessment software developed by the Mid America Earthquake Center in cooperation with the National Center for Supercomputing Applications to estimate losses from earthquakes (Elnashai *et al.* 2008a; Elnashai *et al.* 2008b; MAEviz 2008). These loss estimation models provide increasingly comprehensive estimates of regional risk, but offer little guidance about how to use that information to make mitigation resource allocation decisions (Dodo *et al.* 2005). All these models can estimate losses in relation to structural damage, contents damage, time-based impacts, and only a small set of predefined mitigation alternatives can be considered, but they are not able to account for the stakeholders' side including costs of the alternatives, the budget, and the specific objectives and priorities of each stakeholder (FEMA 2003; Dodo *et al.* 2005; Grossi and Kunreuther 2006). Previous related research on mitigating financial impact of natural catastrophic is divided into four main approaches that include the following:

- Deterministic net present value (NPV) analysis was used where: Kappos *et al.* (1996); Kunreuther *et al.* (2001); Altay *et al.* (2002); Chang (2002); and Kuwata and Takada (2003) calculated the avoided loss in various hazardous situations as the difference of loss estimated with and without implementation of the mitigation alternatives.
- Stochastic NPV analysis was utilized where: (a) Englehardt and Peng (1996) estimated the probability distribution of benefits associated with revising the hurricane requirements in a South Florida building code and compared it with the cost of implementing the revision; (b) Werner *et al.* (2002) compared various levels of proposed seismic design or upgrade for port facilities in California based on both means and standard deviations of losses; and (c) Mostafa and Grigoriu (2002) examined the benefits of adding bracing elements to the water tank in a New York City hospital.
- Multi-attribute utility models were used where: (a) Nuti and Vanzi (1998) compared structural upgrading strategies for hospitals based on various performance indices for the response of the associated system of hospitals and (b) Opricovic and Tzeng (2002) compared post-earthquake regional reconstruction plans in Central Taiwan using a fuzzy, multi-criteria decision analysis approach.
- Optimization models were utilized where: (a) Shah *et al.* (1992) performed integer programming with a budget constraint to maximize the NPV of

earthquake mitigation investment; (b) Augusti *et al.* (1994) used dynamic programming to select structural mitigation alternatives for bridges in a highway network in Italy; (c) Researchers at the International Institute for Applied Systems Analysis (IIASA) have developed a spatial-dynamic stochastic optimization model to select the insurance policy design that best satisfies stated decision criteria, such as maximizing insurance company profits and minimizing the probability of insurance company insolvency (Ermoliev *et al.* 2000; Ermolieva *et al.* 2001; Brouwers and Hansson 2001; Brouwers *et al.* 2001; Brouwers *et al.* 2002; Brouwers and Verhagen 2003; Brouwers 2003-a; Brouwers 2003-b; and Brouwers *et al.* 2004); and (4) Dodo *et al.* (2005) developed a linear program for resource allocation in earthquakes that incorporates spatial correlation among spatially distributed mitigation alternatives, the range of possible earthquakes with their associated probabilities, and decision timing.

Meanwhile Dodo *et al.* (2005) is considered to be the most comprehensive study to address the problems of limited budgeting, dynamic investment scheduling, and resource allocation optimization for financial mitigation in natural hazards, all of the aforementioned valuable studies have only treated the problem through a non-dynamic aggregated simulation modeling techniques. The proposed research aims to build on previous research efforts by developing a transformative micro-level multi-agent stochastic optimization framework that is able to: (1) study financial mitigation of natural hazards from an integrated perspective that concurrently optimizes position of all interrelated stakeholders and (2) provide a dynamic investment mechanism to measure the costs associated with these stakeholders as a result of interdependencies, constraints, and uncertainties.

OBJECTIVES

The paper will model the extremely complex and highly interactive environments governing natural hazards using an innovative micro-level multi-agent stochastic optimization approach. This research will utilize well-founded techniques to: (1) compute the load distribution of insurance premiums; (2) create provisions of reinsurance; (3) minimize the total cost associated with implementing the anticipated resource allocation strategies; and (4) maximize the uniformity of welfare distribution among associated parties including property owners, the government, insurance/ reinsurance companies, and national recovery agencies.

DEVELOPMENT FRAMEWORK

The development of the framework associated with the development of an Automated Micro-Level Multi-Agent Stochastic Simulation Decision Support System for Investment Optimization in Natural Hazards (MASSIP) is based on theory formulation and model implementation.

1) Theory Formulation

To enable MASSIP to search for the optimal post-disaster resource allocation strategies, the authors will develop a comprehensive set of decision variables. These decision variables will be assessed on ex-ante and ex-post basis over time (t) where X

is the set of all feasible stakeholders' resource allocation strategies. Each candidate resource allocation strategy (x_i) will be defined and assessed using a set of input and output variables, as shown below in Figure 1.

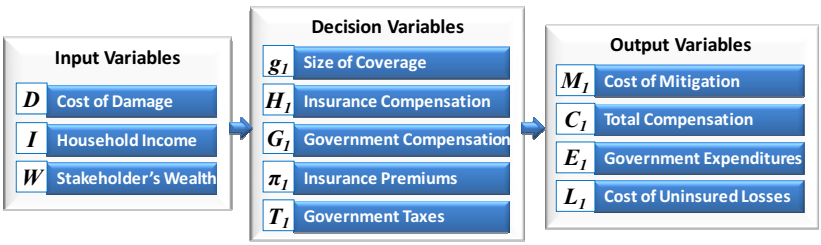

Figure 1: Variables for Resource Allocation Strategies

Two objective functions will be formulated for each candidate strategy to: (1) minimize the total costs using mitigation, vulnerability, damage, and loss functions as well as (2) maximize the welfare distribution using wealth transformation and uniformity distribution functions. These functions will be developed utilizing the scientific basis laid out in previous research studies including Brouwers and Hansson (2001), Brouwers *et al.* (2001), Brouwers *et al.* (2002), Brouwers and Verhagen (2003), Brouwers (2003-a), Brouwers (2003-b), and Brouwers *et al.* (2004).

MASSIP will be designed to support logistic, financial, or environmental constraints. For example, a financial constraint can be set to ensure that the government total expenditures (E) do not exceed a certain allocated amount. Moreover, MASSIP will utilize exploratory stochastic modeling and dynamic investment scheduling to account for the uncertainty of hazards occurrence and timing of stakeholders' resource allocation decisions, respectively (Ermoliev *et al.* 2000; Ermolieva *et al.* 2001; Dodo *et al.* 2005). Also, MASSIP will utilize exploratory stochastic modeling and dynamic investment scheduling to account for the uncertainty associated with hazards occurrence and stakeholders' resource allocation decisions.

The optimization problem is presented below in Equation (1), where the expected values (E) of the two objective functions are Ef(x, p, q) and EU(x, p, q) and the constraint(p) and uncertainty (q) functions are $h_i(x, p, q)$ and $g_i(x, p, q)$, respectively.

$$\begin{aligned} &\text{Find} && x \in X \text{ that minimizes } Ef(x, p, q) \text{ and maximizes } EU(x, p, q) \\ &\text{Subject to} && Eh_i(x, p, q) = 0;\ i = 1, \ldots, n \\ & && Eg_i(x, p, q) \leq 0,\ i = 1, \ldots, m \end{aligned} \qquad (1)$$

2) Model Implementation

As shown below in Figure 2, the framework associated with MASSIP will be designed to develop the following models: (1) stochastic hazards model; (2) multi-agent simulation model; (3) multi-objective optimization model; and (4) multi-attribute utility model.

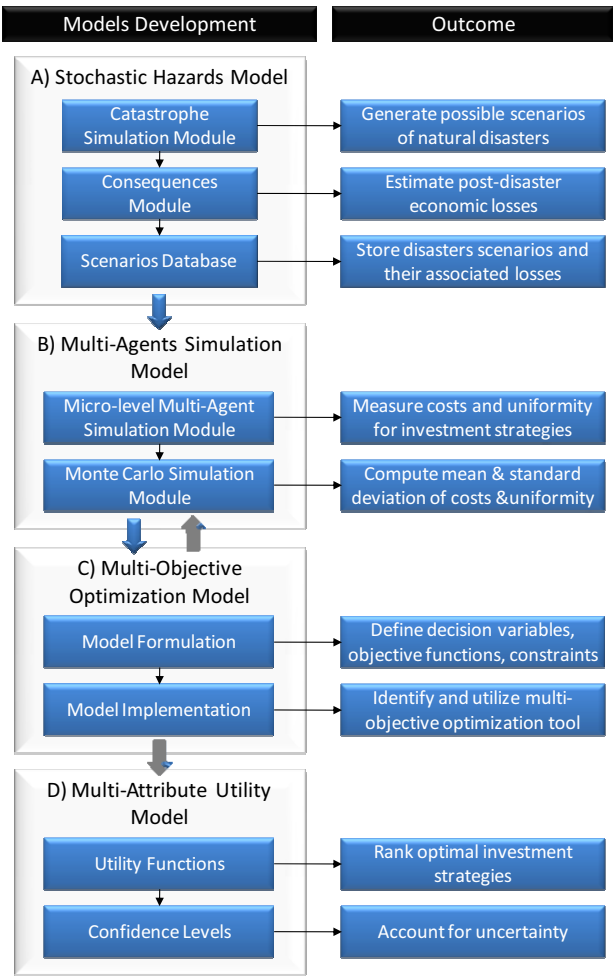

Figure 2: MASSIP Development Framework

A) Stochastic Hazards Model

The purpose of this model is to address the inherent uncertainty in the natural hazard problem. As the model is addressing the outcome of future investment strategies, these consequences must first be estimated instead of assessing the results by looking back at the outcome. To this end, the stochastic hazards model will internally apply stochastic simulation for natural catastrophes before communicating information with other models. This model consists of:

- *Catastrophe simulation module;* used to generate possible scenarios of natural disasters in the area of interest using vicinity and spatial models, which are fed through information provided from U.S Census and geographical information systems (GIS), respectively.
- *Consequences module;* utilized to estimate the economic losses as a result of each catastrophic event generated by the catastrophe simulator. It will benefit from currently available loss assessment software systems, such as HAZUS-MH and MAEviz.
- *Database of scenarios;* where each generated catastrophe and its associated economic losses are considered as one scenario and will be stored in the database of scenarios. These scenarios will be generated once for each optimization problem and will be used to evaluate and optimize possible investment strategies, as described in the following models.

B) Multi-Agents Simulation Model

The objective of this model is to evaluate possible investment strategies for the affected areas when they are subjected to any catastrophic scenario generated by the stochastic hazards model. As shown in Figure 1, this model will be composed of:

- *Micro-level multi-agent simulation module;* used to measure the total costs for possible investment strategies as well as the uniformity of welfare distribution among stakeholders' associated with applying each investment strategy for each generated catastrophe scenario. Three main agents will be used to represent the government, insurance/reinsurance companies, and property owners, where stochastic reinforcement learning techniques will be used to govern the agents' learning functions, such Roth-Erev, modified Roth-Erev, or Gibbs-Boltzmann.
- *Monte Carlo simulation module;* utilized to compute the mean and standard deviation of total costs and uniformity for each investment strategy for all generated catastrophe scenarios. In order to ensure practical computational time, this module will utilize parallel computing capabilities.

C) Multi-Objective Optimization Model

The objective of this model is to identify the Pareto optimal investment strategies. The development of this model consists of two main phases: (1) model formulation in order to define relevant decision variables, construct objective functions, and identify optimization constraints; and (2) model implementation in order to identify the most effective and efficient multi-objective optimization tool for this complex problem.

The model will be implemented using multi-objective genetic algorithms in order to account for the multi-objective nature of the problem and its huge search space. Robust algorithms, such as Non-Dominated Sorting genetic Algorithms II (NSGA2), will be used because of their important characteristics and superior performance compared to other multi-objective genetic algorithms (D'Souza and Simpson 2002; Deb *et al.* 2001; Deb 2005; Weile *et al.* 1996). The model will identify the optimal investment strategies using four main steps: (1) generating an initial population of

possible investment strategies; (2) sending the generated strategies to the multi-agent simulation model to evaluate their performance in minimizing the total costs and maximizing uniformity; (3) ranking the generated strategies using the constrained-domination principle to account for their compliance with all optimization constraints as well as their performance in achieving the optimization objectives; and (4) generating an enhanced population of strategies using selection, cross-over, and mutation operators. Steps (2) through (4) are then repeated until a predefined termination criterion is met and the Pareto optimal strategies are identified, as shown in Figure 3.

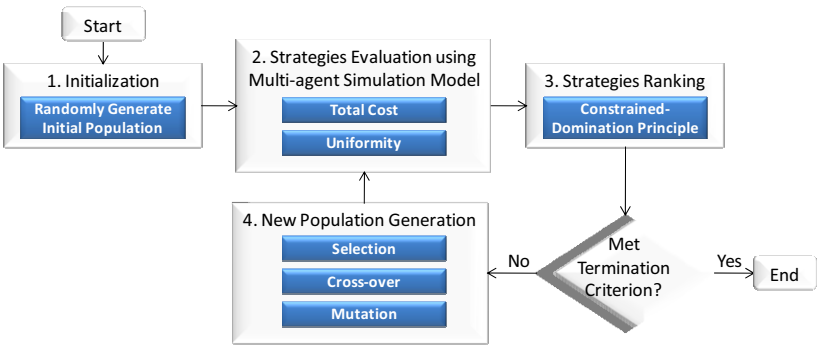

Figure 3: Example of Constrained-Domination Principle

D) Multi-Attribute Utility Model

The purpose of this model is to select an optimal investment strategy for implementation from the set of Pareto optimal strategies, which are generated by the multi-objective optimization model, as shown in Figure 1. Utility functions will be developed for the two main optimization objectives (i.e. minimizing the total costs and maximizing uniformity). These utility functions will also account for the level of uncertainty in the evaluated performance of each of the optimization objectives using their standard deviations, which are computed using Monte Carlo simulation in the multi-agent simulation model. Accordingly, the model will utilize multi-attribute utility theory in order to rank the Pareto optimal strategies based on their utilities and their confidence levels.

CONCLUSIONS

The proposed framework expressly differs from available disaster management models as it provides an explicit shift from the previously known aggregated simulation models for disaster mitigation, which have only partially succeeded in replicating the real world system governing natural catastrophes, to a more comprehensive decision support system, which is capable of capturing an integrated picture of the multivariate factors associated with natural hazards. MASSIP creates a series of intertwined stochastic, multi-objective optimization, and multi-attribute

utility models to provide an efficient decentralized communication across the system and more scalable simulation environment.

Moreover, it provides multi-fold benefits to society where the proposed system (i.e. MASSIP) can be used as (1) preparedness tool to foresee the expected integrated consequences of natural disasters in locations prone to catastrophic events; and (2) decision support tool for the choice of optimal resource allocation strategy that is suitable for a disastrous vicinity in the response and recovery phases of disaster management.

Abstract

In the summer of 2008, two hurricanes made landfall along the Texas coast causing billions of dollars in damage. Texas received presidential disaster declarations, which resulted in the state receiving over $350 million in hazard mitigation funds. Over 500 requests for mitigation projects were submitted to the government from communities impacted by these disasters, but not all requested projects could be funded. As a result, those communities that submitted requests for well-defined mitigation projects were the primary benefactors of the federal mitigation funds. To better understand the factors that characterize a "well-defined" mitigation project, a study was initiated to develop an index for rating the completeness and quality of mitigation project definition. The study incorporated concepts from research on the quality of community planning and from project definition rating methods. A rating tool was developed to evaluate projects that have been successfully funded and to contrast them with projects that have been rejected. The rating tool consists of detailed descriptions of the project scope elements along with a method for scoring the completeness and quality of the project's definition. This paper presents the research results and the outcome from comparing six mitigation project definition packages.

***Keywords*:** project definition, rating, index, mitigation

Research Background and Problem Statement

In 2008, Hurricanes Dolly and Ike made landfall along the Texas coast, causing an estimated $23 billion in loss of life, injuries, and property damage. The damage caused by these two events exceeds all disaster losses in Texas during the past 15 years, making 2008 the most devastating year in Texas history. While these statistics are staggering, the number of communities that have struggled to recover following Hurricanes Dolly and Ike is equally disturbing. Reports indicate that the sheer magnitude of the destruction has resulted in slow recovery that anecdotally has been attributed to the lack of clear methods for prioritizing and implementing mitigation

and reconstruction projects at the community level (Oxfam America, 2008). This problem is especially acute in small communities that lack adequate resources to plan for, develop, and implement projects that will mitigate future disasters. Yet, *mitigation projects are especially critical for reducing future vulnerabilities of communities.*

To assist communities with mitigation efforts, several federal programs exist to provide funding for mitigation projects. Among the many types of projects that can be funded through federal assistance programs are public capital improvement projects, including bridge elevations, drainage improvements, structural hardening, and utility upgrades. In fact, capital improvement projects are *particularly* effective at reducing the vulnerabilities of *entire* communities, making them an especially attractive option to achieve local mitigation goals.

Following Hurricanes Dolly and Ike, over $350 million in federal mitigation funding became available, creating an unprecedented opportunity for communities to address their most critical vulnerabilities. Unfortunately, many communities that requested mitigation funding were unable to develop a viable project that was eligible for a subsidy, and this problem was especially acute for capital improvement projects in small communities. In fact, larger communities in Texas, which make up a small percentage of the total communities, have historically received a significant proportion of the available funding, while the large number of small communities have received a small proportion of funding (Table 1). Based on a recent field study, evidence suggests that larger communities in Texas have been the key benefactors of federal mitigation project assistance, and, furthermore, that this apparent bias may be occurring because these communities have access to engineering resources that are necessary for developing viable mitigation capital improvement projects. Unfortunately, smaller communities often do not have similar access to engineering resources, and as a result, they are less likely to develop viable projects that can be funded through much-needed federal subsidies (Menches et al. 2009).

Table 1. Percent of Communities that Received Mitigation Project Funding since 1989 (source: Texas GDEM Mitigation Section)

Community Population	Percentage of Cities with this Population	Percentage of Mitigation Capital Improvement Projects Awarded
0-10,000	60%	26%
10,001-20,000	6%	18%
20,001-30,000	29%	20%
30,001-100,000	4%	16%
100,001+	2%	20%

Consequently, federal mitigation policy may be inadvertently biased in favor of communities that already have access to mitigation project development resources, causing concern that the present policy may be distributing subsidies in an unintended way that limits small communities' abilities to reduce their hazard exposure. The problem of inequitable distribution of subsidies is not new and was hinted at in a landmark study conducted a decade ago by Godschalk, Beatley, Berke, Brower, and Kaiser (1999). The researchers cite the "scattershot nature of the projects" approved

for funding (p. 530) and propose that local governments should "operate mitigation implementation programs made up of coordinated and prioritized mitigation projects" (p. 532), but the study did not address the detailed and often complex process of developing and implementing mitigation projects. In fact, a decade later, countless communities continue to struggle with the development of mitigation capital improvement projects because they do not have the engineering resources to advance from a *mitigation idea* to a well-developed *mitigation project* that can be funded through federal subsidies. Hence, there is a critical need to address this complex process in order to ensure all communities have equal access to mitigation funding and equal opportunities to reduce their hazard exposure.

Hence, the current research is part of a larger effort to develop and test the effectiveness of a mitigation project development process that is fundamentally different from the public capital improvement project development process. The current research effort will provide tools that can be used by the researchers to investigate why specific projects were selected for funding, what characteristics of the project increased or decreased its chances for being selected for funding, or how and by whom were the successful projects developed. Ultimately, the researchers will use this data to develop a project development process that is uniquely suited for the development of mitigation capital improvement projects.

Research Goal and Objectives

The goal of the research was to develop a method and tool for evaluating the completeness and quality of mitigation capital improvement projects submitted for potential funding under the federal Hazard Mitigation Grant Program (HMGP). The rating tool will ultimately be used to identify the characteristics of projects that have been successfully funded and to contrast them with the characteristics of projects that have been rejected so that this information can be distributed to, and used by, communities as they prepare future mitigation projects. The rating tool, which consists of detailed descriptions of the project scope elements, has a secondary benefit of providing a checklist of items that comprise the project application package (i.e., funding request), which can be used by communities during the project development stage. The specific objectives of the research were to:

1. Develop a checklist of scope elements and associated detailed definitions that can be used by communities to develop high quality, complete mitigation project definition packages
2. Develop a rating method and tool that can be used by state officials to evaluate the quality and completeness of submitted mitigation projects for the purpose of selecting projects for funding through the federal Hazard Mitigation Grant Program
3. Demonstrate the effectiveness of the rating tool for comparing the completeness and quality of mitigation project definition packages

Research Methodology

The research methodology involved reviewing the State of Texas Hazard Mitigation Grant Program Comprehensive Application Package Instructions 2009 and several

completed mitigation project application packages to identify the elements that were required and recommended for inclusion in the project definition/application package. Furthermore, planning and project definition scoring methods were reviewed to develop a tool for rating both the completeness and the quality of mitigation project definition. Following this review, the researchers developed a list of mitigation project scope elements and detailed descriptions that could be used by communities to develop mitigation projects. The result was a checklist of items that should be included in a mitigation project application package in order to produce a quality package. After developing scope elements and descriptions, the researchers developed a quantitative rating system that was largely based on plan quality scoring techniques that are commonly used in the field of community planning. The rating system was implemented as a database tool, and eight projects were entered into the tool and were scored using the rating method. The results confirmed that the scoring system and tool can distinguish the quality and completeness among project packages.

Review of Existing Project Planning and Project Definition Rating Methods

The study incorporated concepts from research on the quality of community planning and from project definition rating methods. Research on the quality of community plans has evolved over the past decade, and was originated by Kaiser, Godschalk, and Chapin (1995), who defined plan quality as consisting of three core characteristics: (1) a strong factual basis, (2) clearly articulated goals, and (3) appropriately directed policies. To measure these three core characteristics, also referred to as plan components, a series of indicators were developed that allow for quantitative assessment and analysis of plan quality. For example, the "goals" component included information on economic goals (e.g., minimize fiscal impacts of hazards), physical goals (e.g., reduce property loss), and public interest goals (e.g., protect human safety). Each indicator that was developed to measure the quality of each plan component was measured on a 0 to 2 ordinal scale, in which 0 = not identified or mentioned in the community plan, 1 = suggested or identified but not discussed in detail in the community plan, and 2 = fully detailed or is a mandatory part of the community plan. Equal weighting was assigned to each plan quality indicator to avoid subjectivity. As described by Brody (2003), the measurement of overall plan quality was calculated by creating indices for each plan component and overall plan quality. There were three steps in the development of the index for each plan component. First, the scores for each of the indicators were summed within each of the plan components. Second, the sum of the scores was divided by the total possible score for each plan component. Third, this fractional score was multiplied by 10, placing the plan component on a 0-to-10 scale. Finally, a total plan quality score was developed by adding the scores of each component. Thus, a maximum score was determined, and the quality of various communities' plans could be contrasted by comparing their plan quality index score.

Berke et al. (1996) expanded the plan quality research by adding two additional factors that impact community plan quality: commitment to planning and community wealth. Berke later added population to the list of factors that impact plan quality (Berke 1998), and Burby and May (1998) further investigated the impact of planning

agency capacity on plan quality. Finally, Brody (2003) incorporated hazard mitigation measures into existing conceptions of what constitutes a high-quality plan. As noted by Brody (2003), the ability to code and measure indicators within a plan has made this technique a widely used instrument for quantitatively assessing the quality of planning efforts.

The standard for rating the completeness of project definition was established by Gibson with the development of the original Project Definition Rating Index (PDRI) (Gibson and Dumont 1996). Gibson first identified and categorized the critical elements that should be included in a capital project's scope definition package by reviewing company documents and conducting workshops with experts. Elements included design objectives, project schedule, site location, and numerous others. Each of the scope elements was then described in detail to ensure consistent understanding of the elements by all stakeholders. Furthermore, recognizing that not all elements will be equally important to overall project success, a series of workshops was conducted with experts to evaluated and assign a weight to each scope element based on its importance to project success relative to all other scope elements. Overall, 70 project scope elements were defined, weighted, and combined into an index that can be used to evaluate the completeness of project scope definition.

The current research combined the method of rating plan quality with the method of rating the completeness of project definition in order to develop a method for rating the completeness and quality of mitigation project application packages. These packages (1) should contain specific elements of project definition and (2) must achieve a relatively high level of quality in order to increase the community's chances for receiving federal funding to execute the mitigation project.

Development of Mitigation Project Scope Elements and Definitions

To develop mitigation project scope elements, the researchers interviewed state officials and reviewed the State of Texas Hazard Mitigation Grant Program Comprehensive Application Package Instructions 2009 and six completed mitigation project application packages. The instructions provide basic guidance on items that must be included in the project application package, but it does not describe the expected quality or the level of detail that is necessary to produce a high-quality project definition. From the instructions, and by reviewing project application packages, the researchers developed mitigation project scope elements as well as definitions of the elements that could be used by communities to develop a detailed project definition package and could also be used by state officials to rate the quality and completeness of mitigation project packages. Figure 1 displays an outline of the project scope elements, and Figure 2 presents an example of a mitigation project scope element, definition, and rating method.

Method to Rate the Quality and Completeness of Scope Definition

In Fig. 2, *completeness* and *quality* of scope definition are conceptualized as a combination of the responses to the Yes/No criteria (i.e., "Are the following items included in the Synopsis?") and the number of criteria that have been met.

SECTION I – ELIGIBILITY STATUS

A. ELIGIBILITY AND DECLARATION STATUS
- A 1. Eligibility of Entity and Project
- A 2. Conformance with Eligibility Criteria
- A 3. Location Proximate to Declared Area

SECTION II – STANDARD FORMS

B. APPLICATION FORMS
- B 1. State Project Application
- B 2. State of Texas Assurances
- B 3. Federal Application SF 424 and Assurance
- B 4. Engineering Checklist

C. DESIGNATIONS, CERTIFICATIONS, AND STATEMENTS
- C 1. Project Officer Designation
- C 2. Floodplain Manager Form
- C 3. Cost Share Certification
- C 4. Record of Environmental Consideration

SECTION III – MITIGATION PROJECT INFORMATION

D. PROJECT OBJECTIVES AND SCOPE
- D 1. Synopsis Statement
- D 2. Narrative Statement
  - D 2-1. Summary
  - D 2-2. Need for Proposed Action
  - D 2-3. Description of the Proposed Action
  - D 2-4. Discussion of Alternatives Considered
  - D 2-5. Coverage in the Mitigation Action Plan
- D 3. Cost Breakdown
- D 4. Proposed Work Schedules
- D 5. Flood Insurance Rate Map (FIRM) with Project Plotted
- D 6. Photographs of Project Area

E. ENVIRONMENTAL & HISTORICAL INFORMATION
- E 1. Description of Environmental and Historical Information

SECTION IV – MITIGATION PROJECT COST EFFECTIVENESS

F. BENEFIT COST ANALYSIS, RATIO, AND SUPPORTIVE DATA
- F 1. Benefit Cost Analysis & Cost Effectiveness Study
  - F 1-1. BCA Cover Sheet with Benefit-Cost Ratio (BCR)
  - F 1-2. Benefit Cost Analysis (BCA) Output
  - F 1-3 BCA Back-up Data and Assumptions

Figure 1. Mitigation Project Scope Elements

D 1. Synopsis Statement
A synopsis statement is a brief summary of project related information. It should include information about the project objective, cost, schedule, and benefit-cost ratio (BCR). Are the following items included in the Synopsis?

Yes	No	1. Project location
Yes	No	2. Problem definition (i.e., need for the proposed project and expected result)
Yes	No	3. Project description and scope
Yes	No	4. Estimated project cost
Yes	No	5. Benefit cost ratio (BCR)

SCORING:

0 = A Synopsis is not included
1 = A Synopsis is included but 5 items from above are missing
2 = A Synopsis is included but 4 items from above are missing
3 = A Synopsis is included but 3 items from above are missing
4 = A Synopsis is included but 2 items from above are missing
5 = A Synopsis is included but 1 item from above is missing
6 = A Synopsis is included and no items from above are missing

Figure 2. Mitigation Project Scope Element Definition and Rating Method

As the number of criteria that have been achieved in the project definition/application package increases, the completeness likewise increases, and as a result, the quality overall increases. Hence, the scoring that has been assigned (i.e., "0 = A Synopsis is not included" or "1 = A Synopsis is included but 5 items are missing") is a reflection of both completeness and quality.

As shown in Fig. 1, there are four sections of a mitigation project definition/ application package: (1) eligibility status, (2) standard forms, (3) mitigation project information, and (4) project cost effectiveness. Hence, completeness and quality of scope definition is conceptualized as consisting of unequal weighting of these four sections based on how important the content of each section is to the overall application package. Experts at the state hazard mitigation office were queried to determine which weights were assigned to each section of the application package. Based on their response, eligibility status was assigned a weight of 30%, standard forms was assigned a weight of 10%, mitigation project information was assigned a weight of 30%, and project cost effectiveness was assigned a weight of 30%.

Together, these four sections of the mitigation project definition/application package enable a local community to develop a viable scope of work for a mitigation capital improvement project. Furthermore, within each section of the project definition/application package, individual indicators (scope elements) further specify the concept of completeness and quality of scope definition. The following process was used to develop an index score for each *section* of the project definition package.

1. Each individual indicator (scope element) received a raw score using a rating system similar to the one identified in Fig. 2.
2. The raw scores assigned to each indicator within a section were summed to determine the total points assigned to all indicators (scope elements) within each section.
3. The sum of the assigned raw scores was divided by the sum of the total possible scores for each section.
4. This fractional score was multiplied by 100 to standardize the section score on a more intuitive 0-100 scale.

The measure of *overall* project definition/application completeness and quality was derived as follows:

1. Each section standardized score was multiplied by its section weight.
2. The weighted standardized section scores were summed to arrive at an overall project definition/application weighted score.

Ultimately, the scores can be used by state officials to compare the quality and completeness of submitted mitigation projects so that they can select the highest quality projects for funding.

Initial Assessment of Mitigation Project Definition Completeness and Quality

To test the scoring method, six mitigation project definition/application packages were examined. Index scores were developed for each of the four sections of the packages and an overall Completeness-Quality Score (CQS) was established. The results are presented in Table 2 (section scoring) and Table 3 (overall scoring). The applicants are identified in rows, and the project definition/application package sections are identified in columns. Future research will involve conducting a reliability analysis to evaluate the utility of the score index as a measure of project definition completeness and quality.

Applicant and Project Information

The applicant and project information is summarized in Table 3. Two of the six applicants were cities, three were counties, and one was a drainage district. All of the projects were intended to mitigate the impacts of flooding, and the types of requested projects included four culvert replacements or installations, one channel construction, and one general drainage improvement project. The projects ranged in value from $253,000 to $902,000.

Mitigation Project Definition/Application Completeness-Quality Analysis

Table 2 displays the unweighted scores for the four application sections. Each row in the table represents the scores received by one applicant. Both the raw score and the standardized score are displayed in the table. At the bottom of the table, the total possible raw score for each section is shown. For example, the first applicant received two points out of three for Section I, 16 points out of 18 for Section II, 54 out of 65 points for Section III, and six out of seven for Section IV. Table 3 displays the standardized scores for each section. For example, Section I has a weight of 30%; hence, the total weighted standardized score possible is 100 x 0.30 = 30. The first applicant received a weighted standardized score of 20 for Section I. The total

possible overall weighted score is 100. The first applicant received a total overall weighted score of 79.5. Comparatively, the first applicant had a relatively high overall standardized weighted score (79.5), whereas the fourth applicant had a low overall standardized weighted score (28.0). The fourth applicant specifically needs to

Table 4. Applicant and Project Information

No.	Entity	Event Mitigated	Type of Project	Cost
1	County	Flood	Culvert replacement	$294,000
2	Drainage District	Flood	Drainage improvements	$902,000
3	City	Flood	Install storm sewers	$458,000
4	City	Flood	Install storm sewers	$715,000
5	County	Flood	Elevate road/install culverts	$253,000
6	County	Flood	Channel construction	$665,000

improve the completeness and quality of the benefit-cost analysis in order to compete more effectively for federal grant funding.

Conclusion and Future Research

The researchers have developed a method to rate the completeness and quality of mitigation project definition, and it is envisioned that this data will be used in three important ways. First, communities will use the information to develop better, more complete, and higher quality projects for submission to federal grant programs. Second, the state mitigation officer will use the information to rate the completeness and quality of projects and applications so that they can select the best projects to receive federal grant funds. Finally, the researchers intend to collect additional data and to further refine the scoring method. A validity and reliability analysis will be conducted to determine the importance of each indicator to the total index score.

OPTIMIZING ALTERNATIVE HOUSING PROJECTS IN THE AFTERMATH OF NATURAL DISASTERS

Omar El-Anwar[1]

[1]Assistant Professor, Department of Construction Management, University of Washington, Seattle, Washington 98195, e-mail: elanwar@uw.edu

ABSTRACT

In 2006 the U.S. Congress appropriated $400 million to the Department of Homeland Security to support post-disaster alternative housing pilot programs as a possible substitution to the highly criticized temporary housing programs. One of the main objectives of these programs is to provide quick and permanent housing solutions to displaced families. Decisions on alternative housing should be carefully analyzed because of their significant impacts on (1) socioeconomic welfare of displaced families; and (2) available budgets for post-disaster housing recovery. This paper presents the development of an optimization model capable of identifying the optimal alternative housing plans that maximizes the net social benefits of these programs. This is achieved by striking a balance between the added social benefits to displaced families provided by alternative housing and the corresponding associated costs. An application example is analyzed to demonstrate the use of the proposed model and its capabilities in maximizing net social benefits.

KEYWORDS

Optimization, Alternative Housing, Temporary Housing, Post-Disaster Recovery, Net Social Benefits.

INTRODUCTION

The large scale and catastrophic impacts of Hurricanes Katrina and Rita (2005) challenged the statutory supposition that temporary housing assistance will generally not be required for more than 18 months (FEMA 2008). In fact, temporary housing continued to be used for up to 44 months after Hurricane Katrina (FEMA 2009a). This prolonged use of temporary housing and its associated impacts on the displaced households led the US Congress to appropriate $400 million to the Department of Homeland Security (DHS) to support alternative housing pilot programs in order to explore the possibilities of providing more permanent housing solutions (FEMA 2009b). The Alternative Housing Pilot Program (AHPP) encourages innovative solutions that can lead to permanent affordable housing (FEMA 2006). In addition, these innovative housing solutions need to be quickly deployed to house families

residing in mass-care emergency shelters. Accordingly, alternative housing should play the role of both temporary and permanent housing.

Among the main objectives of AHPP is to evaluate the efficacy of non-traditional housing alternatives for potential future use after large-scale natural disasters. Evaluating and maximizing the efficacy of post-disaster alternative housing is an important objective because of the long-term nature of alternative housing relative to the traditional temporary housing. Decisions on alternative housing projects can have significant and long-term impacts on multiple parties, including (1) social and economic impacts on displaced households, because housing plays a key role in determining the socioeconomic welfare of its residents (Quercia and Bates 2002; Shlay 1995); and (2) impact on post-disaster recovery plans often executed under tight budgets, because of the additional resources needed to provide alternative housing solutions. Accordingly, decisions on alternative housing need to be carefully analyzed in order to account for its multiple and significant impacts.

Various aspects of temporary housing and post-disaster housing recovery were studied and reported in the literature (Barakat 2003; Bolin 1982; Bolin 1993; Bolin and Stanford 1991; Chandler 2007; Comerio 1997a; Comerio 1997b; Comerio 1998; FEMA – CUSEC 1998; Fox 2002; Golec 1983; Johnson 2002a; Johnson 2002b; Kamel and Loukaitou-sideris 2004; Quarantelli 1985; Quarantelli 1995; Peacock et al. 2006; El-Anwar et al. 2008; El-Anwar et al. 2009a; El-Anwar et al. 2009b; El-Anwar et al. 2009c; El-Anwar et al. 2010b). Despite the significant contributions of the aforementioned research studies, there is little or no reported research on maximizing the net social benefits of alternative housing projects after natural disasters. Accordingly, there is a need for novel research methodologies to evaluate and optimize decisions on alternative housing taking into account its multiple impacts on society. The objective of this paper is to present the development of a prototype optimization model capable of identifying optimal decisions on alternative housing that would maximize the net social benefits to both the displaced families and emergency management and aid agencies. The following sections provide a brief description of the model formulation and implementation followed by an application example.

MODEL FORMULATION

An optimization model is formulated in order to maximize the net social benefits of post-disaster alternative housing. The model is designed to answer the following important questions: (1) What is the optimal number of displaced families to be provided by alternative housing instead of the traditional temporary housing? (2) Which candidate alternative housing projects should be provided and what are their optimal sizes? (3) Which temporary housing projects should be substituted by the alternative housing projects? And (4) how to quantify and optimize the impact of these decisions on the net social benefits of displaced families and emergency management and aid agencies? The following sections briefly describe the formulation of the decision variables and optimization objective that are designed to address these research questions.

Decision Variables

The decision variables are designed to represent (1) the number of families that should be provided by alternative housing; (2) the alternative housing projects selected and their sizes; and (3) the temporary housing projects that will be fully or partially substituted by alternative housing projects. To this end, the decision variables are divided into increments of families (e.g. 10 families). The total number of increments (I) is equal to the total number of families that can be housed in the potential alternative housing projects (N) divided by the increment value. Each increment of families (i) is represented by two decision variables representing (1) which alternative housing will house those families and (2) which temporary housing project will be substituted in return, as shown in Figure 1. Accordingly, the total number of decision variables is equal to twice the total number of increments. For example, for an increment of 10 families and if N = 5,000, then there will be 500 increments and 1,000 decision variables.

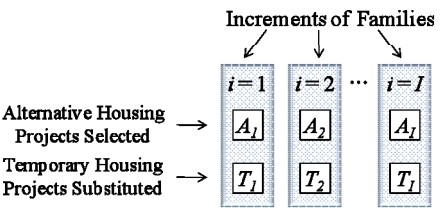

Figure 1. Decision Variables

The first group of decision variables (A_i) represents which alternative housing project is selected for housing the corresponding increment of families (i). For example, if the increment is set to 10 families and decision variables A_1 = 7 and A_2 = 5, this means that the first 10 families will housed in alternative housing project #7, where as the second 10 families will be housed in alternative housing project #5. If no alternative housing project is selected for that increment of families (i.e. A_i = 0), then these families are going to be housed in traditional temporary housing.

The second group of decision variables (T_i) represents which temporary housing projects will be fully or partially substituted by alternative housing. In the previous example, if A_1 = 7 and T_1 = 3, it means that the first 10 families will be housed in alternative housing project #7 instead of temporary housing project #3.

Optimization Objective

The main objective of the proposed model is to maximize the net social benefit of alternative housing projects to displaced families and emergency management and aid agencies. In order to evaluate and maximize the net social benefit, the model is designed to compute two important metrics: (1) the social benefits metric (SB), which represents the value of added social benefits by providing alternative housing to displaced families in substitution of traditional temporary housing; and (2) the total change in cost metric (TCC), which accounts for the added cost associated with providing alternative housing as well as the corresponding savings from fully or partially substituting originally planned temporary housing projects. Accordingly, the

optimization objective of the proposed model is to maximize the net social benefit (*NSB*), as shown in Equation (1).

$$\text{Maximize } NSB = SB - TCC \tag{1}$$

Where, *NSB* is the net social benefit of alternative housing projects; *SB* is the social benefits metric; and *TCC* is total change in cost metric. In regard to computing the social benefits metric, previous research studies have proposed indexes to quantify the socioeconomic impacts of temporary and alternative housing on displaced families, such as the socioeconomic disruption index (*SDI*) and the social welfare index (*SWI*) (El-Anwar et al. 2008; El-Anwar et al. 2009c; El-Anwar et al. 2010a; El-Anwar et al. 2010b). These indexes can account for important social metrics, including (1) employment and educational opportunities at the housing location; (2) housing quality; (3) housing delivery time; (4) capacity of housing location to support healthcare and safety needs for displaced families; and (5) access to public transportation and essential utilities and services (El-Anwar et al. 2008; El-Anwar et al. 2010b).Therefore, the model enables decision-makers to assign a social welfare index for each temporary housing project included in the original temporary housing plan (*SWI(T)*) and for each candidate alternative housing project (*SWI(A)*). Accordingly, the social benefits metric (*SB*) can be computed using Equation (2).

$$SB = \sum_{i=1}^{I} \left[SWI(A_i) - SWI(T_i) \right] \times V_{SWI} \times f \tag{2}$$

Where, *SB* is the social benefits metric; *I* is the total number of increments of families; $SWI(A_i)$ is the social welfare index for the i^{th} increment of families that will be housed in alternative housing project A_i; $SWI(T_i)$ is the social welfare index for the i^{th} increment of families that would have been housed in temporary housing project T_i if alternative housing was not provided; V_{SWI} is the monetary value of the social welfare index, which is an input by the decision-maker; and *f* is the value of the increment of families (e.g. 10 families).

In order to compute the total change in cost metric (*TCC*), the model accounts for four types of costs: (1) the initial cost ($C_1(A_i)$) of providing each alternative housing project A_i, which covers the costs of design, permits, mobilization, etc.; (2) the cost ($C_2(A_i)$) associated with increasing the size of an alternative housing project to accommodate an increment of families, which covers the cost of the construction or installation of new housing units, additional land acquisition, etc.; (3) the initial cost ($C_1(T_i)$) of providing each temporary housing project T_i, which is needed to compute the savings in case of fully substituting temporary housing by alternative housing; and (4) the cost ($C_2(T_i)$) associated with increasing the size of a temporary housing project to accommodate an increment of families, which is needed to compute the savings in case of partially substituting temporary housing by alternative housing. Accordingly, the model computes the total change in cost metric (*TCC*) using Equation 3.

$$TCC = \sum_{i=1}^{I} \left[C_1(A_i) - C_1(T_i) \right] + \sum_{i=1}^{I} \left[C_2(A_i) - C_2(T_i) \right] \times f \tag{3}$$

Where, *TCC* is the total change in cost metric; *I* is the total number of increments of families; $C_1(A_i)$ is initial cost of providing alternative housing project A_i, and it is accounted for only once when the alternative housing project is initiated; $C_1(T_i)$ is the initial cost of providing temporary housing project T_i, and it can be subtracted only once to reflect savings in case of fully replacing temporary housing project T_i with alternative housing; $C_2(A_i)$ is the cost associated with increasing the size of alternative housing project A_i to accommodate an increment of families; $C_2(T_i)$ is the cost associated with increasing the size of a temporary housing project to accommodate an increment of families, and it is subtracted to reflect savings in case of partially substituting temporary housing project T_i with the alternative housing project A_i; and *f* is the value of the increment of families (e.g. 10 families).

MODEL IMPLEMENTATION

The proposed model is designed to identify the optimal decisions on alternative housing that would maximize the net social benefit to displaced families and emergency management and aid agencies. Non-Dominated Sorting Genetic Algorithm II (NSGA2) is used to implement the proposed model because of its (1) superior performance compared to other genetic algorithms (D'Souza and Simpson 2002; Deb et al. 2001; Weile et al. 1996); and (2) unique characteristics such as fast non-dominated sorting and elitism (Deb et al. 2001; Deb 2005). The model is implemented in four main steps: (1) initialization phase, in which a population of random solutions is generated, where each solution represents a possible combination of assignments of increments of families to candidate alternative housing projects and the substituted temporary housing projects; (2) solutions evaluation phase, where the optimization objective is evaluated for each solution based on the computed net social benefit, as shown in Equation (1); (3) ranking phase, in which all the solutions are ranked based on the value of their net social benefit; and (4) population generation, where a new improved population of solutions is generated. Phases 2, 3, and 4 are then repeated until a predetermined number of generations are completed.

APPLICATION EXAMPLE

An application example is presented to demonstrate the use of the model and its capabilities in maximizing the net social benefits. In this example, a configuration of 20 temporary housing projects are planned to house 5,520 displaced families. There are 10 candidate alternative housing projects that are being considered for substituting some of the temporary housing projects with a total capacity of 2,340 families. V_{SWI} is assumed to be $54,000 and the increment of families is assumed to be 20 families. Therefore, there are 117 increments of families that can be housed in alternative housing (2,340 families ÷ 20). Accordingly, there are 234 decision variables that need to be optimized (twice the number of increments as previously explained), and the search space for this problem is approximately 1.16×10^{274}.

The model is used to maximize the net social benefit by identifying the optimal decisions regarding (1) which alternative housing projects should be selected and with what capacities (which is represented using 117 decision variables); and (2) which temporary housing projects should be partially or fully substituted (which is represented using the remaining 117 decision variables). The model is used to search

for near-optimal solutions for this problem with a population size of 1,000, crossover probability of 0.9, and mutation probability of 0.00095.

Figure 2 shows the rapid improvement of the net social benefits (in dollar value) for the optimal solutions identified until a predetermined termination criterion of 1,000 generations. The results illustrate the ability of the proposed model to identify optimal decisions on alternative housing that would maximize the net social benefits to both the displaced families and emergency management and aid agencies.

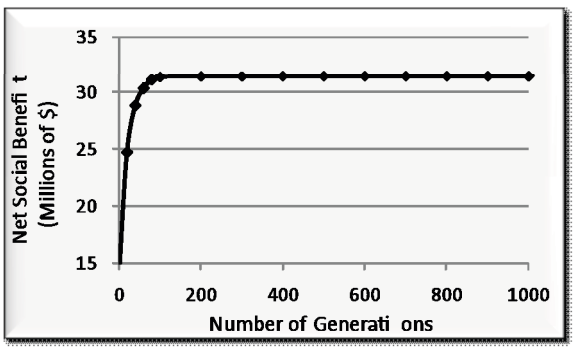

Figure 2. Optimization Results

Figure 3 shows the average rate of improvement in the net social benefits per generation, where the average rate is measured every 20 generations for the first 100 generations and then every 100 generations afterwards. The results show that the rate of improvement starts at high values and then decreases until it approaches convergence approximately after 400 generations.

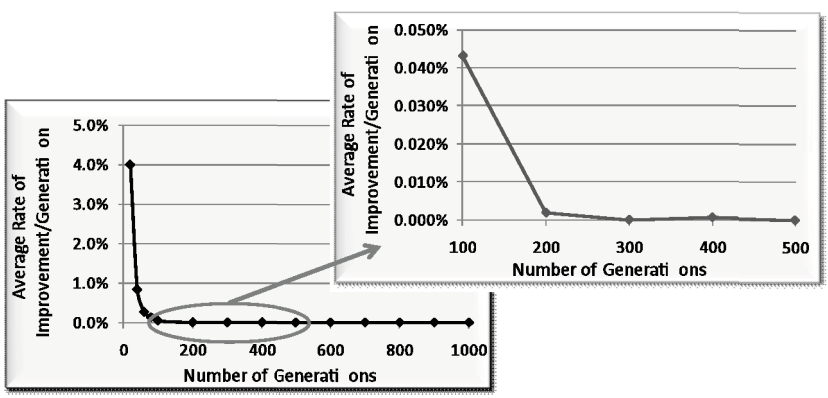

Figure 3. Average Rate of Improvement per Generation

CONCLUSION

An optimization model is developed to support decision-makers in planning for post-disaster alternative housing projects. The decision variables in the developed model

are designed to represent (1) the number of families that should be provided by alternative housing; (2) the alternative housing projects selected and their sizes; and (3) the temporary housing projects that should be fully or partially substituted by alternative housing. The objective of the model is to maximize the net social benefit for displaced families as well as emergency management and aid agencies. In order to quantify and maximize the net social benefit, the paper presents the development of two new important metrics: (1) the social benefits metric (*SB*); and (2) the total change in cost metric. The model is implemented in four main steps using Non-Dominated Sorting Genetic Algorithm II. An application example is presented to demonstrate the use of the model and its unique capabilities in identifying optimal plans for alternative housing that would maximize the net social benefits. The model is currently being expanded to consider other important objectives; including quantifying and optimizing the impacts of alternative housing projects on host communities. Moreover, future research will investigate economic methods to compute the monetary value of the social welfare metric, such as utility theory, in addition to willingness to accept and willingness to pay methods. The presented model should prove useful to emergency management agencies at the state and federal levels and can be used to support officials and decision-makers in planning for alternative housing projects after natural disasters.

Abstract:
Critical infrastructure play an important role in functioning of industries and communities and also responding against natural disasters to reduce their impacts (i.e., routes and bridges for evacuation and public buildings for sheltering). Due to global warming, there is an increase in the frequency of extreme weather events which pose a high risk of functional and structural failure of critical infrastructure. Recent natural disasters (i.e., Hurricane Katrina, 2008 Midwest Flood, etc.) have exposed the vulnerability of critical infrastructure in the U.S. Therefore, it is important for the emergency-related agencies to identify and fortify the vulnerable critical infrastructure ahead of time to significantly reduce the potential damage due to floods. In this paper a decision support system (DSS) using Bayesian Network theory and System Dynamics Simulation method is presented for vulnerability assessment of critical infrastructure. This DSS has been developed to support emergency agencies and industries to prepare customized mitigation strategies and plans for preparedness, response, and recovery using the criticality and vulnerability analyses.

1. Extreme Events and the Role of Critical Infrastructure

Critical infrastructure plays a very important role not only for sustaining industries and communities but also in properly responding against natural disasters to reduce their impacts. Critical infrastructure are considered as life support networks that are essential to sustain the normal activities of the industries and communities, such as production, delivery, and supply chain issues for industries, as well as commuting to work, school, church, healthcare, etc., for communities. Moreover, at the occurrence of natural disasters, the critical infrastructure such as routes and bridges for evacuation support activities for disaster response and recovery.

Thus, if critical infrastructure are damaged due to natural disasters, they in turn affect the services and activities of industries and communities as well as disaster response during disasters. Natural disasters, such as the recent floods in Atlanta and the Midwest (2008), Hurricane Ike in the Gulf coast region (2008), and the earthquake in Sichuan, China (2008), caused severe damage to critical infrastructure and associated industries and communities. The estimated damages due to Hurricane Ike are a staggering $27 billion, third worst in the U.S. after Hurricane Andrew (1992) and Hurricane Katrina (2005). In the case of Katrina, eight (8) percent of the affected population were isolated due to broken levees in the Gulf Coast areas and could not be evacuated whereas about 1,330 were killed or reported missing (Homeland Security and Counterterrorism 2006). Similarly, if the emergency-related agencies in Sichuan had identified and fortified the vulnerable critical infrastructure (i.e., communication networks and main routes) ahead of time the damage and impacts due to earthquake could have been significantly mitigated (New York Times 2008).

The reasons that cause these failures of critical infrastructure are closely related to the conditions of critical infrastructure. The majority of infrastructure throughout the U.S. has been weakened due to age and deteriorated conditions making them vulnerable to natural disasters. For example, the 2009 ASCE Report Card for infrastructure gives an average grade of D to U.S. infrastructure, which signifies a need for urgent rehabilitation.

2. Previous Research of Natural Disaster Impact Analysis

Since critical infrastructure play significant roles during the occurrence of natural disasters, preparedness and mitigation strategies should include identifying and fortifying vulnerable infrastructure based on their interrelationship with the associated industries and communities. In previous research conducted by the authors (Hastak et al. 2008, Oh 2008) this interrelationship has been defined through a basic cell model (Fig 1). However, the inter-relationships that Hastak et al. (2008) emphasized is mainly focused on technical issues, such as critical infrastructure affected by floods, level of inter-relationship, and industrial distribution in the affected areas. However, to understand the inter-relationship between critical infrastructure, industries, and communities, it is important to define their relationships and impacts considering various economic, social and technical factors.

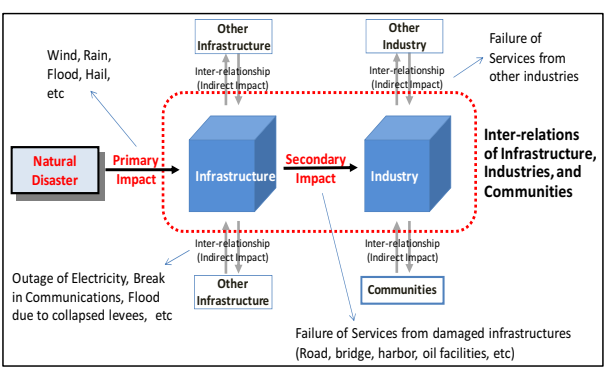

Figure 1: Disaster Impact Mechanism (Basic Cell Model) (Hastak and Oh 2008)

Economic Impacts: Burrus et al. (2002) have used full-day

equivalents lost (FDEL) as a metric for measuring the cumulative impact of frequent business interruption in low-intensity hurricane regions. Whereas, Lian et al. (2007) applied mathematical methods to measure the impact on companies through their input-output (I-O) exchange of goods and services. The model analyzed the interdependency among the industry sectors of the economy and the indirect ripple effects of initial perturbations to the critical infrastructure systems. Rose et al. (2007) also established economic factors to measure the impact of natural disasters focusing on regional economics that are highly dependent on electricity. Computable general equilibrium (CGE) simulation method was applied using factors such as output loss of downstream/upstream customers/suppliers, output loss to all firms from decreased customers, etc. Most of these models are complex and time consuming and combine economic and engineering data along with time based information to generate results (Mantell 2005, Moteff et al. 2003). Hence models that could give quick input-output results providing with an upper end of total loss are most beneficial to emergency response decision making team as they would provide an extent of disaster effects over a region in a short period of time.

Social Impacts: Current research methods can gauge economic gains and losses but are unable to capture the degraded life quality after the floods (Tapsell et al. 2002). With an increase in socioeconomic losses due to natural disasters more emphasis is being placed on improved risk management strategies that consider both social as well as monetary loss (Munich-Re 2007). They have developed a Social Flood Vulnerability Index (SFVI) consisting of three social characteristics and four financial-deprivation indicators to measure the impact of floods on communities. Lindell and Prater (2003) illustrated the relationship of physical and social impacts of natural disasters on communities and emphasize the need for research to identify social and economic characteristics of communities such as type of commercial, industrial or agricultural business, skilled or unskilled workers, etc. and demographic factors such as age, gender, low-income employees, etc. This will help in anticipating the needs beforehand and effective disaster response can be initiated. However, these models do not capture the social and economic impacts caused by failure of infrastructure interrelationships.

Technical Impacts: Rinaldi et al. (2001) observed interdependencies among infrastructure and their importance and influence over functioning of industries. They have provided with a conceptual framework which shows a broad range of interrelated factors and system conditions using “six dimensions” such as infrastructure characteristics, state of operations, types of interdependencies, environment, coupling and response behavior, and type of failure. Chang et al. (2002) provided a loss-estimation decision framework based on Monte Carlo simulation. In addition, Chang (2003) pointed out the significant fact that loss of critical infrastructure, such as electric power, water, transportation, and other lifeline infrastructure systems can have far-reaching societal impacts. Based on this analysis, McDaniels et al. (2007) further characterized infrastructure failure interdependencies in terms of the sectors affected and the consequences for society. In addition, Simpson et al. (2005) have proposed a framework to measure resiliency of community against the risks of multiple hazards using fragility curves at building and infrastructure network level.

These achievements of various researchers have been a foundation to develop a new framework, which was suggested by Oh and Hastak (2008). They introduced a disaster impact analysis model based on inter-relationships of critical infrastructure and associated industries/communities and measured the magnitude of natural disaster impacts on communities and industries. The key components of this framework are vulnerable infrastructure (which are likely to be affected by a natural disaster), the main industries and communities in the affected area, and their varied inter-relationships. Besides, FEMA (the Federal Emergency Management Agency) has developed a GIS-based tool, Hazus-MH as an emergency management tool, to estimate the loss due to disaster impacts on communities. This model has a merit of visualization of the disaster area, however, it also has a shortcoming not to simulate the changeable conditions according to the timeline of a flood. For example, as the flood water rises, the conditions of main routes may change and some of them would fail to sustain their original purpose (i.e., transportation). Thus, experts may not be able to establish safe routes to reach and evacuate isolated people at the right time during a flood. In addition, most previous research focus on the response stages of 'mitigation strategies' and 'recovery after disaster' for communities. As a result, there may not be any support for disaster response during the disaster. Therefore, there is a need for a support system that can identify critical infrastructure for quick response and recovery such as evacuation, functioning and sustenance of communities and industries as well as identify critical vulnerable infrastructure for long term mitigation and rehabilitation strategies. The current paper has addressed these needs with respect to flood disaster.

3. Research Objectives

Therefore, the general objective of this research is to develop a decision support system for identifying region specific disaster mitigation strategies based on the inter-relationships between infrastructure and communities and associated industries in terms of technical, social, and economic dependencies. The model should be able to facilitate the decision making of the local emergency agencies and industries in developing better plans and strategies to maximize the use of available resources and infrastructure for sustaining the community and industrial activities during natural calamities. Where, the inter-relationships are identified in terms of the dependency of communities and associated industries on critical infrastructure.

4. Framework of Decision Support System

Plans and mitigation strategies for reducing the impacts are important at a wide-range of levels in terms of communities, industries, local and federal governments, etc. Thus, various entities, such as city managers, emergency management agencies, industrial experts, and community leaders, should be able to generate plans and mitigation strategies according to their purposes after data collection is complete. The information they need will be similar and can be derived based on the analyses of the collected data. For example, the purpose of disaster preparedness for a city manager and emergency managers in industries would be to identify vulnerable critical infrastructure from their view points. Thus, the information that should be identified for developing the mitigation plans and strategies includes:

- Identification of critical infrastructure for protecting or sustaining industries and communities in terms of the technical, social, and economic aspects (criticality)
- Identification of vulnerable infrastructure or vulnerable parts and sections of the critical infrastructure (vulnerability)
- Impacts on industries and communities if vulnerable infrastructure fail during a disaster (severity or level of impact).
- Mitigation plans to protect industries and communities or reduce the impacts.

Criticality implies, for example, how much a company is dependent on critical infrastructure in terms of its business activities. Vulnerability addresses the threats or potential hazards to industries or communities in disaster situations and can vary according to the condition of infrastructure. Severity implies the extent of damage or impact when a disaster occurs in communities or near industries (Oh et al. 2009a, 2009b, and 2009c). Thus, criticality, vulnerability, and severity can be key metrics for the framework of the decision support system to understand how critical infrastructure, industries, and communities are inter-related in terms of the impacts of natural disasters and how the natural impact can be measured.

5. Data Collection

Data collection efforts included survey questionnaires, interviews, and site-investigations. 65 complete survey questionnaires were collected from the affected areas in the Midwest area focusing social and economic data from residents. 19 interviews were conducted to collect technical, social, and economic data from affected communities as well as experts who were responsible to operate and maintain the critical infrastructure in the affected areas. Industrial experts were also interviewed to obtain information about the critical facilities and infrastructure to sustain their functions and services. This data collection effort was successfully conducted with support from NSF through a NSF SGER project that aimed to collect ephemeral data due to the 2008 Midwest floods. During the NSF SGER project, authors focused on critical infrastructure and the impacts on associated industries and communities through damaged critical infrastructure. Timing of data collection was very important for ephemeral data; however, it was also true that most relevant data was obtained from interviews and survey questionnaires due to limited accessibility to the affected areas at the occurrence of floods.

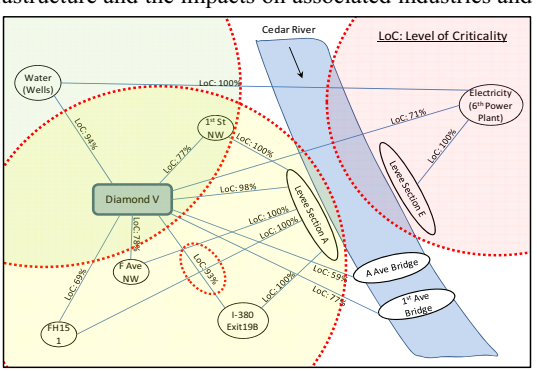

Figure 2: Zone of Influence and Network Structure of Inter-relationships with the Level of Criticality (LoC) of Diamond V (Cedar Rapids, Iowa)

Case Study: The example illustrated below has been developed using a case

study conducted for Diamond V during the NSF SGER study. Diamond V is a feed ingredient supplier in Cedar Rapids, Iowa that provides natural yeast culture products. Figure 2 illustrates Diamond V as a node with all interrelated infrastructure. It falls under the zone of influence of several adjacent critical infrastructure as shown in Figure 2.

6. Criticality Assessment

Criticality is the dependency of a community or an industry on a critical infrastructure in terms of their daily routine activities and it is important to measure the level of criticality (inter-relationship) between critical infrastructure, industries and communities. The level of dependency needs to be established by the community or industry since they understand best the role played by a particular infrastructure in their environment with respect to technical, social, and economic aspects. Thus, based on zone of influence analysis the users can determine the criticality of each infrastructure (Fig. 2). For example, Zone of Influence of Levee Section A covers the entire area of west side of the river including Diamond V, I-380 exit 19B, etc. In addition, the level of dependencies can be established through interviews and the final level of criticality (LoC) can be calculated using the decision tree analysis (Oh et al. 2009). Finally, the network structure (or zone of influence of inter-relationships) that illustrates all the inter-relationships and the level of criticality (LoC) can be represented as shown in Figure 2 (For the details of Criticality assessment, please, refer to Oh, Deshmukh, Hastak, and Dietz. (2009).

7. Vulnerability Assessment

The purpose of vulnerability assessment is to provide emergency-agencies and associated individuals appropriate information for preparing better mitigation strategies from a long-term perspective. It is also very important for them to facilitate their activities regarding the use of temporary methods/tools for mitigating the impact in time and the responses (i.e., evacuation, search and rescue, protecting infrastructure, etc.) during the occurrence of floods. Therefore, the vulnerability assessment should provide the level of vulnerability for each infrastructure based on the varied timeline (long-term and just before/during/after) of the flood. For example, if it is successful to predict the level of vulnerability of an infrastructure as a flood develops, it will be easy for them to react against the flood to mitigate the potential damage that the infrastructure may cause. However, measuring the level of vulnerability is complicated due to unpredictability of flood events and the characteristics of infrastructure. During a flood, critical infrastructure such as levees and bridges are likely to be affected in the primary impact stage. Whereas, in the secondary stage, other adjacent (or indirectly inter-related) infrastructure will be affected by the damaged infrastructure as well as the flood water (Oh et al. 2008). Thus, the level of vulnerability will vary according to the impact stages and the type of infrastructure.

For determining the level of vulnerability, two types of information are important: probability of failure (or inundation) of each component (critical infrastructure, associated industries, and communities) due to a flood; and the extent of potential damage to them. It is noticeable that the probabilities of failure of the infrastructure are linked (or chained). For example, the probability of inundation of a road near a

levee section depends on the probability of overflowing of the levee section. That is, if the probability of levee failure increases, then, the probability of failure of the road also increases. This conditional probability indicates the probable state of a variable that is dependent on the state of another variable.

Bayesian Network for Calculating Probabilities of Failure: A Bayesian network (or a Bayesian belief network) therefore can be applied to calculate the probability of failure for each component (i.e., infrastructure, industry, and community). The Bayesian network consists of nodes that are connected with directional arrows that represent conditional dependence relationships between those nodes. Bayes' theorem is used to recalculate the probability about the state of a node depending on the evidence introduced for another node in the Bayesian network (Jensen 1996, McCabe et al. 1998, and Bayraktar 2006). There are several software packages available to facilitate modeling using Bayesian networks. Figure 3 illustrates an example of Bayesian network using the network structure of Diamond V (refer to Fig. 2). The model described in this paper is created using GeNIe 2.0, a free software provided by the Decision Systems Laboratory of the University of Pittsburgh (http://dsl.sis.pitt.edu).

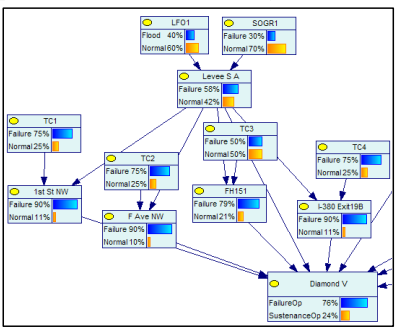

Figure 3: Example of Bayesian Network (Diamond V in Cedar Rapids, Iowa)

The figure shows three types of nodes: prior nodes of input probability (LFO (the likelihood of flood occurrence), SOGR (the State of Good Repair), and TC (Topographical Condition)), intermediate nodes of infrastructure (levee sections, roads (streets and avenues), bridges, and a power plant), and the end node (Diamond V)). The probability of failure (or flood) of Diamond V is affected by the prior probabilities from the adjacent infrastructure. Thus, its probability can be calculated by Bayes' Theorem using all prior probabilities from infrastructure as shown in Figure 3. In order to simulate the probability of failure for each component, i.e., infrastructure, industries, and communities, System Dynamics can be used.

Simulation based on System Dynamics: System Dynamics Simulation method has been used to simulate the vulnerability assessment of critical infrastructure, associated industries, and communities. The characteristics of the vulnerability assessment module are: (1) the system is very complex and mixed with many components and varied factors; (2) the components are inter-related with fixed level of criticality; and (3) the system should be structured in a macro level representing the components (i.e., infrastructure, industries, and communities). Thus, among the varied simulation methods, System Dynamics (SD) was considered the most appropriate for this research. SD can be considered as a set of rules (i.e., equations) that defines how the system is being modeled. In this paper, the vulnerability assessment module has been established using the case of Diamond V as an example of SD modeling (Fig. 4 shows a partial model). A free software, Vensim PLE Software, was used as a tool for the simulation.

There are three types of variables in the model: constant, auxiliary, and level. The sources of flood water (surface water, flood water-1, and flood water-2) and other information (topographical conditions, water pressure, SOGR, etc.) are examples of constant variables which provide basic information of the flood and the conditions of infrastructure as initial values. The box nodes are all auxiliary variables except Diamond V which is a level variable. Auxiliary variables calculate the vulnerability combining the values from constant variables and transfer the result to associated auxiliary and level variables. Thus, the impacts from the flood can be transferred to associated infrastructure and industries through the middle infrastructure which were expressed as auxiliary variables.

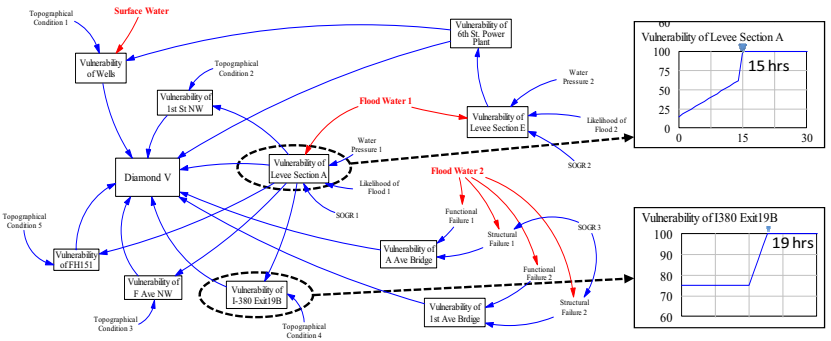

Figure 4: Example of a System Dynamics Simulation (Diamond V, Cedar Rapids, Ia)

The vulnerability of any infrastructure would be influence by its physical characteristics, for example, bridge elevation, levee height, and type of material and construction. For example, the vulnerability of Levee Section A which comprised of functional and structural failure could be determined by the conditions of related factors, such as Flood Water-1 and SOGR (Fig. 4). As Flood water-1 increases according to the rising water for 15 hours, the vulnerability of Levee Section A also increases. However, Flood Water-1 indicates that the flood water overflows at 15th hour and its vulnerability becomes 100% at that point. In sequence, the vulnerability of Levee Section A also gets to the point of 100% at 15th hour. Similarly, the vulnerability of each critical infrastructure can be evaluated through simulation. Each variable (infrastructure) shows its vulnerability change according to the timeline of flood. For example, as shown in Figure 4, the vulnerability of I-380 Exit19B increases rapidly when Levee Section A fails and the flood water runs on the ground for 4 hours, and it becomes 100% when the flood water reaches the exit at 19th hour.

8. Significance of the Results and Conclusion

The criticality and vulnerability assessments of the DSS identify critical infrastructure as well as its vulnerability to flood events. In the response stage, this information can be used for immediate actions to preserve life, property, and the environment. For example, main routes for evacuation can be examined through the vulnerability analysis before the flood water overflows. In addition, the assessment modules will help examine the conditions of critical infrastructure, such as levees, flood walls, and

dams, which are significant to protect industries and communities. The Department of Homeland Security defines the three stages of disaster response as: preparedness, response, and recovery (DHS, 2004). Preparedness includes wide range of activities to prevent/mitigate the impact of disasters, thus, it requires relevant data (i.e., technical, social, and economic) for hazard assessment, infrastructure assessment, planning, and training personnel. Thus, mitigation plans may include proper or emergent protection methods for safeguarding those important infrastructure. Additionally, knowledge about the vulnerability of critical infrastructure to natural (and or manmade) disaster can also be used for developing infrastructure rehabilitation strategies tied to the capital improvement program for the city or the industry.

After the flood water recedes, the efforts of recovery and rehabilitation of damaged industries/communities/infrastructure will follow. Rehabilitation of damaged infrastructure will be decided through criticality and severity analyses results in terms of the level of serviceability of a specific infrastructure. The mitigation strategies can be enhanced by combining the functions of the proposed DSS and the tools that were previously developed, such as Hazus-MH because it has the functions of direct and indirect loss estimates and visualization with GIS, while the proposed DSS provides criticality, vulnerability, and severity analysis based on inter-relationships and time-based mitigation actions during disaster occurrence.

In conclusion, data for disaster impact analysis in terms of social, economic, and technical aspects will be collected for facilitating and improving preparedness against the impact of natural disasters. Based on the data, factors for impact measurements and a framework for the simulation based decision support system will be developed. The decision support system will allow development of customized strategies and plans for each affected area. Eventually, a better understanding of the impact of disasters on infrastructure and the associated industries and communities would assist emergency-related agencies in identifying appropriate disaster mitigation strategies.

ABSTRACT

In construction sites, tracking personnel, equipment, and materials is necessary in many applications such as asset management and progress monitoring. Vision tracking as a tracking technique has two unique capabilities which make it ideal for tracking on large scale, congested construction sites; tracking from a distance and tracking multiple elements from a single camera. 2D tracking results can be obtained through each camera and the 3D positions can be calculated by calibrating multiple cameras. 2D vision tracking methods vary and each method has unique capabilities, but little is known about the appropriateness of each method for tracking construction resources. This paper presents an evaluation of these methods that aims to identify the one most suitable for 3D tracking in construction sites. To satisfy this goal, 2D tracking methods are categorized, metrics are identified and performance of two categories of methods is evaluated based on these metrics. This evaluation has been used to find some preliminary results that can ultimately help with selection of the most suitable category of 2D vision tracking methods for construction applications.

Vision tracking, Image processing, Computer vision, Comparison

1 INTRODUCTION

In construction sites, tracking project related entities (e.g. personnel, equipment, and materials) is necessary in many construction applications such as progress monitoring, activity sequence analysis, productivity measurements, locating resources, and safety management. One potential capability of 3D vision tracking is that it can track tens of hundreds of objects that are present in the view of a camera without installation of any tags on them. 3D vision tracking is expected to be cost-effective and time-effective in large-scale, congested construction sites, where a large number of entities are required to be tracked. This is because of the low cost of cameras and also less pre-processing time needed to install cameras compared with other tracking methods that require installation of tags on each entity being tracked.

3D vision tracking results can be obtained by applying epipolar geometry that can calculate the depth information of objects using 2D vision tracking results (i.e. x,y information) from two or more cameras (Brilakis et al., 2008). The effectiveness of 3D vision tracking methods is directly related to the performance of 2D vision tracking since accurate positions (x, y) of objects being tracked are required for optimum 3D vision tracking results. Therefore, it is necessary to find a proper 2D vision tracking method out of the methods that currently exist to see which one can satisfy construction resource tracking needs and be adaptable to the construction site environment. Since little is known on how these methods compare for this environment, a scientific approach to select an appropriate 2D vision tracking method that can fit construction industry's requirements can greatly enhance 3D tracking results.

There are a variety of 2D tracking methods with different capabilities and specifications in terms of the way of initializing the tracking (i.e. manual or automatic), the processing time, and their effectiveness in terms of handling occlusion, object size, etc. These aspects, along with complications that are in the nature of construction sites (e.g. existence of many different types of entities with high similarity in terms of shape and color (Brilakis et al., 2008)), make the selection of a proper 2D vision tracking method for construction applications a challenging task.

This paper presents a comparative study of existing tracking methods to find the most suitable one for construction site 3D tracking. To accomplish this objective, 2D tracking methods are categorized, studied and compared. A brief literature review shows that there are many different approaches and algorithms under each category of trackers, which results in enormous number of 2D tracking methods. This makes the literature so vast and no attempt can be nor will be made to review them comprehensively. Here, the authors have just tried to look at the main categories of trackers and tested some selected methods under each category to find the most optimum one for the purposes of 3D tracking in construction sites.

The comparison of 2D tracking methods is based on identification of criteria that can affect the efficiency of on-site tracking in construction sites which vary in terms

of their characteristics (e.g. size, complexity, congestion). These criteria have been set up as metrics (i.e. performance indicators) to evaluate and compare tracking methods for construction applications. Two categories of tracking methods (contour-based and kernel-based) were tested based on the number of frames each method can track. Preliminary results revealed that kernel-based tracker is capable of tracking more number of frames in each case.

2 VISION TRACKING

Object tracking has attracted a lot of interest and attention in the field of computer vision because of the large number of applications it has as well as availability of high performance computers and inexpensive digital video cameras. To achieve vision tracking, there are two main steps that must be accomplished. The first step is detection of objects of interest, which can be done manually or automatically depending on the method selected. This step has also been referred to as characterization or initialization step (Marfil et al., 2007). The second step is tracking of the detected objects and prediction of their changes in terms of position and shape in the succeeding image frame, which is also known as localization of targets (Marfil et al., 2007).

2D vision tracking is not sufficient for the general applications of tracking in construction industry and 4D information is required, i.e. 3D spatial coordinates over time. For instance, to avoid collisions at construction sites, the entities' precise position (i.e. 3D) is needed in real time to calculate the relative distance and velocity of objects. In vision tracking, cameras can be used to obtain 2D positions of objects in each camera's view. By integrating information collected from multiple cameras and applying epipolar geometry, it is possible to evaluate the depth information of objects (Brilakis et al., 2008). Consequently, obtaining reliable 3D tracking results depends on the results of 2D tracking. Therefore, selection of a 2D tracking method that is robust to domain specific variations of construction sites and produces valid tracking information is essential. 2D vision trackers can be classified as contour-based, kernel-based, and point-based trackers (Yilmaz et al., 2006). A brief review of each method is brought below.

2.1 Contour-Based Trackers

Many tracking methods use silhouette or contours to track objects by estimating and updating the region or boundary of the target in the current frame and comparing that with the results obtained from the previous frame (Nguyen et al., 2002). Contour-based tracking methods use a variety of algorithms; they may track parameterized contours and non-parameterized contours (Nguyen et al., 2002). Parameterized methods approximate the contour using a parametric model (e.g. B-Splines) or detect the contour by minimization of some energy function (i.e. snake model). Non-parameterized contours are basically represented as boundary of a

region (e.g. geodesic contour model) (Nguyen et al., 2002). The strength of the latter approach is that it can be used to represent the contour of an arbitrary shape (Nguyen et al., 2002) and as a result they have been used in most contour-based tracking methods of recent years.

Algorithms employed in contour-based trackers could use "photometric variables" (e.g. intensity, color, texture), "geometric variables" (e.g. edges, lines, corners), or a combination of both (Freedman 2004). It is argued that trackers that use photometric variables are more advantageous to geometric trackers because they are more reliable in the presence of illumination variations and cluttering and also they take into account the rich amount of information existing in the images (Freedman 2004). Based on literature, it could be safe to say methods that use non-parametric contours and photometric variables are more favorable to use because they are more robust to illumination variations as well as occlusion. The main advantage of contour-based trackers is that they can detect the exact contour, which is useful in applications where exact posture of the target is needed. Occlusion and illumination variations may not be handled as good as other categories of trackers.

One approach to achieve contour-based tracking is employment of variational frameworks (Yilmaz et al., 2006). These frameworks basically integrate variety of information for image segmentation Rousson and Deriche (2002). Bertalimo et al. (2000), Rousson and Deriche (2002), and Cremers (2003) presented different variational frameworks combining different information (e.g. motion estimation and shape regularization in Cremers (2003)). The framework proposed by Rousson and Deriche (2002) is a dynamical framework that works based on a Bayesian model. This method has shown very good results for image segmentation and contour evolution of different objects in a variety of backgrounds.

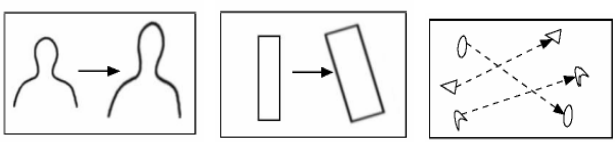
2.2 Kernel-based Trackers

Kernel basically refers to the shape and appearance of the object (Yilmaz et al., 2006). As a result, these trackers are also referred to as region-based or appearance-based methods. These methods compute and update the motion of the kernel in each frame based on the regions' information such as color and texture (Marfil et al., 2007). Color histogram generally plays an important role in these methods since color is a good feature to distinguish objects' regions and enables to manage partial occlusion (Marfil et al., 2007). However, the tracker may get confused if objects of similar colors are occluded by each other. Since these methods do not take any "a priori" knowledge of the objects' appearance into account, initialization of tracking a new object has to be performed manually.

Two sub-categories of kernel-based trackers are template and density-based appearance models, and multiview appearance models (summarized in Table 1 below). Template-based models take into account both color histograms and spatial information. The basic concept of template tracking is finding the region that best

matches with the template that is determined in the first frame (Marfil et al., 2007). One approach to do this is mean-shift procedure, which basically is an analysis technique that works based on the comparison of histograms of the object, Q, with the window approximated around the location of that object, P (Yilmaz et al., 2006). Bhattacharya coefficient is used in this approach to measure the similarity of the two histograms. Templates and density-based trackers are advantageous because of their simplicity and low computational cost. However, they are not suitable if the pose of objects change considerably in each frame (Yilmaz et al., 2006).

2.3 Point-based Trackers



In point-based trackers, objects are represented by some limited points, which are detected and tracked in consecutive frames (Yilmaz et al., 2006). In image frames that objects appear larger, the more points may be demanded for successful identification of the object, which could affect processing time and also when multiple points are employed, grouping of points that belong to the same object becomes an important problem (Yilmaz et al., 2006). Also, it is important to select and keep appropriate feature points that can effectively represent the objects. Yilmaz et al (2006) have divided point-based methods into two categories of deterministic methods and probabilistic methods. In general, point-based trackers using multiple points are beneficial to characterization of non-rigid objects provided that the locations of the feature points are flexible. Also, these trackers are suitable for tracking extremely small objects which can be represented by a single point, but they have more tendencies to fail in the presence of occlusion as well appearance and re-appearance of objects (Yilmaz et al., 2006).

2.4 Summary of Methods

The following table presents a summary of tracking categories outlined above. This table is based on the literature review and especially the survey of object tracking methods done by Yilmaz et al. (2006). It should be noted that the general strengths and limitations listed in this table are addressed and handled by some subcategories/approaches and it cannot be concluded that a category has such limitation regardless of the algorithm or method used. For example, although tracking multiple objects cannot be handled by most kernel-based trackers, there are some algorithms that can track multiple objects.

Table 1: A summary of Main Features of Object Tracking Methods

Category	Main Purpose	General Strength(s)	General Weakness(es)	Performance Evaluation	Sub-categories	Approaches (examples)
Contour-based	Tracking exact contour (object shape)	Ability to represent variety of shapes	handling occlusion and object split and merge	precision and recall	Contour-evolution	Variational Methods
					Matching Shapes	Histogram
kernel-based	estimating object motion (region and direction)	handling occlusion	handling multiple objects	precision and recall	Template-based models	Mean-shift
				distance b/w estimated and actual	Multi-view models	SVM Tracker
Point-based	tracking small objects (single point tracking)	tracking small objects	Handling occlusion and appearance & re-appearance	Precision and recall based on generation of point trajectories	Deterministic	MGE Tracker
					Statistical	MHT filter

3 COMPARISON MATRICS

Construction sites have some unique characteristics, which should be considered when it comes to object tracking, because they affect the appearance of objects in the view of the cameras. The scale of construction sites, the congestion, the clutter, the variety of objects with high similarity in terms of color and shape, the illumination as well as the illumination variations and the existence of both rigid and non-rigid objects (e.g. equipment and workers) that enter and leave the site are the main characteristics of most construction sites. Therefore, to find the most suitable 2D tracking method, one needs to know how well each of these factors can be handled. To satisfy this, a list of metrics that are based on these characteristics is proposed here to evaluate and compare the 2D vision tracking methods presented previously. These metrics are based on the ability of the tracker to handle: 1) occlusions, 2) small objects, 3) objects of different types, 4) illumination variations; 5) absolute value of illumination, and also 6) processing time.

Occlusion refers to the state when an object is partially or fully blocked by itself or another object. In construction sites, there is constant movement of equipment,

materials and personnel. As a result, it is extremely important to select a method that can continue to track objects even in the presence of occlusions. Self-occlusion is a common problem of contour-based methods especially when tracking non-rigid objects. It should be noted that one way to handle and control occlusions is by picking the right position to install cameras. By installing the cameras in higher levels, it is possible to minimize complete occlusion of objects; partial occlusions can be handled well by some methods (e.g. kernel-based).

Small objects can be defined as distant objects that appear to be small in the view of the camera and also those that have smaller dimensions compared to other objects (e.g. hardhats vs. bulldozers). Construction sites vary in size and some objects appear to be very small in the view of camera. Also, some objects move away from the camera and become small in size. Therefore, it is important to select a method that can track small objects and also be able to handle changes in scale.

The types of objects in construction sites refer to their rigidity and non-rigidity of objects. Rigid objects (e.g. wheel loaders, backhoes, steel beams) do not make severe changes in their poses. Therefore, their appearances are adequately predictable. On the other, non-rigid objects (e.g. workers) change their poses dynamically. This makes their appearances in the subsequent frames unpredictable. In most construction related applications, there is no need to track the whole body of a worker. As a result, it is possible to overcome the difficulty of tracking non-rigid objects by tracking a rigid part of their belongings (e.g. hard hat).

Illumination variations are related to changes that occur in lighting conditions. Such variations can affect tracking results because they can significantly alter the appearance of objects in the view of the cameras. Illumination variations are common at open, large-scale and congested construction sites, where shadows and light reflections (from other equipment or adjacent buildings) are present. Therefore, the ability to handle illumination variations is an important factor to be considered.

The absolute value of illumination is another factor related to lighting conditions. Absence of light or presence of strong illumination can affect tracking results depending on how severe each case is. Working hours at construction sites can start from very early hours in the morning when it is still dark and go on until very late hours of the day. Also, construction site locations vary geographically from very illuminated sites at deserts to light reflecting sites by oceans. Therefore, it is important to select a tracker that can perform accurately at different light levels in different locations and during the course of a day.

Processing time can be defined as the amount of time it takes a tracker to process one image frame and send the results to the user. After receiving and processing video data, the tracker should be able to transfer the accurate information to the user in a specified amount of time. For instance, when tracking for safety management, after the tracker detects a short distance that could result in a collision between a bulldozer and a worker, it should warn the worker before the collision occurs. Different

applications have different requirements for 2D vision tracking methods' processing time and the tracker that has less response time than the requirement should be selected.

4 RESULTS AND COMPARISON

The performance of tracking categories was tested and evaluated based on the metrics discussed in the previous section. For comparison purposes, a kernel-based method was selected that uses the Bhattcharyya coefficient as similarity measure and the mean-shift algorithm to carry out the optimization based on a method presented by Comaniciu et al., 2003. Also, a variational framework was selected as a contour-based tracker. Rousan and Deriche (2002) used a Bayesian model to develop their variational method and the authors combined this framework with a knowledge-based segmentation algorithm presented by Haker et al. (2001). These methods were implemented and tests were performed using videos that were taken at construction sites.

Some frames from preliminary tracking test results are shown in Fig. 2 below. In the first row of images, the worker (non-rigid object) is being tracked using the contour-based method. This worker could be tracked for 10 frames until he was occluded by another worker and then the tracking failed. On the other hand, the result from the kernel-based method shows that this method could still track the worker in the equivalent frame and even the subsequent frames. In the second row of images in Fig. 2, a bulldozer that is moving away from the camera is being tracked. The results show that the contour-based method loses the target in frame 2500 while the kernel-based tracker keeps tracking for another 6000 frames (until the object comes to the camera). The last row of images shows the results of tracking of a backhoe's bucket. Complete deformation of the bucket in the view of the camera can be observed in these images. The results revealed that the kernel-based method could track the bucket for 723 frames while the contour-based lost it in frame 101. It should be noted that illumination varies in each frame and affects the appearance of the target in the view of the camera. Therefore, both methods can handle illumination variations to a good degree. The difference in the processing time of these methods was not that significant and as a result it is considered to be a neutral criterion for the purposes of this evaluation and comparison.

To evaluate the performance of tracking methods, it is possible to measure the accuracy of each method by calculating their precision and recall as mentioned in Table 1 in section 2.4 above. It is also possible to assess the performance of tracking methods based on the number of frames successfully tracked to obtain some preliminary results. The authors have closely watched the frames and recorded the number of frames the object can be tracked using each tracking method. A summary of this comparison is shown in Table 2 for each case and criterion.

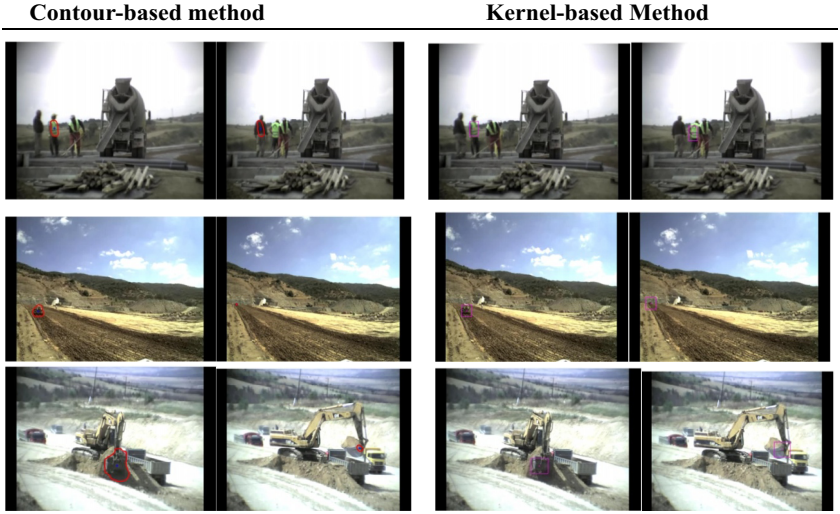

Fig. 2. Preliminary results of tracking in real construction sites.

Table 2. Number of frames successfully tracked.

	Kernel-based (Mean-shift)	**Contour-based (Variation method)**
Occlusion (e.g. worker shown in images a-d)	115	102
Small object and also scale variation (e.g. road roller shown in images e-h)	8564	2500
Object type and quick deformation (e.g. bucket of a backhoe shown in images i-l)	723	101
Illumination variation (e.g. bucket of a backhoe shown in images i-l)	723	101

5 CONCLUSION

Tracking objects in the construction sites is essential in many applications such as progress monitoring, activity sequence analysis, productivity measurements, locating resources, and safety management. These applications require the results of 3D vision tracking over time while calculating the depth information of objects (the 3rd dimension) depends on the results of 2D vision tracking. Selecting the best 2D vision tracking method for construction applications faces some challenges and difficulties. First of all, there are a number of 2D vision tracking methods with different capabilities and specifications. In addition, construction sites have unique tracking requirements, which must be considered in order to select a 2D tracking method that performs optimal under restrictions of construction sites.

This paper presented a systematic approach to compare different categories of 2D

vision tracking methods to find the most optimum one for 3D vision tracking purposes. The 2D vision tracking methods were first categorized and each was briefly described. The characteristics of construction sites that can interfere with the performance of these vision tracking methods were recognized and comparison metrics were set up based on them, to measure the performance of each category in relation with construction site requirements. One method from contour-based and another from kernel-based trackers was selected and implemented. A number of tests under different conditions of construction sites were performed to observe the performance of each tracking algorithm. The methods were compared based on the number of frames each tracker could successfully track. The preliminary results of this comparison revealed that kernel-based methods are more reliable between the two categories of trackers tested for construction related applications.

Future work will focus on measurement of accuracy of each method under each condition. Point-based methods will also be implemented, tested and compared with the results obtained in this study. Ultimately, the preferred 2D tracking method will be used to implement 3D vision tracking systems by employing epipolar geometry algorithm.

ACKNOLEDGEMENT

The authors would like to thank the generous support of National Science Foundation through projects 0933931 and 0904109. Also, they wish to gratefully acknowledge the contributions and help of Ibrahima J. Ndiour and Omar Arif from School of Electrical and Computer Engineering, Georgia Institute of Technology.

Abstract

This paper presents a framework of decision support systems for facilities maintenance management (FMM) with the objective of integrating facilities maintenance management, real-time project management, condition monitoring systems and building information models. Multi-faceted views of maintainable assets are designed to meet the requirements of any potential functional extensions or systems integration. Basic processes for asset management, Corrective Maintenance (CM), Preventive Maintenance (PM), and Condition-based Maintenance (CBM) are implemented in a Web-based FMM prototype system. The generic aspects of the system lay in the fact that: 1) all sources of maintenance work, ranging from manually entered CM orders and system generated PM orders to individual maintenance projects, are normalized and manipulated as projects and tasks; 2) the allocation of various kinds of resources, including equipment, materials, trades, contractors, and tools, is optimized using the proposed algorithms.

1. Introduction

Every company is dependent on "facilities" (also called "assets" or "equipment") that keep the business in business – be it a computer, a centrifuge, or a megawatt transformer. For specific enterprises whose asset replacement cost or equipment failures contribute to a significant part of their operations, efficient facility maintenance management is a top management concern. Downtime in any network, manufacturing, or computing system ultimately results not only in high costs, but also in customer dissatisfaction and lower potential market share.

Facility maintenance is always a matter of equipment uptime and the cost to support that uptime (Hoke and Craig 2008). In a manufacturing organization, the role of facility maintenance is easily neglected since it is a subsidiary stream supporting the main-stream production events. However, facility management in the construction

industry has a higher expectation and it constitutes a separate element in FIATECH's Capital Projects Technology Roadmap (FIATECH 2009), in which "real-time facility and project management, coordination and control" provides a fully integrated facility planning and management system. Built facilities always require large capital investment and a relatively high maintenance and operation cost. Critical facilities like municipal infrastructures, power plants, and airports, have stricter demands on health and safety, a bigger impact on society, and much less tolerance for failures.

Based on the basic concepts of Corrective Maintenance (CM), Preventive Maintenance (PM), Condition-based Maintenance (CBM), and the philosophical relationships between them, this paper presents a framework of decision support systems for facility maintenance management (FMM-DSS). Integration issues and technologies are discussed for integrating the FMM system with real-time project management, condition monitoring systems and building information models. A prototype system for FMM-DSS has been developed using a number of leading edge Java and Web-based technologies and it will be presented at the end of the paper.

2. CM, PM and CBM

The essence of the "run-to-failure" **corrective maintenance** approach is to replace a part with a new part only when it is out of function. It is a traditional method for facility maintenance which is surprisingly, still popular in present. Failure happens in reality no matter how you want to avoid them; so an organization should always have CM processes in place as an emergency plan to handle unexpected failures. The downside is that it always implies facility downtime, low customer satisfaction and is not a programmable operation in terms of time and cost. However, depending on the criticality of facilities, and how we can accept the consequences of a failure, CM is the most economical solution among the three maintenance strategies.

Preventive maintenance involves the planning of periodical replacements of parts, scheduling at regular time intervals, independently of whether the component is still performing satisfactorily or not. PM introduces a way to facility maintenance operations that allows some sorts of controllability into the plate, including planning and scheduling of routine maintenance work of assets. Accompany with explicit definitions of maintenance intervals (frequencies), periodic maintenance jobs (for example, inspections, or routine replacements) can be pre-scheduled and budgeted. However, if the PM intervals are not fine-tuned with asset conditions, PM may lead to "deficient" or "superfluous" maintenance. Failures cannot be totally avoided in theory and in practice in that they might still happen between the intervals.

Condition-based maintenance rationalizes prevention, because the physical variables that determine the symptoms of a failure are monitored. CBM has proven capable of aiding facility managers in identifying anomalies early enough to minimize the impact of operational interruptions; avoid expensive failures, including collateral damage; and significantly reduce the cost of maintenance. Many leading companies in the manufacturing, process, paper, and power generating industries have shifted the majority of their maintenance tasks from time-based preventive to condition based. Other similar terms such as "predictive maintenance" and "pro-active maintenance" can be categorized to CBM since they all continuously monitor variables and make maintenance decisions based on the collected condition data.

Table 1 summarizes the pros and cons for the three maintenance strategies.

Table 1: Pros and cons of CM, PM and CBM

Corrective	**Preventive**	**Condition-based**
Run to failure	*Fix it routinely before it breaks.*	*Don't fix it if it is not going to break.*
+ Facility is not over maintained + No initial investment + Low costs – High risk of secondary failure – Unscheduled and possibly long downtime – High cost of spare parts – Overtime and labor arrangement – Safety hazardous	+ Maintenance is controlled + Fewer catastrophic disasters + Stored parts and cost can be controlled + Unexpected failures should be reduced – Facilities are maintained when there is no fault – Unscheduled breakdowns cannot be avoided	+ Unexpected failures are reduced + Parts are ordered when needed + Maintenance is performed when needed + Facility life is extended – High initial investment – Additional skill is required – High operation cost – Extra instruments need to be maintained

Notes: "+": pros; "-": cons

Although it sounds like the evolvement of facility maintenance management practices from CM to PM to CBM is an improvement process, the reality is that ALL three must co-exist within an organization. For example, as PM and CBM cannot screen out failures theoretically, an organization must have a formal procedure in place to handle emergent breakdowns and the subsequent consequences. Also because CBM is costly and requires high skill sets and advanced technologies, few organizations can afford CBM solutions on all assets.

Hosseini (2009) has a vision that maintenance departments should gradually transform to maintenance systems and he believes that the ultimate goal is to achieve "performance-oriented" systems that are integrated with "operation" and "support" systems. We advocate this "system" viewpoint in that an optimal facility maintenance program should be a balanced distribution of CM, PM and CBM that meets the organization's high level strategic business plans.

3. Related Work

A good number of commercial facility maintenance software tools are available on the market, which can largely be categorized into enterprise-scale asset management (EAM) and specialized computerized maintenance management systems (CMMS). The most famous EAM software is SAP Plant Maintenance (SAP 2009). The main catalyst for SAP PM's success lies in the fact that it is seamlessly integrated into the existing SAP ERP kingdom in both operating and financial aspects. The selling point of CMMS systems (for example, MAXIMO 2009) is their essence and user-friendly features that are specific to the facility maintenance management domain.

In order to somehow standardize the methodology and processes toward CBM, an early effort by Hassanain et al. (2003) proposed a comprehensive framework model to formalize and standardize the business processes of asset maintenance management in which asset management is divided into five major processes: 1) identify assets; 2) identify performance requirements; 3) asset performance; 4) plan performance; 5) manage maintenance operations. The MIMOSA's up-to-date Open Systems

Architecture for Condition-Based Maintenance (MIMOSA 2009) specifies a standard architecture and framework with seven layers (namely, data acquisition, data manipulation, signal processing, condition monitoring, health assessment, prognostic, and decision support) for implementing condition-based maintenance systems. .

In past decades, CBM technologies have been successfully applied to manufacturing, construction, chemical, power, and process industries. A large volume of academic research work has been done in the area of CBM on a variety of topics. Based on the literature review, we noticed that the developed CBM systems are usually separate modules for condition assessment (Zhang et al. 2006; Luan et al. 2006), risk analysis (Narasimhan 2008), wireless and mobile sensing (Emmanouilidis et al. 2009; Sun 2009) of specific facilities or components, for example, diesel generation units (Luan et al. 2006), power distribution (Pathak et al. 2007), and aircraft (Narayanamurthy and Arora 2008). Very little effort has been made to integrate practical asset management and CBM systems in a general purpose. Our goal of FMM research is to build a fully integrated decision support system at both strategic and operational managerial levels that provides full-scale optimization for a balanced blending of maintenance strategies. The resultant system also aims to facilitate the integration of the FMM system with other AEC/FM elements in FIATECH through building information models (BIM) and process technologies.

4. An Integrated Decision Support Framework for FMM

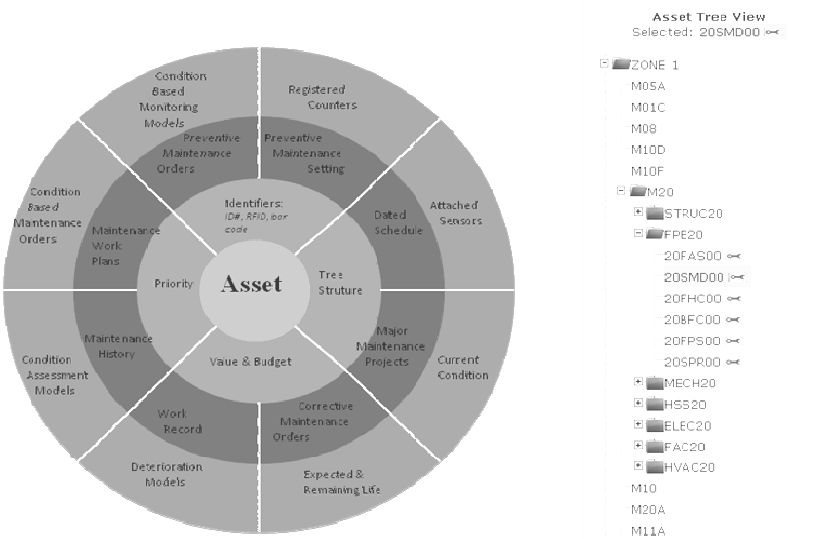

Figure 1: Asset information wheel and the tree structure

We propose a general decision support framework for facility maintenance management (FMM-DSS), in which information and business processes are all centered upon an entity - "asset". The term asset is equivalent to "facility" or

"equipment" in other systems. Figure 1 gives an overview of the general concept of an asset that contains information at three layers.

1) Basic information

The most important item in the basic information is the identification. Apart from the unique ID# that is referred to by the FMM system, an asset has other ways to distinguish itself in various environments; for example, RFID, bar code, and the GUID in BIM models. "Parent-children (1:n)" relationship is used to describe a tree structure and multiple roots are allowed in the hierarchy. In an asset tree, we distinguish two types of entities: "maintainable" and "functional" assets. The "functional assets" can be organized at different layers to group assets into sub-systems or physical maintainable assets; it is equal to the concept of "functional locations" in other EAM or CMMS systems.

2) Maintenance information

Maintenance information is a set of data that defines the rules for maintenance as well as the planned, pending, and past maintenance orders (MO). Regarding the three types of maintenance strategies, we distinguish three types of MOs - CMO, PMO and CbMO. Each maintainable asset can have multiple pre-defined rules/options (called "PM setting") for carrying out its preventive maintenance activities. A PM setting contains the following information:

- Temporal type: periodic or scheduled
- Work type: inspection, minor repair, major repair or replacement
- Work content (trade or skill, e.g., plumbing)
- Cyclic intervals: time-based and/or counter-based
- Shifting flexibility
- Default start time
- Duration and cost
- Project template
- Resource requirements (equipment, trades, materials, tools, contractors)

3) Life cycle condition-based information and models

The information and processes at this level are focused on "condition" as to record and assess the current and future condition of an asset. With deterioration models and condition assessment models in place, life-cycle condition information can be calculated based on real-time data collected from condition monitoring systems and the planned and past maintenance data. This level of information or models can be an integral part of FMM-DSS or more likely, reside in other distributed systems and integrate with the FMM-DSS using integration techniques (Section 5).

Since preventive maintenance is so far the only one of the three maintenance strategies that is programmable and controllable, the processes related to PM are the easiest to standardize and implement. Commercial EAM or CMMS packages already set good PM practices and they are comparable in PM capabilities. The general PM planning process we developed can be divided into six major steps, as shown in Figure 2.

Among all assets defined, the preventive maintenance planning only calculates maintenance work due in the next planning cycle for "maintainable assets" according to their pre-defined PM settings. The PMOs are generated by either resuming a brand new maintenance cycle or adding cyclic intervals to the last maintenance order in the

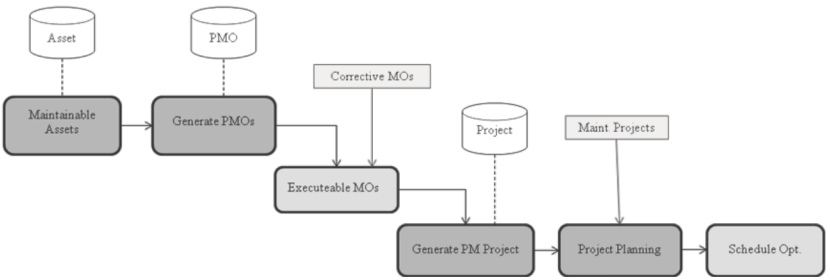

Figure 2: Preventive maintenance planning process

past planning cycle. The "executable MO" and "Schedule Opt." are two major decision points where decision supports are very much required. The objective of selecting executable MOs is to find an optimal collection of PMOs for the next PM planning cycle, based on priority, condition, remaining life, deterioration trend, and life-cycle cost leveling against a limited maintenance and operating budget base. The purpose of schedule optimization at the operational level is to maximize the performance and productivity of an organization through optimizing the daily production and maintenance activities. Multiple objectives can be considered, for example, the greatest resource utilization, lowest cost, and shortest makespan. In Figure 2, the CM and CBM processes are smoothly merged into the main FMM planning flow. Corrective MOs, entered manually by the user directly, become directly executable in the system because the decision of whether it needs to be done is already made. The same decision applies to the CbMOs generated by condition monitoring systems.

In CMMS, "task list" function is provided to group maintenance tasks, but actually it is just a simple checklist-style reminder which cannot handle complex relationships nor consolidate external resource constraints required by the industry. To settle this dilemma, we combine the PM planning and project planning in the FMM-DSS framework, which treats them equally as "projects". Treating all MOs as projects provides a good unification for maintenance orders and maintenance projects, which is one of the most distinguishing features of our framework. Complex relationships and constraints can therefore be defined on tasks and project scheduling techniques can easily be applied to resolve complex problems. We have completed significant R&D work in project management and project scheduling for aircraft periodical maintenance management in a past project (Hao et al. 2009a; 2009b).

5. Integrating FMM with Condition Monitoring Systems and BIM

Condition Monitoring (CM) is a maintenance process where the condition of equipment is monitored for early signs of impending failure. Equipment can be monitored using sophisticated instrumentation such as vibration analysis equipment or the human senses. Where instrumentation is used thresholds can be imposed to trigger condition-based maintenance activity. In reality, the scope CBM is largely dependent on requirements from specific facilities and specific industries; there is no standardized condition monitoring hardware and software tools that can consolidate all kinds of needs from different CBM models. Also, even the choice of performance

indicators, theoretical modeling and algorithms are customized to the maintained assets. For these reasons, the condition monitoring systems are better to exist as stand-alone systems rather than native modules in the FMM-DSS framework. The integration of FMM-DSS with condition monitoring systems may happen at any of the top five layers in the OSA-CBM model (MIMOSA 2009) depending on the scope of the specific condition monitoring systems. If the generation of CbMOs is taken as the final output, the latest integration point would be the "executable MOs" in Figure 2. Another aspect that condition monitoring can contribute to the FMM is to assist with deciding the optimal PM strategies or settings. Traditional preventive maintenance practice is implemented through the fixed calendar-based maintenance intervals. How to determine these intervals is a pure experience-based exercise; and once decided, they are never changed. However, with dynamic condition information, one can reasonably envisage that the PM activities can be carried out smartly, in varied intervals, based on the condition of the actual facility. Sun et al. (2008) believed that the optimal PM interval is dependent on the total expected cost index, PM performance and types of PM strategies.

Building information models (BIM) provide a 3D representation of a building and contain database storage mechanisms for properties about all of the elements of the building. When one believes that BIM is a catalyst propelling the AEC industry through its biggest evolution since the introduction of the personal computer, it is hard to imagine that facility management in the 21st century will remain the same (Valentine and Zyskowski 2009). The benefits that BIM can bring to FM include:

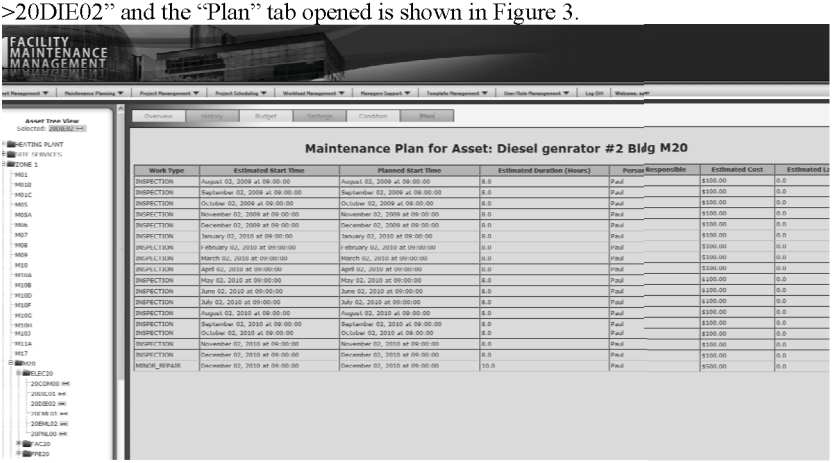
- 3D visualization. Using the geometry information embedded in BIM's 3D models, the FMM can easily present facilities relative to their residing environment. The visualization can be very useful in designing and verifying space changes, facility movements, and renovation projects. Also linking with RFID, sensing and tracking systems, visualization would be useful in the locating and tracking of movable facilities, as well as the movement of maintenance work resources, such as materials, equipment, and people.
- Exchange of information between FMM and other up-stream systems. For facilities maintenance information other than 3D models, none of the other systems would have a better knowledge than a FMM system. Therefore, when considering what kind of interaction will be needed for integrating FMM and BIM, firstly, we need to think of what information will benefit FMM from up-stream processes and reversely, what information other processes might utilize if FMM data is available.

Most of the existing work for integrating BIM and FMM suggests a totally centralized BIM solution for facility management, where BIM provides a simple, centralized facility management data solution in one relational database (Motamedi and Hammad 2009). In contrast, we rely on a different loosely-coupled integration approach such as Web services and agents for integrating FMM, BIM and other systems along the AEC/FM processes. Please refer to our previous publication (Shen et al. 2009) for a comprehensive review of systems integration and collaboration technologies in AEC/FM.

6. Implementing the FMM Using the MVC Architecture

A prototype of the proposed FMM-DSS framework is developed as a pure Web-based application based on the popular Model–View–Controller (MVC) design pattern to maximize the modifiability, extensibility, and reusability of the code. Struts 2.0 framework (Apache 2009) was adopted for the MVC implementation. Other leading edge Java and Web-based technologies used in the development were: *Java EE, JSP, Tomcat, MySQL, Hibernate*, *jQuery*, *AJAX*, and *Yahoo!UI*, to name a few.

Asset management constitutes an asset browser showing an asset tree on the left and a tabbed view on the right. Each tab is implemented as a separate *JSP* page for populating the corresponding aspect of asset information on the screen. The asset management user interface with asset "ASPM-> ZONE1->M20->ELEC20->20DIE02" and the "Plan" tab opened is shown in Figure 3.



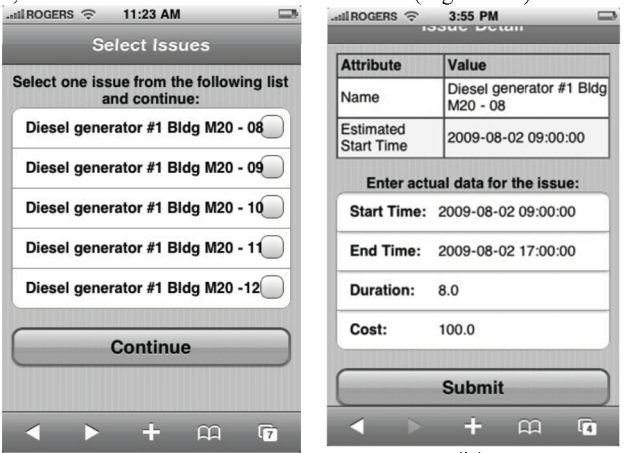


Figure 3: User interface – asset browser

Both corrective and preventive maintenance processes are implemented in the FMM-DSS system. The PM planning is executed for a given year and the strategic decision for prioritizing maintenance activities is currently implemented as a manual selection process. Research of optimization models at this layer is one objective of our future work. The optimization of maintenance activities at the operation level is done through a Workload analysis module. This module is designed to analyze and balance the resource workload (i.e., materials, tools, equipment, craftspeople, and contractors) for all maintenance activities in a given time period. The developed meta-heuristic based optimization algorithm (Zhu et al. 2010) can perform conflict detection, schedule coordination, schedule repair, and schedule optimization.

A set of user interfaces is developed for the iPhone's Safari using iUI (2009) to enter actual information for maintenance orders at the job site. When a user accesses the system's website through an iPhone, the system can automatically recognize the device and display a specific set of iPhone pages from the correct server directory. After a user is logged in, a to-do list of MOs assigned to this person's work trades are shown on the touch screen (Figure 4-a). After the user selects a maintenance item

from the list, he/she can then view the detailed description of the work and after the work is done, enter the actual information of the work (Figure 4-b).

(a) (b)

Figure 4: User interface – iPhone – work list, work details and actual work recording

7. Conclusion

Based on the basic concepts of the three facility maintenance strategies, CM, PM, CBM, this paper presents a decision support framework for facility maintenance management (FMM-DSS) that aims at integrating facilities maintenance management, real-time project management, condition monitoring systems, and BIM. Multi-faceted views of assets are designed to meet the requirements of potential functional extensions and systems integration. Meanwhile, preventive maintenance orders and maintenance projects are unified in the FMM-DSS where they are equally treated as "projects". This feature allows complex relationships and constraints to be defined on or between activities within a maintenance order.

Loosely coupled integration technologies such as Web services and agents are preferable for gluing FMM, BIM, and condition monitoring systems together. Using a number of leading edge Java and Web-based technologies, a prototype FMM-DSS system has been developed for asset management, preventive maintenance planning, maintenance order management and workload analysis.

Our future work on FMM-DSS will be focused on research and development of decision support models for CBM related processes as well as the strategic prioritizing of maintenance activities that accommodate operational data deducted from condition monitoring, condition assessment and prediction models. The integration of the FMM prototype with other application systems using Web services technologies is another topic that we are currently undertaking to investigate the integration framework for asset life-cycle maintenance and management.

Abstract
Efficient request and deployment of resources such as construction equipment is vital to urban search and rescue operations during emergency response. Based on the lessons learned in recent disasters, collecting, prioritizing and distributing of resources are urgent to life-saving operations. Construction equipment is required for shoring of structures, selective debris removal, and lifting of heavy building components. Infrastructure restoration, such as the transportation network, also needs construction equipment to support its operations to bring back services to facilitate disaster response efforts. A Geographic Information System (GIS) framework is presented to expedite equipment management. Within the framework, automation of data collection, transfer and processing for fast decision-making via computer networks, geospatial services and mobile devices is proposed. With the framework deployed, lifesaving operations are expected to have better performance provided with the appropriate equipment.

INTRODUCTION

Distribution of resources, such as heavy construction equipment, is critical to efficient and effective urban search and rescue (US&R) operations during disaster response. On September 11, 2001, the 9/11 terrorist attacks killed 2,819 innocent people, injured more than 6,290, and caused over $105 billion of economic loss (NYM, 2009). Supply of highly demand equipment was insufficient during the disaster response phase, challenging the ability of first responders (Gasiorek-Nelson, 2002). On May 12, 2008, a magnitude 7.9 earthquake struck Sichuan, China. Disaster response operations such as civilian search and rescue missions were hampered due to massive demand not being fulfilled by insufficient amount of equipment (MSNBC, 2008). Without appropriate construction equipment, first responders were forced to

dig for survivors with their bare hands (MSNBC, 2008). The earthquake caused over 69,197 deaths, left 18,222 people missing, and injured 374,176 people (China View, 2008). During disaster response, it is imperative to have efficient and effective equipment distribution to facilitate lifesaving operations (Sullum et al., 2005).

Management of geographically distributed resources has been recognized as one of the most important but challenging tasks in disasters (SBC, 2006; 9/11 Commission Report, 2004). Challenges include identification, assignment and delivery of resources. For example, after 9/11, the authorities were not fully aware of available resources and their deployment. As a result, resources were distributed inefficiently, which compromised the response operations. In order for disaster response efforts to be more effective, resource distribution challenges must be addressed.

Distribution of resources during disasters has been characterized by various shortcomings that inhibit efficient and effective decision-making (NRC, 1999). These decision-making challenges range from prioritization of limited resources and vehicle route selection, to resource location tracking (SBC, 2006; 9/11 Commission Report, 2004). Supply of resources, such as construction equipment (which supports shoring up damaged buildings and selective debris removal in a disaster zone), is usually unable to meet the demand in large-scale disasters. This could lead to additional damage within the disaster zone (Gentes, 2006; Bissell et al., 2004). "***Throughout the government, nothing has been harder for officials than to set priorities, making hard choices in allocating limited resources***" (9/11 Commission Report, 2004). Efficient prioritization and distribution of resources is critical in maximizing the effectiveness of the disaster response efforts.

CURRENT LITERATURE

Without successful resource distribution, disaster response activities including US&R may not be carried out efficiently and effectively. The following sections lay out the challenges within current practice and the available technologies to address these important issues.

Challenges in Current Practice

Challenges relate to resource distribution identified in disaster response operations include: deficiency of command and control, lack of spatial information and services, limited situational awareness, insufficient transportation planning, deficient information interoperability, and lack of resources tracking. Requirements that may improve current resource distribution operations can be derived thorough understanding of these challenges.

Access to heavy equipment is critical to disaster response operations (Gentes, 2006; SBC, 2006; Kevany, 2005; Bissell et al., 2004). Heavy equipment is a necessity during operations such as 1) rapid debris clearance of the transportation network so that first response teams can reach blocked hazard zones, 2) careful lifting of damaged structural elements in conditions when human power is not sufficient, and 3) selected debris removal to clear structural materials which facilitates void space searches and tunneling under collapsed buildings (ELANSO, 2009). However, in major disasters the social infrastructure is not always able to provide immediate supply of heavy construction equipment to support disaster response operations (Gill, 2007; Fessler, 2006). The delay in rescue operations could result to more casualties

(Bissell et al., 2004). Heavy equipment, which supports critical lifesaving activities, should be efficiently located, assigned and distributed to meet the urgent demands of critical disaster response operations.

Vehicle route selections are inefficient due to lack of traffic information. After disasters, condition of the transportation network is highly unpredictable: blockages, such as road debris, bridge collapse, and hazardous zones influence traffic conditions (Kwan and Lee, 2005). As a result, response resources may reach to the disaster zone with great delay. As time is considered the most important factor in terms of lifesaving during disasters, delay of response time could lead to unnecessary casualties (Gill, 2007). Therefore, traffic conditions should be updated in real-time and taken into account for decisions such as safest route selection and shortest traveling time for efficient resource deployment.

Cohesive inter-organization collaboration is needed for effective disaster response. Resources owned by each jurisdiction need to be visible and available to the incident command. Due to lack of command and control during a major disaster, the coordination of resources across different organizations is extremely challenging (Gill 2007; Meeds, 2006). During Hurricane Katrina, between the logistics management systems of the state and federal government, there did not exist an electronic interface for communication and coordination. Resource requests from the state level to the federal level were input by hand. With no tracking mechanism in place, the state was unable to follow up on resource requests, resulting in significant time delays (Holguin-Veras et al., 2007). An electronic interface, supporting collaboration among different jurisdictions, should be established to reduce time delay in disaster response.

Available Technologies

Vast amounts of research related to disaster management are potentially adaptable to address challenges of effective disaster resource distribution. This research focuses on heavy construction equipment distribution during disaster response operations and will seek to integrate the following technologies:

GIS is an essential tool for mapping locations, visualizing dynamic conditions, and making decisions in disasters (Kataoka, 2007). Geospatial data and tools are useful in response to disasters; Real-time data fusion and analysis can be achieved through GIS during the response phase for fast decision-making. A significant quantity of research has been conducted in GIS that focused on areas such as shortest path analysis (Han et al., 2007; Kwan and Lee 2005; Tsai 2002), data visualization (Cutter, 2003; Pundt and Brinkkötter-Runde, 2000), and risk management (Elnashai et al., 2008; Zerger and Smith, 2003). However, GIS for emergency management with rapid capability and access of data and tools that work under difficult circumstances of US&R have rarely been addressed (NRC, 2007).

Radio Frequency Identification (RFID) and Global Positioning Systems (GPS) are popular technologies for location tracking of resources. GPS has been widely deployed for vehicle tracking (Guan et al., 2008; Lu et al., 2007), while RFID products have been broadly applied to warehouse inventory (Oh and Park, 2008; Zeng et al., 2008). GPS and RFID could provide important location information of available resources to emergency management agencies (EMAs). As a result, decision-makers could have better visibility and control of the overall logistics

distribution such as construction equipment deployed for disaster response. However, full potential of these technologies has not yet been reached. For example, tracking of logistics was unsatisfactory during Hurricane Katrina; the Federal Emergency Management Agency was not able to keep track of their assets (SBC, 2006).

Decision models have been formulated (El-Anwar et al., 2008; Elnashai et al., 2008; Kung et al., 2008), along with research conducted in supply chain and logistics (Balcik et al., 2008; Lodree Jr. and Taskin, 2008; Ozdamar and Yi, 2008). The objectives of those models include logistics distribution with multiple resource types and quantities, facility and target locations with special conditions, and vehicle capacity issues for split deliveries. These models are formulated so that decision-makers and first responders can best utilize available information and assets for effective disaster responses. The efficiency of solving these models affects the response time, while the accuracy of real-time input data affects the correctness of the output decisions. Proper graphical visualization is needed to convey and represent the analyzed information to decision-makers and first responders. However, automation of decision-making is yet not deployed in disasters response (Suchyta et al., 2006).

To efficiently solve decision models, exploration of robust natural systems that have been recognized with well-organized systematic behavior, is expected to contribute to this research. Decision models based on entomology produces fast collective decision-making (Seeley and Visscher, 2004). In the selection of a new hive for example, the self-organization capability of a honeybee colony is highly efficient and effective. The scout bees leave the hive to search for profitable alternative locations for their hive. When bees return, each scout enters the dance floor inside the hive to pass on information of a potential new hive and recruit others to support the selection of that potential location. A “more profitable location” dance will be propagated throughout the dance floor. Eventually, a majority of bees will converge to the “best” dance (i.e., the most profitable location). Thus, the dance is completed with the whole colony agreeing on the new hive (Seeley et al., 1991). A distributed model that showed great potential for decision-making in complex and dynamic contexts based on the behavior of honeybees’ foraging is proposed for disasters (Aldunate et al., 2005). Such entomology-based models will be explored and are envisioned to be adopted to facilitate critical decision-making such as equipment prioritization and distribution during disasters.

Various types of resources are required for Urban Search and Rescue (US&R) operations while conditions of the transportation networks are highly unpredictable. These challenges make resource distribution problems complex. Traveling Salesmen Problems (TSPs) are transportation planning problems for resource distribution. Ant colony optimization (ACO) algorithms have been discovered and used to solve TSPs (Blum, 2005; Dorigo and Stützle, 2004). Disaster resource distribution problems are envisioned to be formulated into TSPs with special characteristics, such as split delivery, dynamic depot locations, limited truck capacities, equipment and technician matching, and demand prioritization. ACO can be run continuously and adapt changes in real-time to produce close to favorable solutions. This is of interest in the proposed research due to the dynamic and chaotic characteristics of disasters. Research on ACO algorithm for solving logistics problems in disaster relief

operations has been proposed (Han et al., 2007; Yi and Kumar, 2007). Yi and Kumar (2007) use a meta-heuristic of ACO algorithm for distribution of multiple types of resources. Different types of transportation tools are selected and the capacity of different type of vehicles is incorporated in their model. While this model is considered valuable to the proposed goal, some shortcomings were not addressed in the original work. Decision to set priority of demand was not determined in real-time, traffic conditions were not monitored in real-time, and delivered resources were not tracked for further deployment. Han et al. (2007) use an ACO algorithm to solve shortest path problems in firefighting operations considering traffic conditions. However, incident response prioritization is not considered and road conditions are not real-time updated. The aforementioned research will serve as the base of knowledge for decision-models for equipment distribution in disasters.

In the previous sections, challenges in current resource distribution operations and available technologies have been discussed. Existing systems such as HELIOS (Fritz, 2008) and IRIS (FEMA, 2008) have been developed for supply chain management. However, resource tracking technologies and resource distribution decisions are not adequately considered. Although they serve as a centralized logistics request medium, real-time disaster data collection and information visualizations are not currently complete. Therefore, this makes critical decision-making difficult. Challenges described in the previous sections revealed that a cohesive framework for data collection, analysis, and visualization is necessary for an efficient and effective construction equipment distribution during disaster response.

APPROACH

Responders with better situational awareness —of the impact caused by disasters, where critical resources are, and locations of potential infrastructure damages— are able to respond more efficiently to lifesaving tasks (NRC 2007). An infrastructure for information sharing and decision-making to increase the performance of resource distribution operations is of great importance. As a result, a collaborative framework automating construction equipment distribution is expected to greatly improve current first response activities in disasters. The goal of this paper is to establish such a framework to expedite the process of resource request and deployment. Resources that are taken under consideration include professional personnel and construction equipment, which can be generalized to other types of resources.

The architecture of the framework is shown in Figure 1. The following discusses the three layers the framework is composed of: a front-end layer (data collection and visualization), a middleware layer (communication medium for information dissemination), and a back-end layer (data management and decision-making) for construction equipment distribution.

Front-end: The front-end provides a flexible and general interface for the framework to support future integration with IT plug-ins such as 1) automated inventory, 2) deployed resource tracking, 3) traffic condition monitoring, and 4) on-field resource request and their data transmission. The formalization of the front-end facilitates data acquisition to be further analyzed by decision-models in the back-end. Geospatial equipment inventory based on the MapServer with PostgreSQL database (Peña-Mora et al., 2009) and a mobile client for equipment request implemented in C# (Chen and

Peña-Mora, 2009) currently serve as the source of data input. Once more system components for data acquisition is integrated through this layer, decision-makers and logistics managers can easily and efficiently locate professional personnel and construction equipment, monitor traffic conditions, keep track of deployed equipment, and receive on-site equipment requests for rescue operations.

Figure 1 Five-tier Architecture

Middleware: The middleware provides a level of abstraction so that the layers above and below need not be fixed to a particular communication medium. The communication medium selected will be treated no differently from the upper and lower layers as a result of this level of abstraction. The communication medium is interchangeable to suit the condition at the moment. For example, with the absent of infrastructure based communication, the mobile ad hoc network (Aldunate et al., 2006) will be chosen. The abstraction is still under development and different policies to determine what network to use in different scenarios will be tested. In addition, communication medium with information policies (Kostoulas et al., 2008) such as priority, trustworthiness, and security are envisioned to advance communication for first responders. This layer provides a foundation for digital communication to the collaborative resource distribution framework.

Back-end: The back-end is composed of 3 sub-layers: a *spatial data and service fusion layer*, a *decision support core*, and a *visualization and interaction platform* to support efficient and effective disaster response. *The spatial data and service fusion layer* serves as a façade to separate the *middleware* and *decision support core* and processes input data in the desired format for flexible communication. Decision models, such as fastest and safest route selection and equipment prioritization, reside in the *decision support core*. Complex decisions that involve various parameters are to be made in disaster scenarios. However, these decisions are often too complex to be solved by computers in a satisfactory amount of time. As a result, special formulations for such decisions are to be investigated to meet requirements such as running time, accuracy, and other policies. A distributed decision-making model inspired by honeybees' foraging behavior has been formulated and studied (Aldunate et al., 2005). The honeybees' decentralized learning is envisioned to be formed as an efficient heuristic, to expedite the operation of equipment deployment.

The *visualization and interaction platform* provides decision-makers and first responders with 1) better situational awareness of the disaster and 2) better communication medium to convey information and ideas to others. Through GIS, geospatial operations can be efficiently conducted for fast visualization to support decision-making and effectively communicate with various stakeholders involved in the response operations. For example, a GIS system implemented in C# with ESRI's ArcGIS Engine and a MySQL database is in place for transportation planning in disaster response (Chen and Peña-Mora, 2009). It has a graphical representation embedded for the spatial information. Decisions suggested by the *decision support core* can also be showed graphically to decision makers through this visualization environment. Thus, decisions can be made more efficiently and effectively with a better vision of the overall picture with more stakeholders involved. Information can also be propagated to the *front-end* and shown to first responders through the *communication medium layer* to PDAs for better situational awareness.

With this framework, decision-making such as equipment distribution during disaster response is more efficient. First responders use PDAs to request resources on-site. Through the *communication medium layer*, decision models take the input data and suggest analyzed decisions to decision-makers through the visualization component. Final decisions will be sent to the equipment for deployment. As a result, an automated process for equipment request and deployment for disaster response.

CONTRIBUTION AND FUTURE WORK

A flexible framework is presented in this paper for further integration with existing IT components. Various type of information can be plugged into the framework to facilitate automated decision-making. Once integrated, time overhead for data transmission, input, and output will be reduced. Information can be shown to decision-makers and first responders more comprehensively. This results in better decision-making and situational awareness, which further leads to more effective disaster responses. Future work will be directed towards further integration of systems into the framework and testing. Brian Brauer, Stuart Foltz, and Scott Nacheman, field experts in disaster response operations, will provide practical insights based on their expertise and experience in response to the 9/11 terrorist

attacks, Hurricane Katrina and Rita. Through collaboration with these first response exports, testing of the framework will refine and shape the framework to become deployable in disaster response scenarios. In addition, efficient decision models are to be formed and integrated to support critical decision-making.

ACKNOWLEDGEMENT

The authors would like to acknowledge the United States National Science Foundation for the support of grant number ITR CMS-0427089. In addition, the authors would like to thank Brian Brauer, Stuart Foltz, and Scott Nacheman for their great contributions and also the anonymous reviewers for their invaluable comments.

Abstract
This paper presents a simple, flexible and intuitive approach for activity sequencing and project scheduling. Several construction scheduling professionals were consulted during development of this approach. The most important attribute desired by the industry professionals was flexibility to rapidly revise activity definitions and relationships allowing fast schedule modifications and what-if analysis. Considering the needs and suggestions of construction industry professionals and using the latest visualization technology, a graphics application was developed using Microsoft DirectX Graphics Library. The application interfaces with Revit CAD software to extract a building project's geometry and material information which is then used to create a virtual prototype of the project. Users can walk inside the virtual building for visualization of the project and sequencing project activities by selecting tasks and predecessors. The application interfaces with MS Project and provides an intuitive and flexible method to digitally transfer activity information to the schedule. The visual approach presented in this paper attempts to increase scheduling efficiency by incorporating the findings of modern cognitive theories that suggest human brain interacts more effectively with 3D virtual worlds than a long list of project activities and textual content.

Introduction and Background

Project schedules are the primary tools for communicating the thinking and planning by the management team to all the stakeholders in a construction project. Any advances in project scheduling technology can result in substantial improvements in management efficiency and more wide-spread application of scheduling in construction projects. Sequencing of construction activities is done by reviewing 2D CAD drawings, compiling a long list of construction activities and visualizing the logic mentally which causes heavy cognitive load on a scheduler's memory and

reduces efficiency. It requires special skills and experience to read 2D drawings and relate it to the schedule. Such schedules force planners to visualize and interpret the activity sequence in their minds. Also, some planners will have different interpretations of the same schedule, which makes it difficult to communicate and discuss whether a certain problem actually existed or not (Wang 2007). This miscommunication causes schedule delays and results in monetary losses. Thus there is a need of systems which provide visualization at early planning phase and communicate same idea to all the stake holders.

Construction project scheduling involves choosing a set of actions, arranged chronologically, that will achieve some given goals (Navinchandra, Sriram, Logcher 1988). Traditional network based tools employing critical path methods (CPM) and project evaluation and review techniques (PERT) algorithms can help in analyzing a plan, not in generating it. The definition of activities and their predecessors must be provided to such systems by a human planner (Kartam and Levitt 1990). One of the crucial problems faced when generating a construction schedule is to produce an adequate sequencing of activities involved (Echeverry, Ibbs, Kim 1991).

The scheduling process involves a number of steps including: (1) breaking the project down into a number of activities and estimating activity durations, (2) transferring activity information to scheduling software, (3) developing project logic or the sequence that activities will be carried out during construction and (4) scheduling project activities. The new 3D CAD software and scheduling programs have substantially reduced the time and efforts necessary for performing steps 2 and 4 in the scheduling process. However, step 3 or project logic development is still a tedious process that involves sorting and organizing a long list of project activities. During the past two decades a considerable amount of research has been conducted in activity sequencing and construction project scheduling. Various systems have been developed by researches to computerize the process of sequencing and project scheduling. These systems have migrated from the early AI planning systems to knowledge-based planning systems and ultimately to model based planning systems (F.B. Alami, J.C. Kunz, M. Fisher, 1998).

Construction Planex developed by Hendrickson, Gorostiza, Rehak, Miller and Lim (1987) was a frame-based hierarchical system for scheduling construction projects. Navinchandra, Sriram and Logcher developed a program for Generation of Hierarchical networks for construction (GHOST, 1988). Their methodology generates or modifies the topology of construction activity networks. It starts with a general network and subdivides it into sub activities. N.A. Kartam and R.E. Levitt (1990) studied intelligent planning of construction projects (SIPE) and proposed sequencing to be done based on common principles or constraints such as “supported by” or “enclosed in”. Their approach relies on structural support and generates a network. Echeverry, Ibbs and Kim (1991) proposed formalization of sequencing knowledge for construction scheduling by developing a knowledge-based prototype system. Cherneff, Logcher and Sriram (1990) developed BUILDER which integrates CAD with construction schedule generation. It consists of two main knowledge modules

(KMs) first "Draw" for creating and interpreting architectural floor plans and "Planner" for producing construction schedule.

It is common knowledge that no two schedulers develop the same schedule for the same project since each of them makes different assumptions, selects different construction methods and represents the schedule at different levels of details (Fisher, Aalami 1996). A rule-driven approach or constraint-based schedule logic may not be flexible enough to accommodate every scheduler's style.

Researchers at the Center of Integrated Facility Engineering at Stanford University have carried out a considerable amount of research for automating sequencing of construction activities and developing knowledge-based environments for scheduling. Fischer and Aalami (1995) demonstrated scheduling with computer interpretable construction method models. The feasibility study of 4D in commercial construction by Koo and Fisher in 1999 showed that 4D modeling helps in analyses concerning cost, productivity, safety and resource allocation. It is also helpful in the integration and collaboration among project team members and supports early detection of problems. 4D visualization systems require a project schedule before they can produce a graphical simulation of the project's construction process. It is a tool which facilitates effective visualization but it does not make scheduling easier nor reduces the work involved when manually entering project tasks. Planners mostly use 4D visualization tools as a means of visualizing and comparing, rather than implementing different decision alternative (Waly, et.al, 2002).

The graphical application developed in this study is named Visual Scheduling Application (VSA) and provides a visual, interactive and flexible approach to construction project scheduling. VSA allows visualization of the project at an early planning stage and accommodates scheduling style of every scheduler. Construction scheduling experts were involved during requirement analysis and development phases of VSA. According to the industry professionals consulted, the most important attribute in a sequencing-scheduling application is flexibility to rapidly revise activity definitions and relationships. This would accommodate various scheduling styles and simplifies schedule modifications and what-if analysis. They suggested an approach that minimizes manual data entry by digitally transferring information from a building model to a scheduling program allowing them more time for critical thinking and evaluation of alternative solutions.

In VSA, information extracted from a building's Revit CAD file is used to create a 3D virtual model of the building. Using a first-person camera, the scheduler can navigate the virtual building and select a building element or a group of elements by pointing to the elements. A selected building element or group of elements may be designated as an activity or an activity predecessor. The selected information can then be digitally transferred to a scheduling program. According to the modern cognitive theories, visual approaches reduce memory load. This means developing project logic while walking inside the virtual prototype of the project exerts less stress on

scheduler's memory than working with a long list of activities that requires building a mental image of the project.

Visual Scheduling Application Architecture

VSA is developed for two-way communication between Revit Architecture 2009 for model information extraction, Microsoft Project for schedule preparation and a database for project information storage. The VSA application and its components are shown in Figure 1 and are discussed in the following sections. VSA interacts with Revit for extracting project geometry and element material information. The extracted information is saved in a database. Using the extracted information and Microsoft DirectX graphics library a virtual prototype of the project is created (Van Verth, Bishop 2004). This allows users to interact with the virtual environment by navigating inside and around the 3D model. Input Devices facilitate navigation and interaction with the 3D model once it has been created by the graphics engine. The common input devices used for interactive visualization are keyboard, mouse, game pads and gloves which facilitate navigation in the 3D model. Game pads make navigation easier and have been used by many visualization applications such as video games to provide easier navigation. Gloves are usually used in immersive visualization where a user can grab or move objects in the virtual environment. The graphics engine developed in this research uses keyboard and mouse as input devices.

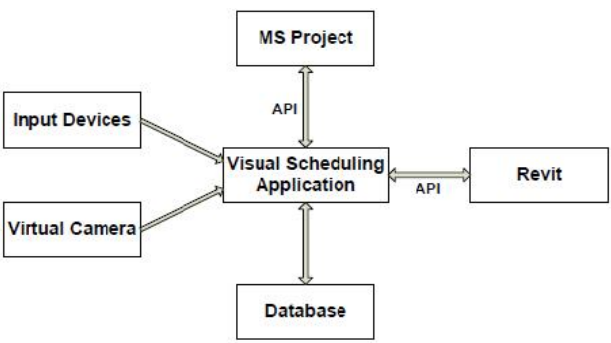

Figure 1-Visual Scheduling Application Architecture

The application uses perspective view to project a 3D model. Both ambient and directional lighting is used to make elements visible. In order to view objects in the virtual world, it is necessary to present the notion of the viewer. This could be the main character's viewpoint in a first person shooter, an over the shoulder view in a third person adventure game, or it could be a zoomed out wide shot in a strategy game. These properties can be encapsulated into a single entity commonly called virtual viewer or camera (Van Verth, Bishop 2004). Virtual viewer or a camera is a combination of the position of the eye and direction in which the viewer is looking. This controls which object lies in the current view. To provide interactive visualization VSA accesses and manipulates a lot of data which is stored by the

application in a database. Figure 2 shows a snapshot of a portion of VSA database. This database saves information about project, elements, faces, material, vertex indices and coordinates in the form of tables and provides fast access to element information. VSA interfaces with Revit using Revit API and C# programming language. Interaction with Revit using its API offers a direct, dynamic link between the application and Revit. Revit API facilitates extraction of information from a model and allows querying the model or modifying model elements. The visualization application extracts not only the geometry of building elements but also their material properties. In order to facilitate visual scheduling of project elements, interaction with Microsoft Project is also implemented using Microsoft Project API. This provides a two way communication with Microsoft Project; that is, the visualization application can send element information to Microsoft Project and it can read schedule information from Microsoft Project.

Methodology

The Visual Scheduling Application allows grouping of 3D elements into construction assemblies, creating activity tasks visually, and visual sequencing of the activities. Using a virtual building as an interface to project scheduling mimics very closely how an individual interacts with the 3D world and how human brain perceives and processes information. A VSA user interacts with a 3D visualization window, a Revit element extractor window, and a dialog box to review information before sending it to the scheduling software.

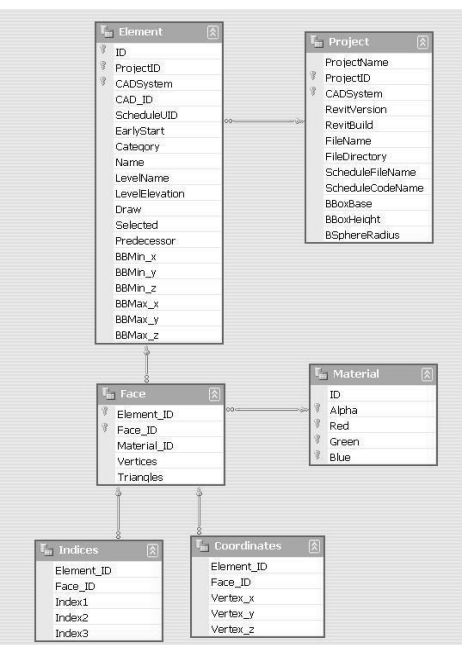

Figure 2: A snapshot of a portion of the VSA database

Visualization of the project can be done by navigating around or inside the building using an orbit camera or a walk camera. The orbit camera allows user to navigate around the building and have a bird's eye view of the building. Walk camera allows the user to walk inside and around the building. An element to be scheduled as an activity or as a predecessor can be selected by pointing to the element and clicking the mouse. For ease of selection, the program provides an option which allows the user to select similar items on the same level or in the whole building. For example, if an activity consists of all windows on level one, user does not have to select individual windows one by one.

When an element is selected, VSA highlights it to allow fast detection of all selected elements. VSA uses different colors for elements selected as an activity and element selected as a predecessor. Elements selected as an activity turn pink on selection whereas elements selected as a predecessor turn blue. An element hidden underneath other elements can be viewed and selected as an activity or a predecessor by temporarily removing the elements that cover it. For example, slab-on-grade and back fill cover wall and column footings in buildings. To expose building footings during a walkthrough, the user can temporarily remove slab-on-grade and backfill for exposing the hidden elements and scheduling them. Figure 3 shows interior of a building where footings are hidden underneath slab-on grade and backfill and Figure 4 shows interior of the same building after removal of slab-on-grade and backfill.

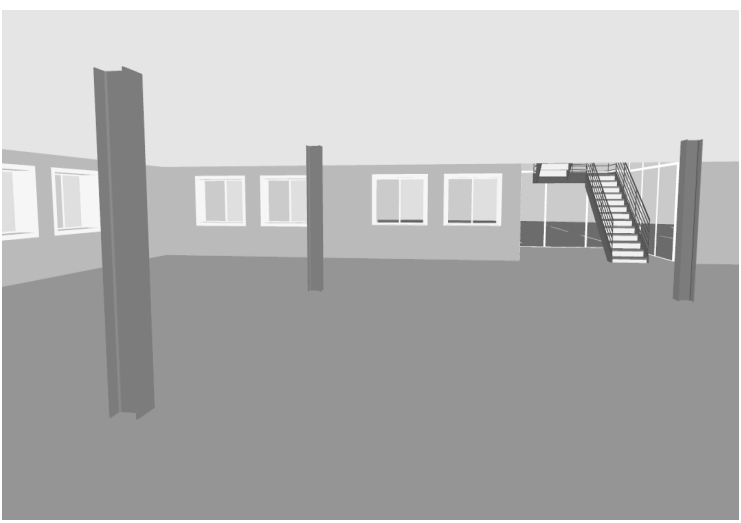

Figure 3: Interior view of a 3D Model

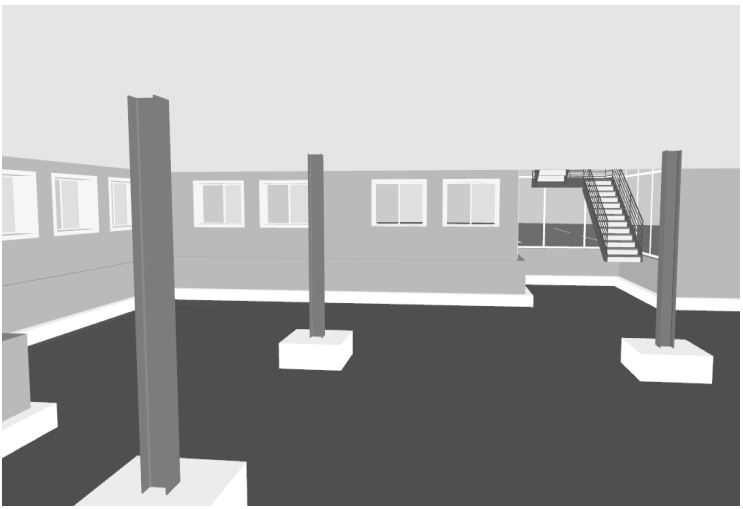

Figure 4: Interior view after removal of slab-on-grade and backfill

After an activity and its predecessor(s) are selected, the information can be submitted to the scheduling program. Figure 5 shows a dialog box for reviewing the building elements selected to represent an activity and its predecessors. As Figure 5 shows, the scheduler can assign a name and duration to a new activity. The dialog box also allows the user to select an appropriate relationship between the activity and its predecessors from a drop-down list and specify a lag time between the activity and its preceding activities.

To make the schedule organized VSA uses work breakdown structure. A project manager can setup a custom work breakdown structure before starting a schedule. Before an activity is submitted to the scheduling software, the scheduler can assign it to an activity outline. As Figure 5 shows, the selected activity outline structure appears at the bottom of the Activity Review Dialog Box. The outline structure shown in Figure 5 is based on CSI format.

After reviewing/editing activity information in the Activity Review Dialog Box, the information is digitally transferred to the scheduling software. Figure 6 shows a snapshot of a portion of a project schedule created with VSA.

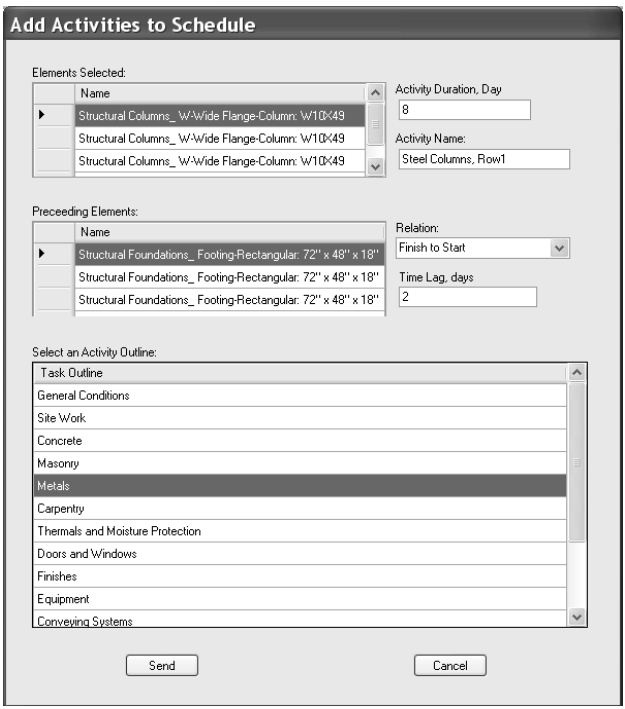

Figure 5: Activity Review Dialog Box

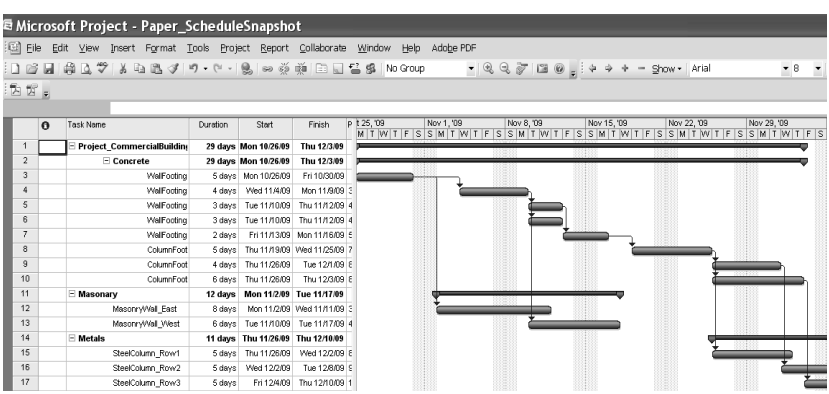

Figure 6: A snapshot of a portion of a schedule created using VSA

Summary and Conclusion

With growing complexity of projects, it is not easy to properly schedule a project by visualizing it mentally. Visual Scheduling Application (VSA) provides a visual approach to activity sequencing thereby making the process more intuitive and simple. VSA was developed based on discussions with construction industry professionals to make it responsive to the needs of construction project schedulers. Application flexibility and ease of re-defining project activities and activity relationships were identified as the most desired attributes for a scheduling application. VSA provides an interactive, visual and flexible approach to activity sequencing and project schedule. It allows visualization of the project before starting the planning and scheduling process. In this approach the scheduling process is reduced to: (1) walking inside a virtual model of the building being scheduled, (2) selecting the element(s) to be included in a new activity and activity predecessor(s) and (3) executing a command that sends the activity information and an estimate of its duration to the scheduling software. In other words, scheduling a building is reduced to a simple excursion inside the building. The project logic is developed while walking inside the project. This approach minimizes manual data entry by digitally transferring project activity information from the CAD model to the scheduling software and exerts fewer loads on scheduler's memory than working with a long list of activities that requires building a mental image of the project. The visual scheduling approach was demonstrated to a few professional schedulers; their feedbacks have been very positive.

Abstract

In the Architectural, Engineering, and Construction (A/E/C) industry, construction products constitute a large proportion of the total cost of construction. In recent years, the range of construction products has grown substantially that users are facing difficulties in selecting products that fit their projects' needs. Due to wide availability of the internet, web-based construction production information (CPI) providers have become very popular as a new source of CPI acquisition. This study identified a typical business operating structure of this new industry sector and also investigated various factors that are critical for successful operation of the business in the A/E/C industry in the United States, through extensive literature reviews, investigations of CPI websites, and three independent surveys of CPI users, web-based CPI providers and construction product manufacturers. The findings of this study will allow stakeholders to find areas to improve in order to continue to grow in this industry sector.

Introduction

In the Architectural, Engineering, and Construction (A/E/C) industry, construction products constitute a large proportion of the total cost of construction. Depending on the project type, construction products account for almost 30-45% of the total construction cost (Hildebrandt 1988). In recent years, the range of construction products has grown substantially that users are facing difficulties in selecting products that fit their projects' needs. Information about various construction products is required at different stages during the life cycle of a project by many project participants including the owner, architects, specification writers, interior designers, cost estimators, contractors, specialty contractors, cost engineers, etc. Traditionally, construction product information (CPI) has been obtained through product catalogs, product manufacturer's distributors, professional magazines, and word of mouth. However, since the internet has become widely available for product information acquisition, internet search engines and internet based CPI providers have rapidly replaced the traditional methods. Specifically, the internet based CPI providers offer strong benefits to both CPI users and construction product manufacturers (CPMs) such as one-stop access to various product information, comparison of different products of same function, quick update on information about new and existing products and the availability of statistics about the visitors of each product information page. These internet based CPI providers have created a promising niche market in the A/E/C industry, in which the CPI providers typically generate revenue by collecting fees from CPMs and in return, the CPI providers upload and maintain the product information of the manufacturers.

This paper investigates this emerging market in terms of two aspects; a) business structure of this unique market and the flow of product information in the web-based CPI systems, and b) critical factors for successful operation of the web-based CPI business in the A/E/C industry through literature reviews, expert interviews, and collection of opinions of stakeholders using three questionnaire surveys.

Web-Based CPI Business Model and CPI Flow

In total, 11 companies were identified as business entities which provide CPI through the internet in the U.S. as of Spring 2009. The research team physically visited two major leading companies in this business sector for interviews and the others were contacted by phone for interviews to identify the characteristics of this industry, business operating models and the flow sequence of product information from the manufacturers to users. Figure 1 illustrates a business operating model of a typical internet based CPI provider.

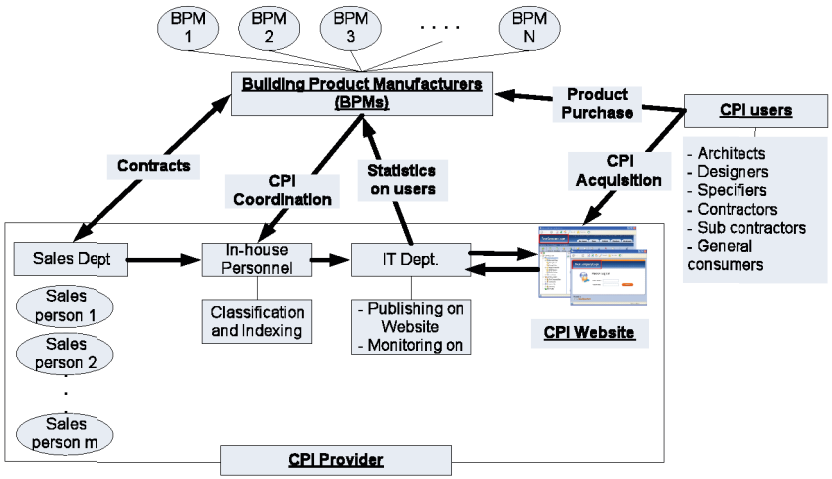

Figure 1. Business Model of Internet Based CPI Providers

A typical web-based CPI provider's business structure consists of sales personnel that make contact with the CPMs and establish contracts between the two parties. These contracts are typically made on annual basis and the manufacturers pay the CPI providers in a form of membership fees. The membership fees have different fee structures based on the number of products advertised and uploaded into the CPI provider's website. Some CPI providers charge special fees if the manufacturers request for easily visible advertisements on the websites. The in-house personnel of the CPI providers collect the product information from the manufacturers and categorize the products abiding to the Construction Specification Institute (CSI) format. It is important to note that none of the current CPI providers redevelops the product information sheets that are obtained from the manufacturers. It is on the contract that the accuracy of the data belongs to the manufacturer's responsibility and the CPI providers are not liable for it. An important role of the in-house personnel is to index the products. Key words and search words are extracted from the collected product information. Some CPI providers identify these key words manually using experienced employees and some others use an indexing computer software program to automate this process and reduce the associated cost.

The product information is then received by an Information Technology (IT) department to put onto the website. The IT department constantly manages the websites and updates new and revised product information onto the websites. The IT department is also responsible for recording the amount of hits a manufacture receives on their products and providing these useful statistics and the perception of the users on the site to the manufacturers. The websites are typically set up by using a server that stores various product information data. The users are able to access the server through various web links found in the website. The Computer Aided Design and Drafting (CADD) models and Building Information Models (BIM) of products

and specification sheets are stored here and are accessed by weblink without referring to the manufacture's website. This enables a user to find many different product specifications without leaving the CPI provider's website. The users are directed from the CPI website if they choose to place a purchase order on an item or they request additional information that is not located on the CPI provider's site. It is noteworthy that no web-based CPI providers currently offer a function to facilitate product purchase orders for the users or the website visitors. It is also important to note that most users of CPI in the design stage such as architects, interior designers, specification writers and cost estimators are not actual buyers of the products. The actual purchase of products takes place in the construction stage. Currently, the major point of attraction or the benefits of these web-based CPI providers for the CPI users are limited to providing information of various construction products under one roof for easy access and comparison of the products of same function.

Questionnaire Surveys

Three independent questionnaire surveys were conducted during summer and fall 2009 to identify the main factors of the CPI market that contribute to its success. The research team investigated the differences on opinions on these factors between stakeholders in the CPI market. These three questionnaires include one for CPI providers, another for CPMs, and the last for CPI users who visit CPI websites. These questionnaires were developed through discussions within the research team and literature review. The potential survey participants for CPI providers and users were selected using an online search. The potential survey participants for CPMs were found from CPI websites. Four popular divisions of the CSI format were considered for surveying CPMs including: concrete, steel, wood and doors, and windows. The survey forms were sent to the participants via email using Microsoft Word or an alternate PDF format after confirming their willingness to participate in the survey via telephone.

Method for Analyzing Survey Data

The survey questionnaires consisted of a set of questions with a 5 point likert scale. The following equation was used to convert the respondents' ratings to questions with five different answer options into a percentage format:

$$Percentage(\%) = \left\{ \sum_{i=1}^{n} \frac{(X_i - 1)}{4} \right\} x \frac{1}{n} x100 \qquad \text{(Equation 1)}$$

Where, X_i = option chosen by the respondent (rating 1 to 5), n = total number of survey respondents on the question

Survey Results and Discussion

The questionnaire surveys were performed to determine the differences of opinion in each group. There were, in total, 11 CPI providers contacted and encouraged to

participate in the survey. Out of the 11 CPI providers, the research team obtained 7 responses. The survey of CPI users resulted in 31 collected responses. The result of the final group, CPMs, was 27 collected responses.

Frequency and Preference of methods to access and advertise CPI

The two groups (CPI users and CPMs) were assessed in terms of the frequency and preference of the methods that they are currently using to access CPI (CPI users) and advertise their products (CPMs). The methods that were evaluated include catalogues, professional magazines, product sale agents/distributors, direct contact with the manufacturers or customers, web-based CPI providers, and Internet search engines.

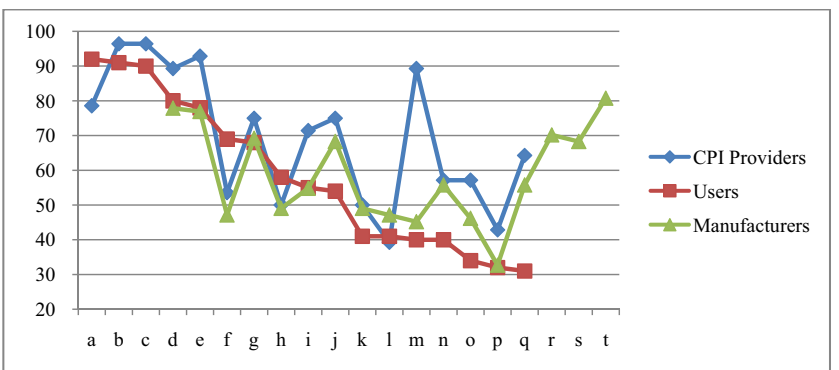

Table 1. Methods to Access and Advertise CPI

Methods		CPI Users		CPMs	
		Frequency (%)	Preference (%)	Frequency (%)	Preference (%)
Non-internet based methods	Catalogue	45	42	49	46
	Professional Magazines	25	22	39	30
	Distributors/ suppliers/ Sales agents	56	51	58	59
	Direct contact with manufacturers or customers	58	56	75	73
Internet based methods	Web-based CPI providers (sweets networks, reedconstructiondata, etc.)	69	67	73	60
	Internet search sites (Google, yahoo) / Company's website	75	62	84	75

Table 1 shows that the user group frequently uses and highly prefers the internet based methods compared to other traditional methods. The manufacturer group uses and prefers the internet based methods and also the method of direct contact with customers. This indicates that the mode of access and advertisement of CPI has significantly shifted to the internet based methods with extensive availability of the internet. CPI users are at least 11% and at most 50% more dependent upon the internet methods than other methods. This dependency on the internet based methods is higher for CPMs. CPMs use the internet based methods at least 11 % and at most 45% more in advertising their products than other non-internet based methods.

Important Factors for Using CPI Websites

Figure 2 shows the factors that the three groups (CPI providers, CPI users, and CPMs) think are important in using CPI websites. For CPI users and CPI providers, basically the same list of factors was provided. For CPMs, three additional factors (factors r, s, and t) were included as potential reasons to hire web-based CPI providers for advertizing their products. Three factors (a, b, and c) were not included in the questionnaire as they are not directly relevant to the manufacturers. In developing a comparative chart in Figure 2, a line for each group was used to easily capture and compare the differences between the responses of different groups even though these data points are not a trend or continuous data. The factors are sorted in descending order based on the CPI users' responses.

Legend:	
a: Accuracy of information, quality	k: Product installation video clips
b: Easier to retrieve information	l: Product delivery information
c: Ease of navigation on the website	m: Product reviews
d: Regular updates about products	n: Finished construction photos, power point presentation
e: Provision for acquiring additional information of the product (by contacting the manufacturer)	o: Cost saving availability/information
f: Comparison with other products	p: Public forum for discussion of products
g: Amount of information (variety of products)	q: Customer feedback system
h: Online technical support/Customer service	r: Users/Customers recommendations
i: Various search options	s: Economical
j: Supporting files (CAD files etc.)	t: More visibility

Figure 2. Important Factors for Using CPI websites

The major factors that attract the three groups in using the CPI websites are different shown in Figure 2. The CPI users who participated in the survey reported the top five important factors to visit the CPI websites as: a) accuracy of information/quality, b) easier to retrieve information, c) ease to navigate, d) regularly updates about the products, and e) provisions for acquiring additional information. The results indicate that quick and easy access to construction product information along with accurate product information is the key to maintaining current users and attracting potential

users to the websites. It means that users are seeking the most updated accurate information about construction products and various features and functions that help quickly obtain required data.

The five main factors that CPI providers think are important to attract visitors are the same as the list identified by the CPI users except that the m) product reviews is included, replacing the most important factor identified by the user group; a) accuracy of information/quality. But this factor a) accuracy of information/quality is still considered as an important factor by the CPI providers as the sixth most important factor. The CPI providers feel that product reviews is an important feature that helps users know the performance of products and make informed decisions. However, CPI user group does not agree and they do not consider the product review as an important factor for using the CPI websites (ranked 13th). The factors such as i) various search options, j) supporting files (CADD/3D/BIM), k) product installation video clips, n) finished product photos/presentation files, o) cost saving availability information, p) public forums and q) customer feedback system were rated much more important by the CPI providers than the CPI users. It appears that the CPI provider group thinks that the functions that are not available from non-web based CPI providers such as product manufacturers and paper catalogs are important to attract their visitors than the level to which the actual users think. The CPI user group rated a factor f) comparison with other products much higher than the CPI provider group did. It indicates that this function is the most important function among the functions that are only available at CPI websites. The CPI providers might have neglected the importance of this function as this function is rated very low in its importance but must actively develop and expand this function to satisfy the users.

The CPMs are clients that the CPI providers require to be successful and profitable in business. Hence, the CPMs' expectations for advertising their products on CPI websites should be met to maintain satisfied and continued relationships with the CPI providers. The five major factors that are considered by CPMs when hiring a CPI provider include: t) more visibility, d) regular updates about the products, e) provisions for acquiring additional information, r) users/customers recommendations, g) amount of information. These results suggest that the popularity or name recognition of a CPI website is the major factor of using web-based CPI providers. CPMs consider the CPI providers as one of sources for providing for more visibility of their products for advertisement. Thus, high name recognition of web-based CPI companies for their potential users is the most critical factor.

Figure 3 provides the summary of responses on difficulties faced by the users of CPI websites. The highest ranked difficulty is retrieving necessary information. Most information is related to the specifications, CAD files, and MSDS documents. Although these may seem basic, they are essential information of products. Furthermore, the absence of supporting files can be a hindrance to having proper knowledge of a product. Through analysis of the survey of CPMs, the results showed that manufacturers also prefer CPI providers that can provide supporting files, frequent updates, and online tech support or customer service.

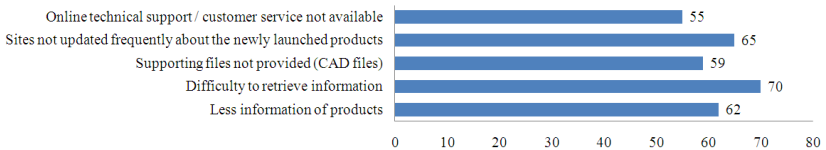

Fig. 3 Difficulties Faced by Users

Strategies to Increases the Number of Visitors

Figure 4 represents the strategies to increase the number of visitors/users of CPI websites. The main strategies that CPI Providers try to implement are i) sale agent benefits for increased contracts with CPMs, and ii) regular introduction of new construction products. It is important to note that the current business model works exactly like a car dealership. The CPI providers believe that the capabilities of each sales agent that they have is critical in increasing their revenue. Thus, the CPI providers feel that they can recruit, attract and retain competent sales agents by providing more salaries or benefits. Most CPI providers have not considered introducing an online ordering function, possibly due to strong resistance of CPMs to having this business relationship yet and consequently, the inability to display cost information of products online.

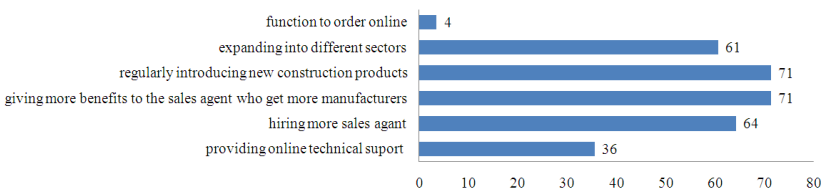

Fig. 5 Strategies to Increase the Number of Visitors/Users

Conclusion

Web-based CPI providers have become very common as a means to access CPI and to advertise construction products since the internet has become widely available. This study identified and discussed a typical business operating model for web based CPI providers. The study also investigated various factors that are critical for successful operation of the construction product information market in the A/E/C industry in the U.S. The collected data from three independent surveys were mainly used for comparing and summarizing different views from three major parties involved in this industry.

From the survey results, it is very apparent that CPI websites are gaining popularity in the A/E/C industry. Manufacturers that traditionally use catalogues and magazines are more dependent on these websites for advertisement of their construction products. CPI users have begun to use CPI websites as a major source of obtaining product information because these sites offer most of the information needed and allow the users to save time. The key competitors for CPI websites were identified to be product manufacturers' websites and popular internet search engines such as Google and Yahoo. Some CPI providers have contractual relations with these internet search engines to have their customers' products be listed first when certain key words are used. This strategic business relationship is suitable considering both are the top methods that users are currently relying on when searching product information.

To successfully maintain and operate a CPI website, the survey identified that the website first must be able to provide accurate product information with frequent updating functions. Second, the product information must be easy to search and access. Comparison function with other products is as equally important as the volume of product information. The other important functions include supporting files and online/tech support. More visibility of the websites and economical fee structure would also be important factors to retain and attract CPMs as customers.

Abstract

Various real-time field data acquisition systems have been developed aiming to automate control of construction projects. Some of those have demonstrated potential for automating project control to a certain extent and most of the systems support a specific function of project control. It is envisioned that successful integration of the systems would create new innovations and opportunities in managing the architecture/ engineering/construction (AEC) projects. In an attempt to facilitate integration among real-time systems, this study explored the feasibility of using building information model as a base of integration. In this study, a large volume of literature was reviewed to understand the state of the art real-time project control systems and building information modeling (BIM). Upon the understanding, this study identified a list of conditions or requirements for successful integration. The findings presented in this paper are expected to provide guidelines that need to be taken into consideration when developing automated real-time systems and building information models.

Key Words:

Building Information Modeling; Real-Time Systems; Project Control; Integration

Introduction

Since the opportunities of computer-aided design and construction were ambitiously prospected in the late 1980s (Howard et al. 1989), a dramatic change has happened to the practices that are implemented to manage the AEC projects. The advancement in information technology, such as computing, sensing, tracking, and communication, allowed invention of remarkable tools for managing projects. In particular, automated real-time project control systems and BIM have brought meaningful evolution to the management of AEC projects.

Filed management is one of the areas that have greatly benefited by the enabling technologies. Traditionally, project control on site required a lot of effort to monitor ongoing operations and to collect field data from the operations. Most of the control activities were performed manually, so that on-site control was time consuming and error prone. Seeking for a solution to the problem, the AEC industry has pursued automated project control for decades. As a result, various automated real-time filed data acquisition systems have been developed. Some of those demonstrated potential for automating project control to a certain extent. Depending on the intended purpose, most of those systems support a specific function of project control, for example, progress monitoring, quality control, and safety control.

BIM has brought a new paradigm of project management into the industry by promoting functional and organizational integration for project management (The buildingSMARTalliance™ 2009). Such integration has been esteemed as a significant breakthrough where the AEC industry has been criticized for lack of integration and high fragmentation in the process of project delivery (Howard et al. 1989). Through many cases of implementation, the technology has been tested and proved to be an effective method and tool for managing construction projects (Eastman et al. 2008). The technology, however, has been implemented primarily as a design tool. It has not been widely and actively used for filed management and process control. When its implementation is extended to construction phase, much effort is needed to maintain building models up to date, which is one of the reasons for such a low application as a control tool (Hajian and Becerik-Gerber 2009).

It is envisioned that successful integration of real-time systems can provide the AEC industry with new opportunities in many aspects of project management. Project control on site in particular can be further advanced. Some real-time systems have been integrated individually with building information models. This study investigated the following questions: what roles can BIM play for integrating individual real-time systems and what conditions or requirements should be satisfied to facilitate such integration? A thorough literature review was conducted in an attempt to find answers to the questions. The following section briefly describes the state of the art automated real-time control systems and BIM technology. However, it was not intended to replicate the benefits of and the technical details of the technologies in this paper, because those are already well documented by many previous studies.

The state of the art Real-Time Project Control Systems and BIM

Real-time project control systems

A large volume of literature has been produced in the area of automated real-time systems for project control. As literature shows, the purpose of existing systems varies and each system implements a variety of technologies depending on its primary purpose. Nevertheless, the core of most existing real-time systems in general is a function for automatic field data acquisition. It is worthwhile to note that, while most real-time control systems directly serve a specific function for project control, data or

information collected by the systems can be used for a variety of purposes. For example, a system developed by Golparvar-Fard et al. (2009) can assist with automatic update of building information model while its primary purpose is to monitor progress. The existing systems can be categorized into two groups from a broad perspective. One group, Group-A, is concerned with monitoring and control of processes and operations on-site during construction while the other group, Group-B, is interested in automating tasks or functions that are conducted to operate or monitor systems in the built environment (Fig. 1).

As illustrated in Fig. 1, Group-A can be divided further into two sub-groups: A-1 and A-2. Systems in A-1 are intended to monitor ongoing field operations constantly. The systems primarily focus on tracking moving objects (Bohn and Teizer 2009; Fullerton et al. 2009; Carbonari et al. 2009) and localizing materials (Wang et al. 2006). Meanwhile, A-2 includes systems that support tasks performed to manage construction operations, such as progress monitoring, with a certain length of interval time (Golparvar-Fard et al. 2009; Roh et al. 2009). Some systems in this category also support document transaction and change management. Group-B also consists of two sub-groups: B-1 and B-2. The primary focus of the systems in B-1 is centered in monitoring the health of infrastructure systems, for instance, monitoring the health of building structures (Zhu et al. 2009). Meanwhile, B-2 includes systems for monitoring and controlling service systems, such as HVAC, security control, and fire-hazard prevention system, which have existed for a relatively long time.

As well-known, in order to collect field data either automatically or semi-automatically, the systems implement various information technologies and computing techniques—to name a few, radio frequency identification (RFID), global positioning system (GPS), ultra wide band (UWB), embedded sensors, 3D LASER scanner, Flash LADAR, high-resolution video camera, digital photogrammetry, and Wi-Fi wireless communication (Hwang 2003; Bohn and Teizer 2009). One notable limitation of such technologies is that it is difficult to implement the technologies to track and monitor processes and environment associated with interior work performed in a confined area. The condition becomes even worse when there are many objects and obstacles in the area. Thereby, more real-time systems to date has targeted on monitoring exterior work, such as excavation, structure erection, and building enclosure installation.

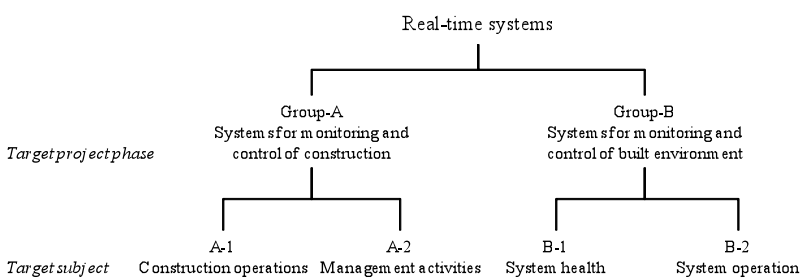

Fig. 1 Classification of real-time systems for AEC projects

Building Information Modeling

While BIM is defined in many ways, a general definition is "a modeling technology and associated set of processes to produce, communicate, and analyze building models (Eastman et al. 2008)." BIM has triggered a paradigm change in project management from the design phase to facility management (The buildingSMARTalliance™ 2009). Accordingly, BIM has been implemented for various purposes. With respect to design, it is widely used for design development and design coordination (Leite et al. 2009). Concerning design coordination, BIM is being more actively used in detecting clash among major mechanical, electrical, and plumbing duct and pipe (MEP) components as well as between architectural/structural components and MEP components. While BIM is primarily implemented for design-related processes, it is used in construction and operation/management to a certain extent. Such implementation includes quantity take-off, scheduling (4D), construction simulation, and work sequence coordination. Concerning energy saving, it is also used for energy simulation (Sumpf et al. 2009) aiming to find an optimal design of a building which can maximize energy efficiency.

Integration of BIM and Real-Time Project Control Systems

Integration of real-time systems with BIM has been under tremendous interest in the AEC discipline. Nevertheless, such integration has been limitedly pursued in certain areas of project control, such as safety, progress monitoring, resource management, and quality measurement. Additionally, among these areas, relatively more active integration has been attempted in progress monitoring and supply chain management. When it comes to technical method for integration, a frequently applied approach is to superimpose digital as-built images on 3D BIM model. This approach is often used for monitoring progress (Golparvar-Fard et al. 2009) and planning path of equipment for coordinating the motions of equipment such as cranes for building construction (Kang and Miranda 2004). In this approach, spatial data of BIM, more specifically boundary data of a building, mainly is used as a reference. Integration of BIM and real-time systems for supply chain management has been centered in tracking and handling materials from manufacturing to delivery to and installation on site (Chin et al. 2008). Existing methods in this category apply various resource tracking technologies such as RFID and GPS. Overall, the integration between real-time systems and BIM remains very low to date and, furthermore, the integration among real-time systems is even lower.

Expected Benefits of the Integration

It has been prospected that successful integration of BIM and real-time systems can create new opportunities in many areas of project control (Hajian and Becerik-Gerber 2009). The following delineates prospects in a few areas that are expected to benefit the greatest synergy effect from successful integration of automatic real-time systems using BIM.

Automatic update of building information models

Being integrated with building information models, real-time field data acquisition systems can increase the degree of automation in updating building information models. Furthermore, updates can be made more frequently, regularly, and accurately. This will remove or, at least, reduce burden of updating building information models up to date along the work progress. Currently, available systems are not able to update the models in real-time. Removing such a critical hurdle will consequently expedite the application of BIM in the AEC industry. All of the afore-mentioned advancements will eventually contribute to accomplishing more proactive and reliable project control in managing the AEC projects.

Advanced data and knowledge management

The advancement in automatic field data acquisition systems will enable more accurate collection of data and knowledge about processes and operations on site. Such critical information assets can be collectively stored and effectively managed within a building information model. Using ontological representation of BIM, data and knowledge can be linked with associated building components and objects. This will allow effective storing, maintenance, and reuse of data and knowledge.

Field management

The afore-mentioned improvement in data and knowledge management will enhance field management in many aspects (Wang and Boukamp 2009). Some exemplary aspects include quality inspection, identification of work hazards and safety requirements, and communications and coordination among project participants. Using wireless communication, the contextual data about processes and objects can be cross-checked in real-time between actual context and that in the building information model.

Robotics

Integration of BIM and real-time systems will make the application of robots in construction more feasible and efficient than ever before. It is expected that robots can use more systematically augmented status information stored in building information model to reason the status of objects under operations. Robots also can utilize current environmental conditions at working areas by communicating with real-time systems. In addition, robot-detected spatial data may be mapped with building information model in real-time to find exact locations.

Conditions and Requirements for the Integration

Successful integration of enabling real-time systems can further enhance project control of AEC projects. The following discusses conditions or requirements to be satisfied or, at least, to be improved for successful integration of real-time systems by means of BIM. The conditions or requirements could be identified by combining and interpreting findings from many previous studies.

Technical Aspects

An effective method for reorganizing BIM components is needed where components are organized differently by designers and planners (Eastman 2008). For example, designers tend to represent a composite partition wall, which consists of metal studs, gypsum boards, insulation, electrical wires, painting, as a single entity. From the perspectives of planners, such an organization presents limitations to project control where the constituents normally belong to different scope of work in contract and built by different trades. In particular, it is difficult to develop schedules and to conduct progress monitoring for management of field operations at a required level of detail. Lack of such a flexible reorganization method currently presents a critical hurdle to facilitating the use of BIM for project control beyond design. Overall, flexible methods for abstraction and representation of building components are needed to enable effective linking between field data and associated components.

As more advanced sensors are implemented for the purpose of controlling construction operations, more building elements as well as resources used are recognized based on sensor data, such as location and other contextual data. Considering such fast growing implementation of sensors, two problems need to be addressed. First, representation of sensor metadata should be supported more effectively by BIM whereas existing standards for BIM like Industry Foundation Classes (IFC) are not fully ready for it (Liu and Akinci 2009). Second, a method for planning sensor deployment on site is necessary to optimize number of sensors, position of sensor, and networking among sensors, taking into consideration the linking between sensors and building components in a building information model.

Excellent mobile environment is essential. As well-known, many decisions relevant to control are supposed to be made promptly on site. This often requires immediate access to relevant data. For instance, an inspector may need specifications and drawing for quality inspection. In a situation like this, mobile computing and wireless communication is essential to acquire needed information in real-time.

It is not difficult to expect the proliferation of data in a building information model when a model is integrated with various real-time field data acquisition systems. "Soon, nearly every piece of information that an owner needs about a facility throughout its life can be made available electronically," prospected the buildingSMARTalliance™ (2009). "The industry, however, does not yet have the standards and infrastructures in place to capture, organize, distribute, and mine that information." Thus, a well-structured ontological representation of data is needed to make user interaction easy with such large and complex data model on site, particularly considering mobile computing environment (Reinhardt et al. 2004). While technical improvement is essential to the successful integration, the significance of non-technical factors should not be forgotten. Nitithamyong and Skibniewski (2004) argued that, despite significant impact of many non-technical barriers on the success of technology implementation, the barriers are often ignored.

Non-Technical Aspects

It may sound redundant that the implementation of BIM is a prerequisite condition for the integration of real-time systems for project control by means of BIM. It, however, is not a meaningless statement in reality. The long-lasting structural problem of the AEC industry—organizational barrier caused by horizontal fragmentation—incurs legal concerns in terms of liability which hinder the use of BIM in the AEC projects (Eastman 2008; Dossick et al. 2009). In this context, it is critical to have a consensus among project participants with regard to implementation of BIM. In particular, owner's role is important where owner determines a project delivery method. A recent report (Brown 2009) shows how influential owner's position is when it comes to implementation of BIM in the AEC projects: "Wisconsin's Division of State Facilities (DSF) issued the new guidelines and standards require architects and engineers to use BIM authoring software in all phases of design, to maintain and update the model during construction, and to submit the model to the owner at the end of the project."

The implementation of BIM also needs to be extended to construction to take a full advantage of the integration. But, the current practices facilitate the implementation of BIM only up to the early stage of construction project (Meadati 2009). Particularly, in a design/bid/build project, the issue of cost compensation plays a critical barrier where contractors need to spend a considerable amount of extra money to develop and maintain building information models.

Last, but not least, education and training need to be fostered with BIM and real-time systems. As noted by Taylor et al. (2009), BIM can be an effective means of integrating the AEC disciplines in educational institutions. A recent survey result (Peterson and Fischer 2009) provides a good indicator to determine whether or not the AEC industry is really ready to adapt BIM and real-time systems to manage construction projects. According to the survey, 55-75 percent of construction professionals do not use software tools beyond Microsoft Office. The same survey also reports an astounding response—a general builder preferred manual data collection method because it is a "good way to train field (engineers) how buildings are built."

Conclusions

Systematic aggregation of real-time systems can be achieved by using BIM as a bridge for integration. Despite the expected benefits of such integration, there are some critical problems that should be overcome to facilitate the integration. This study identified the problems by analyzing a large volume of literature. The problems exist across both technical and non-technical aspects with regard to development and implementation of automated real-time systems as well as building information models. It is expected that researchers and system developers can use the conditions or requirements presented in this paper as guidelines, as they develop real-time systems and building information models.

ABSTRACT

Over the course of a typical construction project, project managers constantly monitor progress and resolve problems. However, it may be not easy to track and identify performance problems when a construction project generates a great volume and variety of ever-changing data during the construction phase. Traditionally, in order to identify performance problems, project managers walk job sites and meet or call several individuals. Since the advent of web-based tools, project managers have been able to obtain information by logging on to a project's web site. However, early efforts at using computers to manage construction projects came up short with technology that was awkward or costly. Today, thanks to advancements in information technology, web-based tools are capable of displaying information in easy-to-read graphics, assembled from data pulled from multiple sources in real time. This paper explores what data should be collected for web-based systems to provide project managers with threshold level information regarding actual project status so that they can focus on the "big picture." This exploration is based on literature review and interviews with fifteen project managers from construction firms in the Puget Sound area. The information presented in this paper may serve as the foundation for the development of visual information systems to support the work of construction project managers.

INTRODUCTION

The primary challenge of project managers is to deliver facilities within a given time frame and budget while satisfying project objectives. Over the course of a typical project, project managers constantly direct and monitor the progress of construction activities and resolve any discrepancies between as-planned and as-built progress. However, it may not be easy all the times to track and identify performance problems during construction when a construction project generates a great volume and variety of ever-changing data. Due to the volume of data, key issues of schedule, productivity, and quality may be overlooked, thereby resulting in the failure of judicious handling of important situations.

Project success is highly dependent on the responsiveness and agility of project managers in managing such discrepancies. Therefore, up-to-date and accurate project data must be transformed into meaningful information for project managers to gain insights into the actual status of a project and make more informed decisions in dynamic and complex environments.

Most research on project data has focused on how to collect, integrate, and consolidate voluminous data into inter-organizational database systems (Hanlon and Sanvido 1995, Kang and Paulson 1997, 2000, Caldas et al. 2002, Chang and Tsai 2003). However, the massiveness and complexity of these database systems may result in confusion and "analysis paralysis" where project managers may have to invest their valuable time looking for relevant information to aid decision-making.

More recently, there have been a few research efforts focusing on the visualization of project data in the construction management domain (Songer et al. 2004, Korde et al. 2005, Russell et al. 2009). Despite such efforts, the construction management community still faces the problem of how to digest large amounts of data and discover the underlying meanings hidden within the data sets. The lack of adequate visual representation within the construction industry causes project managers to struggle with voluminous data (Song et al. 2005), which may cause costly errors or lead to project delays.

Visual information systems; where project control data is organized into an informative form, presented coherently, and communicated visually; may help project managers better analyze projects, identify problems in performance, and take corrective actions. Therefore, to assist project managers in monitoring the progress of construction activities and gaining insights into actual project performance, we propose the development of interactive visual information systems as a model of visual analytics in the construction management domain. The fundamental challenge to address is how to develop effective systems to assist project managers in decision-making. In order to overcome this challenge, several critical questions must be addressed:

- What data should be collected to generate high level information about actual project performance?
- What issues should be considered before designing appropriate visualization schemes?
- How to manage large amounts of data and visually represent their intrinsic meaning?
- How to design visual information systems to enable users to easily comprehend the complex inter-dependencies and discover the underlying meanings?
- How to develop interactive visual information systems to assists the user in data mining and knowledge discovery?
- How to assess the effectiveness of visual information systems?

To develop effective visual information systems, the initial focus should be on the first question. Thus, this paper explores what data should be collected to provide project managers with threshold level information regarding actual project status so that they can focus on the "big picture."

PROJECT MONITORING AND CONTROL

No construction project can be performed exactly as planned due to uncertainty regarding productivity, design errors, conflicts and omissions, change orders, labor strikes, material delivery delays, vandalism, and bad weather among other factors. Consequently, accurate and timely project monitoring is a prerequisite for project management. Construction projects must be continuously monitored by comparing actual progress to the baseline plan. Project monitoring enables project managers to evaluate actual performance and resolve any discrepancies from planned performance in the dynamic nature of construction projects.

Constantly assessing the actual status of a project and identifying performance variances as early as possible is essential to successful project control. Once performance variances are detected, it is necessary to identify their causes and key drivers. This allows project managers to take appropriate actions in a timely manner, if necessary. Project control begins with the process of identifying current or possible problems based on monitored or projected performance during the implementation of the baseline plan. By doing so, project managers can analyze causes of problems and take corrective actions to adjust the project to meet its requirements (Gould and Joyce 2002).

From the viewpoint of project control, it is useful to forecast future variances between actual progress and the baseline plan in advance of facing real performance problems through periodic assessments of project performance. Most forecasts of project performance predict the conditions at the end of the project, such as forecasted completion dates and cost at completion, based on current and known conditions. For example, based on current production rates and the amount of work remaining, the forecasted completion date can be projected. In addition, it can be useful to evaluate "what if" scenarios according to possible corrective actions prior to final decision-making.

The main objective of project monitoring and control is to identify the discrepancies between actual and planned performance and put the project back on the desired track as early as possible (Bradiru and Pulat 1994). A typical project monitoring and control process can be described as information streams and information processes because it includes a series of steps which requires the input of information during the entire construction phase of a project and generate information project managers need (Meredith and Mantel 1995).

Performance Measurement

Each construction project may exhibit a different view of project monitoring and control based on the project's goals and success criteria. For example, some projects may consider 'keeping the completion date' as the most important objective despite manageable cost overruns, while others may put emphasis on high quality work despite minor delays. The important dimensions of project monitoring and control are specifically defined on performance metrics describing the client's requirements and their value (Lewis 1995).

Performance metrics are typically defined before a project starts to facilitate the project monitoring and control process including collecting, analyzing, and comparing actual project data to planned data. Project managers should define quantifiable performance metrics in preparation for project monitoring and control.

Those performance metrics must reflect the critical success factors as well as project objectives. Due to the importance of performance metrics, a considerable amount of research has been done within the subject of performance measurement. Ward et al. (1991) argue that project performance in construction had been traditionally evaluated by the client's requirements in terms of cost, time, and quality. Egan (1998) emphasizes the importance of specific project targets for the improvement of project performance and the role of performance measurement based on those targets. Consequently, Egan (1998) suggests time, cost, quality, safety, productivity, and scope of work as key performance indicators. In addition, Korde et al. (2005) describe that important factors in evaluating construction performance have been categorized into productivity, time, cost, scope, quality, safety, and others.

Performance problems can be identified by comparing actual progress to the baseline plan, which specifies targets for performance measurement such as the amount of work, budget, and duration. Those targets should be the measurable quantities that readily fit the performance measurement. Sine performance measurement can be done only after some tasks have been completed, some consider them to be ineffective to timely manage projects. However, if project managers do not measure what they have done, it is difficult for them to justify additional resources to improve performance. Furthermore, measuring completed work is important because the performance trend of past work could be an indicator of potential problems, allowing project managers to put the project back on the desired course by making adjustments for upcoming tasks.

Performance Variances

Performance variance can be determined by the deviation of a variable from its target. In this context, performance better than the target is also considered a variance, just as performance worse than the target is considered a variance. Performance variances can be simply calculated by:

$$\text{Performance Variance} = \text{Target Performance} - \text{Actual Performance}$$

Performance variances are important inputs especially for the project control process. However, Shtub et al. (1994) argue that the raw performance measures could be deceiving especially for cost performance. For example, a cost variance of $10,000 is significant on a $20,000 activity, but much less important in a multi-million dollar activity. To judge this relative performance, standardized performance indexes are frequently used (Table 1).

Table 1: Example of Performance Indexes

Performance Index	***Formula***
Schedule Performance	Schedule Variance / Planned Duration
Cost Performance	Cost Variance / Budgeted Cost

The scope of this paper is limited to quantitative measures of project performance including time, cost, productivity, and scope of work. Although, safety and quality should also be monitored and controlled, they are somewhat difficult to

measure in a quantitative way. Of course, safety and quality could be measured by the number of incidents/accidents and the number of punch list or rework items, respectively. However, from the project control perspective, this is not a preventive approach. The most useful way to measure both schedule and cost performance is to use Earned Value analysis, which combines scope, schedule, and cost performance in an integrated system.

DEVELOPING VISUAL INFORMATION SYSTEMS

The main objective of visual information systems should be to help project managers monitor actual performance in an intuitive manner and control project progress. In designing and implementing such visual information systems, the user-centered design methodology could be one of the most effective approaches because it continually addresses the usability issues and tests potential users' expectations and goals. For this reason, our research efforts have been initiated with expert interviews to understand project managers more closely, their main tasks, and their work environments. Such understanding can serve as the foundation of the conceptual design for the target visual information systems.

Expert Interviews

Experts have not only insights into aggregated and specific knowledge regarding their domain, but also privileged access to information about decision-making. Literature shows that experts are sensitive to patterns of meaningful information (Bransford et al. 1999). Expert interviews are a useful way of gathering the opinions of people who have specialized knowledge regarding particular subjects within an industry sector (Nasir et al. 2003).

For our study, experts were defined as individuals who are project managers or senior project managers in construction companies. All such individuals should have at least 10 years of experience in the construction industry to be considered experts. Experts were selected based on their experience and knowledge as determined by peer opinions and review of credentials. We contacted fifteen experts who are project managers or senior project managers in construction companies in the Puget Sound area. In-person expert interviews were conducted as individual meetings, one at a time.

The purpose of these interviews was to understand what information should be incorporated into visual information systems, focusing on the threshold level of project monitoring and control.

The interviews included some fundamental questions that cover the most important topics in terms of project monitoring and control. After introducing the research objectives, experts were asked several questions to elicit comments in the following areas:

- Major concerns when managing a construction project
- Data that should be collected for project monitoring and control
- Procedures for collecting and analyzing such data

Findings from Expert Interviews

Project managers have the overall responsibility for construction operations including the management of project information flow within their own team as well as the primary point of contact for the owner, the architect, and subcontractors. Their tasks are related to achieving project objectives and goals with the main consideration of schedule and cost. Most interviewees commonly stated, "My role is to make sure everyone gets their assignments and reports properly and make sure everything is going on as planned."

Through the interviews, we found that the information necessary for different levels of construction management in a hierarchical communication structure can vary, especially in the degree of detail. In this context, high-level project control data can be defined as the data prepared for the review of senior project managers or executives at a summary level.

One of the interviewees stated, "Certain things we need to track on a regular basis are the production to schedule and cost to verify staying on schedule and within budget. Probably, there are the two key things, schedule and cost, we are tracking." Regarding this statement, another interviewee said, "if you make your schedule and make your budget properly, no one gets hurt and the quality is what you expect. Then, everything works properly." In addition, many interviewees specifically mentioned, "Schedule is probably the most important piece to monitor. If you have your budget aligned properly, the schedule is what's important. It keeps things running." "Schedule is the key to really everything, the key to milestones, and the key to progress and expectations. Everything can be tied to the schedule. So, I call the superintendent every day, once a day or twice a day, to check where we are on the schedule." "Probably schedule information is the most critical for typical construction projects because we are in short duration and the owner is very interested in getting it done on time. Cost information is probably the second most important because part of my job is to keep within the budget."

When any performance problems or unexpected issues arise during construction, project managers have meetings or correspondence with other team members to identify their impacts on schedule and budget. An interviewee said, "Construction is a people-oriented business. It's all about people around you." He also said, "Meeting the schedule is probably the biggest challenge because there are so many inputs or factors to adjust the schedule. When a subcontractor misses its deadline, it affects our deadline." One of the interviewees stated, "In such case, I communicate and interact with all of the trade people and team through meetings, phone calls, or e-mails to ask where the job is?, what's behind?, what's coming up?, what are the milestones coming up?, and what's the corresponding cost?"

According to the interviewees, to better monitor and control a project with unplanned interruptions, the major concerns at a summary level should be:

- Prioritizing construction activities and allocating resources
- Monitoring time on project and managing project schedules
- Projecting job costs
- Reducing costs by avoiding wasting resources
- Communicating with the owner, project team, and subcontractors
- Indicating upcoming deliveries and milestones

Therefore, the key data to be collected for project monitoring and control should be related to both schedule and cost concerns. Almost all of the interviewees indicated that the most valuable and important information is monitoring the schedule. They also indicated that it is important to have a constant flow of cost information.

Based on the interviews, we conclude that effective visual information system should provide project managers with data to answer the following questions:

- What is the current status of the project regarding schedule and cost?
- Are there any potential problems or unplanned issues that need to be solved now?
- When will the project be completed?
- Where did we spend our money?
- How much will it cost to complete the project?
- What are the causes for cost or schedule overruns?
- Who is in charge of dealing with the overruns?
- If the overruns could be solved, what would be the impacts on schedule and budget?

Table 2: High-Level Project Control Data for Visual Information Systems

Information	*Item*	*Description*
Basic	Activity	Description of Activities
	Responsibility	List of Entities Assigned to the Activities
	Schedule Criticality	Critical or Non-Critical Path Activities
	Duration Times	Actual vs. Planned Completion Dates
	Float	Amount of Float
	Proportional Cost	Proportional Cost to Overall Project (including direct and indirect costs)
	Resource Usage and Rate	Description of Resources
Actual Performance	% Complete	Amount of Work Accomplished and Remaining Work
	Schedule Performance Index	Value of Schedule Performance
	Cost Performance Index	Value of Cost Performance
	Schedule Variance	Schedule Deviations between Actual and Planned Duration
	Cost Variance	Cost Deviations between Budget and Actual Cost
	Productivity	Actual vs. Planned Labor and Equipment Productivity
Forecasted Performance	Cost Projection	Estimate at Completion
	Forecasted Duration	Forecasted Total Duration

Our interviews revealed that project control data are collected and analyzed from a variety of sources including phone calls, in-person meetings, and written documents (e-mails, typed letters, daily reports, meeting minutes, labor reports, job

cost reports, and weekly or monthly progress reports). The variety of sources and formats make keeping track of the information a challenge. Indeed, as expressed by one of our interviewees, "One of the things that I would like to see in the future is a software or system to track all the important information including schedule, cost, productivity, quality, and scope of work on the same form or in some similar formats."

The result of our interviews and literature review efforts has been summarized in Table 2. For developers of visual information systems, the following considerations should be integrated into the conceptual design of their systems:

- All information necessary for project monitoring and control should be presented in a single view as much as possible to provide the "big picture" of a project.
- Activities should be displayed in time-scaled and the logical sequences of activities need to be presented.
- The current status, trends, and forecasted status of project performance need to be presented simultaneously to provide trend analysis capability and predictive potential.
- The information should be sorted by activities or work packages to easily identify problems.
- The main focus should be placed on on-going activities because they are controllable.

CONCLUSION

Information visualization can assists construction project managers in many ways, but especially in monitoring and controlling the progress of projects. However, before developing interactive visualization systems in the construction management domain, we need to explore what data should be collected to provide project managers with high-level information regarding actual project status. The objective of our research effort is to assist project managers in gaining insights into actual construction projects through visual information systems and this paper presents some of our findings regarding the kind of data that project managers valued. The objective of visualization systems should be to deliver and share relevant information with all project participants. The technology is certainly available, but such systems will not be effective unless they truly satisfy the needs of project managers.

Abstract:
There have been several isolated attempts to automate aspects of the construction project delivery process. These have only been marginally successful and it is increasingly being recognized that significant improvements can only be made through an integrated approach that involves the synergistic integration of information technologies into the project delivery process. A cyber-physical systems approach is expected to reduce the tremendous losses that are directly attributable to the inefficiencies associated with the lack of effective integration. This paper describes a specific effort that seeks to facilitate real-time consistency checking between virtual models and the physical construction. It argues for the effective integration of computational resources (such as wireless sensors, virtual prototyping, real-time tracking and data fusion) with the design and construction process, and outlines how bi-directional consistency can be maintained between the virtual models (which are often ignored once the physical construction commences) and the physical facility. The opportunity offered by the adoption of a cyber-physical systems approach to make the construction process more intelligent and sustainable is discussed and the key benefits highlighted.

1. Introduction

Cyber-physical systems (CPS) are physical and engineered systems whose operations are monitored, coordinated, controlled and integrated by a computing and communication core (Lee, 2009). Presently, a precursor generation of CPS, referred to as embedded systems, has been applied to several industry sectors such as transportation, critical infrastructure, healthcare, defense systems and tele-physical operation and consumer electronics. These embedded systems are information technologies and collaborative communication systems such as wireless sensors, visualization tools, real-time tracking and data fusion tools, whose emphasis is more on computational elements than on the integration between computational and physical elements. Furthermore, unlike the traditional embedded systems, a CPS is designed as a network of interacting elements instead of as standalone devices.

The construction project delivery process is grossly inefficient and in dire need of a paradigm shift that involves, amongst other things, an increased and more targeted investment in cyber-infrastructure. Developments in computational and visualization tools in the design and construction process enable a synergistic integration of computational tools and physical resources in a challenging industrial context. Greater control can be exerted over the project delivery process through appropriate integration of automated systems and emerging information and communication technologies (ICT) in the physical construction process. This cyber-physical systems approach is expected to result in a transformation of the process for the delivery of constructed facilities. The result would be a major reduction in the huge losses (estimated at over $16 billion per year by NIST) that are directly attributable to the inefficiencies associated with the current lack of interoperability (Gallagher et al., 2004). The adoption of a cyber-physical systems approach offers a tremendous opportunity to make the construction process more intelligent and sustainable.

This paper presents an approach to integrating virtual models and physical construction for real time consistency monitoring and control. It reviews and identifies limitations of previous approaches to monitor construction processes. The enabling technologies for the integration are highlighted. It also identifies the need for cyber-physical systems to improve the construction project delivery process, key features and the potential benefits of adopting this approach.

2. Trends in Virtual Prototyping and Physical Construction Monitoring

2.1 Virtual Prototyping

Virtual prototyping provides a realization of an intended design or product to illustrate the characteristics of the product or design to users before actual construction (Gopinath, 2004). Virtual prototyping evolved in response to the requirement for designers and others involved in product development to have a better feel for the end product at the earliest possible opportunity without the expense of building a physical prototype or making the product itself. This is increasingly seen as necessary within the construction industry as it extends the idea of 4D CAD (the integration of 3D geometry to schedule information) by integrating more features (simulation engine, analysis tools and decision support systems), for simulating the real construction process (Li, 2006).

Another aspect virtual prototyping is Building Information Models (BIM), which has the capacity to store embedded information that can be analyzed and utilized throughout the lifecycle of a facility. The construction industry is highly fragmented, involving various key players (Motammedi and Hammad, 2009). Application of cyber physical systems in the construction industry will therefore require efficient information sharing and exchange between the various players. BIM is emerging as having the capacity to create, share, exchange and manage the information throughout the lifecycle between all the stakeholders (Motammedi and Hammad, 2009). Numerous research efforts have identified Virtual Prototyping as having considerable potential for enhancing the construction project delivery process.

Sarshar and Christiansson (2004) described the application of VP in The Divercity research project. They investigated the role of VP in enhancing productivity and effectiveness of construction projects. They discovered that VP can assist in client briefing, constructability and design reviews, enhance communication and co-ordination between project teams. Chau et al. (2004) presented a 4D visualization model which is aimed at helping construction managers plan daily site activities. The 4D visualization model comprises of the activity schedule, associated allocation of resources and layout of facilities on the construction site. They identified 4D model as having strong potential in construction planning and management processes.

Li et al. (2006) described a framework and process for the application of 3D and 4D CAD for virtual prototyping to support project teams on construction planning. With a 3D/4D CAD system, building components from a graphical interface can be related to construction activities. The 4D CAD systems can be used for construction analysis and communication of design to the team.

2.2 Physical Construction Monitoring

Numerous sensing technologies ranging from wireless sensing technologies, tracking systems, and other instrumentation have been adopted for monitoring the physical construction.

Wireless sensor technology offers increased flexibility in terms of placement, reduced cost of installation and maintenance compared with wired sensors; this makes it suitable for adoption in the construction industry. The strength of sensors is that they can form networks such as ZigBee networks, and cooperate according to various models and architectures, capable of processing, sensing, computing and communication throughout the distributed mesh networks. The nature of sensing can vary from embedded sensing such as RFID that assesses some material characteristics of a product, to spatial sensing and imaging technologies that assess both the quality of products being constructed and the safety of processes being utilized during construction (Akinci and Anumba, 2008). In cyber-physical systems, wireless sensors serve as a real time data collection, storage and transmission system. Each sensor captures and communicates sensing information to other sensors, thus forming a wireless sensor network. These wireless sensor networks can be used to acquire and update information stored in the virtual prototype.

Song et al. (2007) developed a ‘Material Tracker’ composed of RFID and ZigBee technology which can identify the data of materials such as bulk or bundle which is loading through RFID reader. ‘Material Tracker’ also has the potential to

check the flow and location of materials in real time using ZigBee technology. From the field test carried out, they discovered that it is possible to track material location within a planned range through the movement of material tracker due to the short coverage range of RFID. On a large construction site, it will be difficult to manually move the material tracker. Xuesong et al. (2008) explored the technical feasibility of applying wireless sensing technologies for resource tracking on building construction sites. They explored various wireless sensing technologies and identified the ZigBee-based wireless sensor network as being the most promising for tracking construction resources.

2.3 Integrated Virtual and Physical Construction

3D laser scanners can analyze construction sites to collect data which is used to develop three dimensional digital models while Photogrammetry is a remote sensing technology in which geometric properties of objects are determined from photographic images. El-Omari and Moselhi (2008) presented a method, which integrates 3D scanning and photogrammetry to support progress measurement and project control. The application of the proposed method was demonstrated using a building under construction. 3D laser scanner scans the construction site from different sides; the method is proven to be time consuming and results in a delay in decision making.

Golparvar-Fard et al. (2009) proposed a method for visualization of performance metrics for progress deviations through superimposition of 4D as the as-planned model into time-lapse photography and videotaping of the as-built progress data collection. The progress information can also be visualized through augmenting the as-built photograph with the as-planned data. Data are collected from as-built and as-planned environments and merged to form a 4D as-planned simulation and time-lapsed photographs. The as-planned model is superimposed on the site photographs. This superimposed image enables discrepancy to be detected, quantified and cost values extracted. This information is appended to the known as-planned and as-built information and allows the budget spent to be properly assessed and the cost discrepancies to be understood but the photograph approach are unsuitable under bad weather conditions.

4D CAD has been applied to the preconstruction phase of projects but is rarely used in the construction phase because of a lack of efficient methods to capture as-built schedule information and to represent the information with 4D CAD to support effective decision making in a timely manner (Chin et al., 2005). RFID tags attached to steel components can be used to collect logistics and as built progress information; this status information can be input to project management information system and 4D CAD, which will reflect the current status of a project in 3D CAD models. Chin et al. (2005) developed RFID+4D CAD, which is an integrated information system that offers the opportunity of managing construction projects automatically. RFID+4D manages progress data from manufacturing to erection at the construction site based on the status of each member. Progress data for each member are collected using RFID readers and then synchronized to RFID+4D PMS (Progress Management System). This approach offers the opportunity to view progress data but does not allow control of the construction process.

2.4 Limitations of Previous Research

While previous studies have demonstrated the potential for significant improvements to the project delivery process based on better modeling of a proposed facility and tracking of construction components and resources, there is still much that needs to be done. Some of these include:

- There are limited or no effective mechanisms for ensuring bi-directional coordination between the virtual prototype and the physical construction. For example, when a key component or sub-assembly is constructed in the physical environment, there is no means of automatically updating the virtual model to reflect this. Conversely, if the design or erection sequence of a set of steel members is altered in the virtual model, there is no real time communication of this change to construction personnel on site.
- There is a lost opportunity to 'instrument' the construction process and to monitor its progress by being aware of when certain key components or sub-assemblies have been installed or built.
- There is limited scope for the use of sensors and other embedded instrumentation to control the construction activities and/or the resulting facility.

3. Need for Cyber-Physical Systems in Construction

Cyber-physical systems refer to the effective integration of, and coordination between, computational and physical systems. The concept of cyber-physical systems emerged from the need for increased adaptability, autonomy, efficiency, functionality, reliability, safety, and usability of various systems (NSF, 2008). 'Research advances in cyber-physical systems promise to transform the world with systems that respond more quickly (e.g., autonomous collision avoidance), are more precise (e.g., robotic surgery and nano-tolerance manufacturing), work in dangerous or inaccessible environments (e.g., autonomous systems for search and rescue, firefighting, and exploration), provide large-scale, distributed coordination (e.g., automated traffic control), are highly efficient (e.g., zero-net energy buildings), augment human capabilities, and enhance societal wellbeing (e.g., assistive technologies and ubiquitous healthcare monitoring and delivery)' (NSF, 2008).

The adoption of the cyber-physical systems approach in the development of buildings and civil infrastructure systems offers opportunities for enhancing construction project delivery process. The construction industry's perennial problems of relatively poor productivity when compared with other industry sectors, the lack of certainty (in terms of outturn cost, quality or delivery date), inadequate client satisfaction (it is estimated that more than 50% of construction clients are dissatisfied with the project delivery process), and the inefficiencies inherent in the use of outmoded, largely manual processes, make it an ideal candidate for a step change (Kamara et al., 2000). The opportunities offered by existing and emerging computational tools provide the enablers that can deliver the required paradigm shift. Point solutions and sub-optimal deployment of discrete tools have only resulted in marginal improvements. A cyber-physical systems approach will enable a more holistic investigation of how the construction of buildings and civil infrastructure systems can be re-engineered to enable greater process control, improved predictability of outcomes, and more intelligent, sustainable facilities. Moreover,

successful implementation of a cyber-physical systems approach will allow rapid identification of potential construction problems, definition and evaluation of alternate solutions or "mid-course" corrections, ability to communicate effectively to the construction team, and quantitative risk assessment and mitigation.

4. Towards a Cyber-Physical Systems Approach

4.1 Overview

It has been suggested that the most appropriate path to the realization of cyber-physical systems in construction lies in the adoption of a 'system of systems' approach (Bulbul et al., 2009). Systems integration has been identified as one of key approaches to help the construction industry to improve productivity and efficiency (Shen et al., 2008). Research to date has identified wireless sensing and virtual prototyping technologies as having the capacity to enhance the construction delivery process: Building Information Models have the potential to enhance creation, sharing, exchanging and management of building information throughout the lifecycle of a project (Motammedi and Hammad, 2009). On the other hand, wireless sensors can collect data and store a wide range of real time information from physical systems. Several research projects have explored the use of bar codes, RFID and other tracking technologies (Jaselskis & El-Misalami, 2003; Domdouzis, 2007) to track the movement of materials and personnel on the construction site. Others have investigated the use of wireless sensors within the context of intelligent buildings, usually to monitor environmental issues such as indoor air quality, temperature and humidity control, and heating, lighting and ventilation (Clements-Croome, 2004). However, no studies have been undertaken on instrumenting both the construction process and the constructed facility in an integrated way such that the sensors and tags enable short term progress and quality monitoring during the construction work, as well as medium and longer term monitoring and active control of the performance of the facility. Shen et al. (2008) identified the need for an integrated approach to support decision making processes in construction sites for real time project management (including dynamic scheduling) and during the operation and maintenance of built facilities for intelligent real time facility management. Thus, this integration will enable construction engineers and facility managers to make the right decisions in a timely manner so as to improve productivity and efficiency.

4.2 Key Features of the Cyber-Physical Systems Approach

The integrated systems approach (see Figure 1) can be divided into three main features, each of which involves the sharing and exchange of information:

- *Development of a virtual model of the proposed facility*: The virtual model of the building facility needs to be developed such that information can be embedded in various components of the model. This information may include material properties, installation methods and all relevant data relevant to the construction process.
- *Mechanisms for tagging and tracking physical components and subassemblies such that their placement in the facility can be monitored*: This could be achieved through the use of wireless sensor networks and other instrumentation that can

record the fact of their placement as well as their relative position to other key components.

- *System Interaction between the virtual model and physical construction*: This involves integrating the Virtual model with the corresponding physical components such that changes in the construction can be automatically communicated and reflected in the virtual model. Changes to the virtual model should also be transmitted to the affected components as appropriate. It is critical in this regard to establish effective protocols for this bidirectional coordination. Wireless sensor networks can be used for this and may be supplemented by other instrumentation; IP cameras and laser scanning.

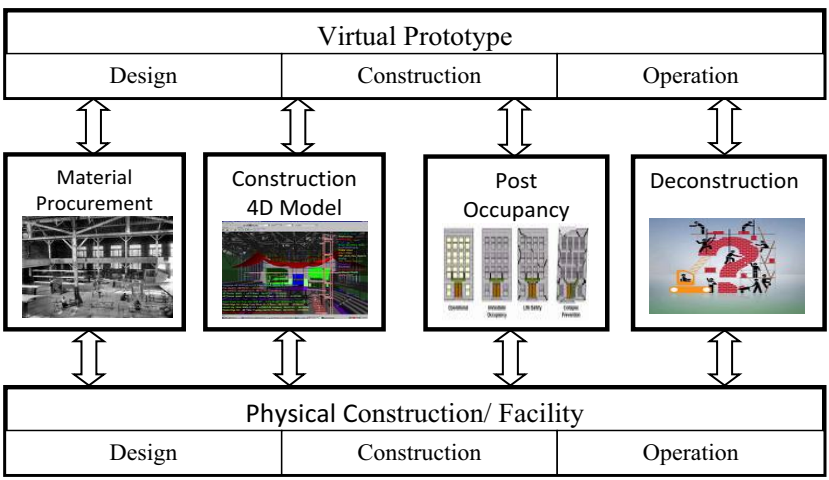

Figure 1: An Integrated Systems Approach

4.3 Potential Approach to Integration

A key aspect of the cyber-physical systems approach involves the development of an effective mechanism for facilitating real-time coordination between the virtual model and the physical construction, such that there is ongoing and evolving intelligence about the facility being built and the associated construction processes (Figure 2). The proposed approach will involve:

- Designing the positioning of the most appropriate sensor types and other instrumentation that will enable real-time data collection and aggregation;
- A plan for laboratory-scale experiments to explore bi-directional coordination between the virtual model and a small physical prototype. This will involve placing sensors on key physical components, tracking the status (placement, removal, construction sequence, etc.) of the components in the physical prototype and developing mechanisms for reflecting changes simultaneously in both the virtual model and the sensed data in the physical prototype.

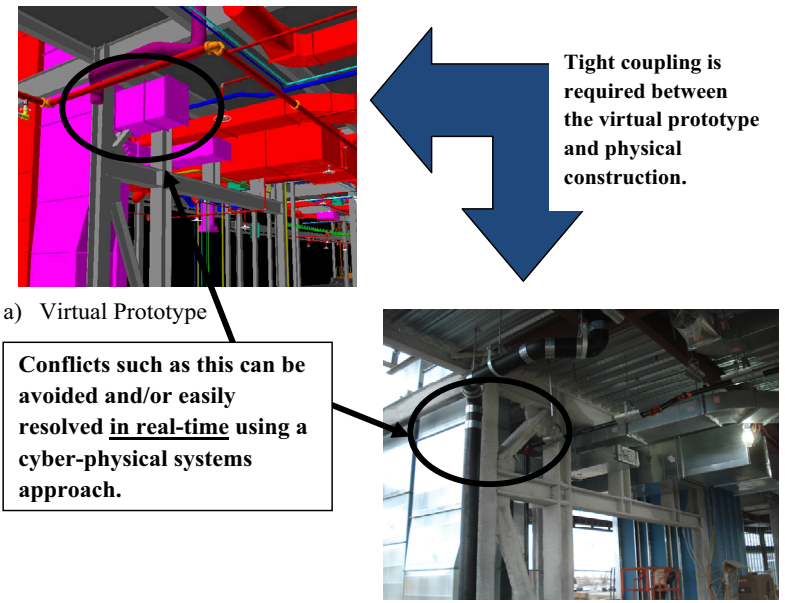

Figure 2: Tight Coupling between Virtual Model and Physical Prototype

- Exploring the most efficient data fusion algorithms for collecting and structuring the sensed data from the virtual model so that it can be used for a variety of short, medium and long term purposes – logistics, quality, safety/security monitoring. A key aspect of task is the formulation of effective rules for synchronization of the virtual and physical prototypes;
- Once effective laboratory scale systems have been proven, further validation will be undertaken on full-scale construction projects on the Penn State campus and elsewhere;
- Identification and resolution of any problems (e.g. interference) from the integrated use of different types of instrumentation on a physical construction;
- Formulation of guidelines for the adoption of cyber-physical systems approach for ensuring consistency and quality of the physical construction.

4.4 Potential benefits of Cyber-Physical Systems Approach

The integration of the virtual model of a facility and its physical construction will provide the following benefits:

- Enhanced computational support to project teams, particularly in their capacity to understand what is occurring at every stage of a project and make real-time interventions;
- Improved certainty and precision in the outcome of projects;

- Clearer understanding of project scope - this will enable better flow of instructions from the design team to the contractors and operators;
- Reduction of construction risks because the activities and processes on the construction site can be more closely monitored and controlled;
- Effective communication and coordination between the design and construction teams;
- Greater opportunities to optimize and meet the construction schedule, and achieve desired quality of work;
- Effective communication of progress information and representation of as-built and as-planned progress discrepancies are key components of successful project management and will allow corrective decisions to be made in a timely manner;
- Greater scope to embed intelligence in the construction process and to harness the potential of emerging computational tools to engender a step-change in the delivery of building and civil infrastructure projects;
- Improved safety on the construction site;
- Construction project team members can retrieve information from, and upload information to, the building information model for consistency checking;
- Access to real-time information about progress of work will reduce uncertainty during construction and thus greatly influence the project outcome and schedule.

5. Conclusions

This paper has proposed a cyber-physical systems approach to construction. This approach aims at integrating virtual models and the physical construction in such a way as to ensure bidirectional flow of information. This information can be used to control the construction activities, thereby reducing uncertainties that lead to unpredictable project outcomes. Building information models of a building facility can be developed and used to store information about the physical building components. Wireless sensors are attached to the physical component to allow the construction and operation teams capture data about materials to be utilized on the construction site and for project performance. The sensors are expected to remain within the facility during its lifecycle and can be used for inspection and maintenance purposes after the construction.

Abstract
With the proliferation of building information modeling (BIM) in architectural design, there will be a rapidly increasing need to create accurate as-built BIM data for existing buildings. Having an accurate as-built model of the existing structure allows owners to visualize and analyze proposed retrofit solutions and ensures that the retrofit meets the owner's requirements and provides the best value. The increased awareness of building energy consumption, green gas emissions, and LEED™ (Leadership in Energy and Environmental Design) also calls for new as-built documents based on BIM. This paper describes a approach for developing as-built BIM coupled with various data acquisition tools. Existing as-built technologies, such as 3D laser scanning, are reviewed and future uses for as-built BIM are suggested. The two case studies presented in this paper are part of an ongoing research project involving a local governmental agency building with significant renovation needs. The first describes a new method of acquiring building energy-related data: BIM paired with a sensor network. The second describes a method of creating as-built BIM using imported 2D plans. Finally, current challenges of as-built BIM technology are addressed to improve the future deployment of the proposed approach for as-built BIM.

Introduction

BIM is one of the most significant innovations in the architecture, engineering, and construction (AEC) and facility management (FM) industry. It has been recognized as a promising tool to become the vehicle of interoperability, integration, and collaboration. The major benefit of BIM is an intelligent, 3D, virtual building model that can be constructed digitally by containing all aspects of building information—

such as 3D geometries; costs; maintenance schedules; materials; structural data; and mechanical, electrical, and plumbing (MEP) systems—into an intelligent format. It can be used to develop optimized building solutions with reduced risk and increased value before committing to a design proposal.

One of the current challenges for the AEC industry is to increase the sustainability of existing buildings that have a significant impact on our natural environment, economy, health, and productivity. Many buildings are undergoing a major sustainability retrofit to reduce energy consumption and the carbon footprint. Commercial and residential buildings account for 72% of electricity consumption, 39% of energy use, and 38% of CO2 emissions (USGBC 2008). Reducing energy use in existing buildings is a high priority for local, state, and national governments. For commercial buildings in the United States of America, 36% of energy consumption is attributed to space heating, 21% for lighting, and 8% for cooling.

The problems cited above are being addressed with energy-efficient retrofit and the adoption of the sustainable guidelines, such as LEED and Green Globes™, by federal, state, and local authorities. There is also an obvious need, primarily driven by owners wanting to maximize the use of their existing buildings and assets, to confirm LEED or Green Globes standards to meet energy efficiency requirements. For example, one of the most famous buildings in the world, the Empire State Building, is undergoing an energy-efficient retrofit and will apply for LEED-EB Gold certification (Content 2009).

Two-dimensional as-built documents currently serve as a graphical communication platform for facility managers. However, that format lacks ability to deliver project data such as cost, specifications, schedules, warranties, or submittals. There is an emergent need for more comprehensive as-built BIMs that describe existing conditions such as existing energy consumption, indoor air quality, and water consumption, as well as solid and hazardous waste production.

Facility management processes, both before and after a retrofit, can be significantly improved through the use of an as-built BIM that can integrate energy-related data via sensors and associated data collection methods. As more information is accumulated in BIM, a higher level of design expertise can be contributed, as required, for sustainable design solutions. As-built BIM also can be used for studying various aspects of building performance.

Objectives

The purpose of this paper is to report the current industry practices regarding the use of as-built BIM and present case studies that demonstrates the process of linking various data sources with as-built BIM and creating as-built BIM using conventional 2D documents.

Developing As-Built BIM

3D Imaging and Laser Scanning

In a study of 3D laser scanning, Xiao, Zhan, and Pang (2007) point out that the use of terrestrial laser scanners for architectural surveying is a promising technique for producing 3D models for as-built documentation and research purposes. Three dimensional imaging and laser scanning technology was used for acquiring the 3D building spatial data which assisted the General Services Administration (GSA) in implementing historical documentation, facility condition assessment, construction as-built, and BIM projects (GSA 2009). The accuracy achieved through this process was well within the tolerances needed for subsequent repairs, maintenance, and/or renovation. A recent development employing the Trimble Total Station allows loading captured 3D spatial data directly into a BIM. The Trimble application can draw a realistic comparison between 3D models and real field situations (http://www.buildingsmartalliance.org/forum/topic.php?id=22). However, this may not be a cost effective solution due to the excessive cost of the equipment and the skilled labor required to operate the Trimble (Goedert and Meadati 2008). The GSA also notes that "important factors affecting the decision include project requirements, project schedule, and cost. For jobs involving simple geometries and readily accessible work sites, 3D imaging may not be the best choice."

Converting from 2D Drawings

The development of 2D as-built drawings through field survey is a time consuming process and, oftentimes, not accurate. BIM, supported by a centralized database, allows as-built models to be modified during construction to record geometrical variations in building components. However, upgrading to BIM from a 2D drafting system is more than simply making a change in CAD software. Rather, BIM is a completely different method of communicating building design information. To accommodate the transition, it is likely that there will be a significant enhancement of the import capabilities of BIM software (Eastman, et al. 2008). This will aid in creating an accurate as-built BIM without requiring 3D imaging.

As architectural designers and facility managers transition to BIM, the need to create as-built BIM for existing buildings is increasing rapidly. It is evident that architects will eliminate the use of 2D as-built once they fully implement BIM in the design phase. As facility managers realize the benefits of a BIM in their day-to-day work, they will want to create 3D models of existing facilities. During the transition, design firms that are quick to adopt BIM will still need to work with firms that are using 2D drafting, but they will want to be able to do the majority of their own work using BIM. Even though designers use BIM, they may be required to provide 2D contract documents to contractors due to the contractual relationships. These situations oftentimes require general contractors to recreate BIMs by tracing geometries from the 2D drawings provided (Bredesen 2009).

The Jackson, Mississippi, courthouse was used as a BIM pilot project by the GSA (Eastman, et al. 2008). The courthouse had an extended design phase, and the decision to switch to BIM was made in the middle of that process. Design began in 2002 using 2D CAD. The BIM pilot began in 2006; construction began in 2008. Because of the late implementation, a hybrid 2D- and 3D-BIM approach was used. The BIM was created from the existing 2D plans. Standard details from the 2D plans were used and several consultants continued to use 2D CAD. This project showed that it may be feasible to switch to a BIM-based design in the middle of the design process and that it is possible to integrate BIM and 2D CAD work. One of the uses of the 3D model for this project produced a virtual review of the proposed design of the courtrooms; building full mock-ups was not required. The authors of this case study expect "virtual review of spatial and environmental parameters to increase as virtual modeling becomes more prevalent."

The Camino Medical Group medical office building presents another case study that shows the coordination possible in implementing BIM while some designers are using 2D CAD (Eastman, et al. 2008). For this project, any team members using 2D design either had to convert their design to 3D or hire a consultant to do so. While this added some cost to the project, the reduction in the overall project duration paid off the initial investment.

The Sydney Opera House was recently presented in a case study showing BIM as a facility management tool. A group of designers created an as-built BIM of the Sydney Opera House using Bentley Architecture, Structure, and MEP (Cooperative Research Centre for Construction Innovation 2008). Due to the complexity of the surfaces, 3D laser scanning was employed to model the acoustic paneling in the auditorium. Using the digital model, Sydney Opera House was able to analyze design proposals and run various building simulations to compare improved solutions (Cooperative Research Centre for Construction Innovation 2008). This case study showed that accurate as-built BIMs can be created for complex structures. The Sydney Opera House BIM was useful for facility management and provided visualization for management of the infrastructure, assets, space, and furniture; tracking for scheduled and unscheduled maintenance activities; and lifecycle project information.

Future Uses for As-Built BIM

Existing Building Energy Simulations

Existing BIM programs, paired with simulation programs, are already capable of calculating energy consumption and predicting building performance for new buildings. However, this is not currently possible for the existing buildings with significant renovation needs due to complicated existing baseline conditions. Sylvester et al (2002) reported that simulation results are often comprised by uncertainty, statistics, and vague assumptions regarding the actual condition of existing buildings. This is unfortunate because there is a significant chance of misunderstanding that affects owner decisions on building energy performance.

One of the most significant opportunities offered by as-built BIM is the ability to collect real-time energy-related data. As-built BIM will be used as a central data repository and integrate diverse energy-related data sources such as utility bills, walk-in surveys, interviews, data loggers, and spot measurements. Dynamic (i.e., real-time) data related to energy performance will include energy and water consumption, temperature, CO2 emission, occupancy, and humidity. It also should be able to capture static data about the size and location of the HVAC equipment, building materials, geometries, and envelope performance (i.e., u-value of the windows). The system will also pass the data to various building energy simulation programs—eQuest, EnergyPlus, or IES <VE>—in order to achieve higher levels of energy savings. The capability to link BIM to various energy analysis programs will provide many opportunities to create more cost-effective retrofitting strategies from earlier design stages (Figure 1).

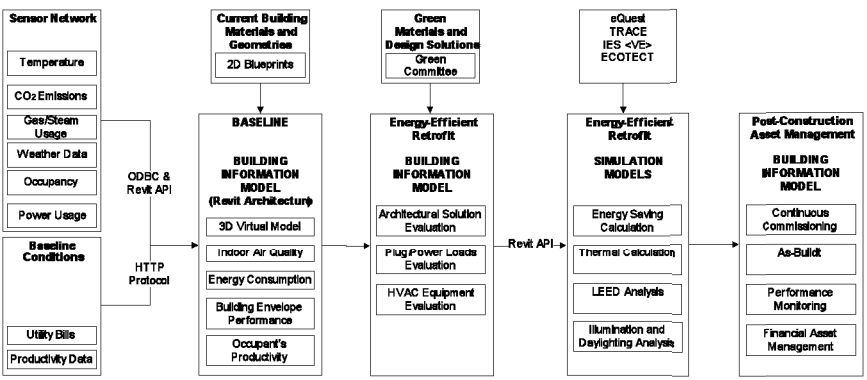

Figure 1: Central Database for BIM linked with Sensor Network

Facility Management for Existing Buildings

Over 40% of building owners currently outsource BIM implementation and 90% of those owners expect to continue or increase outsourcing to improve their facility management practices (Young et al 2008). Case studies such as the Sydney Opera House and Jackson courthouse show that an accurate as-built BIM can be useful for managing facilities and analyzing potential building projects. As tools that use BIM for facilities management expand, owners will be able to use an as-built BIM to maximize the use of their existing facilities, analyze retrofit solutions, and track maintenance. BIM can serve as a real-time monitoring system that continuously provides real-time energy data and actual operating conditions. These capabilities are not possible using traditional CAD tools. Traditional CAD tools require a separate energy analysis performed at the end of the design process, thus reducing the opportunities for modifications that could improve the building's energy performance. There is also a possibility of integrating with the existing building monitoring systems,

such as Metasys™ from Johnson Controls, Inc. Information related with commissioning, tenants, maintenance, or equipment warranty can be integrated with BIM through a building maintenance and asset management system such as Maximo™.

Historical Preservation

A case study by Penttilä et al (2007) reported using BIM for historical building renovation projects. They point out that the design phase of a BIM-based retrofit project should be started early to take full advantage of the expertise, resources, and possibility of optimizing design solutions from the beginning. They also predict the new concept of a BIM that acts as the container for all building inventory, survey, and measurement data. Historic buildings need more extensive surveys and accurate data collection about buildings considering retrofit.

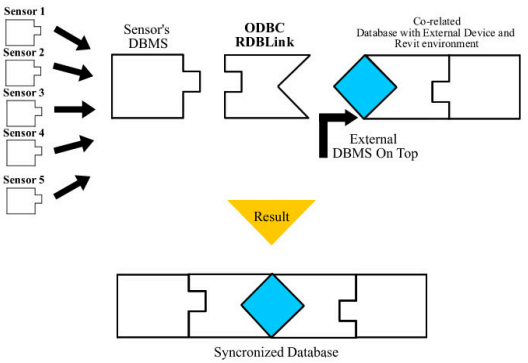
LEED-EB Analysis

The LEED for Existing Buildings (LEED-EB) rating system awards certification for buildings demonstrating enhanced environmental performance in energy consumption, green gas emissions, water consumption, and solid and hazardous waste management. LEED-EB provides a comprehensive guideline for implementing systematic sustainability programs for existing buildings.

As-Built BIM Case Studies

Case Study 1: Implementing Data Import/Export from BIM

This case study demonstrated how BIM can acquire building performance data from data collection tools such as sensors and other facility control modules. This study utilized a commercially-available BIM design tool, Revit Architecture™ from Autodesk, Inc. A sample building was virtually constructed in 3D platform. Then, the model was extended as a baseline database management system (DBMS) via RDBLink, an open database connectivity (ODBC) protocol which is provided in 2009 Revit application programming interface (API). RDBLink is capable of pushing a variety of property changes that are made in the DBMS back to their corresponding elements in Revit. In addition, the RDBLink application can create a new Revit Family based on added records in the DBMS. Figure 2 shows that ODBC links the external DBMS database and Revit's database system.



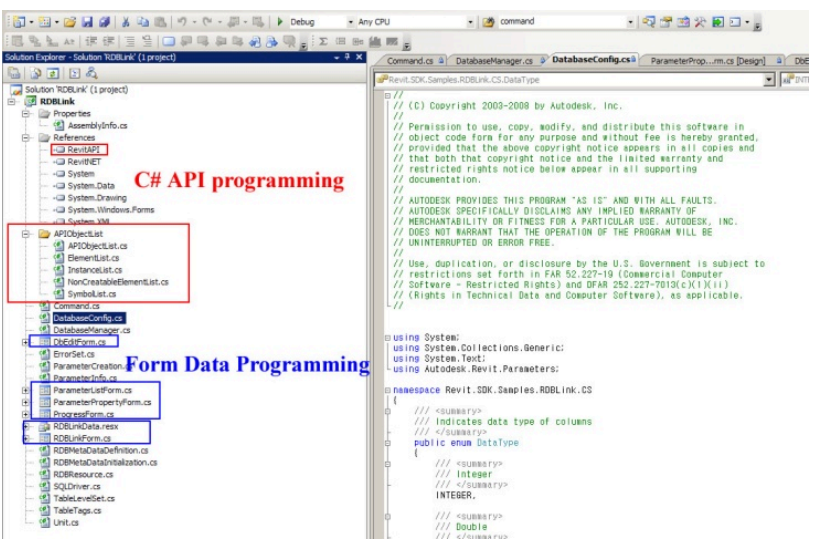


Figure 2: Synchronized Database using RDBLink

Necessary parameters for the energy-related analysis were manipulated in Revit and accessed directly from the DBMS. A prototype system was developed using .NET programming languages, including Visual Basic and C#. Visual Studio.NET was chosen as the development platform to establish the internet-based application via ODBC protocol (Figure 3).

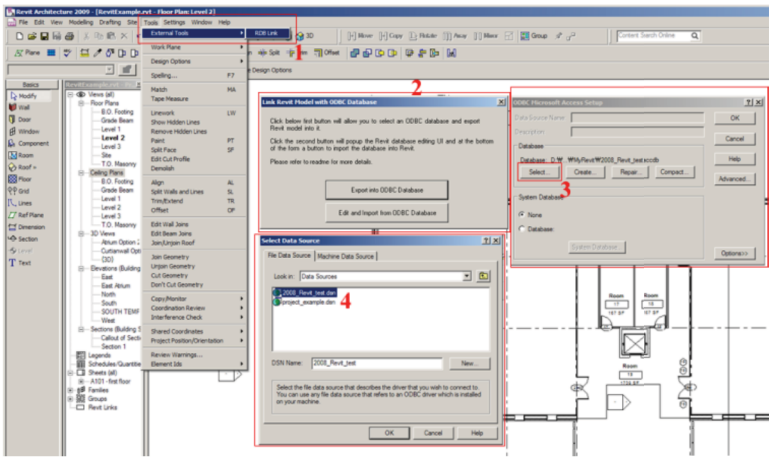

Figure 3: Visual Studio.Net Programming Environment

Case Study 2: Creating an As-Built BIM from 2D drawings

This case study demonstrated how the designers can develop an as-built BIM from 2D drawings. The building used for this case study was a medical office building in Arlington, Texas. The architectural and structural design for the project was done by Excel Engineering in Fond du Lac, Wisconsin. The project, completed in July, 2008, included construction of a new medical facility with physician office, laboratory, and support spaces.

When modeling the plan views of the building, the AutoCAD files were used as a direct reference in Revit. The 2D files were imported directly into Revit and used as a background for trace over. This process simulates the steps that would be required to create an as-built BIM of a building when the original CAD drawings are available. For this study, only the architectural and structural components of the building were included in the model. Currently, these are the two most likely parts of a building to be modeled using BIM according to the BIM SmartMarket Report (Young et al. 2008). The software used to create the BIM for this study was Revit Architecture and Structure.

The import allowed the Pick Lines feature to be used to place walls in Revit and ensured accurate placement while creating the architectural components of the model. Having the imported files as a reference was especially useful when creating the structural framing plans. Including the reference directly in the drawing allowed the beams and joists to be placed quickly and accurately. A portable document format (PDF) version of the site plan was also copied into the model and scaled up to create an approximate model of the site for visualization purposes. The architectural components of the model were created first. The first step created the building shell

and a rough out of the interior. Gridlines were the first elements placed in the model. The required level heights were also set prior to making the model. This helped to ensure dimensional accuracy as the model was created. Before beginning to create the model in place, customized wall assemblies were created in Revit. Then, the building enclosure was modeled.

After completing the majority of the architectural model, the structural modeling was begun. The first step added the foundation walls and footings and placed the columns. Next the framing was added for the second floor and roof. One of the most time consuming parts of the process was ensuring that all the roof framing elements had the proper sloping. Once those were correct, the columns were adjusted to show the correct beam-column connections. Then, the roof was added. This was done last so it could match the roof framing that was already modeled. The final step in modeling was to create the detail components of the exterior of the building. Families were made for the fascia on the clerestory roof and the coping for the walls. The entry canopy and cables were modeled using masses in Revit. Once the building model was complete, a basic copy of the site was added for visualization purposes. Once the model was completed, the final step was to validate the accuracy of the model. This was first done by dimensioning the model and confirming that the model dimensions matched the original plan. Sections of the model were compared to the sections provided in the original plans (Figure 4).

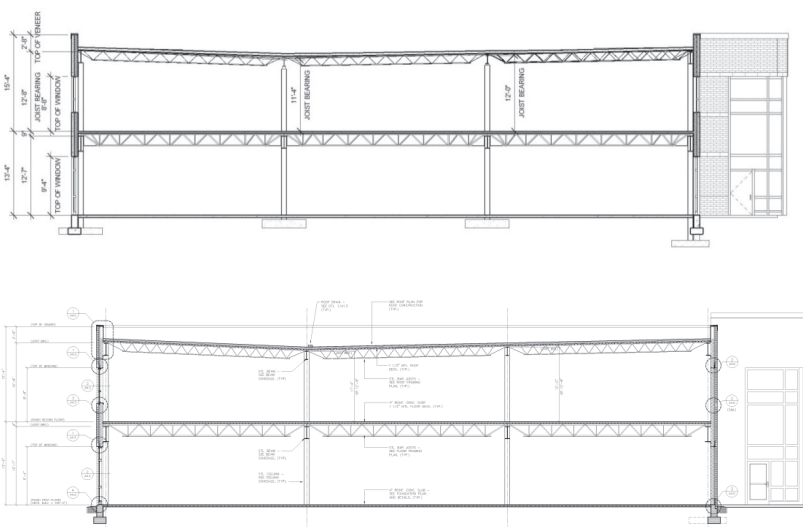

Figure 4: 2D CAD and BIM Sections

Conclusion

Two case studies discussed in this paper were part of an ongoing research project involving a local governmental agency building with significant renovation needs. The next development of the project will include capturing existing building conditions using 3D laser scanning. The approach discussed in this paper serves as an initial step toward implementing as-built BIM for energy-efficient retrofit projects. The as-built BIMs developed in these case studies identify a number of advantages, including linking capabilities with .NET programming environments, enhanced interoperability, web-enabled communication, and accurate and fast model construction. The most challenging part of creating as-built BIM is accurately creating the detail-oriented building components (decorative column crowns and the like) in the architectural model. This was the most time consuming job and had no clear relevance on building energy performance. Most of the building components needed to be created accurately to confirm the future use of the model for building energy analysis. The author noted several important standards required to successfully merge the 2D and 3D BIM efforts. These included using a common naming system, automatic user input, a common reference point, and compatible file formats. There are still many enhancements that can be made to BIM software. Further research will be undertaken to validate the proposed approach to develop as-built BIM for building monitoring and maintenance.

Abstract:

This paper discusses the application of photogrammetric methods to monitor ground movements during trenchless construction projects. Ground movements are a concern as they can cause damage to buried utilities and surface structures. Photogrammetry is a remote sensing technique in which the geometric properties of objects and surfaces can be determined from photographic images. This technique allows for accurate three-dimensional measurements of specific points on the ground surface. Measurements are determined utilizing two or more photographs taken from different positions at specific time intervals. Photographs from specific time intervals are complied using photogrammetry software to determine the position of surface points in three-dimensional space. This paper provides an overview of the photogrammetric method, its application to trenchless projects, and results and analysis of data gathered from calibration and repeatability of measurement studies.

INTRODUCTION

Ground movements associated with trenchless construction operations can cause significant damage to existing buried and surface infrastructure. This may be the result of soil displacement, slurry or drilling fluid pressurization, over excavation, or settlement. The type of ground movement that occurs is related to the trenchless method utilized, soil conditions, and the contractor's methodology or actions during the construction operation (Bennett and Ariaratnam 2008). Subsurface soil movements may damage buried utilities, foundations, structures, and depending on the depth of cover, may manifest in surface movements. Surface movements, either

settlement or heave, can damage pavements, sidewalks, and on grade foundations (Lueke and Ariaratnam 2005).

The advantages of trenchless construction are numerous, and have resulted in rapid adoption of these techniques by municipalities and contractors over the past decade, especially for urban utility installation, rehabilitation and renovation. It is in this urban setting that ground movements are especially critical as there are frequently other utilities and infrastructure in the vicinity of a trenchless project. While some types and magnitude of ground movement may be expected with an operation or particular project, it is frequently the unexpected movement events that cause the most concern for utility owners and municipalities. Often these unexpected ground movements can cause catastrophic failures resulting in severe economic and social consequences. Figure 1 illustrates surface heave from a horizontal directional drilling operation that resulted in lifting of an electrical transformer box. As a result of such incidents, some municipalities are now requiring surface ground profile monitoring above trenchless projects as specified in construction contracts.

Figure 1. Heaving of an Electrical Transformer Box

Measurement of surface movements on a construction site has historically been conducted by conventional survey with rod and level, or total station units. Today this may also be accomplished by global positioning systems for topographic survey. They require direct access to the points to be surveyed, do not allow for simultaneous measurements of multiple points at a specific time interval, and require trained personnel to gather measurements and interpret the results. In some cases, it is not possible to access the points being surveyed or stop the construction process to obtain measurements to record a specific time interval or ground movement event.

This research focuses on the measurement and monitoring of surface ground movements utilizing photogrammetry to provide quality control on trenchless construction projects. A framework for applying this method to an installation of a 1,377 mm (54 inch) steel casing beneath a busy urban street and rail crossing is presented, along with a study to determine the repeatability of the measurement process. Compared to conventional survey techniques, photogrammetry does not require physical access to the surface or targets being monitored, but rather only requires pictures of the site using off-the-shelf cameras that can be taken by anyone familiar with the operation of a digital camera; and can provide measurements at a higher accuracy than conventional survey techniques.

OVERVIEW OF PHOTOGRAMMETRY

Photogrammetry is a remote sensing technique in which the geometric properties of objects and surfaces can be determined from photographic images (Mikhail et al. 2001). It essentially allows measurements to be made from photographs. The method used in this research is more appropriately termed stereophotogrammetry, and it is capable of estimating the location of points on objects and surfaces in three dimensions through analysis of two or more photos taken from different positions of the target area.

The photogrammetric process is based on line of sight and analysis of the geometry of the scene or subject. Utilizing a series or set of photos of the subject area, common points of interest, or targets, are identified in each photograph. A line of sight, or ray, is created between each target and the camera for each photograph. Though the triangulation of these rays for each unique target from each photograph, one can solve for the position of the camera and points relative to each other in three-dimensional space. With knowing at least one dimension in the subject scene, typically the distance between two targets, the solution can be scaled. The solution creates a virtual model of the scene, that allows for accurate measurements to be made of the position of each target.

APPLICATION OF PHOTOGRAMMETRY

This research utilized a software package called PhotoModeler developed by EOS Systems Inc. to conduct the photogrammetric analysis. PhotoModeler photogrammetry software provides image-based modeling, for accurate measurement and three-dimensional models for a variety of applications and industry sectors including accident reconstruction, archaeology and anthropology, architecture and preservation, forensics, and plant and mechanical engineering. This software is commercially available and requires minimal training to utilize.

This research utilized a Canon EOS Rebel XSi digital SLR camera with a 12.2-megapixel CMOS Sensor, equipped with an EF-S 18-55mm f/3.5-5.6 IS lens. In

order for the photogrammetry algorithm to solve for the position of the camera and target points, the cameras utilized in the taking of the pictures must be calibrated. More precisely, the geometry of the camera lens must be determined. In order to do this, PhotoModeler has a camera calibration module.

To calibrate the camera a series of twelve pictures are taken of a calibration grid. Within the grid are four uniquely coded targets near the corners of pattern that can be identified by the software. These four coded targets allow the software to automatically orient the pictures to each other. Four pictures are taken of the calibration grid with the camera in landscape position, four more with the camera rotated 90 degrees (portrait), and the final four with the camera rotated another 180 degrees (inverse portrait). Each set of four pictures is taken at 90 degrees to each other and perpendicular to the sides of the square pattern formed by the calibration grid. Photomodeler analyzes these 12 pictures to determine the parameters of the camera and lens. This is a vital process, as these parameters form the basis for the solution by triangulation.

During the calibration process – as when the cameras are utilized in the field – all parameters on the camera must be kept constant. This includes zoom setting and focal length. Thus for a particular application the calibration process should be taken under similar conditions as one would expect in the field. As a result, the cameras used in this research were calibrated at both an 18 and 55 mm focal length. In the field this allows for both telephoto and wide-angle pictures to be taken depending on what access is available to the photographer on site.

MONITORING OF AN AUGERED CROSSING

An augured crossing in the City of Glendale, AZ was selected as the inaugural project to monitor ground movements utilizing the photogrammetric measurement process. The project required the installation of a 1,372 mm (54 inch) steel casing pipe beneath Grand Avenue, a rail line, and a block wall fence (Figure 2). The installation is approximately 125 m in length, and designed with approximately 5 m of cover beneath the Grand Avenue and 7 m of cover beneath the rail line. The city and rail road company are very concerned with any ground movements that may occur during the installation process, and have outlined specific means to monitor ground movements as part of the construction contract. In the construction specifications for this project, the City requires the contractor to install settlement points consisting of a 150 mm diameter concrete pile to a depth of 1,200 mm into which a leveling hub is set. Elevations of the hub are taken at regular time intervals to monitor the settlement or have that may occur.

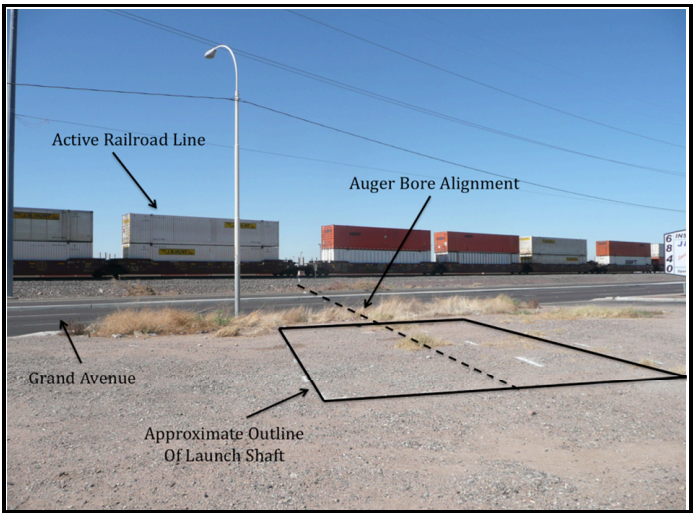

Figure 2. Layout of Augured Crossing in Glendale, AZ

To meet the contract specifications, the contractor proposed utilizing photogrammetry to monitor the ground surface for settlement or heave in three locations above the centerline of the installation. These locations are in the median of Grand Ave, and on either side of the railroad berm outside the zone of the track ballast. By monitoring the ground surface on either side of the rail line with the shallower depth of cover, it is anticipated that the contractor will get advanced warning of potential ground movement that may affect the rail line and then adjust their installation practices accordingly. While the City of Glendale found the concept of utilizing photogrammetry to monitor the installation intriguing, they wanted to maintain their existing monitoring specifications utilizing conventional rod and level techniques. This provided an opportunity to directly compare the photogrammetric method of monitoring ground movements to that of the more traditional surveying techniques.

To monitor the ground movements above the crossing, two rows of targets (10 in each row) will be installed perpendicular to the centerline of the installation, covering a total width of 2.74 m (9 ft). Targets will be spaced 30.48 cm (12 inches) apart. The proposed layout of the targets is illustrated in Figure 3. In this configuration, the settlement trough or surface heave profile can be measured and monitored during the course of the installation. Simply by taking a set of four pictures of the target area, the Photomodeler software can process the set and determine the position of each target in three dimensions. By including a control point (point that will not move during the installation process) as part of the targets, the relative movement of targets to one another can be monitored and determined with each consecutive set of pictures taken. Picture sets can be taken as required, and target positions determined within minutes. Using this methodology, and an off-the-shelf digital camera, ground

movements can be monitored on any project without the need for conventional survey equipment or crews.

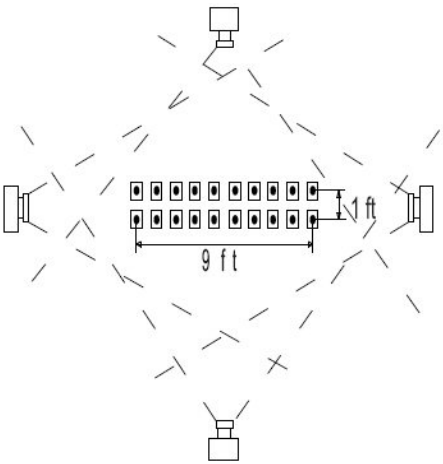

Figure 3. Target Layout for Augured Crossing Monitoring

REPEATABILITY OF MEASUREMENTS

In preparation to measure the augured crossing, a full-scale field test was setup in the same configuration as outlined in Figure 3, in a parking lot at Arizona State University. A total of ten picture sets were taken, half with an 18 mm focal length and half with a 55 mm focal length lens setting. The purpose of using two different focal lengths was to determine the accuracy of measurements at different distances to the monitoring targets. The 18 mm focal length (wide angle) allowed for the camera to be much closer to the targets, while the 55 mm focal length (telephoto) allowed the camera to be a much greater distance away from the targets, while in both cases still recording all targets in the picture frame. It is hypothesized in some applications, and during some operations on site, that having the camera in close proximity to the targets may not always be possible – thus the telephoto pictures would be necessary.

As illustrated in Figure 3, each set of photos consisted of four pictures taken at various locations around the targets. Each photo taken had to be composed in such a manner as to capture all targets within the photo frame. The optimal configuration of photos in a set are each being about 90 degrees to the target stations. However, in each set taken to determine the repeatability of the measurements the position of the cameras were randomly determined, with varying angles separating the line of site for each photo. This was done again to test the process in situations where optimal camera positions on a construction site could not be achieved.

Table 1 and 2 summarize the results of the measurement study for cameras set at 18 and 55 mm focal lengths, respectively. In each table, the average measurement of each target was provided. This is the average of five measurements or photo set analysis. The standard deviation and the average variance, the difference from the measured point to the average, are calculated. In all instances, this variance is within one standard deviation from the average indicating a good statistical correlation. These preliminary results indicate that the measurement process using photogrammetry and PhotoModeler software provides repeatable measurements.

In reviewing the average variance, or tightness of the measurements, it can be seen that for the 55 mm focal length pictures the average difference is about 3.0 mm in the X, 0.4 mm in the Y, and 0.2 mm in the Z axis; while for the 18 mm focal length the average is about 6.0 mm in the X, 1.0 mm in the Y, and 1.0 mm in the Z axis. As expected, the 18 mm focal length produced results that were not quite as good as the 55 mm focal length due to the resolution of the photographs taken. The 18 mm has a wider field of view; therefore each pixel in the photo covers a wider area making identification of the center of the target slightly more imprecise.

In a point-to-point comparison of the difference between the modeled location of the targets between the 18 and 55 mm focal length models. In general, the difference between the modeled points is less than 1.6 mm – this is the average difference between each of the 5 sets of photos taken.

Table 1. Statistics for Repeatability Measurements at 18 mm Focal Length

	Average Measurement			Stdev			Ave Variance		
Pt ID	X (cm)	Y (cm)	Z (cm)	X (cm)	Y (cm)	Z (cm)	X (cm)	Y (cm)	Z (cm)

CONCLUSIONS

Based on these preliminary results, it would appear that utilizing photogrammetry to monitor ground movements on a scale suitable for a large diameter augured crossing is feasible. The quality and repeatability of these initial results prove the feasibility of this technique, and its accuracy will be confirmed in the near future when compared to conventional survey techniques on the City of Glendale, AZ project.

The benefits of using photogrammetric techniques for the monitoring of trenchless projects include: the speed of measurement and analysis; not having to directly access the monitoring area to measure the targets while the project is underway; and the ability to use off-the-shelf consumer grade digital cameras and software with minimal training. While the accuracy of the system still needs to be confirmed, the repeatability of measurements, and the comparison the simulated field measurements are favorable.

These techniques can be applied to various trenchless construction methods where monitoring of the ground surface for movements as part of a quality control process is required. This analysis focuses on a large diameter installation, with a large potential area of influence estimated to be approximately 2.74 m in width. It is anticipated that this technique will be applicable to horizontal directional drilling, pipe bursting, pipe ramming, impact mole, tunneling, microtunneling, and guided boring methods of

construction. The authors are planning additional field monitoring projects for the various trenchless methods.

Abstract

Bridge condition rating is used to make important decisions regarding needs assessment and budget allocation. This study analyzes the use of the fuzzy logic approach to overcome uncertainty problems associated with the bridge condition assessment process. The analysis reveals a number of practical difficulties associated with the application of the fuzzy mathematics to develop an overall bridge condition rating. An alternative probabilistic methodology to rate the bridge elements taking into account the uncertainty issue is developed. The Analytic Hierarchy Process is adopted to evaluate the structural importance of the various bridge elements. A technique is proposed to aggregate the condition rating and the structural importance of the bridge elements into an overall bridge condition rating. The developed methodology uses the detailed visual inspection results to perform bridge condition rating and blends perfectly with the popular Markov chain approach to model deterioration.

Keywords: Bridge, concrete, inspection, condition assessment, Monte Carlo, fuzzy, probabilistic.

Introduction

It has been evident that highway agencies have to deal with an increasing number of deficient bridges which require intervention in the years to come. Maintenance, repair and replacement (MR&R) of deteriorating bridges are among the most expensive items for these agencies. Such a high cost commitment needs rationale justification through a systematic method to assess the current condition and forecasting future

condition of existing bridges. In doing so, current conditions are defined using a condition assessment methodology while future conditions are predicted using a deterioration model. It is essential for the condition assessment and the deterioration model to be consistent in defining conditions of bridge structures for yielding reliable condition assessment.

Sasmal et al. (2006) reported that the existing literature contains extensive studies to develop condition assessment methodologies for existing bridge structures. However, these methodologies are either too simplistic (Qian 1992; Liang et al. 2001) or very complex (Kawamura and Miyamoto 2003). The simplistic methodologies do not reflect the accurate condition of the structures and the complex methodologies require considerable computation time and effort to solve the problem. Sasmal et al. (2006) developed a fuzzy based condition rating methodology for existing concrete bridges using membership functions for structural importance reported by (Melhem and Aturaliya 1996). These membership functions were originally constructed through a survey of a number of bridge engineers and inspectors in Indiana and its neighboring states (Tee et al. 1988).

The membership functions developed by (Tee et al. 1988) for the bridge elements structural importance were constructed to be general and were not bridge specific. This generalization is not supported by the stochastic nature of the deterioration process since several factors control the behaviour of the deteriorated bridge elements. Each bridge is a unique case and should be analyzed through inspection to define the structural importance of its various elements. In this research, the Analytic Hierarchy Process is proposed to evaluate the structural importance factors of the various bridge elements. The process is applied to each bridge individually to develop the structural importance factors specific to the bridge under consideration.

Fuzzy Logic for Bridge Condition Assessment

Fuzzy logic was introduced to model uncertainty of natural language by Zadeh (1965) where a logic was developed to handle the definition of partial truth which is the true value between completely true and completely false. The concept of fuzzy set is an extension of the conventional set theory. A fuzzy set, R, is defined as a set of pairs (t, $\mu R(t)$), where t is an object or an element in the universe of discourse, and $\mu R(t)$ is the degree of membership associated with the element t. If t is a continuous variable, the degree of membership can be defined by a membership function.

Tee et al. (1988) proposed a fuzzy mathematical approach to account for subjectivity, imprecision and personal bias associated with bridge inspection and condition rating process. They presented algorithms for fuzzy weighted average (FWA) computation and since then many of the proposed methodologies to perform bridge condition rating have adopted this approach (Sasmal et al. 2006, Yadav and Barai 2004).
A weighted average technique is normally used to combine pieces of information with unequal weights. The FWA extends the traditional weighted average technique by applying it on fuzzy quantities. The FWA is given by the following equation.

$$FWA = \frac{\sum_{i}^{n} W_i R_i}{\sum_{i}^{n} W_i}$$

where W_i denotes the fuzzy importance factor of the i^{th} element and R_i denotes the fuzzy condition ratting of the same element. Fuzzy addition, fuzzy multiplication, and fuzzy division, proposed by the extension principle (Zadeh 1965), are used to perform the mathematical operations and the resultant average is the FWA.

The FWA computation algorithm for bridge condition consists of the following steps:
1) Develop the membership functions for both the element condition rating and the structural importance of the various elements. The membership function for the element condition rating is a mathematical representation of the natural language rating expressions used by inspectors such as Good, Fair or Poor.

2) Translate the inspector rating variables and the structural importance of the various bridge elements to fuzzy sets by using membership functions developed in step 1.

3) Combine the fuzzy condition ratings and their structural importance using Equation 3 to obtain a fuzzy set representing the entire system.

4) Map the resultant fuzzy set obtained in the previous step to one of the natural language rating expressions. The bridge overall natural language rating is the variable that has the shortest distance from the resultant fuzzy set.
The initial effort of this research targeted the use of the FWA approach to develop a bridge condition rating methodology. However, while analyzing the approach, a number of practical difficulties have been encountered. These difficulties can affect the robustness and reliability of any condition assessment methodology that uses the FWA approach.

The major drawback of using FWA approach is that the resultant fuzzy set might not be convex. The convexity indicates that the membership function has only one distinct peak. Enforcing convexity facilitates the task of finding a natural language expression to describe a computed fuzzy set. As a result, an adjustment has to be made to the resultant fuzzy set to achieve its convexity by replacing multiple peaks with a single peak. Another adjustment that is often made to the resultant fuzzy set is the normalization. The normalization ensures that at least one element in the set has a degree of membership equal to one.

There is no apparent mathematical rationale supporting the use of convexity and normalization operations on the fuzzy set (Tee et al., 1988). However, empirical tests have shown that enforcing convexity and normalization produced a more reliable and accurate final translated results (Mullarky and Fenves 1985).

There are no standard guidelines or procedures to enforce these two constraints and the process is left for judgment. This might not be suitable for atomizing the condition rating process for a network of large number of bridges.

One more problem associated with the FWA technique is the final mapping between the resultant fuzzy set and the rating variables. The shortest distance approach is normally used to map the resultant fuzzy set of the entire system back to a rating variable. The natural language with a membership function that has the shortest distance from the resultant fuzzy set is the one used for the overall bridge condition rating. This approach does not take into account how much shorter the distance between one rating variable and another. In certain cases, the distances between the fuzzy set and the membership function of two rating variables are the same or close to each other. It is not clear in such cases as to which rating variable will be used in order to rate the bridge conditions.

Alternatively, probabilistic analysis using the Monte Carlo simulation technique would be favorable in avoiding these issues. The following section discusses applying probabilistic analysis to develop bridge element condition rating.

Stochastic Bridge Condition Rating Using Simulation

An effective way to deal with uncertainties is through simulation which can provide more accurate estimates using a large number of "what if" scenarios. The Monte Carlo simulation is a stochastic technique that randomly generates values for uncertain variables over and over to simulate a model. This technique can be used to evaluate a bridge element condition index (*BECI)*. The index is estimated using the following equation:

$$BECI = (\text{current element value}/\text{initial element value}) \times 100$$

A range is defined to represent the remaining element value in Excellent, Good, Fair and Poor condition states and a probability distribution can be assigned for each range to represent the variable frequency. For each iteration, the simulation selects random values from the defined ranges and calculates the *BECI*. After running several iterations, the simulation will develop the distribution for the *BECI*. Pessimistic, optimistic, and most likely remaining element values for each condition state are defined in Table 1. Triangular probability distributions are used to define the distribution of each variable within each interval.

Table 1: Remaining value of the bridge deck at the four condition states

Condition State	Pessimistic	Most likely	Optimistic
Excellent	0.81	0.90	0.95
Good	0.576	0.70	0.80
Fair	0.31	0.45	0.575
Poor	0.075	0.15	0.30

Kawamura et al. (2003) identified values of a condition index to represent the different condition states. Similar values of the condition index are used to represent Poor, Fair, Good and Excellent, respectively as presented in Table 2.

Table 2: Values of condition index for the four condition states

Condition State	Condition Index
Excellent	87.6–100
Good	62.6–87.5
Fair	37.6–62.5
Poor	0-37.5

Crystal Ball software is used to run Monte Carlo simulation and to identify the probability associated with each condition state. Many simulations can be run to evaluate the *BECI*. Each simulation uses random values from the range of values defined in Table 1 for each condition state. The purpose of each simulation is to evaluate the *BECI*. The frequencies of having the *BECI* in the range of Excellent, Good, Fair and Poor condition states are estimated. For example, if the simulation runs for 1000 iterations and for 700 iterations the *BECI* is estimated to be between 62.6 and 87.5, then the probability of the element to be in Good condition state is 70 %.

An example to demonstrate the concept is presented in Table 3. The bridge element condition index is estimated using Monte Carlo simulation. Five thousand iterations were performed to evaluate the probability associated with each condition state. The result of the simulation is shown in Figure 1. The $BECI_{Deck}$ ranges from 57.92 to 71.52 with a mean value equal to 64.65.

Table 3: Bridge elements inspection results

Element	**Total Quantity (m^2)**	**Excellent (m^2)**	**Good (m^2)**	**Fair (m^2)**	**Poor (m^2)**
Deck	1000	500	100	200	200
Beams				300	300
Abutments	100		50	50	
Piers	100		50	50	
Barrier	200		120	80	

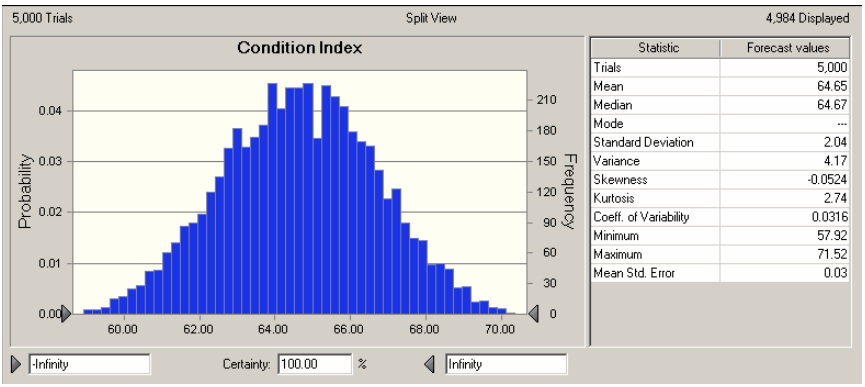

Figure 1: Simulation result for the *BECI*

The probability of the bridge deck to be in a Fair condition state with a BDCI ranges between 37.6 to 62.50 is 15.01% and the probability of the bridge deck to be in Good condition state with BDCI ranges between 62.50 to 87.50 is 84.99% as shown in Figure 2. The final condition vector which holds the probability of the bridge deck to be in Poor, Fair, Good and Excellent condition, respectively, is as follows: [0 15.01% 84.99% 0].

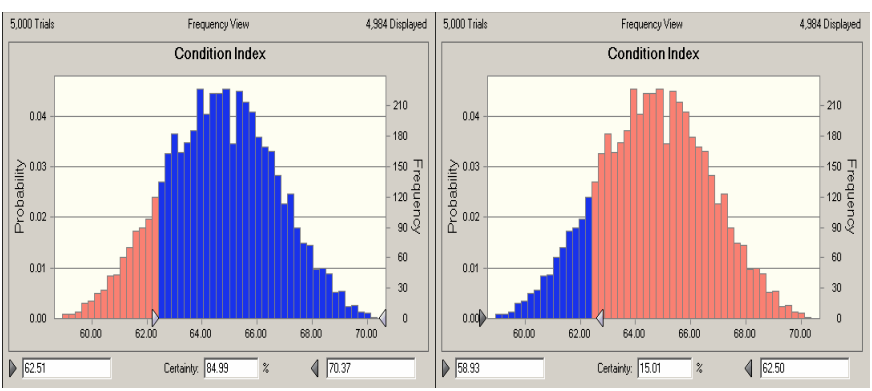

Figure 2: Probability of $BECI_{Deck}$ to be in Good and Fair condition states

Following the methodology presented above, the condition vector for the different bridge elements can be developed. The condition vectors for the bridge elements are presented in Table 4.

Table 4: Bridge elements condition vector

Element	Condition Vector [Poor Fair Good Excellent]
Deck	[0% 15.01% 84.99% 0%]
Beams	[96.77% 3.23% 0% 0%]
Abutments	[0% 94.49% 5.51% 0%]
Piers	[0% 94.49% 5.51% 0%]
Barrier	[0% 80.75% 19.25% 0%]

Structural Importance Factors for Bridge Elements

There is no precise definition of the structural importance of the different bridge elements in literature. Tee et al. (1988) referred to the structural importance as the structural role of the element. This research defines the structural importance of bridge element as the degree the element contributes to the overall structural integrity and safety of the bridge.

The Analytic Hierarchy Process (AHP) is used to extract the expert judgment and to evaluate the structural importance of the different bridge elements. The AHP is a general theory of measurements developed by Thomas Saaty (1980). Two fundamental steps are required to use the AHP methodology. First step is the task of simplifying the problem where the complex system is broken into a hierarchy structure. Second step is the task of performing pairwise comparisons to measure the relative impact of different elements in the hierarchy and to establish relations within the structure. A fundamental scale of absolute values for representing the strength of judgments has been developed and validated (Saaty 1980). In this approach the decision maker expresses his/her opinion about the value of one single pairwise comparison at a time. Usually, the decision maker has to choose an answer among discrete choices. Table 5 presents the scale of relative importance.

Table 5: Scale of relative importance

Intensity of Importance	Definition	Explanation
1	Equal importance	Two activities contribute equally to the objective
3	Weak importance of one over another	Experience and judgment slightly favor one activity over another
5	Essential or strong importance	Experience and judgment strongly favor one activity over another
7	Demonstrated importance	An activity is strongly favored and its dominance demonstrated in practice
9	Absolute importance	The evidence favoring one activity over another is of the highest possible order of affirmation
2,4,6,8	Intermediate values between the two adjacent judgments	When compromise is needed

For the purpose of evaluating the structural importance of the bridge elements, a two level hierarchy structure is developed as presented in Figure 3. The bridge inspector and expert are required to compare each two elements with respect to the overall bridge structural criticality and to specify the intensity of the relative importance. If an element jeopardize the bridge safety and integrity while another one has limited effect on safety and integrity then the first one has absolute importance over the second one. The bridge elements are compared in pairs and the intensities of the relative importance are specified.

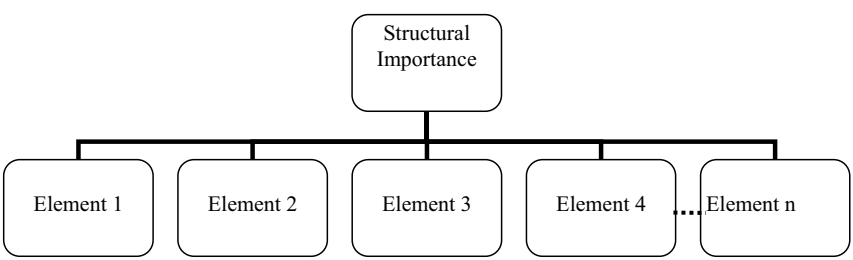

Figure 3: Hierarch structure for the elements' structural importance

Defects and extent of distress of the various elements determine their structural importance. The detailed visual inspection should capture these defects and evaluate the extent of distress of the various elements. The effect of these defects and distress on the structural performance of the elements should be analyzed and included in the judgment.

The results of the pairwise comparison are laid in a reciprocal matrix of comparison as shown in Table 6. In this matrix, a_{ij} is the relative structural importance of element i with respect to j. This matrix is reciprocal once it satisfies the following two conditions: $a_{ij} = 1/a_{ji}$ and $a_{ii} = 1$ for all i and j.

Table 6: Pairwise comparison for elements structural importance

	Element 1	Element 2	Element 3	Element 4	……	Element n	Structural Importance
Element 1	1	a_{12}	a_{13}	a_{14}	……	a_{1n}	S_1
Element 2	a_{21}	1	a_{23}	a_{24}	……	a_{2n}	S_2
Element 3	a_{31}	a_{32}	1	a_{34}	……	a_{3n}	S_3
Element 4	a_{41}	a_{42}	a_{43}	1	……	a_{4n}	S_4
.	.	.	.	.	.	.	.
.	.	.	.	.	.	.	.
Element n	a_{n1}	a_{n2}	a_{n3}	a_{n4}	…	1	S_n

The structural importance of the various elements is developed as a vector of priorities which is a normalized eigenvector and estimated in two steps. First is to normalize the developed matrix of comparison by computing the sum of each column, and then dividing each element in each column by the sum of that column. Second is to compute the average of each row which represents the priority weight of the corresponding element. First row corresponds to the first element and second row corresponds to the second element and so on. The structural importance factors are presented in Table 7.

Table 7: Pairwise comparison of elements structural importance

	Deck	Beams	Abutments	Piers	Barrier	Structural Importance
Deck	1	1/7	1	3	2	0.127
Beams	7	1	7	9	7	0.630
Abutments	1	1/7	1	3	1	0.110
Piers	1/3	1/9	1/3	1	1	0.056
Barrier	1/2	1/7	1	1	1	0.076

An important feature of the AHP methodology is the ability to check for consistency in judgments. Abu Dabous et al. 2007 presents the details of the consistency check in the AHP.

Summary and Conclusions

The fuzzy logic approach to rate bridge conditions was evaluated and its practical difficulties were discussed. Alternatively, a probabilistic methodology to perform

bridge condition rating was developed. Element level bridge condition index based on the remaining value of the deteriorating quantities was also developed. The Monte Carlo simulation technique was used to evaluate the probabilities of the bridge deck being in one of the four condition states namely, Excellent, Good, Fair and Poor. The AHP was adopted to evaluate the structural importance of the bridge elements. A technique to aggregate the condition ratings and the structural importance of the bridge elements into an overall bridge condition rating was proposed. The proposed methodology evaluates the structural importance of the bridge elements in a robust manner. Once the methodology is implemented, it enables the decision maker to retrieve bridges or elements that require intervention from a bridge network.

ABSTRACT:

This paper presents a comprehensive data analysis of recent highway construction zone crashes in the state of Illinois to provide a better understanding of the characteristics of these crashes in order to identify effective safety measures to improve construction zone layouts. The two main research objectives of this data analysis are to (1) analyze the frequency and severity of work zone crashes; and (2) investigate probable causes and contributing factors of these work zone crashes. To accomplish these objectives, two main research tasks were performed that focused on: (a) gathering the most recent and comprehensive set of data and reports on highway construction zone crashes in Illinois; and (b) studying the correlation among all construction zone crash variables that are available in the gathered data to investigate probable causes and contributing factors of this type of highway crashes.

INTRODUCTION

Work zone crashes are defined as crashes that occur in the terrain of a work zone whether it is a construction, maintenance, or utility work zone (MUTCD 2003). Work zone safety and mobility continues to be a major concern for the Federal Highway Administration (FHWA), American Association of State Highway and Transportation Officials (AASHTO) as well as most state Departments of Transportation (DOTs). The current highway construction and maintenance work zone crash data indicates that there is an average of 745 fatalities and 40,700 severe injuries per year (Zech et al. 2005). Figure 1 illustrates the total number of fatalities per year in highway construction and maintenance zones during a 13-year period from 1995 to 2007 (FARS 2008).

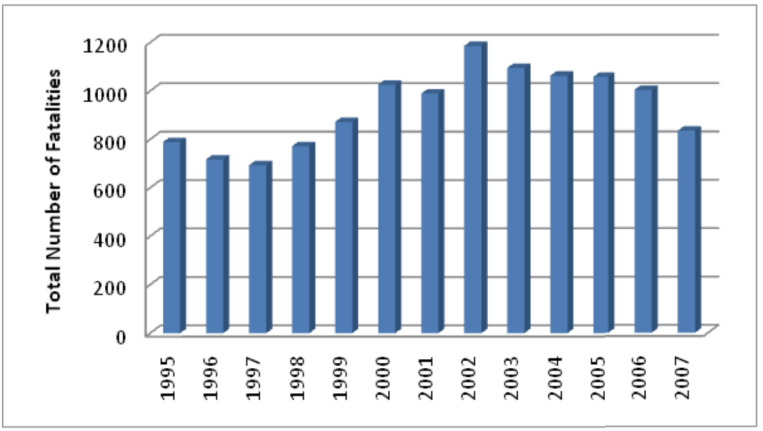

Figure 1: Total number of fatalities in construction/maintenance zones per year (1995-2007) (FARS 2008).

A number of research studies have been conducted to investigate and improve work zone safety in various states (Daniel et al. 2000; Raub et al. 2001; Garber and Zhao 2002; Bai and Li 2006; and Harb et al. 2008). Daniel et al. (2000) examined the difference between fatal crashes within work zones and fatal crashes in non-work zone locations in the State of Georgia to identify the manner of collision, location, and construction activity associated with fatal crashes in work zones. Raub et al. (2001) studied work zone crashes in the State of Illinois between 1994 and 1995. The analysis examined similarities and differences between work zone and non-work zone crashes for these twp years. Garber and Zhao (2002) investigated the characteristics of work zone crashes that occurred in the State of Virginia from 1996 through 1999 based on police crash reports and re-categorized crashes according to work zone layout. Bai and Li (2006) analyzed fatal crashes that occurred in the State of Kansas between 1992 and 2004 to identify basic characteristics. Harb et al. (2008) in a recent study focused on the analysis of work zone crashes in the State of Florida for years 2002, 2003, and 2004 to evaluate basic features of freeway single-vehicle and two-vehicle crashes in work zones. Despite the significance and contributions of these studies, work zone safety remains a critical and pressing concern nationwide since most of these studies investigated work zone crashes characteristics aside from work zone parameters that may affect the injury severity of work zone crashes.

There is a pressing need to investigate and indentify various work zone parameters that correlate with the injury severity of work zone crashes in order to improve safety in and around construction and maintenance work zones. To address this research need, a comprehensive data analysis of recent highway construction zone crashes in the State of Illinois (2003 ~ 2007) is presented in this paper to provide a better understanding of the characteristics of these crashes in order to identify effective safety measures to improve construction zone layouts. The objectives of this paper are to (1) analyze the frequency and severity of work zone crashes; and (2) investigate probable causes and contributing factors of these work zone crashes. To

accomplish these objectives, two main tasks were performed that focused on: (a) gathering and fusing the most recent and comprehensive set of data and reports on highway construction zone crashes in Illinois; and (b) studying the correlation among all construction zone crash variables that are available in the gathered data to investigate probable causes and contributing factors of this type of highway crashes.

CRASH DATA COLLECTION AND FUSION

The first task in this analysis focuses on gathering available data and reports on work zone crashes in Illinois from all available resources to build a comprehensive dataset. This was accomplished by collecting the latest available data on work zone crashes in Illinois from all available resources, including: (1) the National Highway Traffic Safety Administration (NHTSA); and (2) the Highway Safety Information System (HSIS).

NHTSA crash data files for the state of Illinois contains data on approximately 400,000 accidents per year structured in three main files: (1) crash file; (2) vehicle file; and (3) person file (NHTSA 2007). A single crash case may occupy multiple rows in the person file depending on the number of persons involved in a crash. HSIS crash data contains only a subset of the aforementioned NHTSA crash data records as it includes between 105,000 and 205,000 crashes per year (www.hsisinfo.org). The main reason that the HSIS data was collected and analyzed in this study is the additional road and traffic data that it provides that are not available in the aforementioned NHTSA data files (Council and Mohamedshah 2009). The crash dataset provided by HSIS for the State of Illinois has, in addition to the aforementioned three NHTSA files, a fourth file (Roadlog file) that contains additional data on the road and traffic such as number of lanes, lane width, median type and width, Annual Average Daily Traffic (AADT), commercial volume, and speed limit.

The work zone crash dataset that was used in this study included 1,729 records that represent recorded injury and fatal work zone crashes in the State of Illinois during a 5 year period from January 1, 2003 to December 31, 2007. This work zone crash dataset was created and organized in four main steps. The first step involved extracting work zone crash records from all the available records and combining them in a single spread sheet. The second step involved extracting work zone injury and fatal crash records excluding property damage only (PDO) work zone crashes. The third step involved joining crash files and roadlog files using both “Cntyrte: County Route” and “milepost” in crash files and matched with “cnty_rte: County Route” and “begmp: Beginning milepost” in roadlog files. This link resulted in a dataset that included records of 1,729 work zone injury and fatal crashes with data on 30 different variables. The fourth step was to reorganize the observations of 26 variables among a total of 30 variables into sub-categories to better quantify the correlations among variables. For example: the contributing cause variable encloses 31 observations that were regrouped in 6 subcategories. Another example: 6 sub-categories were developed to represent the AADT of each road in which a work zone crash occurred instead of using the actual number. The list of the 30 crash variables is shown in Table 1.

Table 1: Work zone crash variables

Major Category	Variable
1- Time Data	1- Accident Year
	2- Acc Hour
2- Crash Data	3- Severity
	4- Injury Severity
	5- Total Killed
	6- Total Injured
	7- Type of Collision
	8- Number of Vehicles
3- Contributing Causes	9- Cause 1
	10- Cause 2
	11- Traffic Control Type
	12- Traffic Control Condition
4- Road Data	13- Road Classification
	14- Class of Trafficway
	15- Route Prefix
	16- One way Indicator
	17- Intersection Relevance
	18- Type of Construction
	19- Number of Lanes
	20- Surface Type
	21- Road Surface Condition
	22- Median Type
	23- Median Width
5- Traffic Data	24- AADT
	25- Multiple Daily Volume
	26- Commercial Volume
	27- Million Vehicle Mile Travel
	28- Speed Limit
6- Environment	29- Light
	30 Weather

CORRELATION ANALYSIS OF WORK ZONE CRASH VARIABLES

Tests for independence were performed to identify the association and potential correlation among the aforementioned crash variables. Two statistical tests for independence were used in this study: Pearson chi-square and likelihood-ratio chi-square (Bai and Li 2006; SAS Institute Inc. 2006). Regardless of the different advantages of these two independence tests, they were both adopted in this study to assure the maximized accuracy when identifying all possible correlations. A dependent relationship was determined if and only if both tests supported it (i.e., p-value < 0.05). Each crash variable was tested against all other variables. The p-values for both statistical tests were calculated to test whether a null hypothesis could be accepted or not, and at a significance level of 5%, if p-value is larger than or equal to 0.05, the null hypothesis H0 is considered and the two factors are not correlated. If the p-value is less than 0.05, the alternative hypothesis H1 is considered and the two factors are correlated.

Correlation Results

All possible correlations among the work zone variables were evaluated using the aforementioned two correlation tests and a correlation matrix has been developed showing all possible correlations. This paper presents an example set of the identified correlations between the injury severity variable and five other variables as shown in Table 2. These correlations are discussed in more details in the following sections including their crash frequency percentages.

Table 2: Identified correlated variables of the severity of injuries in work zone crashes

Correlated Crash Factors		Pearson Chi-Square		Likelihood Ratio Chi-Square	
		P-Value	Related	P-Value	Related
1- Injury Severity	Type of Collision	<0.0001	YES	<0.0001	YES
2- Injury Severity	Contributing Cause	<0.0001	YES	<0.0001	YES
3- Injury Severity	Surface Type	0.0057	YES	0.0295	YES
4- Injury Severity	Median Type	0.039	YES	0.0324	YES
5- Injury Severity	Speed	0.052	YES	0.04	YES

Injury Severity and Type of Collision

The results of the correlation analysis show that the severity of work zone injuries is correlated with the type of collision as different collision types tended to cause different degrees of injury severity, as shown in Figure 2. The results show that the majority of rear-end crashes had only complaints with no visible injury while the majority of other collision types such as angle and fixed object crashes produced visible injuries rather than complaints of pain.

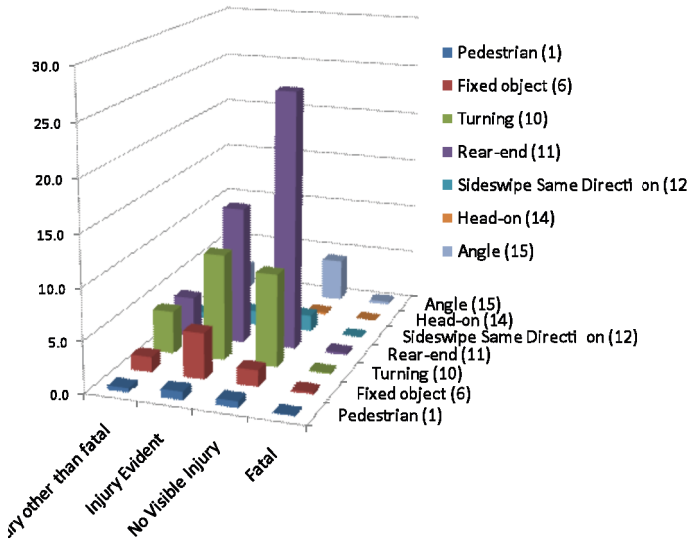

Figure 2: Crash frequency percentages by injury severity and type of collision

Injury Severity and Contributing Cause

A detailed analysis of this correlation indicates that speed was the dominant contributing cause of fatal crashes while improper driving was the leading cause of injury crashes, as shown in Figure 3. The results also show that the top three causes of injury crashes are improper driving, speed and work zone environment.

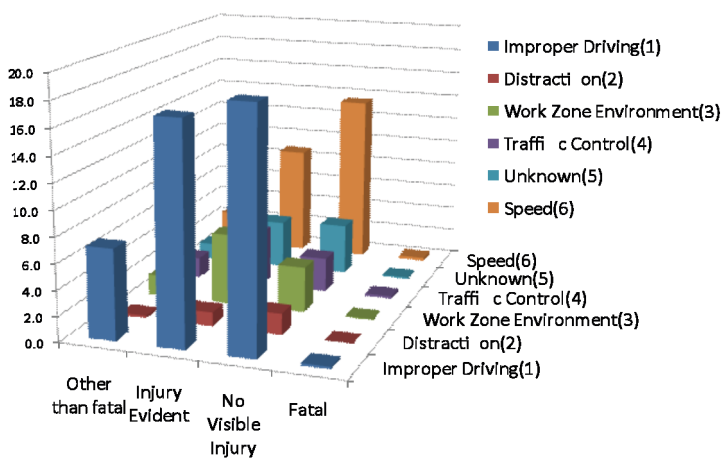

Figure 3: Crash frequency percentages by injury severity and contributing cause

Injury Severity and Surface Type

The results of the correlation analysis show that the severity of work zone injuries is correlated with the surface type of the road. A detailed analysis of this correlation indicates that more than 40% of the reported evident injury crashes occurred on Portland Cement Concrete (PCC) roadways with unknown reinforcement (type 600) as shown in Figure 4.

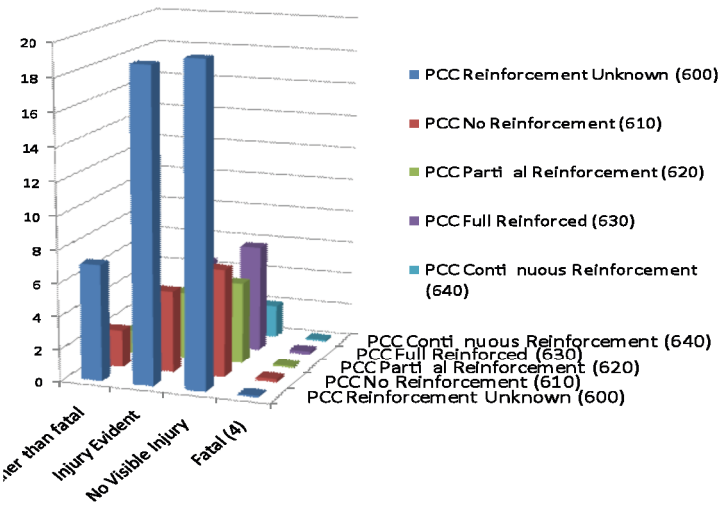

Figure 4: Crash frequency percentages by injury severity and surface type

Injury Severity and Median Type

The results of the correlation analysis show that the severity of work zone injuries is correlated with the type of median in the road. A detailed analysis of this correlation indicates that more than 37% of fatal crashes occurred in roadways that had no medians while no fatal crashes occurred in roads with rumble strips and painted medians, as shown in Figure 5. The results also show that more than 50% of injury crashes occurred on roadways that had no medians or curbed medians.

Injury Severity and Speed Limit

The results of the correlation analysis show that the severity of work zone injuries is correlated with the speed limit of the road. An in-depth analysis of this correlation indicates that more than 50% of fatal work zone crashes occurred in roads that have a speed limit of 50 mph or higher, as shown in Figure 6. In roads with a speed limit of 65 mph, more than 70% of work zone crashes had evident injuries while that percentage dropped to 57% in roads with lower speed limits. This confirms that injuries sustained in work zone crashes are more severe in roads that have higher speed limits.

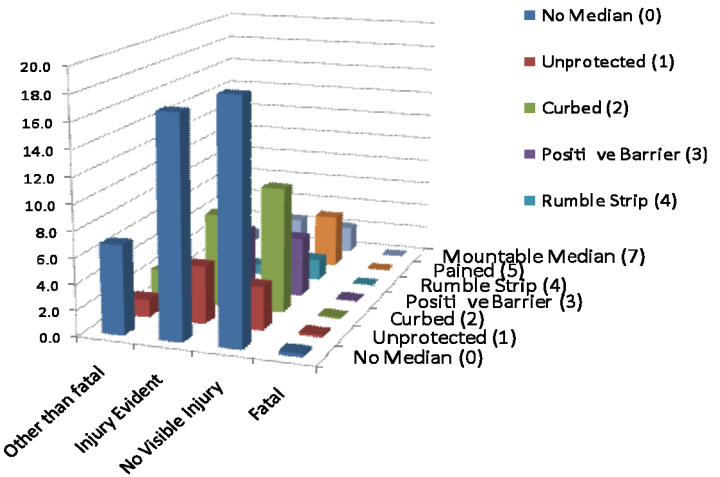

Figure 5: Crash frequency percentages by injury severity and median type

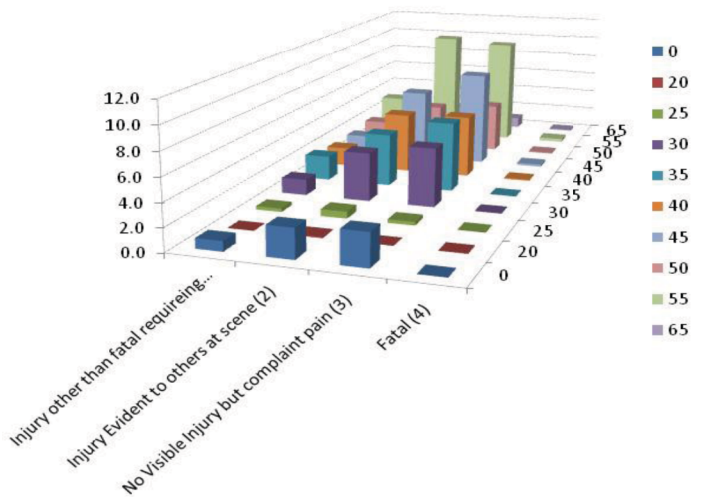

Figure 6: Crash frequency percentages by injury severity and speed limit

SUMMARY AND CONCLUSION

This paper presented a comprehensive data analysis of 1,729 highway construction zone fatal and serious injury crashes in the state of Illinois during a 5 year period (2003~2007). The main research objectives of this data analysis were to: (1) analyze the frequency of work zone crashes corresponding to various crash variables; and (2)

investigate probable causes and contributing factors of these work zone crashes. Thirty variables representing (1) crash data; (2) vehicle data; (3) driver data; and (4) roadway and traffic data were studied. The methodology of data collection and fusion was presented in more details. The $\chi 2$ statistic at a significance level of 0.05 revealed more than 120 possible correlations. Five correlations pairs between the injury severity variable and five other variables were analyzed in more details and crash frequency percentages were developed. The main findings of this analysis include:

(1) The severity of work zone crashes was found to be correlated with and affected by the type of collision, the drivers' actions that caused the crash, the type of road surface, the type of median and the speed limits of the road.
(2) The majority of rear-end crashes had only complaints with no visible injury while the majority of other collision types such as angle and fixed object crashes produced visible injuries rather than merely complaints.
(3) More than 40% of the reported work zone crashes that caused evident injuries occurred on PCC roadways with unknown reinforcement.
(4) More than 37% of fatal crashes occurred in roadways that had no medians while no fatal crashes occurred in roads with rumble strips and painted medians.
(5) The correlation results show that more than 50% of injury crashes occurred on roadways that had no medians or curbed medians.
(6) More than 50% of fatal work zone crashes occurred in roads that have a speed limit of 50 mph or higher.

ACKNOWLEDGEMENT

This study was funded by the Illinois Department of Transportation for research project ICT-Project R-27-52, Studying and Minimizing Traffic-related Work Zone Crashes in Illinois. The authors would like to thank Marshall Metcalf of IDOT and Yusuf Mohamedshah of HSIS for their valuable help and advice.

ABSTRACT

City managers and elected officials in many municipalities are frequently faced with the challenge to cater for public expectations on one hand and to comply with technical/engineering requirements on the other. This paper presents a four phased level of service driven reliability based methodology for allocation of budget to water mains. This methodology comprises of: (1) development of an Analytical Hierarchy model of LoS; (2) a sub-network criticality model to account for certain quantitative and qualitative characteristics of a given sub-network (3) a sub-network reliability assessment model and 4) a budget allocation model. Combination of the above contradicting requirements, i.e. level of service and network reliability, is expected to assist decision makers in quantifying the required condition improvement to meet service goals and to make more informed decisions on interventions and relayed priorities. To show the robustness of the developed models, a hypothetical case study is developed and analyzed.

INTRODUCTION

The Canadian Federation of Municipalities (InfraGuide 2004), defines asset management as: "The combination of management, financial, economic, engineering, operational and other practices applied to physical assets with the objective of providing the required level of service in the most cost-effective manner". Best practices for municipal asset management require municipalities/communities to clearly define and state their respective goals that reflect their expectations (e.g. levels of service). Establishment of level of service should be a fact-based, rational, transparent, reproducible and systematic process that not only assists in planning, but also in tracking and monitoring assets' performance against those initially set by the communities. Developing levels of service is essential to the rationalization of asset management decision making processes. In a way, levels of service define the terms of reference, set by the community either directly, through public consultation, or indirectly via elected officials, for the quality of services rendered by the municipality (Moselhi 2005). Levels of service are composite indicators, which may vary from one community to another, and account for the social, environmental and economic goals of the community as well as for its budget constraints. Establishment and achievement of levels of service are therefore important for sustainable development, which has been defined as "meeting the needs of the present generation without compromising the ability of future generations to meet their own needs" (InfraGuide 2003). Generally, the risk associated with assets is directly related to the condition and probability of failure of the assets whereas the targets for asset condition and risk tolerance are related to the levels of service to be delivered to the public by the authority (InfraGuide 2006). Depending on the age and condition, the potential for infrastructure failure or reduction in level of service can increase. This risk arises from the deterioration of assets. Knowing the representative condition and the historic deterioration and failure/ break rates of the various groups of assets is therefore, a prerequisite of asset management decision making. An asset management plan must ensure that current users pay a fair share for the service so future users do not have to pay a higher cost for the same level of service. It is therefore rational to suggest that an efficient asset management plan, while maintaining an adequate level of service should also minimize level of risk, which may be measured and expressed in terms of system reliability. Level of service can, therefore, be considered as an integral part of sustainable municipal asset management which has an upward link with sustainable asset management plan and a downward link with asset condition assessment and network reliability. The objective of this paper is to develop a community driven and network reliability based methodology for sustainable management of water distribution networks.

PROPOSED METHODOLOGY

The data requirement for the proposed methodology can be grouped into two categories. First is the segment related information where data relating to asset identification and performance is required. Ranges of values of performance measures corresponding to each level of service and the failure threshold values of

each indicator are to be set. Second is the network related information which involves population size, sub-network tax base, level of complaining by local residence and the type of sub-network. Further details can be found in InfraGuide (2002a). Additional information on benchmarking can be found in AWWA (1996), AWWA-RF (1996) and Keehley et al (1997). The proposed methodology consists of four integrated models the detailed description of which is given below:

Model 1: Level of Service (LoS) Model

This model accounts for community goals and expectations. The Analytical Hierarchy Process is used for quantification and measurement of Network Level of Service accounting for a set of tactical and operational level indicators and performance measures of water distribution networks. A hypothetical example is designed to illustrate the working of model 1 and is presented in Table 1.

Table 1. Ranges and thresholds of performance measure for different LoS

Performance Indicator	Pefromance Measure	Range of Performance Measure for Different Levels of Service (LoS)					Service Thresholds
		LoS 1	LoS 2	LoS 3	LoS 4	LoS 5	
Physical Condition	Annual Break Rate (Breaks/km/Yr) *	0 - 0 (1.0 - 1.0)	1 - 1 (0.75 - 0.75)	2 - 2 (0.5 - 0.5)	3 - 3 (0.25 - 0.25)	4 - 4 (0 - 0)	4 (0.0)
	No of Leaks (No/km) *	0.0 - 0.5 (1.0 - 0.75)	0.51 - 0.75 (0.74 - 0.63)	0.76 - 1.25 (0.625 - 0.38)	1.26 -1.75 (0.375 - 0.125)	1.76 - 2.0 (0.12 - 0.0)	2.0 (0.0)
	Leakage Volume (cum/hr) *	0.0 - 0.1 (1.0 - 0.80)	0.11 - 0.2 (0.79 - 0.60)	0.21 - 0.3 (0.59 - 0.40)	0.31 - 0.4 (0.39 - 0.20)	0.41 - 0.50 0.19 - 0.0)	0.5 (0.0)
Operational Condition	Fire Flow (C-Factor)	150 - 101 (1.0 - 0.62)	100 - 81 (0.61 - 0.47)	80 - 61 (0.46 - 0.31)	60 - 41 (0.30 - 0.16)	40 - 21 (0.15 - 0.0)	21 (0.0)
	Loss in Internal Water Pressure at peak demand (psi) *	0-5 (1.0 - 0.8)	6-10 (0.79 - 0.60)	11-15 (0.59 - 0.4)	16-20 (0.39 - 0.2)	21-25 (0.19 - 0.0)	25 (0.0)
	Frequency of Interruption (No/Yr) *	0-3 (1.0 - 0.83)	4-6 (0.82 - 0.67)	7-10 (0.66 - 0.44)	11-14 (0.43 - 0.22)	15-18 (0.21 - 0.0)	18 (0.0)
Water Quality	Lead Concentration (% of threshold) *	0-10 (1.0 - 0.9)	11-25 (0.89 - 0.75)	26-45 (0.74- -0.55)	46-70 (0.54 - 0. 30)	71-100 (0.29 - 0.0)	100 (0.0)
	Iron Concentration (% of Threshold) *	0-10 (1.0 - 0.9)	11-25 (0.89 - 0.75)	26-45 (0.74- -0.55)	46-70 (0.54 - 0. 30)	71-100 (0.29 - 0.0)	100 (0.0)
	Sepaeration from Sewer (m)	2.25-2.01 (1.0 - 0.81)	2.00-1.76 (0.8 - 0.61)	1.75-1.51 (0.6 - 0.41)	1.5-1.26 (0.4 - 0.21)	1.25-1.0 (0.2 - 0.0)	1.0 (0.0)

*-- The normalized values are subtracted from 1 to change the order so that increase in normalized value results in increase in LoS

The performance measures used in the hypothetical example, along with respective failure thresholds and ranges corresponding to different LoS are presented in Table1. Using the Water Main Service Percentile (WMSP) model developed earlier (Khan, Moselhi and Zayed, 2009) reproduced below, the service percentiles for the studied network can be determined. It should be noted that 'WMSP' described in Eq.(1), upon grouping leads to cluster level of service. In this study level of service has been

clustered in five categories from 1 to 5, with 1 representing the best possible scenario and 5 representing the least acceptable.

Water main service percentile = WMSP = $\sum_{i=1}^{n} \sum_{j=1}^{m} (Wij) * (PMij)$ ……..……...(1)

where: Wij = weight of sub-factor 'i' in factor 'j', PMij= value of performance measure 'i' in performance indicator 'j'
The overall network level of service (NLoS) quantified from segment level of service is worked as follows:

NLoS (%) = $\sum$ LoS_i x L_i / $\sum L_i$ .....(2)

where: LoS_i = Level of service of the segment *'i'*(%), L_i = Length of the segment *'i'* in meters

To facilitate data processing with reliability measures as will be described later, Network Level Un-Serviceability (NLoUS) is introduced and is given as:

NLoUS= 1- NLoS ……. (3)

Network Level of Un-Serviceability to be used for budget allocation of the case study, is calculated based on hypothetical data (Table 1). It should be noted that for criticality and reliability models data collected directly from the City of Moncton, New Brunswick is used.

Model 2: Weighted Score Sub-network Criticality Model

This model accounts for the following qualitative and quantitative factors:

1. Level of complain by local residence

A significant number of complaints by local residences indicate that the specific sub-network has reached a critical state. Residence complaints are divided into two types; either due to low quantity or due to low quality of water. A scale of 1 to 5 is suitable for this purpose. A score of 1 represents no complaints by residences implying excellent performance of the network whereas 5 signifies the opposite i.e. the highest level of complain.

2. Type of the sub-network

A sub-network can be classified as residential, commercial, industrial or recreational. The type of sub-network signifies the nature and the extent of the impact that may occur in the case of failure to provide the expected level of service. Stated alternatively, the consequences of failure of a network having a hospital will be far more serious than the consequences of failure of a sub-network having parking

facilities. A scale from 1 to 5 is suitable for this purpose with 1 being the most critical and 5 as the least.

1. Number of local residence

The density of population serviced by a sub-network is a principal factor is establishing the demand. The higher the population density the higher is the demand and the more critical is the sub network

2. Tax return

The desired levels of service have specific costs associated with them. If the tax payers are not willing to accept the costs, then the levels of service are to be reduced to the point where costs are acceptable. This means service levels are adjusted. This is an iterative process that means returning to the Delphi panel until levels of service and willingness to pay are aligned. The revenue collected from the community to provide services forms the tax base. The bigger the tax base the more critical is the network.

Budget allocation for sub-networks can be performed by weighting the criteria of all sub-networks, as shown in the Tables 2 and 3. The process of allocating budget to a sub-network involves the determination of the criticality weight of the sub-network. The user has the freedom to decide upon the weights of importance of the population number (Wlc), tax rate (Wtx), level of complaint by local residents (Wloc) and sub-network type (Wt) based on the specific situation of the sub network. By multiplying sub-network criticality factors (population number tax return, level of complaint, and type of sub-network) by their weights, the criticality of sub-networks can be determined. For details readers may refer to Salman et al. (2009).

Table 2. Budget allocation criteria

Sub Network No.	Sub Network Factors		
	Unreliability(%)	Unserviceability(%)	Criticality(%)
	Wq	Wus	Wcr
1	Q_1	US_1	CR_1
2	Q_2	US_2	CR_2
....	....	....	....
.....	.....	.....	.....
n	Q_n	Usn	CR_n
Summation	ΣQi	ΣUSi	ΣCRi

Model 3: Reliability Assessment

In this model the reliability based condition assessment of sub networks is determined. First of all, the city network is administratively broken down into zones. These zones are constituted of sub-networks. Each sub-network is further divided

into segments. Each segment may comprise of pipes and accessories. The last level of detail is the component; a component (a pipe or an accessory) represents the smallest entity of the water distribution network. In this study, reliability assessment using reliability theory is performed at component level and then aggregated bottom up in the hierarchal order, to determine the sub network level reliability as described below:

Component Reliability: To calculate the reliability of a component deterministically, the average failure rate (λ) of a component can be calculated first, as shown in Eq. (4):

$$\lambda = \frac{N_{Failure}}{Time} \quad \text{……..……...…(4)}$$

$N_{Failure}$ is the number of failures of pipe during the period considered. For a water main pipe, the average number of failures that have occurred from the time of installation can be calculated, as shown in Eq. (5):

$$\lambda_{Pipe} = \frac{N_{Failure\ /\ Km}}{T_{analyzing} - T_{inst.}} \quad \text{……..…...…....(5)}$$

$T_{analyzing}$ and $T_{inst.}$ are respectively the time of analysis and pipe installation.To calculate the average failure rate (λ) of a hydrant or a valve, Eq. (6) can be utilized:

$$\lambda_{hydrant,valve} = \frac{N_{Failure}}{T_{analyzing} - T_{inst.}} \quad \text{……..……...…...…(6)}$$

After determining the average failure rate of a component, the reliability of the component can be found using Eq. (7), (Billinton and Allan, 1983). Reliability is considered to follow the negative exponential function, which means that reliability decreases exponentially with time because the average failure rate increases with time.

$$R(t) = e^{-\lambda t} \quad \text{……...……...(7)}$$

In this case, average failure rate (λ) means the hazard rate, while failure rate *f(t)* is :

$$f(t) = \frac{-dR(t)}{dt} = \lambda e^{-\lambda t} \quad \text{……...…...……..… (8)}$$

All failure numbers and ages of water network components are collected to determine their reliabilities. Segment reliability ($R_{seg.}$) and sub-network reliability ($R_{sub\text{-}net.}$) are determined after finding their respective component reliabilities.

Segment Reliability: Figure 1 shows a typical segment of a water main network. Following Eq. (5) above the reliability for each component of the segment (pipes, valves and hydrants) was analyzed.

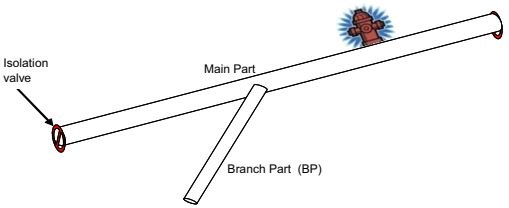

Figure 1. Components of a segment

The reliability of the segment can be calculated as:

$$R_{seg.} = e^{-(\lambda_{Segment}\ t_{Segment})} \quad \text{.....(9)}$$

where

$$\lambda_{Segment} t_{Segment} = \lambda_{Pipe}.t_{Pipe} + \lambda_{B.P}.t_{B.P} + \lambda_{Hydrant} t_{Hydrant} + \lambda_{Valve} t_{Valve} + \lambda_{Others} t_{Others} \text{....(10)}$$

Sub-network Reliability

In modeling reliability of large networks, it has been reported that the Cut-set and Path-set are the most suitable methods (Quimpo, 1996). Sub-network reliability is used to determine failure density function, Q (t), which is used with other factors to determine budget allocation of a sub-network. Failure density function is calculated as follows:

$$Q(t) = \int_0^t \lambda e^{-\lambda t} dt = 1 - e^{-\lambda t} \quad \text{..... (11)}$$

From Eq. (7) and Eq. (8), the relationship between R(t) and Q(t) can be expressed as Eq. (12), where 'R' and 'Q' are respectively the reliability and un-reliability of the given sub-network:

$$Q(t) = 1 - R(t) \quad \text{..... (12)}$$

Model 4: Budget Allocation Model

The criteria used are sub-network reliability, water sub-network level of service and sub-network criticality. Based on the community and agency preferences, weights are assigned to the three criteria respectively in terms of un-serviceability (Wus), sub-network criticality (Wcr) and un-reliability (Wq), as shown in Table 2. Outputs of models 1, 2 and 3 are utilized to determine the relative weight of each sub-network for budget allocation.

Table 3. Budget allocation of a city

Sub Network No.	Sub Network Factors				
	Unreliabilty(%)	Unserviceability(%)	Criticality(%)	Weight(%)	Budget Allocation
	(1)	(2)	(3)	(4) =(1)+(2)+(3)	(4)*TB
1	$(Q_1/\Sigma Qi)*Wq = Q_{11}$	$(US_1/\Sigma US_i)*Wus = US_{12}$	$(CR_1/\Sigma CR_i)*Wcr = CR_{13}$	W_1	$TB * W_1$
2	$(Q_2/\Sigma Qi)*Wq = Q_{21}$	$(US_2/\Sigma US_i)*Wus = US_{22}$	$(CR_2/\Sigma CR_i)*Wcr = CR_{23}$	W_2	$TB * W_2$
...	...	...	...	...	...
...	...	...	...	...	...
n	$(Qn/\Sigma Qi)*Wq = Q_{n1}$	$(US_n/\Sigma US_i)*Wus = US_{n2}$	$(CR_3/\Sigma CR_i)*Wcr = CR_{33}$	W_n	$TB * W_n$

CASE STUDY (CITY OF MONCTON)

The city of Moncton, New Brunswick (Figure 2) has been considered as a case study for the application of the developed method. The population is 126,424 and its area is 141.17 km². The total length of the water mains is 448 km and the average water consumption is 462/capita/day. The data collected for the city can be divided into two parts; the first part concerns the pipes, such as age, material, diameter, length, and number of breaks. The second part is related to the accessories that are attached to these pipes, such as valves and hydrants. However, the age and failure rate of these accessories are not provided and will be assessed to generate scenarios. To apply the methodology described in this proposal, the following steps are followed:

1. The first step is to divide the city into 14 sub-networks. This process is called the Break Down Structure of the City area (BDS). To apply the reliability assessment model, sub-network number one has been chosen using a GIS map (Figure 3). The GIS map shows the water mains, isolation valves and hydrants. The total number of segments is 113. The reliability of other sub-networks has been assumed.
2. Calculate Network Level of Un-Serviceability using Model 1
3. Assign different failure rates to the isolation valves and the hydrants.
4. Assume an amount for the city's available budget. This available budget is specified for rehabilitation only.

In this model, the reliability of each sub-network has been used in conjunction with sub-networks un-serviceability and sub-networks criticality. By normalizing the criteria and the sub-networks, the weight of each network has been found. Based on this weight, the ideal available budget can be obtained. For this case study, it is assumed that there is 16.5 million dollars are specified for the rehabilitation of the

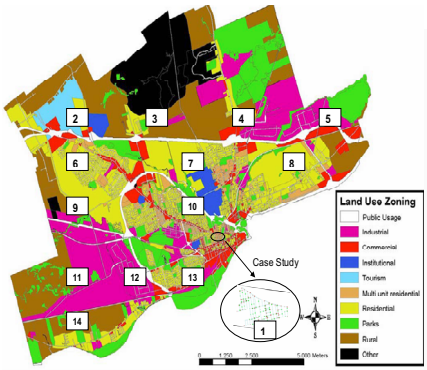

Figure 2. BDS of City of Moncton

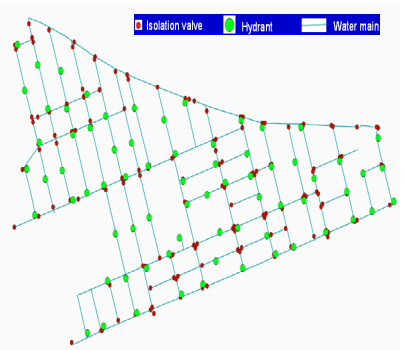

Figure 3. Sub-network 1- Moncton

city of Moncton for the next year. Therefore, 16.5 million dollars will be divided into the 14 sub-networks based on their reliabilities, water consumption, and contingency. The output of this model is the available budget of each sub-network, which is shown Table 4.

Table 4. Expected input and output of the budget allocation model

SUMMARY AND CONCLUSION

A methodology has been presented for budget allocation of water distribution networks. The developed methodology is intended to assist public work departments to internally distribute the budget, originally allocated for the water distribution

network, in their respective areas. An example has been analyzed to demonstrate the use of the developed method in allocating the budget assigned internally to water distribution network. The allocation will be for the individual zones, sub-networks and their respective components. The developed methodology accounts for community preferences expressed in defined targeted level of service and on the other hand it accounts for condition of the network expressed in terms of reliability of its components, segments and sub networks. The developed methodology is expected to help municipal engineers in making decisions that account for technical and financial plans of the city.

Abstract:

Line leakage of oil and natural gas systems can result in significant financial and environmental consequences. Often, small leaks lead to ruptures in the pipeline that result in product escaping into the surrounding soil. Oil product can taint water supplies by migrating into aquifers, while natural gas leaks are susceptible to catastrophic explosions. A joint academic-industry research initiative funded by the U.S. Department of Transportation's Pipeline and Hazardous Materials Safety Administration (PHMSA) has lead to the development and refinement of a free-swimming device capable of detecting small leaks in oil product and natural gas pipelines. The SmartBall® swims through a pipeline being assessed and produces results at significantly reduced cost to the end user compared to current leak detection methods. GIS based above ground loggers that are GPS synchronized capture low frequency acoustic signatures and digitally log the passage of the SmartBall® through a pipeline. This paper presents the development, laboratory and field validation testing of the SmartBall® for both oil and natural gas applications with discussion of demonstrated case studies.

INTRODUCTION

Early detection of leaks in hazardous materials pipelines is essential to reduce product loss and damage to the environment (Carlson 1993; Zhang 1996). Small leaks, if undetected, can result in elevated clean-up costs and have the potential to grow to more serious failures (Figure 1). On July 30, 2003 a 200mm (8-inch) steel pipeline carry fuel between Tucson and Phoenix, AZ ruptured resulting in over 50,000 gallons of gasoline being spilled. This resulted in contamination to the soil and groundwater.

Fortunately, an adjacent 68 lot housing subdivision was only under construction at the time and thus did not have any residents present. This incident not only resulted in physical damage, but also economic consequences due to elevated prices at gas stations due to limited supply while the line was under repair.

There are a variety of available methods capable of detecting leaks in pipelines, ranging from manual inspection to advanced satellite-based imaging. Typically, most operators opt for a combination of Computational Pipeline Modeling (CPM) and direct observation methodologies including aerial or ground patrols. Permanent monitoring sensors based on acoustic or other technologies are also available; however, these methods can be costly, and none can reliably detect small leaks regardless of their location in the pipeline.

Figure 1. Consequences of a leaking pipeline

Most pipeline operators also employ in-line inspection (ILI) programs using "smart pigs" that detect cracking, wall thinning, and other anomalies (Turner 1991). However, a major of pipelines are typically only inspected at intervals of several years, and all ILI technologies have limits on the minimum cross-sectional area of the defects they can detect. Furthermore, they are unable to differentiate between a deep defect and a leak. Through-wall pinhole leaks resulting from aggressive corrosion mechanisms such as MIC are not typically detected. Also many lines, particularly in the gathering and distribution sectors, are never pigged.

SmartBall® is a new approach that combines the sensitivity of acoustic leak detection with the 100% coverage capability of in-line inspection. The free-swimming device is spherical and smaller than the pipe bore allowing it to roll silently through the line and achieve the highest responsiveness to small leaks. It can be launched and retrieved using conventional pig traps, but its size and shape allow it to be launched by other means and to negotiate obstacles that could otherwise render

a pipeline unpiggable. Figure 2 illustrates the internal components and polyurethane outer shell that can withstand external pressures up to 2,000 psi (138 bars).

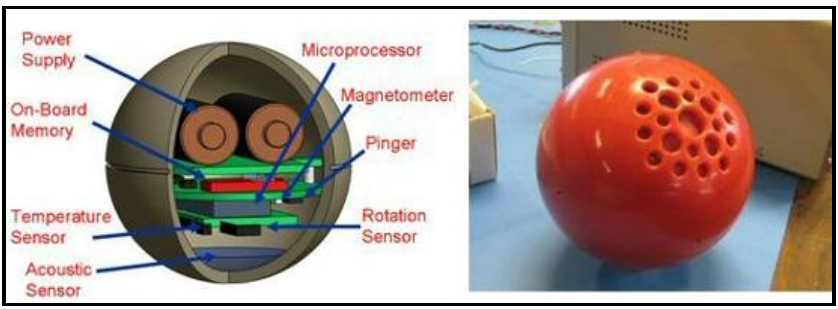

Figure 2. SmartBall internal components (L); Outer shell (R)

TECHNOLOGY DEVELOPMENT BACKGROUND

When pressurized product leaks from a pipe, it creates a distinctive acoustic signal that is transmitted through the product flowing in the pipeline. Acoustic leak detection equipment identifies the resulting sound or vibration (Klein 1993). Such systems have proven to be one of the most effective and reliable means for identifying leaks in pipelines, but fixed sensors have limited range due to the rapid attenuation of sound. A free-swimming, un-tethered acoustic leak detection device avoids this limitation by passing directly by any leak, regardless of its location along the pipeline. By operating inside the pipe, the device is not affected by ground cover or environmental conditions, and there is never any concern that sections of the line could be missed.

Recognizing the value offered by acoustic technology, but also the range limitations for a fixed sensor system, a research and development program was undertaken to develop a free-swimming (non-tethered) acoustic leak detection device. The goal of the program was to develop a technology that would provide operators with the ability to detect leaks at an early stage (i.e. small leaks), to determine the location with sufficient precision to allow remedial work to be performed without additional surveying. It had also to be available at an affordable cost without the need for major changes in the pipelines construction or operation.

The resulting system, named SmartBall®, was initially developed in 2005 for water transmission pipelines because of the magnitude of the leak problems in the water industry and the lack of alternative solutions. However, the SmartBall® principle is equally applicable to oil and gas pipelines, so the research and development program was extended in 2007 to modify the technology for use in the hydrocarbons industry. This led to a two year research project funded by the U.S. DOT's Pipeline and Hazardous Materials Safety Administration (PHMSA) in collaboration with Pure Technologies Limited and Arizona State University.

The SmartBall® device diverges from the traditional cylindrical shape of in-line equipment or "pigs". The spherical shape greatly reduces the noise produced by the device as it passes along the pipe, thus permitting the sensitive acoustic sensor to operate free of external interference. The net result is a tool that is sensitive to very small acoustic events and, therefore, very small leaks.

An additional benefit of the spherical design is that it allows much greater flexibility in the methods of deployment and retrieval compared to a cylindrical tool, and it is able to negotiate a much wider range of bore changes, small radius bends and other obstacles that may exist within the pipe. SmartBall® can run in lines without pig traps, and in a wide range of traditionally unpiggable locations. Both liquids and gas pipelines can be inspected. With the current series of tools, any pipeline size of 100mm (4-inch) diameter or greater is accessible.

The device is inserted into an operational pipeline in the same manner as a smart pig and can monitor many miles of pipeline during a single deployment (Figure 3). The SmartBall's position is logged internally by on-board accelerometers and the ball can also be tracked by GPS synchronized surface sensors in the same way a conventional pig. This combination of tracking systems allows the location of any leaks to be determined within ±1 meter.

The SmartBall® is fully sealed with no electronic components exposed to the pipeline environment. This allows us to achieve high levels of reliability in a wide range of hostile conditions, and ensures that the device is intrinsically safe for use in flammable products such as oil and gas.

Following a run, the data are downloaded to a computer for analysis. This process is relatively fast; subsequently the initial decision on whether a leak exists in the line can often be made before the field crew leaves the inspection site. The SmartBall® log comprises of a continuous, high-fidelity acoustic record of the inspected section over a wide range of frequencies. Leaks are identified by a combination of increased acoustic power and a characteristic frequency spectrum. Subsequent logs may be overlaid to identify changes between inspections, further enhancing sensitivity.

FIELD PROJECT USING SMARTBALL

A 250mm (10-inch) SmartBall® was deployed to inspect a 300mm (12-inch) steel portion of MOL's Oil pipeline from Szajol to Tiszaújváros in Hungary on April 23 and 24, 2009 (Figure 3). Total run length was approximately 126 km. The SmartBall® was inserted and extracted through MOL's existing pig traps. One known simulated leak (Figure 4) was generated along the pipeline as both a test of the SmartBall's® ability to locate leaks and as reference points for calibrating unknown leaks. A second unknown leak was discovered upon running the analysis on the data retrieved from the SmartBall tool. Analysis of the data allowed for an estimation on the location and size of the leak. Leak location was estimated at Sta. 76+458, and the leak rate was estimated at 3 L/min.

Figure 3. SmartBall® setup for field installations

Figure 4. Simulated leak point along the pipeline

During the inspection, the SmartBall® and SmartBall® Receivers (SBRs) collected data to aid in determining an accurate size and location of all leaks detected. Frequency spectrum data were recorded for the two leaks (Figures 5 and 6).

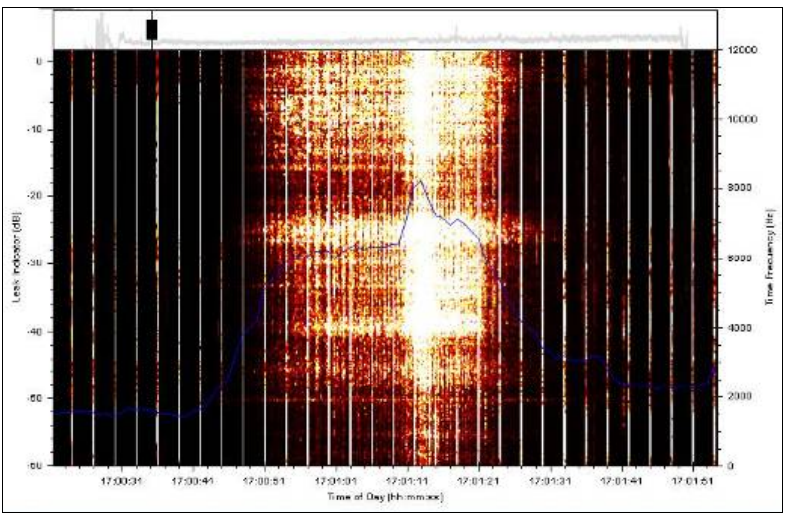

Figure 5. Frequency spectrum recorded at the first simulated leak point

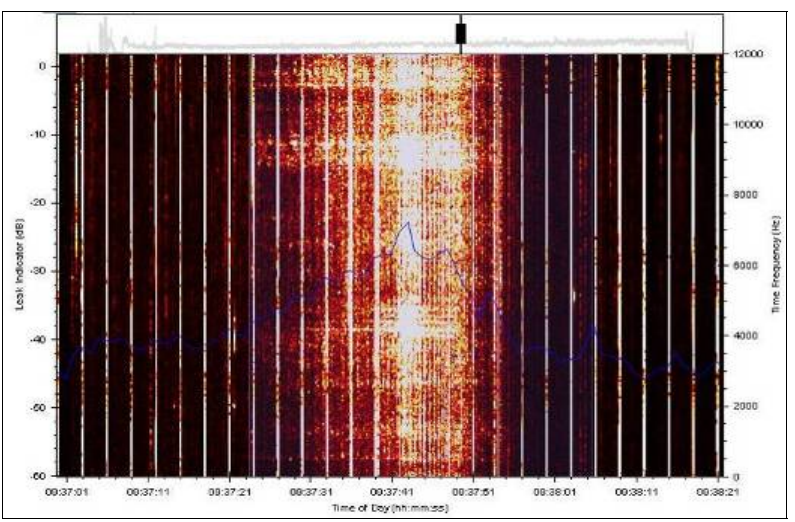

Figure 6. Frequency spectrum at the unknown leak location.

Knowledge of the position of the SmartBall® within a pipeline is critical for locating important features, such as leaks. The methodology used to track the tool involves obtaining a velocity profile using data obtained from the accelerometers and magnetometers on board the SmartBall®. Then, absolute position reference points obtained from the SBRs are applied to time stamped data. Individual SBRs are able to track the ball's progress through the pipeline for up to 150m. The result of the rotation profile and SBR tracking is a position versus time relationship for the entire run of the tool.

To assist in identifying the approximate leak rate of any identified leak, an end-user can compare the leak indication power of a detected leak with that of a known leak rate. Known leak rates and corresponding leak indication power (in dB) are developed by holding the SmartBall® in the launch trap at the start of the survey run. The acoustic analysis of the calibration leaks were compared with the leak rate of each leak detected during the inspection of the MOL pipeline. The leak indication power is the single most important indicator of a leak's presence and size.

Because the simulated leaks are controlled and released through a threaded outlet, the comparison to actual field condition leaks may vary. This is because the acoustic frequency and power indication of any leak will vary with many factors, including pressure, pipe diameter, size and configuration (i.e. pin-hole, rolled gasket, split pipe, etc.). However, a leak calibration curve provides a useful tool in approximating leak rates for identified leaks. The leak calibration curve increases in accuracy as more data points and calibration leaks are added to the curve.

A 3-dimensional accelerometer also aids in locating the position of the SmartBall® tool within the pipeline as well as providing an indication of motion of the ball as it travels through the pipeline (i.e. uniform rotation, slipping/skidding, etc). Figure 7 illustrates a typical accelerometer profile. This enables the user to identify locations where flow was interrupted or the exact time the ball departs and arrives at the pigging facilities.

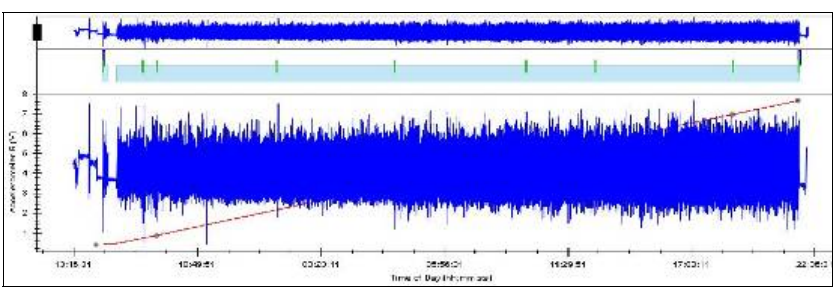

Figure 7. Accelerometer profile

CONCLUSIONS AND RECOMMENDATIONS

SmartBall® was initially developed in 2005 for inspecting leaks in water pipelines. Since its introduction, it has been successfully run in 48 water inspections totaling over 300km. Within those, more than 120 leaks have been detected. Introduction to the oil and gas industry has been more recent with research and development efforts currently on-going between Arizona State University and Pure Technologies Limited. Limited field testing has been undertaken using SmartBall® for assessing leaks in oil product pipelines. Modifications to the device and further testing should result in a fully commercial version of this device.

Further technological developments are planned. Refinement of the SmartBall® for use in gas pipelines is currently underway. The requirement is to modify the outer shell material to reduce rolling noise, and simultaneously to increase the drag to weight ratio to enhance propulsion.

Manufacture of additional sizes of SmartBalls® for oil and gas applications will continue. Beyond 250mm (10-inch) pipelines, overshells with standard 250mm (10-inch) SmartBalls® mounted inside will be used to eliminate the need to create a large inventory of individually sized SmartBalls®.

Additionally, increased internal memory and battery capacity will be added to extend the range of SmartBalls in larger sizes. The upper temperature limit will be increased to allow SmartBall® to operate in an even wider range of pipelines. Typical high temperature applications include the production from the Alberta Oil Sands.

A simplified arrangement for data download that avoids the need to open the ball will be introduced. This will have the additional advantage of reducing the risk of damage to internal components and help ensure that the seals remain intact.

The customer version of the analysis software is in the process of being developed and modified to increase the level of automation and reduce the need for technical expertise from the user

[2] Assistant Professor, Department of Civil and Environmental Engineering, Michigan Tech, Houghton, MI 49931; email: amlan@mtu.edu

Abstract:

The objective of this research is to analyze historical records of random non-mechanistic failures in civil infrastructure systems. In this paper, we particularly focus on blockage failures in sewer systems that result from combination of external factors, such as variations in usage loads, construction quality and soil characteristics. The study uses historical blockage failure records maintained by municipalities. However, such datasets often tend to be incomplete and/or not representative of failure patterns. We discuss the application of statistical tests – specifically the Kolmogorov-Smirnov (KS) test and Anderson-Darling (AD) goodness-of-fit test – to estimate (i) if the datasets are complete and representative enough, and (ii) estimate parameters of distributions that appropriately characterize failure event arrival pattern. A dataset consisting of sewer blockage failures for ten years from a small municipality in the State of Michigan was used. The methods discussed in this paper can be used to implement reliability models of other related infrastructure systems as well.

Introduction

The motivation of this research is to provide decision-makers in state and municipal agencies tools to estimate and budget expenditures for sewer line maintenance. Specifically, the focus is on aiding efficient and cost effective decision-making in municipalities with aging sewer systems. Sewer pipes are often inspected using closed circuit television (CCTV) to apprehend blockages before backups occur (Sinha 2004). Instead of depending on inspection methods, our approach uses historical records of blockage failures maintained by municipalities. Analysis of such historical data can significantly enhance the decision-making process involved in prioritizing maintenance decisions. We illustrate the application of this method using sewer line blockage failure data from a small municipality in the State of Michigan.

Background

Literature pertaining to serviceability predictions of sewer infrastructure systems can be classified using the following approaches to service assessment:

(i) By studying mechanistic system failures using hydraulic properties of sewer lines and pumping (Bennis et al. 2003; Ermolin et al. 2002),

(ii) By studying system failures as random events that can be a direct or indirect outcome of mechanistic and non-mechanistic events. The methods used in this approach are:

   a. Use historical failure data from case studies to predict behavior of specific systems. Typically, specific random failure events such as sewage pump failure and sanitary sewer overflows are modeled using historical data (Korving et al. 2006; Sumer et al. 2007).

   b. Assume the Markov property to develop general models that assess the condition of infrastructure for modeling pipe condition and deterioration, and optimizing maintenance schedules. (Abraham et al. 1998; Chughtai and Zayed 2008; Micevski et al. 2002; Wirahadikusumah et al. 2001).

The research presented in this paper specifically falls in category (ii.a). It analyzes sewer system failures resulting from blockages using historical failure data for a small municipality.

Stochastic methods are used in assessing failure of infrastructure systems due to discrete events, such as sewer overflows and sewer blockages that are modeled as random events. By definition, a stochastic process $X=\{X(t), t\in T\}$ is a collection of random variables $X(t)$, which denote the state of a process at time t (Ross 1993). When time is measured discretely, $X(t)$ is either true or false based on whether an event occurs or not at the time point t. When time is continuous, the inter-arrival times between failure events are recorded. A continuous stochastic process in which events occur independently of one another with no overlapping arrivals at a constant rate reduces to a Poisson process (Kingman 1993). Then the inter-arrival times are exponentially distributed. In other areas of Civil Engineering, similar approaches have been used in modeling rainfall (Cowpertwait et al. 2007) and analyzing motor vehicle crash frequencies (Ma and Goulias 2007). In such studies, the challenge has been in appropriately estimating parameters that define the processes. Indeed, the attractive memoryless property, unique to the exponential distribution (and its discrete counterpart the geometric distribution) provides significant analytical advantages (Vaughan 2008). While the assumption may be justified in certain cases, often in the absence of validation, it leads to conservative estimates of reliability (Chu and Durango-Cohen 2008).

In reality, failure rates often are not constant. The Weibull and Gamma family of distributions provide alternative better fits in such cases. The exponential distribution is a special case of both these families of distributions. Specifically, a 2-parameter Weibull distribution is a continuous probability distribution with the density function:

$$f(t;\alpha,k)=\frac{k}{\alpha}\left(\frac{t}{\alpha}\right)^{k-1}e^{-(t/\alpha)^k} \qquad t\geq 0$$

and cumulative distribution function:

$$F(t;\alpha,k) = 1 - e^{-(t/\alpha)^k} \qquad t \geq 0$$

where k is the shape parameter, α is the scale parameter. When $k=1$, the Weibull distribution has constant failure rate at any time t and reduces to the exponential distribution. The 3-parameter Weibull introduces an additional location parameter τ on top of two-parameter Weibull to describe a right shift of the distribution. The density function is given by:

$$f(t;\alpha,k) = \frac{k}{\alpha}\left(\frac{t-\tau}{\alpha}\right)^{k-1} e^{-((t-\tau)/\alpha)^k} \qquad t \geq \tau$$

and distribution function is

$$F(t;\alpha,k) = 1 - e^{-((t-\tau)/\alpha)^k} \qquad t \geq \tau$$

Our research efforts in this study is similar to Korving's (2006) work as both aim to evaluate reliabilities of sewer systems through analysis of failure data. Instead of focusing on pump failure data, sewer blockage dataset is the target. This study also supports the use of interactive simulations to support decision making in co-dependent infrastructure systems (Mukherjee et al. 2010).

Methodology

The main challenges in characterizing failure datasets using stochastic models are 1) datasets could be incomplete or not representative, 2) finding suitable distributions to describe the event arrival process. While the Poisson process is often assumed, other distributions might provide better fits and provide deeper insight into the behavior of the system. These challenges were addressed by analyzing a sewer blockage dataset. The municipality under observation is a small town with no major industry located in the vicinity. The predominant use is housing while commercial use only accounts for a small portion. The town consumes about 1.1 million gallons of water per day. There are about 1500 customers, of which 1100 are single-family units (Houghton-City 2009). Sewer event data was obtained from hand written records and manually organized in digital spreadsheets. The dataset covers sewer events collected on all sewer pipelines running through the town. Events recorded were categorized into new construction, maintenance activities, failures and blockage rescues. Sewer blockage event information included occurrence date and location, type of obstruction, and total time required to repair the problem. The entire dataset consisted of records from 1996 to 2006. The study used records from 1996 to 2003, as the records between 2004 and 2006 were ill maintained and incomplete. Most blockage events reflected in the historic data records are related to pipes with sizes smaller than 24 inches in diameter. No repeated blockages were found at one specific location. Data analyses were performed on the inter-arrival times datasets derived from blockage events.

The analysis procedure is described in Figure 1. Raw failure data was evaluated and blockage failures were identified by occurrences of sewage backup events or overflow events. In order to ensure that the dataset provided a representative sample, a two sample Kolmogorov-Smirnov test was done to check if sub-sets of the data were similar to each other – and therefore by extension, if the dataset was a suitable sample for study. This was followed by a goodness of fit analysis using the Anderson-Darling test to select a distribution that suitably

characterized the inter-arrival times. In particular, exponential and Weibull inter-arrival times were compared for the accurate description of failure arrivals.

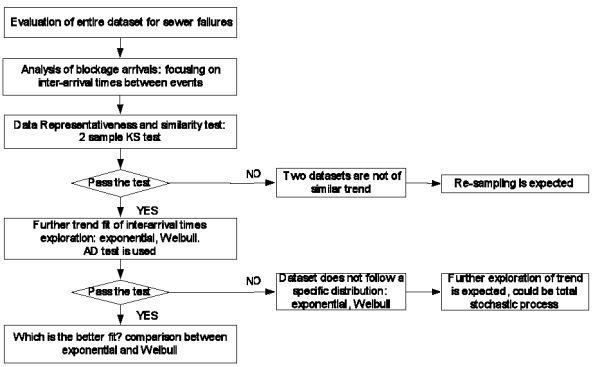

Figure 1: Procedure for blockage arrivals analysis in sewer systems

Inter-event Times Analysis

Theoretically, in a continuous Poisson process, no more than one event occurs at the time interval Δt. However, the dataset contained instances in which more than one blockage failure was recorded per day. Hence, a day could not be used as a suitable time increment. Instead, the smallest unit of time was chosen to be an hour, and events were randomly assigned occurrence times over the 24-hour period within which they were recorded.

The longest inter-arrival time in the dataset was found to be 83 days – significantly longer than all the other records, which were less than 45 days. This instance was considered an outlier, most likely an outcome of incomplete records. Hence, the data point was truncated and tests were done upon the corrected dataset.

Data Representativeness Analysis

Data used in this study covers a time duration from 1996 to 2003, which have relatively complete records of blockage occurrences (henceforth referred to as the *applied dataset*). We believe that this dataset suffices to represent blockage failure patterns for this municipality after 1996. To prove this, two sets of tests were performed. Firstly, inter-arrival times of dataset in this study were tested against all available data to test for representativeness. Secondly, tests to validate consistencies between datasets were performed by comparing the entire dataset to split sub-datasets. Collected blockage events were grouped into 2 split datasets, which were noted as split1 and split2. Split1 covered all samples collected in the first 4 years and split2 included data recorded in the next 4 years. To test if there was a significant difference between these datasets, a two-sample Kolmogorov-Smirnov (KS) test was performed. The null and alternate hypothesis was as follows:

H_0: The two datasets have a common distribution.

H_a: The two datasets do not have a common distribution.

Figure 2(a) below illustrates comparisons between the sub datasets and the applied dataset, plotted on a cumulative fraction basis. Under a given 95% confidence level, the null hypothesis cannot be rejected (p=0.8004). Figures 2(b)-(d) display comparisons between samples from data split1, data split2 and applied dataset. The hypothesis of a common distribution can be accepted for data split1 and data split2. Similar conclusions can be made regarding the split datasets and applied dataset as illustrated in Figures 2(c) and 2(d). Having confirmed that the dataset has a common distribution the next step was to establish specific distribution trends to characterize blockage arrivals.

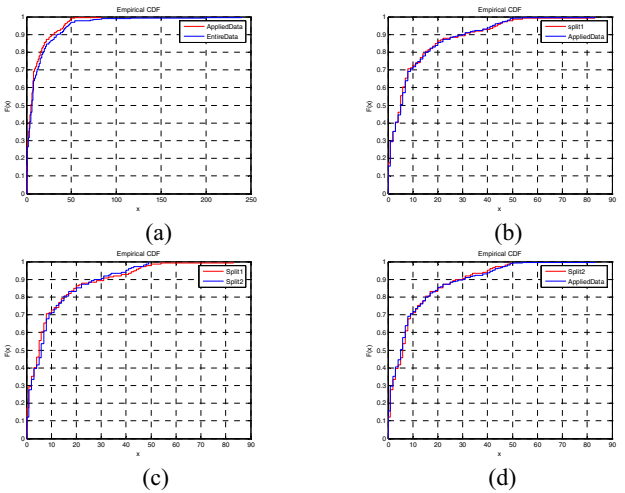

Figure 2: KS-test Comparison Fraction Plot between: (a) Applied dataset and Entire dataset, D=0.0532, P=0.8004; (b) data Split1 and Split2, D=0.0976, P=0.4799; (c) Split1 and Applied dataset, D=0.0503, P=0.9697; (d) Split2 and Applied dataset D=0.0472, P=0.9796.

Distribution Fitting of Inter-event Times

This section describes how the distributions of inter-event times were determined. The Anderson-Darling (AD) goodness-of-fit test was used. This null and alternate hypothesis for this test is as follows:

H_0: The dataset follow a specific distribution,

H_a: The dataset does not follow a specific distribution,

Significance level: 0.05.

Tests were performed upon datasets based on a yearly duration as well as datasets combined per wider time ranges, namely per 2 years, per 4 years and per the entire dataset. Test results were compared and discussed respectively for each timing combination.

Exponential distribution fitting and analysis: Table 1 lists exponential fitting results applied upon categorized datasets. Given a 95% confidence level, the

null hypothesis of an exponential distribution could not be rejected for each annual dataset. When the period was expanded to 2 years or higher, the null hypothesis could be rejected at the given 95% confidence level. There are multiple factors leading to such test failures. Major external weather events, and/or variations in external forces may induce high frequency events may be one reason. To further explore this, a Weibull distribution was applied upon the inter-arrival times datasets.

Table 1: Exponential distribution tests results for all timing combinations (1year, 2 years, 4years and entire dataset)

Year	λ	Failure rate	P value
1996	12.57	0.0796	0.138
1997	8.332	0.1200	0.664
1998	12.04	0.0831	0.052
1999	7.989	0.1252	0.109
2000	10.72	0.0933	0.204
2001	7.831	0.1277	0.245
2002	13.19	0.0758	0.589
2003	9.446	0.1059	0.084
96-97	10.17	0.0983	0.018
97-98	10.16	0.0984	0.011
98-99	9.930	0.1007	0.005
99-00	9.310	0.1074	0.024
00-01	9.147	0.1093	0.041
01-02	10.37	0.0964	0.039
02-03	10.92	0.0916	0.045
96-99	10.39	0.0962	<0.003
00-03	10.19	0.0981	<0.003
96-03	10.28	0.0973	<0.003

Weibull distribution fitting and analysis: Multiple factors contribute to blockage occurrences. As a result, failure arrivals are not completely random, as a Poisson process would imply. Hence, the Weibull distribution was tested for a suitable fit. Table 2 lists Weibull test results, it can be seen that except data sub-sets 2000-2003 and 1996-2003, all others generate *p* values greater than 0.05, which support a Weibull distribution fit for the inter-arrival times. Further examination on the tests reveals that the shape parameters are smaller than *1* for all datasets. This means that compared to an exponential distribution, a higher probability density was noticed for short inter-arrival times. Given that a Weibull distribution reduces to an Exponential distribution when the shape parameter equals to *1*, it can be seen from the shape parameters in Table 2, that the behavior of the dataset can be approximated using a Poisson process over short observation periods. However, when the observation period is extended, various impacts skew this exponential trend. Thus, a Poisson process cannot be validated for the entire observation period. Instead, blockage arrivals are better characterized by Weibull distributed inter-arrival times.

In order to understand why Weibull is a better fit, we further investigated the underlying contexts. Such Weibull inter-event times are mainly caused by more frequent than a 'general random' arrival of blockages during certain times of the year. To illustrate this, figure 3 below depicts total blockage numbers versus each month categorized from the entire data population. High numbers of blockages were noticed from March to May. This can be attributed to increased flow from snowmelt. Another gentler increase was also observed at the end of year, which is believed to be caused by intensive human activity.

Results in Table 2 also reveal that the dataset fails the null hypothesis of a Weibull distribution for dataset 00-03 and the entire dataset respectively. To handle this situation, a 3-parameter Weibull distribution was further applied, where a new location parameter is introduced. It can be seen from Table 2 that all datasets tests have p values greater than 0.05. These additional location parameter adjustments assist to handle the heavy tails accumulated over time, although they do not significantly impact parameters for distribution shift. Analysis of inter-arrival times datasets was also performed by using the Gamma distribution family. Test results were found to be similar to those from Weibull distribution tests, both of which are two- or three- parameter distributions. Weibull distributions provide better fits for datasets covering wide time periods.

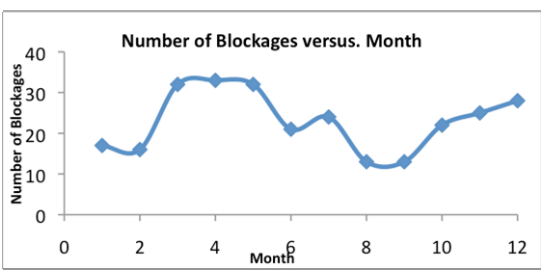

Figure 3: Number of blockages versus month

Table 2: Weibull distribution tests results for all timing combinations

Year	Shape parameter	Scale	P value
1996	0.7990	11.11	>0.25
1997	0.8868	7.490	>0.25
1998	0.8101	10.73	>0.25
1999	0.8180	7.144	>0.25
2000	0.8438	9.800	>0.25
2001	0.8836	7.318	>0.25
2002	0.9435	12.85	>0.25
2003	0.8297	8.487	>0.25
96-97	0.8201	9.096	>0.25
97-98	0.8192	9.085	>0.25
98-99	0.8052	8.795	>0.25

99-00	0.8305	8.418	>0.25
00-01	0.8666	8.468	>0.25
01-02	0.8720	9.645	0.21
02-03	0.8702	10.15	0.231
96-99	0.8042	9.178	>0.25
00-03	0.8612	9.042	0.037
96-03	0.8351	9.308	0.012

Table 3: 3-parameter Weibull tests for datasets

Year	Shape parameter	Scale	Location parameter	P value
96-99	0.7817	8.965	0.05938	>0.50
00-03	0.8343	9.154	0.08414	0.105
96-03	0.8102	9.079	0.07006	0.061

To sum up statistical analyses in this section, Figure 4 depicts all test results upon available inter-arrival times datasets. Specifically, a one parameter exponential distribution fits annual datasets favorably. Standard Weibull (2-parameter) distributions generate better fits for datasets covering 2 years ranges. Similar results are indicated from Gamma distribution test fits. The exponential distribution fit can only be approximated for short observation periods. A Weibull distribution fit or close approximations were also noticed for 4-year datasets and the entire dataset, an additional location parameter assists to produce better fits at this level. Theoretically, an exponential distribution of inter-arrival times implies an underlying Poisson arrival process. However, multiple real life impacts usually skew this exponential trend to a certain extent. Specifically in this study, snowmelt and intensive human activity lead to Weibull inter-arrival times of blockage event sequences.

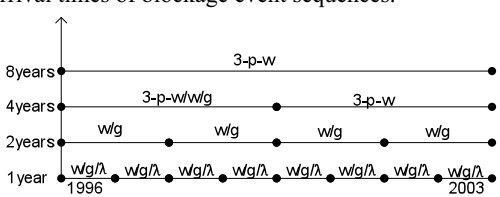

Figure 4: Test results for different time duration combinations (1year, 2years, 4years, 8years)

Note: only successful tests are shown in the chart. w/g/**λ**=all Weibull, Gamma and exponential distributions pass tests, Weibull is the best fit; **w/g=** both Weibull and Gamma distributions fulfills tests, approximate exponential distributions are noticed; 3-p-w=3 parameter Weibull distribution pass AD tests, which are only used on datasets 4years and entire dataset, approximate 2 parameter Weibull is noticed.

Discussion

Three target distributions were tested, namely, the one-parameter exponential distribution, the two- and three-parameter Weibull distribution and the Gamma distribution. Usually, a two- or three- parameter distribution is always more likely to fit a data set as additional parameters provide a more complete description of data

sets characteristics. In this study, the shape parameter in the Weibull distribution provided insight into the nature of blockage failures. In addition, a detailed analysis over sub-data sets and consideration of time trends, illustrated the possible influence of local factors and usage patterns. Trend of inter-arrival times in this study displayed a Weibull distribution with a shape parameter $k < 1$, a close approximation to an exponential distribution ($k = 1$) as shown in Figure 5. This implied a higher density of shorter inter-arrival times, that identified higher frequency of event occurrences due to snowmelt and periods of increased human activities. Data sets used in this study were collected from a sewer system of a small town. For a large sewer infrastructure system, the same method can be extended and used across data subsets classified by usage areas, blockage scenarios, and soil conditions to get a better understanding of underlying system behavior.

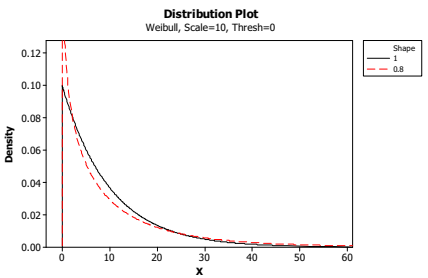

Figure 5: Probability density function for shape parameter k=1 and k=0.8

Conclusion

This paper proposes a methodology to study sewer systems serviceability given a blockage occurrence dataset. Blockage events were found to arrive in a process with Weibull inter-arrival times. Specifically, a Poisson arrival process holds true over short observation periods and an approximate Poisson model can be assumed over longer observation periods. However, a more precise description of Weibull inter-arrival times was noticed resulting from real life impacts that vary regionally. Further applications can be performed by employing properties of a Poisson process and distribution in order to estimate failure rate in order to assist stalk-holders in the decision making process.

ABSTRACT

As an on-going project, the main objective of this research is to develop a framework for the functional and widely accessible Geographic Information System tools to track information collected throughout the highway construction and maintenance projects in the state of Nebraska. Microsoft's Bing Maps and Google's Google Earth are both being investigated for possible integration with the Nebraska Pavement Management System. A test system has been built utilizing an increasingly large data pool previously created from the past hot mix asphalt (HMA) projects. Different data types including: physically marked locations, digitally marked locations, density reads, moisture readings, weather information, and temperate segregation were linked together using Google Earth that can be accessible from the field or the office. The developed framework is identified as a feasible solution to supplement the existing Nebraska Department of Roads (NDOR) pavement management system(PMS) with an upgradeable, efficient, and user friendly web-based interface.

Keywords: Hot Mix Asphalt (HMA), geospatial data management, Pavement Management System (PMS), GIS, interoperability

1 INTRODUCTION

There are over 5.7 million miles of roads stretching across the United States (FHWA 2008). These roads are comprised of concrete pavements, hot-mix asphalt pavements, overlays, sections paved recently, sections paved 15 years ago, and the list goes on. It

is crucial that some form of data management system be used to effectively monitor, maintain, and improve the national roads system. Wlaschin, director of the Office of Asset Management for the Federal Highway Administration (FHWA) describes such factors as "an aging national infrastructure, increasing congestion, expanding traffic, and limited funds," as weighing heavily on state and local transportation agencies. Wlaschin goes on to explain that one of the keys to lightening the load on these agencies is through the use of Transportation Asset Management (TAM). TAM is a systematic and strategic approach at maximizing system performance and minimizing life-cycle costs while providing the greatest return on each transportation dollar invested. TAM can almost be seen simply as a system that provides decision makers with efficient tools to most appropriately make informed decisions that are aligned with the maximization of utilizing transportation assets (Washington 2008). Perhaps the most important tool in a TAM system is the concept of a pavement management system (PMS).

Currently, every state uses some form of a pavement management system although it was reported that only five states were using such tools in 1980 (Finn 1997). The evaluations of roadways under these fledgling systems were rudimentary at best. Road tests often simply involved the subjective and monotonous process of visually surveying of the pavement (Finn 1997).

Initial management systems would use databases of collected data to rank and prioritize roadway projects on a "worst first" basis (Finn, 1997). Through the use of their PMS, Washington State was able to investigate pavement repair, overlay and overhead costs for the rehabilitation of hot mix asphalt (HMA) for various pavement conditions and couple that data to evaluate their programming and funding distribution policies. What Washington found was that they were often times rehabilitating a road too soon or too late and in turn either wasting the useful life of the road or roadway maintenance funds. By effectively utilizing a pavement management system, Washington has found the worst first philosophy to be flawed and transitioned into a life-cycle cost philosophy to determine which roads are slated for primary attention (Washington 2008).

Today's pavement management system is quickly being recognized as a vital decision making tool for pavement managers. To be an effective tool, pavement managers are beginning to demand (or expect) their PMS to provide a high level of visualization, be easy to use, and accessible whenever and wherever needed.

Visualization is the key in clearly communicating data and ideas to one another. Whether it is from a simple graph of complex data to complete virtual Building Information Models tied to schedules and estimates; visualization of data promotes understanding. PMSs have historically provided a means of representing data in simple tabular charts and graphs; however pavement managers are now demanding 2D or 3D geometrically mapping tools to sort and explain collected data. A graphical representation of what components make up a Geographic Information System (GIS) is shown below in Figure 1.

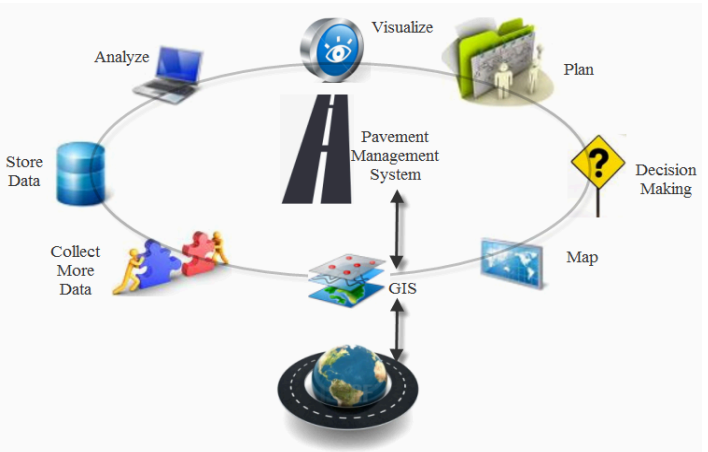

Figure 1 GIS Cycle

Usability has been a problem with PMSs in the past. During the 1980's when PMSs were still coming of age, the civil engineers typically in charge of these systems found it hard to fully trust their results. Basic knowledge of economics, computer programming, statistics, and operations research were required to fully understand how the systems functioned, unfortunately most civil engineers were untrained in these areas. PMSs have proven their usefulness to today's pavement engineers; however usability remains crucial in supporting the user's confidence in the system's outputs. Integrating GIS software allows for a map interface to provide mangers with an overview of an entire roadway network, or focus in on data parameters of a specific stretch of road. Managers are also able to create user specified preferences like color coding or user formatted results all with the click of a mouse (Allen 2007).

Transportation asset management involves the coordination of a number of agencies on a number of levels. It makes little sense for the water company to rip up a stretch of road to make repairs, and then repair that section of road if the gas company will need to do the same thing two months later. This often happens because of a lack of coordination and communication among different agencies. PMSs must be widely accessible and interoperable to all those who have a stake in roadway management. PMS-GIS integration allows users from many organizations, from traffic, and sanitation, to public safety and public works, to quickly identify specific pavement areas of interest for their agency while promoting coordination to mitigate project rework and loss of pavement service life (Saunders 2005; Allen 2007).

2 RESEARCH OBJECTIVE AND APPROACHES

As an on-going project, the primary objective of this investigation is to develop a framework for the practical development of a functional and widely accessible

system to manage and track collected data while representing that data in a highly graphic, and user friendly manner. The approaches to accomplish this objective are as follows: (1) investigate an appropriate geospatial framework in which to implement the proposed data management system, (2) utilize a geospatial program such as Google Earth or Bing Maps application as a means of providing users roadway data in a highly visual, highly accessible, and user-friendly manner, (3) personally validate the effectiveness of the selected geospatial program as a data tracking system in highway applications while testing its interoperability between current and proposed components of the Nebraska Department of Roads(NDOR)'s PMS(NPMS). Figure 2 illustrates these proposed approaches through the current NDOR research projects.

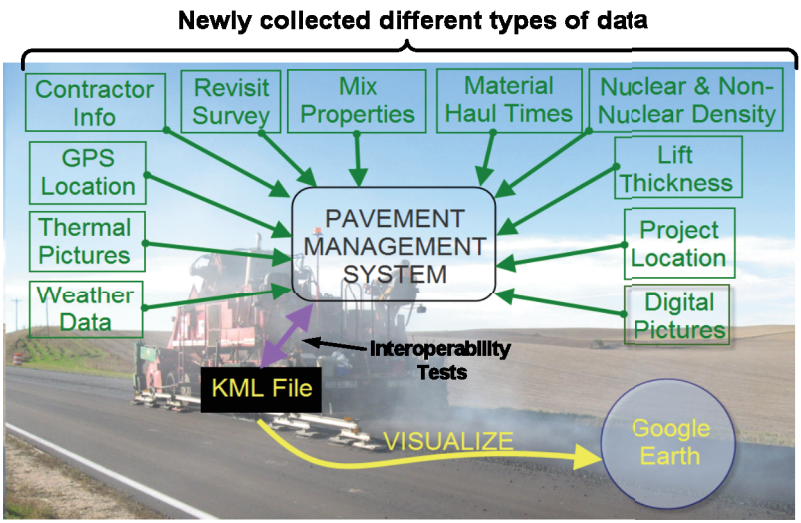

Figure 2 Proposed approaches to develop a framework for a web-based integrated pavement management system

3 IMPROVING THE GEOSPATIAL FRAMEWORK WITHIN THE STATE OF NEBRASKA

Before developing the project specific data management tool, a preliminary investigation was carried out to analyze the State of Nebraska's current geospatial management system and viewing framework. The analysis was completed in order to understand how the State's existing framework might be improved for both internal and external staff.

An overview of proposed framework layout is shown in Figure 3. NDOR's current framework is structured in such a way that one stake holder has complete control of all information that is distributed out to other interested parties. The core of the data

structure is the NPMS which is where all data and analysis take place. Relevant geospatial data pertaining to roadway construction and maintenance is funneled through a Pavement Optimization Program (POP). The POP program is maintained and controlled by internal staff at the NDOR headquarter, where it performs all geospatial data analysis through a number of programs. Furthermore, these analyses are updated once a year and mailed to the appropriate district offices. The district offices also have the capability of using at least three different needs specific software programs to view geospatial data from the State's database, e.g., FHWA GIS. The current NDOR PMS is built upon an intranet connection; meaning that only individuals within the organization have the security to access the needed information.

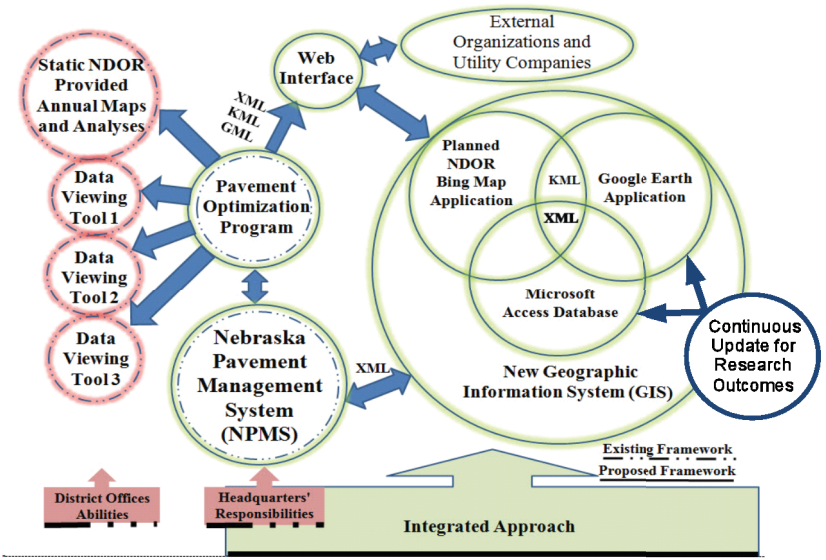

Figure 3 Proposed framework for data Integration (interoperability) with Nebraska's Pavement Management System

The NDOR has recently begun to investigate possible options to upgrade their current system due to its limited data visualization capability and difficult accessibility from the users. As one of the options, the State has begun the surveying of its roadway system with the Pathway, an advanced road profiling system. The profiling system collects information on rutting, cracking, raveling and other pavement flaws, while it continuously records video footages of the road and tags all collected information to an exact location. The level of geospatial detail this new profiling system generates necessitates the need for updated software.

After the data has been collected and uploaded to the State's mainframe, up-to-date information should be able to be viewed year round. The viewer should also be

flexible enough to be easily customizable by its users. It is identified that mainstream geospatial mapping programs like Microsoft's Bing Maps and Google's Google Earth programs are most appropriate as a web-based user interface. It is because these mapping programs have been widely tested, and once implemented come with vast support communities making further development and troubleshooting easier. Additionally, these geospatial programs allow for unique layers to be created that could contain almost any assortment of information. The layers features within these programs will allow the NDOR to combine the different viewer programs currently in use into one simple geospatial platform, and in turn save software maintenance cost and annual licenses fees.

The proprietary nature of the current State framework should also be addressed. Although it is understandable that the State does not wish to share all database information with whoever is interested in looking at it, certain information should be provided to relevant stakeholders. Rather than giving direct access to the organization's intranet, access to specific data layers within the geospatial program should be granted to certain stakeholders via a secured simple internet connection. Allowing outside viewing and contributions to the State's transportation information promotes an increase in the level of coordination that be achieved between organizations. For example, utility and railway companies are able to coordinate when scheduled maintenance or construction can more easily take place.

Also, the proposed framework includes the research information component which is connected to State's PMS as shown in Figure 3. The related academic or industry research outcomes can be continuously updated through one of the introduced geospatial programs above. In this research, research outcomes were continuously updated through Google Earth as a main research progress communication tool between the university research group and the NDOR research group during the entire period of research. Further details will be introduced in Section 3.1.

Data Interoperability

It is important to consider how such web-based geospatial programs will be integrated with the existing and future PMS. The Texas Transportation Institute of Texas A&M University highlighted this issue in their development of a web-based tracking system for flexible pavement. The Institute noted that a system based on the eXtensible Markup Language (XML) schema promoted easy data or file exchange (Krugler et. Al 2006).

The current Google Earth program is built on a Keyhole Markup Language (KML). In turn, the KML language schema is based on XML and was created specifically for the representation of geographic data (Open Geospatial Consortium 2009). To reduce the file size, a KMZ file format is widely used. A KMZ file is simply a zipped KML file. KML files can be converted to XML files and vice versa by opening the KML file in a text file followed by opening and saving that text file in Excel as XML data.

As an initial attempt, the Nebraska Department of Roads (NDOR) has been testing Bing Maps within their organization for its adoption. It is convenient to note that Bing Maps is also capable of reading KML files in much the same way Google Earth is as shown in Figure 3. However, the interoperability between competing programs is always a concern. In an effort to formulate the pavement data management system as well as test the interoperability between the State's new and existing geospatial framework, Google Earth was selected in this study as the program upon which to build the project specific database.

As previously shown in Figure 3, the XML file schema was found to be common between the State's current Pavement Management System(PMS) as well the two geospatial programs and Mircosoft Access used in this study, providing the bridge between the recommended software programs and existing framework components. As an on-going project, several different data types shown in Figure 3 are being tested among Microsoft Access, Bing Maps, and Google Earth to identify the interoperable formats of data structure and data file. It is identified from this study that a KML file (as well as an XML file) working for Google Earth is not always readily working for Bing Maps, or vice versa for certain types of data format such as image data and multimedia data. The current test results of interoperability are not yet at the stage for the further discussion in this paper, thus the detailed test results and recommended data formats will be introduced in near future.

3 GOOGLE EARTH'S APPLICATION ON HIGHWAY PAVING CONSTRUCTION PROJECTS

It became apparent that the research group's undertaking of a project for the Nebraska Department of Roads (NDOR) necessitated a system to efficiently manage the growing pool of collected and analyzed data that had been accumulated up to that point. The research project involved the visitation of several paving sites across the State of Nebraska to investigate the relationship between temperature segregation and material density in hot mix asphalt (HMA)(Cho et al. 2009). Figure 4 shows a site summary of an individual research site in Google Earth after data analysis.

3.1 A Case Study of Google Earth Usefulness as a PMS Tool

In order to perform this investigation, a number of devices were utilized, those devices included: 1) a portable anemometer to record current weather conditions, 2) portable GPS unit to digitally mark areas of interest for later revisit, 3) a thermal imaging camera to locate areas of HMA temperature segregation, 4) a penetrating thermometer to validate the thermal camera, 5) a digital camera to record site conditions and procedures, and 6) nuclear and non-nuclear pavement density devices to measure the compacted density of the material. In addition to the data collected via portable devices, site specific information was noted that included: 1) pavement or mix type, 2) lift thickness, 3) haul time, 4) equipment used, and 5) location. As shown in the proposed framework in Figure 3, Microsoft Access was used to build a database for all collected data and results of analysis and comments.

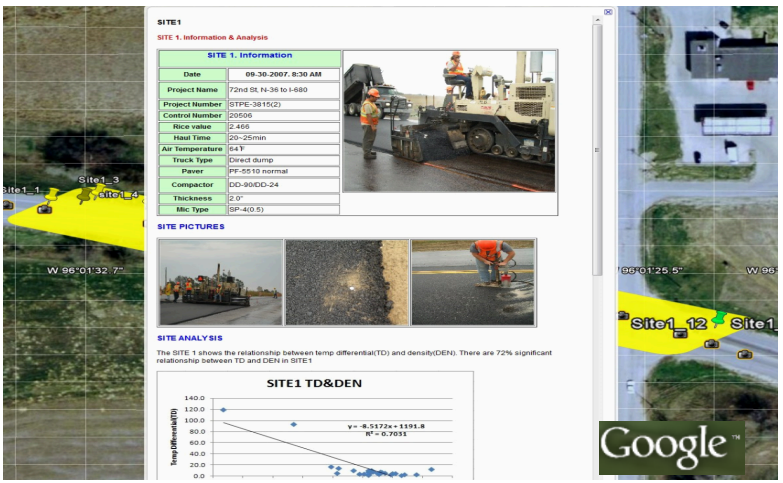

Figure 4 Google Earth Based Visualization of Pavement Data

The system was constructed during the paving offseason, and ready to be utilized at the start of the paving season in Nebraska. That spring all previous sites were revisited in an effort to measure and identify any change in overall pavement quality. Changes in quality were documented in MicroSoft Access and imported into the Google Earth Data Management System that had been created. After all information from the revisit was uploaded, users were able to simply "fly" around within the Google Earth program and select individual sites to focus on, and view relative site specific information (Figure 4). Once a particular site had been selected, users are able to further focus on a site specific data point (Figure 5). For instance, when a flaw was noted at a specific location during site re-visitation users were able to immediately call up that exact location to view germane information that was logged at the time of construction that might explain the pavement's premature failure. Paved road sections were highlighted and high temperature segregation spots were pin-pointed with different color based on the severity of temperature segregation (Figures 4 and 5). Not only virtually marked in the Google Earth database system, the pin points were physically marked at the corresponding locations on the pavement for the purpose of site revisit later (Figure

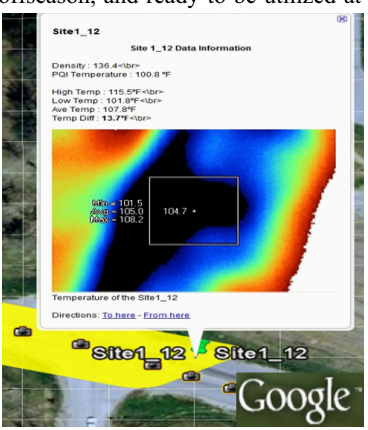

Figure 5 Specific Pavement Data (thermal)

6). These marks were used to locate an exact spot to inspect any premature failure or distress developed around the mark after a couple of freeze and thawing cycles.

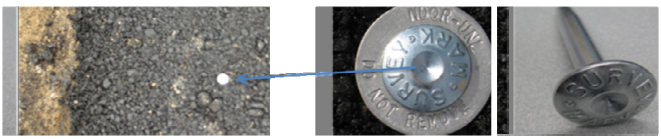

Figure 6 Marking a high temperature segregation point on the pavement

Google Earth used as a part of the NDOR research project enabled the sponsored NDOR research group to have a better understanding of the research outcomes and progresses. It is because the NDOR research project sponsors/managers were able to instantly recall location specific data, typically in a highly visual manner, making decision making more fluent and reliable, which are not available from the current NDOR PMS. Its inclusion made the university research team communicating research conclusions easy to relay to them.

4 CONCLUSIONS AND RECOMMENDATIONS

This paper has introduced web-based geospatial data management system as a cost-effective GIS tool to be integrated with the State of Nebraska's Pavement Management System. After compiling a brief analysis of available literature, as well as current pavement managers' needs regarding pavement management systems, a simple model encapsulating those findings was created and tested through a real life application in HMA pavement construction and maintenance.

A brief study was also conducted on the State's current geospatial framework and how changes might be made to improve it. The research team found that a number of the standalone programs used for specific tasks should be integrated into one consistent platform. Current mainstream geospatial mapping programs like Bing Maps and Google Earth were recommended as capable in fulfilling the State's needs. The investigation also found a need to share up–to-date information with outside organizations including companies and universities in an effort to promote synergistic coordination. The level of sharing could easily be accomplished by making certain layers of NDOR provided data which is viewable on programs like Google Earth via simple web interfaces.

Users of the created management system including the NDOR research sponsors and the authors found its application in tracking pavement information very useful and intuitive. The developed system in this study was highly customizable and portable. Adjustments to the system are continuous as data and procedures are constantly updated from other pavement research projects. The system's use has improved how this research group's transportation research data is collected, analyzed, and shared.

For future study, such geospatial data management systems including Google Earth and Bing Maps need to be further investigated for their interoperability with different data types and data structures commonly used in States' PMS or Transportation Asset Management (TAM) systems to be successfully utilized for State's infrastructure management.

Infrastructure and Energy OR Energy and Infrastructure: How Energy Demand and Infrastructure Impact Each Other and What Carbon Limits Will Mean for Both

Stephen Sewalk[1] And Ken Strzepek[2]

ABSTRACT

This paper examines how energy and infrastructure impact each other and what that means for carbon limits and peak oil. Throughout history mankind has always had ample sources of energy to rely on. This reliance on energy, particularly through the industrial revolution, allowed mankind to build a modern lifestyle. However, as infrastructure has evolved and become more complex the world has demanded greater supplies of energy. Initially this demand for energy was met with nearby supplies. However, as those supplies have decreased, more energy is needed from further and further away. This has meant that greater and more complex infrastructure has had to be built to supply the energy resources from greater distances. The easy energy resources have also been tapped resulting in a need to expend more energy to unlock the remaining sources of energy. Now, as the world ponders carbon limits and potentially faces peak oil the viability of our existing infrastructure and the energy that supports it is a cause for great concern. Are we taking into account our future energy sources as we build more and more infrastructure? In a world of constrained resources building infrastructure without regard to energy could significantly impact the price we pay for energy as well as the viability of the infrastructure. Infrastructure and energy is an important discussion as it will impact our standard of living and how we plan now for 2050.

INTRODUCTION

The demand for energy around the world has accelerated. With the advent of cheaper energy sources, global demand for energy has doubled every 25 years since 1900, and in 2000, the world demanded 16x more energy than in 1900 (Smith 2009). From houses to transport to commerce mankind has increased its demand for energy significantly by increasing its infrastructure. Prior to the automobile and modern transport, transport was limited, goods were consumed locally and only specialty products would travel great distances. With the advent of the oil and its refined products the demand for autos, ships and airplanes has grown tremendously. With

these in great demand infrastructure had to be build to support them. However, once built the infrastructure makes it easier to consume greater amounts of energy.
One need only look at what happens when we build a highway expansion. The infrastructure allows more people to live further from the city in less expensive and larger housing. As infrastructure expands society demands more energy to use the infrastructure. The need for more energy increases the demand for greater infrastructure to ensure the energy can be supplied. Which further increases the demand for both energy and infrastructure. From living, to transport, to work, to eating, each has resulted in an expansion of both energy and infrastructure. The automobile requires gasoline, gasoline requires refineries, refineries need trucks, pipelines and ports, both require paved highways, which requires asphalt. Energy and infrastructure feed each other, with both requiring greater amounts of the other.
However, in an energy or carbon constrained world, we are not able to continue to build energy demanding infrastructure or pursue infrastructure demanding energy, otherwise we hit the constraint before achieving our objective. A Cap & Trade may well limit the amount of alternative energy infrastructure that can be built as well as how far away one can commute to work. Distant infrastructure requires significant energy to maintain. Peak oil would have a similar impact. Yet this understanding is not present in any discussion on carbon limitations nor on how it could affect the real estate and construction industry.

LIFESTYLE & INFRASTRUCTURE

Lifestyle is a choice, one that has a significant impact not only on our infrastructure requirements but also on our energy demands. In the US we have chosen to live in suburbs and in distant communities and as the US covers a much larger geographic area than Europe, this choice limits our ability to build efficient public transportation systems. However, given this choice the country has had to develop significant highways, bridges, and streets thereby facilitating the ability to move by car. The challenge is that these infrastructure projects have allowed further developments in more distant suburbs, thereby increasing our energy demand.

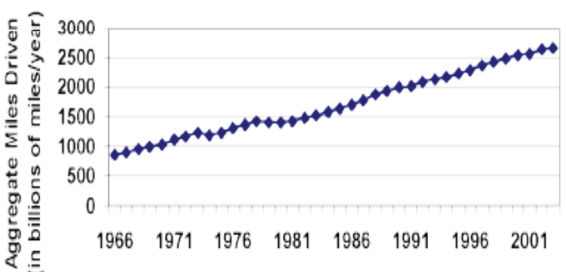

Figure 1: Aggregate Miles Driven in the USA

Source: FHA's *Highway Statistics* Table VM-1 (passenger cars plus single-unit 2-axle 4-tire trucks)

And although cars are more efficient than they used to be, Americans have chosen to drive more miles than they ever have before.

Year	Population	% Increase from Previous Decade	Millions of Vehicle Miles Driven	% Increase from Previous Decade
1970	203,302,031		1,039,986	
1980	226,542,199	11.4%	1,402531	34.6%
1990	248,709,873	9.8%	1,979,276	41.1%
2000	281,421,906	13.2%	2,523,346	27.5%

Within urban areas the public can rely on mass transportation (buses and subway), take a taxi or even walk as everything tends to be conveniently located. Cities, due to limited land availability and cost, favor apartments and high-rise buildings, while suburbs with cheaper land costs favor single homes. As a result of suburban sprawl, more infrastructure is needed to supply energy (power & gas lines, gasoline stations) as well as food, electronics and clothing (shopping malls, grocery stores). All which require more trucks to resupply.

A carbon cap or peak oil would have a significant impact on lifestyle as witnessed in this current recession. Both would increase the cost of existing energy sources resulting in economic disruption. As gasoline prices rise resulting in inflationary pressures throughout the economy, people became unable to pay their mortgages resulting in rising defaults. High transport fuel prices would favor infrastructure that uses less fuel, i.e. cities over suburbs, city center stores over suburban malls, and public transport over individual cars.

ENERGY & POWER UTILITY INFRASTRUCTURE

Based on the demand of cities and suburbs, along with industrial parks and government requirements, utilities planned and built in cooperation with the government an extensive energy and power network to meets the demands of society. With technology unable to provide distributive power in the quantities needed, large power plants were built to provide the power demanded.

With a massive increase in cars and miles of roads the oil industry had to build fueling stations and refineries to produce the gasoline, diesel and asphalt needed. This included a large increase in pipelines and trucks to transport the products to the ever growing and spreading population. Power utilities built large nuclear, hydro, coal and gas powered plants to provide electricity to the growing masses and to the economy. In each case when an oil company or a power plant company makes a decision to expand operations they take the assumption that they are price takers and that the energy source needed for their facility will be available in sufficient quantities to meet the demand of the society.

Today's society relies heavily on fossil fuels with transport being completely dependent on oil and electric generation relying on coal for 50% of power generation. However, under a regime of peak oil or carbon caps with naturally declining production or enforced cuts, prices would tend to rise rapidly significantly impacting infrastructure and energy demand.

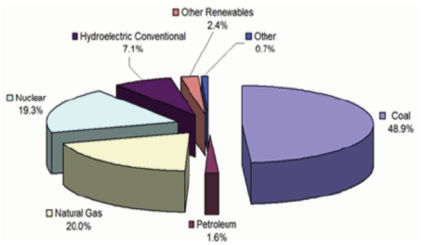

Figure 2: Electric Generation by Source

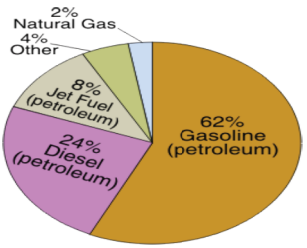

Figure 3: Transportation Fuel Use

Sources: http://www.eia.doe.gov/cneaf/electricity/epa/epat1p1/html and http://www.swivel.com/graphs/show/34587197

This is a significant threat to the current infrastructure in terms of maintenance and expansion, however, in planning, designing, approving and extending infrastructure projects this discussion is not taking place. In a country such as the US, if it were to achieve an 83% reduction in emissions of carbon dioxide equivalent (Energy 2009), then there would be need to be a corresponding decrease in the 200 million vehicles, 4 million miles of roads and over 1TW of electric generating capacity unless we are capable of restructuring our entire infrastructure from a high-carbon to low-carbon.

ECONOMIC GROWTH & PROJECTIONS

Rapid economic growth (as well as population) increased demand for energy significantly, not only in America but also in Europe, Japan and the Soviet Union after WWII. Recently the significant economic growth in China and India followed by Brazil and Russia has further increased the demand for energy. Economic growth and energy are closely correlated.

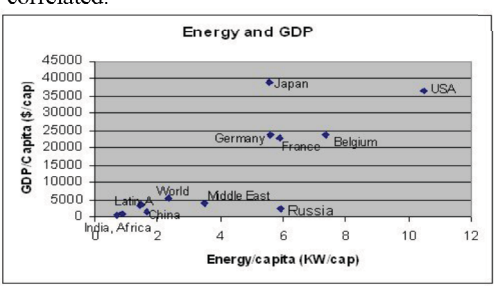

Figure 4: GDP versus Energy Consumed

Source: Graph produced from data in the 2006 Key World Energy Statistics from the IEA.

Based on the assumption of continued growth, agencies such as the EIA and IEA project global energy demand will rise significantly between now and 2030 based on rosy economic projections. This demand is due to increasing global infrastructure (roads, ports, pipelines, buildings, power plants) due to growing demand for vehicles and household appliances from increasing populations and increasing global GDP. The EIA in the International Energy Annual 2004 projects global energy demand to increase from 447 quadrillion BTU in 2004 to 702 quadrillion BTU in 2030

(International Energy Annual 2004). And while demand for energy within the OECD is only expected to grow by around 1% annually between 2004 and 2030, the projection for the developing world is between 2.5 and 3.75% annually for the same period (International Energy Annual 2004).

However, a key deficiency of these forecasts is the failure of them to take into account the supply of energy and the price of energy. These forecasts assume that energy sources, as they have always been available, will continue to be available at prices that will not impact demand. This can be clearly observed in the figures below, where energy demand continues to rise unhindered and the sources of these energy supplies are assumed to be available to provide for the demand. It is assumed that the demand and supply of liquid fuels (crude oil and petroleum liquids) will rise from about 120 quadrillion BTU in 1980 to almost 250 quadrillion BTU by 2030, the same holds true for coal, rising from around 70 to almost 200 quadrillion BTU, and for natural gas, rising from a little over 50 to over 150 quadrillion BTU (International Energy Annual 2004).

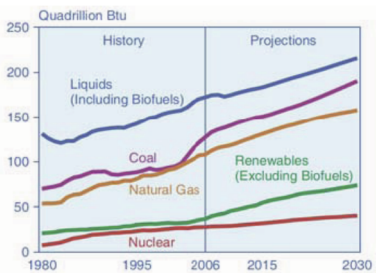

Figure 5: World Marketed Energy Use by Fuel Type, 1980-2030
Sources: http://www.eia.doe.gov/oiaf/ieo/world.html

The ability of the world, or for that matter OPEC, to supply the resources is not considered. The EIA and IEA project world oil production to rise from 80 million barrels per day in 2004 to over 120 million barrels per day by 2030. This estimate anticipates that OPEC will increase production from 30 to 50 million barrels per day and unconventional sources (tar sands, heavy oils and shale oil) will supply the remainder of 15 to 20 million barrels per day. There are several problems with these estimates, 1) OPEC and especially Saudi Arabia has publicly stated that they will not, 2) it does not take into consideration peak oil which is a real concern, and 3) there is a concern that the US pressured the IEA to be overly optimistic on supply forecasts.

More importantly with these projections of energy resources come forecasts of how much infrastructure will need to be built to extract those resources. For oil and natural gas exploration, development and production a significant number of drilling rigs, drilling muds, cement, and tubing among others need to be produced and delivered by truck or ship. As production increases or shifts to new areas this entails building new processing facilities, refineries, filling stations and roads, all of which require more infrastructure, particularly as more distant resources are brought into production. The same with electricity generation, expanding suburbs, and others, all of which require significant new infrastructure and will demand greater amounts of energy.

In 2000 the IEA (International Energy Agency) forecast that world energy investments would need to be $16.5 trillion between the years 2001 and 2030 (see table on next page) in order to supply the energy the world would need. Again, the key assumptions are very important, they are: 1) resources are available (geologically and politically), 2) peak oil and a carbon constrained world do not exist, and 3) that the world has the resources available (cash and materials) to build the infrastructure needed by the energy industry so that the energy industry can continue to supply the energy demanded by society.

The challenge with these projections however, is that they do not take into account how minerals are produced. In the case of oil production, a reservoir is discovered, it takes up to ten years before production begins, after several years production peaks and then declines. To achieve the goal of raising production to 120 million barrels per day by 2030, it would be necessary to stream (or bring into production) approximately 250 million barrels per day of capacity in order to raise total global production to the 120 million barrels per day. This is because on average production from existing fields is declining by approximately 4.5% per year.

Due to this concern, and the oil industry speaking out against these projections, the EIA and IEA have recently revised their forecasts to around 106 million barrels per day. However, the concern of a peak in production is not only an issue for oil production, but is also a significant concern for both natural gas and coal (McKillop 2006; Strahan 2008; Zittel 2007) which may also soon peak. These peaks are anticipated to occur after the peak in oil.

Table 2.2: **Global Energy Supply and Infrastructure**

		Units	2000	2030	Annual average rate of growth (%)
Oil	Production*	mb/d	75	120	1.6
	Refining capacity	mb/d	82	121	1.3
	Tanker capacity	million DWT	271	522	2.2
Gas	Production	bcm	2,513	5,280	2.5
	Transmission pipelines	thousand km	1,139	2,058	2.0
	Distribution pipelines	thousand km	5,007	8,523	1.8
	Underground storage working volume	bcm	328	685	2.5
Coal	Production	Mt	4,595	6,954	1.4
	Port capacity**	Mt	2,212	2,879	0.9
Electricity	Generating capacity	GW	3,498	7,157	2.4
	Transmission network	thousand km	3,550	7,231	2.4

* Oil production includes processing gains.
** The port capacity figures in this table do not include the capacity required for internal coal trade in China, India and Indonesia (cumulative additions for internal trade are 192 Mt of capacity).

Figure 6: Global Energy Supply and Infrastructure (Current vs. Forecast)
Source: EIA

The anticipated date for peak oil is sometime between 2008 and 2012. Peak oil while traditionally viewed as a geological phenomenon may also be a political phenomenon. After all political interference in oil production is very common and includes: the US government limiting exploration on over 75% of offshore coastal areas as well as Alaska; OPEC limiting international oil companies from exploring in their countries as well as national production limits; and the Russian government interfering with oil companies such as Yukos, Shell and BP. The biggest political limit could well be a cap-and-trade accord which by limiting emissions would significantly limit the amount of oil that could be consumed.

These individual country limitations as well as the geological limitations are not accounted for in the projections of how much energy resources will be produced in order to meet global demand. The assumption is that energy will be available to meet demand, without considering physical or investment constraints.

ENERGY INFRASTRUCTURE AND THE IMPORTANCE OF ENERGY

Taking natural gas as an example, as it is used heavily in both Europe and the US, one trillion cubic feet of natural gas (TCF) is sufficient to heat 10 million homes for one year. To bring that natural gas to market a significant amount of infrastructure needs to be in built to transport the gas from the field to the household. While this infrastructure is expensive to build and maintain, because of the previous availability of natural gas, the US is reliant on it for 23% of its energy needs.

To transport the natural gas, pipelines have been built across the USA and Europe/Russia. As older fields deplete it is necessary to add remote fields to the network. However, there is a supply constraint within the existing pipeline network, therefore the infrastructure needs to be expanded to accommodate the growth and the distance with which the newer gas needs to travel. In Europe, natural gas can travel over 3,000 miles in pipelines that connect Russian fields to European consumers. Greater distances require larger amounts of energy to bring the same amount of gas to market, thereby increasing GHG emissions for the same amount of natural gas supplied.

Of greater concern is that a cap-and-trade program on carbon would limit the amount of steel and concrete that can be used for energy each year, thereby limiting the ability to change the energy infrastructure the longer we postpone changing the infrastructure. Most renewable energy (wind, solar, geothermal) as well as nuclear power require significant amounts of concrete and steel. The majority of GHG emissions from these facilities are produced upfront during construction. Therefore, limited future emissions means renewable and alternative energy power plants need to be built sooner while caps and higher, as waiting could mean there are no excess carbon emissions allowed to build these facilities.

ESCALATING COSTS – THE LIMITS OF PRODUCTION

The major impact on both energy and infrastructure today is the escalating costs of production of energy and the resulting increase in the cost of infrastructure. These costs have been significant and are driven by the globalization process that has occurred worldwide. This globalization process meant that places like India, Brazil, China and Russia could join the world economy, grow rapidly, expand their manufacturing output and export their way to riches, much like Japan, Taiwan and Korea have done. This was possible during the 1980s and 1990s because the world was awash in excess capacity. This surplus capacity allowed for continuous rapid growth and besides the energy consumption of India and China was particularly low, so even though the growth was rapid it had a minimal impact on global demand. By the year 2000 things began to change, while rapid growth continued, the excess capacity began to dry up because growth was now significant. This impacted at first oil, then coal, steel, iron ore and many other minerals and fuels. China has had the biggest impact and it does not, for now, seem to be slowing down. This has led to rapidly escalating prices for all of these resources.

WORLD TRADE

Global trade has been based on cheap energy. China's and India's significant global expansion was predicated on cheap energy allowing corporations to take advantage of their cheap labor resources and manufacture goods for export without regard to transport costs or for that matter to the resulting pollution. However, as oil has risen from $ $30 to over $100 per barrel, transportation costs are beginning to have a significant impact on trade. At $100 per barrel transport costs are approximately 40% of total shipping costs and at $200 per barrel transport costs are 80% of total shipping costs (Hennigan 2008).

It may no longer be cheaper to move production from Europe and the US to China due to these significant transport costs, which would be exacerbated with peak oil. The labor cost advantage is being diminished by the energy cost of transporting goods thousands of miles. This could have a significant impact on future trade between countries, future growth rates, levels of pollution and per capita incomes.

Reverse globalization due to either increased oil prices or carbon limits would reduce pollution but this would also significantly impact world trade. The impact to world trade could result in more local construction but less heavy infrastructure used to move goods between nations. It is also important to note that while significant manufacturing capacity has moved to China in the past twenty years, this industrial capacity has been sustained by China only through the addition of significant coal generated electricity. This has generated significant construction activity, but made China the number one country in terms of GHG emissions. A move towards a carbon tax or a cap-and-trade that is properly applied to imports would end globalization as production center's move to demand centers.

THE FUTURE

The future depends significantly on the approach and policy of what we as a society decide with regards to energy and infrastructure. Let's examine two different approaches: 1) We seek to keep the infrastructure we have today while planning (hoping) to change the energy resources consumed, and 2) We attempt to keep using the same energy resources but change the infrastructure to make it more efficient. These two models will depend heavily on what we decide to do about global GHG emissions.

Infrastructure

Our current infrastructure is energy intensive. To replace oil, gas and coal it would be necessary to build an extensive energy system based on hydroelectric power, nuclear power, wind, solar, geothermal, and biomass. The need to replace the energy system is two-fold, 1) oil, gas and coal are carbon intensive and release significant levels of carbon along with other pollutants, 2) globally oil is projected to peak between 2008-2012, natural gas anticipated to peak around 2020-2030 and coal will peak in around 2025-2030 globally. With a global peak in energy, the cost of energy would continue to increase significantly. This increase is predicated on whether production peaks and then declines or peaks and plateaus for a significant period of time. The plateau would buy us time to change the energy used in the infrastructure. A world in this instance could develop battery powered cars, buses and trucks to save the oil for petrochemicals, plastics, medicines, and air travel. It could also develop hydrogen powered vehicles which could be extracted from nuclear, wind and solar. However,

solar and wind will not save the day, at least with present technology because of a lack of mega-storage facilities. But these sources could slowly replace oil, gas and coal and we could continue to live a similar life style, which is energy intensive, and revolves around the suburb.

Energy

Our current energy needs are derived from the infrastructure that we have developed, including large suburban areas, reliance on the car, and large homes as well as inefficient buildings. Given the fact of peak energy it would be necessary to improve our infrastructure to make it significantly more energy efficient. This could very well include a mass movement from the suburbs to the cities, resulting in the need for less cars and more public transport. This would be the high cost energy scenario where we continue to use our current energy resources, in great response to poor legislation from the government.

An alternative to this would be a pro-active government that stressed developing existing resources, including exploring for oil and gas offshore, in national parks, and in Alaska, as well as forcing other countries to abandon their national oil companies and closing down OPEC. This would entail the development of shale oil and a pro-nuclear policy to expand our energy resources.

The Impact of Carbon Limits

It is interesting to note that due to the hysteria of global warming, society or more aptly the politicians appear to be focusing their attention on limiting carbon and GHG emissions rather than understanding that should oil, gas and coal production peak within the next 5-20 years that this would in fact imply that the global emissions of carbon and GHG may have in fact a natural limit, which we cannot exceed. The danger being that unless alternative energy forms, along with more efficient buildings, infrastructure and transport systems are developed and made available, there could be a significant impact on economic growth and on the world's forests as people seek energy.

Should society decide to pursue carbon limits then it depends significantly on how the carbon limits are structured. We as an industry need to ensure that there are sufficient carbon emissions to allow for construction of new infrastructure that will utilize low-and-no-carbon emissions energy. An across the board carbon tax would be fairer but would impact agriculture, construction (infrastructure) and manufacturing. If levied properly it would provide no advantage to exporting pollution to other countries by moving manufacturing or energy production across our borders. The construction industry needs to ensure that the legislation moves towards a carbon tax rather than a cap-and-trade, otherwise it could significantly limit future construction.

This is because the current discussion in Congress focuses on a carbon cap-and-trade. A carbon cap-and-trade limits the amount of carbon that could be released within US borders, there is concern it will not cover imported goods. The legislation however would impact the cost of energy and reduce the demand for energy intensive infrastructure. This would be beneficial to the construction industry in terms of increasing demand for energy efficient buildings, because current building infrastructure consumes 40% of all energy and approximately 70% of electricity, 50% of which is currently derived from coal. The future of infrastructure with carbon limits and higher energy prices would result in greater density within cities, larger buildings

to accommodate the need to reduce travel, and could significantly reduce the number of cars the average family has assuming families migrate back to the cities to save costs. This could present a great opportunity for the industry as large buildings along with energy efficient ones are in high demand, this could well include retrofitting existing buildings for not only energy efficiency but also to accept solar panels and wind energy. However, it could well reduce the demand and maintenance for the transportation infrastructure as demand lessens due to emissions limits.

CONCLUSION

Peak oil, gas and coal, combined with rising energy prices and the high potential of carbon limits will result in demand for larger more efficient buildings, more energy efficient infrastructure, greater mass transport and more alternative energy resources (wind, solar, geothermal and nuclear). This presents an opportunity for the construction industry to ensure that they have access to not only people but to the raw materials needed for the coming construction boom to alleviate the energy shortages that the world is already experiencing. Those companies that develop a reliable supply chain of materials (with a focus on local sourcing) and people to build these projects will have greater opportunities as industry and people realize the impact of ever rising energy costs and how by altering the way they live and work can significantly improve their and their company's bottom line. To ensure this the construction industry needs to work with Congress to ensure that any carbon legislation includes provisions to allow for significant amounts of construction to replace the existing infrastructure to move the US into a low-carbon future.

ABSTRACT

The U.S. continues to face the challenge of correctly identifying underground utilities before beginning a construction project. Having accurately mapped utilities and knowing their location will increase efficiency in the construction process, reducing accidents and utility interruptions.

A methodology to integrate Global Positioning System (GPS) and laser technology will be outlined. This process will assist field technicians in collecting underground utility field location data, accurately and consistently, in a minimal amount of time, with less effort, while maintaining maximum safety. It will also form a framework to develop a permanent data solution in which data collected can be stored in a database and retrieved in a three dimensional geo-referenced map for future use.

This research focused on utilities which were installed using an open trench method. The integrated technology was tested under construction field conditions. The results of the research indicate that utility data can be collected quickly and cost effectively through this process. The positional accuracy of underground utilities was mapped in three dimensions (3D) within ± 0.45m accuracy.

KEYWORDS: Underground Utilities; Damage Prevention; Global Positioning System; Laser; Utility Locating Methods; Urban System Framework; Utility Safety; Utility Mapping.

INTRODUCTION:

While the concept of a buried asset is not new, the function that the buried assets serve is vital to modern living. It is fundamental that the buried asset networks are recognized as an important resource and one that requires careful management. The

underground world has become increasingly complex and more difficult to manage. The United States has a massive network of underground pipelines and cables including such items as gas pipelines, telecommunications, water pipelines, fiber-optic cables, storm water lines, wastewater lines, steam pipes, conduit systems and hazardous waste lines. In all, the U.S. underground infrastructure comprises about 20 million miles of pipe, cable and wire. Construction related damage to gas distribution systems increased 50 percent from 1996 to 2005 (PHMSA 2006). Records of location of utilities are rarely available and if available, most of the data is located relative to the ground level or physical features which may no longer be available or have been altered. Thus the exact location information of many utilities is unknown or very inaccurate.

Ground Penetrating Radar (GPR), Global Positioning Systems (GPS), acoustic, seismic, Radio Frequency Identifiers (RFID), electromagnetic and low frequency electromagnetic, and gyroscopic duct runners are various geophysical methods available to locate underground utilities. Detection of buried assets without excavation is difficult because of the ground conditions, age of the asset, the material the buried asset is made from, its contents, and the condition of the asset and the number of buried assets at a given location. None of these geophysical methods provide the complete solution for locating the utilities. No single technology or combination of devices is available to locate existing underground utilities with 100 percent accuracy (Costello et al. 2007).

A method that is less costly and which uses common equipment to collect location data of utilities accurately, safely, with less effort, and time during their installation will provide a foundation for finding the location of buried utilities at a later time. A data base that provides information on all existing underground infrastructure over a geographic region is essential for efficient planning and construction of both surface and sub-surface infrastructure.

The nation's drinking water supply needs $334.8 billion in infrastructure investments over the next 20 years for thousands of miles of pipeline to ensure the public health and economic well-being of our cities, towns, and communities (EPA 2009). Since the U.S. Government is planning to invest a significant amount of money for new installation, replacement, or maintenance of underground assets, this gives an idea about the need to locate existing utilities when they are exposed for maintenance or new utilities during installation.

BACKGROUND

Many times the location of a utility shown on site drawings varies from the actual position on site. This happens due to changes during design or plans. For example, another utility is found on the proposed alignment and the location of the line was not known at the time of planning. Questions often arise: Is the location information accurate? Can the reference used be located? Is the information from an "as-built" drawing or its design location? "Current practice of data collection is done on an 'as need basis', that is, there is not much coordination between who is doing what and what is located where" (Baffour et al. 2002).

The Common Ground Alliance (CGA), a member-driven association dedicated to ensuring public safety, environmental protection, and the integrity of utility services, promotes effective damage prevention practices. In May 2007, the CGA launched a national "Call Before You Dig" campaign to increase public awareness about the importance of using 811 (CGA). Arizona Blue Stake is an organization developed in Arizona as a one call notification system to assist excavators in meeting statutory requirements of locating (within ± 0.6 m (2 feet)) underground utilities prior to excavation. For example, the Arizona State Constitution, Section 40-360.22, discusses excavation, determining the location of underground facilities and providing that information to excavators prior to excavation (Arizona State Constitution 2007). It is a damage prevention measure taken to avoid catastrophe during construction.

Conventional ground surveying and mapping are still the primary methods used to collect as-built location data of underground utilities. The advantage of conventional surveying techniques is that it provides a very accurate location data. However there are some disadvantages of using this method: it is time consuming, resource intensive and requires skilled technicians to reach a centimeter level surveying accuracy; it is difficult to operate conventional surveying equipment like an auto level and/or a total station in bad weather, or during night-times; data requires processing before any useful information is available and data collected with reference to physical features may be altered in the future.

Tulloch et al. proposed a model to provide location information where "as-built" utility data is collected using both photogrammetry and GPS. A GIS is also required to store and organize the utility information so that accurate asset management can be accomplished by municipal engineers (Tulloch et al. 2005). Drawbacks of this method include requiring a skilled person for operation in order to reduce human error. The camera should also be dust proof, cold and heat resistant, and moisture free to eliminate the addition of errors.

The Global Navigation Satellite System (GNSS) based technology can be used to map underground assets; however, for built up areas GNSS signals can be lost, unavailable or have large errors (Taha 2008). Taha proposed integrating GNSS and Total Station and developed a technique called Continuous UPdating Technique (CUPT) by which readings can be taken at centimeter level precision. This technique requires at least two people and is comparatively expensive. It would be difficult to use this technique at a construction site when a utility is exposed for a short period of time, for example, utility installation during road construction projects.

This paper proposes a model by which a single technician, without prior knowledge of surveying, would be able to take "as-built" readings of underground utilities, safely, correctly, and effectively during the installation process. Installations of utilities are usually done by one of two methods: trenchless and/or open trench. This paper addresses a system by which the location of utilities installed by the open trench method or exposed for maintenance or repair can be mapped, stored, maintained and retrieved when required.

MODEL FOR LOCATING AND MAPPING UNDERGROUND UTILITIES

Often, last minute changes are made to drawings and/or the alignment of utilities due to unknown existing field conditions. It is difficult to note on a drawing when a change is made. Furthermore, changes noted on site often do not reach the utility database. "As-built" readings help record the coordinates of installed utilities, as well as other utilities that are discovered during excavation. The proposed method integrates GPS and Laser technology to take "as-built" coordinates readings. Figure 1 proposed a flow chart for collecting, mapping and retrieving utility location data.

The data collected is then stored in a database where the data can be exported to 3D geo-referenced software such as Google Earth®, Minerva®, Virtual Earth®. This framework stores, maintains, and retrieves data using the Urban Systems Framework (USF) developed in the Digital Phoenix project at Arizona State University. USF framework is a structure that allows handling diverse data sets in a concise fashion. It provides methods for visualization, hookups to simulation tools, and supports web-access tools that allow working on datasets in a distributed fashion (Pahle et al. 2009). USF runs on the PostgreSQL database system. Metadata is stored in PostgreSQL and is compatible with the Open Geospatial Consortium standards (Pahle et al. 2009).

Data collected using the integration of GPS and Laser is differentially corrected and is uploaded to the USF framework. The steps in this framework are: first, calculation of best fit line through the collected data points; second, simulation of best fit line to resemble a pipe in 3D; third, visualization of results. Figure 2 shows the flow process of the data through the USF frame work. The program for best fit line was written such that it can be used for the pipes having turns and bends. Storage and organization of data, automation of data processing, conversion, automated execution of simulation, and interoperability of results are the challenges that were dealt with using the USF framework (Pahle et al. 2009)

With the available data in 3D and the simulated view of the location, the utilities can be located using a GPS receiver in open areas and survey techniques in built-up areas. It also provides information which can be useful during the pre-construction and/or construction phase of a project.

To check the accuracy that can be obtained using the integration of GPS and Laser technologies, a GPS Pathfinder Pro-XH receiver and TruPulse 360 laser receiver were used in field trials under construction conditions.

INTEGRATION OF GPS AND LASER (GPS-Las) – OVERVIEW

The GPS is a satellite-based navigation and surveying system for determination of a precise position in time, using radio signals from the satellites. The positional data can be determined in either real time or with post processing. GPS is a powerful tool which can locate utilities accurately in open areas. GPS receivers are portable and easy to use. It can be useful in bad weather or even at night. Nevertheless, the accuracy of GPS readings is reduced in built-up areas due to multipath and poor

geometry of satellites. Additionally, the issue of safety exists for a technician taking readings of utilities over an open trench (Figure 3).

By integrating GPS and Laser the issues of coverage and safety can be efficiently addressed. In addition, the data collection process is easier, faster, and more cost effective. The GPS and laser receiver are mounted on the same tripod stand and the field technician can record readings within a few minutes correctly and safely (Figure 4).

INTEGRATION OF GPS AND LASER (GPS-Las) - INFORMATION SEQUENCE OF METHODOLOGY

Visual representation of the flow of information from data collection to visualization is shown in Figure 5. Field data was collected using GPS and laser with TerraSync® software on a field tough book. The technician collecting data can stand at a safe distance from a trench while taking the coordinate readings. The GPS and laser are connected to the computer and the data point readings are collected by shooting a laser beam to the utility. Additional features of any data point can also be noted using the comment tool in the software. Once recorded, data is transferred to GPS Pathfinder for post processing which applies the differential correction to the collected data. Post-processed data can be exported in various formats such as CAD files (DXF, DGN, etc.) or Shape-files (SHP). Shape-file data is then stored and maintained using the USF framework. Utility "as-built" data (CAD file) can be superimposed on CAD site drawings. Once the utility coordinates are known in 3D the profile view of the utility with respect to the ground surface can be drawn. After analyzing data with CAD software, data can then be transferred as a Shape file to the USF framework. Data can then be retrieved and visualized as needed.

INTEGRATION OF GPS AND LASER (GPS-Las) - DATA COLLECTION AND RESULTS

To assess the accuracy of the integration of GPS-Las technology, five different field trials were accomplished at different locations. The data was collected by a single person. Table 1 shows the length of the various utilities, number of data points collected and the time needed to collect the points. The data collected were compared with site measurements to validate the accuracy of the data. Table 2 shows the accuracy obtained in the X, Y and Z planes using the proposed GPS-Las method. The GPS receiver used for this research was a post-process Trimble® GPS receiver which can achieve accuracy up to 0.3m (≈1 foot). The accuracy obtained by the GPS receiver depends upon the visibility and geometry of the satellites. By recording more points, the error due to the geometry of satellites can be reduced (Costello, 2007). To reduce the effect of geometry of satellites and to achieve accuracy of ±0.45m (≈1.5 feet), it is recommended that at least 5 data points be taken per 20 meters (66 feet) of utility length (Table 2).

CONCLUSION

This paper proposes a model of collecting and mapping location information for underground utilities. The use of integrated GPS and Laser technology has been identified for locating utilities in difficult GPS environments. This integrated technology enables a single person to record "as-built" readings of utilities safely, efficiently and quickly. The technology does not require a skilled technician for its operation. Accuracy of approximately ±0.45m can be achieved noting five points per 20 meter of utility length. Accuracy of the integrated system was limited to the accuracy obtained by GPS receiver. The accuracy recorded by this integrated system is within the bylaws outlined by the Arizona State Constitution (2007) and provides some information regarding the depth of the utility to the contractor. The framework noted in the paper is a simple three step process of collecting, correcting and uploading data to visualize a utility in all three dimensions. This technology should provide contractors and engineers an efficient and cost-effective method to map underground utilities and improve construction productivity.

ACKNOWLEDGEMENT

The authors would like to thank Dr. Robert Pahle with Decision Theater, ASU to allow access to USF frame work and to Joe Cronn with Laser Technology Inc. for providing the TruPulse 360 laser equipment for the research. We would also like to thank all project management teams and field personnel of the participating companies at the test locations.

ABSTRACT

Manually inspecting bridges is a time-consuming and costly task. There are over 600,000 bridges in the US, and not all of them can be inspected and maintained within the specified time frame as some state DOTs cannot afford the essential costs and manpower. This paper presents a novel method that can detect bridge concrete columns from visual data for the purpose of eventually creating an automated bridge condition assessment system. The method employs SIFT feature detection and matching to find overlapping areas among images. Affine transformation matrices are then calculated to combine images containing different segments of one column into a single image. Following that, the bridge columns are detected by identifying the boundaries in the stitched image and classifying the material within each boundary. Preliminary test results using real bridge images indicate that most columns in stitched images can be correctly detected and thus, the viability of the application of this research.

KEYWORDS

Column detection, bridge inspection, image stitching, image processing

1 INTRODUCTION

According to the latest data from the Bureau of Transportation Statistics, there are over 600,000 highway bridges in the USA (BTS 2009). Each of these bridges requires inspection at regular intervals (usually not exceeding two years) to ensure that they

continue to satisfy present service requirements (AASHTO 2001). Routine inspections are carried out manually by certified bridge inspectors following the National Bridge Inspection Standards by the Federal Highway Administration (FHWA 2004) and the Manual on Bridge Evaluation by the American Association of State Highway and Transportation Officials (AASHTO 2001). Inspection results represent the condition state information of the bridge elements (e.g. columns, abutments, decks/slabs, and girders) and are mainly based on the inspectors' visual observations. This information is then entered into a bridge management system to help transportation agencies make system-wide prioritization decisions with regards to the allocation of limited inspection and maintenance resources. Several limitations of manual inspections have been identified in previous research studies. For example, manual inspection results are subjective (Phares et al. 2004), and manually collecting bridge inspection data is costly and time-consuming (Koglin 2007).

In order to overcome these limitations, it is necessary to create an automated bridge inspection toolkit that can considerably reduce inspectors' field work as well as automatically produce bridge inspection reports. Toward this objective, several methods have been proposed, most of which focus on automating the collection of as-built bridge condition data (Jaselskis et al. 2005; Jauregui et al. 2006) and the detection of surface damage and defects (Abdel-Qader et al. 2006; Hutchinson and Chen 2006). The importance of detecting bridge elements (e.g. columns) in automated inspection lies in the fact that the damage measurements are of little value unless they can be spatially correlated with the member on which they lay. For example, a diagonal crack versus a horizontal (flexural) crack indicates a completely different type of damage on a column. Therefore, bridge elements have to be detected, so that the damage and defects can be automatically spatially correlated with the corresponding elements to produce relative measurements.

However, existing element detection work cannot achieve satisfactory results for bridge inspection purposes. This is because bridge elements are usually large-scale. In order to detect these elements and retrieve their dimensions, existing methods require structural elements to be completely visible in the field of view (FOV). Considering that the FOV of a typical compact camera is limited to 50°(H)x35°(V) but that of a human can reach 200°(H)x135°(V) (Freeman and Durand 2006), this forces users to fully extend the zoom of their cameras or stand far away when capturing large-scale columns (Fig. 1). Thus, the detailed defect information on these elements is lost, since the same amount of image pixels are used to capture larger element surface areas.

This paper presents a novel method for automated detection of large-scale concrete bridge columns in visual data. The method begins by combining multiple images containing different column segments of one column into one image using SIFT feature detection and matching, affine transform matrices calculation, etc. Then, the long vertical lines are extracted using edge detection techniques and the Hough Transform from the stitched image, and the bounding rectangle of each pair of long

vertical lines is formed. If the resulting rectangle resembles the shape of a column (i.e. the rectangle's width is smaller than its length) and the color/texture contained in the rectangle are matched with that of concrete samples stored in a knowledge base, the region between the pair of lines is assumed to be a concrete column surface. The method was tested using real bridge images. Preliminary results indicate that most bridge columns can be correctly detected in stitched images.

2 BACKGROUND

2.1 Manual Bridge Routine Inspection

Highway bridge inspections are carried out manually by certified inspectors following established National Bridge Inspection Standards AASHTO Manuals on Bridge Evaluation. During inspection, they record actual bridge conditions by observing existing damage and defects that lay on primary bridge components, such as decks, exterior beams and piers. This information is used to rate bridge conditions. So far, there are two rating systems that can be adopted, both of which are built upon qualitative definitions. The FHWA Recording and Coding Guide defines one system which uses the National Bridge Inventory zero to nine scale for rating a bridge deck superstructure and substructure. The other, the PONTIS rating system, uses a set of three to five condition states to describe the condition of bridge elements (e.g. column, girder and truss).

One inherent limitation associated with these manual inspections is their inefficiency. Reviewing previous reports, preparing inspection plans, and collecting and analyzing field data take a lot of inspector hours (Koglin 2007), which results in significantly large costs over time. In Tennessee, in 2006 and 2007, the annual cost of bridge inspections was $7.6 million; considering the Tennessee Department of Transportation lost $22 million in Federal bridge funds, some bridge inspections and maintenance projects had to be pushed back (Wasserman 2007). In addition, manual inspection results are subjective and highly variable. An on-site survey conducted by the Non-Destructive Evaluation Center indicated that manual inspections were completed with significant variability (Phares et al. 2004).

2.2 Recent Research Efforts towards Automated Bridge Inspection

Researchers have proposed many methods regarding the aim of automated bridge inspection. Much work has been performed in automating the collection of bridge as-built data and the detection of surface damage and defects. With regards to the data collection process, recent efforts mainly include the use of remote spatial sensing techniques, such as laser scanning and photogrammetry. Laser scanning is a terrestrial laser imaging system that can create highly accurate and detailed 3D range images and has been used in many bridge survey applications (Jaselskis et al. 2005). Photogrammetry relies solely on the present light energy to retrieve bridge as-built information. Examples of using photogrammetry to document bridge conditions were found in the work of Jauregui and White (2003) and Jauregui et al. (2006).

As for damage and defection detection, many automated detection methods have been created to detect surface damage and defects. These methods use image processing techniques, such as wavelet transforms and segmentation to extract this information from image background, and their effectiveness has been verified in inspecting concrete structures like bridges (Abdel-Qader et al. 2006; Hutchinson and Chen 2006) and concrete pipes (Guo et al. 2009).

2.3 Structural Element Detection

Automating the collection of bridge as-built data and the detection of surface damage and defects is not entirely sufficient to provide a comprehensive bridge inspection. The impact of existing damage and defects on bridge elements needs to be further evaluated, which requires the detected damage and defects to be spatially correlated with the member on which they lay. For this reason, bridge elements also need to be detected (Fig. 2).

In general, object detection is defined as locating a desired object in a scene (Ge et al. 2008). It can be performed in either range data or visual data. The methods of detecting objects in range data rely on the object's global or local shape features. According to Bosche and Haas (2008), these methods are computationally complex, especially when the number of search objects and the number of scanned points is increased. So, they suggested representing a 3D CAD model using range points so that the matching can be performed at the point level. However, this method requires the model to be registered first in the laser scanner's spherical coordinate frame.

Object detection methods in visual data are classified as: 1) scale/affine-invariant feature-based, 2) color/texture-based or 3) shape-based. Scale/affine-invariant feature-based methods use image scale/affine-invariant features extracted by feature detectors such as SIFT (Lowe 2004) to locate an object. Such methods are powerful in detecting a specific object, but they are not appropriate for object category detection. For example, they can match the same car in multiple pictures, but cannot detect similar cars. Structural elements are characterized by large topographical variations, and therefore, no simple scale/affine transformation can be used to characterize them.

Color/texture based methods rely on the objects' interior color and texture values. Neto et al. (2002) observed that the color and texture values for most materials (e.g. concrete and steel) in an image do not change significantly. Therefore, material regions in an image can be identified by checking their color and texture values, and a region's dimensions can be used to determine the type of structural element that the region represents (Brilakis and Soibelman 2008). Shape-based methods make use of object boundary information which is retrieved by analyzing the distribution of edge points, but the sole reliance on edge information renders these methods inadequate in complex scenes. Zhu and Brilakis (2009) therefore, recently proposed a new column detection method using both boundary and material information in an image.

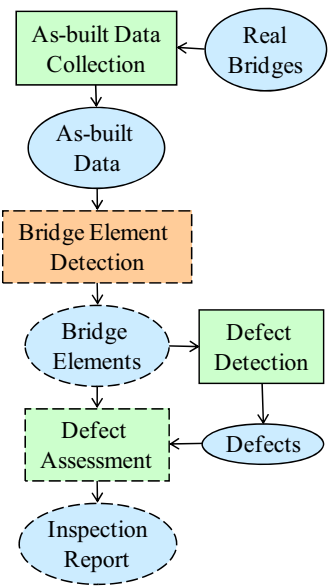

Fig. 2: Automated bridge inspection

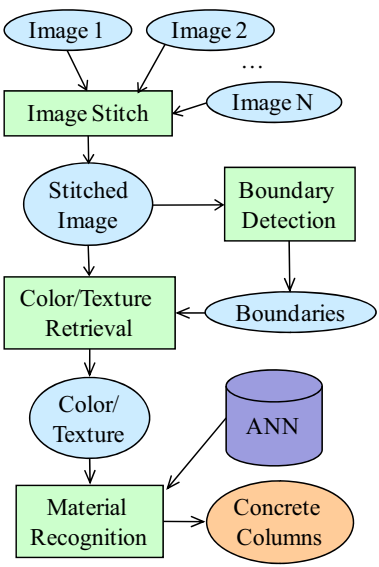

Fig. 3: The proposed method for large-scale bridge column detection

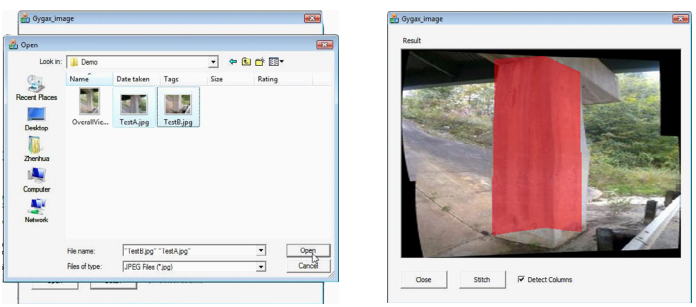
3 THE FRAMEWORK OF THE PROPOSED METHODOLOGY

In order to overcome the limitations mentioned herein, a novel method of detecting a large-scale bridge column captured in multiple images is proposed (Fig. 3). The method is divided into two chief stages: 1) image stitching, and 2) column detection, which includes three main steps: a) boundary detection, b) color/texture retrieval and c) material recognition using an artificial neural network. Details in each stage are explained in the following sections.

3.1 Image Stitching

The purpose of the first stage, image stitching, is to combine multiple images into one high-resolution image based on their overlapping FOVs. The motivation behind image stitching in bridge inspection lies in the fact that the FOV of a typical compact camera is limited to 50°(H)x35°(V) but the human's FOV can reach 200°(H)x135°(V) (Freeman and Durand 2006). This way, information concerning structural elements and defects that can be captured by the human eye cannot necessarily be captured by a single shot of a camera. Multiple shots are always taken of the different parts of one large-scale element.

In this research, image stitching is performed in the following order. First, the feature detector developed by Lowe (2004) is used to extract and match the features that are invariant to image scale and affine distortion between these images. The locations of these features are then retrieved. For any two images, the affine transform matrix between these two images can be calculated using Eq. 1 and Eq. 2, where $(x_1^1, y_1^1)^T, (x_2^1, y_2^1)^T \ldots (x_n^1, y_n^1)^T$ are feature locations in the first image, $(x_1^2, y_1^2)^T, (x_2^2, y_2^2)^T \ldots (x_n^2, y_n^2)^T$ are the matched feature locations in the second image and matrix $A^{12} = \begin{pmatrix} a_{11}, a_{12}, a_{13} \\ a_{21}, a_{22}, a_{23} \end{pmatrix}$ is the affine transform matrix that can transfer the locations of any image pixel in the first image to the second one. Thus, these two images can be combined into one image with the affine transform matrix. The combination can be performed iteratively until one composite image is created from all individual images.



$$\begin{pmatrix} x_1^1, y_1^1, 1 \\ x_2^1, y_2^2, 1 \\ \ldots\ldots\ldots\ldots \\ x_n^1, y_n^1, 1 \end{pmatrix} \times \begin{pmatrix} a_{11} \\ a_{12} \\ a_{13} \end{pmatrix} = \begin{pmatrix} x_1^2 \\ x_2^2 \\ \ldots \\ x_n^2 \end{pmatrix} \quad \text{(Eq. 1)} \qquad \begin{pmatrix} x_1^1, y_1^1, 1 \\ x_2^1, y_2^2, 1 \\ \ldots\ldots\ldots\ldots \\ x_n^1, y_n^1, 1 \end{pmatrix} \times \begin{pmatrix} a_{21} \\ a_{22} \\ a_{23} \end{pmatrix} = \begin{pmatrix} y_1^2 \\ y_2^2 \\ \ldots \\ y_n^2 \end{pmatrix} \quad \text{(Eq.2)}$$

3.2 Concrete Column Detection

The second stage, concrete column detection, consists of identifying long near-vertical lines for each column surface as well as determining whether or not the material contained between two lines is concrete. In order to detect column boundaries, the Canny operator is used to produce an edge map, a binary image composed of edge points (marked as white) and non-edge points (marked as black). The Hough transform is then used to analyze the distribution of edge points and retrieve long vertical line information in the edge map. Each retrieved vertical line is compared to its neighboring vertical lines. If two vertical lines have similar size, they

are regarded as a pair. This comparison is performed iteratively, until no further pair can be found. A bounding rectangle for each pair of vertical lines is then constructed based on their Cartesian coordinates, and the aspect ratio (length/width) of each bounding rectangle is calculated. Considering the large-scale bridge columns investigated in this research, the ratio can be assumed to be on the order of six or seven.

An artificial neural network is designed to classify the material within a boundary. The network is composed of three layers (input, hidden and output). In the input layer, the network takes the visual features and transfers them to the hidden layer, where a material classification boundary in the feature space is created on each neuron-node. Then, these boundaries are combined together using an AND operation in the output layer to form a concrete material classification model. The number of neuron-nodes in the hidden layer is determined experimentally. Technically, the more neuron nodes in the hidden layer, the more classification boundaries can be found, which results in a more precise classification approximation. The network is trained through supervised learning (back-propagation). The training process is repeated thousands of times. Although it is possible to have more repetitions to further reduce the error rate, long training to achieve a very low number of errors will result in an overtraining problem.

(a) (b)

Fig. 4: The process of column detection using the prototype

4 PRELIMINARY IMPLEMENTATION AND RESULTS

The methodology presented in this paper is implemented into a C++ based prototype. The prototype was written in Microsoft Visual Studio 2005. Intel® Open Source Computer Vision Library was used as the prototype's main image processing toolbox. The Fast Artificial Neural Network Library was used to implement neural-network based material classification. The work developed by Brown and Lowe (2007) was used for image stitching.

Figure 4(a), an open file dialog, popped up to allow the user to select multiple images for stitching. Figure 4(b) is the resulting column detection in the image

stitched by these selected images. The image shown is slightly stretched because it is resized for display purpose only. Figure 5 shows an example of column stitching and detection. Table 1 illustrates the detection precision and recall for five stitched images, which are combined from two to four images separately. The final average precision and recall for the 114 concrete bridge column images stitched from 373 original images are 89.7% and 84.3%, respectively. The detected column surfaces are compared with the manually identified surfaces to determine the true positive (TP), false positive (FP) and false negative (FN) of the method (Wickens 2002). Then, the detection precision (TP / (TP+FP)) and recall (TP / (TP+FN)) are calculated. It can be seen that large-scale concrete bridge columns can be correctly detected in most stitched images. Image 4 in Table 1 represents the columns that could not be detected due to their large curve edges in the stitched images (Fig. 6).

Fig. 5: An example of column stitching and detection

No.	TP	FP	FN	Precision	Recall
				TP/(TP+FP)	TP/(TP+FN)
1	1	0	1	100.0%	50.0%
2	2	0	0	100.0%	100.0%
3	1	0	0	100.0%	100.0%
4	0	1	2	0.0%	0.0%
5	1	1	1	50.0%	50.0%

Table 1: Detection precision and recall

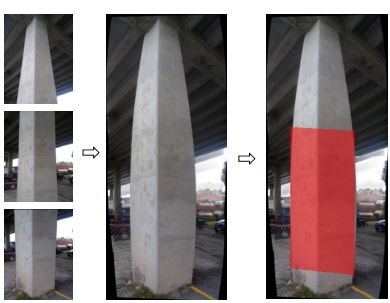


Fig. 6: Failed detection of column with high curve edges

CONCLUSION

Manual bridge inspection has several inherent and fully-recognized limitations, such as high cost, subjective results and the requirement of experienced inspectors. Therefore, the concept of automating the current manual practices in bridge inspection is proposed to overcome these limitations. Much work has been performed in bridge as-built data collection and surface damage and defect detection. In order to evaluate the impact of the detected damage and defects on bridge elements, the property measurements of these detected damage and defects have to be spatially correlated with the member on which they lay. Therefore, bridge elements have to be detected from the collected as-built data for the sake of this spatial correlation. Existing detection methods require that structural elements be completely in the FOV for detection and property retrieval. However, due to the limited FOV of a camera, it is always impossible to make large-scale bridge elements (e.g. columns) fit entirely in the view and at the same time, maintain proper view of all detailed defect information (e.g. cracks) on the element.

This paper presents the authors' recent work in detecting large-scale concrete bridge columns. Image stitching techniques are first used to combine multiple images containing different FOVs for one bridge column into a stitched image. Then, the Canny operator and the Hough Transform are used to recognize the pair of long vertical lines of a concrete column in the stitched image. The visual features of the region of the line pair are presented to an artificial neural network to indicate whether the region contains concrete or not, so that a concrete column surface can be detected. Real bridge images were used to validate the work presented in the paper. The preliminary test results indicate that a large-scale bridge concrete column that is captured in multiple images can be detected in the stitched image in most cases. Future work will focus on removing the effects of curve edges introduced in the image stitching process and testing more images to confirm the method's validity.

ACKNOLEDGEMENT

The authors would like to thank the National Science Foundation for its generous support of this project through Grants # 0933931 and 0904109.

Review of Wireless Sensors for Road and Bridge Asset Management

J. R. Kim[1], M. J. Chae[1], J. W. Park[1], G. Lee[1], and M. Y. Cho[1]

[1]Department of Construction Systems Innovation Research, Korea Institute of Construction Technology, Goyang-si, Korea, Correspond to +82-31-910-0024; chae@kict.re.kr

Abstract

According to the Ministry of Land, Transport and Maritime Affairs, the price of social infrastructure asset, including nation-wide roads, railways, airports, harbors, water and sewage systems, and water resources management facilities, amounted to 515.2 trillion won as of 2004 (Ministry of Land, Transport and Maritime Affairs, 2007). When it comes to social infrastructure, the emphasis has been placed on the construction aspect for decades. But the need is being raised for more comprehensive management of the infrastructure. In most of developed countries, infrastructure asset management has been implemented for the effective and efficient operation and management of infrastructure. Infrastructure asset management is also being implemented in Korea. The purpose of this study was to review the current data collection methods to help implement better asset management and to address the need to utilize wireless sensor technologies and propose implementation strategies for the implementation.

Keyword: asset management, RFID, USN, measurement

1. Introduction

1.1 Background and Purpose

The Ministry of Land, Transport and Maritime Affairs of the Republic of Korea estimated that as of 2004 the price of nation-wide social infrastructure (road, rail, airport, harbor, water and sewer system, water management facility, etc.) stock amounted to KRW 515.2 trillion (Ministry of Land, Transport and Maritime Affairs, 2007). The social infrastructure is maintained under the supervision of a full-time management agency appointed by the government. The maintenance, however, remains at the individual optimization level, failing to involve comprehensive management based on accurate value appraisal of various facility assets at the national level. Such management approach could cause unexpected budget problems in the future. For instance, the costs of maintaining social infrastructure constructed in the 1950s and 60s in the US, Australia, and Canada soared during the 1990s, threatening national financial safety. The countries have since treated social infrastructure as state-owned comprehensive assets and

introduced asset management techniques to systematically manage the facilities and solve related problems. Observed effects include cost reduction and increased usability.

In Korea, the majority of social infrastructure was built in the 1970s and 80s. Given that, the rapid increase in upkeep costs is expected in 2010 and beyond. However, the current maintenance program focuses on individual facility management as mentioned earlier. The downside calls for an approach from systematic asset management based on accurate appraisal of state and value of state-owned social infrastructure. To address the issue, the Ministry of Strategy and Finance passed a bill in October 2007 with the legislation of the National Accounts Act (enforcement scheduled to begin on 1 January 2009), introducing the accrual accounting. And the Ministry of Public Administration and Security introduced in 2007 the double entry book-keeping system which includes information on assets and liabilities in the book, via "Guidelines for Implementing Double Entry Book-Keeping on the Accrual Basis by Local Autonomous Bodies" to lay the foundation for managing social infrastructure as collective assets (Ministry of Land, Transport and Maritime Affairs, 2008). The Korea Institute of Construction Technology (KICT), too, began a research program on collective asset management of social infrastructure called "Development of a Public Infrastructure Asset Management System (KTAM-40)" in 2008.

To implement asset management programs, accurate data collection must first be ensured. The purpose of this study was to review the methodological problems in the current data collection stage which is the early phase of asset management implementation and to address the need to utilize IT technologies (RFID/USN) and propose strategies to implement them.

1.2 Scope and Method

In general, asset management is implemented as shown in Figure 1 below. First, asset management strategies are established; then the target asset data are collected; and lastly, the performance is analyzed. This is followed by analysis/forecast of asset demand, based on which asset management plans are established and implemented. This paper focused on the data collection stage and in particular asset management data collection methods being adopted locally as well as internationally. Then problems in the stage were identified, and implementation possibilities of RFID/USN technologies were reviewed based on local case studies. This paper also addressed RFID/USN technology implementation strategies and considerations as the introduction of social infrastructure asset management is being considered in Korea.

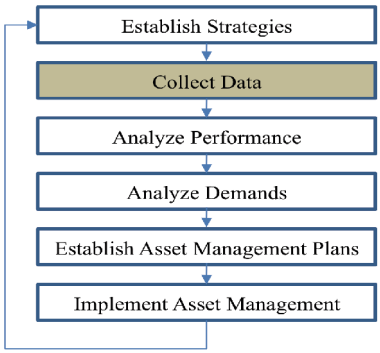

Figure 1. Stages of Asset Management Implementation

2. Asset Management Data Collection Method

2.1 Asset Management Data Collection Methods used in Korea and Elsewhere in the World

Asset management data are roughly divided into inventory data and condition data as summarized in Table 1 below. Inventory data refer to the data for physical components of assets, such as location and traffic lanes, that change very little with time. Condition data, on the other hand, are the data that concern the condition of asset components and change with time (The World Bank 2005). In this paper, local and international asset management data collection methods were reviewed with emphasis on condition data that can be measured.

Table 1. Types of Asset Data

Data type	What is indicated	Time-induced change	Techno-logical reliance	Details of information	Application
Inventory data	physical elements of the assets	very little	relatively low	location, specific description, history (design, construction, management)	asset information
Condition data	condition of elements of the assets	some	relatively high	condition, performance, risk	decision-making support

Condition data collection methods are divided into: (a) routine inspection and precision inspection (special inspection) based on collection time (cycle); and (b) visual inspection and survey/monitoring (destructive and non-destructive) based on collection technique. Some of the examples of collection methods are described below.

Figures 2 and 3 each show the hydraulic lifts and snooper-type trucks used in bridge substructure inspection. The equipments are easy to use, have excellent trafficability and accessibility, offer sufficient work space, and can be used with

various transportation means like automobiles and vessels (The World Bank 2005). They are frequently used in the local construction industry as well, mainly during precision inspection for bridge structures.

Figure 4 shows an equipment used by the British Columbia Ministry of Transportation (BCMoT) in Australia to investigate damages to road pavement and evenness of road surface. Inspectors of the agency routinely use the equipment as they drive around their district and collect data on road condition (NAMS et al. 2006).

Figure 2. Hydraulic lifts

Figure 3. Snooper-type trucks

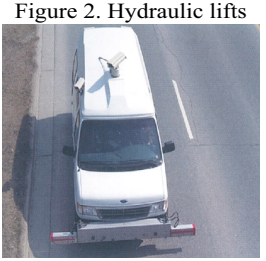

Figure 4. Road condition monitoring vehicle

Figure 5. FWD

Korean institutes such as the Korea Institute of Construction Technology (KICT) and the Korea Expressway Corporation, too, are using similar equipments. One such example is the falling weight deflectometer (FWD) shown in Figure 5.

2.2 Summary

In addition to the facility condition inspection using the aforementioned equipments, various visual inspection and site survey techniques are being utilized to collect data on the condition of assets. However, the majority of the equipments are expensive and cause traffic problems when used. They also pose problems such as longer data collection period, subjective evaluation by inspectors, and difficulties in identifying long-term behavior of structures due to time constraint during investigation. Therefore, new methods allowing continued monitoring of facilities at reasonable pricing are needed.

3. Local Case Studies Using RFID/USN in Infrastructure

Gong Jeong-sik et al. (Gong Jeong-sik et al. 2007) analyzed technological trends in social infrastructure asset management adopted by a number of countries and introduced the possibilities of using various information technology (IT)

programs such as 3D-based design drawing and RFID programs for future development in the field. Examples described below verify such application possibilities.

3.1 Examples of Bridge Survey

The Korea Institute of Construction Technology (KICT) conducted between 2006 and 2007 SK Telecom-sponsored monitoring of a bridge structure in service, using USN technology (see Figure 6).

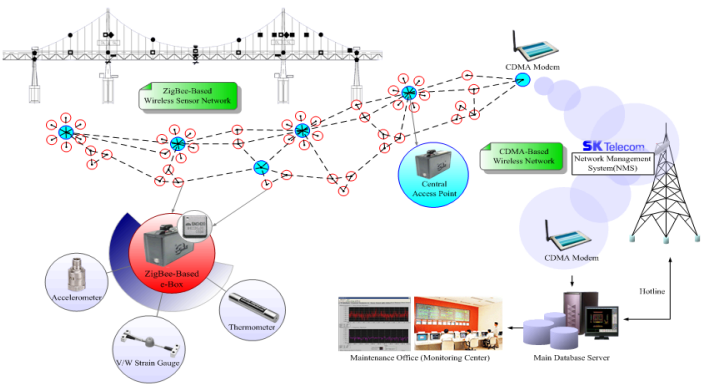

Figure 6. Example of Bridge Monitoring Project by KICT and SK Telecom

During the monitoring, static and dynamic surveys were conducted to measure acceleration (vibration), strain, temperature, and wind direction and speed as the testbeds were operated for three months. Results of the surveys showed performance that was equivalent to that of the current monitoring systems. The data also showed superior installation and removal convenience and a 30 percent reduction in costs (economic benefits) based on an assumption of six years of service. The example verified the application possibility of USN system for routine monitoring of bridge structures.

3.2 Examples of Road Survey

The Korea Institute of Construction Technology (KICT) and SK Telecom jointly established a cheap USN sensor-based monitoring system in roads constructed in a mountainous region where heavy rain and snowfall are frequently reported to monitor freezing and flooding incidents and ran testbeds for three months. The installed system was geared to collect data on road surface temperature, surface moisture level, and saline contents to help determine the status of freezing and flooding. The system was found to be able to monitor road conditions more accurately than some of the current systems and to offer an approximately 20 percent cost cut (economic feasibility). This case study, too, verified the application possibility of USN system as it was used for routine road-condition monitoring.

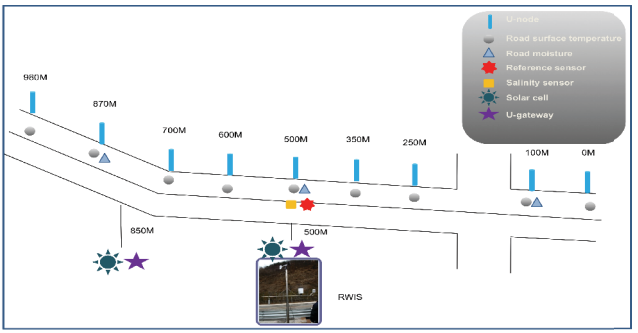

Figure 7. Road freezing/flooding monitoring system

4. Strategies to Utilize RFID/USN Technology

4.1 Considerations to Make to Implement RFID/USN Technology

In addition to the aforementioned case studies, a number of research projects are underway, using USN to collect facility data for bridges, sloped surfaces, roads, and construction structures and satisfactorily verifying the applicability of the technology. Therefore, a long-term monitoring program focusing on survey fields that are core areas and can accommodate the characteristics of USN would greatly increase the efficiency in social infrastructure asset management, despite its foreseeable limitations in replacing all monitoring programs.

The World Bank proposed considerations to be made while collecting data for asset management as listed below (the World Bank 2005).

- What kinds of decision-making are needed when managing and maintaining road networks?
- What types of data are required by such decision-making?
- Can the data be collected during the early stage of the implementation?
- Can the data be stored for longer terms?

The considerations listed above are some of the essential questions to be asked when selecting data collection methods in the entire asset management system implementation. Therefore, based on the questions suggested above, considering the information listed in Table 2 during RFID/USN technology-based data collection will likely ensure effective implementation of RFID/USN technology.

Category	Description
Survey importance	better for monitoring items that directly affect structural characteristics and aging of material
Survey frequency	better for monitoring items with higher survey frequency (allows necessary frequency for items that used to limit frequency due to cost and technical limitations)

Accessibility	better for survey items concerning survey sites posing access problems for routine inspection, precision inspection, and field survey
Cost efficiency	consider economic feasibility while replacing with USN
Technical difficulty	technological possibilities of USN-replaced monitoring
Wireless communication possibilities	wireless communication environment of the target structures

Table 2. Types of Asset Data

4.2 Strategies to Coordinate RFID/USN Based Survey

Implemented in long-term data collection, RFID/USN technology will help identify the long-term condition of each facility network and will enable the operators of each network to obtain overall information on each facility's performance distribution. The technology can be used in asset management as summarized in Table 3 below.

Table 3. Types of RFID/USN Application in Asset Data Management

Technology	Application
RFID	a tool to integrate inventory data and condition data
USN	a tool to collect condition data of assets

RFID technology can be used for entering accurate condition data in an accurate asset inventory via RFID reader which will be carried by investigators during visual inspection while USN technology can be applied to monitoring condition changes in each facility.

Figure 8 shows the asset management implementation process using RFID/USN technology. Though it cannot replace all of the current data collection methods being used (visual inspection, site survey, etc.), the technology is able to monitor long-term behavior of core components of each facility. And based on the long-term information, specialized routine inspection and precision inspection can be implemented for each facility, which will likely increase the accuracy of the inspections and make the prioritization of inspection and placement of staff more efficient. In addition to the longer-term monitoring benefits, RFID/USN based field investigation applications will also bring benefits.

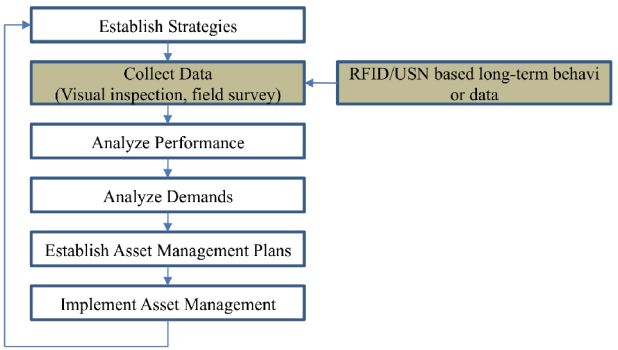

Figure 8. Strategies to coordinate RFID/USN based asset management

5. Conclusion

This study reviewed local and international asset management data collection methods used in the data collection stage, i.e., the early phase of asset management implementation, identified problems, examined local case studies of RFID/USN technology to review the possibilities of RFID/USN technology application, and proposed the technology implementation strategies for managing and maintaining local social infrastructure as collective assets. Given the accelerating aging of social infrastructure, introducing the asset management concept and implementation of IT technology (RFID/USN) which Korea is known for among a number of outstanding industries will help the country carry out social infrastructure asset management with more international competitive power.

Semantic Representation of Infrastructure Interdependencies: Rethinking infrastructure design and management

El-Diraby, T. E.

Dept. of Civil Engineering, University of Toronto, 35 St. George St., Toronto Ontario M5S 1A4, tamer @ecf.utoronto.ca

Abstract

This paper presents a semantic system for coordinating the management of infrastructure projects. The proposed system starts from three fundamental premises: the use of knowledge (through ontologies and semantic systems), covering all facets of infrastructure projects (products, processes and human actors), and consideration of project aspects other than direct costs.

Introduction

There is a need for a new paradigm in the design and management of infrastructure systems. Traditionally infrastructure has been designed at the project level without much consideration to the overall performance of the network. With increasing concerns over interdependency, we have to address the impact of a new project on the overall performance of the network(s). Projects were further designed according to pure technical specifications (engineering-dominated design) that are normally influenced by short-term business requirements (mainly project direct costs). The fact that these infrastructure systems are being rehabilitated in the midst of congested urban areas requires more rigorous consideration for the impacts on individual projects on local communities.

A semantic system for coordinating the management of infrastructure projects is proposed. The proposed system starts from three fundamental premises:

1. Focus on knowledge: The management of infrastructure utilizes multitudes of data, information and knowledge. Data is a representation of the simplest facts about a system with a limited usability or meaningfulness. Information is the

composition of various data to establish a meaningful representation of facts. Knowledge is the wisdom gained from experience. Knowledge can be seen as spanning three spheres: software (means for static capture of knowledge), work processes (reflection of best practices and value generation), and human judgment (the wisdom/intelligence of human experts). It is sad to notice that except for the software facet, knowledge management practices in the infrastructure domain have lagged almost every other industrial sector. Semantic (ontology-based) systems represent the state-of-the-art means to encapsulate knowledge in any management system.

2. Infrastructure projects are connected complex systems: Infrastructure is composed of a set of over-layered, interlinked networks of heterogeneous systems that span vast geographic areas. Each project (shown as a circle in Figure 1) is composed of a set of interlinked components (shown as a square in Figure 1). Theoretically, each project (no matter how small) at one end of a single network (a sector) can have an impact on other projects in the other end (impacts are denoted with triangles in Figure 1). The optimum design of one project has to take into consideration all related projects within the same sector and across related sectors. It could be infeasible/unnecessary/overwhelming to consider all possible impacts on all possible projects. Consequently, we need to devise tools to investigate in a hierarchical way different scenarios and different scales of these interdependent networks.

3. Expanded view of project costs: several new costs are assuming a greater importance in the context of the design of urban infrastructures systems:

    - Indirect costs: The majority of our infrastructure systems are located in urban areas, leading to an ever-increasing importance to indirect costs over direct costs such as business and traffic costs (especially during construction).
    - The costs of sustainability: real dollars can now be associated with the negative impacts of an infrastructure project on sustainable development (especially the environment).
    - Costs of interdependency: greater concerns are now being expressed over the analysis of interdependency. While business requirements are pushing for a minimalist design of projects with elimination of any redundancy or unneeded capacity (to reduce costs), addressing interdependency concerns requires embedding adequate redundancy in individual projects to enhance the resilience of the overall network.

The Proposed Framework

A common knowledge management system for collaborative design of infrastructure is envisioned to allow stakeholders to work so closely that there are ***interoperable computer systems*** that allow partner *A* to seamlessly access the corporate data of partner *B*, manipulate certain data in compliance with pre-agreed ***profit sharing/collaboration protocols*** that are encouraged by incentives from ***government policies.***

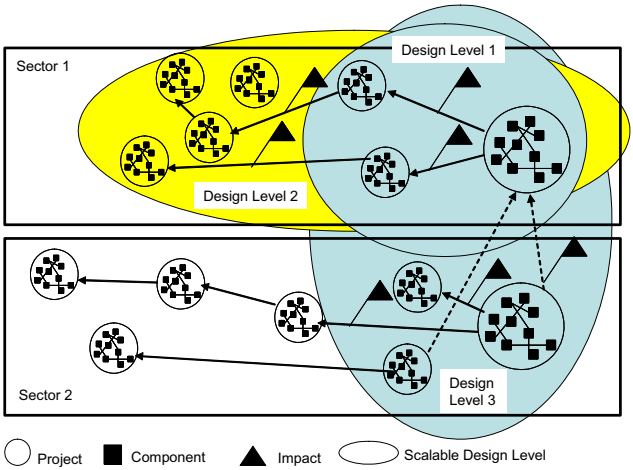

Figure 1: Outline of Project Interdependency

An interoperable knowledge model is at the core of the proposed architecture (see Figure 2). This includes a set of ontologies that encapsulate knowledge of different domains/ stakeholders (for example, El-Diraby and Kashif, 2005). In addition, a set of related ontologies for products (Osman and El-Diraby 2006), processes (El-Gohary and El-Diraby 2008) and actors (Zhang and El-Diraby 2008) are also included. These ontologies define the basic interrelationships between different infrastructure systems.

The portal integrates CAD and GIS tools to visualize information. The portal provides access to information at three levels: corporate level (full access to corporate information), partner level (access to certain information to partner organizations) and public level (free access to a limited set of information). This is done through a basic access policy protocol.

Information will be also viewed in product, process and actor view. For example, all technical details of the infrastructure system being designed or managed will show up on the product view. A set of decision making services are provided to study the overlap and interaction of different product designs. Workflow and business transactions will show on the process view. Here, web services help visualize the work processes of parties involved. In addition, the portal allows system users to weave a new work process for project partners based on the semantic description of their processed (which is established by accessing the ontology). Status, interest, and tasks of stakeholders will be shown in the actor view. This view utilizes publish-subscribe technology to pull and push relevant information to the proper person at the right time. Future development will focus on using data mining to enrich the ontologies. In addition, a set of semantic web services, agents and other software tools will be built to provide services to stockholders, analyze information exchange patterns and wrap existing software system.

Four major components have been implemented in this architecture—they are:

Ontologies and ontology merger

A domain ontology for construction has been developed. The ontology describes major domain concepts and their interrelationships. It also describes the basic and most common axioms relevant to infrastructure construction. Three additional sub-domain ontologies have been developed to represent construction knowledge in products (Osman and El-Diraby 2006), processes (El-Gohary and El-Diraby 2009) and actors (Zhang and El-Diraby 2009). A set of application ontologies have been developed to handle specific tasks (for example, routing pipes in urban streets). By defining computer-understandable models, ontologies facilitate computable interoperability. Ontologies are thus the foundation of content-based information access and semantic interoperability over the web, providing the construction industry with the opportunity to create semantic interoperable environments for seamless exchange of information. However, the development of a single shared ontology to serve as 'the one and only one' process model for the whole domain is not feasible. No single ontology can fully cover a domain of interest (Gruber 1995) and no single optimum way for modeling a domain exists (Taivalsaari 1996). Given the inevitable existence of a set of heterogeneous and distributed ontologies within one domain, an ontology merger becomes essential for facilitating computable interoperability. Ontology merging is the process of deriving a new ontology based on two existing ontologies in order to facilitate interoperability. A standalone software was created to help merge other ontologies with existing ones. Finally, a software wrapper has been developed to link ontology representation to GIS standards.

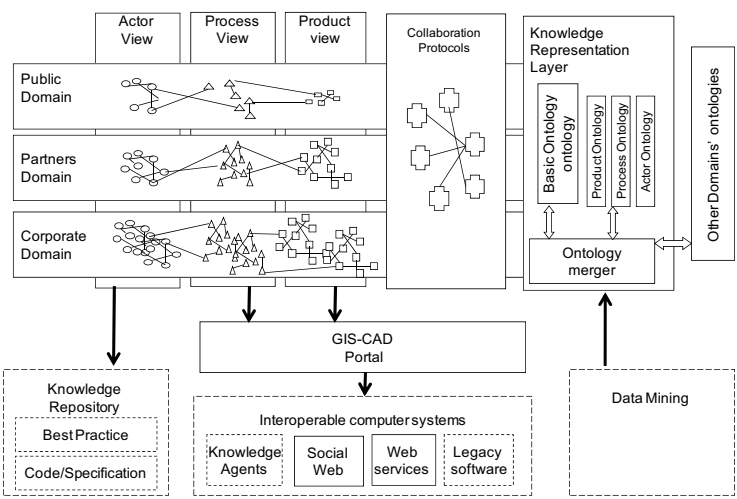

Figure 2: Portal Architecture

Product Analysis Portal:
This software is intended to assist infrastructure designers to optimize the routes of such utilities on a macro-level (which streets to use) and on the micro-level (which side of the street to use). The portal can also support the coordination of infrastructure routing in urban streets. First, the user interfaces with the Ontology Portal (entry point to modify/extend the ontology). The user then can upload route options as GIS layers. The user can then select the constraints to be checked. An OWL Spatial Constraint Satisfaction Reasoner (OSCSR) builds a 3 dimensional database that relates the attributes of route and those of surrounding area/products to the constraints. The database is subsequently examined by the constraint violation algorithm. The algorithm iterates through instances of all products and checks to see if any routing constraints have been violated. Products that violate a constraint are added to a database that links instances of products (infrastructure products and generic products) with violated routing constraints.

The main components of the software are:
1- User interfaces with a Fuzzy DSS through Product Portal
3- Wrapped OWL instance file is sent to spatial reasoner for decision-support
4- Wrapped OWL instance file is sent to Fuzzy DSS
5- OWL wrapper exchanges mapping and XML files with XMLINOUT module
6- XMLINOUT reads standard mapping files
7- XMLINOUT reads GIS data
8- GIS files exported into standard XML files as per the ESRI geodatamodel.
9- Matlab used to create standalone Fuzzy Inference System

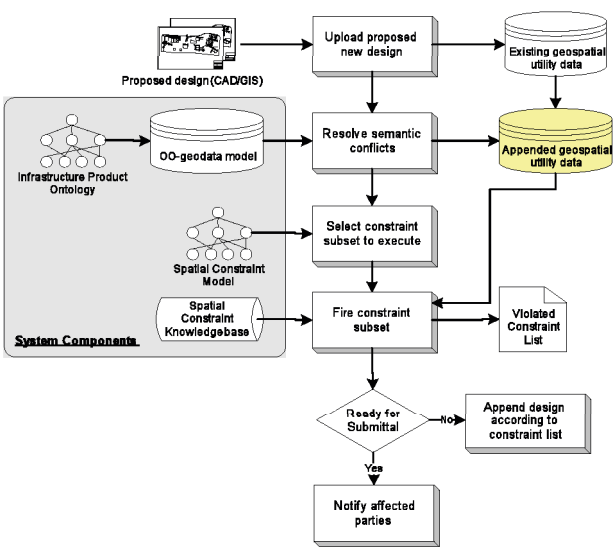

Figure 3: Product Portal

Process Coordination Portal

The importance of understanding and modelling the construction process to enhance the performance of construction projects has been emphasized by many researchers in the construction domain (Abeysinghe and Dominic 1999; Halpin 1993). Process orientation allows construction organizations to depict and manage resources, information, and people in a more integrated way (Lindfors 2001).

The proposed web portal is founded on two main pillars: an ontological representation and an ontology merger. Ontologies and ontology mergers, integrated in one portal, will support the knowledge-based integration of several processes in a dynamic way. Each collaborating entity can semantically represent its processes through an ontology. The portal will allow stakeholder ontologies to evolve over time, as their processes and/or nature of collaboration change. The merger would then dynamically merge these ontologies to create an integrated ontological representation of stakeholder processes. Each collaborating entity can use the integrated ontology, in a drag-and-drop-like fashion, to independently build its structure of processes (sequential flow of knowledge-carrying processes). The portal automatically analyzes these individual process structures for identifying similarities and interactions between these processes. Based on this analysis, a user (or portal coordinator) can build an integrated, knowledge-carrying process for all participating stakeholders. The integrated process encapsulates valuable knowledge: who is involved in the project at which time, what products (or parts of products) are being designed at which time and by whom, what are the constraints affecting each process?, etc.

A prototype portal was developed to help streamline a common workflow for project parties. The aim is to get a representation of each party's process structure and then allow an administrator to discover, dynamically, synergies and communication needs to weave a common process structure (for these independent agencies) without changing their internal process structure. The portal functions are (see Figure 4):

1. Semantic representation of processes: The portal starts by collecting the current process structure for each stakeholder. Partners can use the proposed process ontology to model and enter their processes. If a partner has an independent ontology, they can upload such ontology and use it to enter/model their work processes. Parties that do not have an ontology and are not willing to use the proposed ontology, can enter a simple semantic table of activities and their attributes. Using an algorithm, this will be transferred to a simple ontology, which can be used by this party to model their processes.

2. Semantic interoperability: The ontology merger then starts to discover similarities between all ontologies and create a common (ad hoc) ontology through communication and consultation with users.

3. Process analysis: now that all processes are represented in an interoperable semantic fashion, system administrator can find activities with similar requirements, matches between attributes, etc. the administrator can create a common work flow for all related parties.

The kernel layer is to provide: 1) semantic representation of user-individual process knowledge (ontologies) and processes, 2) merging user-individual process knowledge (ontologies) and processes into an integrated ontology and/or process sequence, and 3) navigation and exploration of the defined process knowledge. The following functionalities are available for users. .

- Process-structure builder and editor: to build a sequence (a Critical-Path-Method-like sequential flow) of processes from processes defined in the integrated ontology.

- Process-structure merger: to perform merging of two or more process-structures into an integrated process-structure.
- Process explorer: to navigate and explore the knowledge defined in the process-structure. This includes: navigation of process knowledge (as defined in the ontologies), developing schedules of integrated processes, sorting processes according to defined sorting criteria, automated identification of related processes, creation and exploration of other sequences (such as 'actor-sequence' which shows when each project actor is involved in the project), and semantic search of process knowledge. A wrapper exports and imports schedule information to and from Microsoft Project.

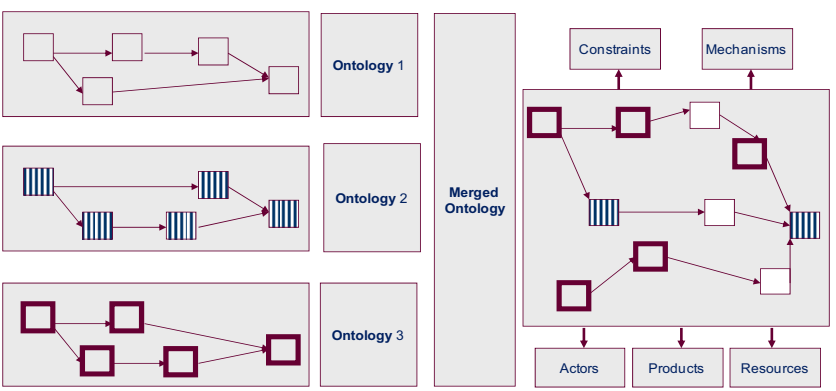

Figure 4: Process Portal

Actor Communication Portal

The goal of the communication portal is to facilitate information exchange and knowledge sharing in the AEC industry is to deliver the right information and knowledge to the right party in a timely manner. Three services must be effectively performed if this goal is to be achieved: (1) the semantic linking of people with project information, (2) the semantic linking of people with domain knowledge, and (3) the social linking of people with their peers. Based on these three requirements, three service scenarios have been suggested in the CIKP framework.

In the first service scenario, various individuals and organizations coordinate actions with each other by effectively exchanging project information and knowledge. Each industry participant (either an individual or an organization represented by someone) is treated as an actor in the system. The system will inform its users of the information and knowledge that they really need in a timely manner, based on their profiles (the actor they claim to be and the role that the actor is playing). In this way, people are linked with project-specific information.

The second service scenario envisions the sharing of domain-specific knowledge. The experience and lessons learned in the course of construction projects, whether successful or not, should be kept and shared among the people who need them. Knowledge sharing will help the industry to avoid mistakes from previous projects and people will not have to constantly reinvent the wheel. In this way, people are linked with domain-specific knowledge.

The last service scenario supports the knowledge learning and sharing process through the creation of virtual teams or Communities of Practice (CoPs). For a variety of reasons, industrial people have interests in information and knowledge not only about projects and science, but also about other people in industry.

Social networking is partially included in the CIKP framework through the creation of CoPs, although the functions of social networking are limited. Currently, system users are able to send a piece of information or knowledge to all group members of any CoP by assigning the suggested destination, but there are no other social networking functions suggested. Deeper social networking interaction should include finding and connecting with friend's friends, following up friends' events and thoughts, communicating through private messages, etc.

The system serve three purposes: exchange project related information, share general domain knowledge, and link industry people. A prototype application has been developed to be a showcase of semantically-rich, socially-savvy and technically-efficient system to support effective flow of information. Each user has access to some basic functions: (1) edit profile by claiming who you are, what role you play, and what attributes you have, (2) publish information and knowledge item by describing the item as complete as possible, (3) subscribe to information and knowledge items of interest by defining the attributes of those items, (4) browse items published and profiles of other users, (5) query the system by submitting a specific one-time subscription, (6) tag any item/profile using ontology concepts to enrich the description of that item, (7) express opinion about tags placed by other users by "agree", "disagree" and "flgs" buttons, (8) comment on any published item, (9) approve or reject tags placed by other users on items this user published, (10) join, leave, or create any virtual communities or team and interact with members, and (11) manage everything in a user interface page, including user profile, communities, published items, received items, participated items, etc.

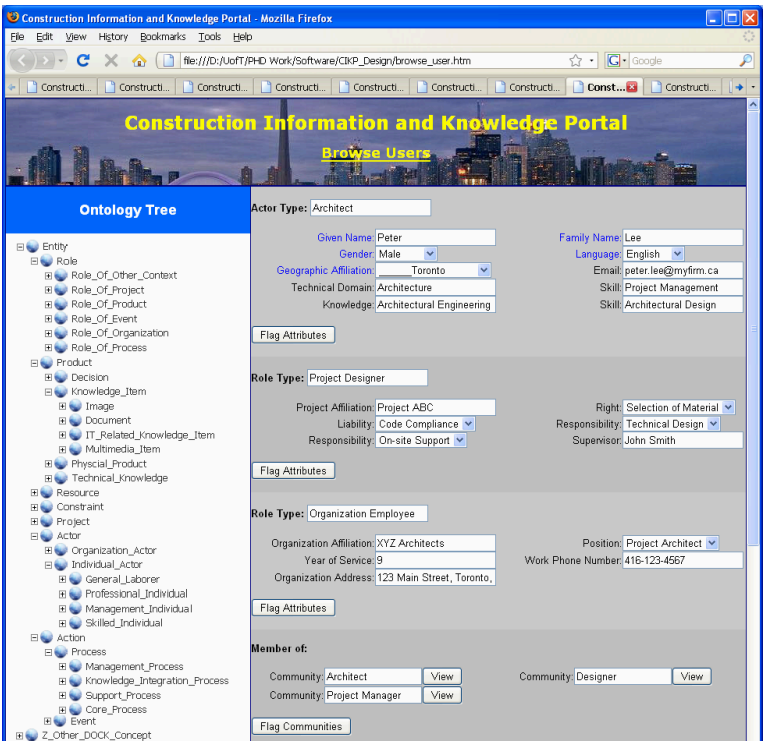

Figure 5: Actor Communication portal

Future Work: Virtual e-City Organizations

The realization of e-city is a necessary component for achieving the green city. Future projects will focus on creating an e-city platform for knowledge brokerage in the green city. The proposed platform will be a venue for creating dynamic virtual organizations to harness collective intelligence of knowledge hubs to analyze and manage sustainability knowledge in urban areas. Knowledge assets of participating organizations will be presented in three dimensions: process structures, human profile and software systems. These three facets of knowledge will be accessible and viewable through a self-describing mechanism. Cities can post their geospatial and real-time data on project network. Relevant environmental and energy-use data will be extracted using topic maps and data extraction services. Local decision makers can synchronize work processes (from participating hubs) to create an integrated workflow for a new ad hoc virtual organization to collaboratively analyze the multifaceted nature of sustainable decision making.

Fundamentally, the aim is to build a user-friendly service-oriented integration platform. This platform sits on top of existing software systems, databases and process structures of civil infrastructure.

The e-city platform will be realized through intelligent, agent-like, domain-specific middleware (KnowWare). Through triangulation between people, software and processes, these KnowWare will discover, negotiate, integrate, reason and communicate knowledge (related to energy and environment) from across organizations to the right person at the right time. KnowWare is fundamentally, a portal of social semantic services that resides on a cloud computing infrastructure. Knowware exploits thee main tools: 1) existing ontologies to represent knowledge in a semantic manner, 2) topic maps to profile sources of knowledge and match these to the complex needs of sustainability analysis, 3) domain-specific middleware for knowledge integration and reasoning.

ABSTRACT

With ageing water and sewer infrastructure in North America, assessing the condition of these assets has received increased attention in the past few years. Condition assessment is an integral component in any asset management program. Determining the condition of buried infrastructure tends to be more cumbersome, costly and error-prone compared to other surface infrastructure like roads and buildings. For sewers, CCTV is considered the industry standard for condition assessment technologies. For pressurized water pipelines, technologies tend to be more costly and uncertain (e.g. electromagnetic, sonar, acoustic leak detection, infrared etc…). Faced with constrained budgets and the need to obtain reliable condition information to drive their asset management processes, infrastructure owners must balance the value of information obtained through condition assessments with the cost of obtaining this information.

This paper presents an analytical framework and decision support system to evaluate the value of information for condition assessments of water and sewer infrastructure. The framework considers: 1) risks associated with operating the asset, 2) potential direct and indirect costs of infrastructure failure, and 3) customer expectations for the system's level of service. The decision support system utilizes Partially Observable Markov Decision Process (POMDP) to compare between the reliability and cost of the condition assessment technology.

The system is demonstrated on the water and sewer networks for the City of Hamilton, Canada.

Introduction

Condition assessment is one of the cornerstones of any infrastructure asset management program. Obtaining reliable condition information is a necessary precursor to the development of asset rehabilitation policies, setting levels of service and determining the true value of an infrastructure network (FCM, 2005). Compared to surface infrastructure systems like roads and buildings, condition assessment of water and wastewater infrastructure tends to be a time consuming, costly and error-prone activity. For pressurized water pipelines, direct assessment technologies (e.g. electromagnetic, sonar, acoustic leak detection, infrared etc…) tend to be costly and uncertain. Indirect assessment of water pipelines are common practice and include measuring factors like corrosivity potential, water quality, and surrounding soil properties. Indirect assessments tend to more affordable but correlation with actual pipe deterioration is not as accurate as direct assessments. Faced with constrained budgets and the need to obtain reliable condition information to drive their asset management processes, infrastructure owners must balance the value of information obtained through condition assessments with the cost of obtaining this information. In order to develop a condition assessment policy, the asset manager must answer the following question: 1) What condition assessment technique should be used and 2) What is the most suitable frequency to inspect or re-inspect an asset. The answers to these questions rely on the expected condition state of the asset, the risk associated with asset failure and the user's tolerance of a reduction on level of service. This paper presents a framework for developing condition assessment polices that balance the cost of assessment with the value of information revealed by the assessment.

Condition Assessment of Water and Sewer Infrastructure

Condition assessment facilitates the ongoing estimation and tracking of asset condition. Without reliable data, no rational decisions are possible. Inspection technologies enable detecting the deterioration processes of a pipe via identifying distress indicators and aggregation of all measured indicators to establish condition states. Non-destructive techniques (NDT) refer to inspection methods that provide conditional information about pipes without destroying them or impairing their future usefulness. Generally speaking, techniques for buried pipe condition assessment fall into two categories – direct and indirect. Direct techniques are based on the physical properties of the pipe wall. Ultrasonic technologies (UT), remote field eddy current (RFEC), visual inspection (CCTV), techniques are examples of direct techniques. These techniques all require the direct examination of the pipe and tend to be costly in most cases. On the other hand, indirect techniques rely on assessing environmental factors surrounding the pipe that are likely to influence deterioration rate (e.g. soil properties, presence of stray current, excessive pipe loading, etc….). Indirect

techniques tend to be less costly and cause less disruption but are less accurate compared to direct assessment.

The past decade has seen the adoption of new technologies for the condition assessment of water and sewer pipelines. Many of these technologies were initially developed for other domains like the oil and gas industry for pipeline integrity management. The economic viability of their application in municipal infrastructure applications has been questioned. Ageing pipeline infrastructure, coupled with the interest in adopting these technologies motivated the development of a model to assess the value of information provided by the technologies. The following section presents the framework of the model.

Optimized Condition Assessment Model

Developing optimum condition assessment policies basically involves answering two fundamental questions; 1) What technology should be used for a particular asset, and 2) How frequent should a condition assessment be performed. In order to answer these questions the asset manager must consider several factors simultaneously. These factors can be grouped into two sets of attributes; infrastructure asset attributes and condition assessment technology attributes (Figure 1). Asset attributes that have a strong impact on determining condition assessment policies include asset criticality and required level of service (LOS).

Asset Criticality: This attribute describes the risk associated with operating the asset. More specifically it is a measure of relative consequence of failure associated with operating the asset. High criticality assets exhibit high economic, social or environmental consequences upon failure. Examples would include large diameter transition mains, assets on busy downtown streets, or those close to environmentally sensitive areas. For high criticality water and sewer infrastructure the cost of using accurate condition assessment technologies at relatively short intervals would be justified due to the dire consequences associated with their failure. Quantifying asset criticality in strictly monetary terms is a difficult undertaking especially when indirect costs are considered. The OCAP model utilizes the Grand Central Model (Cromwell, 2002) for calculating social costs.

Required Level of Service: Customer expectations for LOS are core to developing asset management policies (NAMS, 2007). When customers expect higher levels of service and municipalities aim to meet those expectations, spending on asset maintenance, repair, rehabilitation and condition assessment will increase. In order for a municipality to meet higher LOS standards they are likely to become more proactive in the inspection of their assets. Adopting a more proactive approach will lead to more frequent inspections and less tolerance for uncertainty in condition data. As such when required LOS increases, more frequent and reliable condition assessments are likely to be deployed.

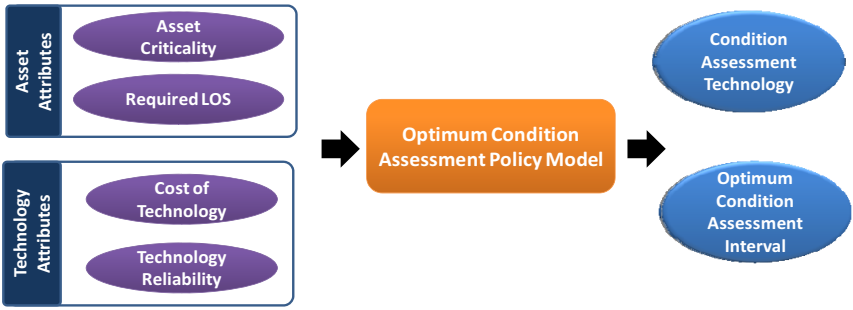

Figure 1. Framework for optimum condition assessment model

The OCAP model aims to that allocate the most suitable condition assessment technology to the right infrastructure asset. The two key attributes of the inspection technology that are considered in the model are the cost and reliability.

Technology Cost: Condition assessment costs for buried infrastructure tend to be higher compared to surface infrastructure like buildings and pavement. As such the OCAP model aims to strike a balance between the value of information revealed by the technology and the costs required to obtain this information.

Technology Reliability: The reliability of some condition assessment technologies for water and sewer infrastructure cast a shadow of doubt on the usefulness (and certainty) of inspection results. For water infrastructure in particular, the use of indirect assessments has shown to weakly correlate with actual pipe condition. Even when direct assessment techniques are used (e.g. electromagnetic detection of broken pre-stressing wire in PCCP pipe) perfect correlation between distress data and pipe condition cannot be guaranteed (Semanuik and Mergelas, 2006).

The OCAP model relies on special form of Markovian Chains called Partially Observable Markov Decision Process. The following sections present the theoretical background of the models.

Markov Decision Process

Markov Decision Process (MDP) is a decision tool to model several sequential decision-making situations involving uncertainty and multiple objectives, including applications related to infrastructure maintenance problems (Scherer and Glagola 1994.). MDP is based on determining of the state variables (asset states in different time horizon), determining transition matrices (asset deterioration through lifecycle), identifying controlling decision (maintenance actions), and calculation of the rewards (costs) associated with taking actions in each time step. Markovian models have been used to model bridge, pavement and road deterioration. One of the shortcomings of Makovian models is that they consider that a

condition assessment will always yield a perfect estimation of the current asset condition. Subsequently the MDP model assumes that the forecast of future condition is perfectly accurate. Partially Observable Markov Process is a modeling approach that overcomes this shortcoming. Jiang et al. (2000) and McCann (2000) incorporated a measure of inspection reliability in the MDP to compare the accuracy of various condition assessment techniques of bridges.

Partially Observable Markov Decision Process

POMDP is an approach towards a more realistic model for infrastructure deterioration where there is inherent uncertainty in the results of a condition assessment. Different inspection technologies have different costs with varying reliability; however no inspection technique can always yield a perfectly true state. Accordingly, POMDP adds another space to the MDP; namely the 'observation space'. The observation space represents the relative reliability of an assessment technique. The mathematical background of POMDP is discussed explicitly in (Ellis et al 1995, McCann 2000 and Cassandra 1994). As such the following discussion is limited to applications of POMDP for developing optimum condition assessment policies.

The variables $[X^t, t\epsilon T, X^t \epsilon S]$ represent the core evaluation processes of the system so that x_t represents the state of the system at time t and S= $(0,1,2, \dots m)$ is the state space of m states. The set of T is consisting of non-negative discrete time points where the system is observed and controlling decision is taken. Since the system is modeled as discrete time MDP and every successive state is independent of the previous state, the stochastic process can be represented as $\Pr(x_{t+1} = j | x_0 = k_0 \cap x_1 = k_1 \cap \dots x_{t-1} = k_{t-1} \cap x_i) = Pr(x_{t+1} = j | x_t = i)$. For t ∈ (0,1,2 ,…) and every possible subsequent decision $i, j, k_0, k_1 \dots \dots k_{t-1}$. In this equation conditional probability $Pr(x_{t+1} = j | x_t = i)$ is called one step transition probability and it represent the probability that variable X will be in state j after one step given the current state is i. The one step transition probability is said to be stationary if $Pr(x_{t+1} = j | x_t = i) = Pr(x_1 = j | x_0 = i)$ and also implies that $Pr(x_{t+n} = j | x_t = i) = Pr(x_n = j | x_0 = i)$ for every i, j and n= (1, 2, 3,..n). This is called n-step transition probability (p_{ij}^n). Transition probability follow probability axiom $p_{ij}^n \geq 0$ for all i, j and $\sum_{j=1}^{m} p_{ij}^n = 1$ for all i where m is the number of the discrete states of the system.

Based on observation an action $a_t \in A$ is performed to control the behavior of the system. Each action has a corresponding transition matrix $P(a_t) \in \hat{P}$, and this represents the system evolution processes till next decision is made. Since no inspection technique is cable of yielding a complete estimation of the actual condition, an estimation of the actual state will be through incomplete observation Y_t. This observation process is donated by $(Y^t, t\epsilon T, Y^t \epsilon O)$ where O is the observation space. Relationship between the observation at time t and core process is given by $R(a_{t-1}) = r_{jo}(a_{t-1}) = Pr(Y_t = O | x_t = j, a_{t-1})$ where $R(a_{t-1}) \in \hat{R}$ is called the relationship matrix. Each $r_{jo}(a_{t-1})$ donates the probability that observation O is received when the system is in state j at time t and action a_{t-1} is performed at time t-1.

Model Implementation

The model is implemented on a programmable Excel spreadsheet with links to a GIS system for visualization. The case study presented in this section illustrates how an observation matrix for a condition assessment technology is used to modify the predictive capability of a Markovian state transition matrix. The case study presented in this section is for the City of Hamilton (ON, Canada) water main network. The City of Hamilton owns 1950 km of water distribution infrastructure with an estimated value of C$1.5 Billion (SOI Report, 2005). In 2006, the City embarked on a series of studies to develop an integrated management framework for managing their water main inventory. As a part of this exercise the City developed a criticality model that serves as a risk-based classification of water mains based on their consequences of failure and LOS.

The risk analysis for the city network divided the network in to three main categories; 'A' which represent the highest and the most critical categories asset, 'B' which represent assts that have less significant cost of failure compared to 'A' category and 'C' which represent the type of assets that have lowest failure costs and reduced LOS that can be tolerated. The case study focuses on selecting optimized condition assessment policies for high and medium criticality water mains (A-B). These assets pose a significant risk in case of failure and hence the there is a need to proactively collect condition assessment information in order to prevent failures from occurring. Roughly 30% of the network has been categorized as critical (10% as 'A' and 20% as 'B'). The following discussion will focus on these ~ 600 km of water mains.

A five-state annual Markov transition matrix for water main assets is shown in **Error! Not a valid bookmark self-reference.**. The Markov transition matrix was developed based on CCTV sewer inspections. Lacking a reliable water main deterioration model, it is assumed that the deterioration of water mains will follow a similar pattern to sewers. This is a somewhat loose assumption that will need verification once sufficient condition data are available for water mains. Penalty costs are associated with the 'Poor' and 'Failure' states and reflect the actual cost of a water main failure and the costs associated with a reduced level of service. The failure costs are taken as $5,000 for criticality 'A' pipes and $2,000 for criticality 'B' pipes. The model also considers costs associated with reduced level of service. Reduced level of service could include factors such as poor water quality, insufficient water pressure or planned water shut downs for maintenance activities. A cost of reduced LOS of $700 is taken for pipes that reach a state of 'Poor'.

Table 1. Markov annual transition probabilities for water main assets

	Excellent	Good	Fair	Poor	Failure
Excellent	0.9	0.1	0	0	0
Good	0	0.96	0.04	0	0

Fair	0	0	0.92	0.08	0
Poor	0	0	0	0.9	0.1
Failure	0	0	0	0	1

To account for differences in cost and reliability of condition assessment technologies, observation matrices are defined for three technologies. The observation matrix relates the percentage of observed to actual condition state. For example in

Table 2. Observation matrix for three condition assessment technologies

below, using the medium accuracy technology only 90% of those assets observed as being in a state of 'Excellent' are actually in that state as 10% of them are actually in a condition state of 'Good'.

Table 2. Observation matrix for three condition assessment technologies

	Low Accuracy	**Cost/m:$5**

		Actual				
	State	1	2	3	4	5
Observed	1	0.85	0.15	0	0	0
	2	0	0.85	0.15	0	0
	3	0	0	0.85	0.15	0
	4	0	0	0	0.85	0.15
	5	0	0	0	0	1

	Medium Accuracy	**Cost/m $15**

		Actual				
	State	1	2	3	4	5
Observed	1	0.9	0.1	0	0	0
	2	0	0.9	0.1	0	0
	3	0	0	0.9	0.1	0
	4	0	0	0	0.9	0.1
	5	0	0	0	0	1

	High Accuracy	**Cost/m $100**

		Actual				
	State	1	2	3	4	5
Observed	1	0.98	0.02	0	0	0
	2	0	0.98	0.02	0	0
	3	0	0	0.98	0.02	0
	4	0	0	0	0.98	0.02
	5	0	0	0	0	1

State 1= Excellent, State 2 = Good, State 3 = Fair, State 3 = Poor, State 5 = Failure

The model calculates the transition matrix which represents the expected deterioration processes of the single asset in the future. As the information reliability of the conducted inspection affect the accuracy of determining the current condition of the assets, asset assumed condition is calculated via different inspection techniques. The condition that is calculated via observation matrix and transition matrix is called belief state. Determining the difference between the transition matrix and the belief state will result in obtaining the expected error. The result of multiplying of the error matrix via the associated costs of failure and reduced LOS costs yields the cost of imperfect information. The value of information is shaped by adding the inspection costs to the costs of imperfect information. The optimum policy for the segment pipe is determining by choosing the least of these added costs. Table 3 show an example on determining the optimum policy for various inspection accuracies with different conditions assuming pipes are inspected every five years.

Results of the analysis highlight the interaction between value of information revealed by condition assessment and the cost of obtaining that information. For example the cost of imperfect information of a low reliability condition assessment technique for criticality 'A' pipe in poor or fair condition is quite high ($380.9 and $290.4 respectively). This high cost swings in favor of conducting a high-reliability condition assessment as the added cost of assessment does not outweigh the costs that are a consequence of low reliability assessment (high cost of failure and impact on reduced LOS). Looking at criticality 'B' pipes, it seems that high-reliability assessments are not a good investment as the added value of reliable information is still less than the cost of obtaining this information. Pipes that are in deterioration state of 'Poor' are not recommended to be inspected with low reliability assessment methods. This is due to the high cost associated with a 'misdiagnosis' and subsequent possible failure of the asset. Figure 3 shows the result of the analysis on a portion of the water main network assuming a 5-year inspection frequency.

Table 3. Results of value of information analysis using partial observation matrix

					Cost of Inspection			
					5	15	100	
Criticality	Condition State	Cost of imperfect information			Total Cost			Decision
		Low	Medium	High	Low	Medium	High	
'A'	Excellent	$4.4	$2.9	$0.7	$9.4	$17.9	$100.7	Low
	Good	$73.9	$49.3	$4.4	$78.9	$64.3	$104.4	Medium
	Fair	$290.4	$193.6	$32.8	$295.4	$208.6	$132.8	High
	Poor	$380.9	$253.9	$50.8	$385.9	$268.9	$150.8	High
'B'	Excellent	$2.5	$1.7	$0.4	$7.5	$16.7	$100.4	Low
	Good	$37.8	$25.2	$2.3	$42.8	$40.2	$102.3	Medium

	Fair	$126.6	$84.4	$14.8	$131.6	$99.4	$114.8	Medium
	Poor	$132.9	$88.6	$17.7	$137.9	$103.6	$117.7	Medium

At the global level, results are quite intriguing. The majority of water mains (around 85% by length) are recommended to be inspected using a low accuracy inspection technology. High accuracy inspection technologies, (shown as red in Figure 2) are only recommended for less than 2% of water mains. As such the results allow the asset manager to target high cost assessment technologies to only those assets that need are in greatest need. It should be noted that the analysis assumed that an unlimited inspection budget is available. Attempting to allocate a limited inspection budget to all assets is an interesting application of the model that is currently under investigation.

Figure 2. Condition assessment policy map – 5 year inspection interval

Summary and Conclusions

Condition assessment facilitates the ongoing estimation and tracking of water main asset condition. The lack of reliable condition data is a tremendous impediment to any asset management program. Water and wastewater infrastructure condition assessment is costly and uncertain compared to other surface infrastructure. Decision makers need to 'sell' the idea of obtaining condition data to drive their asset management programs. This paper presents the results of an ongoing research effort to create a framework for rationalizing condition assessment policies across water and wastewater networks. An illustrated example of the City of Hamilton water network was presented to showcase how the model can be deployed. Further extensions to the framework are underway to assist in 1) Optimum allocation of condition assessment budgets across assets and 2) Setting condition assessment budgets taking into consideration potential failure costs and reduced levels of service.

In order to balance the value of information revealed by a condition assessment technology

with the cost of obtaining the information, the decision maker must consider several factors simultaneously. The first factor that needs to be considered is a quantification of the direct, indirect, and social costs associated with an asset failure. In order to prevent costly failures, decision makers are more likely to spend money to obtain condition information for assets that have a high cost of failure. The second factor that needs to be considered is the desired Level of Service (LOS). User expectations for higher LOS will translate into more proactive asset management practices that involve more comprehensive assessment of asset condition. As such an integrated framework for Optimized Condition Assessment Policies (OCAP) has been developed to assist asset managers in striking this delicate balance between value and cost of condition assessment information.

Abstract

A majority of construction projects often have a significant impact on the surrounding neighbourhoods and the environment at large. In city scale infrastructure projects, this impact can be detrimental to project success. The affected populations often have concerns and more importantly local knowledge relevant to the project. Capturing and integrating this feedback enhances project sustainability. This integration is a feature of smart city initiatives that have increased collaboration between regulatory bodies and project planners. However, the community has not been able to effectively engage in this process. Accordingly there is a need to facilitate two-way communication to promote community involvement beyond the capabilities of a smart city; this will be achieved through e-Society. An e-Society boosts citywide sustainability by contributing to an expanding pool of knowledge. This research investigates the use of semantic and social web technologies and Information and Communication Technologies (ICT) to facilitate public engagement in construction projects. The proposed framework features a core ontological model that is integrated with web-based middleware. It will contribute to the sustainability of construction projects through enhanced two-way communication and enriched public participation.

Introduction

As most urban areas are heavily developed, a majority of new projects in those areas involve rehabilitation rather than raw construction. Rehabilitation often requires disruption of existing infrastructure operations such as flow in transportation networks. In addition, there is the effect on the environment among other impacts. To the residents of these cities, this disruption has a direct impact on their day-to-day activities. Infrastructure projects, in general, have an impact that spans several communities. It is thus required by law in most cases that the public are well-informed and involved in the planning and decision-making process.

The importance of this kind of community involvement is evident in regulations for Environmental Impact Assessments (EIA) in many countries, including Canada. There has also been a recent shift in focus to low impact development in construction (Yu et. al, 2008). This shift promoted an emphasis on minimal disruption as it minimizes costs and the chance of introducing delays to the project. In addition to the introduction of enhanced construction technologies, public participation has been an integral component of this minimal disruption trend.

The aim of this project is to establish a social, web-based, semantic environment in which community ownership of construction projects is encouraged and facilitated. This research investigates the use of semantic and social web technologies and Information and Communication Technologies (ICT) to facilitate public engagement in construction projects. The proposed framework features a core ontological model that is integrated with web-based middleware. It will contribute to the sustainability of construction projects through enhanced two-way communication to enrich public participation and the planning process.

Similar studies in this area have emphasized the need for promoting effective public participation using visualization and web tools. A recent example is the implementation of several projects that use Public Participatory Geographic Information Systems (PPGIS). Meng and Malczewski (2009) evaluate these tools and specifically web-based PPGIS which focuses on usability by making the process more intuitive and collaborative. They also present a Canadian case study which will be discussed later in this paper.

In this paper, we will establish the need for public participation in the area of construction engineering through a review of the literature. This review will be followed by our proposed framework and validation method.

Public participation

The current process typically takes the traditional form of an open house meeting. Members of the public are provided with a chance to request and review certain documents relevant to the project under consideration. The meeting then takes place at a specific time and venue where members of the public attend a presentation by the project planners, usually accompanied by maps and other forms of visual aid. Attendees can then respond with concerns and questions. Periodically, the planning committee proceeds to acknowledge the public's concerns in the order they are received, and provides responses to some of them within the time limitation of the meeting. Forms of concern are also accepted within a certain deadline, usually a few months after the meeting. The main limitations identified in this process are: 1) need for physical attendance, 2) time limitation, 3) space limitation, and 4) limited media of communication.

In current systems, the involvement of the community is often perceived by the participants and practitioners as a costly and inefficient process. This perception leads to resentment on part of the construction planners as well as the members of the community; hence, undermining the role of community involvement in the planning process. In the case that the rationale behind a project is not communicated clearly nor efficiently, the project could be affected adversely by not meeting the actual needs of the public or through misuse in the future. Furthermore, construction

projects often have significant impacts as mentioned earlier. Impacts such as traffic holdups can be detrimental to project success as they raise legitimate concerns that need to be addressed. Besides those concerns, community members could also possibly have suggestions that need to be tested and local knowledge that should be captured. An example would be a substitute route that would fit as an alternative implementation of a project. They need the means to experiment with the options, perhaps through a model, so that the communication would be two-way rather than one-way information flow from the construction team. The project proposed here offers a solution that builds on current projects while utilizing the best available collaboration technologies to promote community involvement.

Several channels have already been made available through recent advances in web technologies and the recognition of the importance of engaging stakeholders. Evidently, smart city initiatives have increased collaboration between regulatory bodies and project planners. However, the community has not been able to effectively engage in this process. As mentioned earlier, the social aspect of the project would allow for more efficient community involvement as the project would link people as a community rather than acquiring individual responses. In order to achieve a wider community reach, the participation process should be web-based. This web-based nature will provide greater accessibility and less logistical limitations. Finally, in order to bridge communication between people and computer systems (in other words, the linguistics of the people and the way computers process data), this process necessitates the integration of semantics. This bridging enables the project planners to interact with the public in a language that they understand, rather than have them inconveniently adapt to technical language. The semantic web presents the best available technology to represent knowledge. Effective knowledge retention and community involvement have both been proven to develop a sense of community ownership that is vital for achieving sustainability within an e-society.

E-society

An information society is defined as a community that employs a smart infrastructure to exchange information. An e-society builds on that definition as an engaged community that effectively utilizes a smart infrastructure to facilitate two-way communication and the exchange of knowledge. Within our context, in addition to the usual economic dimensions of a construction project, an e-society enables the incorporation of other dimensions within the scenic, environmental, historic, aesthetic and social context. To achieve that broad context, the concept of e-society involves several disciplines, shown in Figure 1.

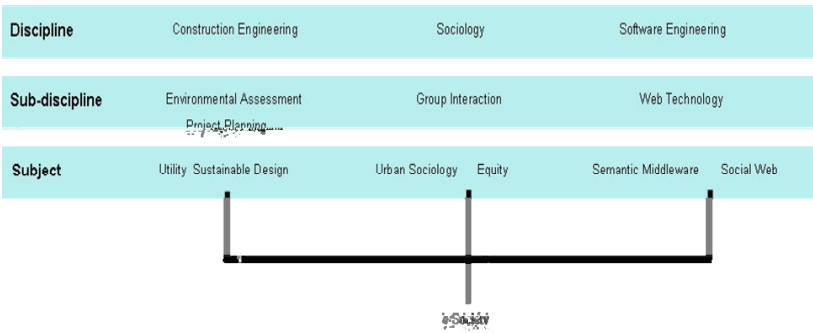

Figure 1. Disciplines involved in e-Society

A review of the literature

The focus of this review is the role of collaboration and, more specifically, public participation in construction projects. There is an abundance of literature on the use of software to enable visualization of building models, facilitate communication of information, and develop Building Information Models (BIM). While these tools are an essential component of the practitioners' work, they are not utilized to their best in information gathering and knowledge management for the purpose of sustainability.

This review starts by describing the processes involved and the social aspects. Relevant projects are discussed as a sample of current work in this area. This description is complemented by a compiled definition of an e-Society in relation to a smart city.

Smart city and e-society

A community in which ICTs are used to enable and enhance two-way communication between the public, organizations and governing bodies formulates the basic definition of an e-society. The core of this system is the existence of two-way communication. The literature reveals a number of initiatives that involve the creation of smart cities as a backbone to aid in the realization of an e-society. What makes a city a "smart city" is discussed by Hollands (2008) who explains that it is not just a connected infrastructure but also the "human capital side" or the culture on a city-wide scale.

For further effectiveness, communication between the members of this society should be empowered through the use of technologies such as social networking applications. The creation of an e-society involves a social, economic, technological and political aspect, in addition to the engineering component in infrastructure projects. Naturally, an e-society would be based on a web-based portal as the core engine of the system. While a few portal implementations have been developed, the literature lacks a comprehensive implementation of a portal in the construction domain that would enable full integration of existing software applications, in addition to the use of social web technologies.

On the other hand, in order to achieve an e-society, cities must first achieve e-readiness. An annual report by the IBM Institute for Business Value and the Economist Intelligence Unit ranks countries according to an e-readiness score, which measures the capacity to use ICT to develop a country's economy. The Economist Intelligence Unit has assessed the world's leading economies on their ability to absorb ICT since 2000. In 2009, Canada came in 9th place with a score of 8.33 on a scale of 10, trailing behind a mix of European and Asian countries in addition to the United States. While this score reflects an overall good world ranking, it shows that there is still a lot of room for improvement. The detailed e-readiness report (EIU, 2009) focused on various aspects of e-readiness such as connectivity, e-inclusion programs and Internet literacy, and adapting the legal system and policymaking.

Process

Public participation has become a common component of the construction process in most projects, specifically infrastructure projects. The Canadian Environmental Assessment Agency encourages public participation in the federal environmental assessment to promote quality through a process that is equitable and non-biased (CEAA, 2003). In addition, the local and traditional knowledge about a project's physical site can help to identify and address potential environmental effects at an early stage of the environmental assessment process (CEAA, 2003).

Infrastructure construction projects that involve transportation are among the projects that have higher impact on the public. In the Greater Toronto Area, Metrolinx (2009) succeeded in creating a two-way communication channel through an online portal. On the Metrolinx portal, members can register as consultees to express their own opinion and post comments or as agents that would make comments on behalf of other individuals or organizations. A list of projects is available for the user to navigate. An additional view is available through a map that can be pointed to a specific postal code. Since the nature of most transportation projects is based on proximity, the map view would prove to be a very useful tool. This portal provides improved accessibility to the public, yet it might not intuitively support collaborative participation or predictive features.

In addition to maps and visualization techniques, there is increasing interest in the prospect of social networking as a potential means of collaborative participation and networked decision making. Several studies provide evidence that supports the importance of public involvement at a normative level in reducing delays and conflict in the different stages of planning. For instance, Smith (1983) emphasized the lack of public participation at a normative level in Ontario in 1983 when three alternative approaches were presented for the specific case of Ontario Hydro. The recommendations proposed by Smith include: 1) instituting a representative public advisory board, 2) that board should ensure that the release of major position papers is synchronized with public involvement, and 3) facilitate public review of energy planning a standing committee for legislation (Smith, 1983). This kind of public involvement at an early planning stage ensures that potential issues can be addressed promptly or preemptively. There is evidence of a social need for public participation.

Public participation in construction

In the aforementioned projects, it is evident that more emphasis is being placed on the public as more decision makers are taking into consideration that engineering projects, by design, involve the creators and the users: the public in this case. Nevertheless, many of the mechanisms available today do not provide sufficient tools to aid in effective public participation. The Canadian Environmental Assessment Agency (CEAA) emphasizes that public participation in the general environmental assessment process guarantees the openness, proper balance and credibility of the process. More importantly, the public can help identify and address potential problems at an early stage through their first-hand knowledge about a specific site (CEAA, 2003). Another facet of public participation is the review panel: a group of experts who contribute their knowledge to a project. The review panel is as important as other forms of public participation as it provides a way for the public to offer their expertise. The capture and retention of this experience as knowledge can have a major role in the sustainability of infrastructure projects. This practice is heavily used in an area known as Knowledge Management.

To enable public participation successfully, the technology has to support those initiatives at the process and social level. There is evidence that the current technology and existing standards are capable of nestling the aspired level of public participation in infrastructure projects. A review of the current use of ICT in the area public participation presents evidence that a significant amount of work is needed for integrating the existing technologies and making better use of social networking technologies (Rivard et al., 2004).

Middleware

Middleware systems facilitate integration by modeling common services of software applications. The World Wide Web (the Web) itself is an example of a networked environment. An issue that had to be dealt with on an urgent basis was the successful integration of legacy systems that contained highly sought information that should be accessible over the Web (Perrochon, 1995). Application integration is a relatively seasoned yet very current field. It has seen great progress from tedious custom-made interfacing software to the creation of Web-based middleware. For the purpose of this review, the interest is in the integration capabilities of middleware. In principle, middleware enables communication between applications that can be geographically separated or designed to run on different platforms, while providing additional functionalities.

Best practices for middleware mash-ups

In an interesting position paper, Ankolekar et al. (2007) explain how the semantic web and Web 2.0 are complementary rather than competing. Both approaches lack certain aspects. For instance, building semantic web infrastructure would not be an easy task without the creation of online communities through Web 2.0 to aid in knowledge mining (Ankolekar et al., 2007). IBM provides examples of distributed middleware with business applications in the areas of asset management, transportation, trade and banking (IBM middleware, 2009). These applications focus on interactive two-way communication applications like integrated mobile fleet

management. IBM's Maximo middleware introduced this functionality in transportation while other middleware systems provide integration of fleet management with supply chain management systems. Through better management of information, these systems can be easily integrated with other IBM software systems to provide additional functions such as security. The best practices outlined by IBM (IBM middleware, 2009) included a combination of context-aware middleware, event-based publish/subscribe system, domain-specific ontology and social networking tools. Web-PPGIS is an example of such mash-ups that hide the complexity of underlying technologies from the users. Meng and Malczewski (2009) assessed its positive contribution to the process of siting a parkade in Alberta, Canada. They indicated that Web-PPGIS enhanced the quality of the experience for the users, while it lacked features that could aid the users in making decisions.

Ontology & semantic web

The semantic web is an extension to the Web which adds context and meaning to the content, and improves predictive capabilities. In the engineering context, many of the terms and standards have not been unified across the industry yet, and this dynamic, distributed environment paves the way for semantic web applications. Figliozzi and Tufte (2009) discuss the essence of adding semantics to enable the integration of freight data. An Internet-based system is proposed that also provides visualization through semantic data models. These models facilitate the use of existing applications. It has become a best practice to use ontologies to represent entities, relationships and axioms within models in semantic web systems. SWIM is a framework that combines the semantic web, and virtual organizations to enable the management of traffic incidents on freeways in a real-time manner (Abou-Beih et al., 2009). In this project, taxonomy has been built to model the incident management process, including the actors, rules, relationships and products. This taxonomy forms the base of the interaction of different parts of the system while efficiently routing incident information. This kind of mash-up usually requires the development of a separate middleware system to handle this integration. Semantic middleware systems are used to reduce the complexity of the integration process with examples from the software industry (Oberle et al., 2004).

Proposed framework

The proposed framework will include a web-based portal with an ontology as a core component. This portal will employ semantic and social web principles for enhanced usability. These principles employ relatively well-tested technologies that can be integrated into the middleware system. A semi- or fully-automated middleware component is currently being designed as the core engine of this project. Figure 2 shows the main aspects that would be featured in the portal.

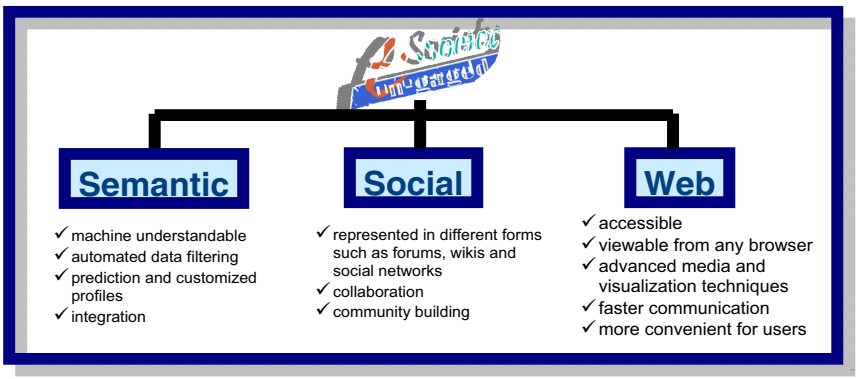

Figure 2. Main elements of the e-society portal

The methods used to carry out this research follow the standard research methodology which involves incrementally designing, implementing and assessing the ontology and portal system. Surveys and literature reviews are the primary tools used for building the ontologies and formulating the model. On the other end, validation is the main tool used to ensure that the different modules of the ontology properly model the processes they represent.

As a first step, the current public participation process is being modeled. This step is performed using the literature as well as passive and active observation of public meetings. Following the completion of that model, the main products have been identified as: 1) a comprehensive ontology (following the method outlined by Grüninger and Fox (1995)); 2) prototype implementation of portal and social software; 3) use cases for validation; 4) pilot project for benchmarking. The pilot project would validate that "better" participation is attained, based on the following criteria: number of visits by participants, quality of participation (diversity and quality of feedback) and feedback from project managers on the quality of feedback and potential integration into design. The main tasks can be summarized as follows:

1. Describe current processes and online participation practices in the construction domain. This process involves identifying roles, common issues and mechanisms, as well as best practices.
2. Build an ontology to represent knowledge in the public participation process. This stage of research involves developing a set of requirements or questions that the ontology should answer (Grüninger and Fox, 1995).
3. Conduct interviews to validate the concepts, relationships and axioms.
4. Analyze requirements for the social web-based portal.
5. Create a web-based portal implementation that incorporates the ontology.
6. Test and validate the system with the integrated ontology. Validation would involve benchmarking the performance of the system.

The validation process here is a primary component of the research methodology. In addition to the benchmarking criteria already mentioned, validation will include tools such as interviews, focus groups and surveys for gathering primary

data. The subjects of these interviews are practitioners who are directly involved in the planning and design process of selected construction projects. In addition, use cases outlining several scenarios such as that shown in Figure 3 will be used to define the scope of validation and acceptance criteria.

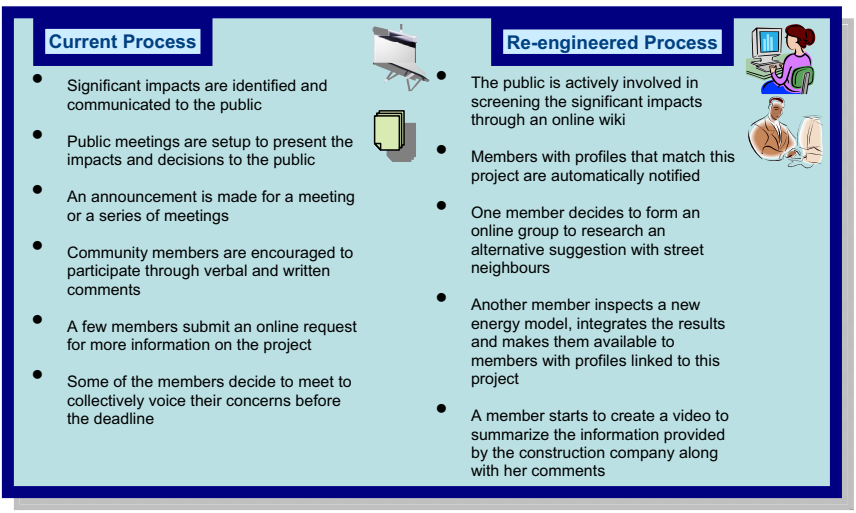

Figure 3. A typical scenario comparing the current participation process and the future vision

Conclusion

Within the context of construction projects, this paper has established a need for public participation that is based on two-way communication. An important tool for achieving the facilitation of this type of participation is the Web and its various collaboration and visualization tools. Similar projects have been shown to successfully foster public collaboration, with success of web-based PPGIS projects which focus on usability. However, the paper reveals that many of these systems lack the semantics specific to the construction domain, which would enhance the user experience as well as help in gathering information and retaining the knowledge component. This knowledge can be transferable from one project to another.

The review shows that Canada has a high rank in e-readiness, yet also indicates that there is a lot of room for growth. With regards to the construction industry, public participation seems to be one of the potential channels for promoting sustainability of projects by focusing on engaging the users. We have proposed a framework that utilizes semantic web-based middleware and web-based concepts such as social networking. This middleware will interface with users in the form of a web-based portal for easy access. A validation plan has also been outlined to test the first prototype and final product with the aid of practitioners from the construction industry. Despite concerns raised by some scholars around the usability and long-term sustainability of similar systems, we believe that its semantic and social networking

features place this framework as a replacement and not just a supplementary system to the current process in the construction domain.

Abstract:
Over the last ten years, there has been growing interest in the implementation of knowledge management (KM) systems within the construction industry. The fragmented and transient nature of construction project teams makes the industry ideally suited to benefit from improved management of the knowledge generated in the course of construction projects. This paper is concerned with the evolution of knowledge management systems for construction. It starts with an exploration of the adoption of KM systems by construction sector organizations over the last decade and identifies some of the emerging trends. It also reviews some of the major knowledge management systems developed over the period and highlights the strengths and limitations of these systems in relation to what the industry needs. It argues for a new generation of knowledge management systems that are better suited to the dynamic, global and complex environment within which contemporary construction projects have to be delivered. The key features that such next-generation KM systems should have are also discussed and conclusions drawn on their significance.

1. Introduction

According to Quintas (2005), "it is palpably obvious that without creating, accumulating, sharing and applying knowledge, no human civilization could have existed. Even though the phrase 'knowledge management' only came into common usage in the West during the last five years of the 20th century, it is emphatically *not* the case that the management of organizational knowledge processes began in the mid 1990s". He feels that the case studies of Honda, Matsushita and other firms in Nonaka and Takeuchi's influential and widely quoted book *The Knowledge Creating Company* (1995) were not examples of designated 'knowledge management' initiatives but rather descriptions of actual knowledge processes such as knowledge sharing, knowledge combination, etc.

Knowledge Management (KM) is a relatively new concept and there are many definitions, generally illustrating the variations in scope and content. KM is narrowly defined, in some instances, to emphasise the capture, access, and reuse of information and knowledge using information technology. This definition implies that tacit

knowledge can be converted to explicit knowledge using IT. However, it is generally accepted that tacit knowledge is more difficult to capture and manage. Examples of knowledge management definitions are shown below:

- Knowledge management is the discipline of creating a thriving work and learning environment that fosters the continuous creation, aggregation, use and re-use of both organizational and personal knowledge in the pursuit of new business value definition from Xerox Corporation Source: Cross (1998);
- Knowledge management is 'any process or practice of creating, acquiring, capturing, sharing and using knowledge, wherever it resides to enhance learning and performance in organizations' (Scarbrough et al, 1999).

There are several other perspectives on knowledge management. For example, there is the social/human resource perspective which focuses on knowledge management as 'the distribution, access of human experiences and relevant information between related individuals and work groups' (Excalibur Technologies, 1999). The IT/technology perspective focuses on the 'capture, access and reuse of knowledge using information technology' (O'Leary, 2001). There is also the intellectual capital or economic perspective which sees knowledge management as the 'systematic and organised attempt to use knowledge within an organization to transform its ability to store and use knowledge to improve performance' (KPMG, 1998). Irrespective of the different KM perspectives, all definitions focus on the fact that knowledge is a valuable asset that needs to be managed and that managing this knowledge is important to improve organizational performance.

Within the context of this paper, Knowledge Management (KM) can be simply defined as a systematic process of capturing, transferring, and sharing knowledge to add competitive value (Drucker, 1993; Skyrme and Amidon, 1997) and to improve performance (Robinson et al, 2001). KM provides several benefits such as facilitating staff training, problem solving, and decision-making. It also enables the intellectual capital of an organization (its skills, knowledge, and processes) to be used effectively, creatively, and consistently to improve business performance and customer satisfaction (TFPL Ltd, 1999). KM is therefore critical to an organization's survival in competitive markets and it is becoming a strategic necessity for organizations willing to lead the market and even to those just wishing to keep their places in the market.

The rest of this paper focuses on knowledge management within a construction context. The importance of KM in construction is explored and is followed by a discussion of the industrial uptake of knowledge management. A brief review of KM systems is then presented and the features expected of next-generation KM Systems for construction sector organizations outlined. The concluding section of the paper summarises the salient points.

2. Importance of Knowledge Management in Construction

Much of the training and experience of construction professionals is based on a balance between codified (explicit) knowledge and tacit knowledge. Case study interviews with structural design firms shows that about 80% of knowledge used during concept design is tacit compared to about 20% of explicit knowledge, whilst the reverse is true at the detailed design stage - 20% tacit and 80% explicit (Al-Ghassani, 2003). It is the dynamic interactions between tacit and explicit knowledge, which facilitates decision making in the implementation of construction projects. This is why construction project documents are understood and interpreted by those who have been through the same or similar type of training. For example, structural

engineers could extract meanings from design codes or interpret construction drawings easily whilst accountants cannot.

Research conducted by den Hertog and Bilderbeek (1998), and Windrum et al (1997) identified design, architecture, surveying and other construction services as knowledge-intensive service sectors. An important feature that distinguishes knowledge intensive sectors from manufacturing firms is the type of 'product' they supply and, following this, the role they play in regional and national innovation systems. Whereas manufactured products and processes contain a high degree of codified knowledge (they are 'commoditization' of knowledge), knowledge intensive sectors' are characterised by a high degree of tacit ('intangible') knowledge. Specialised expert knowledge and problem-solving know-how are the real products of knowledge-intensive industries (Egbu and Robinson, 2005).

Professional knowledge (i.e. knowledge produced by consultants while interacting with their client's settings) is deeply embedded in a mutual socialisation process, where consultants and their clients design together their final output. This is often seen in the kinds of services provided by professional/ consultancy firms of architects, quantity surveyors and engineers. For consultancy or professional firms, their main capital is intellectual assets, and most of their processes are geared towards the exploration, accumulation and exploitation of individual and firm expertise (Egbu and Robinson, 2005).

3. Industry Uptake of Knowledge Management

Knowledge Management as a practice has a trajectory in many other industries and professional practices. At its core, KM provides tools that enhance and support the core functions of an organization. It facilitates the objectives of any team, department, organization and industry. Because its principles are granular, they can be easily interchanged with project management or change management practices. For any industry, the successful adoption of KM represents a managerial commitment and often a cultural change. Therefore, its adoption is often slow, starting with a particular initiative or department. It then gradually spreads or diffuses throughout the organization, eventually becoming an integral part of its practice or operations.

In the US, the A/E industry `is just beginning to address the relevance and benefits of KM. The term is not commonly used and very few AE firms hold a position for a KM leader. The concept of knowledge as an asset that must be supported and managed is being discussed for the first time in many architectural and engineering forums. More than tradition and success in the use of technology and management of information, specifically CAD data and presentation materials, knowledge encompasses more than simple data, thus requiring a holistic or enterprise approach to information and its management.

Understanding knowledge at the enterprise level requires an awareness and balance between the day to day tasks, the generation of data, the collection and communication of data, fostering and sharing of unique ideas, and the goals of the organization. All these components interact within the context of new technologies and business trends.

For the AE industry, the challenge to successfully adopt KM is to expand its definition and implementation beyond the project and the project team; to understand the interdependencies and need for integration among the various groups and departments of the business and not to reduce KM to the use of technology and implementation of CAD/BIM standards.

In the airline industry, the practice of KM faces similar challenges; the large size of the airlines and their longevity in the business makes for slow KM adoption. Newer airlines tend to have faster successes because they are able to define and build a culture of knowledge from the ground-up. Specifically, technology platforms, business processes, and incentives that will guarantee the identification, collection, and sharing of corporate knowledge.

Civic agencies such as the United Nations are currently exploiting KM by adhering to its technology applications and idea sharing principles. By providing incentive programs for groups to share successes and best practices; and implementing Web-based portals and social networking tools, certain sectors of the UN are able to help governments in smaller countries solve a variety of socio-economic issues. Employing KM, the UN is able to provide advice and connect various segments of the population and even different governments so they can share their experiences and successes. In so doing, these countries are able to foster a culture of knowledge among its government groups and private institutions.

Many consulting firms have based their practice on KM principles. However, in today's global economy, the commercial aspects and competitive environment that consulting firms operate in makes it difficult to reconcile and benefit from the idea of knowledge as a common, shared resource. With the proliferation of information management mechanisms, consulting firms are challenged to re-evaluate their approach to knowledge management and sharing to find ways in which their KM practice helps differentiate their practice and becomes an integral part of their value proposition.

The longevity of construction as a business and the structured approach to its practice provide unique challenges and opportunities to implementing KM. For example, the business of construction is highly regulated. There are many standards, codes and guidelines that shape or even dictate the processes involved. Since many of the processes are repetitive and common from one project to the next, the use of technology, templates and technical standards are also in existence. Because of this, there are many technology solutions to help support these practices - that is, the standardization of tacit processes and the redundancy of technology systems.

4. Knowledge Management Systems

A knowledge management system is the technology platform and infrastructure that an organization employs to support knowledge management (Robinson et al, 2010). It typically consists of a set of tools, made up of technologies (IT Tools) and techniques (non-IT tools). Both technologies and techniques are equally important to support different KM processes (Anumba et al, 2005) and are briefly described below.

4.1 KM Technologies

KM technologies rely on an IT infrastructure. Examples of KM technologies for capturing knowledge are: Knowledge Mapping Tools, Knowledge Bases, and Case-Based Reasoning. Although there is a debate about the degree of importance of such technologies, many organizations consider these important enablers that support the implementation of a KM strategy (Skyrme and Amidon, 1997; Kanter, 1999; Anumba *et al*, 2000; Egbu, 2000; Storey and Barnet, 2000) as they consume one third of the time, effort and money required for a KM system. The other two-thirds mainly relate to people and organizational culture (Davenport & Prusak, 1998; Tiwana, 2000).

KM technologies consist of a combination of hardware and software technologies. Hardware technologies and components are important for a KM system as they form the platform for software technologies to perform and are the medium for storage and transfer of knowledge. Some of the hardware requirements of a KM system include personal computers or workstations to facilitate access to knowledge, powerful servers to allow the organization to be networked, open architecture to ensure interoperability in distributed environments, media-rich applications requiring Integrated Services Digital Network (ISDN) and fibre optics to provide high speed and use of the public networks (e.g. Internet) and private networks (e.g. Intranet, Extranet) to facilitate access to and sharing of knowledge (Lucca *et al*, 2000). Software technologies play an important part in facilitating the implementation of KM. The number of software applications has increased considerably in the last few years. Solutions provided by software vendors take many forms and perform different tasks. The large number of vendors that provide KM solutions makes it extremely difficult to identify the most appropriate solutions. This has resulted in organizations adopting different models for establishing KM systems. Tsui (2002) identifies five emerging models for deploying organizational KM systems where one or a combination may be adopted: customised off-the-shelf, in-house development, solution re-engineering, knowledge services, and knowledge marketplace.

4.2. KM Techniques

KM techniques do not depend on IT although they provide support in some cases. Knowledge sharing, for example, is a sub-process of KM, which can take place through face-to-face meetings, recruitment, apprenticeships, mentoring, and training. The importance of KM techniques comes from several factors. Firstly, KM techniques are affordable to most organizations as no sophisticated infrastructure is required. Some techniques, however, require more resources than others (e.g. training requires more resources than face-to-face interactions). Secondly, KM techniques are easy to implement and maintain due to their simple and straightforward nature. Thirdly, KM techniques focus on retaining and increasing the organizational tacit knowledge, a key asset to organizations.

KM techniques are not new; most organizations have been implementing these for a long time under the umbrella of management approaches such as organizational learning and learning organizations. Using these tools for the management of organizational knowledge requires their use to be enhanced so that benefits, in terms of knowledge gain/increase, can be fully realised. Examples of KM techniques include brainstorming, communities of practice (CoPs), face-to-face interactions, post-project reviews, recruitment, mentoring, apprenticeship and training.

4.3 Examples of Knowledge Management Systems

There are a variety of tools to support knowledge management implementation. However, very few of these adequately address all the stages in the KM lifecycle. Examples of some research prototypes, which address critical and problematic areas for many construction sector organizations, include: CLEVER_KM™, IMPaKT, STEPS and CAPRI.NET. These were developed to facilitate (respectively) the development of knowledge management strategies, evaluation and benchmarking of knowledge management initiatives, assessment of an organization's KM maturity, and to enable the live capture and reuse of knowledge in construction projects.

CLEVER_KM: The CLEVER_KM tool provides a structured approach to KM problem definition and strategy formulation based on specific steps shown in Figure 1. The CLEVER tool consists of several stages that take an organization from an initial definition of a knowledge problem, an identification of where they wish to get to, specification of the critical migration paths required, through to the provision of appropriate knowledge management processes to aid in the resolution of the organization's knowledge management problem (Anumba *et al,* 2005a).

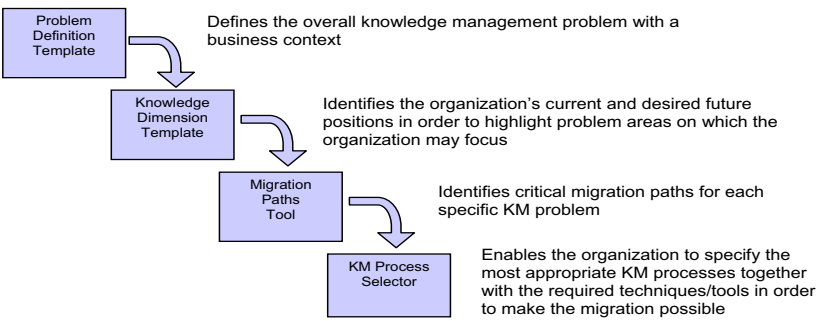

Figure 1: Steps in the CLEVER_KM Tool

The CLEVER_KM system has been commercialised and is useful for KM strategy formulation at both organization and project organization level.

IMPaKT: The IMPaKT framework enables organizations to evaluate the business impact of their KM initiatives (Carrillo *et al*, 2003; Robinson *et al*, 2004). The framework facilitates: (1) an understanding of the strategic context of business problems and their knowledge management implications; (2) the planning and alignment of KM strategy to address business problems or objectives so as to ensure that they are coherent and consistent with the overall strategic objectives of an organization; and (3) an evaluation of the impact of KM on business performance in terms of effectiveness and efficiency by providing a set of complementary measures for assessing the impact of KM initiatives on business performance. Evaluation with industrial practitioners showed that the framework could significantly facilitate the implementation of a KM strategy in construction project organizations. The framework enables a useful thought process, is well focused and easy to use, and is considered to be an innovative KM tool that incorporates issues not adequately addressed in other frameworks.

STEPS: The STEPS maturity roadmap provides a structured approach to determine the steps and action plan required and to benchmark knowledge management implementation efforts (Robinson et al, 2006). The five steps in the maturity roadmap, (Start-up, Take-off, Expand, Progress, and Sustain) reflect varying levels of knowledge management maturity. Each level of maturity is characterised or associated with certain attributes and attribute dimensions, reflecting the different emphases at various stages.

CAPRI.NET: The Capri.Net system resulted from the Caprikon Project at Loughborough University (Tan et al, 2007). It is based on a framework that enables construction project organizations to undertake 'live' capture of knowledge on projects such that the knowledge can be reused at the later stages of the same project and/or subsequent projects – see Figure 3. The framework comprises:

- A Web-based knowledge base – This is where the Project Knowledge File (PKF) of a project is stored. The PKF contains relevant project information and project knowledge that can be reused both during the execution (e.g. in subsequent phases) and after the completion of the project;

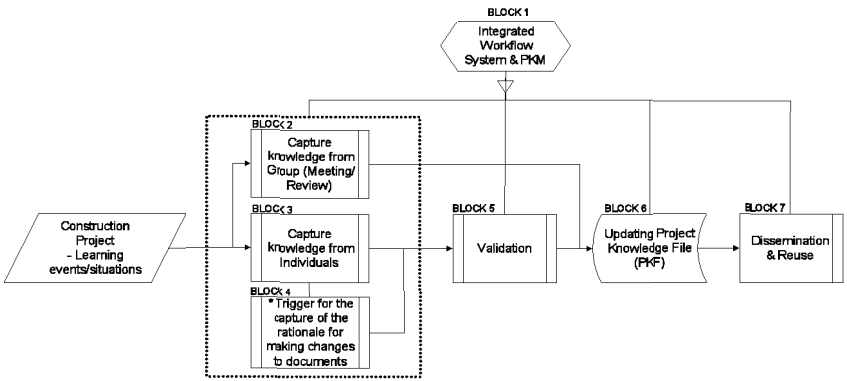

Figure 3: Framework for Live Capture and Reuse of Project Knowledge

- An Integrated Workflow System (IWS) - It delineates, executes and monitors the mechanisms for the capture, validation and dissemination of the project knowledge captured; and

- A Project Knowledge Manager (PKM) – This is a designated person who manages the knowledge base (i.e. the development of a Project Knowledge File for a project) and the Integrated Workflow System (IWS) for a given project.

5. Towards Next-Generation KM Systems for Construction

The longevity and stability of construction management tasks and build processes led to the definition and implementation of construction standards. These standards have facilitated the creation of software applications to support the processes. These two conditions give the construction industry the false sense of having accomplished KM objectives.

The various technology systems, although commonly used and very similar to each other, do not necessarily foster a culture of knowledge. The basic architecture of the multiple systems commercially available and in predominant use by the construction industry today tackle the various phases and tasks of the construction process as isolated events and in a proprietary manner.

In order to benefit from the identification, collection, and sharing of ideas and best practices the basic infrastructure of any software system must facilitate the exchange of data and provide easy access to information and knowledge. The

information and knowledge must be collected from different systems, at different phases, and remain available to the organization beyond the completion of any and all constructions projects. Higher function knowledge (organizational wisdom, if you will) that derives from the integration and awareness of needs and contributions among the participant parties is often obstructed by the technology platforms in which these tools are built.

With the advent of BIM, there is the need for reconciliation and integration of practices and standards among the AE and Construction industries. This reconciliation transcends the organization of the BIM model and the level of detail /nomenclature of the BIM components; it impacts the economic models that have been in place within the design/build umbrella for more than half a century.

The current generation of knowledge management systems are proving reasonably effective in helping organizations to manage their intellectual assets. While many organizations are content with the small gains made, others are wondering what to do next. The true test of the extent to which a KM system has transformed an organization lies in the answer to the question: 'To what extent are our knowledge management practices now regarded as regular business practice?' The more fully integrated that KM processes, tools, techniques and practices are with a company's business processes, the greater the potential benefits. This is a trait that will be commonly exhibited by next-generation KM Systems (Anumba, 2009).

Just as the phrase 'Computer-Aided ...' was widely used in the 70s and 80s but is now declining in usage (as computer-based systems are now mainstream business systems), next-generation KM systems are expected to make seamless the linkage between KM processes and business processes, thereby leading to relative disuse of the term 'KM'. In addition to this, next-generation knowledge management systems for construction sector organizations will (Anumba, 2009):

- Have demonstrable or self-evident performance benefits such that Knowledge Managers no longer have to justify investments in KM. No universally accepted metrics exist and it will become increasingly necessary for organizations to develop measures that are tailored to their circumstances; these will have to be linked to higher level corporate objectives;
- Have an intelligent agent-based component. Such systems will be able to act on behalf of their owners in interacting with any existing IT tools and knowledge repositories, and can build user profiles based on a course of interaction;
- Incorporate more sophisticated tools and techniques for knowledge capture and reuse, some of which will be based on artificial intelligence (AI) techniques. These will enable more automatic capture of knowledge as it is generated and facilitate knowledge sharing across organizational boundaries.
- Enable more ubiquitous, context-specific and, where appropriate, location-based delivery of knowledge and associated services. This will allow an unprecedented degree of personalisation, while enhancing the utility and relevance of these systems;
- Support effective integration of personal knowledge management systems with corporate knowledge management systems in such a way that organizations can better leverage the knowledge held by their employees without privacy violations;
- Have sophisticated mechanisms for supporting communities of practice and, in particular, capturing storytelling and anecdotes which are rich in knowledge content;
- Support the development and management of 'knowledge chains', which facilitate the flow of knowledge within and across construction supply chains;

- Contribute even more to the market value of construction sector organizations as the value they provide becomes more of a distinguishing factor in the evaluation of organizations;
- Be supported by an increased number of people whose roles involve the management of knowledge assets in organizations.

The above are just some of the elements that next-generation KM systems are expected to have. The list is not exhaustive but it is indicative of what is possible.

6. Summary and Conclusions

Knowledge management is very important for the success and continued improvement of construction projects. It offers numerous benefits that can help to increase the returns for construction-sector firms involved in collaborative projects. This paper has sought to provide a review of knowledge management systems for construction. It reviewed aspects of KM adoption and KM systems, and outlined the key features that need to be incorporated into next generation KM systems.

The complexity associated with the delivery of construction projects by a transient project team made up of individuals/teams from a variety of organizations makes the implementation of knowledge management systems in construction challenging. However, it is also for the same reasons that construction sector organizations cannot afford to ignore KM. They must embrace the core principles and tailor their KM strategy and implementation to the needs of their particular firms. At project level, next-generation KM systems will better facilitate the 'live' capture and reuse of knowledge, and collaborative learning during the course of the project. It is important that construction sector organizations continue to invest in knowledge management as it offers considerable benefits at both corporate and project organization levels.

The Embedment of a Knowledge Management Program in an AEC Organization

Amy Javernick Will

ABSTRACT

This paper examines the embedment of a knowledge management (KM) program within an individual global engineering organization, Fluor Corporation (Fluor). Although many knowledge management initiatives fail, the program established by Fluor achieved increasing legitimacy and became a taken-for-granted practice over time. This paper examines the process of embedment by analyzing the changing use of the program through participant quotes. In addition, it identifies factors that contributed to the ongoing use and embedment of the KM program in Fluor's operations. These include the alignment of the program with Fluor's culture, the continued maintenance and ease of use of the program, social influence factors, and external changes that together evolved the KM program into a well-used, award-winning program around the world. This case study offers the rare opportunity to investigate a KM program that has been established in the AEC sector for almost a decade and offers insights and suggestions to firms seeking to implement knowledge management programs in the industry today.

INTRODUCTION

Over the last decade, interest in knowledge management has surged. Although the importance of knowledge to organizations was recognized in the past, the knowledge-based-view of the firm brought new meaning to the value of knowledge to an organization by identifying it as a resource with at least as much importance as capital (Conner and Prahalad 1996; Grant 1996; Spender 1996). In the increasingly competitive and global marketplace, firms are especially keen to integrate and capitalize on the knowledge of their employees and make it available when and where it is needed. As a result, many organizations implement KM initiatives. Unfortunately, while estimates vary, most (over 50%) KM systems implemented in practice fail to achieve their original goals(Akhavan et al. 2005). As Argote noted, more attention has gone into identifying knowledge as a source of competitive advantage than in realizing how organizations can actually acquire, integrate and share their knowledge (Argote et al. 2003). Organizations wishing to implement KM programs are left to grapple with how to develop an effective and sustainable KM program.

Knowledge Management in the AEC industry

Like other sectors, the engineering/construction industry began recognizing the need to share knowledge, diffuse best practices, respond quickly to customers and reduce re-work (Carrillo et al. 2004). As a result, many companies in the industry are starting to embrace KM programs to combine and share their knowledge more effectively. A recent survey of firms in the UK found that approximately 40% of engineering design and construction organizations have a KM strategy, and another 41% plan to have one within a year (Carrillo et al. 2004). In an attempt to uncover best practice within the United States AEC sector, Carrillo and Chinowsky found that there is still confusion amongst companies over KM terminology, however, some are starting KM initiatives, and KM is beginning to gain ground within the United States AEC sector (Carrillo and Chinowsky 2006).

Due to the relative infancy and paucity of KM initiatives within the US construction industry, few studies have been able to follow the implementation and embedment of a knowledge management program over time. Of the existing studies, some have focused on demonstrating the need for knowledge management programs, such as a study by Robinson and colleagues that presented a framework to develop a business case for KM (Carrillo et al. 2004). Others have identified factors that appear to influence or hinder knowledge sharing within the company. For instance, Fong and Chu found that the top three critical factors for sharing knowledge successfully included an understanding of the benefits provided by knowledge sharing, time, and participation and cooperation from colleagues (Fong and Chu 2006). Another study found similar strategies including demonstrating the benefits and obtaining "buy in" from the employees through communication initiatives (Chinowsky and Carrillo 2007).

These prior studies address some of the common barriers to, and critical factors affecting, knowledge sharing within organizations. However, KM is still in the early stages of development within the AEC industry. A gap exists in our understanding about how companies can gain value from a KM program by embedding it within a firm over time. In an ongoing effort to identify how different types of organizations are able to acquire, integrate and transfer their knowledge, we witnessed a KM program that has become integrated within a single global engineering firm. The motivation for this particular paper came from a desire to understand how the KM program became embedded within the company's culture over the last decade. Therefore, this paper extends past research with an in-depth case study on the process of embedment of a KM program within a company and examines the dynamic factors that appear to have encouraged the program's success and maintenance over time. By identifying some of these factors, this research offers suggestions for practices that can be used in other KM initiatives being implemented today.

METHOD

A single case study is used for this analysis. This case was part of a research project that investigated how multinational organizations acquired, integrated and transferred local area project knowledge. This paper analyzes one of these companies, Fluor, to analyze the embedment of Fluor's KM program. Fluor is a global, publicly owned engineering, procurement, construction and maintenance service (EPCM) company. Fluor was selected as a case study due to its award-winning KM program. It received

the North America Most Admired Knowledge Enterprise (MAKE) in 2005, 2006 and 2007 and is the only company within the AEC Industry to be a Global MAKE winner (in both 2006 and 2007). The MAKE research program seeks to "identify organizations which are using knowledge-driven strategies to out-perform their peers by able average growth in intellectual capital and wealth creation".

I visited Fluor in their Aliso Viejo office over a three-day period. Following the ethnographic approach recommended by Spradley (Spradley 1979), I conducted open-ended interviews with the KM team and various engineering employees within the firm. This technique provided the opportunity to question participants regarding the history of the KM program and the employee's use of the program. In addition, I was able to observe knowledge searches in action. During the data collection, I wrote field notes and audiotaped interviews. The informants also provided various forms of documents, including presentations, statistics, examples, system print outs, success stories, and other evidence. The combination of interviews, observations and documentation enabled the triangulation of data to enrich the case analysis and view the system in a larger context.

The interviews were transcribed and imported along with field notes and collected documents into a computer software program, NVivo, by QSR. This data was coded and analyzed using the grounded theory method (Eisenhardt 1989; Glaser and Strauss 1967; Miles and Huberman 1994). During this highly iterative phase of the process, evidence emerged that helped identify critical success factors that helped to embed the program into the overall organizational culture.

THE FLUOR CORPORATION KNOWLEDGE STORY

The Fluor KM initiative began in 1997 but officially kicked off formally in 1999. The company wanted to link people and provide timely solutions to address project and customer demands. To address these goals, it put together a small KM team that collaborated with consultants. Due to the company's size, scale, and global presence, the team knew that technology would be a significant part of the solution; however, they wanted to ensure that people-to-people connections remained strong. Originally, they planned to implement a consultant's system, believing that they could:

> *"plug their system in ….and one year later the team would be done. The system would be handed over and the business units would be charged to use the system".*

However, the team quickly discovered that using another company's system was the wrong answer. While the proposed system worked well for the client's consulting organization, it did not fit within Fluor's existing culture; therefore, they decided that they had to create a custom, tailored solution to fit Fluor's culture and operations:

> "*We needed to build a solution that would work for **our** company and **our** culture…we quickly got into the software development business because we couldn't find what we wanted from a commercial solution".*

Knowledge Online

The resulting solution was a web based KM platform called "Knowledge Online" [KO]. In order to link people and documents globally, the KM team knew the solution would require a strong technical platform. KO uses the technology to combine social networking and document management to meet the business objectives of the firm.

The document management tool contains up-to-date processes, procedures and data to ensure that all employees use correct information. In addition, KO includes people profiles and discussion forums to encourage people-to-people connections.

The home page of KO features a news story that is updated twice a week, a member spotlight (the most recently updated member profile), and other featured content. In addition, the home page takes employees to the two most commonly used features of KO: Knowledge Communities (or Communities of Practice) and the global knowledge search function.

Knowledge Communities

Fluor recognized the need to align the platform to the company's existing social structure; therefore, they established knowledge communities around the existing functional and business lines. In 1999 they deployed two communities as a test run. After the successful implementation of these communities, Fluor quickly added other communities. By 2000 they had 32 communities and 4,000 members enrolled in KO. Membership grew rapidly and as of March 2008 there were over 26,000 members and 43 communities. The knowledge communities include everything from functional lines (i.e. Civil, Electrical) to business needs (i.e. Strategy, Business Intelligence).

Similar to KO, each community has a homepage. This can feature news stories, links to other news sites, knowledge objects (documented practices, guidelines, etc.), and featured content. In addition, the homepage contains community information with community-specific help, a list of the community's leaders and Subject Matter Experts (SME) with contact information, and orientation material. It also provides links to the community's discussion forums, community members, calendar and a search function.

Searches

One of the most commonly used features within KO is the "Search" feature. After searching for a subject, the employee may chose to view "All Results", "Knowledge" (knowledge objects), "K-Packs" (packs of knowledge grouped together), "People" (SME or people with the subject in their profile), "Forum", "News", or "Resources". In accordance with its mission to link people with people, each knowledge object or forum discussion lists the contributor and provides a link to their profile. The profile link enables the searcher to both evaluate the response by looking at the knowledge provider's experience and past projects and contact the person for additional information. In addition, search results are sorted by relevance. This means that the results are scanned for the number of times the keyword appears in a document, the location it appears (such as the title), and the form of knowledge (forum, etc.).

Forums

Although Fluor encourages "Searching First", employees can start a discussion forum within their communities by "Asking a Question". To start the discussion forum, they add the title, question, context and required response date. These questions are sent automatically to the inbox of community subscribers, including the community leaders and SME. The email contains a link to the forum and to the responses for ease of use.

THE EMBEDMENT OF FLUOR'S SYSTEM

KM was originally a strategic management initiative introduced by top management. Luckily, this gave the program the attention and support of leadership within the firm. The company funded the development of tools and dedicated a team to oversee the

program and implementation. At the beginning of the KM initiative, Fluor was focused on creating a system to capitalize on and access the firm's collective knowledge around the globe. They customized the tool to align it to their business and focused on linking people globally within existing Fluor communities. After the platform was created, they shifted their attention to enrolling employees and producing communities that added value to the business. This shift is often where KM initiatives fail to deliver desired results.

Obtaining Employee Participation

In order to educate its employees and achieve the necessary critical mass, the knowledge management team realized that it needed global buy-in from the employees around the world. The team focused on making the program a global initiative, emphasizing the benefits that all Fluor employees could receive, regardless of location. To underscore this, they chose to conduct 24-hour community launches in order to call each office location on their own time zone.

Once employees were aware of the system and the communities, the team focused on getting them enrolled and using the system. Originally, the team planned to offer incentives to employees who used the system on a point basis, for instance, if you used a knowledge object or submitted a knowledge object; you would receive a point for various prizes. Fluor ultimately decided against the strategy as it was thought to encourage "junk" and today they are happy they made the decision. As one employee commented, *"management by tokens doesn't work"*.

Instead, they chose to integrate the program into employee's daily lives at Fluor. They placed resources that employees needed to access on the system. They focused on showing the employees the benefits KO could provide on a daily basis, highlighting that the tool developed enabled them to locate solutions quickly. In addition to educating existing employees, they made KO a key feature of new hire orientation to engage new employees from the start.

Global communications, including emails and newsletters, played a key role in promoting the benefits of KO. They started an annual "Knowvember Campaign" in 2002 to promote knowledge sharing behaviors by increasing awareness of the program and recognizing outstanding members within the knowledge communities. For instance, the KM "Pacesetter" Program awards employees through peer recognition. Similar to rankings of buyers and sellers on Amazon, these selected employees receive a "Pacesetter star" on their KO profile for each year they receive the award. The KM team believes that the peer-to-peer recognition that this program is the best way to promote KO. In prior KM efforts like Xerox's acclaimed Eureka project, this kind of status recognition accorded to members of a "natural community" has been found to be equally or more effective than financial incentives for employees to formalize and share their knowledge (Moore 1999).

The campaign also gathers and shares "Success Stories" of the specific ways employees (and the company) have benefited from using KO. For instance, in one story, an employee asked a question regarding a leaking fired heater transfer line. The leak was costing approximately US $120,000 per day and time was of the essence to obtain a solution. Without the expertise available locally, he posted a discussion forum topic to the piping community and within 2 days received responses from Houston, Haarlem and New Delhi providing the answers needed to fix the plant.

Over the years, KO grew from 4,000 employees in 2000 to over 25,000 members today. Fluor's KM team recruited new members through three primary means: the directive of global management to establish communities and encourage knowledge sharing expectations; the education of employees through global launches, new hire orientation and Knowvember campaigns; and by highlighting the benefits of the program through success stories.

Producing Communities

The Knowledge Communities are the primary location for people with similar functions or business objectives to capture, share, improve and apply their collective knowledge. Fluor chose to organize around the "natural communities," that already existed. The communities are central to KO; therefore, the first challenge was to get the communities deployed so that communication within these communities would be online.

Fluor has a stringent process for deploying a community. The community leadership must prepare a charter and undergo a series of readiness assessment meetings with the KM Team. Each community must prove that they have an existing network of people, available leaders, executive support and resources. In addition, they must have business objectives that would benefit from the use of KO. The preparation for community deployment can take 6 months to complete. As one member said:

> *"We only deploy knowledge communities when there is a strong business justification and committed people resources.… The KM team will push back on the community to ensure that they have identifiable business objectives that will add value to Fluor."*

Fluor helps the community to identify the most critical knowledge that they need. Originally, the KM team provided the communities with lists of types of knowledge and asked the communities to identify ***all*** of the types of knowledge they would need. They learned that too many types of knowledge and choices for navigating create barriers as it confuses users searching for knowledge. Now they push the community to identify the ***minimum*** amount of knowledge types/categories that the community needs. They also help them create a plan to collect data and eliminate redundant knowledge databases. They ask the leaders to identify the content that belongs within the community and where it currently resides. They then eliminate all of the old information and place the up-to-date knowledge on the system. This not only helps Fluor ensure that employees are using the latest, up-to-date system, but it also forces individuals to familiarize themselves with KO and use it as the primary source of their information.

In order to launch a community, all critical and available content must be uploaded. The community is then ready for deployment with live, up-to-date knowledge. The KM team has a simple philosophy:

> *"We do not open the store until our shelves are fully stocked with fresh information".*

Adding Value through Embedment

Although Fluor continues to educate employees on the benefits of KO, the goal has shifted from obtaining employee participation and establishing communities to adding value for the company. This was always the original goal; however, the team

"needed to get a critical mass [of participants] who understood Knowledge Management before we could get to that point".

For instance, judging the "Success Stories" has changed over the years. One employee commented that they are now much more critical of the stories they judge. What was once a great story is now commonplace. They are now looking for additional value that was received through the success story. As an example, a recently awarded knowledge sharing story resulted in the elimination of a salt bed dryer, which saved the client over $1 Million Euros and resulted in new work-orders between the client and Fluor.

In order to add value, Fluor had to ensure that the communities were meeting their objectives. The Fluor KM team works with the community leaders on a regular basis to maintain a level of consistency, keep the front page updated and steward the content. They make sure that each knowledge item is only uploaded once—others can link to this information but not repost it. In addition, every piece of knowledge content has a review and expiration date to maintain accuracy. Finally, the KM team uses community audits to ensure community performance. As one executive commented:

"Other companies just stop when the community is launched. We don't stop at that point. We set up performance objectives…There is not a lot of breathing room after they launch before the community hears from us."

Due to its success, KO has also become a platform to push other initiatives within the organization. For instance, when distributing work across offices was the exception, they launched a "workshare" community. Today, worksharing is the standard way Fluor operates; the "Workshare" community has disbanded and the content was moved into the individual functional and business communities. As one employee commented:

"We are now using KO to launch other company objectives. KO is so popular that other communities within Fluor want to use it to update staff on other events. It really is a statement of how engrained the knowledge community has become within the organization."

Fluor's KM program has become embedded within the overall Fluor culture. Once a management directive, the program is much more of an employee driven initiative as more people use and gain value from KO. The embedment of the program can be seen via the changing use of the system (enrollment to meeting business objectives), changes witnessed in judging the knowledge stories (answering a question to providing added value), and the increased participation in the program. For many within Fluor, KO has become a taken-for-granted means to get their work done. For example, one employee commented that people are asking questions within the forum and getting responses from within the same office. In one case, a person posted a question and received an answer from a colleague three desks away.

UNPACKING THE BLACK BOX: CRITICAL SUCCESS FACTORS

Recognizing the failure of many KM programs, this paper now analyzes the factors that contributed to the ongoing use of the Fluor program. During the data analysis, 4 overarching themes became prevalent, including the alignment of the program with Fluor's culture, consistency and maintenance of the program, social influence factors, and external causes that together enabled the embedment of the program into culture at Fluor.

Alignment of the program with Fluor's Culture

Many employees commented that the system was easy to use because it was aligned to the existing Fluor culture. The knowledge communities were drawn from existing functional and business lines within Fluor. Because the communities already existed, the platform was used as a ***tool*** to ask and answer questions and establish even stronger connections between people. In other words, it was used primarily as a tool to improve the existing communities and not to create new communities. In addition, many of the processes had already existed within the overall Fluor community, such as the audit process. Use of these existing tools helped to ease employee's familiarity with the system and make it a natural and seamless fit within the company.

Maintenance of the Program

Employees feel confident with the responses and knowledge in the system. Within the forums, the combination of the written response with the link to the personal profile allows the employee to assess the validity of the response to their specific situation. In addition, the required review dates for knowledge and community audits provide additional measures to ensure up-to-date and non-duplicated knowledge within the community and the firm. The elimination of other databases also helps to confirm that the latest knowledge and best practices are being used throughout the globe.

Social Influence Factors

One of the primary elements that continued to emerge from the data analysis was the importance of social influence factors. Social influence has been studied as a persuasive tool in marketing campaigns and the workforce. In his book, "Influence: The Psychology of Persuasion" (Cialdini 1993), and other articles, he identifies six "Weapons of Influence": reciprocation, commitment and consistency, social proof, authority, liking, and scarcity. Many of these "weapons" were identified as potential reasons why people used KO. But two in particular, "Commitment and Consistency" and "Liking" stood out.

Commitment and Consistency

"Commitment and Consistency", indicates that once people commit to a cause, they are more likely to continue to honor and sustain that commitment. Studies have shown that this is particularly true if people have voluntarily stated their commitment either verbally or in writing (Cialdini 1993; Cioffi and Garner 1996). Although it may not have been intentional, Fluor's use of the "Community Franchise" concept and the "Pacesetter" awards encouraged this level of commitment and consistency. The process of creating and deploying a community requires a considerable amount of effort and time. In addition, the community leaders and knowledge managers are required to commit to keeping the material up-to-date and remaining active within the community. In order to ensure that they are consistent with these earlier commitments and to get value out of the system they worked so hard to create, most chose to remain actively engaged in the community. The "Pacesetter" awards also encourage this consistency. Previously nominated or awarded members feel the need to live up to expectations for the award.

Liking

People are more easily persuaded by people they like. By observing the implementation and auditing of the communities, the KM team discovered a direct correlation between the community leaders and the performance of the community.

The involvement and enthusiasm of the leader and SME's were identified as critical factors; and the ongoing level of participation of the leaders is now examined during the audit:

"You will often find that the whole community will be performing based on the commitment and involvement of the leader."

In some cases, Fluor decides to replace a leader, identifying a replacement from a pool of enthusiastic, well-respected and liked candidates. This has helped revamp underperforming communities.

Other Social Influence Factors

The other "weapons" identified by Cialdini were also important to the development of KM within Fluor. *Social Proof* was critical. People will often follow a trend and conform to the behaviors of others. Fluor needed to obtain a critical mass of users onto the system for others to follow. In addition, *Reciprocation* is often involved in sharing knowledge with colleagues. Sharing knowledge takes time; however, the majority of people feel a natural indebtedness that comes from receiving help. If people receive help from KO, they often wish to reciprocate and provide responses to others questions.

External Influencing Factors

The establishment of KO coincided with the use of external platforms, such as Google, and a changing strategy towards work execution that helped to encourage the use of technology for handling exceptions (Galbraith 1972) — i.e., for answering questions that arise in the course of attempting to complete tasks. One employee commented that Fluor purposefully designed the search tool to be similar to Google because Google had already trained people to search for information. In addition, networking sites such as Facebook have made people more comfortable interacting on web forums. As one employee stated: "*KO makes the company a bit smaller for me".* The convergence of external factors with the development of a program aligned to the company's culture that focuses on maintenance, value, consistency and social influence has resulted in an award-winning, embedded program within Fluor.

CONCLUSION AND PRACTICAL IMPLICATIONS

This study uncovers critical success factors enabling a KM initiative to succeed and become embedded within an organization over time. Although there is great interest in KM, the relative infancy of programs in use within the AEC sector has left a gap regarding how these programs can become embedded within a company's practices. Through a qualitative case study, we uncovered factors that appear critical to the program's success. The combination of management directive, communication of the benefits of the system, and a changing work strategy encouraged employees to begin using KO. These findings are in line with previous research that identified the demonstration of benefits, obtaining employee participation and the use of a corporate mandate (Chinowsky and Carrillo 2007; Fong and Chu 2006). Furthermore, we examine the factors encouraging the continued use of the program. These include the alignment of the program with the existing Fluor culture, the consistent and continued maintenance of the program, social influence factors and a changing external environment.

Companies trying to implement KM programs and initiatives today can gain valuable insights from this study. Instead of purchasing an "off the shelf solution",

businesses should consider their specific company culture and create a strategy aligned to their practice and existing networks. In addition, they should identify a set of natural communities within the company, and choose leaders who exemplify knowledge sharing behaviors and who are well-liked members of those communities to encourage participation. Finally, companies need to realize that KM is not something that can be "plugged in" and left to run itself. It is an ongoing, continuous program that involves the commitment of staff time and effort to ensure that communities are performing and adding value and that the knowledge is up-to-date.

Past research, such as a study conducted by Hansen and colleagues has identified two distinct strategies for KM solutions: *codification* and *personalization* (Hansen et al. 1999). Codification revolves heavily around the use of technology tools for connecting people to reusable, explicit knowledge. Personalization, on the other hand, relies primarily on social processes to share tacit knowledge. Companies choosing a strategy thus invest more heavily in IT if they choose the codification strategy while those emphasizing personalization invest more moderately in IT, choosing to emphasize personal interaction (Hansen et al. 1999). This case study has shown that heavy investment in IT can also facilitate personal connections, enabling employees to respond quickly to questions from colleagues around the world. As many employees noted during the interviews, this often required additional interaction and communication to provide needed context and the more "tacit" knowledge; however, the IT software enabled them to identify the appropriate people rapidly, reducing the time required to determine an appropriate solution for a given problem. Additional research can expand these findings to determine the extent to which IT centered approaches can follow a personalization strategy and whether "people-centered" and "IT-centered" KM solutions can overlap.

Using Lean Theory To Identify Waste Associated With Information Exchanges On A Building Project

Craig R. Dubler[1], John I. Messner[1], Chimay J. Anumba[1]

[1]Computer Integrated Construction (CIC) Research Program, Department of Architectural Engineering, The Pennsylvania State University, 104 Engr Unit A, University Park, PA 16802; PH (814)865-4579, Email: crd137@psu.edu

Abstract: Building Information Modeling (BIM) provides a means for owners, designers, contractors, and operators to generate, organize and use detailed information throughout a project lifecycle. When properly implemented, these models can improve the efficiency of designs, allow for better feedback from project participants, and improve the accuracy and effectiveness for performing future construction tasks. An important aspect to the success of BIM is the process in which information is exchanged. Information should be both accessible and usable when required. This paper serves to identify categories of information exchange (IE) waste on a building project through the application of lean theory. Using this methodology, a pilot study was performed on a laboratory facility being constructed on The Pennsylvania State University campus. The results determined that lean theory can be applied and adapted to effectively determine IE waste. Future work includes calculating the cost associated with this waste, and converting the waste into an efficient information exchange process.

Key words: Building Information Modeling, BIM, Information Management, Lean Thinking

Introduction

The U.S. construction industry is currently going through a large transformation to improve efficiency. An important factor in improving construction efficiency is the emergence of Building Information Modeling (BIM) technology. The National Building Information Modeling Standards (NBIMS) Committee defines BIM as "*a digital representation of physical and functional characteristics of a facility. A BIM is a shared knowledge resource for information about a facility forming a reliable basis*

for decisions during its life-cycle; defined as existing from earliest conception to demolition. A basic premise of BIM is collaboration by different stakeholders at different phases of the life cycle of a facility to insert, extract, update or modify information in the BIM to support and reflect the roles of that stakeholder (NIBS, 2007)." For Building Information Modeling to be an effective tool, all parties involved must work together towards a common goal to produce an accurate representation of a building project including information that is necessary to operate the facility (see Figure 1). However, many owners and project teams are struggling with defining the appropriate level of modeling to perform on a project based on the current state of practice and future information needs. This has led to a very interesting agenda focused on the collaboration between the project team members, such as Owner, Architect, Engineers, Contractors, and Facility Manager in the development of a BIM Project Execution Plan.

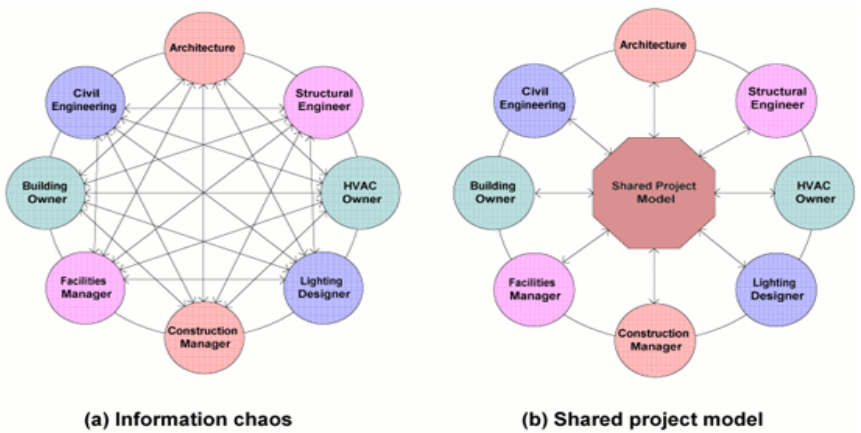

Fig. 1. BIM Concept – Eliminating Information Chaos (IAI, 2009)

Project Execution Planning for BIM

BIM Project Execution Planning is "a process performed by a project team to design the execution strategy for implementing BIM on the project. The final product of the execution planning process is a documented BIM Project Execution Plan (CIC, 2009)." In order to maximize the effectiveness of BIM, the execution plan should be designed in the early stages of a project and focus on the decisions required to define the scope of BIM implementation on the project, identify process impacts of using BIM, define the team characteristics needed to achieve the modeling, and quantify the value proposition for the appropriate level of modeling at the various stages in the project lifecycle.

During the development of a BIM Project Execution Plan, four steps should be followed: 1) Identify BIM Goals and Uses; 2) Design the BIM Project Execution

Process; 3) Develop Information Exchanges; and 4) Define Supporting Infrastructure for BIM Implementation (CIC, 2009). These steps, depicted in Fig. 2, have been developed by the CIC Research Group through the BIM Execution Planning Research Project. Prior to implementing BIM, the project team should identify the appropriate tasks that the team would like to perform using BIM. This analysis of BIM Uses should be focused initially on the outcomes desired by the overall process. Therefore, the team should start with the Operations phase, and identify the priority for each of the BIM Uses on the project (High, Medium or Low priority), and then move through the project phases in reverse order (Operations, Construction, Design and Planning). This perspective of 'starting with the end in mind' will identify the downstream desired uses of BIM which should be supported by earlier processes in the lifecycle of the project.

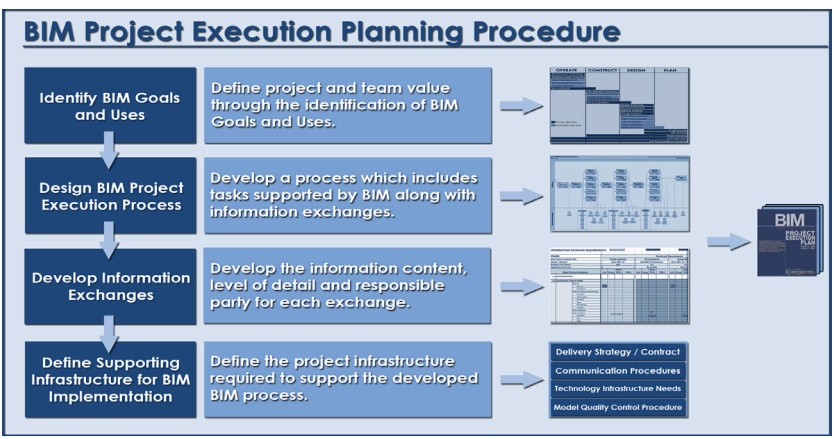

Fig. 2. BIM Project Execution Planning Procedure (CIC, 2009)

Research Methods

The focal point of step three for the aforementioned procedure is to development an effective information exchange (IE) process which the project team can use to add value to downstream BIM Uses. In the development of the IE process, the first step was to review and compare any ongoing project with a similar approach. Next, the information exchange process should add value to downstream BIM users. According to lean principles, adding value means eliminating waste (Womack, 2003) Therefore, the goal of this paper is to identify the categories for waste associated with the information exchange process. The following research steps were conducted to develop the concepts addressed in this paper:

1. Identify categories of waste through a content analysis of lean theory literature;
2. Conceptually map the categories of waste to inefficiencies in the information

exchange process; and
3. Perform a pilot analysis of a case study project to determine the actual waste that occurred through the information exchange between Design and Construction teams.

The case study results were gathered through the participation in meetings and interviews with project participants. Research team members attended each of the following meetings to evaluate the information exchange process: BIM Execution Planning meeting, Pre-Coordination meeting, four 3D Coordination meetings, and a 4D schedule review meeting. In addition to meetings, the project manager responsible for BIM implementation was interviewed using the breakdown of information exchange waste categories in this document. During the semi-structured interview, the lean concepts were described in terms of information exchange, and the interviewee identified waste that pertains to each topic area. This structure was used to determine the effectiveness of lean theory as it pertains to the IE process.

The Information Exchange Process

One of the largest challenges of implementing Building Information Modeling on a project is the transfer of information between disciplines (buidlingSMART Norway, 2009). To improve the effectiveness of BIM, information required should be both accessible and usable when needed. This is the goal of the Information Delivery Manuals (IDMs) being produced by the buildingSMART International Alliance for Interoperability (IAI). According to the IAI, an IDM will specify (buidlingSMART Norway, 2009):

- Where a process fits and why it is relevant
- Who are the actors creating, consuming, and benefitting from the information
- What is the information created and consumed
- How the information should be supported by software solutions

Although the concept of the IDMs will greatly benefit BIM software developers and ultimately project team members, it is difficult to standardize the information exchange process for unique project implementation processes at the project level. Each project team members uses different means and methods when implementing BIM. The goal of the BIM Project Execution Plan is for the information exchange process to be tailored to fit each project team member's needs and capabilities. Therefore, the development of the information exchange process should focus on the value stream associated with the transfer of models.

Applying Lean Theory to Information Exchange

Lean Theory was developed by individuals that would not settle for "How things were always done." They questioned each method of production to invent a better way to manufacture a product: lowering inventory and moving decision making to production workers (Womack, 1990). Over the years, these theories have been applied successful across many disciplines. For example, Microsoft used lean theory to balance the

interaction between operations and managers by standardizing practices and centralizing information (Herbold, 2002) When appropriately applied, lean thinking is a well-tested and well understood platform upon which to build an effective information exchange process.

Taiichi Ohno, the mastermind of the Toyota Production System, defined several areas of manufacturing waste (Ohno, 1988). Table 1 is a summary of seven types of waste along with a definition that pertains to production systems. According to Ohno, overproduction means to produce sooner, faster or in greater quantities than the absolute customer demand. When applied to information exchange overproduction occurs when the author includes additional information that is not needed for any downstream users. This leads to end users having to: 1) delete unnecessary components / information, 2) group and sort elements, and 3) manipulate large files.

Table 1. Seven Types of Manufacturing Waste (Ohno, 1988)

Production System Waste	Definition
1. Overproduction	To produce sooner, faster or in greater quantities than the absolute customer demand
2. Inventory	Any raw material, work in progress (WIP) or finished goods which are not having value added to them
3. Extra Processing Steps	Processing beyond the standard required by the customer
4. Motion	Individuals move more than is necessary for the process to be completed
5. Defects	A component which the customer would deem unacceptable to pass the quality standard
6. Waiting	People or parts that wait for a work cycle to be completed
7. Transportation	Unnecessary movement of parts between processes

In table 2 the seven types of waste are translated to define information exchange waste. This breakdown of waste was used to identify the waste associated with the transfer of information on a case study project at Penn State.

Table 2. Seven Types of Waste adapted for the Information Exchange Process

Production System Waste	Information Exchange Translation
1. Overproduction	More information than required by BIM users Revisions to Model after release
2. Inventory	Early delivery of information Push instead of Pull – take what is given approach
3. Extra Processing Steps	Producing more detail than required by users
4. Motion	More file transfers than necessary Not placing the model in a common location
5. Defects	Model inaccuracy / Incorrect information
6. Waiting	Late delivery of information
7. Transportation	Inoperable hand-off of information - file type & version

Case Study Results

The Pennsylvania State University is currently constructing a large laboratory science facility. When the project was in the schematic design phase, the owner and design team decided to implement BIM, therefore the architect, structural engineer and MEP engineer were contracted to develop 3D information models for the design. Using a CM Agency delivery method, the contractor was brought onboard during design development with intensions to use the design team's model for 3D coordination and 4D planning (a 3D model with a time-based simulation).

In terms of the information exchange process, the design team produced an element structure breakdown of the components in the model including: Structural, Mechanical Equipment, Exterior Façade, Interior Walls, and Ceilings. The level of detail was determined by the design team, and was delivered to the contractor as an Autodesk Revit model via an ftp site. The results of the actual waste which occurred through the information exchange between the design team and construction team on the case study are shown in Table 3. These results are the product of meeting evaluations and interviews of project team members.

Table 3. Seven Types of Waste related to the IE for the Case Study Project

Production System Waste	Description	Waste
1. Overproduction	Furniture and Electrical Outlets were modeled	Delete additional items
	Building not broken into areas	Break-up model
2. Inventory	Push rather than Pull – use what was provided	Model whatever is needed and not included (ceilings)
	Several ceilings were not drawn	
3. Extra Processing	Additional detail in lab rooms for space studies	Remove detail
4. Motion	Files were made available in a central location	None
5. Defects	Wall type was not confirmed	Model Validation
	All walls were modeled to under-slab	Reduce height of some walls
6. Waiting	Information for 4D Model should have been delivered earlier	Time lost due to delivery
7. Transportation	Revit –Navisworks; Revit–Synchro	None

In detail, overproduction occurred on the project because the design team modeled the furniture and electrical outlets. Although, these items may be considered valuable for a downstream use of BIM, this led to the construction team having to delete all furniture and electrical outlets because they were not needed in the coordination process. Also, the floors in the model were not divided for planning procedures. the contractor spent time and resources reorganizing the design team model in quadrants for the 4D model, and to simplify the coordination process. If this simplification was not done, the file size would have slowed down meeting productivity because of sluggish model manipulation. According to the project manager responsible for BIM on the construction team the "most difficult task was breaking up the model into quadrants. Any revisions also needed to be broken up – and it was very time consuming."

Conclusions and Future Work

This paper presented a method for evaluating the waste associated with information exchange on building projects. Specifically, lean theory was utilized to identify seven areas of waste that relate to the IE process. According to the project team on the case study project, when this method was applied to the project, the seven areas of waste led to an accurate identification of the problems that arose from the information exchange process. When applied to information management, these concepts provide a broad framework for an effective process for standardization. To improve information exchange between project team members, it is essential that the non-value added processes are eliminated.

The overarching goal for this research is to provide a standardized method in which

future studies can more precisely measure the waste associated with the information exchange process. Although this paper provides an initial pilot study aimed toward this goal, additional research needs to be conducted to develop a standardized process. Potential research could include the identification and analysis of the cost of the waste by allocating time and resources to each non-value added aspect of information exchange. This could provide additional insight to the industry related to high potential value added improvements to the IE process, and could also document the scale of the economic benefits that may be achieved by the industry. For example, currently the most frequently cited study related to the scale of the challenges related to inefficient interoperability is the important study performed at NIST (Gallihar et al. 2004) which projected an overall industry cost of $15.8 billion in 2002 due to poor interoperability. This counterfactual analysis study provides significant value toward identifying the scale of the challenges related to interoperability, but further, more detailed project analyses can provide additional insight into the root causes for the waste in the process and identify more accurate means of measuring this waste at a project level. To extrapolate any future findings, case studies with different project characteristics would need to be evaluated to ensure the process can be standardized.

Acknowledgements

We would like to acknowledge the Charles Pankow Foundation, Construction Industry Institute (CII), The Pennsylvania State University's Office of Physical Plant and the Partnership for Achieving Construction Excellence (PACE) for sponsoring the BIM Project Execution Plan research project. We would also like to thank The Pennsylvania State University project team for their help and support in the performance of this research. A GAME THEORETIC APPROACH TO UNDERSTAND OPPORTUNISTIC BEHAVIOR IN PROJECT NETWORK SUBCONTRACTOR SELECTION

H. I. Unsal[1] and J. E. Taylor[2]

Abstract
The construction industry has been shown to suffer from poor productivity performance and a lack of innovation. One area where substantial improvement potential lays is subcontractor selection. Subcontractor selection strategies employed by contractors can significantly impact the success of individual organizations and the overall efficiency of the market. Long-term partnerships are promoted by experts from both academia and industry as a means of achieving improved project network productivity; however, opportunistic bidding behavior that may accompany its implementation has been largely ignored. We conducted a bidding experiment to simulate whether opportunistic behavior would emerge in the subcontracting process. The purpose was to observe whether the hold-up problem occurs as previous simulation research focused on game theory indicates. The empirical data was collected through an internet based interactive bidding simulation developed by the investigators. The findings contribute to the project management literature by empirically demonstrating how opportunistic behavior occurs in the bidding process and how it leads to different partner selection strategies by contractors and different market outcomes in terms of efficiency.

Introduction

Research that links subcontracting strategy to improved performance and faster innovation adaptation is abundant (Kumaraswamy and Matthews 2000; Russell et al. 1990; Holt 1998). Many researchers suggest that through a collaborative approach, firms can minimize their transaction costs and maximize inter-organizational learning. They argue that this will lead to higher productivity. In the 1990s this approach was investigated exhaustively under the term "partnering" (Chan et al. 2004). During this time period, the Construction Industry Institute (CII) prepared a report describing the benefits of and the barriers to partnering (CII 1991). Several

[2] Assistant Professor, Department of Civil Engineering and Engineering Mechanics, Columbia University, 618 S.W. Mudd Bldg., 500 West 120th Street, New York, NY 10027; PH (212) 854-1182; FAX (212) 854-6267; e-mail: taylor@civil.columbia.edu.

case studies also found that partnering improved firm productivity and innovative capacity (DeVilbiss and Leonard 2000; Barlow 2000). Partnering can refer to project partnering where companies form an alliance for the duration of the project or long-term partnership where companies agree to work together over several projects. The focus of this paper is on long-term partnerships as these partnerships have a strong impact on the structure and efficiency of the industry overall.

A recent simulation study argued that in a more relationally stable environment where firms subcontract from fewer firms, the inter-organizational networks adapt to changes faster (Taylor et al. 2009). Relationally stable networks realized the benefits of innovation sooner. There appears to be a continuum where at one extreme is the pure market transaction and at the other extreme is long-term partnerships. The argument made by Taylor and colleagues (2009) would indicate that project networks get more efficient as they become more relationally stable. However, despite the benefits, not all construction networks eliminate the bidding process and employ long-term partnering strategies. One cause may be related to a fear of opportunistic behavior by partners in the project network. In this paper we seek to first ascertain whether opportunistic behavior will emerge in a project network over repeated bidding interactions and second to examine the impact this may have on overall market efficiency.

Background

The concept of opportunism in inter-organizational interactions originated from the work of Williamson (1975) and has since been central to discussions of inter-organizational collaboration. Strategy researchers adopt a transaction cost economics perspective to demonstrate the existence of opportunistic behavior potential in different industries, how it impacts the outcome of collaboration or the managerial decision making of the parties involved (Provan and Skinner 1989). Some provide contractual remedies for avoiding the threat hence providing a hope for more effective collaboration (Rogerson 1992). The definition of opportunistic behavior is made by Williamson (1975: p. 9). Williamson distinguishes the opportunism from hyper-rationality as the hyper-rational "economic man" is self-interest seeking whereas opportunistic behavior is "self-interest seeking with guile." Organizations are vulnerable to opportunistic behavior for two reasons. The bounded rationality of the agents combined with the uncertainty of future makes it impossible to write complete contracts that will cover every contingency. However uncertainty by itself would not be a problem if the resolution of the conflicts between parties was not costly. Firms would adapt the contract to the changing conditions and requirements of the transaction and eliminate the asymmetric bargaining power. However the cost of using the legal system to arbitrate disputes creates a zone for parties where they can take advantage of the situation.

Opportunistic behavior in the context of project networks drew attention from construction researchers as well. Chang and Ive (2007a) focused on the bargaining power that the contractor has over the client after the project initiation and discussed the opportunistic behavior potential that emerges as the design is modified throughout the project. If the client wants to discontinue working with a contractor in case of any dispute, they are left with two options: terminate the project and try to get a salvage

value out of the completed portion or switch the contractor. Either of these two options is costly which gives the contractor bargaining power. Lo et al. (2007) examined the impact of opportunistic bidding behavior in construction markets. They mainly focused on the fact that the contractors submit abnormally low bids and try to increase their margin by cutting corners or finding loopholes in the contract in order to charge more for change orders. The enabler of the opportunistic behavior for both examples is the post-contractual dependency of the client on contractor.

Dependency between firms is caused by asset specific investments which by definition lose value significantly if not usable for their intended purpose (Williamson, 1975). The asymmetric bargaining power caused by the asset-specific investment will create what the transaction cost economics (TCE) literature refers to as the "hold-up problem." In a case study of the Chunnel project, Chang and Ive (2007b) demonstrated the existence of the hold-up problem in the presence of process specificity which operates similarly to asset specificity.

Construction researchers have recognized the significance of inter-firm dependency and the resultant hold-up problem in a single contractual agreement. However the dependency and the potential of the hold-up in a long-term collaboration where repetitive transactions occur are largely ignored. By long-term collaboration we refer to the quasi-firm governance structure defined by Eccles (1981) where the buyer purchases the service from a limited pool of suppliers as opposed to the committed partnership where the competition between suppliers is minimized.

Continuous collaboration between firms will minimize transaction costs and maximize inter-organizational learning benefits. Firms prefer to work with a subcontractor with which they have experience not only because of the reputation effect but also because it will be less costly and risky (Miozzo and Dewick 2004). However, the potential rent that the client can receive if they contract with the same subcontractor in the next project is also the opportunity cost of not working with the same subcontractor if they decide to hire another subcontractor. This implies the existence of a switching cost from one subcontractor to another in between two transactions. By working with the same subcontractor for several projects, the client can inadvertently give the subcontractor bargaining power during the bidding process. Therefore another form of asset specificity, relational specificity, can exist.

If there is a benefit to continuous, relational collaboration, the subcontractor might realize the switching cost of the contractor and adjust their profit margin accordingly. Previous agent-based simulation has provided algebraic proof of the existence of relational hold-up in an oligopolistic market (Unsal and Taylor 2009). However in order to argue its existence and impact on the market, a further experimental study is needed. The first reason is that the actual behaviors of individuals usually differ from those predicted by game theory due to the rationality assumption. Secondly, unless the technical specification or geographical constraints of the companies limits the number of bidders in a contract, the bidding process in construction market resembles perfect competition. The pool of the bidders might be limited but there are usually numerous potential qualified bidders in the market. In this paper we replicate a market to show that opportunistic behavior exists in repetitive transactions under perfect competition if there is an incentive for continuous collaboration. We further investigate how opportunistic behavior, if it

exists, will impact the market efficiency and structure over time.

Methodology

We developed an interactive bidding game to create an artificial market. From the vast behavioral game theory literature it is known that decisions of individuals deviate from what Nash Equilibrium suggests (Nash 1951). Therefore an experimental study with human subjects has stronger validity than a simulation of individuals where each agent is assumed to be identical, behave rationally and have unlimited computational capacity. In fact, analytical game theory is often criticized because people do not think with equations and are not capable of making too many iterations (Camerer 2003). When people do limited iteration in a single game, they approach the Nash equilibrium when the game is repeated. So we designed the experiment as a repeated game in which the behavior of a large group impacts the decision of an individual. For this reason, we also encouraged participants to participate in several bidding games. This not only compensated for the limited iterative thinking but also allowed us to observe how the market evolved over time as participants became more experienced. Having participants receive feedback from the market over time, we expected to reach the Nash equilibrium that was identified by the earlier simulation work of Unsal and Taylor (2009).

Experimental design

Each participant was assigned one of the two roles: contractor (bid-taker) or subcontractor (bid-submitter.) Each bidding game was comprised of 10 successive projects. Each project was considered as a period. In each period, there were three stages. In the first stage the contractor requested bids from their pool of subcontractors. In the second, the subcontractors responded to the bid request by submitting a bid price. In the third stage, the contractors decided to which subcontractor they would award the bid. Each role had a unique objective function and cost structure. To ensure the motivation of the participants, the participants were compensated based on their relative financial success in the game compared to the other participants.

In each period, contractors completed projects and earned $200,000 in revenue. The 10 projects were assumed to be identical so revenue was constant for each project in the game. The contractors' objective was to maximize their profit by minimizing their cost. The following equation is the objective function of contractor:

$$Max\ \pi = \sum_{i=1}^{10} 200{,}000 - TCc_i - p_i$$

Where; π = total profit, TCc_i = total transaction costs for the contractor in period i, and p_i = the winning bid price of the period i.

The total transaction cost (TC) is the sum of three different types of transaction costs. One of the reasons why firms do not keep their pool of potential subcontractors infinitely large is that there is a cost associated with collecting and evaluating bids. There are also long term costs of working with a large pool of suppliers. Every time a contractor requests a bid and every time they evaluate a bid, the transaction costs of "bid request cost" and "bid evaluation cost" apply respectively. We assumed the cost

of a single bid request to be $1,000 and the cost of a single bid evaluation to be $3,000. A third type of transaction cost for the contractor represents the inter-organizational learning benefits. Firms decrease transaction costs that are associated with collaboration significantly as they gain experience working with each other. They create more effective solution methods to problems by developing inter-organizational routines, resolving conflicts more efficiently and decreasing monitoring costs. Also, as the partners become more familiar with each other the potential risk goes down. In the Unsal and Taylor (2009) simulation study this cost was referred to as the boundary cost. However for the participants to understand it better we referred to it as collaboration cost. The collaboration cost follows the learning curve that was defined by Wright (1936). The equation is as follows:

$$CC_{c,s} = CC_0 \times (n_{c,s})^{\log_2 \lambda}$$

Where; CC_0 = coll. cost of working with any firm for the first time, $n_{c,s}$ = number of projects that contractor c worked on with subcontractor s, and λ=learning rate.

Contractors are expected to employ the best subcontractor selection strategy in order to maximize their profits. A screenshot of a typical contractor user interface in the bidding game is included in Figure 1-1.

Subcontractors compete with each other by submitting bids to contractors. Their objective function is to maximize their profit by both minimizing costs and maximizing revenue. For any subcontractor s the objective function is:

$$Max\ \pi = \sum_{i=1}^{10} \left[\sum_{c=1}^{C} \left(p_{c,i} - c_{c,i}\right) \times I_c(winning) \right] - TCs_i$$

Where; $p_{c,i}$ = price that the subcontractor sent to contractor c in i^{th}period, $c_{c,i}$ = cost of the subcontractor if they get the project from contractor c in i^{th}period, $I_c(winning)$ = indicator that shows whether the contractor c awarded the bid to subcontractor, and TCs_i = the transaction cost of the subcontractor in period i.

The transaction cost for the subcontractor is the cost they spend on preparing the bid. Subcontractors will send bids as long as they think their bids are considered seriously. For this, if a contractor does not hire a subcontractor for several projects, the subcontractor will often stop sending bids. This is what can eliminate the price mechanism in industry. A buyer cannot get price information by requesting bids from every subcontractor. The transaction cost that represents this factor in the game is "bid preparation cost" which is applied if the subcontractor decides to submit bid to a contractor. The subcontractors can submit a bid even if one is not requested from them but then they have to compensate the contractor for their bid request and bid evaluation costs.

Assuming the contract is lump-sum, the subcontractors' profit is the difference between the revenue and the cost of the project to them. The cost is estimated internally based on the material and labor the subcontractor will spend on the tasks. To represent the changes in cost estimation between subcontractors the cost

of the work for subcontractor is determined randomly between $80,000 and $100,000. The subcontractors took into account their own cost values and the uncertainty about the opponent subcontractors' cost values when bidding. Subcontractors were allowed to bid below cost. However, they start with a set amount of money in their bank account and if the bank account goes below zero during the game they go bankrupt and are not allowed to continue. A screenshot of the subcontractor user interface is included in Figure 1-2. Information on the previous winners of each project and the collaboration costs are shared with all subcontractors and contractors.

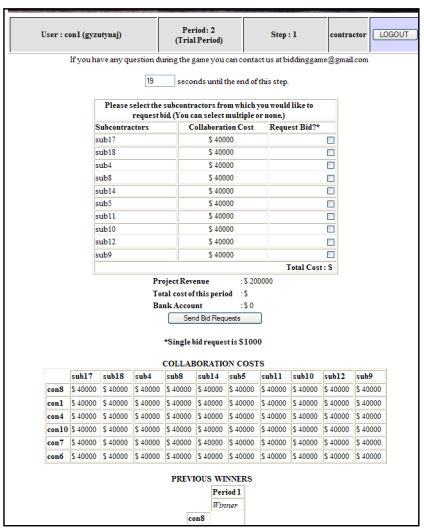

Figure 1-1 Contractor User Interface

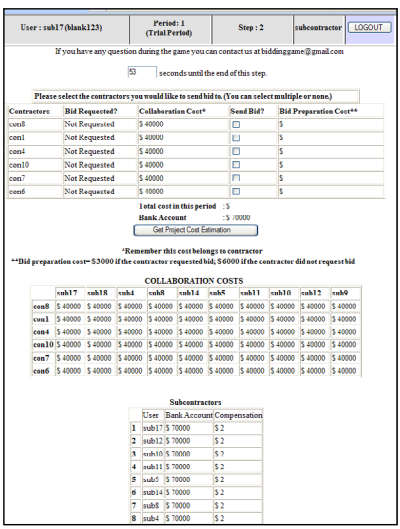

Figure 1-2 Subcontractor User Interface

Data Collection

The participants were recruited in the online workplace website Amazon Mechanical Turk (AMT). AMT has registered users all over world completing tasks that employers submit. The assignments, or as they refer them "Human Interface Tasks," usually consist of subtasks that require human intelligence that computer programs are unable to complete. The users interested in participating were directed to the game website and were asked to enter the bidding game virtual room and wait until the game started. The applicants were required to reside in U.S. in order to be able to participate. There was no prequalification criterion other than location. Each game had the capacity to hold 25 participants, 15 of which were subcontractors and the remaining of which were contractors. After participants joined the game 40-50% of them stayed and successfully participated in the game. The rest either changed their mind after joining the game or they had technical problems such as the browser not loading the game. Each participant was compensated with a minimum of $2 compensation plus a bonus based on their earnings in the game. This strategy was employed to increase the motivation of the players to succeed in the game. At the end

of each game the participants were asked to respond to a short questionnaire describing their strategy. The following section presents the data that was collected in 18 bidding game experiments.

Results

As contractors gain experience working with specific subcontractors their collaboration costs decrease. This makes the subcontractors who have experience with the contractor comparatively favorable to others. The first objective was to examine whether opportunistic behavior emerged as one or a few subcontractors gain a comparative productivity advantage compared to their rivals. Figure 2 includes the winning bid price of 18 games for each of the 10 projects. The solid line represents the average of the 18 games for each project. In the beginning of the collaboration, the average winning bid was very close to the expected cost of the subcontractors. However, as subcontractors won bids and realized they have a significant advantage over their rivals they began to submit higher bids that take more of the economic rents created by the inter-organizational learning. As a result the average winning bid in the 10th project was 22% higher than the average winning bid in the 1st project.

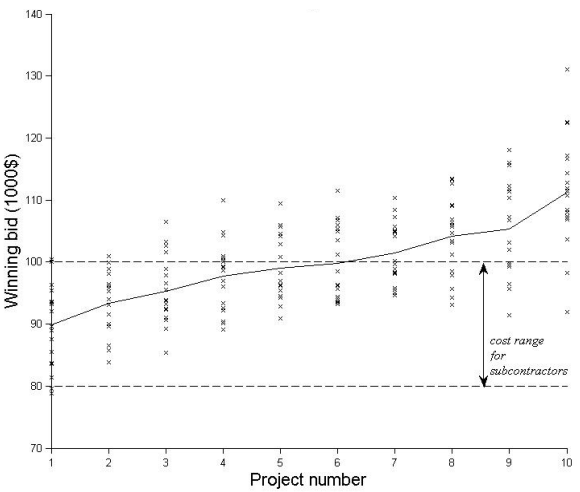

Figure 2 Average Winning Bid in Each Period

We found that opportunistic behavior did exist in the case where there were costs for contractors to switch to another subcontractor. However the discussion of how it emerges and how it impacts the efficiency of the market has further value. In the initial games when players were not as experienced, the common approach by the contractors was to request bids from several subcontractors and try to pick the one that provided the highest profit. Players on average soon realized that the strategy of sticking with one subcontractor minimizes the transaction costs, therefore maximizes profit. At this stage the subcontractors followed a cost-plus strategy so subcontractors who were fortunate enough to get low bids in the initial few rounds ended up as

winners of the game. However as the subcontractors got more experienced they realized that a loss in the first few rounds can be compensated by future earnings if they can lock in a contractor. As a consequence, the bids in the first rounds got abnormally low with the expectation of future benefits. This is similar to the case in the industry when subcontractors bid low to become a qualified supplier and earn future work. But when all participants in the game (or subcontractors in the industry) realize that this is the best strategy it becomes commonplace in the market. As opportunistic behavior becomes the only way to survive by subcontractors, the contractors begin to protect themselves by switching subcontractors from project to project in order to have an additional option or to make the subcontractor they are dominantly relying on aware that they can select other subcontractors for the work. Then the market is back to where it started with contractors selecting from a pool of 2-3 subcontractors. This is an example of how the market does the iteration on behalf of individuals for whom computational capacity is limited. If a group of inexperienced people can respond to a market and develop survival strategies in 18 games, it is reasonable to assume that industry professionals with years of experience will respond similarly in the existence of opportunism threat.

We were also interested in examining how opportunistic behavior, if it exists, would impact market efficiency. Drawing upon Williamson's work in transaction cost economics (1975), we represented the efficiency of the market with the amount of transaction costs spent on each project. Figure 3 shows how transaction costs in the market changed over time as participants became more experienced. The evolution of the market explains the change in the total transaction costs. The market reached an optimum point where all players realized the benefits of collaboration. However this was before the subcontractors realized that they can have an advantage by following an opportunistic strategy. Once the benefits of opportunism became common knowledge, the contractors' self-protection strategies led to their desire to increase competition by working with more subcontractors. The result is an inefficient market with a more fierce competition and higher bankruptcy rate.

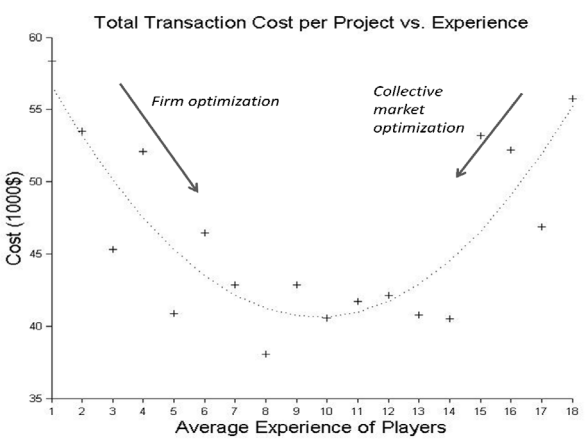

Figure 3 Evolution of Market Efficiency over Time

Discussion and Conclusion

Preventing opportunism is a more challenging problem than defining it. For a single project, the natural reaction for self-protection is to attempt to write more powerful contracts and facilitate conflict resolution processes. However, not only is this practically infeasible due to the complexity of construction projects but also, according to some researchers, limits the flexibility of the project (Chang and Ive 2007a). Boukendour (2007) proposed an innovative method of procurement where the clients are given the option to switch from lump-sum contract to cost-plus contract which alters the incentive system and limits the opportunistic behavior of the contractor. The case for repetitive projects is a bit more complicated. Writing contracts that will limit opportunistic behavior in repetitive transactions is extremely difficult if not impossible. While academicians and experts propose companies seek long-term partnerships the underlying assumption is that industry is at the left-most point of the curve in Figure 3. However the industry is more likely to have evolved to the right-most point of the same curve. Although it is true that the optimum efficiency of the market is where there are long-term partnerships, the methodology to reach the middle of the curve is different for those two points. The optimization by individual firms moves the market toward the right. This makes the left-most point an unstable one and therefore the shift of the market to the right is a natural consequence.

By simulating a bidding market where there are financial benefits for close collaboration, we showed that the opportunistic behavior does exist. We also showed that through many transactions the market iteratively evolves towards the Nash Equilibrium point. Near the equilibrium point, the contractors follow a self-protection strategy which increases the total transaction costs therefore decreases the efficiency of the market. Although it is not visible at the equilibrium point, the opportunistic behavior is the driving force behind the inefficient subcontracting behavior. We hope that the findings of this paper can shift some of the focus of subcontractor selection strategy literature from individual partnering cases to market level analyses. We can then explore the underlying dynamics in the market and demonstrate its effect in overall efficiency. We do not suggest firms become paranoid due to the threat of opportunistic behavior. However, we do suggest that the impact of the potential for opportunistic behavior on the overall market should be acknowledged and included in the discussions of collaboration and partnering in project networks.

ABSTRACT

Nearly 200 interviews and surveys collected by a Construction Industry Institute research indicate that innovation is valued within large engineering-procurement-construction (EPC) organizations but is hindered by organizational factors such as lack of resources allocated to innovation efforts; low risk tolerance; and a failure to establish innovation-enhancing processes. To enable EPC organizations to evaluate and improve their innovation capabilities, the team created an Innovation Maturity Model (IMM) that evaluates an organization in each of 61 innovation-related attributes. The IMM, which is based on the data collected and a review of relevant innovation literature, includes a macro-enabled spreadsheet that aggregates the individual survey data, identifies the ten attributes offering the greatest opportunity for improvement, and provides the recommendations for improving these ten attributes. The IMM was pilot tested using six large EPC organizations and will be available through the Web.

INTRODUCTION

Although the ability to innovate is considered to be a fundamental requirement for long-term business success in nearly all industries, the need for innovation has been undervalued within the industry that provides engineering and architectural design, construction procurement and construction services in the industrial, infrastructure and building construction markets (hereafter referred to as the "EPC industry"). In response to the need to enhance innovation, the Construction Industry Institute (CII) established a research team (RT 243) to "Explore and document the current levels of innovation in the E&C industry, identify opportunities for enhanced levels of

innovation; and best practices for E&C companies individually (and the industry collectively) to become more innovative." The research was co-sponsored and guided by the Charles Pankow Foundation (CPF). The joint CII/CPF research team actively performed research between November 2006 and August 2009. This paper summarizes the research team's methodology, findings and the tool it developed to enhance innovation within EPC organizations.

It is important that the reader keep in mind that every aspect of the research reflected the unique context underlying the research team. One key aspect of the research was the composition of the research team: four academics and eight industry professionals with between two and twenty years of industry experience, including two senior managers who were appointed as Co-Chairs. In other words, the research was a joint academic-industry effort, as is the expectation for all CII-funded research projects. Another key aspect was the objectives of the research: rather than contributing to the theoretical understanding of innovation held by academics, the research was directed to providing practitioners with knowledge and tools that offered immediate and practical value.

LITERATURE REVIEW

The team elected to begin the research process by reviewing the relevant literature on innovation and establishing seven specific research questions. The following paragraphs present the seven research questions and a very brief summary of the literature related to each question.

1. Is innovation perceived to lead to higher profit margins? Although researchers and practitioners have found that innovation is required for organizations to prosper or survive in competitive markets (Damanpour and Schneider 2006; Howell and Higgins 1990), one of the key findings of the literature search was that there has been no published research analyzing the relationship between EPC firms' investment in innovation and their financial performance. Findings establish an indirect link between investment in innovation and enhanced business performance. For example, LePatner (2007) found that construction's low investment in innovation has contributed to the EPC's very low growth in productivity since 1964 (25% compared to 250% for other industries).

2. How is innovation measured? Metrics for assessing the success and impact of an innovation have been identified and discussed in literature but practical application of these metrics is limited. Egbu (2001) and Tucker (2004) suggest tracking innovation success by measuring lagging indicators such as the percentage of profit/sale derived from the innovation. Dikmen et al. (2005) built upon these studies by identifying trailing indicators of innovation such as technological advancements, improvements in schedule, budget, and quality, and increased effectiveness of the firm.

3. What are the key perceived drivers of innovation? Toole (1998) suggests that the adoption of innovative products and processes can directly improve the

achievement of product and firm goals because they can decrease project cost and duration and increase the performance of the final structure or system. Dikmen et al. (2005) also points out that that innovation should be evaluated in terms of the overall value that results, which transcends products and service metrics. For example, innovation can lead to competitive advantage through improved firm reputation, easier work processes and improved ability to attract new employees (Slaughter 1998).

4. What are the key perceived barriers to innovation? Unfortunately, many organizations focus on optimizing the current value system rather than pursuing more radical, systemic improvements (Hamel 2006). Sawhney and Wolcott (2004) suggest the lack of innovation in EPC is not due to employees lacking innovative ideas but to a lack of mechanisms for implementing these ideas. According to LePatner (2007) EPC organizations' lack of economies of scale, lack of financial cushion and the process interdependency of many separate firms each trying to maximize individual profits hinder innovation.

5. What are the management characteristics that promote innovation? A recent study of innovation within homebuilding organizations identified management strategies that differentiate successful firms including: (1) motivated leaders, (2) a technology advocate within the firm, (3) stressing the importance of being creative and the first to use new products, and (4) using technology transfer programs (Koebel et al. 2004). One of the most impactful factors on innovation within organizations is the specific characteristics of project managers and supervisors themselves. Researchers have found that senior managers' tenure in position (Hambrick and Mason 1984; Huber et al. 1993), industry experience (Damanpour and Schneider 2006), age (Damanpour and Schneider 2006; Huber et al. 1993), gender (Sonfield et al. 2001; Stelter 2002), education (Hausman 2005; Lee et al. 2005), willingness and ability to manage conflicts (Hausman 2005) willingness to share control (Scott and Bruce 1994; Timmons and Spinelli 2004) highly influence the innovative capacity of an organization.

6. What are the project related characteristics that promote innovation? Success in the construction industry requires effective inter-organizational management. That is, construction projects often require collaboration among and management of diverse firms in order to achieve a common goal. Gambatese and Hallowell (In Press) identified specific project-related factors that promote co-innovation including Owner vision; funding from the Owner; contractor input during the design phase; overlap of the different project development phases; an innovation "champion" and entrepreneur; and co-location of the project team.

7. What are the elements of a successful innovation process? In the 1990's there were significant efforts to create process models for successful achievement of innovation within organizations (e.g., Abd El Halim and Haas 2004; Kangari and Miyatake 1997; Bernstein et al. 1998; Rogers 1995; Subramanian and Nilakanta 1996; Schroeder et al. 2000). Bernstein et al. (1998) identify four key steps: (1)

generalization or conceptualization of an idea; (2) development and production of the new technology; (3) transfer of knowledge; and (4) subsequent application to solving problems. These steps are similar to those identified by Kangari and Miyatake (1997) who found that the innovation process incorporates three major activities in the progression from new idea to implementation: envisioning new work strategies, designing the process, and implementing change.

METHODOLOGY

Another aspect of the research that reflected the unique context of the research team was the research methodology, which was pragmatic and designed by the team based on preliminary findings. The team planned, coordinated and analyzed much of its work through a dozen face to face meetings, approximately 50 conference calls, and hundreds of email conversations. Based on the findings from the literature review the team drafted an interview script and performed approximately twenty-five semi-structured interviews of EPC professionals using a convenience sample. This script was modified based on the feedback obtained through the interviews and converted to a survey. The written survey was initially completed by 46 members of the CII Board of Advisors at their Spring 2007 meeting.

The survey was subsequently converted into an online version and made available on www.surveymonkey.com. The approximately 110 EPC practitioners who completed the anonymous survey represented a convenience survey of CII members, CPF members, and a few alumni from the academic research team members' universities. Univariate and multivariate analysis was performed using SPSS and Excel. Analysis of the demographic data on the survey indicated the sample was fairly well stratified by market sector (commercial, process or infrastructure), geographic location across the U.S., and number of years in the EPC industry.

The results of the survey provided clear evidence that innovation was valued in most EPC organizations but attributes needed to effectively innovate was frequently missing. The research team found the attributes can be appropriate grouped into eight areas: Culture, Resources, Risk perspective, Customer focus, Learning, Collaboration, Leadership and Processes. It was clear from the interviews, surveys and team members' analysis of their own organizations that with regards to innovation, EPC managers don't know what they don't know—that is, they do not realize that weakness in two to three of the above areas can outweigh strengths in other areas. As such, the team decided to create a tool that could be used to evaluate an organization's innovation capabilities, identify weak areas, and suggest ways to strengthen weak areas. This tool was named the Innovation Maturity Model (IMM).

The IMM evaluation survey consisted of 61 Likert scale items, each associated with an important organizational attribute that facilitates innovation. The IMM also contained a brief set of recommendations on how to improve the attribute associated with one of the 61 statements. (See Table 1 for an example.) These recommendations reflected a synthesis of the literature the research team had reviewed as well as the

survey and interview data. The IMM evaluation survey and a macro-enabled spreadsheet that allows managers to aggregate their surveys and identify recommendations to improve their organizational attributes most hindering innovation can be downloaded from www.facstaff.bucknell.edu/ttoole/innovation.

Table 1: Example of an IMM Evaluation statement and the associated recommendation

Our organization expects individuals to share ideas through formal forums.	Continuous learning is essential for highly innovative organizations. One of the best ways to really learn about a subject is to prepare to explain or teach it. Companies can stimulate the participation of their employees in learning activities by engaging as many employees as possible in defining and optimizing processes and sub-processes. Tracking the new techniques and processes learned by employees during the annual performance review and encouraging employees to prepare and deliver presentations on new ideas and approaches in non-threatening environments can be highly effective. Firms may also want to establish a "process improvement suggestion" program and track the number of suggestions generated by various employee groups.

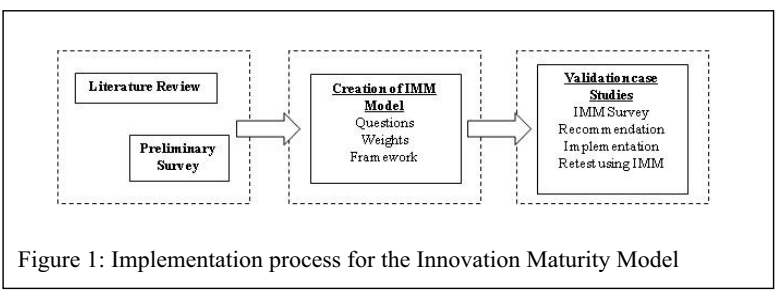

Figure 1: Implementation process for the Innovation Maturity Model

Figure 1 summarizes the process used to create and validate the IMM. The IMM was presented at the 2008 CII annual conference with a call for volunteer organizations to help validate and refine of the tool by pilot testing it. Five of the approximately twenty firms who volunteered were requested to participate as case study firms. In addition, one CPF member company identified by the CPF Board was requested to participate. The identities of the six organizations that participated in the case study process are being kept confidential due to the sensitive nature of the data recorded for each firm. Each case study firm was asked to perform the following actions:

1. have a small set of employees review the format and overall content of the IMM evaluation questions and the specific wording of each question and provide the team with constructive criticism;
2. have a larger set of employees (25-100) complete the IMM evaluation tool, adding demographic questions as appropriate to allow the organization to identify statistically significant differences in data from different groups within the organization (such as supervisory versus non-supervisory personnel, geographic locations, etc.);
3. allow the research team to analyze the results and provide the organization with recommendations for improving the organizational characteristics that

offered the most potential for improving the organization's innovation potential;
4. implement the recommendations within at least one portion of the organization and share the outcomes with the research team; and
5. provide any feedback regarding the effectiveness of the IMM.

The number of completed evaluation surveys in each organization ranged from 20 to 90 responses. The selection of the respondents was left up to the organization. In each case, the organizations selected a segment of the organization to focus upon, although this focus was different in each organization. Once the surveys were completed, the following four-step process was utilized for each organization:

1. The results were analyzed to determine the top ten attributes with the highest potential for innovation improvement within the organization. RT 243 determined an individual weighting factor for each of the 61 IMM questions that reflected the relative importance of each item based on the literature review and surveys. The Innovation Potential is calculated for each question by subtracting the average score (e.g., 3.6) for the organization from the maximum potential (5) and then multiplying this result by the weighting factor.
2. The detailed findings and specific recommendations for improvement in the ten areas with greatest innovation potential were reported to the case study liaisons.
3. After agreeing on the specific recommendations to adopt, the implementation process was placed under the direction of the individual companies. The RT 243 team provided advice when requested but ensured the implementation remained independent.
4. The case study liaisons were contacted several months later to determine what progress had been made on the suggested implementations. In one case, the same group of respondents as well as a new group of employees were asked to complete the IMM survey several months later to measure innovation-related changes in the organization since the implementation.

FINDINGS

The survey data combined with interview notes provided strong empirical support for the overall finding alluded to in the previous section and to the general finding that typical EPC organizations value innovation but lack key organizational attributes necessary for sustained, organization-wide innovation. The key attributes for successful innovation are summarized below. The eight areas that underlie the IMM are underlined. A very small portion of the data analysis is presented to illustrate the points due to space limitations but the full analysis can be downloaded from www.facstaff.bucknell.edu/ttoole/innovation/innovationsurveyresults.docx.

Risk Perspective. While typical EPC firms have a culture that generally affirms the importance of innovation, managers apparently enable innovation only on a project basis. They do not adopt a long-term, appropriate risk perspective that

enables innovation on an organization-wide basis. Most firms reported low agreement with survey statements related to risk perspective, such as, "My firm encourages risk taking and trying new approaches" and the differences in means between innovative and non-innovative firms was statistically significant (p=0.001). EPC managers must allow the costs and risks of an innovation to be spread across multiple projects, such that the risks of using an innovation is not unacceptably high for one project or one set of project leaders. 70% of survey respondents agreed with the statement "Schedules and budgets are too tight to take a chance on something new."

Resources. Innovation-related resources include expense budgets as well as staff time. The majority (61%) of survey respondents indicated their companies lack the resources necessary to identify, nurture, track and apply innovations. The majority of innovations (60%) proposed on projects are funded from the original project budget. Only 33% of respondents agreed with the statement "My firm has personnel explicitly tasked with promoting and facilitating innovation within the firm" and only 9% of respondents agreed that "Workloads are managed to ensure staff have sufficient time to pursue innovation." Especially as a result of the global economic downturn over the past few years, EPC organizations are now "lean, mean design and construction machines," with little slack resources. Austere staffing promotes short-term earnings but not long-term success through innovation.

Processes and Structure. The innovation literature makes it clear that innovation will rarely happen when there is not an organizational structure and formalized processes for methodically identifying and evaluating potential innovations and effectively adopting them on appropriate projects. Organizations must also have structure and processes to enable organizational learning to occur which will allow innovations to be effectively implemented on subsequent projects. The survey data showed that firms that viewed themselves as innovative were more apt to have innovation occurring through departmental or organizational practices, rather than on individual projects (p=0.003). The survey also showed that innovative firms are more likely to have methodical or rigorous innovation decision processes (p=0.000).

Changed Project Environments. Successful innovation requires real and sustained commitment by all project entities. Organizations with a genuine customer focus will not hesitate to collaborate with other entities serving the same customer yet nearly one-third of survey respondents agreed that "Lack of communication between project participants" and "Too many players in the process" were critical barriers to innovation. Project delivery and contract methods that inhibit collaboration between entities during design and construction and prevent risk taking are not conducive to the creative integration needed to innovate. Nearly half of the respondents indicated that the design-bid-build delivery method hinders innovation.

Leadership and Culture. All of the organizational traits that enable innovation mentioned above cannot occur without the appropriate leadership and organizational culture. They are the cornerstones that must underlie all innovation initiatives.

The results of the six case studies provided two valuable sets of empirical information. First, the pilot tests of the IMM provided confirmation that the content and wording of the IMM questions and recommendations were appropriate and useful. The organization who had employees retake the IMM several months after IMM recommendations were implemented experienced statistically significant improvement in the scores for the attributes that were targeted for improvement. Second, the pilot tests supported the overall findings from the survey, namely that the organizational culture and leadership may support innovation, but resources, processes and risk perspective do not.

CONCLUSIONS

EPC organizations focus on bringing capital projects in on time, under budget and without injury. They believe the best way of achieving these goals are by implementing best practices, that is, by adopting what has worked on past projects and eliminating all unnecessary sources of risk to achieving project goals. EPC organizations are rightfully proud of their strategic abilities to manage successful capital projects and of their lean organizations that facilitates positive financial performance even during market downturns.

The trouble is that EPC organization's project management strengths are exactly what keep them from being innovative, despite the value attached to innovation by managers. EPC organizations like the idea of being innovative but most are poor at identifying, trying, nurturing, and managing knowledge regarding innovations within their organizations. New methods, processes, products and systems may sound exciting, but the reality is that they are treated as too costly and too risky to pursue even on the smallest projects. Project and corporate budgets are too lean to allow personnel from pursuing innovation-related activities.

This paper has summarized the research that led to the development of a tool to allow EPC managers to identify the attributes of their organization that are hampering their ability to innovate. Although the research process reflected a pragmatic approach that best suited the strong industry composition of the research team, the positive feedback received from the six organizations who pilot tested the IMM indicates the tool has promise for helping EPC organizations identify and implement the changes needed to enhance innovation within their organization.

Abstract:

Despite increasing industrial interest in Concurrent Design, little empirical research has been undertaken on design conflicts that occur during such concurrent engineering design efforts. To overcome this gap, this paper presents results from a case study we conducted at the Chinese office of a worldwide operating design consultancy firm. This paper presents the sources of conflicts that practitioners of this design office encountered during concurrent design activities on a number of historical and ongoing projects. The paper also presents a number of strategies to effectively detect and manage conflicts on concurrent engineering projects that we derived together with practitioners of the design consultancy company. These strategies include processes for effective change management, communication management, quality management, and risk management.

Introduction

Conflict in design is not a novel principle and has plagued projects throughout construction history. Design conflicts occur because of interfering designs between different parties. These interferences can be either physical or conceptual in nature. Possible parties include various disciplines within a team of engineers as well as external parties such as the client and contractor involved in the engineering process.

Managers continually face the challenge of managing design conflicts within their design teams to achieve the prerequisite deadlines. With the application of concurrent engineering (CE) in the construction industry and the growing complexity of building requirements, conflict in design is increasing in occurrence and severity. Additionally, the increasing complexity of the industry requires larger design teams, so that conflicts become increasingly difficult to resolve.

To overcome this gap, this papers presents the results of an empirical case study with the aim to increase understanding about how to manage design conflicts that occur during CE efforts. We analyzed the causes of design

conflicts that occurred on a number of historical projects carried out by the Shanghai China office of an internationally operating design firm. We identified four major reasons why design conflicts occurred: Discipline fragmentation, missing heritage relationships, insufficient client integration, and the introduction of new design innovations. Based on these four root causes, we then developed a number of strategies to improve design management procedures together with the design office's practitioners.

This paper is structured as follows: We start with a short introduction to CE. Afterwards, we describe our research methodology. We then continue with describing the research results. We close with a short discussion of the findings that result in a number of practical recommendations.

Concurrent Engineering

CE as defined by Evbuomwan and Anumba (1998) attempts to optimize the design of the project and its construction process to achieve reduced lead times, and improved quality and cost by the integration of design, fabrication, construction and erection activities and by maximizing concurrency and collaboration in working practices.

Evbuomwan and Anumba (1998) see CE as a method to avoid the pitfalls that traditional 'sequential' engineering deals with:

- The fragmentation of the different participants in the construction project,
- The fragmentation of design and construction data,
- The occurrence of costly design changes and unnecessary liability claims,
- The lack of true life-cycle analysis efforts, and
- The frequently occurring miscommunication of design rationale and intent.

In this way, CE theoretically can lead to a number of benefits (Anumba, Baugh, & Khalfan, 2002), such as:

- Getting the job right the first time around,
- Increased Client satisfaction,
- Reduced product development time and costs, without compromising quality,
- Eliminating waste, and costly and time consuming downstream changes, and
- The reduction or elimination of non-value-adding activities.

Because CE organizes work so that different parties work concurrently on tasks, effective knowledge transfer between the various disciplines and team members is a cornerstone to prevent problems from occurring. CE design teams require specific communication methods to ensure minimal ambiguity and rework (Loch & Terwiesch, 1998)and function best if they are able to:

- Invest in signature relationship practices,
- Model collaborative behavior,
- Create a 'gift' culture,
- Ensure the requisite skills,
- Support a strong sense of community,
- Assign team leaders that are both task- and relationship-oriented,
- Build on heritage relationships, and
- Understand role clarity and task ambiguity (Gratton and Erickson 2007).

Even if CE teams promote co-design and intend to achieve the same goals (Kleinsmann & Valkenburg 2008), tensions have been frequently reported in practice between the various disciplines (Lu, Cai, Burkett, & Udwadia, 2000, Cicimil & Marshall, 2005, Erkamp, 2009). For example, Cicmil and Marshall (2005), analyzing a case study, found that there is a lack of trust between various parties which prevents team members from communicating about mistakes, design decisions, and possible areas of improvements. Cicmil and Marshall (2005) show that CE has an extremely high risk of communication failure. This high communication risk can lead to significant rework and long decision times, and subsequently to long delays in projects. Next to communication, political issues also cause problems during CE efforts. External parties such as the contractor or the client have their own agenda's and, thus, parties frequently have conflicting views of the design project.

Overall, despite a number of mainly theoretical efforts to overcome barriers between the different disciplines (Détienne, 2005; Evbuomwan & Anumba, 1998; Kleinsmann & Valkenburg, 2008), little empirical research with the potential to deepen our understanding about how conflicts occur in practice exist.

To overcome this gap, we conducted a case study. The aim of the study was to analyze conflict that occurs during CE, to discover the causes of these conflicts, to map out the effects of these conflicts, and to provide practical suggestions which CE team can use to improve conflict management.

Research Methodology

We conducted this case study research with the Chinese division of an international consultancy firm based in Shanghai. Employing a workforce of approximately 60 people, the office fulfills an advisory role on most of its projects, acting as a conduit between the client, the Chinese government, and local companies. In house experts from other company offices across the world support the design capabilities of the Shanghai office. Overall, the company offers a great case to study conflict because it houses many experts in this field that are able to indicate the largest issues encountered over the past few years on the subject of conflict management in CE. Additionally, the company implements CE; which they refer to as "Total Design Management". The company is involved in all phases of the design and construction process and engineers concurrently perform tasks.

	Description	Duration	Main issues
Project I	*The design and construction management of a chemical research and development campus.*	*4 years*	• *Large client with multiple departments each with different demands: Complex and difficult communication* • *Innovation of LEED Gold certification* • *Discrepancies between final building and client vision* • *Lengthy project; difficult integration of new employees into the project team which led to difficult communication.*
Project II	*The Design and construction management of a chemical factory*	*3 years*	• *Discipline engineers had too little time to effectively work as a t* *External designers were frequently used for design reviews leading to a lower quality and increase in conflicts.* • *Client requested 125 design changes throughout the project*
Project III	*The Design and construction management of a factory including warehousing*	*2 years*	• *Project joined at a later phase, company had to resolve issues caused by previous mismanagement.* • *Communication with client was troublesome; poor documentation led to rework for the company* • *Client requested 500 design changes throughout the project*
Project IV	*The design and construction management of a factory specialized in the manufacturing of robotics.*	*2 years*	• *The company was bypassed in important decisions by client and contractor*

During the case study we focused on four different projects[1] the company completed within a year of the interviews. Table 1 summarizes a number of characteristics from these projects.

To learn about these projects we followed a four phase research strategy:

1. First round of interviews with 2 project managers and 5 engineers to learn about the conflicts that occurred on the projects and to learn about processes the project team applied to manage these conflicts.
2. Second round of interviews with 4 project managers and 11 engineers including the interviewees from step 1 to validate and deepen our understanding from research phase 1.
3. Development of an improved conflict management strategy for the company
4. Validation of our strategy by presenting our findings to the interviewees asking for critical feedback.

Research Results

In summary, the data shows four causes of conflicts on the case projects: Discipline fragmentation, missing heritage relationships, insufficient client integration, and the implementation of new design innovations on the project.

Discipline Fragmentation

We observed discipline fragmentation during a number of interviews with company staff. A quote from an architect illustrates this well:

"I am the architect, I focus on the looks of the building and the layout, the rest is up to the other discipline engineers. This is my job; it is not my job to look at what the other discipline engineer is doing."

The above displays exactly the kind of mindset that causes internal fragmentation. This mindset is confirmed by one of the project managers:

"Engineers were very passive during design review meetings. They were not straightforward with each other, didn't listen well to engineers of different disciplines, didn't have much patience with each other and were looking at the project exclusively from their own discipline (perspective)." And, *"The amount of communication between the engineers was very low. The engineers were very reluctant to look over to other disciplines. Everyone is working on their own little island and hoping it will fit in the end. "*

These comments display that engineers are very reluctant to look past their own discipline and are hesitant to try and integrate someone else's field of expertise into their own work. The following statement of an engineer provides an overview of his experiences at the company and claims:

"Design team engineers here are very reluctant to break the discipline 'walls'. Integrated design requires all discipline engineers to participate proactively in the process. It doesn't work if only one person is trying to communicate his discipline to others."

One engineer presented a specific example of how discipline fragmentation hindered the project:

"During project II the structural and HVAC engineer didn't communicate

[1] We removed all project names and all names of informants to ensure the anonymity of the involved parties.

efficiently so when we reached the construction phase of the project we discovered that the design drawings indicated that the air-conditioning ducts passed straight through a horizontal structural beam designed to support a crane system. Of course, we couldn't just move the piping under it because it would prevent the crane from functioning; above the structural beam we also lacked space due to the roof of the building. Eventually we had to redesign the air-conditioning system to split up into two separate, smaller ducts that could pass above the crane beam. This entire process cost us several days to resolve."

Overall, our data clearly shows that despite the application of CE, team members still need to make a complete transition to a more collaborative mindset. Engineers still have difficulty applying collaborative design techniques effectively, which is a very real cause of conflicts. Discipline fragmentation led to several costly design conflicts in the final design such as the following one that an engineer indicated during the interviews:

"The design conflicts didn't come to light until the contractor reviewed the final design and this in turn led to changes in the design during the construction phase and consequently led to an increase in the overall costs and a reduced quality of the final construction."

Missing Heritage Relationships

In addition to discipline fragmentation, missing heritage relationships play a large role in causing conflicts during CE activities. In the case firm, engineers were frequently dealing with new people and this led to a lack of trust between engineers and to problems with the integration of someone into the team who is not familiar with CE methodology. When asking a project manager about project I, she said,

"Almost everyone was replaced in the duration of this project at one point or another; it would be extremely beneficial if we somehow created a procedure to reintegrate the knowledge that is lost with this employee quickly." When questioned about the effects that leaving employees had on the project: "Of course, when an engineer left the team, it took a lot of time to find a new employee and get him up to date on the project, this cost us a lot of time and effort."

Statements from other interviews further confirm the lack of heritage relationships.

"One of the biggest problems is that people here do not stay at the company long enough to reach a level of seniority that is needed for integrated design to work. For integrated design to function, there need to be a few people in the team that are very knowledgeable of not only their own discipline, but also have extensive knowledge of how the other discipline engineers work."

"The problem is that when people leave during a project, much of their knowledge isn't written down and that makes is hard to train a new person to replace the empty position. This is especially a problem on longer projects"

"The discipline engineers were changing throughout the engineering project. The designers were not the same people that were involved with solving the onsite

construction projects. This meant that the discipline engineers had to take a lot of time to study the design drawings when a problem occurred during the construction phase."

Insufficient Client Integration

As indicated earlier, it is essential in the CE process to involve the client into the design at an early phase. In this case study, cooperation between multiple design firms, the contractor, specialists and the client often led to conflicts. The tensions that exist between the different parties are usually related to the field of expertise and the lack of knowledge of other companies and disciplines. These conflicting views often lead to the lack of compatibility between various elements in the design.

The interview results suggest that there were various cases in which the communication between the design team and the client was troublesome and that the client was not involved in several elements of the design. One project manager recalls that during project I

"Electrical engineers designed an electrical system where there were many different electric rooms spread throughout the building. During the construction, however, the client indicated that this was not what he was expecting and that they would much rather have had a single electricity control room. We didn't discuss the electrical system expectations with the client, and in the end we were unable to modify the system to completely satisfy the client requirements. In the future we should communicate these things better."

In addition, the project manager recalled another case during the same project,

"The general contractor wanted to implement a design change: They wanted to increase the concrete thickness of a certain part of the pavement because they believed that it would be insufficient to carry the loads that were required. The design team rejected the change due to the increased costs it would have incurred on the client, but didn't communicate this issue with the client. Now, after the construction has been built the client is stuck with a pavement that doesn't meet the required quality standards. In hindsight, the client indicated that they would much rather have paid a bit of extra money for the durability gain in the concrete."

In project II, an engineer indicated that *"The client made 125 design changes in the duration of the construction period."* When asked about the amount, the engineer claimed*: "This is because the client cannot predict and see everything in the design drawings. It is difficult to read these drawings and although they may look fine on paper, when the building is being constructed this view may change and the client will file a change order."*

This means that the client will generally be unable to understand the design drawings and translate them completely to a finished product. The result is that they will order these design changes to ensure that the final result is still what they envisioned.

Findings from project III reinforce all the above. An engineer, for example, indicated that *"The client only had a very basic Idea of what he wanted. He was*

only able to indicate the type of rooms that he wanted, and nothing else. Our company joined (project III) when the design was already completed, and we discovered that the design was not what the client wanted. During the construction of the building a total of about 500 change orders were filed costing us well over 3 months of extra time. Combined with a severe error on behalf of the contractor, the project was delayed about 8 months!"

Our data shows that, despite the effort to involve the client early in the design phase, the client still changed demands for the building, especially on projects with long durations.

The design changes occurred when the client came to certain realizations during a specific phase of the project, or changing requirements that the company has of the building. These design changes frequently conflict with completed work, and thus force the design team to alter the designs. Consequently, client induced design changes caused unplanned delays depending on the severity of the design change.

Introduction of Design Innovations

Integrating new technological elements into a design has a significant impact on the amount of conflict that occurs in a design team. From our data, it appears that innovation aggregates all the conflict causes presented earlier. Project I was the most innovative of all the projects researched, incorporating new sustainable building technologies as well as specialist R&D requirements for various different departments because the design included highly complex laboratory spaces with which the company had no experience in the past.

'PM A' indicates, *"Integrating the new LEED requirements (An American based Green Building Certificate) into the design (of project I) proved very difficult, it was difficult for the engineers to detail the design to comply with the rules set by the standard."* 'PM E' indicates, *"Despite the presence of a lead engineer specialized in LEED in the team, engineers indicated that they often had difficulty integrating the new requirements into their designs."*

During team meetings for project I the team discovered that the design was frequently not up to the required demands and that the design team had to rework certain areas. Most of the conflicts occurring were between the specialist and the design engineers of all the other disciplines, specifically due to design errors attributed to a lack of experience of the engineers in appropriately integrating the new technology into their designs.

Next to problems with implementing new sustainable design technologies, project I, showed difficulties relating to the development of new laboratory spaces, which was not only affected severely by the client constantly changing their demands for the laboratory spaces, but also by the design team being unfamiliar with the design of laboratory spaces in general. The engineering team invited an expert from the Netherlands to assist in the design work, but similarly to integrating LEED technology into the design work, the team had difficulties integrating the specialist requirements into the designs. One project manager explained a specific example of this problem: *"The (design)-engineers had produced a design for the lab spaces that included the ducts for air filtering. The client, however, wanted to change the locations of several machines in the labs due to changing technologies and keeping*

up with the industry. The locations of the ducts, however, were incompatible with the newly suggested machine locations. Engineers has to change the design to the ducts would be in the right location."

In addition to technical issues, innovation created tough new communication issues between the various involved parties on Project I. Because the design team had very little experience creating the specialist spaces required, this led to numerous conflicts between the clients' representatives and the design team. These issues appeared on a biweekly basis during meetings between the design team and the client. According to interviewees, a significant portion of time was spent on managing the specialist requirements for the laboratories. An engineer claimed:

"There were three different divisions (Client-side) that were going to use the laboratories. Each of these wanted to handle different design elements that often conflicted with each other. A special job was created for me to handle the communication between these different stakeholders and the design team."

Findings and Recommendations

We found effective team cooperation to be the main cause for conflicts to occur within the design team. Ineffective communication between the various parties was pointed out by the engineers and project managers on all four projects as a large cause of conflicts. This led to conflicts causing delays and a significant amount of rework for the team on a number of projects.

Additionally, this research shows that engineers and project managers perceive design conflicts in CE as being overwhelmingly negative in effect. Our data suggests that the conflicts are a major cause for delays and redesign work for the engineering team, and can frequently lead to increased costs for parties involved. It is, therefore, important to reduce the amount of conflict occurring during CE to increase overall project performance for all involved parties.

Such an effective conflict management strategy requires three different elements: prevention, detection, and effective management of detected conflicts.
