Notwithstanding social pressures to devalue its impact, odour is undoubtedly important in human communication [28], as Havelock Ellis recognized in his comprehensive and entertaining, if almost entirely anecdotal, review in 1905 [29]. The odorous steroids 5-α-androsterone and 5-α-androsterol, known to act as pheromones in pigs, have been found in axillary sweat, as well as in human urine, plasma and fatty tissue [30–34]. The role of odour in human social behaviour is discussed in Chapter 4.

The limited evidence available suggests that at least some of the tubular glands of apocrine type are, like the sebaceous glands, controlled by hormones. In the rabbit, all three sets of apocrine glands are stimulated by androgens and inhibited by oestrogens [35].

It seems likely that the human apocrine glands of the axillary and pubic regions are similarly under some androgenic control [36]. The glands do not become active until puberty, at the same time as the development of the sexual hair with which they are associated.

Anatomy and physiology of human eccrine glands [1–4]

Human eccrine sweat glands have two distinct functions: they allow body cooling by evaporation, and have thus contributed in a major way to adaptation to a hot environment by humans (major illness or death may ensue with sweat gland failure, even in temperate climates); they also moisten the skin on the palms and soles at times of activity, and thus improve their grip.

Eccrine sweat glands are distributed over the whole skin surface, including the glans penis and foreskin, but not on the lips, external ear canal, clitoris or labia minora. The number varies greatly with site, from 620/cm^2 on the soles and about 120/cm^2 on the thighs to 60/cm^2 on the back [5]. The total number on the body surface is between 2 and 5 million, and is the same in black people as in white people. It has been calculated that the weight of the eccrine glands totals 100 g. The glands vary in size from person to person by a factor of five, and this probably accounts for individual as well as regional differences in sweat rate (maximal individual gland secretion rates ranging from 2 to 20 nL/min/gland).

Embryologically, sweat glands are derived from a specialized down-growth of the epidermis at about the third month of intrauterine life on the palms and soles and at about 5 months elsewhere, and they resemble adult glands by 8 months. Sweat glands are morphologically normal at birth, but may not function fully until about 2 years of age. No new eccrine glands develop after birth. Unlike the apocrine glands, they have no developmental relationship with the pilosebaceous follicle, although some glands may eventually come to open into the follicular neck. The gland consists of a secretory coil in the lower dermis and subcutaneous tissue, and a duct leading through the dermis to the intraepidermal sweat duct unit. Apoeccrine glands have features of both eccrine and apocrine glands, but seem to be nearer to eccrine in function. They open onto the surface, and produce a copious watery fluid. Some authors claim that they may account for 10–45% of adult axillary glands [6]; others more recently have studied serial sections of axillary skin and cast doubt on their existence in humans [7].

The *secretory coil* contains three types of cell: large clear cells, which are the main secretory cells, small dark cells, which resemble mucus-secreting cells of other organs but whose function is not known, and myoepithelial cells [7] (Figs 44.2 & 44.3). The large and small cells of the secretory coil, unlike those of the duct, are attached to the basement membrane, although individual sections may at times suggest a double layer. Outside the basement membrane are the longitudinally arranged myoepithelial cells, whose function is probably to support the gland, but they may also help propel the sweat towards the surface. They respond to cholinergic stimuli. The function of the coil is to produce from plasma a watery isotonic secretion which can subsequently be modified by the duct. Ultrastructurally, the large clear cells are characterized by the presence of many mitochondria and by both intricate basal infoldings and intercellular canaliculi. Paranitrophenyl phosphatase activity, which reflects catalytic activity of Na-K-ATPase, is evident in the basal infoldings but not the intercellular canaliculi, suggesting that the basal areas are the sites of active ion transport requisite for sweat secretion. The classical theory suggests that acetylcholine passively increases entry of sodium into the cell, and this is then pumped out by the sodium pump into the intercellular canaliculi rather than directly through the luminal margin. However, there are other theories [4]. Fluid secretion is believed to be mediated osmotically, but

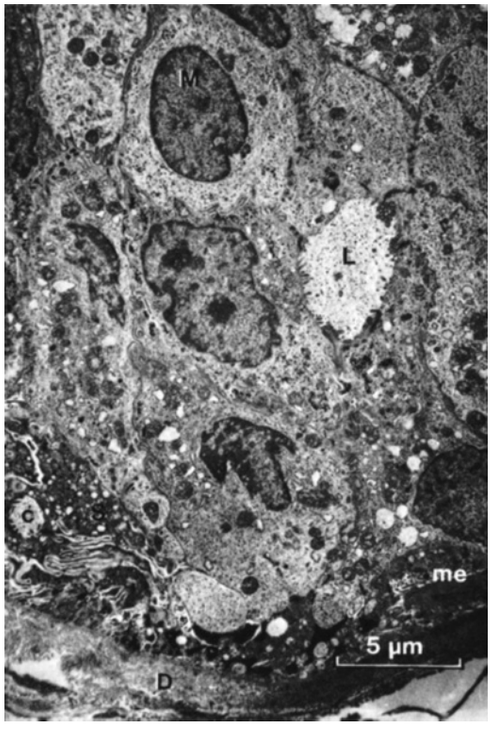

Fig. 44.2 Section of a secretory coil of an eccrine sweat gland stained with osmium. The coil contains three types of cell: (i) serous or clear cells (S) containing finger-like processes and bordering a canaliculus (c); (ii) mucous or dark cells (M); and (iii) myoepithelial cells (me). D, dermis; L, lumen of coil. (Courtesy of the late Professor A.S. Breathnach, St John's Dermatology Centre, London, UK.)

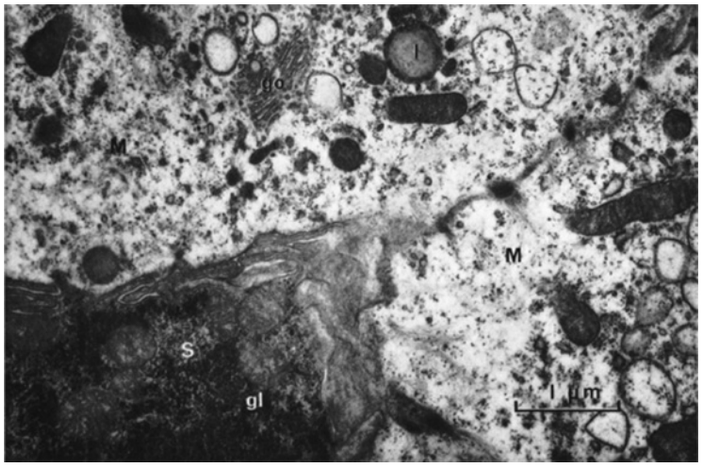

Fig. 44.3 Portions of two mucous (dark) cells (M), showing a Golgi complex (go) and lipid globules (l) and a serous (clear) cell (S) with glycogen granules (gl). (Courtesy of the late Professor A.S. Breathnach, St John's Dermatology Centre, London, UK.)

the mechanism by which water moves has long been obscure. However, recently a membrane protein with water transporting properties has been described in a range of tissues, including the human eccrine sweat gland [8]. The sodium pump in the gland can achieve a pressure up to 500 mmHg [9]. During active secretion, and in certain pathological conditions, well-marked histological changes occur in the gland [10]. Many different monoclonal antibodies can be shown to react with different portions of the sweat glands [11].

The *duct* consists of two or more layers of relatively uniform cuboidal cells. About one-third of the coil has this histology, as well as the uncoiled part passing up to the epidermis. The basal cells are rich in mitochondria and their entire membranes are rich in Na-K-ATPase activity, suggesting that sodium pumping occurs along the entire duct membrane and performs an active part in modifying the secretion produced by the coil.

It has been suggested that sweat glands do not cool the skin only by evaporation of heat from the surface, but also act as heat pipes. According to this theory, evaporation of the fluid at the base of the duct allows water vapour to pass up the duct and condense nearer the surface, and thence return to the deeper parts by capillary action. Such systems are a very effective way of transferring heat quickly [12].

The *intraepidermal sweat unit* is lined by a layer of specialized cells which may sometimes be distinguished only with difficulty from the surrounding epidermis. On the palms and soles, it has a well-developed coil structure that is not so apparent in other sites.

The *techniques for studying the function* of the eccrine sweat glands [12–14] include the following:

1. Collection of sweat in bags or pads at rest, after heat, or after injection or iontophoresis of pilocarpine or other cholinergic agonists.
2. Direct measurement of water loss.
3. Microcannulation of the duct or coil [15].
4. Measurement of electrical potentials and electrical resistance of the skin, which depends on both the sweat present on the epidermis and the column present within the duct [16,17].
5. Visualization of the individual sweat droplets. This may be achieved by direct microscopy, by *in vivo* staining, by forming plastic impressions [18] or by indicators that become coloured on contact with water, such as the starch/iodine technique [19], bromophenol blue [13], quinizarin [20] and the food dye edicol ponceau. The plastic or silicone impression techniques are probably the most reliable, and can produce a permanent record. A simple modification of the starch/iodine test is to dry the skin, paint it with 2% iodine in alcohol, allow it to dry, and then press the skin against a good-quality paper. The starch in the paper reacts with iodine in the presence of water, so that each sweat droplet shows up as a minute dark spot. Alternatively, the starch may be suspended in castor oil (50 g in 100 mL) and painted onto the iodine-treated skin (Fig. 44.4). Special dry starch/iodine powders can be dusted directly onto the skin [21].
6. Isolated glands. Recently, it has become possible to isolate single eccrine glands (and also hair follicles, sebaceous glands and apocrine sweat glands) by the relatively simple technique of shearing tissues with scissors [22,23]. This allows the physiology, biochemistry and tissue culture behaviour to be studied *in vitro*.
7. Cutaneous microdialysis–microperfusion of the skin with perfusate containing various pharmacological agonists and antagonists allows for the study of continuous stimulation of sweat glands [24].

Control of eccrine sweating [1–4]

Eccrine glands alter their activity in response to thermal, osmotic, mental and gustatory factors. When the core temperature of the body rises above a certain level, termed the temperature set point, eccrine sweating is initiated. Thermosensitive receptors are present in both the preoptic area and the anterior hypothalamus, and, in experimental animals, warming of these areas of the brain activates functions to facilitate cooling, including sweating, panting and vasodilatation. Conversely, cooling the same areas initiates shivering. Different receptors respond to heat and cold. Microelectrode recording has demonstrated that the firing rate of the warm-sensitive receptors is increased not only by the local receptor temperature, but also by a rise in skin temperature, indicating the effect of local skin and spinal thermoreceptors. The effect of core temperature rise is about nine times more efficient than skin temperature in stimulating sweating. The efferent pathways from the hypothalamus involve nerve fibres relaying in the medulla, lateral horn of the spinal cord and sympathetic ganglia [2].

Thermoregulatory sweating occurs especially on the upper trunk and the face [25], but also over the whole body surface, including the palms and soles. The hypothalamic thermal set point is also influenced by alterations in blood osmotic pressure. Hyperosmolarity results in an elevation of the thermal set point and reduced sweating (as sweat is hypotonic, this is a response to conserve further water loss).

The centres and pathways controlling mental sweating are not fully known, but responsible centres within the frontal region of the brain have been identified. Mental stimuli produce sweating, especially on the palms and soles, perhaps to improve the grip at times of activity. Mental activity also produces some general increase in sweating over the body surface. The activity may be emotional or intellectual—for example, mental arithmetic.

Innervation of the eccrine sweat gland

The efferent sudomotor pathway consists of the cerebral cortex to the hypothalamus, hypothalamus to medulla, medulla (mostly crossed) to the lateral horn of the spinal cord, then to the sympathetic ganglia, and finally from the ganglia to the sweat gland as postganglionic non-myelinated fibres.

The functioning of the eccrine sweat gland is dependent on intact non-myelinated C fibres of sympathetic nerves. Glands deprived of their postganglionic nerve supply soon cease to respond to any stimuli, although they remain histologically normal. The main sympathetic nerve supply of sweat glands is unusual in being muscarinic cholinergic. Work in rats has shown that there is a complex interrelationship between the developing sweat glands and peripheral nerves. The glands influence the nerves to produce the appropriate neurotransmitter [26]. Adrenergic agents and nerve stimulation also increase sweat-gland activity [27–29], and a single isolated eccrine gland can respond to both cholinergic and adrenergic stimuli. The ratio of maximal secretory rates for human sweat glands *in vitro* and *in vivo* is 5:1:1 for cholinergic, α-adrenergic and β-adrenergic stimulation, respectively. The adrenergic nerve supply seems to play little part in the normal control of eccrine sweating in humans. Vasoactive intestinal peptide (VIP), calcitonin gene-related peptide, atrial natriuretic peptide and galinin immunoreactivity can be found in human axillary periglandular neurons, but whether physiologically relevant concentrations are present remains to be established [30].

Other factors may modify the quantity and quality of sweat in the presence of an intact sympathetic nerve supply—for example, local temperature [31], hormones, circulatory changes, and axon and spinal reflexes. Sweat coils contain androgen receptors [32], and androgens may be at least partly responsible for the increase in sweating around puberty, and for the greater activity in males. Androgens do not play a significant role in the day-to-day regulation of eccrine sweat gland activity.

By these mechanisms, the quantity and quality of the sweat may be varied greatly. Under basal conditions, there may be few or no impulses passing to the sweat gland. Some insensible perspiration always occurs, partly due to transepidermal water loss and partly to sweat gland activity. Only the latter can be suppressed by atropine. Under maximal stimulation, the body can produce up to 12 L in 24 h, or for short periods 3 L in 1 h; this rate exceeds the ability of humans to drink [33].

The composition of sweat [4,34] varies greatly from person to person, time to time and site to site. It has a basic similarity to the plasma from which it is derived. The sweat duct is largely responsible for the modification in sweat constituent concentration which occurs, and this will therefore vary according to how rapidly the sweat is passing through the duct. The most important constituents are sodium, chloride, potassium, urea and lactate. Sweat is hypotonic and this is largely due to reabsorption of sodium in the duct. At increased sweat rates, the sodium concentration rises, presumably because there is reduced time for ductal reabsorption. The normal sodium concentration is between 10 and 20 mmol/L at low sweat rates, and up to 100 mmol/L at high rates. Ald-

osterone can increase ductal sodium reabsorption and in Addison's disease high sweat sodium can be demonstrated (70–80 mmol/L). Antidiuretic hormone may reduce sweat rates in humans, but it also induces local vasoconstriction.

An increase in sweat electrolytes occurs in cystic fibrosis, and is sufficiently constant to be a most useful diagnostic test [35]. The basic defect seems to be an abnormal, diminished permeability of many cells to chloride ions [36–38]. The gene responsible has been identified [39]. Sweat may be collected after intradermal injection or iontophoresis of pilocarpine or methacholine (Mecholyl), or after heating. In normal children, it is not unusual to have a sweat sodium level above 60 mmol/L, but the majority of children with cystic fibrosis have levels greater than this, often above 90 mmol/L. Sometimes a normal level is present, but the normal fall in sweat sodium concentration after deoxycorticosterone acetate (DOCA) or aldosterone is not seen. In adults, the normal levels are higher, and the test is of much less value. Initial suggestions that partial forms and carriers of cystic fibrosis could be diagnosed in this way have not been substantiated. An increase in sweat potassium has been reported in infants with apparent life-threatening events ('near-miss sudden infant death syndrome') [40].

Lactate is found in a concentration of 4–40 mmol/L, which greatly exceeds the concentration found in plasma. It is formed in the gland from glucose from the blood. It is interesting to speculate whether urea and lactate can act to moisturize the stratum corneum.

Glucose is present in small quantities only (usually 0–3 mg/100 mL, although levels up to 11 mg/100 mL may be found). High sweat glucose may be found in uncontrolled diabetes and this may create a favourable environment for skin infections. The pH is 4–6.8.

The concentration of these substances varies greatly in health and disease. Such changes seldom give rise to any symptoms referable to the skin, but may help in the understanding of disease.

A variety of other substances may be found in sweat, including pharmacologically active substances and inhibitors, antigens, antibodies and drugs [4]. Some of these seem to be excreted, and have no special function; others may have a definite function—for example, a urokinase-type plasminogen activator may play a part in digestion of glycoprotein plugs in sweat pores [41]. Active excretion or secretion of drugs such as griseofulvin and ketoconazole may contribute to their efficacy.

Atopic dermatitis patients often have IgE antibodies against an antigen found in their own sweat. The importance of this in the pathogenesis of the disease is uncertain [42].

Hyperhidrosis [1,2]

Hyperhidrosis is the excessive production of sweat, and can be a major inconvenience to sufferers. In theory, when there is over- or underproduction of sweat it should be possible to determine whether the change is in the sweat glands, due to pharmacologically active agents acting on the gland, to abnormal stimulation of the sympathetic pathway between the hypothalamus and the nerve ending, or to overactivity of one of the three different 'centres' responsible for thermoregulatory, mental and gustatory sweating. Any difficult case should be approached from first principles in this way. In practice, most cases of hyperhidrosis fall into the clinical groups outlined below.

Generalized hyperhidrosis

There is marked physiological variation in thermoregulatory sweating from person to person in the absence of disease. An increase in the temperature of blood bathing the hypothalamus increases heat loss by sweating and vasodilatation. Some instability of the sweat regulating centre is caused by many febrile conditions, so that sweating may occur at times when there is no fever. This instability may persist for days, or even months, after the fever has subsided, and in some cases is such a prominent feature that the term 'sweating sickness' has been used [3]. Generalized sweating may occur in disorders of unknown aetiology, which alter the setting of the thermoregulatory centre, and may be associated with episodic hypothermia [1]. Generalized sweating can occur with a wide range of medical and neurological disorders, but seldom in the absence of other neurological symptoms or signs (Table 44.1). Thermoregulatory sweating occurs during or after many infective processes, and may be the presenting manifestation of malaria, tuberculosis, brucellosis, lymphoma, subacute bacterial endocarditis, etc. Night sweats are often part of the clinical picture. A similar mechanism may account for the hyperhidrosis associated with alcohol intoxication or gout, and after vomiting. The mechanism of generalized hyperhidrosis which may be associated with diabetic autonomic neuropathy, hyperthyroidism, hyperpituitarism, hypoglycaemia, obesity, the menopause and malignant disease is unknown. Increased sweating has been documented in some patients with Parkinson's disease, but others have noted the combination of patchy anhidrosis and compensatory hyperhidrosis, suggesting autonomic dysfunction. Paroxysmal sweating, tachycardia and headaches strongly suggests phaeochromocytoma. Hypertension is noted during attacks. Two sisters have been reported who had generalized sweating in a thermal pattern, but induced by cold [4]. Hyperhidrosis is seen in association with peripheral neuropathies, as in familial dysautonomia, or the Riley–Day syndrome, a recessively inherited disorder of Ashkenazi Jews comprising an absent axon reflex flare after histamine injection, pupillary meiosis, diminished tendon reflexes, diminished pain sensation and absent fungiform papillae of the tongue. Excess sweating is thought to be due to sweat centre excitability. Congenital autonomic dysfunction with universal pain loss is similar, but individuals are not Ashkenazi Jews, have complete absence of pain sensation with accidental self-mutilation, corneal opacities and episodic fever. Cold-induced profuse sweating has been reported with a peripheral motor and autonomic neuropathy. Generalized hyperhidrosis may be associated with brain lesions (diencephalic lesions, malformations of the corpus callosum, microgyria) and may be accompanied by episodic hypothermia. Some drugs—for example, fluoxetine—are able to cause generalized hyperhidrosis. In many cases of generalized hyperhidrosis of the thermal type, but with no obvious underlying disease, the aetiology remains unknown, even after extensive investigation.

Table 44.1 Causes of generalized hyperhidrosis.

Febrile infective illnesses
Tuberculosis, malaria, brucellosis, endocarditis, etc.
Metabolic diseases

Fluoxetine

Palmoplantar, axillary and craniofacial ('emotional') hyperhidrosis

Emotional or mental activity increases sweating, especially on the palms, soles, axillae and, to a lesser extent, groin and face. It should be emphasized that mental activity devoid of any clear emotional content may provoke sweating. There may be some generalized increase in sweating. Thermal stimuli and physical effort increase this effect in many cases. Most cases of hyperhidrosis presenting to the dermatologist are of this type, affecting especially the palms, soles and axillae, and may affect up to 1% of the population in the UK. The head, neck and scalp may be affected

Fig. 44.5 Disabling palmar hyperhidrosis.

Fig. 44.6 Symmetrical lividity. Hyperhidrosis of the feet, with cool macerated soles and pitted keratolysis. (Courtesy of the late Dr R.H. Champion, Addenbrooke's Hospital, Cambridge, UK.)

in craniofacial hyperhidrosis in the absence of other areas being affected. Although mental or emotional factors are the usual trigger for this type of sweating, and in some patients deep-seated emotional disturbances may be found, in many there seems to be some facilitation of the nervous pathways causing physiological mental sweating.

The sweating of the palms and soles may be either continuous or phasic [5,6]. When continuous it is worse in the summer, and not so clearly precipitated by mental factors. When phasic, it is usually precipitated by minor emotional or mental activity, and is not markedly different in summer and winter. The hands may be cold, and show a tendency to acrocyanosis. Hyperhidrosis may be associated with Raynaud's phenomenon and reflex sympathetic dystrophy [6], or may follow cold injury.

Hyperhidrosis may be a significant disability, in that sweat drips from the hands onto the floor (Fig. 44.5), rusting of metal objects may be an occupational problem, or clothing may be saturated. This disorder occurs in either sex, and commonly begins in childhood or around puberty. Frequently there is a family history, and it is one component of various syndromes in which palmoplantar keratoderma occurs (Chapter 19). It also occurs with the nail–patella syndrome (Chapter 65). Hyperhidrosis may persist for some years, but there is a tendency to spontaneous improvement of the axillae and hands after the age of 25 years. Apart from the embarrassing nature of the disorder, complications include pompholyx (Chapter 23) and contact dermatitis. Control of plantar hyperhidrosis may reduce the exacerbations of contact dermatitis to footwear constituents.

Sweating affects the hands, feet and axillae in any combination, but only a minority of patients with axillary hyperhidrosis also have involvement of the palms and soles. Troublesome hyperhidrosis of the feet occurs especially in young adult men. When this is associated with vasomotor changes, so that the sodden skin is also cold and cyanotic, the name 'symmetrical lividity' is sometimes applied (Fig. 44.6). The condition of pitted keratolysis (Chapter 30) of the feet, due to infection with *Micrococcus sedentarius*, is associated with hyperhidrosis.

Axillary sweating may be continuous, or more commonly phasic, and may or may not be aggravated by heat or mental activity. It is uncommon before puberty. Axillary sweating on undressing is very common. Axillary hyperhidrosis is due to overactivity of eccrine glands, unlike axillary odour which is mainly apocrine in origin. Craniofacial hyperhidrosis is often phasic, occurs in middle age and may be exacerbated by heat, exercise and eating, but, unlike true gustatory hyperhidrosis, not exclusively so. It may be more persistent and presents at a later age than palmoplantar hyperhidrosis. Sweating sufficient to soak the hair is an additional embarrassment (Fig. 44.7).

Cold-induced sweating syndrome. This is a rare, familial condition in which profuse sweating of the trunk occurs when the skin is cooled to between 7 and 10°C [7]. There are associated physical anomalies including a high arched palate, inability to fully extend the elbows and scoliosis. Chromosomal anomalies have recently been identified [8].

Localized and asymmetrical hyperhidrosis

The causes of localized hyperhidrosis are outlined in Table 44.2. Excessive sweating may be due to neurological lesions involving

Fig. 44.7 Craniofacial hyperhidrosis producing persistent saturation of the hair.

Fig. 44.8 Idiopathic circumscribed hyperhidrosis on the wrist (indicated by edicol ponceau powder, which turns scarlet on hydration). The rest of the patient's sweating and neurological examinations were normal.

any part of the sympathetic pathway from the brain to the nerve ending. It may be the presenting symptom, but it is quite exceptional for this to occur as an isolated phenomenon in the absence of other neurological symptoms or signs. Such lesions may be within the central nervous system [1,7–11] (cortex, basal ganglia or spinal cord), the sympathetic pathway and ganglia, or in the peripheral nerves. It must be remembered that the distribution of the sympathetic nerves does not exactly correspond with sensory dermatomes. One sympathetic grey ramus may supply 10 or more sensory segments, and one white ramus extends over at least five. Asymmetrical sweating may also occur reflexly from visceral disturbances [12], adjacent to an area of anhidrosis or due to axon reflex stimulation, around a leg ulcer, for example [7], or around glomus tumours, blue rubber bleb naevi or sudoriparous angioma [13]. Compensatory hyperhidrosis occurs in normal sweat glands when those elsewhere are not functioning because of neurological or skin disease, or after sympathectomy (see also Ross's syndrome). Functional sweat gland naevi have been reported [14], but must be distinguished from sweat gland hypertrophy associated with local hyperhidrosis of some other aetiology. There are some bizarre cases of hyperhidrosis which cannot be explained in these ways. Areas of skin that may be localized [15] (Fig. 44.8), termed idiopathic circumscribed hyperhidrosis, or as extensive as one-half of the body [16], may sweat continuously, or, more commonly, with mental activity. They may represent functional naevi, where the eccrine glands show increased sensitivity to cholinergic neurotransmitters. Sometimes, some psychological disturbance accounts for the distribution [17], but more often such cases remain a mystery. In the absence of other neurological symptoms or signs, they are seldom a manifestation of a progressive neurological lesion.

Gustatory hyperhidrosis (Table 44.3)

Sweating on the lips, forehead and nose after eating certain foods occurs physiologically in many people. Hot spicy foods are the most likely cause. The central connections of this reflex are not fully known. Gustatory hyperhidrosis also occurs in pathological conditions involving the autonomic nervous system. Localized areas of intense hyperhidrosis may occur on the face [1], and even on the knees [2]. These disorders are very rare, usually start in childhood and are not progressive (Fig. 44.9). Their nature is little understood.

Also uncommon is gustatory hyperhidrosis due to a lesion within the central nervous system [3].

Much the commonest cause is damage to the sympathetic nerves around the head and neck. After damage to sympathetic nerves, regeneration occurs not only from the proximal ends of the damaged sympathetic nerves, but also from damaged or undamaged parasympathetic nerves [4,5]. In this way, abnormal connections are made. Thus, the reflex arcs that normally allow chewing or taste stimulation to cause parotid or gastric secretion may cause sweating in a localized zone corresponding to the area of the skin in which the sympathetic innervation has been damaged. The commonest site is within the distribution of the auriculotemporal nerve, following injury, abscess or operation in the parotid region (auriculotemporal or von Frey's syndrome) [6–8]. Submental gustatory sweating [9,10] follows injuries involving the chorda tympani, and sweating in the distribution of the greater auricular nerve commonly follows radical neck surgery [11]. On the upper arm, fibres from the vagus may cause gustatory sweating after cervical sympathectomy [12].

Gustatory sweating may occur in diabetes as part of a widespread autonomic neuropathy [13,14]. It has also followed herpes zoster [15].

Peripheral autonomic neuropathy
Diabetes mellitus

Fig. 44.9 Auriculotemporal or von Frey's syndrome without any neurological abnormality and not preceded by surgery or injury. Cheek flushing and sweating was precipitated by eating. (Courtesy of Dr P. Hudson, Peterborough District Hospital, Peterborough, UK.)

Gustatory sweating is by no means uncommon, and occurs in 50–80% of patients subjected to operations on the parotid gland [16,17]. Usually the symptoms appear 4–7 months after operation, and either persist indefinitely or wane after 3–5 years. The stimuli required to initiate the reflex vary, as does the severity. Sometimes chewing, without taste sensation, is the most important stimulus. In many cases, it is merely a curiosity, but in others it can be a significant disability. As well as sweating there is usually vasodilatation, which rarely occurs by itself in the absence of visible sweating.

Treatment of severe cases may require surgical interruption of the parasympathetic pathway—for example, section of the glossopharyngeal nerve within the skull, or tympanic neurectomy [4]. Excision of the auriculotemporal nerve is usually followed by recurrence. Topical therapy with aluminium chloride [18], topical glycopyrronium bromide [19] or botulinum toxin injections may be helpful.

Olfactory hyperhidrosis, in which the trigger stimulus is olfactory in origin, has also been recorded [20].

Treatment of hyperhidrosis. In many patients all that is necessary is simple reassurance and explanation of the nature of the disorder, and that it is likely to improve spontaneously, perhaps in several years. Topical and systemic treatments are by no means satisfactory and, at best, only temporarily suppressive.

Topical treatment

Topical anticholinergics. Atropine-like drugs may be absorbed sufficiently to produce a beneficial local effect without associated systemic side effects, but none of those at present available can be relied upon to do so [1]. Poldine methosulphate, 1–4% in alcohol, suppresses experimentally induced sweating, but unfortunately is less valuable on the palms, soles and axillae [2]. Topical 0.5% glycopyrronium bromide cream has been successfully used in gustatory hyperhidrosis in diabetics and 2% aqueous solution has been used in scalp hyperhidrosis.

Eccrine duct blocking agents. These drugs act by impeding the delivery of sweat to the skin surface. Formalin 1% soaks have long been used for treatment of hyperhidrosis of the feet, but are unsuitable for the hands and axillae. Glutaraldehyde 10% in a buffered solution, pH 7.5, swabbed onto the feet three times weekly, has helped some patients [3], but may cause allergic sensitization and stains the skin, so that it is suitable only for the feet. For axillary hyperhidrosis (as opposed to bromhidrosis) the most commonly used topical applications are aluminium (or other metal) salts. Aluminium chloride, the first to be introduced, is in many ways the best, but may be irritant to the skin and damage clothes. Many other salts—for example, the chlorhydrate—are in use in cosmetic preparations [4]. Improved results can be achieved by applying 20% aluminium chloride in absolute ethanol at night, when the axilla is dry, with or without polythene occlusion, at first nightly and later every 1–4 weeks [5,6]. Commercial preparations are available. Mild irritation of the skin from such therapy may be helped by a weak topical steroid. The same treatment can also be tried on the hands and feet, or other localized areas of hyperhidrosis, but usually with rather less success. The mode of action of aluminium salts is uncertain, but they can be shown to affect both the duct and the secretory coil [7].

Iontophoresis. One of the more satisfactory methods of controlling hyperhidrosis of the hands and feet is by iontophoresis, either using tap water or anticholinergic drugs such as glycopyrronium bromide [8–11]. The mode of action of tap water iontophoresis is not known. It is more effective than using saline, and duct occlusion does not occur. Direct current is usually used, with each palm or sole being treated for 30 min with 20 mA, initially three times a week. Once euhidrosis is established, monthly maintenance treatment may be sufficient. Alternating current is less effective, but may usefully be combined with direct current (alternating current offset) to produce a safer, more comfortable treatment [12]. Once control has been achieved, a single treatment may prove effective for some weeks. Minor systemic side effects due to absorption of anticholinergic agents, such as dry mouth and eye symptoms, are not uncommon, and can be avoided if tap water alone is used. The author's practice is to initiate thrice-weekly treatment on a hospital outpatient basis, and if this is successful, a small battery-operated home unit can be purchased for maintenance therapy [13]. Less frequent treatment will then be required. When the sweating is controlled, the associated lividity, coolness and oedema improve. Similar treatment has also been used for the axilla, but is less often needed because topical applications or injections of botulinum toxin are more effective in this site.

Botulinum toxin A injection. This compound produces prolonged blockade of neuronal acetylcholine release at the neuromuscular junction and in cholinergic autonomic neurons, and has been used to treat dystonic conditions for many years. In recent years, intradermal injection has been used to produce marked reduction of sweating in hyperhidrotic areas associated with a variety of conditions [14–17]. Different preparations of botulinum A toxin have different activities, and dose schedules differ for each product; 0.1 mL of appropriately diluted botulinum toxin administered by high intradermal injections can be given to 1 cm^2 areas of skin appropriately anaesthetized—topical eutectic lignocaine/prilocaine is sufficient for axillary skin, but palms and soles require regional nerve blockade. Each axilla usually requires 12 injections, hands 20 and each foot 24–36 injections. It will produce reduction in sweating within 48 h and the benefit will last for up to 8 months in axillary and 6 months in palmar and craniofacial hyperhidrosis [18]. Reinjection seems to be effective, and to date resistance has not been seen in hyperhidrosis, although it eventually occurs in 5% of patients treated intramuscularly for dystonia. Botulinum toxin has been used for idiopathic circumscribed and gustatory hyperhidrosis, including Frey's syndrome, the hyperhidrotic areas in Ross's syndrome, and frontal and craniofacial hyperhidrosis. Slight transient reduction of thenar and hypothenar muscle power is a minor problem after palmar injections [18]. The use of botulinum toxin on the forehead may produce short-lived frown reduction [19].

Systemic drug treatment

Atropine-like drugs have been used to block the effect of acetylcholine on the sweat glands, but their side effects are often more troublesome than the hyperhidrosis itself. These include dryness of the mouth, constipation, urinary retention and disturbances of vision, due to paralysis of accommodation, but more serious side effects, for example glaucoma, hyperthermia and convulsions, can occur. Atropine itself is seldom employed. Propantheline may be prescribed in doses of 15 mg three times daily, increasing, if tolerated, to as much as 150 mg daily [20], but overall the results are disappointing. The oral antimuscarinic agent oxybutinin, usually used to treat bladder instability, has been reported to be effective for generalized hyperhidrosis in a small series of cases [21]. Ganglion-blocking drugs can inhibit sweating, but side effects from hypotension are usually too troublesome. Calcium-channel blockers, such as diltiazem [22], have helped some cases. In cases with a pronounced emotional factor, sedative or tranquillizing drugs are often useful, but psychiatric treatment may be necessary. Both clonazepam [23] and amitriptyline have helped isolated cases of unusual localized hyperhidrosis.

Surgical treatment

Sympathectomy, whether cervical, transaxillary or endoscopic, when complete, causes anhidrosis [24–27]. Sweating may return after a period of some years, due either to regeneration of sympathetic fibres or to fibres that do not pass through the sympathetic ganglia [28]. The open approach has been largely replaced by an endoscopic procedure, which may be successful in treating palmar, axillary and craniofacial hyperhidrosis. A pneumothorax is induced, and an operating endoscope inserted into the thorax via a small axillary incision, allowing visualization of the sympathetic trunk. Interruption of the sympathetic fibres between the second and fourth thoracic ganglia can be achieved by surgical transection, radiofrequency ablation, phenol destruction, cautery or clipping [29] (the latter technique has the potential advantage of partial reversibility). Most surgeons treat both sides at a single session. With both the open and endoscopic approaches, satisfactory reduction of palmar hyperhidrosis is achieved in over 95% of cases; it is a little less successful for axillary hyperhidrosis. In a series of 650 patients treated endoscopically, the initial failure rate was 2%, and there was recurrence in 2%; overall, 98% were satisfied with the result [30]. Large case series using endoscopic techniques in children show it to be an acceptable option, with a low recurrence rate [31]. Complications of sympathectomy include haemothorax, pneumothorax, chylothorax, nipple sensitivity and Horner's syndrome. There are rare instances of transient or permanent bradycardia complicating the technique. Other disadvantages are that the palms or soles may become excessively dry, and irritant eczema after sympathectomy has been reported [32]. Postoperative compensatory hyperhidrosis is a problem, particularly in warmer climates, as it may occur in up to 80% of those treated, affecting the trunk, legs and face, where it may be gustatory. It is usually mild and preferable to severe palmar hyperhidrosis, but rarely is more disabling than the original condition. In five patients who had undergone a clipping procedure and subsequently developed compensatory hyperhidrosis, removal of the clips resulted in return of the palmar sweating and abolition of the compensatory hyperhidrosis [29]. It has been suggested that ablation at the level of the third thoracic ganglion does not produce this side effect. Abolition of severe facial blushing may be a desirable consequence, and resolution of palmar eczema has been reported after endoscopic sympathectomy. In general, only those patients in whom a severe disability is arising from the hands or axillae warrant surgery, and in these selected cases the results can be very gratifying. Endoscopic sympathectomy has been used successfully in the treatment of severe craniofacial hyperhidrosis [33]. Pedal sympathetic denervation requires lumbar sympathectomy; if more cranial lumbar ganglia are removed, ejaculatory impotence may occur. A selective retroperitoneal approach has recently been advocated that has no effect on sexual function in either men or women [34].

Axillary hyperhidrosis may be greatly helped by local excision of the axillary vault [35,36]. Variations of this technique include subcutaneous curettage of the axillary skin [37], directly trimming the eccrine glands after reflection of the axillary skin using only a short incision [38], and tumescent liposuction of the axillae [39].

Anhidrosis

Anhidrosis is the absence of sweat from the surface of the skin in the presence of an appropriate stimulus. This may be caused by an abnormality of the sweat gland itself, or at any level in the nervous pathway. There are many causes [1], and a number of the more important of these are listed in Table 44.4. A full account of the assessment of sympathetic nerve activity is beyond the scope of this book [2–10].

Extensive anhidrosis may impair heat regulation to such a degree that hyperpyrexia occurs on exposure to heat. It characteristically occurs in anhidrotic ectodermal dysplasia and in otherwise normal premature or full-term infants under the age of 1 month [11]. It may be associated with compensatory hyperhidrosis of the remaining functionally active glands. It has been reported as an isolated finding [12,13]. Cessation of sweating is the cause of heat hyperpyrexia. The anhidrosis associated with ichthyosis may be more apparent than real. Localized areas of anhidrosis are of little clinical importance, except that they may help in the diagnosis of neurological lesions or leprosy. Sweat gland function can be a useful way to assess damage to the sympathetic nervous system—for example, in patients with postural hypotension [2,10,14]. Sweat retention is the cause of miliaria (see below), and plays an important part in producing crises of irritation in patients with atopic dermatitis, eczema and other dermatoses. It also occurs in psoriasis, where sweat duct blockage, and perhaps also impaired ductal absorption, occurs [15]. A rare disorder termed idiopathic acquired anhidrosis results in skin pain during exposure to stimuli that would usually induce sweating. Ductal occlusion by a PAS-positive material thought to emanate from dark cell granules was identified [16].

Botulism
Sweat gland lesions
Aplasia
Congenital ectodermal dysplasia
Ichthyosis
Any cause of atrophy (e.g. acrodermatitis chronica atrophicans)
Mepacrine eruption
Scleroderma
Myelomatosis
Lymphoma
Sjögren's syndrome
Incontinentia pigmenti
Fabry's disease
Plugging of the eccrine duct
Miliaria
Eczema and atopic dermatitis
Lichen planus
Psoriasis
Uncertain
Neonatal
Sweat gland fatigue
Idiopathic acquired anhidrosis

Ross's syndrome [17]

This rare syndrome consists of widespread hypohidrosis combined with patchy, sometimes very striking, compensatory

(a)

(b)

(c)

Fig. 44.10 Ross's syndrome. (a) There is generalized anhidrosis, with large islands of severe compensatory hyperhidrosis (delineated with edicol ponceau powder, which turns red in the presence of water). (b) The hyperhidrosis is sufficient to soak the underclothes, with consequent embarrassment. (c) An abnormal pupil, showing an irregular outline and meiosis. It responds sluggishly to light.

hyperhidrosis (Fig. 44.10), together with tonic pupils (appearing asymmetrical and irregular in their outline, constricting and dilating slowly to light and dark, respectively) and loss of deep tendon reflexes (Holmes–Adie syndrome). Patients with the Holmes–Adie syndrome often show asymptomatic changes in sweating [18]. The anhidrosis may be quite localized—for example, mainly on one palm, mimicking a *Trichophyton rubrum* infection [19]. When the anhidrosis is extensive, remaining areas of functioning eccrine glands may show compensatory hyperhidrosis. Cardiac sympathetic denervation which may be asymptomatic has been shown to develop [20]. The compensatory hyperhidrosis may be striking and severe enough to require therapy, for example with iontophoresis [21] or botulinum toxin injection [22], although eventually it may be lost as complete anhidrosis develops. The changes are due to selective degeneration of the sympathetic pathways [22].

Miliaria

Aetiology and pathology [1–3]. The three forms of miliaria—miliaria crystallina (sudamina), miliaria rubra (prickly heat) and miliaria profunda—occur as a result of either obliteration or disruption of the eccrine sweat duct. They differ in clinical form due to the different levels at which obliteration occurs, although some authorities have suggested that disruption of the duct rather than obliteration is responsible [4]. In miliaria crystallina, the obstruction is very superficial within the stratum corneum and the vesicle is subcorneal. In miliaria rubra, the later changes include keratinization of the intraepidermal part of the sweat duct, with leakage and then formation of a vesicle around the duct. In miliaria profunda, there is rupture of the duct at the level of or below the dermal–epidermal junction.

Miliaria crystallina can easily be produced experimentally by minimal non-specific epidermal injury and profuse sweating [5]. It is often seen in febrile illnesses associated with profuse sweating. It occurs commonly in infants due to a delay in patency developing in the sweat ducts. In a large Japanese study, it was identified in 4.5% of babies, with a peak frequency at 1 week [6].

The incidence of miliaria rubra is highest in hot, humid conditions, but it may occur in desert regions, affecting up to 30% of people exposed to these climatic conditions [7]. It may begin within a few days of arrival in a tropical climate, but is maximal after 2–5 months. There is a striking variation in individual susceptibility. Infants are especially prone. Lesions may be produced experimentally in susceptible subjects by epidermal injury. They can be reproduced regularly by occlusion of the skin under polythene for 3–4 days, following which anhidrosis lasts for about 3 weeks. Prolonged exposure of the skin to sweat achieves the same effect. The first event may be an increase in the skin flora, perhaps with *Staphylococcus epidermidis* being responsible for producing an extracellular polysaccharide substance or slime that blocks the lumen of the sweat duct [1,8]. The parakeratotic plugs which are a notable feature of the later stages of the disease are not the primary cause of the obstruction, but arise in the repair process, and may further aggravate the obstruction. Leakage of sweat into the epidermis is responsible for the final production of the lesions, and for their further aggravation.

Miliaria profunda is due to more severe damage to the sweat duct, and usually follows repeated attacks of miliaria rubra. It may be reproduced by experimental injury [8].

Rarely, miliaria may be associated with pseudohypoaldosteronism; high sweat sodium levels produce damage of the eccrine ducts, causing lesions similar to those seen in miliaria rubra [9].

Clinical features of the three types of miliaria are as follows.

Miliaria crystallina. Clear, thin-walled vesicles, 1–2 mm in diameter, without an inflammatory areola are usually symptomless and develop in crops, mainly on the trunk. In persistent febrile illnesses, recurrent crops may occur. The vesicles soon rupture, and are followed by superficial, branny desquamation.

Miliaria rubra. The typical lesions develop on the body, especially in areas of friction with clothing, and in flexures. They may also commonly be seen after occlusive therapy with polythene. The lesions are uniformly minute erythematous papules, which may be present in very large numbers (Fig. 44.11). Miliaria rubra is common on the trunk in hospitalized patients, who have to be

Fig. 44.11 Miliaria rubra on a baby's cheek. (Courtesy of Dr Richard Logan, Bridgend General Hospital, Bridgend, Mid Glamorgan, UK.)

nursed on their backs on bedding that has waterproof occlusive membranes below the sheets. Characteristically, the lesions produce intense discomfort in the form of an unbearable pricking sensation. Relief is often instantaneous when the stimulus to sweating is abolished by a cool shower. Outbreaks on the legs in miners working in tropical climates have been reported [10]. In infants, lesions commonly appear on the occluded skin of the neck, groins and axillae, but also occur elsewhere.

Miliaria profunda. This nearly always follows repeated attacks of miliaria rubra, and is uncommon except in the tropics. The lesions are easily missed. The affected skin is covered with pale, firm papules 1–3 mm across, especially on the body, but sometimes also on the limbs. There is no itching or discomfort from the lesions.

Patients often wrongly refer to polymorphic light eruption as 'prickly heat', but the relationship of the rash to light, particularly on newly exposed sites, is usually straightforward.

Natural history. The course depends mainly on environmental factors. If continued sweating occurs, recurrent episodes lasting a few days are usual, but discomfort may be continuous. However, after a few months some degree of acclimatization occurs, and the disorder becomes less prevalent.

The most important complications of miliaria are secondary infection and disturbance of heat regulation. Secondary bacterial infection is common and sometimes serious. This may present as impetigo. In other cases, the pustules are more clearly related to sweat ducts, although in *pustular miliaria* factors other than bacterial infection are concerned [11]. Periporitis staphylogenes [12] is the name given to multiple staphylococcal abscesses superimposed on miliaria rubra in young infants. In most cases of miliaria rubra, the changes are reversible if further sweating is avoided, but permanent damage to the sweat duct may occur, especially after miliaria profunda.

Treatment. The only really effective prevention or treatment for miliaria is avoidance of further sweating. Even if this is achieved only for a few hours a day, as in an air-conditioned office or bedroom, considerable relief is experienced. For the very susceptible person, a move away from tropical climates may be essential. Avoidance of excessive clothing, friction from clothing, excessive use of soap and contact of the skin with irritants will reduce the incidence. The large number of treatments advocated for prickly heat is the best indication of their relative ineffectiveness if sweating is not reduced. In the absence of gross secondary sepsis, the effect of topical or systemic antibiotics or other antibacterial preparations on established miliaria is disappointing, but they may have some role in prophylaxis [1]. Oral ascorbic acid 500 mg twice daily was found to diminish the severity of miliaria, as was the degree of subsequent anhidrosis in experimentally-induced disease [13]. Calamine lotion is probably as effective as anything for the relief of discomfort, but because of its drying effect, a bland emollient, for example oily cream, may subsequently be required to prevent further epidermal damage. Isotretinoin was reported to help a recalcitrant case of miliaria profunda [14].

The role of sweating in some other dermatoses

The role of sweating in pompholyx or dyshidrosis is discussed in Chapter 23, in Grover's disease or transient acantholytic dermatosis in Chapter 40 and in cholinergic urticaria in Chapter 22.

Disorders associated with abnormal eccrine histology

Neutrophilic eccrine hidradenitis

Necrosis of the eccrine epithelium and secretory coil with a dense surrounding neutrophilic infiltrate is seen in a variety of clinical entities (Table 44.5, Fig. 44.12).

Chemotherapy-induced neutrophilic eccrine hidradenitis. The most common variant occurs during cancer chemotherapy [1–3], and has been reported in adults and children. The clinical presentation is of painful erythematous papules and plaques arising on the limbs, neck, face and ears 8–10 days after the start of chemotherapy, often associated with fever and neutropenia. Cases featuring only erythematous swelling of the periorbital areas [4] and the ears [5] have been described. The eruption lasts for about 10

Table 44.5 The classification of neutrophilic eccrine hidradenitis.

days, resolving without therapy, and only rarely recurs at subsequent chemotherapy exposures [6]. No one chemotherapeutic agent has been identified as the culprit; indeed, most cases have arisen after administration of a cocktail of chemotherapeutic agents given for myeloproliferative disorders, lymphomas and solid tumours. It has been reported after granulocyte colony-stimulating factor [7]. The histological changes have been experimentally induced in healthy volunteers given intradermal bleomycin, suggesting that a direct toxic effect of the drug on the eccrine gland is responsible [8]. In a case of recurrent chemotherapy-triggered disease, dapsone prophylaxis was effective [9].

Neutrophilic eccrine hidradenitis (NEH) and other diseases. NEH has recently been associated with Behçet's disease [10], and has been reported in association with human immunodeficiency virus (HIV) infection [11]. Although often reported as a consequence of chemotherapy in leukaemia, it may arise as a paraneoplastic condition with chronic myeloid leukaemia [12].

Infectious neutrophilic eccrine hidradenitis [1]. The eccrine sweat glands are resistant to infection, and there are few reports of bacterial hidradenitis. *Serratia* and staphylococcal hidradenitis have been reported in immunocompromised hosts. Enterococci have been cultured from an otherwise healthy woman with hidradenitis on the trunk.

Idiopathic recurrent palmoplantar hidradenitis

This disorder, first described in 1994, is probably more common than the literature suggests [13]. Tender, erythematous plaques develop on the soles and occasionally the palms of children; it has been reported between the ages of 18 months and 15 years [14]. It may mimic a vasculitis. Attacks, lasting up to 3 weeks, are more frequent in autumn and spring. Resolution occurs spontaneously and, in almost half of the cases, the condition is recurrent. Vigorous exercise has been implicated in initiation of some attacks; exposure to cold, damp footwear was believed to be important in another small series [15]. Histology shows eccrine epithelial necrosis, dense infiltration of the periglandular dermis with neutrophils and sometimes abscess formation. Rest, cool compresses, and topical and oral steroids have been used as symptomatic treatment.

Syringosquamous metaplasia

Syringosquamous metaplasia is a histopathological term describing the transformation of normal cuboidal duct epithelium into cells with an eosinophilic cytoplasm and a larger more irregular nucleus, so that in some areas it seems that ducts appear in islands of squamous epithelium mimicking squamous carcinoma, or as dilated structures reminiscent of syringomas. The eccrine gland coils are not affected [16]. The histological changes may be seen around areas of cutaneous ulceration of diverse causes, such as burns and arterial ulcers, but also adjacent to pyoderma gangrenosum and extravasated chemotherapy sites [17]. It may represent a non-specific reaction pattern.

Drugs and eccrine glands

A number of drugs are concentrated and secreted by eccrine glands, and in part this may account for their therapeutic effect. Drugs known to be secreted include sulfaguanidine, sulfadiazine,

amphetamines, iodides, phenytoin, phenobarbital, carbamazepine, griseofulvin, ketoconazole, fluconazole, ciprofloxacin, diamorphine, cocaine and nicotine. Thiotepa excretion may result in hyperpigmentation of the skin where it is occluded under bandages.

Coma-induced eccrine necrosis

Necrosis of the eccrine glands is the most consistently reported feature of drug-induced coma, whether it be caused by barbiturates, benzodiazepines, narcotics or antidepressants. Similar changes are seen in blisters resulting from coma induced by hypoglycaemia or neurological events, suggesting that the changes are due to pressure rather than the drug *per se*. Areas not usually subject to pressure are the areas that usually show these changes. Early features are necrosis of the secretory coil; later, the duct may be similarly affected. Subsequently, epidermal spongiosis, and subepidermal and intraepidermal blisters form with minimal dermal inflammatory infiltrate.

Radiation-induced eccrine damage

High-dose radiation (>50 Gy) resulting in radiation dermatitis will abolish eccrine function. Lower doses of radiation will reduce eccrine function within 2 weeks of exposure, reaching a nadir at 8 weeks and recovering to a final dose-dependent deficit by 30 weeks. Radiation-induced keratoses have been described that block the eccrine duct, resulting in milia-like lesions. Histologically, dilated eccrine orifices filled with keratin were identified. Resolution occurred a few months after completion of the radiotherapy.

Disorders with sweat gland cellular inclusions

Accumulation of substances within the secretory cells occurs in a number of metabolic conditions, and their identification in skin biopsies can be used diagnostically. In the Hurler and Sanfilippo types of mucopolysaccharidosis, membrane-bound vacuoles may be seen in the secretory cells [1]. Intracytoplasmic lipid occurs in Sandhoff and Niemann–Pick lipid storage disease [2]. Secretory cell inclusions are seen in Fabry's disease, fucosidosis [3] and Kanzaki disease [4], and in amaurotic idiocy, maltase deficiency and adrenoleukodystrophy [5]. Periodic acid–Schiff (PAS)-positive granules in the outer duct cells characterize Lafora's myoclonic epilepsy [6].

Granulosis rubra nasi [1–3]

The pathogenesis of this rare disease is obscure. Most cases are genetically determined, but the mode of inheritance is uncertain.

The disease usually starts in childhood, from the age of 6 months to 10 years. Excessive sweating may precede other changes by several years. Diffuse erythema first appears on the tip of the nose, gradually extends, and may involve the cheeks, the upper lip and the chin. The erythema is covered by small beads of sweat, which may also be evident over a wider area. Small, red macules and papules, and sometimes vesicles, later form at the sweat duct orifices. The condition usually subsides spontaneously at puberty, but may persist indefinitely. In such cases, telangiectasia becomes a conspicuous feature, and small cysts may be present. Many of those affected have poor peripheral circulation and hyperhidrosis of the palms and soles. Response to treatment is usually disappointing. A single case has been associated with phaeochromocytoma [4].

Apocrine sweat glands

Anatomy and physiology [1–4]

Apocrine sweat glands derive their name from the way that their secretion appears, on light microscopy, to be derived by pinching off parts of the cytoplasm. They are epidermal appendages, and develop as part of the pilosebaceous follicle in the fourth to fifth month of intrauterine life. In the embryo, they are present over the entire skin surface, but most glands subsequently disappear, so that in the adult the characteristic distribution in the axillae, perianal region and areolae of the breasts is found. So-called ectopic glands may be found elsewhere. The mammary glands and glands in the external auditory meatus are modified apocrine glands. Apocrine glands are poorly developed in childhood, and begin to enlarge with the approach of puberty. The activity of the glands is androgen-dependent, and the glands show marked testosterone 5α-reductase activity [5]. The glands are larger than eccrine glands, and in the dissected specimen are visible to the naked eye. They are situated in the subcutaneous tissue. Each consists of a tubule and a duct. The latter is often quite short, and

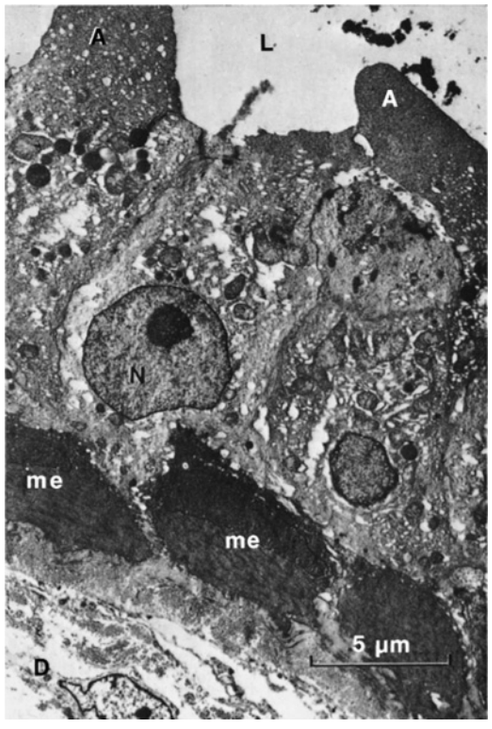

Fig. 44.13 Section of a secretory coil of an apocrine gland from the human axilla; lying next to the basement membrane are myoepithelial cells (me), followed by cuboidal secretory cells, with prominent nuclei (N) and apical caps (A), projecting into the lumen (L). D, dermis. (Courtesy of the late Professor A.S. Breathnach, St John's Dermatology Centre, London, UK.)

opens into the neck of the hair follicle above the sebaceous gland. Despite their embryological origin from the hair follicle, some apocrine glands eventually come to open on the surface of the skin. The secretory coil is a simple convoluted tube. It is lined by a single layer of columnar or cuboidal cells resting on a basement membrane. The free edge of the cells may show the appearance of apocrine secretion. Electron microscopy shows that this may be partly an artefact, but eccrine, apocrine and even holocrine secretion may all be found in places [3,6,7] (Fig. 44.13). The apocrine duct closely resembles the eccrine duct, and consists of a double layer of cuboidal cells. Outside the basement membrane of the gland and duct is a longitudinal layer of myoepithelial cells. Their function is to support the duct and to propel the secretion to the surface, and waves of peristalsis have been seen in them [8]. Where the duct opens into the neck of the hair follicle, there is the equivalent of the acrosyringium of the eccrine duct, although it is less obvious [9].

Apocrine glands secrete very small quantities of an oily fluid, which may be coloured. This secretion is odourless on reaching the surface, and bacterial decomposition is responsible for the characteristic odour; *trans*-3-methyl-2-hexanoic acid, which is water-soluble, is one of the substances which contributes to the odour [10]. The glands have no thermoregulatory function in humans, although they may play some part in human olfactory communication. The epithelium of the secretory coil produces its secretion continuously, with some variation depending on hormonal factors—for example, menstruation and pregnancy. The ducts have an adrenergic sympathetic nerve supply and are also stimulated by circulating epinephrine. Nervous control of secretion is unimportant, and it is even disputed whether the glands have any motor innervation [4,11]. Expulsion of apocrine sweat may occur continuously or be provoked by emotional stimuli. It seems possible that histologically normal apocrine glands may fail to produce any secretion, and that only the axillary glands in humans are important in producing body odour [12].

Abnormal sweat odour (bromhidrosis and osmidrosis) [1–3]

Odour of the skin in humans is, to a large extent, determined by apocrine gland secretion, although there are other sources. Sebaceous secretion has some odour, and decomposition products of keratinization, especially in the presence of hyperhidrosis, produce offensive smells. Eccrine secretion is usually odourless, but various substances may be excreted in it—for example, garlic, drugs, arsenic. Characteristic odours may be associated with various uncommon amino-acidurias (see below). Old textbooks of medicine report that sweat has a characteristic odour in gout, diabetes, scurvy, typhoid and other diseases [4]. Cases of generalized bromhidrosis associated with nasal foreign bodies have been recorded in children [5,6], and the symptom may be a clue to premature puberty. Other patients complaining of body odour may be suffering from paranoia or phobias (monosymptomatic delusions of malodour) or from organic lesions of the central nervous system.

Apocrine secretion is odourless as it reaches the surface, apart from excreted substances such as garlic. Bacterial decomposition liberates fatty acids, etc., with characteristic smells. This process

occurs only after some hours, and frequent removal of apocrine sweat prevents its decomposition. A strong axillary odour tends to be associated with a richer bacterial flora, and especially with more corynebacteria [7,8]. Increased axillary pH may facilitate the overgrowth of these bacteria, and some deodorants may help by acidifying the axillary skin.

There is marked individual and racial variation in body odour, and what is socially acceptable varies greatly with race and social upbringing. Recent studies have demonstrated histological differences between normal and bromhidrotic apocrine glands; in the bromhidrotics, the apocrine glands were larger and more numerous [9]. Elevated activity of type I 5α-reductase activity has been shown in those with bromhidrosis [10].

Treatment of axillary bromhidrosis includes omission of foodstuffs such as garlic from the diet, frequent washing of the axillary regions and local antibacterial substances [2]. There is little evidence that measures used to control axillary eccrine hyperhidrosis—for example, aluminium salts and anticholinergic drugs—have much effect on the apocrine glands, although excessive eccrine excretion may favour the spread of apocrine secretion. Botulinum toxin has been used to treat genital osmidrosis with good effect; the effect on eccrine sweating and rendering the area anhidrotic may prevent bacterial activity and thus have an effect on odour [11]. Surgical excision of axillary subcutaneous tissue by a variety of surgical techniques (axillary shave and subsection of subcutaneous glands, laser ablation, ultrasound ablation and liposuction), which remove both eccrine and apocrine glands, has been performed with good effect in those dissatisfied with conservative measures [12–14].

Fish odour syndrome (trimethylaminuria)

This disorder results from excessive amounts of the offensively smelling tertiary amine trimethylamine appearing in both eccrine and apocrine sweat, breath and urine, which imparts an unpleasant rotting fish smell to sufferers [1]. Affected individuals are unable to oxidize this substance, which is produced by the intestinal bacterial degradation of choline and carnitine in food to the odourless trimethylamine N-oxide. This can occur as a primary problem, as a result of a mutation in the flavin-containing monooxygenase 3 (*FMO3*) gene [2]. The ability to N-oxidize trimethylamine is distributed polymorphically, and sufferers are homozygous for an allele that determines this impaired reaction. One per cent of the population are heterozygous carriers of the allele. Secondary trimethylaminuria can occur when there is an increased burden of trimethylamine, and is seen when there is an increased production of trimethylamine (TMA) from its precursors by gut bacteria, in conditions such as blind loop syndrome, uraemia and liver disease.

The unpleasant odour, which is often worse after eating seafood, during periods of stress and during menstruation, can be the source of much distress, rejection and resentment. Sufferers are sometimes unaware of their smell, which may be intermittent and may not be detected by physicians when consulted. Trimethylaminuria was found in 7% of a series of individuals who perceived themselves to be malodorous [3]. The condition can be diagnosed by direct estimation of TMA in the urine; both affected individuals and heterozygous carriers have abnormal elevated excretion of TMA after an oral TMA challenge. A diet low in carnitine and choline may help. Short courses of metronidazole or neomycin may temporarily reduce the bacteria that degrade the carnitine and choline in the gut. Charcoal and copper chlorophyllin have been shown to reduce urinary trimethylamine concentrations to normal levels in sufferers [4].

Chromhidrosis [1,2]

Apocrine sweat may be tinged with a yellow, green or blue hue in up to 10% of the population, but only rarely does it occur to the striking degree that merits the term chromhidrosis (Fig. 44.14). Most commonly blue–black, yellow or green, it results from the secretion of lipofuscins in apocrine sweat, and may be associated with the secretion of coloured breast milk. The more oxidized lipofuscins appear deeper in colour; the lighter-coloured pigments may fluoresce. The diagnosis can be confirmed by finding lipofuscin pigment granules that may fluoresce on fluorescence micros-

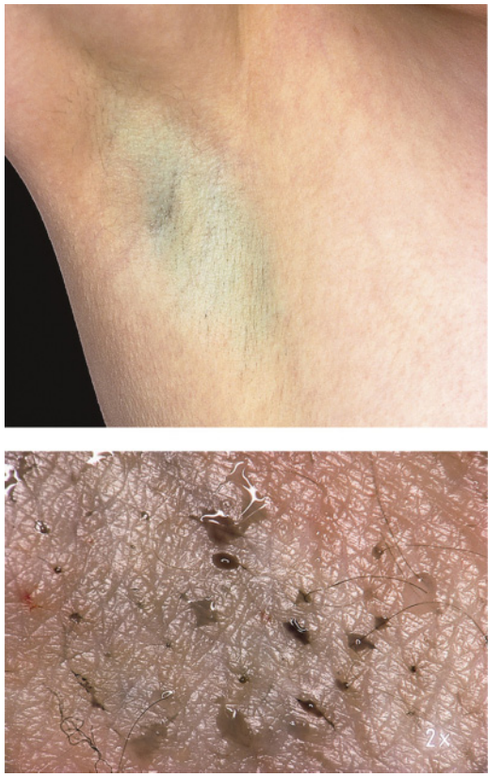

Fig. 44.14 Axillary chromhidrosis. (Courtesy of Dr D. Shuttleworth, Essex County Hospital, Colchester, UK.)

Fig. 44.15 Axillary Fox–Fordyce disease.

copy in the apocrine secretory cells. The secretion of coloured sweat starts at puberty and persists until there is a gradual regression of apocrine function in old age. Coloured sweat may be discharged from the glands in response to exercise and emotional stimuli, and after manipulation of the skin. The axillae are the most frequently affected sites, although facial [3] and areolar chromhidrosis [4] are recorded. Topical capsaicin has satisfactorily reduced facial and nipple chromhidrosis. Botulinum toxin has been used to successfully suppress facial chromhidrosis [5,6].

Pseudochromhidrosis refers to the coloration of otherwise colourless sweat when it reaches the surface of the skin due to dyes, paints or chromogenic or porphyrin-producing bacteria on the skin. Blue pseudochromhidrosis has been reported in workers occupationally exposed to copper salts. An outbreak of red pseudochromhidrosis occurred in a group of flight attendants who had new red-dyed labels put into their uniforms [7]. Erythromycin eradicated a presumed bacterial pseudochromhidrosis of the face in a young girl [8]. Eccrine chromhidrosis is usually due to exogenous dyes and is usually weak in hue. A case of red pseudochromhidrosis resulting in red staining of underwear was attributed to eating excessive quantities of a snack containing a red food dye [9]. Dark perspiration has been reported to occur in alkaptonuria (ochronosis).

Fox–Fordyce disease

Aetiology and pathology [1]. Fox–Fordyce disease is a disorder of the apocrine glands comparable with prickly heat of the eccrine glands. The aetiology is unknown. Obliteration of the apocrine duct at the infundibulum is felt to be the cause. The earliest visible change histologically is a small vesicle in the apocrine duct [2]; early changes may be seen most easily in transverse histological sections. This progresses to an inflammatory lesion, followed by rupture and plugging of the duct. Apocrine sweat retention therefore follows. Hormonal influences are important, but there is little evidence of a primary hormonal abnormality.

Clinical features. The disease occurs mainly in women soon after puberty, but can be postmenopausal [3]. It can occur in males or in children, and has been reported in females with Turner syndrome and in identical twins [4]. Itching, which may be intense, occurs in the axillae, and to a lesser extent in the anogenital region and around the breasts. Objectively there may be little to see at first, but later skin-coloured, or slightly pigmented, dome-shaped, follicular papules develop (Fig. 44.15). Hair loss in the axillae usually ensues. The itching is often provoked by those emotional stimuli that normally cause apocrine secretion. The disease runs a very prolonged course, and may persist until the menopause. Some remission may occur in pregnancy. A condition resembling Fox–Fordyce disease has been reported due to accumulation of xanthoma cells obliterating the axillary apocrine ducts [5].

Treatment. Response to treatment is unsatisfactory. Topical and intralesional steroids provide some benefit, but their use is limited by atrophy. Topical pimecrolimus may reduce itch and does not have the atrophogenic potential of steroids [6]. Topical clindamycin is reported to have been of help [3]. Treatment with four to six weekly doses of ultraviolet radiation (UVR), sufficient to cause exfoliation, helps some patients [7]. Topical retinoic acid may also be helpful [8], as may oral contraceptive agents [9,10], and oral retinoids [11]. Other cases are sufficiently severe to require electrocautery [12] or surgical excision of the affected skin, or subcutaneous removal of the apocrine glands [13].

Introduction

The connective tissue of the normal skin is discussed in Chapter 3.

Diseases that predominantly affect the cutaneous connective tissue (collagen, elastin and ground substance) can be divided into three main groups [1,2]:

1 Genetic abnormalities that affect connective tissue formation or metabolism. Examples include Ehlers–Danlos syndrome (EDS) (which affects collagen), pseudoxanthoma elasticum (PXE) (elastic tissue) and the mucopolysaccharidoses (ground substance).
2 Acquired metabolic or degenerative disorders, such as scurvy and solar elastosis, which are liable to affect people with no genetic defect if the environmental cause is present.
3 Inflammatory 'collagen vascular' or 'connective tissue' diseases, which damage connective tissue as a result of complex immunological reactions involving autogenous antigens. This group includes systemic lupus erythematosus, rheumatic fever, systemic sclerosis and dermatomyositis. Both genetic and acquired factors (including the possibility of infective agents) may play some part in producing these conditions, which are fully discussed in Chapter 51.

The attempt to classify the pathological changes according to whether ground substance, collagen, elastin or cellular components are mainly or wholly involved is not always easy, and may have been inaccurate in the past.

In this chapter, some of the genetic and acquired diseases that affect mainly collagen or elastin are discussed. Disorders of the ground substance are discussed elsewhere (see myxoedema, cutaneous mucinosis and mucopolysaccharidoses).

There are, in addition, many other disorders, including developmental defects, reactive or scarring conditions and benign or malignant neoplasms, that may involve the connective tissue.

Cutaneous atrophy

Atrophy of the skin is a term that is applied to the clinical changes produced by a decrease in the dermal connective tissue. It is characterized by thinning and loss of elasticity. The skin usually appears smooth and finely wrinkled, and it feels soft and dry. Veins or other subcutaneous structures may be unduly conspicuous. There is often associated loss of hair follicles, and telangiectasia may also be present, due to the loss of connective tissue support of the capillaries. There may or may not be an associated atrophy of the epidermis.

Atrophy of the skin occurs in varying degree in a large number of skin conditions, and the underlying histological changes are also variable, because the several components of the connective tissue may be involved to a different degree. Atrophy that includes subcutaneous tissue or even deeper structures is referred to as *panatrophy*.

The main causes of cutaneous atrophy are as follows.

1 Generalized cutaneous thinning:
   (a) ageing
   (b) rheumatoid disease
   (c) glucocorticoids (exogenous or endogenous)
2 Poikiloderma
3 Atrophic scars (striae)
4 Anetoderma (see p. 45.17)
5 Chronic atrophic acrodermatitis (borreliosis)
6 Follicular atrophoderma
7 Vermiculate atrophoderma
8 Atrophoderma of Pasini and Pierini (probably morphoea)
9 Atrophic naevi
10 Panatrophy:
   (a) local panatrophy
   (b) facial hemiatrophy.

Generalized cutaneous atrophy

The skin becomes increasingly thin and atrophic in elderly people, and both the epidermis and the dermis are affected [1] (see Chapter 8 for further details). As a result, the aged skin becomes fragile, translucent, lax and wrinkled, with a tendency to easy bruising. Intrinsic ageing of skin may be compounded by environmental factors, such as chronic sun exposure and smoking. Dermal thickness is considerably decreased in the elderly [1]. Wound healing is delayed in the elderly because of a decrease in the numbers and synthetic capability of fibroblasts [2]. With increasing age, both keratinocytes and fibroblasts show a decreased response to various growth factors [3].

Ageing and wrinkles

Wrinkles may be defined as creases or furrows in the skin surface. They are generally distinguished from the lax pendulous folds of skin which occur in conditions such as PXE and cutis laxa, but the distinction is somewhat arbitrary, because loss of dermal elastic tissue is common to all these conditions. Deepening of the furrows occurs with advancing age [4]. Histologically, there is epidermal thinning, decrease in chondroitin sulphate and deposition of abnormal elastic tissue in the papillary dermis [5].

Wrinkles can be classified into three morphological types [6]:

1 **Crinkles.** This is a very fine wrinkling which occurs in aged skin, even in areas protected from sunlight. These fine wrinkles disappear when the skin is slightly stretched. They are caused by deterioration of elastin, especially the vertical subepidermal fine elastic fibres which keep the epidermis in tight apposition to the dermis [7,8]. Ultrastructural studies have shown that even in normal people the elastic fibres begin to deteriorate from the age of 30 years onwards, regardless of the amount of sun exposure, although sunlight undoubtedly increases the damage [9]. Crinkles are seen in a marked form in mid-dermal elastolysis (see below).
2 **Glyphic wrinkles.** These creases are an accentuation of the normal skin markings. They occur on skin which has been prematurely aged by elastotic degeneration caused by sunlight, for example on the sides and back of the neck (see actinic elastosis).
3 **Linear furrows.** These are long, straight or slightly curved grooves that are usually seen on the faces of elderly people. They include the horizontal frown lines along the forehead, the 'crows' feet' radiating from the lateral canthus of the eye and the creases from the nose to the corners of the mouth.

The facial skin has a remarkably complex and dense intradermal elastic tissue mesh. This sheath of elastin is unique to the face, not being found in such complexity elsewhere. In youth, the linear furrows caused by facial muscle contraction disappear due to elastic recoil, but in older people they become permanent. There is some controversy regarding the histology of these linear furrows. Several groups have claimed that the linear wrinkles cannot be distinguished by light or electron microscopy from the surrounding skin, and Kligman *et al.* [6] claim the furrow is merely a configurational change, like the crease in an old glove. Tsuji *et al.* [8], however, claim that the upper dermis in the furrow shows less elastotic change than the surrounding skin. Other authors [9,10], on the other hand, claim that the trabeculae of the retinacula cutis (which anchors the dermis to the underlying fascia) are broader and much shorter underneath the wrinkles than in the surrounding skin. The hypertrophy of these subcutaneous septa is probably related to repetitive mechanical stimuli generated by the facial muscles over the years.

Wrinkles are a characteristic feature of photodamaged skin (Chapter 29). Cigarette smoking is also a potent, independent cause of wrinkling. The so-called 'cigarette face' is characterized by pale, grey, wrinkled skin with rather gaunt features, so that heavy smokers can often be recognized from their facial appearance alone. Heavy smokers are five times more likely to be wrinkled than non-smokers of the same age, and cigarette smoking probably has at least as much effect on facial wrinkles as sun exposure [11,12]. The pathogenesis of these deleterious effects on facial skin is unknown, but causative factors might include ischaemia due to the vasoconstriction induced by nicotine or sympathetic nerve stimulation, decreased tissue oxygenation, increased tissue carboxyhaemoglobin, increased platelet aggregation, decreased prostacyclin formation and reduced collagen deposition [12]. Both UVA and tobacco smoke may cause wrinkling through additive induction of matrix metalloproteinase-1 (MMP-1) expression [13].

Treatment of wrinkles

See Chapter 80.

Atrophic skin with rheumatoid disease

In rheumatoid patients over the age of 60 years, especially women, the skin on the dorsa of the hands may become thin, loose, smooth, inelastic and transparent, so that the details of veins and tendons are clearly seen. The change is generalized but is seldom conspicuous, except on the hands and forearms. Histologically, the dermis is thinned but shows no distinctive changes.

There is a significant association between transparent skin, rheumatoid arthritis and osteoporosis, and it is assumed to form part of a general connective tissue defect [1]. Steroid therapy is not a factor but it will potentiate the problem [2]. Skin collagen is structurally abnormal [3]. A reported association with PXE may be coincidental [4].

Glucocorticosteroid-induced atrophy [1]

Both systemic and topical steroid therapy can produce cutaneous atrophy by a dose-related pharmacological effect. The effect is more severe with the more potent steroids (as assessed by the vasoconstrictor assay test), but both fluorinated and non-fluorinated topical steroids can cause atrophy. The effect is most marked when potent steroids are applied topically under an occlusive dressing. The skin becomes thin, fragile and transparent, and striae may develop (see below) (Fig. 45.1).

Severe dermal atrophy can follow injection of intralesional steroids, such as triamcinolone acetonide (particularly if the higher concentration of 40 mg/mL is used, instead of the more usual 10 mg/mL, which is less likely to cause atrophy) (Fig. 45.2).

Fig. 45.1 Striae of the legs due to long-term application of a potent topical steroid in a young woman with psoriasis.

Fig. 45.2 Localized atrophy due to injection of a steroid (triamcinolone, 40 mg/mL) into the skin between the second and third metatarsals.

The earliest histological change is marked thinning of the epidermis, with flattening of the rete ridges and decreased corneocyte size [2]. This is followed a few weeks later by thinning of the dermis, which can be measured by skinfold callipers, ultrasonography or a radiographic technique [3–5].

The epidermal thinning probably results from a reduction of mitotic activity in the germinal layer [6], but the mechanism by which dermal thinning is produced is uncertain.

Loss of dermal ground substance leads to a reorganization of the dermal architecture. The spaces between the collagen and elastic fibres become smaller, so that the dermis becomes more compact but thinner [7]. Steroids are known to inhibit the formation of glycosaminoglycans, and hyaluronate and the major cell-surface hyaluronate receptor CD44 are depleted in atrophic skin [8,9]. The fibroblasts become shrunken, although their numbers do not decrease, but the number of mast cells is markedly reduced.

Topical steroids also inhibit the activity of enzymes involved in collagen biosynthesis [10], and they have been shown to depress synthesis of types I and III collagen *in vivo* [11–13]. Type III collagen synthesis is preferentially reduced in fibroblast cultures [14]. They can also depress collagenase production and collagen breakdown [15], and the rate of collagen turnover is probably decreased. Even a weak steroid, such as hydrocortisone, can suppress the stimulatory effect of cyclic nucleotides on collagenase production. Studies of the effect of topical steroids on collagen and elastic fibres *in vivo* have given conflicting results [7,16,17]. Collagen microfibrils may form globular microfibrillar bodies, although the changes are not specific for steroid atrophy [18]. These ultrastructural changes can develop in the early stages before there is clinical or histological evidence of atrophy. Digestion of collagen fibrils in the endocytic vesicles of fibroblasts may be involved in the production of steroid-induced atrophy [15].

Capillaroscopic studies have shown that steroid-induced vasoconstriction involves the superficial capillary network, and prolonged superficial ischaemia could also play a role in producing atrophy [10].

Treatment. It has been suggested that local and oral vitamin C therapy might help restore the normal skin thickness [19]. Concurrent application of retinoic acid may partially prevent the epidermal atrophy due to steroids [20]. Intralesional saline injections can restore surface contour [21]. Hyaluronate fragments are reported to induce skin thickening in corticosteroid-induced atrophy [9].

Achenbach's syndrome [1–4]

Synonym
- Paroxysmal haematoma of the finger

This syndrome presents with the sudden spontaneous onset of one or more painful haematomas in the fingers, usually in a middle-aged female (Fig. 45.3). It may recur at intervals for several years. The cause is unknown—there is no evidence of vasculitis or amyloid on skin biopsy, and the condition, although troublesome, has a good prognosis. It may be mistaken for easy bruising due to steroid atrophy.

Striae

Synonyms
- Striae atrophicans
- Striae distensae
- 'Stretch marks'

Fig. 45.3 Achenbach's syndrome. (Courtesy of Dr J. Verbov, Royal Liverpool University Hospitals, Liverpool, UK.)

Fig. 45.4 Striae due to obesity in a young man.

Definition. Striae are visible, linear scars, which form in areas of dermal damage produced by stretching of the skin. They are characterized histologically by thinning of the overlying epidermis, with fine dermal collagen bundles arranged in straight lines parallel to the surface.

Aetiology. The factors that govern the development of striae are poorly understood. Many authors have suggested that striae develop as a result of stress rupture of the connective tissue framework [1], but others disagree. It has been suggested that they develop more easily in skin that has a critical proportion of rigid cross-linked collagen, as occurs in early adult life [2]. They are common during adolescence [3], and they seem to be associated with rapid increase in size of a particular region. They are very common over the abdomen and breasts in pregnancy, and they may develop on the shoulders in young male weightlifters when their muscle mass rapidly increases [4]. They are a feature of Cushing's disease, and they may be induced by local or systemic steroid therapy [2,5]. The effects of glucocorticoids on the dermal connective tissue are outlined above. Together with other steroid effects, striae have been reported in human immunodeficiency virus (HIV)-positive patients receiving the protease inhibitor, indinavir [6].

The importance of genetic factors in determining susceptibility of connective tissue is emphasized by their presence as one of the (minor) diagnostic criteria for Marfan's syndrome (MFS) [7], but they are commonly absent in pregnancy in EDS.

Pathology. In the early stages, inflammatory changes may be conspicuous; the dermis is oedematous and perivascular lymphocytic cuffing is present. In the later stages, the epidermis is thin and flattened [8]. The dermal collagen is layered in thin eosinophilic bundles, orientated in straight lines parallel to the surface in the direction of the presumed stress. Scanning electron microscopy shows amorphous, sheet-like structures [9,10]. With Luna's stain, the elastic fibres are numerous, close together, fine and straight, in the same direction as the collagen bundles [9]. On scanning electron microscopy, in collagen-free preparations there is an abundance of thin, curled and branched elastic fibres. The histology is that of a scar.

Clinical features. Striae are very common, and occur in most adult women, as they readily develop at puberty or during pregnancy. Adolescent striae may first develop soon after the appearance of pubic hair. The commonest sites are the outer aspect of the thighs and the lumbo-sacral region in boys (Fig. 45.4), and the thighs, buttocks and breasts in girls, but there is considerable variation, and other sites, including the outer aspect of the upper arm, are sometimes affected. Early lesions may be raised and irritable, but they soon become flat, smooth and livid red or bluish in colour. Their surface may be finely wrinkled. They are commonly irregularly linear, several centimetres long and 1–10 mm wide. After some years, they fade and become relatively inconspicuous.

The striae in Cushing's syndrome or those induced by steroid therapy may be larger and more widely distributed, and involve other regions, including sometimes the face. In pregnancy, the striae appear first and are most conspicuous on the abdominal wall, and later on the breasts, but may involve most or all of the pubertal sites [11].

The striae induced by topical steroid therapy occur particularly in the flexures, but may appear in other sites if occlusive plastic films increase absorption [12,13]. They may disappear or become less conspicuous when treatment is stopped.

Usually, striae are only a cosmetic problem, but occasionally, if extensive, they may ulcerate or tear easily should the patient be involved in an accident.

Diagnosis. The diagnosis of striae is usually simple. The possibility of Cushing's syndrome must be considered, although this is rarely the cause. In linear focal elastosis the lesions are yellow and palpable (p. 45.25).

Treatment. In the case of common adolescent striae, the patient may be reassured that in time they will become less conspicuous. Numerous unproven remedies are available from cosmetic companies.

Some cases appear to respond to treatment with topical tretinoin [14]. The erythema of 'younger' striae is claimed to respond to the 585 nm pulsed dye and Nd:YAG lasers [15,16]. Fractional photothermolysis has been used in chronic striae [17].

Congenital reticulate scarring

Three children have been described who presented at birth with vesicles, deep erosions and erythematous patches. The vesicles were generalized, but spared the palms, soles and face, superficially resembling 'scalded skin syndrome'. Healing at around 3 months was followed by fragile reticulate scars; the affected areas were anhidrotic [1]. Two further children with this condition had epilepsy and delayed intellectual and motor milestones [2]. Histological examination showed that the reticular dermis was partially replaced by collagenous scar tissue, and eccrine glands were absent. The differential diagnosis includes Goltz syndrome, Rothmund–Thomson syndrome, acrodermatitis chronica atrophicans and aplasia cutis [1,2].

Localized cutaneous atrophy

Focal facial dermal dysplasia

Scar-like depressions on the face are a feature of this syndrome, which may be a variant of the Setleis syndrome (Chapters 15 & 18) [1,2].

Atrophic scars and pseudoscars

Atrophy may result from the destruction of connective tissue by trauma or by inflammatory changes. The distribution and character of the atrophic lesions may be so distinctive as to betray their origin, and is sometimes of considerable importance in diagnosis. Viral infections, such as varicella, can leave widespread, small, circular, atrophic scars [1]. The scars left by tertiary syphilis, certain tuberculides and some deep mycoses, especially sporotrichosis, are usually completely atrophic. Lupus erythematosus may also leave atrophy without clinical evidence of sclerosis. Lupus vulgaris and the chronic follicular pyodermas, and some cases of lupus erythematosus, leave a combination of atrophy and sclerosis, in which the latter predominates. Lesions that have been treated by intralesional steroid injections may also leave atrophic scars.

Exposure to ionizing radiation gives rise to a very striking combination of atrophy, pigmentation and telangiectasia (Chapter 79).

The wide atrophic scars which follow injuries in EDS (p. 45.31) emphasize the importance of constitutional factors in determining the pattern of dermal response to a known external injury.

Stellate and discoid pseudoscars [1,2]

Stellate pseudoscars are white, irregular or 'star-shaped' atrophic scars (Fig. 45.5). They are common on light-exposed skin, particularly on the extensor aspects of the forearms, often in association with senile purpura. These are seen in 20% of patients aged 70–90 years, and a much less common presenile form occasionally occurs before the age of 50 years. These pseudoscars are secondary to mild trauma, and are probably always preceded by haemorrhage into the dermis.

Stellate scars following trivial trauma can also occur in other conditions that cause fragile skin, for example porphyria cutanea tarda and prolonged use of potent topical steroids.

Brown pseudoscars may also develop over the shins of diabetic patients with no history of trauma (Fig. 45.6).

Spontaneous atrophic scarring of the cheeks

Synonyms
- Varioliform atrophy
- Atrophia maculosa varioliformis cutis

Fig. 45.7 Spontaneous atrophic scarring of the cheeks (varioliform atrophy). (Courtesy of Dr S. George, Amersham Hospital, Amersham, UK.)

This is a very rare condition in which spontaneous scars develop on the cheeks (Fig. 45.7) in young adults [1,2] or children [3]. The shallow atrophic lesions have sharp margins and may be linear, rectangular or varioliform. They may be preceded by slight erythema and scaling. Histology shows mild loss of collagen or elastic fibres; there may be thickening of the stratum corneum [4]. Familial cases are recorded [1,5]; inheritance is probably autosomal dominant [6]. The differential diagnosis includes vermiculate atrophoderma (p. 45.8), chickenpox scars and artefact.

Atrophoderma

Follicular atrophoderma

In this distinctive syndrome dimple-like depressions at the follicular orifices are present from birth or early life, usually on the backs of hands (Fig. 45.8) and feet and sometimes in the elbow region.

Fig. 45.8 Follicular atrophoderma in Conradi's syndrome. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Fig. 45.9 Vermiculate atrophoderma on the cheek of a child. (Courtesy of Dr P. Frosch, Heidelberg, Germany.)

Histology shows widened follicular ostia with thickening of the connective tissue sheath of the follicle.

It appears to be due to a variety of genetic defects and it may be associated with the following conditions [1]:

1 Calcifying chondrodysplasia (Conradi's syndrome) (Chapter 19)
2 Bazex syndrome (Chapter 15) [2]
3 Hyperkeratosis palmoplantaris, follicular keratosis or palmoplantar hyperhidrosis.

It may also occur as an isolated defect of limited extent.

Vermiculate atrophoderma

This rare condition has been described under a variety of other names, including atrophoderma reticulatum, folliculitis ulerythematosa reticulata and honeycomb atrophy. It is a characteristic reticulate or 'honeycomb' type of atrophy, which seems to develop as a late reaction to inflammation around horny follicular plugs on the cheeks (Fig. 45.9). The condition is now regarded as part of the keratosis pilaris syndrome, and is further discussed in Chapter 19.

Familial focal facial dermal dysplasia

Atrophic macules occur on the temples in this rare autosomal dominant disease (Chapters 15 & 18).

Hallermann–Streiff syndrome

There may be focal atrophy of the scalp skin in this condition (Chapter 18) [1].

Atrophoderma of Pasini and Pierini

Definition. This condition appears to be an atrophic variant of morphoea (Chapter 51) in which one or more patches of skin become bluish and sharply depressed, with no surrounding erythema [1–3].

Aetiology. The cause is unknown. No genetic factor has been reliably incriminated, although familial cases have been reported [4], and morphoea and atrophoderma of Pasini have occurred in siblings with phenylketonuria [5].

Pathology [3]. The histological changes are slight. There may be increased pigmentation of the basal layer. During the earlier stages, the collagen in the lower dermis may be oedematous, and elastic tissue clumped and scanty. There may be a dermal perivascular infiltrate consisting of macrophages and T lymphocytes. Immunofluorescence studies may show IgM and C3 staining in the dermal blood vessels [6]. Later, the oedema subsides and there is some reduction in the total thickness of the dermis. Collagen

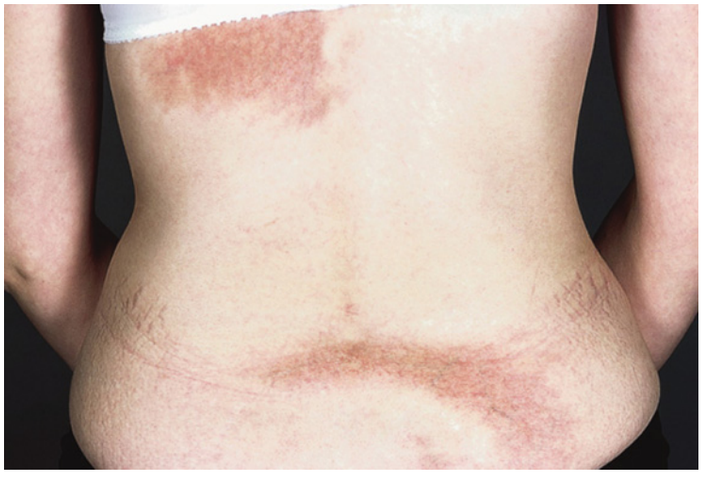

Fig. 45.10 Atrophoderma of Pasini and Pierini. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

bundles appear homogeneous and clumped in the reticular dermis. Eventually there may also be some epidermal atrophy.

Clinical features [3,7,8]. The lesions, which may be single or multiple, range in size from 2 cm to many centimetres in diameter, and are round or oval in shape, but may become confluent to form irregular patches (Fig. 45.10). They are smooth, slate-coloured or violet brown, and are slightly depressed below the level of the entirely normal surrounding skin. The back is almost always involved, the chest and abdomen frequently, and the proximal parts of the limbs occasionally. The patches extend very slowly, increase in number for 10 years or more, and then usually persist unchanged. The eventual development of sclerodermatous changes within the patches has been observed, as has the presence in the same patient of lesions typical of atrophoderma and of morphoea.

Diagnosis. Clinical differentiation from morphoea, possibly an academic exercise, is based on the ivory-white, indurated plaque with an oedematous lilac ring so characteristic of the latter. Histologically, sclerosis may be prominent in morphoea and is usually absent in atrophoderma. Serological tests for *Borrelia burgdorferi* are negative [3].

Treatment. None is of proven efficacy, but psoralen and UVA (PUVA) has helped some patients. Hydroxychloroquine has been used [9].

Linear atrophoderma

Pigmented atrophic bands follow Blaschko's lines [1] on the trunk, arms and legs. Histologically, collagen bundles are normal or thickened; the apparent atrophy may be due to loss of fat. Leukonychia has been associated [2]. The condition may reflect mosaicism for an autosomal lethal gene [3].

Acrodermatitis chronica atrophicans

Synonyms
- Chronic atrophic acrodermatitis
- Late-phase Lyme borreliosis

Definition. This is a late skin manifestation of Lyme borreliosis (Chapter 30). It is characterized by the insidious onset of painless, dull-red nodules or plaques on the extremities, which slowly extend centrifugally for several months or years, leaving central areas of atrophy.

Aetiology. The condition is due to infection with a spirochaete, *Borrelia burgdorferi sensu lato*, which is transmitted by ticks [1]. The disease occurs mainly in northern or central Europe, Italy and the Iberian Peninsula. Occasional cases occur in other parts of Europe and Africa, but it is very rare in the UK, America, Australia and Asia [2]. These geographical variations are related to different strains of the organism [3–5]. *Borrelia afzelii* is the predominant species associated with acrodermatitis chronica atrophicans. This species is transmitted by ticks in Western Europe, but is rare in the USA, where *Borrelia burgdorferi sensu stricto* predominates.

Pathology [6]. During the early stages, there is non-specific dermal oedema with perivascular inflammatory infiltration. Subsequently, the epidermis becomes atrophic and the epidermal appendages are destroyed. Beneath a subepidermal zone of degenerate connective tissue lies a dense, band-like infiltrate, predominantly consisting of lymphocytes, histiocytes and plasma cells. Ultimately, the infiltrate is reduced to narrow bands between collagen fibres. In some patients, scleroderma-like changes may develop [7,8]. *Borrelia afzelii* has been cultured from the atrophic skin [7] but culture is usually negative. *Borrelia afzelii* can be identified by polymerase chain reaction (PCR). The organism may be

resistant to attack by the complement system and may lurk in immunologically protected areas such as fibroblasts and endothelial cells. Expression of cytokines, such as interferon-γ (IFN-γ), is impaired [9].

Clinical features [10]. Most cases occur in country dwellers between the ages of 30 and 60 years.

The onset is usually insidious, and constitutional symptoms are exceptional. Painless, dull-red or bluish-red nodules or plaques, more or less infiltrated, develop on the feet or legs, and less often on the forearms and hands. The lesions themselves are typically painless, but there may be associated acral pain or paraesthesiae. Erythema chronicum migrans (Chapter 30) may have been present at the same site some years earlier. Extension to the trunk and the greater part of the body, including the face, is sometimes seen. Single or multiple lesions may be present. They slowly extend centrifugally, the active inflammatory stage persisting for months, years or even decades. Marginal extension may continue once the central areas have already entered the atrophic phase, in which the skin is smooth, hairless and tissue-paper-like, dull red, pigmented or poikilodermatous (Fig. 45.11).

Subcutaneous nodules may develop around the knees or elbows, and fibrous bands along the ulnar margin of the forearms. Gaiter-like sclerosis of the lower third of the legs, often accompanied by ulceration, is a further complication. Morphoea of the trunk and lichen sclerosus et atrophicus (both genital and extragenital) have also been reported as associated lesions [2,11], and it is interesting that *Borrelia* antibodies have been found in five of 10 patients with morphoea [12], although others have not confirmed this [13].

Fig. 45.11 Atrophic skin of the knee in acrodermatitis chronica atrophicans. (Courtesy of Dr T. Robinson, University College Hospital, London, UK.)

In some cases, involvement of the joint capsule or bone results in limitation of movement of the joints of the hands and feet, or of the shoulders.

Very rarely, squamous carcinoma has developed in the atrophic skin, and lymphoma has also been reported in the non-affected skin [14,15].

Other late syndromes of Lyme borreliosis (lymphocytoma, neurological, etc.) have been fully reviewed by Steere [1].

Diagnosis. The appearance of erythema chronicum migrans may be similar, but the evolution of the annular lesions establishes the differentiation. In the atrophic stage, diagnosis is usually readily made, and can be confirmed histologically.

Immunoblotting, using *B. afzelii* flagellar antigen (41 kDa) is confirmatory [5]. Serology is used to confirm the diagnosis of Lyme disease, but false-negative and false-positive results are common. In chronic atrophic acrodermatitis, however, the antibody titre is very high. Serology may be positive on enzyme-linked immunosorbent assay (ELISA) but negative on immunoblotting, particularly in patients with neurological disease [16]. A high titre of antibodies may reflect occult central nervous system involvement, when the antibodies can also be demonstrated in colony-stimulating factor [17].

When it occurs on the lower legs, the condition can mimic venous insufficiency [18], with thick, cyanotic, itchy skin.

Treatment. Oral antibiotics should be given for 1 month, for example doxycycline or amoxicillin in standard doses [1]. The improvement occurs gradually, several weeks after the course of treatment, but there may be no response if treatment is delayed until atrophy has developed. If the antibody titre is high, or there are clinical features of systemic disease (e.g. neuroborreliosis), intravenous penicillin G, ceftriaxone or cefotaxime should be given for 3 weeks [17]. There may be a case for chemoprophylaxis or even vaccine development in endemic areas [19].

Local panatrophy

Definition and aetiology. Local panatrophy is a rare disorder involving partial or total loss of subcutaneous fat and atrophy of overlying skin, sometimes associated with atrophy or impaired growth of muscle or bone. A primary neurogenic disturbance has been postulated but not proved. The syndrome may represent the end result of more than one pathological process, but many cases may be due to a variant of morphoea.

The atrophic areas exhibit a reduced sympathetic response and aberrant production of non-esterified fatty acids after stimulation with norepinephrine (noradrenaline), and it has been suggested that there may be a primary abnormality of the sympathetic nervous system [1].

Two groups of cases can be differentiated:

1 **Panatrophy of Gower:** no scleroderma or other sclerotic process accompanies or follows the loss of subcutaneous tissue. Most cases have occurred in women, usually in the second to fourth decades.
2 **Sclerotic panatrophy:** either typical morphoea or similar sclerotic change in dermal collagen precedes the atrophy [2].

Clinical features of the two groups are as follows.

Panatrophy of Gower [3]. Sharply defined areas of atrophy, irregular in size, shape and distribution, develop over a period of a few weeks, without preceding inflammatory stages. In each affected area, the subcutaneous tissue disappears and the overlying skin appears atrophic but is otherwise normal. There may be a single area of atrophy or two or more. In size they range from 2 to 20 cm across, and in shape they are very variable but are sometimes triangular or quadrangular. Most lesions have occurred on the back, buttocks, thighs or upper arms, but some have involved forearms or lower legs. The atrophy reaches its maximum extent within a few months and then remains unchanged indefinitely.

Sclerotic panatrophy. Atrophy of the subcutis, and sometimes of underlying muscle and bone, may follow clinically and histologically typical morphoea, especially when the process begins in childhood and involves a limb (Chapter 51).

Sclerotic panatrophy may also occur in the absence of morphoea. The sclerosis involves subcutaneous tissue and muscle, and dense, sclerotic, scar-like, linear bands develop along a limb, or encircle the trunk in a metameric distribution, or encircle a limb. These lesions have also usually occurred in childhood. They cease to progress after a few months and, although new areas may be involved, most lesions have been solitary.

It is possible that Gower's panatrophy and linear morphoea are at the ends of a continuous disease spectrum. The histology of linear morphoea reveals thickened bundles of collagen, which appear to be intact on B-scan ultrasound imaging [4].

In the differential diagnosis of panatrophy, the various forms of panniculitis must be excluded. The preceding inflammatory changes are the single most distinctive feature, but they are not always easy to distinguish.

Facial hemiatrophy

Synonym
- Parry–Romberg syndrome

Definition and aetiology. Facial hemiatrophy is an atrophic dysplasia of the superficial facial tissues, but the underlying muscles, cartilage and bone may also be affected. The cause is unknown, but it may be a disorder of the sympathetic nervous system in some cases. Other cases have followed lupus panniculitis [5].

There is no evidence that it is usually genetically determined, but it appears to be hereditary in a few pedigrees. Some cases have been associated with syringomyelia, epilepsy or cerebrovascular disease, but in 90% of cases no such association is demonstrable. The sexes are equally affected.

Clinical features [6–8]. This rare disease usually starts within the first two decades. The first manifestation is usually increased or decreased pigmentation in irregular patches on cheeks, forehead or lower jaw. Occasionally, there may be premonitory muscle spasms or neuralgia. Progressive atrophy gradually develops in the affected sites, involving skin, subcutis, muscle and bone, and may extend in area—and sometimes in depth—for months or years with temporary remissions. The skin becomes dry, thin and atrophic, but may be scar-like and adherent in some areas. When the atrophy is fully developed, the contrast between the sunken, haggard, pigmented affected half of the face and the unaffected half is dramatic. The hair may be lost in the frontoparietal region on the affected side but is often normal; occasionally, localized canities is an early change. A variety of neurological signs have been reported, of which Horner's syndrome is the most frequent. Heterochromia of the iris has developed at the same time as the facial atrophy in about 5% of cases, and retinal changes may also be present [9]. There can be ipsilateral cerebral atrophy [10].

The atrophy may remain limited both in extent and depth. It may be confined to the distribution of one division of the trigeminal nerve or involve the whole of the side of the face, sharply demarcated at the midline. Rarely, it may be bilateral, and very rarely may involve half the body, usually on the same side as the face but exceptionally the opposite side—crossed hemiatrophy. The atrophy may, in such cases, begin on the trunk or a limb and only later involve the face.

The degree of bone atrophy as established radiologically is usually much less than the clinical appearance suggests, and is severe only in some cases of early onset. In such cases, the cerebral cortex may also be affected, and contralateral epilepsy may result.

Localized scleroderma of the 'coup de sabre' paramedian form may be associated with some degree of facial hemiatrophy, especially if it begins early in life. However, it is a more superficial process than progressive facial hemiatrophy. The skin in scleroderma is bound down and adherent, and loss of hair and pigmentary changes are conspicuous. In progressive facial hemiatrophy, the skin may remain mobile and grossly normal. The two processes have been confused frequently in the literature, and may coexist [11].

Diagnosis. When the cutaneous involvement is early and conspicuous, the diagnosis presents few difficulties. Hypoplasia following radiotherapy given in infancy, perhaps in treatment of a naevus in the region of the temporomandibular joint, could cause confusion. If the skin changes are slight, or of later onset, physiological asymmetry, unilateral mandibular agenesis, hemihypertrophy and atrophy secondary to facial paralysis must be excluded. Hemihypertrophy is always congenital. When the limbs are involved, infantile hemiplegia and lipodystrophy must also be considered.

Treatment. Plastic surgery using large, buried pediculated flaps of dermis and fat, or silicone implants, offers some cosmetic benefit [5,11–14].

Scleroatrophic syndrome of Huriez

This autosomal dominant congenital syndrome is discussed in more detail in Chapter 19. It comprises a triad of diffuse scleroatrophy of the hands, mild palmoplantar keratoderma and hypoplastic nail changes [1–4]. Scleroatrophy is accentuated on the palms and fingers, which are tapered as in sclerodactyly; however, Huriez syndrome is congenital, and Raynaud's phenomenon is absent. The acral hyperkeratosis is associated with dry skin, resulting in painful fissures in winter months. Nail changes include prominent lunulae, elongated cuticles, longitudinal and transverse ridging, increased longitudinal curvature [5] and V-shaped notches [6]. Squamous carcinoma may develop in the scleroatrophic skin, sometimes as early as the third or fourth decades of life [1,6]; fatal metastases may occur [7].

Histology shows marked orthokeratosis, acanthosis with a prominent granular cell layer, and mild fibrosis of the upper and mid-dermis. Elastic fibres are reduced. Epidermal Langerhans' cells are reduced in number, perhaps contributing to the risk of malignant change [6]. A gene has been identified which maps to chromosome 4q23 [7].

Patients should be followed throughout life, with early excision of suspected malignancies. Acitretin reduces the painful hyperkeratosis [8] and could reduce the incidence of skin cancer.

Localized abdominal wall atrophy

Congenital cutis laxa (p. 45.14) may rarely be confined to an area such as the abdomen. There may be other associated defects, for example dysplasia of the abdominal muscles, deformity of the thorax or mediastinal hernia. This condition must be distinguished from centrifugal abdominal lipodystrophy (Chapter 46) and the prune belly syndrome, in which wrinkled abdominal skin due to underlying abdominal muscle deficiency is associated with malformation of the urogenital tract [1,2].

Poikiloderma

Poikiloderma is a descriptive term, often somewhat loosely applied. Atrophy, macular or reticulate pigmentation and telangiectasia are the essential features. Depigmentation, miliary lichenoid papules, fine scaling and small petechial haemorrhages are less constantly present.

Congenital poikiloderma

Poikiloderma may occur as an apparently primary abnormality in certain genetically determined syndromes, including the Rothmund–Thomson syndrome, dyskeratosis congenita (Chapter 15) and the Mendes da Costa syndrome (Chapter 19).

Several other syndromes have been described in which poikiloderma is a prominent feature [1].

Hereditary sclerosing poikiloderma of Weary [2]
This rare, autosomal dominant syndrome was described in a large black family. Generalized poikiloderma, which developed in early childhood, was accompanied by sclerosis of the palms and soles, and linear hyperkeratotic and sclerotic bands developed in the flexures of the arms and legs.

Kindler syndrome [3,4]
This is an autosomal recessive disorder characterized by acral blistering, which is usually present at birth, and early poikiloderma. The poikiloderma is progressive, resulting in thin, wrinkled skin without surface markings. Cutaneous atrophy is most pronounced on the hands and feet. Clinical overlap with epidermolysis bullosa and hereditary acrokeratotic poikiloderma may cause diagnostic confusion. Photosensitivity is common and, like other cutaneous features, tends to improve with time. However, recurrent acral blisters have been described in a 46-year-old Japanese male [5]. Kindler syndrome is caused by loss-of-function mutations in the *KIND1* gene, which encodes kindlin-1. This protein is involved in anchorage of the actin cytoskeleton to the extracellular matrix [6,7].

Hereditary acrokeratotic poikiloderma of Weary [1,8,9]. Weary described an autosomal dominant condition of vesicopustules of the hands and feet, which start at the age of 1–3 months and resolve in childhood. There is also a widespread eczema, and the gradual appearance of poikiloderma, which persists into adult life. Keratotic papules develop in childhood on the hands, feet, knees and elbows, and these also persist indefinitely. Mucosal involvement is frequent. Some cases do not fit clearly into either Weary's or Kindler's syndromes [10].

Diffuse and macular atrophic dermatosis [11]
This rare condition is characterized by the presence from birth of generalized poikilodermatous changes that give the appearance of prematurely sun-damaged skin. The facies, hair and skeleton are normal. Biopsy shows thinning of the epidermis, with large hyaline bodies in the superficial dermal collagen, and these stain positively with periodic acid–Schiff (PAS) and elastin stains. Electron microscopy shows that these globular structures consist of microfibrillar material, and the adjacent fibroblasts may be degenerative.

Degos–Touraine syndrome [12]
In this condition, incontinentia pigmenti is accompanied by poikiloderma of light-exposed areas, often with gastrointestinal symptoms. Both gastrointestinal and skin manifestations are said to disappear following treatment with diiodohydroxyquine. Small bullae on the extremities have been described, but the initial bullae appear on the face. Hyperpigmentation follows a chronic erythrodermatous phase.

Acquired poikiloderma

Poikiloderma may occur as a pattern of cutaneous response to injury by cold, heat or ionizing radiation [13]. So-called poikiloderma of Civatte (Chapter 58) is a similar reaction mediated by photosensitizing chemicals in cosmetics. Some inflammatory dermatoses, such as lichen planus, may also give rise to poikilodermatous changes.

Poikiloderma is also a feature of some inflammatory 'connective tissue' diseases, and is particularly characteristic of dermatomyositis. It is also seen in lupus erythematosus and rarely in systemic sclerosis. Poikiloderma occurs as a manifestation of some lymphomas, especially mycosis fungoides (Fig. 45.12).

Disorders of elastic fibres

The capacity of the skin to adapt to local or general changes in body size and contour, and to allow for movement of head and limbs and a wide range of facial expression, depends upon its tension, elasticity and tensile strength. These properties may be congenitally defective or modified by ageing or disease [1–3]. Acquired disorders of elastic tissue have been reviewed in detail by Lewis *et al*. [4,5].

Elasticity. Elastic fibres are abundant in the skin, arteries, lungs and ligaments. They provide tissues with resilience and elasticity (the ability to resume its original shape after deforming forces have ceased to act). There is wide individual variation, but a tendency to decrease with age. Several diseases, such as cutis laxa, decrease cutaneous elasticity. Elastic fibres also provide adhesion for cells and play a role in regulating growth factors' (e.g. transforming growth factor-β) availability [2].

Tensile strength. The tensile strength of the skin is the degree to which it can be elongated before it tears. It is greatest in infancy and decreases with age, but is also abnormally low in diseases associated with collagen defects such as EDS and Cushing's syndrome [3].

Lax skin

Increased laxity of the skin due to ageing (accelerated by dermal photodegradation) is of course extremely common, but cutaneous laxity can occasionally be due to marked weight loss (especially after gross obesity) or can follow recovery from severe oedema. Less commonly, the skin may become lax due to localized or generalized defects in elastic tissue resulting from other causes, and these may be grouped as follows.

1 Generalized elastolysis (cutis laxa):
  (a) congenital
  (b) associated with other inherited disorders (PXE, SCARF syndrome (*s*keletal abnormalities, *c*utis laxa, *c*raniostenosis, *a*mbiguous genitalia, *r*etardation and *f*acial abnormalities), de Barsy syndrome, geroderma osteodysplastica)
  (c) acquired (numerous associated disorders, for example inflammatory skin disease, multiple myeloma, systemic lupus erythematosus, hypersensitivity reactions, complement deficiency, penicillamine therapy)
2 Localized elastolysis:
  (a) anetoderma
  (b) blepharochalasis
  (c) chronic atrophic acrodermatitis (due to *Borrelia*)
  (d) granulomatous slack skin (due to lymphoma)
  (e) other localized lesions, including mid-dermal elastolysis, post-inflammatory elastolysis and cutis laxa (PECL), elastic tissue naevi etc.

Generalized cutis laxa [1]

Synonyms
- Generalized elastolysis
- Generalized elastorrhexis
- Generalized dermatochalasis

Definition. Cutis laxa is characterized clinically by lax, pendulous skin and histologically by loss of elastic tissue in the dermis. It is a heterogeneous condition, with several causes and associations, and it may be inherited or acquired.

Aetiology. Cutis laxa may be *inherited*, either as an autosomal dominant or autosomal recessive trait [2]. Occipital horn syndrome was originally described as X-linked recessive cutis laxa and subsequently EDS type IX, but is now classified with Menkes' syndrome as a condition in which secondary changes in connective tissue are caused by abnormal copper metabolism [3–4] (p. 45.15 and Chapter 66).

Since the initial identification of mutations in the elastin gene in autosomal dominant cutis laxa [5,6] only a few similar families have been reported [7]. Abnormalities of the microfibrillary protein, fibulin-5, can also lead to autosomal dominant cutis laxa, indicating genetic heterogeneity [8]. Both fibulin-4 and some fibulin-5 mutations cause the more severe autosomal recessive phenotype [9,10]. Loss-of-function mutations in *ATP6V0A2*, encoding the α2 subunit of the V-type H^+ ATPase, have been identified in several families with autosomal recessive cutis laxa type II, resulting in abnormal glycosylation [11].

Cutis laxa may also be *acquired* following inflammatory skin disease [12], and it has occurred in babies born to women taking penicillamine [13]. An immunological pathogenesis has been suggested in some acquired cases because of the rare associations with drug hypersensitivity, complement deficiency, systemic lupus erythematosus, multiple myelomatosis and coeliac disease [14–18].

Amyloidosis seems to provoke cutis laxa in some cases [19], and it is known that amyloid can coat elastic fibres [20,21]. Cutis laxa may also accompany inherited disorders of connective tissue such as pseudoxanthoma elasticum and Ehlers–Danlos syndrome [22].

Pathology. The skin is of normal thickness, but the elastic fibres are sparse, short, fragmented and clumped, particularly in the upper dermis, and they show granular degeneration [23]. The elastic fibres are deficient in elastin, but their microfibrils appear normal [24,25]. Similar changes in elastic fibres may occur in the lungs and aorta.

Various ultrastructural changes have been described, including separation of the elastin microfibrils from the amorphous matrix, the presence of a 'wood-grain' pattern and aggregation, fragmentation and clumping of the elastic fibres [11,23,24].

Clinical features. In this rare condition, the skin becomes inelastic and hangs in redundant folds. The face and neck are often affected, which produces a 'bloodhound' appearance of premature ageing. The internal elastic tissues may also be affected, and emphysema and cardiovascular abnormalities occur in some types.

Hereditary forms [26] (Table 45.1)

Various clinical types have been described [27,28]. In the *autosomal dominant* form, the skin changes may develop at any age, but tend to present later than in the recessive form. Those presenting in adult life usually have no internal defects, and the life expectancy is normal [28]. When the condition presents in infancy there is intrauterine growth retardation, delayed fontanelle closure and ligamentous laxity [29]. The skin changes may be preceded by episodes of oedema, usually within the first 2 months of life, and the child may look aged by the end of the second year. Affected males may be impotent, with infantile genitalia and scanty body hair. Pulmonary emphysema due to a loss of elastic tissue in the lungs is common [2].

In the commoner, but more severe, *autosomal recessive* form there is a characteristic facies with downward slanting palpebral fissures, a broad flat nose, sagging cheeks and large ears. There are prominent skin folds around the knees, abdomen and thighs [28]. Herniae, diverticula, severe pulmonary emphysema and cor pulmonale are important complications. Death due to respiratory complications is common in the first few years of life. Dental caries, aortic aneurysm and osteoporosis may also occur.

The *de Barsey syndrome* is a rare type in which cutis laxa is accompanied by retarded psychomotor development and corneal clouding due to degeneration of the tunica elastica of the cornea [30–32]. Growth is retarded and there may be pseudoathetoid movements. Congenital cutis laxa has also been associated with SCARF syndrome [33], osteoporosis [34] and geroderma osteodysplastica, which is characterized by skeletal abnormalities, including joint hypermobility, Wormian bones and osteoporosis [35].

Although there are many similarities between the wrinkly skin syndrome and cutis laxa type II, the skin changes in the former are limited mainly to the abdomen, hands and feet. Facial dysmorphism is less pronounced in wrinkly skin syndrome and the large fontanelles have not been described [36].

Table 45.1 Cutis laxa syndromes.

Type	Molecular defect	Major clinical features
Autosomal dominant	*ELN*, *FBLN5*	Symptoms less severe than autosomal recessive types Onset usually childhood/early adult Cutis laxa, gastrointestinal diverticula, herniae, uterine prolapse, aortic dilatations
Autosomal recessive Type I	*FBLN4* and *FBLN5*	Cutis laxa, pulmonary emphysema, gastrointestinal and bladder diverticula, arterial aneurysms, pulmonary artery stenosis, herniae
Autosomal recessive Type II	Loss-of-function mutations *ATP6V0A2*	Cutis laxa, growth and developmental delay, skeletal abnormalities, large fontanelle with delayed closure, oxycephaly, herniae, hip dislocations
Autosomal recessive Type III (de Barsey syndrome)	Unknown	Cutis laxa, corneal opacities, mental retardation, pseudoathetoid movements
Other syndromes with cutis laxa		
X-linked (occipital horn syndrome)	*ATP7A* (allelic with Menkes syndrome)	Bladder diverticulae, inguinal hernias, slight skin laxity and hyperextensibility, joint laxity and coarse hair Skeletal abnormalities, including persistent open anterior fontanelle and occipital exostoses
SCARF syndrome	Unknown X-linked recessive	SCARF acronym: *s*keletal abnormalities, *c*utis laxa/craniostenosis, *a*mbiguous genitalia, *r*etardation, *f*acial abnormalities
Geroderma osteodysplastica	Unknown Autosomal recessive	Dwarfism with premature aged appearance, lax skin, osteoporosis, Wormian bones, mandibular prognathism, malar hypoplasia
Costello's syndrome	*HRAS*	Phenotypic overlap with cardiofaciocutaneous syndrome Characteristic coarse facies, short stature, cutis laxa particularly hands and feet, severe feeding difficulty and failure to thrive, cardiac anomalies, facial warts Often presents in childhood

Acquired forms [37]

Cutis laxa may rarely develop at any age following episodes of urticaria or angio-oedema, extensive inflammatory skin disease (such as systemic lupus erythematosus or erythema multiforme) or febrile illness. It may also follow hypersensitivity reactions such as penicillin allergy [14].

Cutis laxa has also been reported in association with complement deficiency, sarcoidosis, syphilis, multiple myeloma [15,17] and the Klippel–Trenaunay syndrome [24]. Focal elastolysis can also occur in association with lupus erythematosus [38], severe rheumatoid arthritis [39] and coeliac disease [18]. D-Penicillamine disrupts elastic fibre formation and may cause cutis laxa, elastosis perforans serpiginosa and pseudoxanthoma-like changes [40]. Congenital cutis laxa may also occur in offspring of mothers taking penicillamine [13].

There may be widespread, massive folds of lax skin, or the changes may be mild and confined to a limited area, in which case it cannot be distinguished from anetoderma. Purpura may follow slight trauma and fibrotic nodules may form over bony prominences. Organs other than the skin may also be involved. Emphysema, gastric fibromas and tracheobronchomegaly have been reported [41].

In acquired cutis laxa, dermal elastic tissue is markedly reduced, although collagen is normal. Fibroblasts express increased elastolytic activity (cathepsin G). Levels of serum α_1-antitrypsin and elastase inhibition are decreased [42].

Post-inflammatory elastolysis and cutis laxa also appears to develop as a distinctive syndrome in African children, with clinical features intermediate between anetoderma and cutis laxa [43] (p. 45.17). This condition might represent an unusual reaction to an arthropod bite, as the lesions are preceded by urticaria or multiple red papules, which slowly enlarge to form rings 2–10 cm in diameter.

Diagnosis. The diagnosis, which is suggested by finding loose skin that recoils only slowly after stretching, may be confirmed by histology.

In EDS, the skin is hyperextensible but not lax, and it recoils quickly. In PXE, the skin may be lax, but it is yellowish and the face is usually spared. It is distinguished histologically by the presence of calcification. There may be circumscribed folds of lax skin in neurofibromatosis, and loose folded skin may also occur in leprechaunism, Patterson syndrome and trisomy 18, but these conditions are distinguished by their associated features.

In Costello's syndrome there is skin laxity, especially on hands and feet, with joint hyperextensibility, but the elastin fibres are normal under both light and electron microscopy [44]. The other features of this rare syndrome include poor postnatal growth, developmental delay and a distinctive facies with macroglossia, bilateral ptosis, epicanthic folds and posterior rotation of the pinnae, with prominent helices and thickened lobes.

In severe actinic damage, there may be marked skin laxity due to damage to elastic fibres.

Treatment. Plastic surgery ('face-lift') may reduce the cosmetic disability. Investigations for emphysema are indicated, with referral to a pulmonary physician if necessary.

Anetoderma

Synonym
- Macular atrophy

Definition and nomenclature. The term anetoderma (*anetos* = slack) refers to a circumscribed area of slack skin associated with a loss of dermal substance on palpation and a loss of elastic tissue on histological examination.

'Primary' anetoderma implies that there is no associated, localized, underlying cutaneous disease, whereas 'secondary' anetoderma can be attributed to some associated condition.

In the past, cases of primary anetoderma were divided into the *Jadassohn–Pellizari* type, in which the lesions are preceded by erythema or urticaria, and the *Schweninger–Buzzi* type, in which there are no preceding inflammatory lesions. This is now of historical interest only, because in the same patient some lesions may be preceded by inflammation and others may not, and the prognosis and histology are identical in the two types [1–3].

Primary anetoderma

Aetiology. In a few cases there appears to be an underlying structural defect of connective tissue. Familial cases are reported [4,5] and there is an association with inherited bony or ocular abnormalities. The Blegvad–Haxthausen syndrome comprises anetoderma, blue sclerae and osteogenesis imperfecta (OI) (p. 45.14).

Recently, it has become apparent that 'primary' anetoderma is strongly associated with antiphospholipid antibodies, with or without a prothrombotic state [6,7]. It is probable that these antibodies underlie the association historically noted with syphilis, and more recently with borreliosis [8] and systemic lupus.

The histology of anetoderma suggests that the basic abnormality is focal elastolysis [1,9,10]. This may be secondary to the release of elastase from the inflammatory cells, which are probably always present in the early stages. Metalloproteinases are increased in lesional skin [11].

Complement activation may be involved, as C3 is deposited on the remaining elastic fibres [12]. It has been suggested that decay-accelerating factor (DAF) and vitronectin (an inhibitor of the membrane-attack complex) may protect elastic fibres against this type of damage [13]. Abnormalities in the protective system could play a role in primary anetoderma.

Secondary anetoderma

This arises in association with another identifiable disease, but the atrophic areas do not always develop at the sites of the known inflammatory lesions. They are soft, round or oval areas which occur mainly on the trunk.

Lupus erythematosus. Anetoderma has occurred in association with systemic or chronic discoid lupus erythematosus, not always in relation to the lesions. Biopsy shows a focal loss of elastic tissue, and a perivascular infiltrate with prominent plasma cells [1,2]. Generalized elastolysis (cutis laxa) has also occurred [14]. Anetoderma is also associated with lupus profundus [15,16] and discoid lupus with hereditary complement (C2) deficiency [17].

Some cases of primary anetoderma have direct immunofluorescent findings similar to those of either chronic cutaneous or systemic lupus erythematosus, even though there may be no other features of lupus erythematosus [18,19].

No antibodies have been demonstrated against elastic fibres [19].

Other diseases [2]. Some of the other reported associations may be coincidental, but it is probable that many inflammatory diseases may occasionally be complicated by anetoderma. It has been reported in association with tuberculosis and leprosy [20], urticaria pigmentosa [21], pityriasis versicolor [22], granuloma annulare [23], and B- and T-cell lymphoma [24–26]. Localized anetoderma-like changes on histology have been reported in association with pilomatricoma [27], dermatofibroma [28], juvenile xanthogranuloma [29] and hamartomatous congenital naevi [30]. Penicillamine-induced anetoderma has also been reported [31].

Localized anetoderma may occur in premature infants, possibly due to the application of transcutaneous oxygen monitoring devices [32,33].

Lesions resembling anetoderma occur in post-inflammatory elastolysis and cutis laxa (p. 45.14).

Pathology [2,8]. During the early stages, the dermis is oedematous, and a lymphocytic infiltrate (predominantly helper T cells) surrounds the blood vessels and appendages [1,10]. Plasma cells and histiocytes, with some granuloma formation, may also be seen. Later, the oedema and perivascular infiltrate subside and elastic fibres become scanty. The persistence of fine, irregular or twisted elastic fibres is common. The dermal collagen may also be

diminished, but the fragmentation and disappearance of elastic tissue is the essential change, beginning superficially in the subpapillary zone and extending downwards. Electron microscopy shows phagocytosis of elastic fibres by macrophages [34,35].

Clinical features [2]. This rare disorder occurs mainly in women aged 20–40 years, but is occasionally reported in younger and older patients of both sexes. It is perhaps more frequent in central Europe than elsewhere, which suggests a possible relationship to chronic atrophic acrodermatitis (due to *Borrelia* sp.) in some cases. In the most usual form, crops of round or oval, pink macules 0.5–1.0 cm in diameter develop on the trunk, thighs and upper arms, less commonly on the neck and face and rarely elsewhere. The scalp, palms and soles are usually spared. Each macule extends for a week or two to reach a size of 2–3 cm. Sometimes, there are larger plaques of erythema, and nodules have also been reported as a primary lesion [36]. Slowly, each lesion fades and flattens from the centre outwards to leave a macule of wrinkled, atrophic skin, which yields on pressure, admitting the finger through the surrounding ring of normal skin (Fig. 45.13). The colour varies from skin colour to grey, white or blue. The number of lesions varies widely, from less than five to 100 or more. The lesions remain unchanged throughout life, and new lesions often continue to develop for many years. If the lesions coalesce they form large atrophic areas, which are indistinguishable from acquired cutis laxa [2].

In some cases, the lesions are initially urticarial weals which, after a succession of exacerbations and remissions, perhaps continuing for many weeks, are succeeded by atrophy. They may become confluent, to cover large areas, especially at the roots of the limbs and on the neck.

Diagnosis. The white cicatricial lesions of 'white spot disease' (extragenital lichen sclerosus) (Chapter 51) around the base of the neck and shoulders should not be confused with anetoderma.

Histological examination establishes the diagnosis. Focal dermal hypoplasia and atrophic scars (e.g. following varicella) must also be considered.

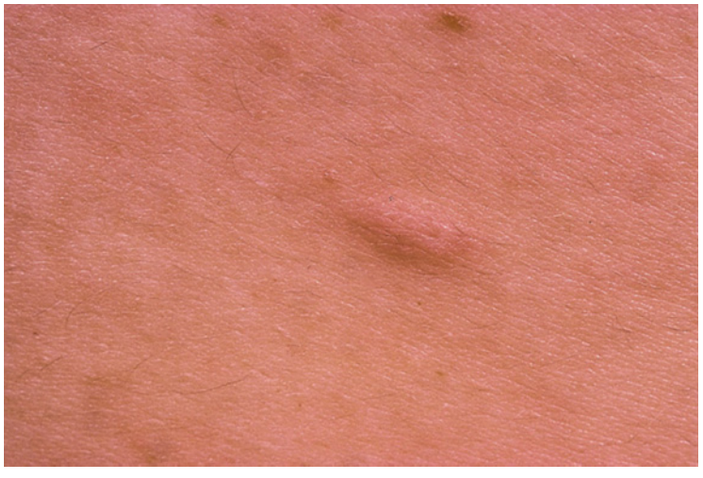

Fig. 45.13 Primary anetoderma. (Courtesy of Dr J. Ellis, Swindon, UK.)

Acquired cutis laxa is probably a variant of anetoderma.

The diagnosis of 'primary' anetoderma can be established only by excluding the presence of any of the diseases known to be associated with 'secondary' atrophy, for example perifollicular elastolysis (p. 45.20).

Treatment. Penicillin and the antifibrinolytic drug ε-aminocaproic acid have been advocated [37], but Venencie *et al.* [2] studied 16 patients and found no treatment was beneficial once the atrophy had developed. Colchicine may prevent some atrophic changes [38]. In patients with primary anetoderma it is important to test for antiphospholipid syndrome and treat appropriately, for example with aspirin.

Other localized forms of elastolysis

Idiopathic mid-dermal elastolysis

Several cases have been described in which idiopathic loss of the elastic fibres in the mid-dermis has led to widespread wrinkling of the crinkle type in an otherwise healthy, young or middle-aged woman (Fig. 45.14) [1,2]. The exact relationship between this condition and other elastolytic disorders, such as acquired cutis laxa (p. 45.16) and anetoderma (p. 45.17), is uncertain.

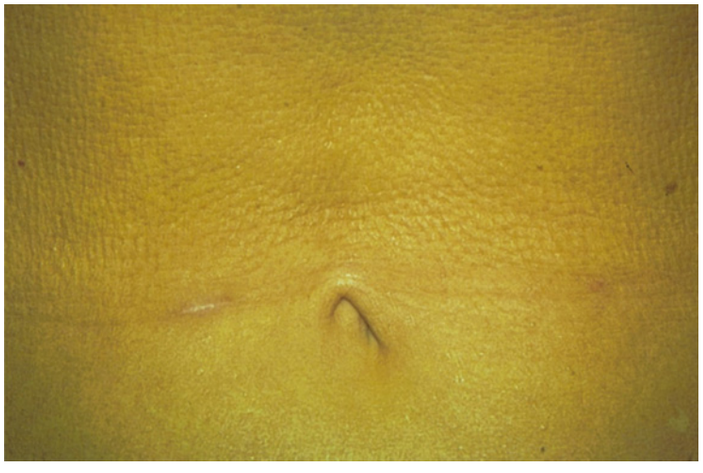

Fig. 45.14 Idiopathic mid-dermal elastolysis. (Courtesy of Dr L. Ostlere, St George's Hospital, London, UK.)

Maghraoui *et al.* [3] have distinguished post-inflammatory elastolysis, with or without features of cutis laxa, from non-inflammatory elastolysis. Inflammatory triggers may include UV radiation, insect bites, borreliosis and acute neutrophilic dermatosis [4]. Localized elastolysis adjacent to varicose veins has also been reported [5].

Ultrastructural studies of mid-dermal elastolysis demonstrate elastic fibres engulfed by macrophages [6]. Immunological studies of affected skin show a non-specific profile of immune activation [7]. Localized areas may clinically resemble PXE, although they are histologically distinct [8,9]. Cultured fibroblasts from lesional dermis exhibit increased elastolytic activity and reduced elastin mRNA compared with normal skin [10].

The histology of idiopathic mid-dermal elastolysis is similar to that of post-inflammatory elastolysis and cutis laxa (PECL), which occurs in young African girls (see below). Those lesions are preceded by inflammatory lesions, but the lesions of idiopathic mid-dermal elastolysis may also occasionally be preceded by erythema, urticaria or a burning sensation, and the two conditions are similar, if not identical.

No definite treatment exists but topical retinoic acid (0.01% gel) produced some cosmetic improvement in one patient [7].

Upper dermal elastolysis

Selective loss of elastic tissue in the papillary dermis has been described in an otherwise healthy 86-year-old woman, who presented with numerous yellowish papules on the neck and upper trunk, and associated coarse wrinkles [1].

Post-inflammatory elastolysis and cutis laxa

PECL is a distinctive severe variant of anetoderma (p. 45.17), which occurs predominantly in black girls living in a tropical climate [1–3]. It has a prolonged course, with relapsing inflammatory

phases lasting for months or years. In the acute phase, there are firm, infiltrated plaques or rings, with a collarette of scale, and these progress to leave a diffuse, fine, wrinkled skin with the appearance of premature ageing. In some cases, most of the body surface may be involved. There is no internal involvement, and no preceding infection, such as syphilis or tuberculosis. Histological examination shows destruction of the elastic fibres in the upper and mid-dermis.

It is thought that PECL is a reaction to arthropod bites because some patients have eosinophilia, other family members may suffer from papular urticaria, the lesions show a predilection for exposed parts and no new lesions develop when the patient is in hospital. There is a resemblance to erythema chronicum migrans (Chapter 30).

Perifollicular elastolysis

Anetoderma-like changes in a perifollicular distribution have been described in three women aged 30–40 years [1]. The lesions were small, grey–white, finely wrinkled, round or oval areas, each with a central hair follicle. Some exhibited a balloon-like bulge above the surface. They occurred on the upper trunk, neck, earlobes and arms. Histology showed a non-inflammatory perifollicular loss of elastin fibres, and it was suggested that the lesions might have been caused by an elastase-producing strain of *Staphylococcus epidermidis* [2]. Similar changes are more commonly seen in acne scars (Chapter 42) [3].

Granulomatous slack skin

Granulomatous slack skin is a rare disease characterized by the slow development of pendulous folds of lax erythematous skin, which on histological examination contains a dense granulomatous dermal infiltrate, with destruction of dermal elastic tissue. It is now considered to be a type of lymphoma (Chapter 57).

Blepharochalasis [1–3]

Definition. Laxity of the eyelid skin due to a defect in the elastic tissue.

Aetiology. The cause is unknown. Most cases are sporadic, but some pedigrees show autosomal dominant inheritance. Some cases may be a localized form of post-inflammatory elastolysis or follow angio-oedema [4].

Fig. 45.15 Blepharochalasis. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Pathology [3]. In the early stages there may be a mild dermal lymphocytic infiltrate, and in the later stages the elastic fibres in the lids fragment and decrease. Normal elastin gene expression suggests other factors may be involved in elastic fibre loss [5]. IgA deposition may be detected on fibres, implying an immunopathogenic mechanism may be involved [6]. Disintegration of collagen fibres has also been observed in one case [7].

Clinical features. Blepharochalasis is an uncommon condition that usually develops insidiously around the time of puberty. Repeated, transient attacks of painless swelling of the eyelids lasting for 2 or 3 days are followed by laxity, atrophy, wrinkling and pigmentation, predominantly of the upper eyelids (Fig. 45.15). There may be multiple telangiectases. These changes produce an appearance of tiredness, debauchery or premature ageing.

Reduplication of the mucous membrane of the upper eyelid is associated with blepharochalasis in about 10% of cases, and this may make the eyelids appear thick.

Blepharochalasis is occasionally a manifestation of generalized cutis laxa, and it may form part of Ascher's syndrome (see below). Laxity of the eyelid skin also occurs in EDS, but other features of this syndrome will also be present. Occasionally, laxity particularly affecting the upper eyelid, occurs in otherwise healthy individuals [8].

Diagnosis. The many other causes of eyelid swelling must be excluded (Chapter 67). Ptosis is easily distinguished because the skin appears normal.

Treatment. Plastic surgery can be performed, but the condition may recur [2].

Ascher's syndrome

Ascher's syndrome is the association of blepharochalasis with progressive enlargement of the upper lip due to hypertrophy and inflammation of the labial salivary glands [1–5]. The lip feels soft and lobulated and there may be excessive salivation. In some cases, the accessory lacrimal glands are also affected, with increased thickness of the eyelids. Enlargement of the thyroid has also been reported.

Pseudoxanthoma elasticum

Synonyms
- Systematized elastorrhexis
- Grönblad–Strandberg syndrome

Definition. PXE is an inherited disorder characterized by generalized fragmentation and progressive calcification of elastic tissue in the dermis, blood vessels and Bruch's membrane of the eye. This leads to laxity of the skin, arterial insufficiency and retinal haemorrhage.

Aetiology. Until recently the basic defect was unknown. Because the pathology affects elastic fibres the genes responsible for elastin and microfibrillary proteins were initially studied, but linkage analysis excluded these early candidate genes [1,2]. Positional cloning identified candidate genes on chromosome 16p13.1 and mutations have subsequently been identified in the *MRP6/ABCC6* gene [3–5]. This is a member of the ATP-binding cassette (ABC) family and acts as a transmembrane transporter. Mutations in the gene affect transport of anionic peptides [6]. *ABCC6* is expressed primarily, if not exclusively, in the liver and kidneys and absence of normal *ABCC6* may allow certain metabolic compounds to accumulate, resulting in progressive calcification of elastic fibres. This suggests that PXE may in fact be a primary metabolic disorder with secondary involvement of elastic fibres [7]. Genotype–phenotype analysis has failed to identify any correlation [8].

The inheritance of PXE has been controversial over the past few years, and historically at least five genetic groups have been described [9–11]. With molecular testing it is now apparent that familial inheritance is autosomal recessive and no confirmed autosomal dominant form has yet been shown [12]. Clinical features of PXE can be seen in unambiguously identified heterozygous carriers, and this, as well as pseudodominance, explains some earlier reports of different clinical types and modes of inheritance.

Pathology [13–19]. In the fully developed skin lesions, the elastic fibres in the mid-dermis are clumped, degenerate, fragmented and swollen, and the abnormal fibres stain positively for calcium. The collagen fibres are also abnormal, being split into small fibres.

Similar changes occur in the connective tissue of the media and intima of the blood vessels, Bruch's membrane of the eye, and in the endocardium and pericardium. The heart may occasionally be enlarged, with extensive calcification [20], and pulmonary calcification has been reported [21]. Calcification may occur in other viscera [22].

The vascular involvement may be generalized but may involve predominantly the larger arteries, the mesenteric and visceral arteries, or those of the extremities [23]. Calcification of the internal elastic lamina of the arteries leads to vascular occlusion. Hypertension, angina, myocardial infarction, cerebrovascular accidents and recurrent mucosal haemorrhages may result. The changes in Bruch's membrane give rise to angioid streaks, and rupture of the retinal vessels to haemorrhages and choroiditis.

The complete syndrome consists of the distinctive skin lesions, retinal changes (angioid streaks) and vascular disturbances. The characteristic skin changes and angioid streaks have also been reported as isolated findings, but this is unusual, and in ten patients with angioid streaks but no obvious skin abnormalities, a biopsy of scar tissue, regardless of site, was diagnostic of PXE in six patients, with three also having histological changes in elastic tissue in normal-appearing flexural skin [18]. The relatively low yield from biopsy of normal-looking axillary skin of patients with PXE at other skin sites has also been demonstrated [24].

Skin changes. The skin lesions are characteristic. They consist of small (1–3 mm), yellowish papules in a linear or reticular pattern, in confluent plaques, although the changes are sometimes very subtle. The skin is soft, lax and slightly wrinkled, and may hang in folds, especially in elderly people. There may be a slightly pebbly surface, which has been variously described as a 'cobblestone', 'Moroccan leather' or 'chicken skin' appearance (Fig. 45.16). The sites of predilection are the sides of the neck, below the clavicles, the axillae (Fig. 45.17), abdomen, groins, perineum and thighs. Reticulate pigmentation on the abdomen may occur [25]. Numerous acneiform lesions have been reported [26]. Although usually limited, the eruption may occasionally involve most of the body. It may develop in early childhood, and usually does so before the age of 30 years, but it may also first appear in old age. It usually persists unchanged indefinitely. Similar changes may occur in the soft palate, inside the lips and in the mucous membranes of stomach, rectum and vagina. In the mouth, the lesions may mimic sebaceous glands (Fordyce spots). Rarely, chronic granulomatous nodules have developed in the skin lesions [27].

Fig. 45.16 Pseudoxanthoma elasticum, showing the typical 'chicken skin' appearance involving the neck.

Fig. 45.17 Pseudoxanthoma elasticum of the axilla, showing the characteristic yellow discoloration of the skin and the loose folds. The changes in this condition are often much more subtle than in this patient.

Occasionally, there may be spontaneous perforating lesions, with transepidermal elimination of the fragmented elastic fibres. These present as hyperkeratotic papules, which leave a bleeding surface when dislodged.

The presence of an exaggerated mental (chin) crease has recently been shown to be a sensitive and highly specific finding in patients under the age of 30 years with PXE [28].

Fig. 45.18 Angioid streaks of the retina in pseudoxanthoma elasticum. (Courtesy of Professor D. Easty, Bristol Eye Hospital, Bristol, UK.)

Cardiovascular changes. The arteries throughout the body are affected. There may be intermittent claudication with diminished peripheral pulses, and there is accelerated atheroma, often with hypertension [29]. The circulatory disturbances are detectable by plethysmography or oscillometry, and angiography may show angiomatous malformations, aneurysmal dilatation, and narrowing or occlusion of peripheral or visceral arteries [30]. Signs of arterial degeneration may be seen by the age of 30 years, and death may result from cerebral haemorrhage, coronary occlusion or massive haemorrhage into the gut [31]. Cardiomyopathy has been reported [32,33].

Arterial involvement may not be clinically manifest until adult life, but intermittent claudication and angina have occurred in early childhood. Some patients, however, survive to old age.

Mitral valve prolapse occurs in about 5–8% of the normal population. In one series of 14 patients with PXE, 11 had mitral valve prolapse [34], but these individuals probably had an overlap with Marfanoid features [35].

Ocular changes. Angioid streaks [36,37] of the retina are seen as slate-grey, poorly defined streaks radiating from an incomplete greyish ring surrounding the nerve head (Fig. 45.18). They are bilaterally symmetrical, and usually first appear between the ages of 20 and 40 years. There may be no impairment of vision, but progressive visual failure may occur, and haemorrhages and choroiditis occasionally result in total blindness.

Other associated ocular findings include small, raised, pearly white *drusen*, or punched-out atrophic areas in focal areas of dehiscence of Bruch's membrane [38]. There may also be speckled yellowish mottling at the posterior pole, and this change, which has been called 'leopard spotting', may antedate the angioid streaks [39]. About 50% of patients also have a random scattering of small, round pigment dots throughout the macula and optic nerve [40]. These may resemble a string of pearls in some cases, and they are best seen on fluorescein angiography.

Abnormal visibility of the choroidal vessels has been present in some apparently unaffected members of some families with PXE [41].

Obstetric risk. There is an increased risk of miscarriage in the first trimester, possibly related to failure of placental development [42], and abdominal striae develop during pregnancy in virtually all patients [43]. Opinions differ regarding the risk to the mother. Berde *et al.* [44] reviewed the literature and concluded that there was a serious risk of cardiovascular complications during pregnancy, but Viljoen *et al.* [43] reported 54 pregnancies in which there were no serious maternal complications. Subsequent reports also agree that although skin manifestations may worsen, the risks of pregnancy have been overstated [45].

Associated abnormalities. In most cases of PXE the serum calcium and phosphate levels are normal, but in a few patients the phosphate levels are increased, with mild hypercalcaemia and abnormalities of vitamin D metabolism [22,46]. The biochemical changes resemble those of tumoral calcinosis [47], although the clinical changes are those of PXE. This seems to be a distinctive, rare type of PXE which may be associated with renal failure in other members of the family. Some of these patients also have systemic sclerosis [48].

Other patients have been reported with multiple, calcified cutaneous nodules, with angioid streaks and hyperphosphataemia, but without pseudoxanthoma [49].

Skin changes of PXE and/or angioid streaks are occasionally seen in patients with osteitis deformans (Paget's disease). Pseudoxanthoma elasticum has also been reported in association with osteoectasia, which is characterized by dwarfism, bizarre radiographic changes and elevated serum alkaline phosphatase levels [50].

The development of both clinical and histopathological PXE-like changes, involving skin, eyes and vasculature, in sickle cell disease and β-thalassaemia has been well documented [51]. The abnormalities are most probably acquired and related to the consequences of the primary disease. The clinical features are of later onset and milder than in inherited PXE.

The typical features of PXE have been reported in a patient with true Marfan's syndrome, but it is likely that this is a chance association [52].

A group of patients with PXE-like phenotype with cutis laxa and deficiency of vitamin K-dependent clotting factors has been identified without causal mutations in *ABCC6* or *VKORC1* (vitamin K 2,3 epoxide reductase) [53]. This suggests a separate clinical and genetic entity.

Diagnosis. The clinical and histological changes of PXE are often distinctive, and the diagnosis is usually readily made when skin lesions are present. The disseminated form of dermatofibrosis lenticularis (Buschke–Ollendorff) can be clinically similar, and juvenile elastoma, which is a feature of this condition, shows thickened elastic fibres on histology. If laxity of the involved skin is extreme, other forms of dermatochalasis must be excluded.

In cases without skin lesions the diagnosis may be difficult, and attempts have been made to establish diagnostic criteria [1,19]. These are summarized in Table 45.2. It should be suspected in obliterative arterial disease of early onset and in unexplained gastrointestinal haemorrhage. The presence of angioid streaks or mucosal lesions should be sought. A skin biopsy from the side of the neck may be helpful, even if there are no clinically evident changes, although the characteristic histological changes are not necessarily diagnostic [18,19]. The diagnosis can be difficult in the presence of marked solar elastosis and/or macular degeneration [54]. Soft-tissue or vascular calcification may be detectable radiologically [55], and angiography may be helpful [30]. Ultrasonography can detect early renal parenchymal calcification, although its prognostic significance remains uncertain [56].

Table 45.2 Diagnostic criteria for pseudoxanthoma elasticum (PXE). (From Lebwohl *et al.* [19].)

Major criteria

1 Flexural yellow cobblestone lesions

2 Characteristic histological features of lesional skin, using elastic tissue and calcium stains (e.g. van Gieson and von Kossa)

3 Angioid streaks in the retina

Minor criteria

4 Characteristic histological changes in non-lesional skin

5 Family history of PXE in first-degree relatives

Definitive diagnosis is made by molecular analysis of the *ABCC6* gene. This also provides a means for prenatal and presymptomatic testing in families at risk for recurrence [7,8]. Emerging evidence also suggests that heterozygosity for an *ABCC6* mutation (*R1141X*) confers a fourfold risk of developing coronary artery disease [57].

Treatment. It is important that the condition is accurately diagnosed so that appropriate genetic advice may be given. The most important aspect of treatment is to ensure that complications from vascular involvement are prevented or dealt with speedily by the appropriate specialist. Ophthalmologists will recommend that the patient learns to use an Amsler grid in the early detection of visual loss. Patients should avoid any activity that might cause sudden increase in blood pressure or contact injury to the eyes. Laser photocoagulation may be helpful in preventing further retinal haemorrhage. Cardiovascular risks should be minimized with control of blood pressure and serum lipids, and avoidance of smoking. The cosmetic appearance of the skin lesions may be improved by plastic surgery. Restriction of dietary calcium has been tried, with apparent benefit in some cases [47], but this treatment remains controversial.

Acquired PXE-like syndromes

Perforating PXE

Synonym
- Perforating calcific elastosis

Transepithelial elimination (TEE) of altered elastic fibres can occasionally occur in generalized hereditary forms of PXE (see above), but it can also occur as a localized, acquired defect in patients who do not have the other features of PXE [1]. These localized lesions usually occur in the periumbilical area in obese, multiparous black women, and it is possible that this represents a response to repeated cutaneous stretching, for example ascites or previous abdominal surgery [2,3]. Similar lesions on the breast have been reported in patients undergoing haemodialysis [4,5].

Clinically, asymptomatic yellow macules and papules coalesce into well-demarcated, hyperpigmented plaques which slowly enlarge. The surface may be atrophic, grooved, fissured or verrucous, and compression of the edge of the lesion may produce a liquid discharge.

It seems likely that most cases previously described as elastosis perforans serpiginosa in association with PXE were really examples of perforating PXE [6]. The histology of the two conditions is similar, but in perforating PXE there is TEE of altered basophilic, calcified, elastic fibres, which are short, fragmented, curled and predominantly in the mid-dermis, whereas in elastosis perforans serpiginosa the fibres are abnormally large, non-calcified, eosinophilic and straight.

Spontaneous resolution has been reported [7].

Pseudo-PXE

Skin changes which are virtually identical to those of PXE can rarely be produced by penicillamine, although the systemic features do not occur [1]. The skin changes can be explained by the known effect of penicillamine in inhibiting collagen and elastin cross-linking, with the production of vastly increased amounts of abnormal elastin in the dermis [2]. Transepidermal extrusion of elastin has been reported in this condition [3]. Lesions clinically resembling PXE are reported in the eosinophilia–myalgia syndrome; dermal calcification is absent on histology [4]. Yellowish papules and plaques resembling PXE are seen in some patients with amyloidosis; amyloid deposits are seen and, again, dermal calcification is absent [5,6].

Saltpetre disease [1–3]

A condition which resembles the skin changes of PXE clinically, histologically and ultrastructurally has been described in a group of elderly farmers, who decades earlier had spread a fertilizer containing calcium-ammonium nitrate (Norwegian saltpetre). The patients developed cutaneous ulcers at sites of exposure (including antecubital fossae). These quickly healed to leave yellowish-white papules and plaques. None of the patients had a positive family history or other signs of PXE.

Williams–Beuren syndrome

The Williams–Beuren syndrome is a developmental disorder characterized by premature laxity of the skin, congenital heart disease (notably supravalvular aortic stenosis), metabolic abnormalities and dysmorphic facial features, which include baggy connective tissue around the eyes, full cheeks, prominent lips and dental malocclusion [1]. Delayed motor and perceptual development are sometimes masked by above-average language skills allied to a 'cocktail party' personality [2].

In situ hybridization techniques have revealed both inherited and new deletions at the elastin locus on chromosome 7q11.23 [3]. Size heterogeneity of the deletion exists, with multiorgan involvement as a consequence of contiguous gene deletions. At least 24 genes may be involved in the critical region [4]. Only the elastin gene deletion is associated with a specific phenotype (supravalvular aortic stenosis). An 'epidemic' of the Williams' syndrome was reported in the UK following the administration of excessive doses of vitamin D to prevent rickets in pregnant women [5]. Vitamin D is known to downregulate elastin gene expression [6].

Linear focal elastosis

Synonym

- Elastotic striae

This condition is characterized by asymptomatic, yellow, linear bands arranged horizontally on the lower back [1–4]. It less commonly occurs on the lower limbs and shoulders. Superficially, the lesions resemble striae distensae, but they are palpable rather than

depressed and yellow rather than purplish or white. Although the two conditions are generally unrelated, linear focal elastosis has been reported adjacent to striae distensae [5], and in one case following potent topical corticosteroids [6]. The condition was originally described in elderly males [1], although it has been reported in a young black male whose father was similarly affected [7]. It may be commoner than is suggested by the paucity of reports. Ultrastructural studies reveal active elastogenesis. The middle and lower dermal collagen is separated by bluish grey, fine, fibrillar material, which is composed of thin, wavy elastic fibres and fragmented elastic fibre bundles. Early lesions may, in contrast, show elastolysis, with decreased elastin and microfibrillar proteins [8]. The elastic fibres are near to, or even in contact with, fibroblasts [9], and elastogenesis may occur in response to local trauma, ultraviolet light or perhaps following the development of striae distensae [10]. However, these mechanisms do not adequately explain the increasing number of cases reported, particularly in the young, and it may be that intrinsic defects of elastic fibre metabolism play a role [4].

Late-onset focal dermal elastosis

Yellowish papules with a *peau d'orange* appearance appear on the flexures. Clinically and histologically the lesions resemble elastomas, but this rare condition has only been reported in elderly Japanese men [1,2].

Actinic elastosis

Synonym
- Solar elastosis

Definition. This is a degenerative change in the dermis caused by prolonged exposure to electromagnetic (usually solar) radiation. It is characterized clinically by yellowish discoloration and histologically by degeneration of elastic fibres.

Aetiology. Actinic elastosis usually results from prolonged exposure to sunlight, but it can also result from infrared (IR) radiation [1,2]. It is related to the cumulative dose of radiation, as it is more common in older people, outdoor workers and in sunny climates. There is, however, considerable variation in susceptibility between individuals. Fair-skinned people are the worst affected, although the condition can occur in black people [3,4]. Severe elastosis may occur in photosensitized skin, for example in porphyria cutanea tarda. UVB wavelengths are the most likely to cause solar elastosis, although UVA and PUVA therapy can also accentuate it [5,6].

Ageing normal skin becomes atrophic, with fewer elastic fibres [3]. In contrast, sun-damaged ('photo-aged') skin exhibits hypertrophy of elastic tissue, secondary to a prolonged inflammatory process [7]. Skin on the back of the neck exposed to chronic UV radiation shows partially degranulated mast cells in close apposition to fibroblasts. Metalloproteinases produced by mast cells and macrophages degrade skin collagen [8].

Pathology [9,10]. At an early stage, there is a perivenular lymphohistiocytic infiltrate, with degranulating mast cells [7,11]. The vessel walls become thickened due to deposition of a basement-membrane-like material [4]. The elastic fibres of the upper and middle dermis then become curled and fibrillar to form thick, irregular masses [12]. At a later stage, the elastotic degeneration becomes more diffuse, forming long, swollen bands of irregular texture, with finely granular elastin and dense microfibrillar masses. Actinic elastosis originates in elastic fibres rather than collagen, as shown by the findings that the abnormal fibres stain with antielastin antibody HB8, disappear with elastase but resist collagenolytic enzymes, and have a high desmosine content.

In the early stages of actinic elastosis, there is also an increase in collagen and in glycosaminoglycans, although ultimately fibrillar (types I and III) procollagens decrease. Anchoring fibrils (collagen type VII) and the fibrillin-rich microfibrils at the dermoepidermal junction are also reduced [13–15]. Collagenolytic enzymes, notably matrix metalloproteinase-I, are increased [16]. Eventually, the fibrous network degenerates into an amorphous, elastotic mass, and the dermal blood vessels become sparse and tortuous [3,4]. Increased dermal glycosaminoglycans are deposited on the elastotic material in the superficial dermis [17].

Clinical features. The condition is more common in later life. In temperate climates, it is rare before the fourth decade, but it starts earlier and is more severe in sunnier climates. The light-exposed areas are affected, particularly the forehead and the back of the neck. Mild degrees of elastosis may not be apparent until the skin is pinched up, when it may assume a wrinkled appearance. Elastosis is usually more advanced in the tissue than the clinical appearance would suggest.

The affected skin is diffusely thickened and yellowish (Fig. 45.19), and on the neck it may be divided by well-defined furrows into an irregular rhomboidal pattern (cutis rhomboidalis nuchae). There may also be more sharply marginated, thickened plaques on the face or neck. These are usually, but not always, symmetrical.

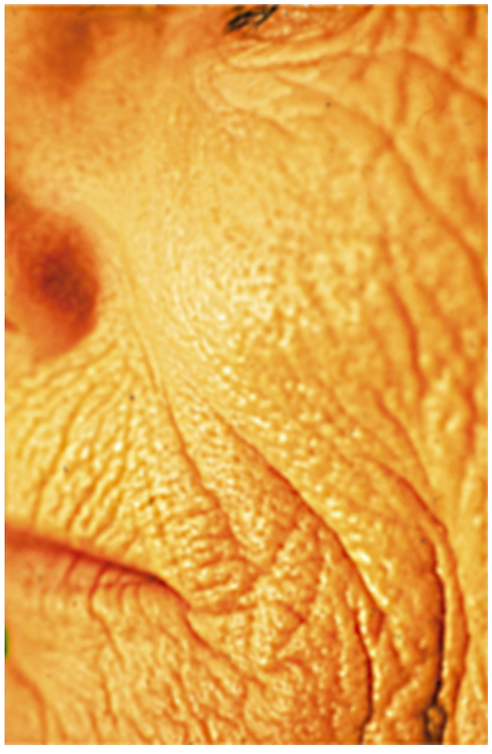

Fig. 45.19 Actinic (solar) elastosis, showing the characteristic yellowish discoloration, thickening and wrinkling of the facial skin.

When the skin around the orbits is affected, it is often studded with numerous comedones, and this has been called the *Favre–Racouchot syndrome* (Fig. 45.20). Favre–Racouchot syndrome is usually confined to facial skin and is bilaterally symmetrical, but unilateral and circumscribed forms have been reported [18]. The term actinic-comedonal plaque has been suggested for similar lesions which can rarely occur on other parts of the body, such as the forearm [19,20].

Skin which is affected by actinic elastosis is likely to develop other signs of sun damage, including irregular pigmentation, wrinkling, scaling, solar keratoses and malignancy. This range of changes due to chronic sun damage has been called *dermatoheliosis* [21].

Actinic elastosis may also be complicated by actinic granuloma (see below).

Photodamage is markedly exacerbated in smokers [22].

Diagnosis. Plane xanthoma, PXE and colloid milium may sometimes cause confusion, but the combination of the clinical and histological features is distinctive.

Treatment. Sunscreens protect against the development of photodamage both in humans and animals [23]. In hairless mice exposed to UVB radiation, synthesis of subepidermal collagen has been demonstrated in animals protected with a sunscreen [24]. Topical application of α-hydroxy acids ('fruit acids'), that is lactic, glycolic and citric acids, led to a modest improvement in photodamaged skin [25]. More impressive results have been obtained with topically applied tretinoin cream [26–28]. A double-blind study [29] demonstrated a decrease in papillary dermal collagen type I in photodamaged skin, and subsequent treatment with 0.1% tretinoin cream for 10–12 months resulted in an 80% increase in dermal collagen. Several studies have shown clinical and histological improvement after prolonged use [23]. Tretinoin may also repair skin changes due to intrinsic ageing [29,30]. Retinoids reduce MMP-1 expression *in vitro*, partially restoring levels of fibrillin-1 and collagens I and VII in the papillary dermis [27,31]. Similar results have been obtained in double-blind trials of topical isotretinoin [32] and tazarotene cream [33]. There has been interest in the use of so-called non-ablative lasers, including the 1320-nm Nd:YAG and 1540-nm erbium glass lasers, which are claimed to wound the upper dermis without epidermal damage [34]. Restoration of fibrillin-I in the microfibrillar network of the papillary dermis may prove a useful 'biomarker' for the efficacy of topical products used in the treatment of actinic elastosis [35,36].

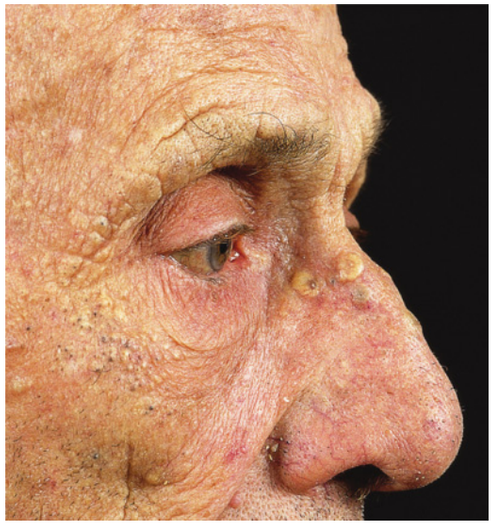

Fig. 45.20 Favre–Racouchot syndrome, showing comedones and actinic elastosis. (Courtesy of Professor R. Marks, St Vincent's Hospital, Melbourne, Victoria, Australia.)

Elastotic nodules of the ear

In this variant of actinic elastosis, single or multiple firm papules occur on the anterior crus of the antihelix, usually in middle-aged or elderly males. Sometimes lesions have a pearly edge, clinically suggesting BCC, but histology reveals large aggregates of amorphous elastotic material, sometimes with degradation of underlying cartilage [1,2].

Digital papular calcific elastosis

Synonyms
- Keratoelastoidosis marginalis
- Collagenous and elastotic marginal plaques of the hands

Digital papular calcific elastosis (DPCE) is an acquired papular eruption in which keratoderma is associated with changes in dermal connective tissue. Predominantly it affects the radial aspect of the index finger, first web space and ulnar aspect of the thumb on the dominant hand [1,2]. Histologically there is hyperkeratosis, with sawtoothing of the rete ridges. The dermal collagen fibres are thickened and arranged haphazardly; there are basophilic elastotic masses, often containing calcium, in the upper reticular dermis [3]. Cases are sporadic, unlike the clinically similar disorders acrokeratoelastoidosis and focal acral hyperkeratosis (Chapter 19) [4]. Chronic friction and photodamage have been proposed as aetiological factors; the condition has been reported in manual workers and entirely from geographical areas with high solar irradiation. Digital papular calcific elastosis has been regarded as a variant of actinic elastosis [5], although actinic damage is not always observed clinically [6]. Furthermore, in DPCE, the elastotic process relatively spares the papillary dermis, and the basophilic areas containing calcium differ from the changes in actinic elastosis. Squamous carcinoma has been reported, arising from the lesion [7].

Actinic granuloma

Synonym
- O'Brien's granuloma

Definition. This is an annular inflammatory reaction with a giant cell dermal infiltrate, which develops in an area of actinic elastosis. Some authors feel that this is not a specific entity, and the changes could be a feature of granuloma annulare or some other granulomatous disease that happens to occur on light-exposed skin [1]. Others point out that a similar granulomatous reaction to elastotic material can occur in pinguecula of the eye [2]. Histopathological studies support histological distinction of the two conditions [3–7]. There is minimal or no lysozyme activity in the histiocytes in the inflammatory area of actinic granuloma, in contrast with those of granuloma annulare, which exhibit abundant lysozyme activity [4].

The condition is more common in sunny countries, and fair-skinned or freckled subjects are particularly susceptible. It has been associated with doxycycline photosensitivity [8]. A similar condition has been described in dark-skinned people under the name of granuloma multiforme (Chapter 60).

Pathology [3–7]. A biopsy taken radially across the thickened edge of the lesion shows three distinct zones in the dermis. In the external 'normal' skin, there is actinic elastosis. In the thickened annulus, there is a histiocytic and giant cell inflammatory reaction in relation to elastotic fibres, and in the centre, within the annulus, little or no elastic tissue remains. The cellular infiltrate slowly expands outwards, leaving behind a central area from which elastic fibres have been removed by 'elastoclasis'.

The epidermis may be normal or it may show signs of actinic damage.

Clinical features. Lesions develop in the exposed 'weather-beaten' skin of patients after the third decade, particularly in fair-skinned or freckled subjects. They start insidiously as small, pink papules, which progress slowly to form an annulus of firm, superficial, dermal thickening. This is smooth, slightly raised and measures 0.2–0.5 cm in width. The ring may expand up to 6 cm in diameter. The centre may become slightly atrophic, and variable depigmentation may occur. The lesions are usually asymptomatic, but a sunburn reaction may provoke severe erythema and irritation.

Diagnosis. The condition must be distinguished from granuloma multiforme, granuloma annulare, serpiginous perforating elastosis, Miescher's disciform granuloma, sarcoidosis and necrobiosis lipoidica. The lesions of actinic granuloma are confined to light-exposed skin, and the infiltrate lacks the tidy palisaded arrangement that is normally seen with granuloma annulare. Rarely, granuloma annulare can occur in an actinic distribution [9].

Treatment. Infiltration of the annular edge of the lesions with triamcinolone may be effective. Sunscreens should be used to prevent further damage.

Isotretinoin (0.5 mg/kg/day) [10] and acitretin 25 mg/day [11] arrested the development of lesions in elderly males.

Elastofibroma [1–5]

Elastofibroma occurs predominantly in elderly women. Most cases are reported from Southern Japan. There may be a history of prolonged manual labour. The painless or slightly tender swelling situated beneath the lower angle of the scapula, and from 2 to 10 cm in diameter, is often discovered fortuitously. It may enlarge slowly, displacing neighbouring structures, and it can be clinically confused with a sarcoma. This is a benign lesion, however, despite the fact that it is poorly circumscribed. The growth is composed of mature fibrous tissue, containing fibres which stain as elastic fibres. The lesions may be solitary or multiple.

Histologically, the lesion contains abundant, large elastic fibres, some broken into irregular masses, and large amounts of relatively acellular collagen. The elastic fibres are composed of true elastin surrounded by a large amount of hydrophilic material forming an orderly array of tubules [4]. It is generally regarded either as a type of reactive hyperplasia, or as a hamartoma, arising either from dermis, subscapular connective tissue or periosteum [6]. It is cured by simple excision [7].

Elastoderma

Elastoderma is a very rare condition which is due to excessive elastogenesis, as distinct from acquired cutis laxa, where there is a loss of elastic tissue. A young woman developed a localized

defect of the skin of one arm, which became pendulous and lax, but lost its elastic recoil. Histological and biochemical investigation showed this was due to accumulation of excessive elastin, with derangement of elastin fibrillogenesis [1].

In a further case, clinically uninvolved skin showed thin elastic fibres on haematoxylin and eosin staining [2].

Marfan's syndrome (MFS)

Definition. This is an autosomal dominant inherited disorder of connective tissue with variable clinical manifestations, both between and within families, and a prevalence of one in 5000–10 000 [1]. Up to 30% of cases are new mutations [2]. The full syndrome is characterized by aortic dilatation, ectopia lentis and skeletal abnormalities [3].

Aetiology. Mutations in the fibrillin-1 (*FBN1*) gene, located on chromosome 15q21.1, cause Marfan's syndrome [4]. Fibrillin is one component of the elastin-associated microfibrils, which are especially important in the ciliary zonule of the eye (the suspensory ligament of the lens). Patients with MFS show a striking lack of fibrillin in their skin and on culture of their dermal fibroblasts [5,6]. It has recently been recognized that changes in growth factor signalling are critical in MFS. As well as its structural role, fibrillin-1 also binds transforming growth factor β (TGF-β), and abnormal fibrillin leads to a detrimental increased expression of TGF-β [7]. In addition, a number of disorders with phenotypic overlap with MFS, for example Loeys–Dietz syndrome, are caused by mutations in the TGF-β receptor genes, *TGFBR1* and *TGFBR2* [8].

Pathology. The cardiovascular lesions are the most important. Fragmentation and sparsity of elastic fibres, with accumulation of mucinous material, occur in the media of the aorta [9–11]. These changes lead to aortic incompetence, dissecting aneurysm, or rupture of the aorta [12]. Mitral incompetence is common [13]. Dermal elastic fibres are narrower than normal and more resistant to neutrophil elastase [14]. Mild to severe degenerative changes in elastic tissue are also seen in the lungs [15].

Clinical features [3,10,16,17]. Despite recent advances in mutation detection, the diagnosis of MFS is primarily clinical and relies on the Ghent nosology [3]. The full syndrome comprises skeletal, ocular and cardiovascular defects. The patient is often, but not invariably, exceptionally tall, and the skeletal proportions are abnormal. The limbs are long, the excess being greatest distally, giving rise to arachnodactyly, and the length of the hallux is often particularly conspicuous. The skull is dolichocephalic, the paranasal sinuses are large and the palate high and arched [18]. Lax capsules result in unstable or hyperextensible joints, kyphoscoliosis, pectus excavatum and flat foot. Muscles may be underdeveloped and hypotonic, and subcutaneous fat is sparse.

The common ocular abnormalities [19] include ectopia lentis (usually upward), a trembling iris, myopia and retinal detachment; less frequent are blue sclerae and heterochromia of the iris.

Aneurysmal dilatation of the ascending aorta is the most important abnormality of the cardiovascular system, and aortic and mitral incompetence are common. Aortic dilatation may begin in childhood. Mitral valve prolapse occurs in 80% of cases [20].

Skin changes may be under-reported. Serpiginous perforating elastosis may occur [17]. In a recent study [21], striae atrophicae were observed in 7% of children and 35% of adults. Other features include papyraceous scars and skin hyperextensibility [22]. Several patients have been described with concomitant EDS and MFS [23].

Other abnormalities are frequent—nerve deafness occurs in 6%; pulmonary malformations are often reported at autopsy; renal abnormalities are manifest as proteinuria and raised blood urea [16].

The prognosis is related to the severity of the cardiac defects, the localization and progression of which are dependent on haemodynamic stresses [10,24]. Survival beyond the fifth decade is unusual, and some cases die in childhood. The average age at which dissection of the aorta develops is 30 years. Early death from cardiovascular disease may occur, even in apparently mild cases, and the correlation between cardiac and skeletal problems is poor [25–27].

Diagnosis [3,28]. The full syndrome is unmistakable, but diagnostic certainty is impossible in the partial forms. Clinical features are divided into major and minor according to their specificity. To make a diagnosis major criteria must be present in two organs and involvement in a third is required [3].

Simple screening tests that may be helpful include the thumb sign (positive if the thumb when completely opposed in the clenched hand projects beyond the ulnar border), the wrist sign (positive if the thumb and little finger overlap when wrapped around the opposite wrist) and the ratio of the lower segment (pubic ramus to floor) to the upper segment (height minus lower segment), but this ratio varies with age and sex.

Some tall people have high, arched palates and some degree of arachnodactyly. This is probably of no consequence in many cases, although a marfanoid habitus in women may be associated with mitral valve prolapse [20,29].

Joint hypermobility may also be associated with mitral valve prolapse [30]. Other causes of joint hypermobility, such as homocystinuria, may be confused with the partial forms of the syndrome. Homocystinuria should be considered in marfanoid patients with myopia or downward ectopia lentis. Urine screening is unreliable; blood levels of methionine and homocysteine should be measured. Prompt diagnosis and treatment reduce the risk of coronary artery or cerebrovascular thrombosis [31].

The marfanoid habitus has been reported in association with distal pigmentation, neuroma of the eyelids and tongue, medullary carcinoma of the thyroid and phaeochromocytoma [32] (see also multiple endocrine neoplasm syndrome (Chapter 62)).

Congenital contractural arachnodactyly is another fibrillinopathy, which is caused by mutations of the fibrillin-2 gene [33]. It is primarily an orthopaedic condition unrelated to MFS [34,35]. It produces multiple joint contractures, arachnodactyly, kyphoscoli-

osis, distorted pinnae and dolichostenomelia (long, thin limbs), but there are no cardiovascular complications.

Management [28]. Patients should be seen by an ophthalmologist and an orthopaedic surgeon, and they should be reviewed regularly by a cardiologist. Beta-blockers may be used to retard the development of aortic dilatation, and surgical replacement before the diameter exceeds 5.5–6.0 cm is recommended [11,36]. Losartan, an angiotensin II type I receptor antagonist has anti-TGF-β effects and, if administered postnatally to fibrillin-deficient mice, reverses aortic root dilatation [37]. Trials are underway to determine whether similar effects can be observed in young patients with Marfan's syndrome.

Oestrogen therapy has been used to prevent excessive stature in female patients [38].

Pregnancy is inadvisable, because of the 50% risk of inheritance in the fetus, and because of the risk of acceleration of aortic degeneration and vascular rupture. A pregnant patient with no cardiac signs needs monthly checks from the third month. Those with aortic or mitral valvular disease or dilatation of the aortic root are at high risk during pregnancy [39,40].

The majority of *FBN1* mutations are unique to one affected individual or family, but despite this and the presence of sporadic cases, prenatal and preimplantation diagnosis is feasible [2].

Disorders of collagen

Ehlers–Danlos syndrome

Synonym

- Cutis hyperelastica

Definition. Ehlers–Danlos syndrome (EDS) is a heterogeneous group of inherited disorders of connective tissue. Estimates of its prevalence vary between 1:560 000 and 1:5000 [1]. For many patients the symptoms are so mild that they may not be recognized. The hallmarks of EDS are fragility of the skin and blood vessels, hyperextensibility of the skin and joint hypermobility [2]. The original classification divided EDS into 11 clinical types; however, in 1986, the International Nosology of Heritable Disorders of Connective Tissue redefined EDS into subtypes I–VIII and X [3]. It is now clear that certain phenotypic subtypes (EDS types I and II) overlap and some patients do not fit neatly into one category. Progress in molecular biology has been rapid in recent years, enabling further subdivision of some types [4].

Aetiology. Specific molecular and biochemical abnormalities have been identified in several types (Table 45.3) [5,6]. Attempts should be made to delineate the clinical, biochemical and, if possible, molecular abnormalities in a patient with EDS in view of the widely differing prognosis between different types. Defects predominantly involve collagen, although a fibronectin defect has been reported in type X [7], and most recently mutations in tenascin-X have been found to cause a newly recognized autosomal recessive form of EDS.

Pathology [8,9]. Skin histology is variable and often within normal limits. Typically, there is a loose, disordered dermal collagen network. Elastic fibres are usually increased and orientated irregularly. The 'pseudotumours' seen in classical EDS (type I) consist of fat and mucoid material in fibrous capsules; they may be calcified. Bone mineralization is decreased, and the collagen fibres are irregular. Adventitial defects of small arteries and inadequate support from the surrounding connective tissue account for the vascular vulnerability in vascular EDS (type IV) [10,11]. Although bruising can be explained on the basis of skin and blood vessel fragility, a few patients also exhibit both ultrastructural and functional platelet defects [12,13]. Clotting factor deficiencies have

Table 45.3 Clinical and molecular subtypes of Ehlers–Danlos syndrome.

EDS type	Synonym	Villefranche classification*	Mode of inheritance	Clinical features	Ultrastructural findings	Molecular defect
I II	Gravis Mitis	Classical	AD	Soft, velvety, hyperextensible skin; easy bruising; atrophic scars; hypermobile joints; pseudotumours	'Cauliflower' fibrils	*COL5A1* & *COL5A2* (& *COL1A1*) mutations
III	Hypermobile	Hypermobility	AD	Hypermobile joints; minimal skin abnormality	As above	?
IV	Acrogeric or ecchymotic	Vascular	AD	Thin skin; easy bruising; small joint hypermobility; vascular and bowel ruptures	Small variable fibrils	*COL3A1* mutations
V	X-linked	Other form	XLR	Resembles mild classical type; bruising more pronounced	—	?
VI	Ocular-scoliotic	Kyphoscoliosis	AR	Soft, hyperextensible skin; hypermobile joints; scoliosis; ocular fragility; keratoconus	Small collagen bundles; fibrils normal or similar to classical type	Lysyl hydroxylase *(PLOD)* mutations
VIIA, B	Arthrochalasis multiplex congenita	Arthrochalasis	AD	Floppy infant; congenital hip dislocation; hypermobile joints; soft skin; normal scarring; short stature	Angular fibrils	A & B: *COL1A1* & *COL1A2* mutations, respectively, result in loss of exon 6 (procollagen *N*-proteinase/ *ADAMTS2* cleavage site)
VIIC	Dermatosparaxis	Dermatosparaxis	AR	Markedly hypermobile joints; very soft and extremely fragile skin; easy bruising	Hieroglyphic fibrils	Procollagen *N*-proteinase (*ADAMTS2*) mutations
VIII	Periodontal	Other form	AD	Severe periodontitis; pigmented pretibial plaques and scarring	Small fibrils in some patients	Occasionally collagen III deficient
X	Fibronectin	Other form	AR	Similar to mild classical type	Large, irregular fibrils	Fibronectin deficiency abnormality
—	Progeroid	Other form	AR	Atrophic scars; lax skin and joints; aged appearance; short stature; osteopenia; mental retardation	—	*XGPT1* mutations
—	Tenascin-X	—	AR	Similar to mild classical type but no scarring	Normal fibrils but reduced density	Tenascin-X mutations

* The Villefranche classification simplifies EDS into six major types. The other types have been provisionally grouped under 'other forms' until more is known about their molecular basis.

AD, autosomal dominant; AR, autosomal recessive; EDS, Ehlers–Danlos syndrome; XLR, X-linked recessive.

been only rarely reported. Electron microscopy of dermal collagen consistently shows irregularities of fibril shape and size, although reliable subclassification of the more common subtypes is not possible [14]. Tenascin-X deficient patients have uniform collagen fibrils which are less densely packed and not as well aligned [15]. In contrast, arthrochalasia type EDS is characterized by angular fibrils in cross-section, and dermatosparaxis by grossly distorted, hieroglyphic fibrils. Biomechanical studies confirm increased skin elasticity and hyperextensibility, particularly in classical EDS (type I) [16,17].

Clinical features. These are summarized in Table 45.3. The india-rubber men and circus contortionists who are affected by EDS turn the syndrome to their advantage. More details are given in the accounts of each type.

Classical type (EDS I/II)

This subgroup, which is inherited as an autosomal dominant, includes both EDS type I (gravis) and II (mitis).

Pathology. Histology may be within normal limits; alternatively there may be thin, weakly polarized, dermal collagen bundles. Elastic fibres may be irregular and relatively increased [8,9]. At ultrastructural level, collagen bundles are of variable size with abnormally large, composite 'cauliflower' fibrils, reflecting abnormal fibrilogenesis [14,18,19]. Linkage to *COL5A1* was originally identified in a British family with EDS II, and analysis of further families subsequently showed that EDS I and II are allelic [20,21]. Up to half of all classical EDS patients have mutations in *COL5A1* or *COL5A2*, which encode the α_1 and α_2 chains of type V collagen, respectively. Although quantitatively minor (approximately 2–5% of dermal collagen), collagen V plays an important role in the regulation of type I collagen diameter [22]. Missense and exon skipping mutations with dominant-negative effects or mutations giving rise to haploinsufficiency may occur [15,23]. Genetic heterogeneity is apparent with reports of classical EDS caused by a mutation in the collagen I gene [24]. Furthermore, knock-out experiments with mice suggest other extracellular matrix components such as decorin, fibromodulin, thrombospondin-2, lumican and biglycan may be important [25,26].

Clinical features. The skin is soft, velvety and hyperextensible (Fig. 45.21) but retains its normal recoil. The skin on the palms and soles may be redundant, like a loose glove. The skin is not usually otherwise lax until later in life, when redundant folds occur on the eyelids (blepharochalasis), face and limbs. Secondary cutis laxa has been described on the lower back of a patient with mild classical EDS [27]. Striae do not develop during pregnancy. Trivial lacerations form gaping wounds that heal very slowly to leave broad, atrophic 'cigarette paper' scars (Figs 45.22 & 45.23). Sutures may tear out repeatedly. Blue-grey, spongy tumours (molluscoid pseudotumours), due to accumulation of connective tissue, may form on the skin, especially in scars or over pressure points. Smaller, firm, subcutaneous nodules (spheroids), which show calcification on X-ray, develop on the shins and forearms in up to a third of patients.

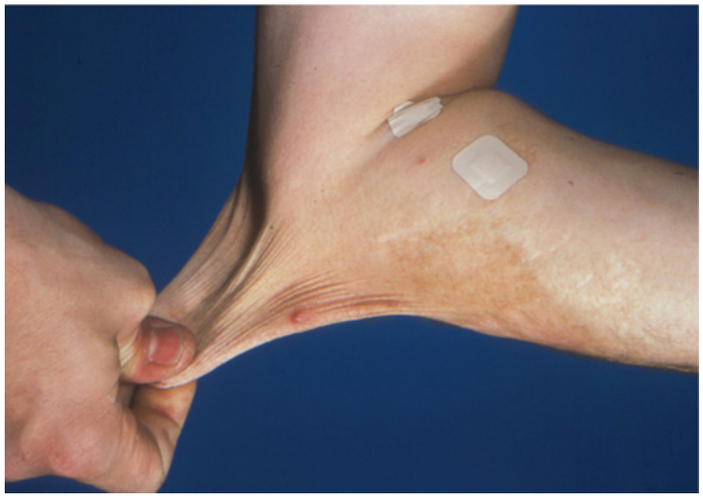

Fig. 45.21 Cutaneous hyperextensibililty in classical Ehlers–Danlos syndrome.

Fig. 45.22 Atrophic scarring of the elbow in classical Ehlers–Danlos syndrome.

Fig. 45.23 Scarring of the forehead in classical Ehlers–Danlos syndrome.

Easy bruising may be the presenting symptom, and pigmentation due to haemosiderin deposition is often found on areas of repeated trauma.

The facies may be distinctive, with widely spaced eyes, a wide nasal bridge, and epicanthic folds. The sclerae are sometimes blue.

There is marked joint hypermobility, which can impair walking, especially during pregnancy. Subluxation of the large joints may occur, and genu recurvatum and kyphoscoliosis are frequent [28]. Muscle tone is often poor, and hernias develop. Pedal piezogenic papules are seen more frequently. Diaphragmatic eventration and gastric torsion have been reported [29]. Symptomatic bladder diverticula may develop [30]. Varicose veins may develop in early life. Prematurity due to ruptured fetal membranes is common.

As physical and mental development are normal, life expectancy is not reduced, hence large family pedigrees are not unusual. A mild variant of classical EDS has been described in 9% of a general dermatology population less than 50 years old, and merges with benign hypermobility syndrome and the normal spectrum [31]. A simple clinical scoring system, based on an assessment of joint hypermobility, skin extensibility and bruising might be useful in predicting which members of the general population are likely to produce poor scars following cutaneous surgery [32].

Hypermobility type (EDS III)

Hypermobile EDS and benign joint hypermobility syndrome (BJHS) are autosomal dominant and considered by some authors to be the same disorder. Revised criteria have been proposed for their diagnosis [33]. The Beighton score (Table 45.4) is a useful, quick method for assessing global joint hypermobility, and an adult score of four or more out of nine either currently or historically is considered hypermobile [34]. Ultimately, molecular analysis will determine whether these two groups are genetically heterogeneous. Haploinsufficiency of tenascin-X results in reduced dermal collagen and may account for 5–10% of hypermobile type EDS, although this has only been found in females [35]. There is one report of a family with hypermobile EDS phenotype due to collagen III deficiency, as occurs in vascular EDS [36]. The ultrastructural changes resemble those in classical EDS. The skin is only minimally affected by scarring and hyperextensibility, whereas joint mobility is markedly increased, and dislocation and joint pains are common [37,38]. A study of a small number of hypermobile patients showed they were resistant to the effects of intradermal or topical local anaesthetic compared with BJHS patients or controls, suggesting that the disorders are distinct [39]. However, the criteria used to diagnose the hypermobile group were not clearly documented. In the authors' experience, patients with classical EDS may also rarely be resistant to local anaesthetic. Symptoms such as syncope, palpitations and fatigue suggest dysautonomia and are significantly more common in joint hypermobility patients, although the mechanisms remain unclear [40].

Table 45.4 Beighton score [34].

Movement	Score
Dorsiflex L and R 5th finger >90°	2
Apposition L and R thumb to forearm	2
Hyperextend L and R elbow >10°	2
Hyperextend L and R knee >10°	2
Palms to floor	1
TOTAL	9

Vascular type (EDS IV)

This very severe form is inherited as an autosomal dominant. Cases previously reported as autosomal recessive inheritance were probably due to sporadic mutations [41–43]. It is rare, the prevalence being between one in 10^5 and one in 10^6 [41].

Pathology. The condition is characterized by an abnormality of the synthesis, secretion or structure of type III collagen due to an abnormality of the collagen III gene (*COL3A1*) [6,44]. Segregation studies using polymorphic restriction sites in the gene may be of use in prenatal diagnosis [45]. The syndrome is biochemically heterogeneous [5]. Several changes have been reported, the most common of which are point mutations (substituting other amino acids for glycine residues in the triple helical domain). Exon-skipping mutations are nearly as common; small genomic deletions within one exon and multiexon deletions have also been described [5,6,46]. It has been suggested that the region of the type III collagen molecule where mutation occurs may be linked with the clinical severity [6], although this has not been found in other studies [46].

These abnormalities all result in abnormal structure, synthesis or secretion of type III procollagen. Often, the skin is reduced to 25% of normal thickness, with small collagen fibre bundles. Fibril diameter is markedly variable in some patients [47]. In many patients, the fibroblasts contain prominent rough endoplasmic reticulum containing abnormal type III procollagen [47,48]. Cell strains from other individuals show markedly reduced extracellular accumulation of procollagen and collagen but without intracellular accumulation, perhaps due to rapid degradation of mutant chains [49]. Bizarre elastic fibres are often abundant.

The condition affects tissues rich in type III collagen, notably arterial media, bowel and uterus. Interestingly, type III collagen production by fibroblasts is decreased in some patients with ruptured cerebral aneurysm, even though they have no other stigmata of EDS [50]. The collagen deficiency in these patients does not appear to arise from *COL3A1* mutations, but may relate to abnormal post-translational modification or altered collagen metabolism [51].

Clinical features. The major clinical features are spontaneous rupture of large arteries, colon and gravid uterus. Dissecting aortic aneurysm is a common cause of sudden death [52]. Spontaneous carotid–cavernous fistula can also occur, resulting in unilateral exophthalmos [53]; it may respond to surgical repair or embolization [54]. Repair of rupture of the colon (usually sigmoid) is complicated by tissue friability and peritoneal contamination [55]. In one series complications of pregnancy led to death in the peripartum period in 12 of 81 women who had a total of 183 pregnancies [46]. Seven died following vessel rupture and five following uterine rupture.

Fig. 45.24 Cutaneous atrophy in vascular (acrogeric) Ehlers–Danlos syndrome.

Other features include prematurity (due to rupture of friable placental membranes), low birth weight, short stature, easy bruising (which may lead to the mistaken accusation of child abuse) [56] and pneumothorax [57,58]. Elastosis perforans serpiginosa is seen more commonly in this EDS subtype.

Two phenotypic groups are recognizable. In the *acrogeric* type, individuals appear prematurely aged with thin, translucent, fragile skin (Fig. 45.24), a hollow-eyed appearance, thin, peaked nose and thin lips. Easy bruising predominates in the *ecchymotic* type, often falsely suggesting a primary disorder of coagulation [13]. Unlike other forms of EDS, the skin is not hyperextensible, and joint hypermobility is chiefly restricted to the small joints of the hands and feet. Surface veins are usually readily visible. There is a tendency to form keloid scars.

The largest case series to date of 220 index cases of vascular EDS patients and 199 affected relatives showed the median survival as 48 years, with 25% of index cases having their first significant complication by 20 years [46]. Most deaths follow arterial dissection or rupture, mainly of the thoracic and abdominal vessels. Milder variants may occur, presenting with cardiac features in later life [59].

Recently a new autosomal dominant aneurismal disorder, Loeys-Dietz syndrome, has been described. The major features of Loeys-Dietz syndrome type I patients overlap clinically with Marfan's syndrome whereas type II patients have a phenotype similar to vascular EDS. In a cohort of 40 patients with a presentation suggestive of vascular EDS, but normal type III collagen, Loeys and colleagues found mutations in the transforming growth factor-beta receptor genes *TGFBR1* and *TGFB2* [60]. Therefore Loeys-Dietz syndrome should be considered in any vascular EDS phenotype with normal collagen III.

X-linked type (EDS V)

Two families have been described as type V EDS. Clinically, it resembles mild classical EDS, but bruising is more marked. However, it is distinguished by X-linked inheritance [61]. The biochemical defect is unknown, and skin collagen cross-links are normal [62]. Lysyl oxidase activity has been reported to be reduced in one family [63], but these patients appear to form a clinically distinct subgroup. In other families, the lysyl oxidase levels have been normal [64]. Until a precise genetic or biochemical abnormality is found, the status of this type must remain in question [5].

Kyphoscoliosis type (EDS VI; ocular-scoliotic)

This autosomal recessive condition was the first true disorder of collagen structure to be described [64–66]. The biochemical abnormality in most, but not all, patients, is a deficiency of lysyl hydroxylase [65]. Different mutations in the lysyl hydroxylase gene (*PLOD*) have been identified in unrelated families. One is homozygous for a stop codon at residue 319 (R319X) [67]. In another, duplication of 180 base pairs in the coding sequence of the complementary DNA resulted in decreased enzyme function [68], and a further family revealed a compound heterozygote combining a three-base pair deletion and an amino acid substitution (G678A) [69].

Deficiency of the enzyme leads to reduced hydroxylation of lysyl residues in types I and III collagen in skin; hydroxylysine-containing cross-links are not formed [70]. Lysine-derived cross-links appear not to be as stable as those derived from hydroxylysine; the former do not mature as rapidly to stable intermolecular cross-links [71]. Types II, IV and V collagens are hydroxylated normally, which suggests that there may be different isoenzymes or different affinities of a single enzyme for specific collagen types [5]. Detection of abnormal pyridinoline cross-links in urine can be used as a diagnostic aid [72].

Clinical features include soft, velvety, hyperextensible skin and increased joint mobility. Scoliosis is common. Eye manifestations include microcornea, glaucoma, keratoconus and ocular fragility. Some patients have a marfanoid habitus. Bleeding may occur from major wounds, and there may be delayed motor development [73].

The kyphoscoliotic type of EDS appears to be rare, with less than two dozen cases reported in the literature [5]. Because it is inherited recessively, after the birth of an affected child there is a 25% risk of recurrence in each successive pregnancy. Measurement of lysyl hydroxylase activity in amniotic fluid enabled the prediction of a phenotypically normal heterozygous infant in a family at risk [74].

Some patients respond to treatment with ascorbic acid, which regulates collagen biosynthesis [75].

Arthrochalasia type (EDS VIIA and B; arthrochalasis multiplex congenita)

This rare autosomal dominant condition, like OI, results from mutations causing defects in type I collagen. Phenotypic overlap therefore occurs.

All or part of exon 6 of the *COL1A1* or *COL1A2* gene is deleted in types A and B, respectively, resulting in a defect in the cleavage sites of the substrate pro-α_1(I) or pro-α_2(I) chains [75–79]. Mutations appear to affect cross-link formation, decreasing tensile strength of tissues rich in type I collagen. Partially processed molecules accumulate in the dermis and other tissues, where they interfere with tissue function without much effect on fibrillar organization [76,80].

Arthrochalasis is characterized clinically by extreme joint hypermobility and multiple dislocations affecting both large and small

Fig. 45.25 Extreme cutaneous fragility and laxity in dermatosparaxis.

Fig. 45.26 Premature periodontal recession in periodontitis type Ehlers–Danlos syndrome (VIII).

joints [27]. Bilateral hip dislocation presents a major surgical problem. Some individuals have a short stature. There may be a chubby facial appearance due to lax facial tissues, and a depressed nasal bridge [80].

Dermatosparaxis type (EDS VIIC)

This very rare autosomal recessive form is characterized by extreme skin fragility (Fig. 45.25), bruising, droopy skin, joint laxity, umbilical hernia and blue sclerae [81–84]. The condition is akin to dermatosparaxis, a disorder causing fragile skin in animals [85–86]. It is caused by homozygous mutations in the gene encoding procollagen I *N*-terminal proteinase (*ADAMTS2*), the enzyme that excises the *N*-propeptide of type I and II procollagens [87]. Collagen fibrils from affected children and animals are small, with a bizarre hieroglyphic-like appearance in cross-section; they are ribbon-like in longitudinal section [5].

Periodontitis type (EDS VIII)

This type has features similar to classical EDS but there is often only moderate small-joint hypermobility. The distinguishing clinical features are premature periodontal recession (Fig. 45.26), resulting in loss of teeth by the third decade, and heavily pigmented, pretibial plaques (Fig. 45.27) [88,89]. Little is known about the biochemical defect, although there is a reduced proportion of type III collagen in skin [89]. Some patients have small collagen fibrils [89]. It is inherited as an autosomal dominant and linkage has been shown to chromosome 12p13 in three out of five families, indicating genetic heterogeneity [91].

Fig. 45.27 Pigmented pretibial plaques in periodontitis type Ehlers–Danlos syndrome (VIII).

EDS IX (occipital horn syndrome)

This is an X-linked recessive disorder allelic to Menkes' syndrome and is no longer considered a variant of EDS [3]. It was formerly known as X-linked cutis laxa or 'occipital horn syndrome' and has been reclassified as a disorder of copper transport (p. 45.39).

Fibronectin-deficient type (EDS X)

Only one family has been identified to date with this autosomal recessive disorder. Skin and joint changes are mild, but bruising occurs readily due to defective platelet aggregation [7]. This defect is reversed *in vitro* by adding purified fibronectin to the assay. Some patients have composite fibrils in the dermal collagen, possibly due to a defect in fibronectin interactions [92].

Progeroid EDS

A rare association of EDS with progeroid facies, short stature, osteopenia and mental retardation is recognized [93]. Patients lack the full phenotype of progeria (p. 45.58) and do not fit in to the more well-defined progeroid syndromes. Galactosyltransferase I activity is reduced in patients' fibroblasts due to mutations in the *XGPT1* gene [94]. This enzyme is involved in the synthesis of glycosaminoglycans, suggesting that they may be involved in the

process of senescence. The phenotype of decorin/ biglycan double knock-out mice is similar to human progeroid EDS and occurs as the result of impaired binding of glycosaminoglycans to decorin and biglycan [25].

Tenascin-X-deficient type EDS

Tenascin-X deficiency causes a recently identified, clinically distinct, autosomal recessive form of EDS [95]. Patients have hyperextensible skin, bruising and joint laxity, but no scarring. The gene for tenascin-X (TNXB) overlaps the steroid 21-hydroxylase gene, and it was originally identified as a candidate gene for EDS in a patient with a contiguous-gene deletion giving rise to both 21-hydroxylase deficiency and EDS [96]. Tenascin-X is the first EDS gene that does not encode a fibrillar collagen or collagen-modifying enzyme. It is a large extracellular matrix protein that appears to be an essential regulator of collagen deposition by dermal fibroblasts [97].

Associated syndromes

Various unclassified forms of EDS overlap with other disorders, such as OI, PXE, MFS [98], renal tubular acidosis and medullary sponge kidney [99], and osteolysis of the terminal phalanges.

Diagnosis. The diagnosis is mainly clinical; a scoring system may be helpful in doubtful cases [100]. Confirmation of the subtype can require a combination of electron microscopy of dermal collagens, protein chemistry analysis from cultured fibroblasts and mutation detection. Immunofluorescent staining of fibroblasts for retained type III collagen may be a faster and cheaper method for the diagnosis of the important type IV EDS [101]. Similarly, the finding of reduced type III procollagen aminopropeptide in the serum of some, but not all, patients with EDS IV may help diagnosis [102]. Chorionic villus sampling may enable prenatal diagnosis of abnormalities of type I (and II) collagen [103]. Measurement of the ratio of urinary lysyl and hydroxylysyl pyridinolines is a non-invasive, reliable diagnostic test for kyphoscoliosis type EDS [72].

EDS should be distinguished from cutis laxa, in which the skin hangs in flaccid redundant folds. In EDS, redundant skin folds may develop in late adult life, but they are usually limited to the elbows and the skin around the eyes. Hyperelastic skin is a feature of Turner's syndrome (Chapter 15), but the dwarfism, cubitus valgus and webbed neck are distinctive. Hyperelastic skin with abnormal elastic fibres in the papillary dermis has been reported in the rare cartilage–hair hypoplasia syndrome [104].

Treatment. All patients should receive genetic counselling. Treatment is highly unsatisfactory, although some features of EDS VI may respond to oral ascorbic acid [74]. Patients with type IV EDS should be advised to avoid pregnancy and trauma, including physical contact sports, and to avoid activities, such as trumpet playing, which raise intracranial pressure by the Valsalva effect. Bleeding should be managed conservatively if at all possible. The fragility of blood vessels makes arteriography and surgical procedures dangerous and difficult. Surgeons must be made aware of the patient's diagnosis prior to surgery. Sutures should be buttressed, and tension avoided. Although re-excision of ugly scars can give a good cosmetic result it is not generally recommended [105].

Occipital horn syndrome

Synonyms
- X-linked cutis laxa
- Ehlers–Danlos syndrome type IX

In this rare, X-linked, recessive disorder, affected males have a defect in distribution of intracellular copper to copper-dependent enzymes, as in Menkes' syndrome [1]. Lysyl oxidase is a major copper-dependent enzyme, and its activity is markedly decreased in some patients [2], resulting in defective collagen cross-links. Serum copper and caeruloplasmin levels are low [1]. The disorder, like Menkes' syndrome, is caused by mutations in the gene (*ATP7A*) encoding for Cu^{2+}-transporting adenosine triphosphatase (ATPase) α-polypeptide [3,4].

Clinical manifestations include the development of bladder diverticula during childhood, inguinal herniae, mild laxity of skin and skeletal defects such as short humeri and clavicles. Bony occipital horns appear during adolescence [2]. Other features include mild chronic diarrhoea and orthostatic hypotension.

Prolidase deficiency

Definition. Prolidase (peptidase D) is involved in the latter stages of degradation of endogenous and dietary proteins and is particularly important in collagen catabolism. Deficiency of prolidase is a rare inborn error of collagen metabolism, associated with chronic skin ulceration, mental retardation and recurrent respiratory infections.

Aetiology. The deficiency is inherited as an autosomal recessive [1,2]. Mutations in the prolidase gene (*PEPD*) result in loss of prolidase activity [3]. Some siblings of patients have the enzyme deficiency without clinical manifestations [4].

Pathology. Light and electron microscopy of cultured fibroblasts from affected patients suggest necrosis-like cell death with abnormal morphology and increased cytosolic vacuolization, and abnormal plasma membranes and mitochondria [3]. Large amounts of imidodipeptides are excreted in the urine [5,6], and the proline/hydroxyproline ratio in collagen is increased.

Abnormal laboratory findings include mild anaemia, thrombocytopenia and hypergammaglobulinaemia.

Clinical features [7]. Most patients are mentally defective, with an abnormal facies, but there is no characteristic or consistent pattern. Skin changes occur in about 85% of cases. The skin may feel spongy, with pitting and scarring, especially on the legs (Fig. 45.28). The skin is fragile and leg ulcers are common. Occasionally, there may be photosensitivity, telangiectasia, purpura, premature greying and lymphoedema.

Fig. 45.28 Pitted skin in prolidase deficiency. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Splenomegaly, recurrent infections and obesity or a protuberant abdomen occur in about 30% of cases. Families have been described with associated chronic lung disease, resembling cystic fibrosis [8].

Diagnosis. This is confirmed by the finding of massive imidodipeptiduria with prolidase deficiency in the red cells, white cells or cultured fibroblasts. Mutations can be detected in the gene encoding for prolidase [3].

Treatment. Topical proline has been successfully applied to the leg ulcers [9]. Oral proline administration produces no clinical improvement. Enzyme replacement by transfusion of prolidase-containing red cells is a possibility, perhaps using manganese activation of the enzyme before transfusion [10]. Pulsed corticosteroids may help [11]. Apheresis exchange has improved skin ulceration in two patients [12].

Osteogenesis imperfecta (OI)

Definition. This term is applied to a heterogeneous group of heritable disorders characterized by osteoporosis with fractures, due predominantly to type I collagen abnormalities. Patients may also have blue sclerae (Fig. 45.29), deafness, skeletal deformity, abnormal dentine formation (dentinogenesis imperfecta), mild joint hypermobility, hernias, mitral valve prolapse, arterial fragility and thin, fragile skin [1,2].

Aetiology. Approximately 80–90% of patients with OI, who fit into types I–IV, have mutations in one of the type I collagen genes (*COL1A1*, *COL1A2*) [3]. The aetiology of the remainder is unclear. A variety of mutations are seen but very few families share the same mutation. Furthermore, considerable intrafamilial variation of phenotype occurs in type IA [4].

Pathology [5]. The bones are markedly collagen deficient, and often have a distorted architecture. The dermis is thin, with a relative increase of argyrophil and elastic fibres, and a deficiency of adult collagen [6].

Clinical features [1,2,5]. The following broad groups exist, although some patients are difficult to classify.

Type IA: Classic form. This is the commonest form. It is inherited as an autosomal dominant, although sporadic cases also occur [7]. Fractures are common in childhood. The sclerae are blue or grey, and easy bruising and early-onset deafness are common, but skeletal deformity is absent or mild. Joint laxity is common. The incidence of mitral valve prolapse is increased, and the aortic valves are thin and occasionally incompetent [8–10]. A few patients (type IB) have dentinogenesis imperfecta, but this is more common in the type IV group. Most patients have increased skin collagen, with an increased ratio of type I/type III [6]. Other patients have an abnormal α_2 chain, which is unduly susceptible to proteolysis by pepsin [11].

Type II: Lethal perinatal form. This is the rarest form. There are multiple fractures *in utero* and infants rarely survive for more than a few days after birth [12]. Avulsion of the limbs may occur during delivery due to a generalized connective tissue fragility. Radiography shows beaded ribs, crumpled femora and little skull calcification. This form has been subdivided on the basis of rib and limb bone abnormalities [6,13]. Inheritance is usually autosomal dominant. Multiple recurrence of gonadal mosaicism can mimic autosomal recessive inheritance [14].

Type III: Progressively deforming form. In this condition, there are fractures *in utero* or at birth, and the long bones are thin and occasionally cystic. As the child grows older, progressive scoliosis and bowing of long bones cause crippling deformities. The sclerae are blue in childhood but become normal in the adult. The inheritance is uncertain, but the disease may be genetically heterogeneous. Some patients with this form seem unable to synthesize α_2 chains [7,15].

Type IV: Mild form with normal sclerae. This condition is similar to type I in clinical features and inheritance, but the sclerae are not blue, dentinogenesis imperfecta is frequent and deafness is rare.

Diagnosis. Patients with short extremities and a large skull may be confused with achondroplasia, but bone fragility and thin skin do not occur in achondroplasia. Prenatal diagnosis of the more severe forms is possible, using ultrasonography from week 16 [16]. The skin of patients with OI is stiffer and less elastic than normal skin, and these differences in mechanical properties may prove useful in diagnosis and prognosis [17].

Treatment. This is essentially an orthopaedic problem, although many children die of respiratory infections [18]. Bisphosphonates have become standard care for patients with this condition although it is unclear how long therapy should be maintained [2]. Somatic cell therapy, using allogeneic bone marrow and mesenchymal stromal cell transplantation have been used [19,20].

Pachydermoperiostosis (see also Chapter 15)

Synonyms
- Primary (idiopathic) hypertrophic pulmonary osteoarthropathy
- Touraine–Solente–Golé syndrome

In this rare condition [1,2], inheritance is autosomal dominant, but autosomal recessive families probably also occur [3]. Digital clubbing is associated with cylindrical thickening of legs and forearms, hypohidrosis, seborrhoea, sebaceous gland hyperplasia and folliculitis. X-rays reveal symmetrical, irregular periosteal ossification, predominantly affecting the distal ends of long bones. Histology shows cutaneous sclerosis and hyalinosis, with perivascular infiltration by lymphoid cells in the dermis [2]. Additional clinical features include carpal and tarsal tunnel syndrome, chronic leg ulceration and calcification of the Achilles tendon [4]. Cultured dermal fibroblasts synthesize increased amounts of collagen and α_1(I) procollagen mRNA, and exhibit up-regulation of transcriptional activity of the α_1(I) procollagen gene promoter [5]. Proteoglycan synthesis is also affected [6].

When conventional treatments fail, intravenous pamidronate may help rheumatological manifestations [7].

Relapsing polychondritis

Synonyms
- Atrophic polychondritis
- Systemic chondromalacia

Definition. In this non-infective condition, focal inflammatory destruction of cartilage is accompanied by fibroblastic regeneration. It is characterized by: (i) recurrent chondritis of the pinnae; (ii) chondritis of nasal cartilage; (iii) inflamed cartilage in the larynx, trachea or respiratory tract; (iv) ocular inflammation; (v) cochlear or vestibular lesions; and (vi) non-erosive arthritis. Three or more of these features are required for the diagnosis [1].

Aetiology. Relapsing polychondritis has been recorded as rare, but recent reports suggest that it is not so uncommon but is easily overlooked. The cause is unknown, but the association with rheumatoid arthritis, lupus erythematosus, vasculitis, Behçet's disease and Hashimoto's disease suggests that autoimmune mechanisms may be concerned (see also MAGIC syndrome, p. 45.44). Other reported associations include ulcerative colitis, Crohn's disease, psoriasis, glomerulonephritis, Sjögren's syndrome, thymoma, ankylosing spondylitis, myeloproliferative disorders and following intravenous injections [2–7]. Cutaneous manifestations have been reported in a patient treated for prostatic adenocarcinoma with goserelin, a luteinizing hormone releasing analogue [8].

Relapsing polychondritis probably overlaps with Wegener's syndrome. Auricular chondritis has been described in some patients with the latter [9], and cANCA, an antibody once regarded as specific for Wegener's syndrome, has been reported in patients with relapsing polychondritis [10].

Antibodies to type II collagen have been detected in the serum in acute polychondritis, and granular deposits of IgG, IgA, IgM and C3 at fibrochondrial junctions have indicated a possible role of immune-complex deposits [11–15]. Antibody production is T-cell dependent and major histocompatibility complex (MHC) restricted; the arthritis in experimental animal models can be suppressed by synthetic type II collagen peptides [16]. The intravenous injection of papain into rabbits produces loss of cartilage rigidity, manifested by floppy ears [17], and it has been suggested that local protease activity may play some part in causing relapsing polychondritis [18]. Cartilage oligomeric matrix protein (COMP) is decreased and cartilage matrix protein (matrilin-1) increased. Both revert to normal levels during successful therapy [19].

Pathology [20]. Areas of damaged cartilage, which have lost the normal basophilic staining, are separated by areas of predominantly lymphocytic infiltration. Later, the fragments of cartilage are surrounded and replaced by abundant granulation tissue and even nascent cartilage. Occasionally there is evidence of vasculitis [21].

Clinical features [1,22–24]. The condition affects both sexes equally and usually begins between the ages of 30 and 50 years. Chondritis ultimately involves three or more sites in most patients but may be limited to one or two for long periods. The following tissues may be involved in decreasing order of frequency: auricular, joint, nasal, ocular, respiratory tract, heart valves and skin [25,26]. During the acute stage, the affected area is swollen, red and tender, and may be mistaken for cellulitis (Fig. 45.30). Sparing of the ear lobe is a useful differentiating sign. Serous otitis media can occur, and there may be loss of hearing even in the absence of chondritis [27]. Involvement of the nasal cartilage leads to obstruction and later to a saddle-nose deformity (Fig. 45.31). Cutaneous and systemic vasculitis, cerebral aneurysms, superficial thrombophlebitis and toxic erythema have been described [1,21,24,28,29].

The joint changes, usually affecting the smaller peripheral joints, may simulate rheumatoid arthritis [30]. Involvement of the larynx, trachea or bronchi produces respiratory embarrassment and recurrent infection. Permanent tracheostomy may be required

Fig. 45.32 Relapsing polychondritis, showing ocular involvement. (Courtesy of Dr N. Cox, Cumberland Royal Infirmary, Carlisle, UK.)

[20,27]. An association with granulomatous lung disease has also been described. Ocular abnormalities are found in some cases—episcleritis, conjunctivitis and iritis (Fig. 45.32), or more rarely keratoconjunctivitis sicca or chorioretinitis. Proptosis occurs in 3% of cases [31,32]. Involvement of the heart valves may cause serious complications, including sudden valve rupture, even in a patient otherwise in remission [1,33,34].

The course of the disease is extremely variable [7]. Relapses are the rule, but they vary in frequency and severity. Some cases continue to relapse for over 20 years, but others become inactive within a short period. Pregnancy does not appear to affect the course of the disease, although complications are more frequent [35]. Deformity of the ears and nose is common, but in general the disease is a source of discomfort and disfigurement rather than a threat to life. Plasma viscosity or erythrocyte sedimentation rate is usually raised and anaemia is frequent. The rheumatoid factor and antinuclear factor are often positive. Leukocytosis is inconstant, but eosinophilia is found in 40% of cases. The characteristic biochemical finding is the increased urinary excretion of acid mucopolysaccharides during each relapse.

Radiological abnormalities are not pathognomonic, but evidence of extensive destruction of joint cartilage without changes in adjacent bone is suggestive. In some cases, the changes are indistinguishable from rheumatoid arthritis.

Diagnosis. Polychondritis may present to the dermatologist as 'chronic otitis externa with cellulitis of the pinna'. The diagnosis is established by biopsy, or by other associated changes, and by the examination of urine for acid mucopolysaccharides. Wegener's granulomatosis and lethal midline granuloma can produce a similar histology, but in these two conditions the involvement is more purely destructive.

Treatment. The progression of the acute relapse can be controlled with corticosteroids. An initial daily dose of 30 mg prednisone can be gradually reduced and finally discontinued as remission develops. Remissions may also be induced with indometacin or dapsone [13]. Colchicine is also helpful in some patients [36]. Immunosuppressive agents such as methotrexate and ciclosporin [15] may have a role. Pulsed intravenous cyclophosphamide has been used for renal disease [37]. Intravenous immunoglobulin [38] and anti-TNF therapies have been successful in a small number of patients [39]. Remission has followed autologous stem cell transplantation [40]. Surgical reconstruction of the nose or larynx is sometimes required.

MAGIC syndrome

At least 13 patients have been described with features of both relapsing polychondritis and Behçet's syndrome [1]. The term MAGIC syndrome (*m*outh *a*nd *g*enital ulcers with *i*nflamed *c*artilage) has been used for this overlap syndrome. The underlying immunological defects are still unclear, but circulating immune complexes and autoantibodies to elastic tissue have been suggested as possible factors [1,2].

Aortic valve disease and aneurysmal aortitis have been associated with the syndrome [3,4], and features of the MAGIC syndrome have been described in an HIV-positive individual [5].

Fibromatoses

Fibrous overgrowth of dermal and subcutaneous connective tissue occurs most readily in certain sites and at certain ages, and some of the resulting syndromes are clinically and histologically distinctive and well defined. There are some cases, however, that defy precise classification, and others in which histological criteria may be a poor guide to prognosis. Invasiveness and a high local recurrence rate may or may not be associated with a tendency to metastasize. The borderline between simple overgrowth and a benign tumour may be equally difficult to define.

Fibromatosis is a benign, fibrous tissue proliferation, which is intermediate between benign fibroma and metastasizing fibrosarcoma. The lesions of fibromatosis tend to infiltrate and recur when removed, but they do not metastasize. The term should not be applied to reactive fibrous proliferation, or to keloid, which is usually secondary to injury. The lesions in fibromatosis may be single or multiple, and the likelihood of recurrence after surgical removal varies with the location of the lesion and the age of the patient. The fibromatoses occur in two major groups.

1 Superficial fibromatoses (fascial fibromatoses):
   (a) palmar (Dupuytren's)
   (b) plantar
   (c) penile (Peyronie's)
   (d) knuckle pads

2 Deep fibromatoses (non-metastasizing fibrosarcoma). These are rapidly growing tumours that usually involve the musculature or aponeuroses. Their tendon-like consistency accounts for their alternative name of desmoid tumours.

These conditions are discussed in more detail elsewhere (Chapter 56).

Fig. 45.33 Palmar fibromatosis (Dupuytren's contracture). (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Palmar fibromatosis

Synonym
- Dupuytren's contracture

Definition. This is a fibromatous hyperplasia of the palmar aponeurosis, which is characterized by nodular thickening of the fascia with associated flexion contractures of one or more digits (Fig. 45.33).

Aetiology. The condition seems to be due to a reactive proliferation of fibroblasts with no inflammatory component, and the basic cause is obscure. Free radical production secondary to ischaemia may be involved, and the concentration of hypoxanthine substrate capable of releasing free radicals is greatly increased in the affected tissue [1]. Localized ischaemia has been thought to play a part, and in animal studies allopurinol (a competitive inhibitor of xanthine oxidase) has been shown to limit the damage associated with acute ischaemia [2]. High concentrations of free radicals are toxic, but in low concentration they stimulate fibroblast proliferation [1]. The contractures, which are a late complication, appear to follow the conversion of the fibroblasts to contractile myofibroblasts [3].

Palmar fibromatosis is often familial, and may be inherited as an autosomal dominant trait [4].

Some families are described in which there is a predominantly female expression [5]. The prevalence in the general adult population is around 2–6% [6], but it may approach 20% or more in elderly males [7–9], in diabetic patients and in patients with acquired immune deficiency syndrome (AIDS). It is relatively rare in black and oriental races.

Associated disorders. The condition occurs more commonly in patients with alcoholic cirrhosis, epilepsy [10] and diabetes mellitus [9,11], but the prevalence is decreased in rheumatoid arthritis [12].

Palmar fibromatosis is also associated in about 5% of patients with other fibrosing conditions, such as knuckle pads, Peyronie's disease, keloid scarring or plantar fibromatosis [13], and this has been termed the *polyfibromatosis syndrome*. Other conditions which have been less convincingly claimed to be associated with Dupuytren's contracture include periarthritis of the shoulder, chronic lung disease, gout, trauma and ulnar nerve damage [14]. Phenytoin appears to stimulate fibrosis in the polyfibromatosis syndrome [15] and it may also cause gingival hypertrophy by stimulating fibroblasts and increasing collagen production [10,16].

There is one case report of a girl aged 14 years who developed Dupuytren's contracture while receiving growth hormone therapy for hypopituitarism [17].

Pathology [18]. Fibroblasts in Dupuytren's contracture are identical to those in normal palmar fascia. However, there are more of them in Dupuytren's contracture and they tend to be clustered around narrowed microvessels [19]. In the early stages, there are nodules in the subcutaneous tissue, or within the fascia, composed of proliferating fibroblasts with irregular hyperchromatic nuclei, but with no excess of collagen. Later stages are characterized by the presence of myofibroblasts which have a fibrillary ultrastructure in the cytoplasm and seem to have some other properties of smooth muscle. The nuclei are deeply indented, and these constrictions may be related to the contractile properties of the cell. The cell also has surface membrane differentiations which provide attachment to neighbouring cells and stroma. Myofibroblasts have also been identified in the normal aorta and in granulation tissue, hypertrophic scars, keloids, liver fibrosis, dermatofibroma, etc. [3], in which their contractile properties may be important. The advanced stages of Dupuytren's contracture are characterized by dense, fibrous connective tissue with a few elongated cells. An increased concentration of type III collagen is present in the nodules [20]. This may be due to decreased degradation caused by increased levels of tissue inhibitors of metalloproteinases in the lesions [21]. Structural abnormalities of glycosaminoglycans, notably dermatan sulphate, may predispose to abnormal fibrillogenesis [22].

Clinical features. The age of onset is generally between 30 and 50 years, and the disease is less common and progresses more slowly in women [14]. The earliest sign is the development of a palmar nodule, usually in the ulnar half of the hand. There are usually no symptoms, but there may be a dull ache or tingling. Insidious progression of the fibrosis over several years causes flexion contractures of the affected fingers. There is often puckering of the overlying skin. Eventually, the function of the hand becomes impaired due to fixed flexion of one or more digits. If left untreated, there may be some improvement after many years.

Diagnosis. There are few diagnostic difficulties. There may be a histological resemblance to fibrosarcoma, but this is more pleomorphic, with larger nuclei and more mitoses. Juvenile aponeurotic fibroma may produce palmar or plantar nodules, but Dupuytren's contracture does not occur in young children.

Treatment. The advice of an orthopaedic or plastic surgeon should be sought. Complete removal of the palmar aponeurosis is generally recommended [23], although subtotal fasciectomy and direct closure may be an alternative approach [24].

Medical treatments are disappointing. Allopurinol may help by decreasing free-radical production [25], and it has been suggested that vitamin C might prevent progression of the disease by acting as a free-radical scavenger [7]. Many other non-surgical approaches have been tried, including continuous slow skeletal traction, radiotherapy, dimethyl sulfoxide, vitamin E, steroid injections and interferon, although none has been proven to be clinically useful [26]. However, placebo-controlled trials of collagenase injections look very promising [27].

Another suggestion, which has yet to be tested clinically, is the use of immunosuppressive therapy as an adjunct to surgery, on the grounds that the presence of CD3 lymphocytes and the expression of MHC class II proteins in the affected tissue imply that Dupuytren's disease is a T-cell-mediated autoimmune disorder [28].

Camptodactyly

Camptodactyly is a non-traumatic flexion deformity affecting the proximal interphalangeal joint of one or more fingers [1]. It may be a feature of a variety of syndromes; the molecular defects in several of these have been identified. Congenital camptodactyly is most notably associated with non-inflammatory arthropathy [2]. Additionally, other serous membranes undergo fibrosis, leading to *c*onstricting pericarditis *a*nd *p*leuritis (*CAP syndrome*) [3,4]. Familial camptodactyly of later onset has been described in association with an inflammatory arthritis with erosive changes [5]. *Blau's syndrome* encompasses familial camptodactyly, granulomatous arthritis, uveitis and an erythematous eruption with phenotypic overlap with early onset sarcoidosis [6]. Mutations in *NOD2/CARD15* have been shown to confer susceptibility to several chronic inflammatory disorders, including Crohn's disease, Blau syndrome and early-onset sarcoidosis [7]. In one family, taurinuria was associated [8]. Bilateral camptodactyly is also part of an autosomal recessive disorder (Crisponi syndrome) characterized by muscular contractions of the face, trismus, facial anomalies and death due to fevers. The syndrome is caused by *CRLF1* mutations and is allelic to cold-induced sweating syndrome type I [9].

Microdeletion of 1p36 is a relatively common syndrome, affecting 1:5000 neonates. Clinical features include camptodactyly, facial dysmorphism and low-set ears, cardiac and CNS defects; it is responsible for around 1% of idiopathic mental retardation [10]. Sporadic cases of camptodactyly have been linked with accelerated growth and osseous maturation, unusual facial appearance (including large ears, small mouth, broad forehead and hypertelorism), a hoarse, low-pitched cry and hypertonia (*Weaver's syndrome*) [11]. Other associated features include pectus excavatum and scoliosis.

Treatment, if required, is surgical [1,12,13].

Streblodactyly

Streblodactyly [1] is inherited as a sex-linked, autosomal, dominant character. The affected females show from birth a flexion deformity at the metacarpophalangeal joints of the thumbs and the proximal interphalangeal joints of the little fingers. Some fingers show swan-neck deformities and hyperextensible metacarpophalangeal joints. In one family there was an abnormal α-amino aciduria.

Plantar fibromatosis [1,2]

Synonym
- Ledderhose's disease

This is a much rarer condition than palmar fibromatosis. The lesions, which occur most often on the medial half of the mid-foot, present as one or more nodules, which may become painful and may ulcerate (Fig. 45.34). They rarely produce contractures, but they tend to be locally invasive and to recur. Total excision of the lesion and the entire plantar fascia seems to give the best results, with the lowest incidence of recurrence. The differential diagnosis includes keloid and fibrosarcoma, and in younger patients aggressive infantile fibromatosis and aponeurotic fibroma must also be considered [3]. Similar nodules have been described symmetrically affecting the anteromedial heel pads in children. They are asymptomatic and may resolve spontaneously [4,5]. Surgery is contraindicated.

Penile fibromatosis

Synonyms
- Peyronie's disease
- Plastic induration of the penis
- Fibrous sclerosis of the penis

Definition. Penile fibromatosis is characterized by one or more irregular, dense fibrous plaques in the penile shaft.

Aetiology. Penile fibromatosis may occur as an isolated abnormality, or as one component of polyfibromatosis in association with palmoplantar fibromatosis, keloids and knuckle pads. Atheroma predisposes to the condition, and it is now thought that the association with the use of β-adrenoreceptor blocking drugs is probably attributable to concomitant atheroma [1,2]. There may be a genetic factor, but reliable studies of the mode of inheritance are lacking. The condition is rare below the age of 20 years, and the highest incidence is between 40 and 60 years. It is much less common than palmar or plantar fibromatosis.

Pathology [3]. The thickened plaque shows cellular fibroblastic proliferation surrounded by dense masses of collagen. Calcification and ossification may occur. The process appears to begin as a vasculitis in the areolar connective tissue beneath the tunica albuginea, whence it extends to adjacent structures.

Clinical features. The disease presents with painful erections and curvature of the erect penis due to a thickened subcutaneous plaque, rubbery or hard, usually on the dorsal aspect of the penis in its distal third. The erectile deformity may make vaginal penetration impossible, and pain or anxiety about performance may cause secondary impotence. Fibrosis of the underlying cavernous erectile tissue may lead to a constriction or 'waisting' of the penile shaft, leading to flaccidity of the distal portion.

The course is unpredictable [4]. The pain generally subsides within a few months, but the fibrous plaque may resolve, remain unchanged or progress [5].

The severity of the disease and the response to treatment can now be evaluated by high-resolution ultrasonography [6], computed tomography [7] or magnetic resonance imaging of the erect penis [8]. If necessary, an erection can be induced by the intracavernosal injection of papaverine [9].

Treatment. Many treatments have been tried, but there is little evidence that vitamin E, potassium aminobenzoate, orgotein, radiotherapy, ultrasonic therapy or intralesional steroids affect the long-term outcome, although they may relieve the pain [4]. Clostridial collagenase injections have given promising results [10]. Surgery is probably the treatment of choice, using Nisbet's operation, in which ellipses of normal tunica albuginea are excised from the side of the shaft, opposite the point of maximum curvature. An alternative is venous grafting, using the deep dorsal vein [11]. A semirigid penile prosthesis may also be inserted.

Knuckle pads [1–4]

Synonym
- Holoderma

Definition. Knuckle pads are circumscribed thickenings overlying the finger joints. The term is a misnomer as most lesions occur over the proximal interphalangeal rather than the metacarpophalangeal joints (knuckles).

Aetiology. The condition is usually sporadic but several pedigrees have shown an autosomal dominant inheritance. The age of onset and the distribution of the lesions tend to be more or less constant in each family, but show interfamily variation. The condition is not rare but the true prevalence is uncertain, as most patients ignore the lesions. Knuckle pads are thought to be idiopathic in children, although they occur at sites prone to picking, chewing or 'knuckle cracking' [4].

Pathology [1]. The epidermis is grossly hyperkeratotic and acanthotic. The dermal connective tissue is hyperplastic and individual collagen fibres may be obviously thickened. Histologically, the changes resemble those of palmar fibromatosis.

Clinical features [2,3]. Flat or convex, smooth, circumscribed keratoses develop slowly and almost imperceptibly over the course of months or years. In some patients they become very much raised and obviously indurated, but in others the dermal component is not clinically apparent. They are most commonly seen over the dorsa of the proximal interphalangeal joints, but occasionally develop over the knuckles or the distal interphalangeal joints. Any single site or combination of sites may be involved. Sites other than the hands are not often affected, but similar lesions on the knees were also present in one family [2].

The age of onset is variable but it is more common after the fourth decade. In some individuals, the lesions may not be conspicuous until they have been present for some years.

An association between Dupuytren's contracture and other fibromatous lesions has been recorded in some families. In one large family, knuckle pads were associated with sensorineural deafness and with leukonychia [5]. Knuckle pads have also been associated with epidermolytic palmoplantar keratoderma in a Chinese family due to keratin 9 mutations [6].

Another family has been described with knuckle pads in association with oesophageal cancer, hyperkeratosis and oral leukoplakia [7].

In differential diagnosis, occupational callosities, Heberden's nodes of osteoarthritis, pachydermodactyly, granuloma annulare, erythema elevatum diutinum and rheumatoid nodules must be excluded.

Treatment. There is no satisfactory treatment. Excision may be followed by keloidal scarring.

Pachydermodactyly [1–7]

This is a benign fibromatosis of the fingers that usually affects young adult males (Fig. 45.35). It produces a symmetrical, diffuse swelling of the skin around the dorsal and lateral aspects of the proximal phalanges of the index, ring and middle fingers. Pachydermodactyly has been recently reported in women [4,5] and two young girls, one of whom had tuberous sclerosis and the other EDS [6]. It may be associated with bilateral carpal tunnel

Fig. 45.35 Pachydermodactyly. (Courtesy of Dr A. Chamberlain, Churchill Hospital, Oxford, UK.)

syndrome [2] and varioliform atrophy [8]. A distal variant has been described in an elderly woman, who also presented with nodules over the extensor aspects of the elbows [9]. Affected families have been reported [10].

It has been suggested that repeated rubbing of the fingers or mechanical injury to the joints may contribute to the condition [3,6], but pachydermodactyly must be distinguished from occupational callosities, obsessive 'chewing pads' and true knuckle pads [11,12], although knuckle pads and pachydermodactyly coexisted in one family [13].

Histology shows epidermal hyperplasia and marked dermal thickening, with extension of collagenous fibres into the subcutaneous tissue. Types III and V collagen are increased, and electron microscopy shows increased numbers of fine-diameter collagen fibres.

Juvenile fibromatoses

The term juvenile fibromatosis has been applied to a group of disorders occurring in infants and children, and characterized by proliferative activity of the fibroblasts [1–6]. There is a tendency to local recurrence but, unlike fibrosarcomas, they do not metastasize. The group includes a number of well-defined clinical entities that affect the skin:

1 infantile myofibromatosis
2 fibrous hamartoma of infancy
3 juvenile hyaline fibromatosis
4 infantile digital fibromatosis
5 calcifying aponeurotic fibroma
6 giant cell fibroblastoma.

These conditions are described in Chapter 56.

Juvenile hyaline fibromatosis

Synonyms
- Systemic hyalinosis
- Puretic syndrome

Definition. This is a disorder of glycosaminoglycan synthesis, which is characterized clinically by skin papules or tumours, gingival enlargement, osteolytic lesions and joint contractures, and histologically by deposition of amorphous hyaline material.

Aetiology. The cause is unknown, but increased chondroitin synthesis has been demonstrated in skin fibroblasts cultured from the tumour tissue [1]. The disease is very rare and occurs sporadically, but it has occurred in siblings.

Pathology [1–4]. The skin lesions contain 'chondroid' cells embedded in amorphous eosinophilic ground substance in the dermis. In the early lesions, this consists of glycosaminoglycans, but in the later lesions the matrix is mainly composed of chondroitin sulphate [5]. The dermal collagen is decreased and the collagen fibrils are fewer and thinner than in normal skin. The hyaline material may also be present in the muscles and bones. Absence of pro-α_2 chains and type III collagen has been demonstrated in affected skin [6].

Clinical features [4,7–10]. Skin lesions are present at birth or develop in early childhood. There may be small, pearly papules or nodules, particularly on the face or neck. Large subcutaneous tumours may also occur, particularly on the scalp. These may be hard or soft, fixed or mobile, and they may ulcerate. Gingival hypertrophy is commonly present, and flexion contractures of the fingers, elbows, hips and knees may develop. Osteolytic lesions can occur in the skull, long bones or phalanges. The musculature is poorly developed. The condition persists into adult life and the joint contractures are disabling. Infantile systemic hyalinosis is probably an extreme variant, leading to death in infancy.

Treatment. This is unsatisfactory. The tumours do not respond to radiotherapy, and they may recur after excision [11]. Joint

contractures may respond to intralesional steroid injections in the early stages and they may also respond to systemic steroids and physiotherapy.

Other benign fibrous cutaneous nodules

Nodular fasciitis

See Chapter 56. In this condition, there is fibroblastic proliferation of one or more nodules, usually on the limbs or trunk.

Collagenoma

Multiple fibrous dermal nodules with coarse, collagen fibres may develop as sporadic cases (*eruptive collagenoma*) or as a genetic disorder with a dominant inheritance (*familial cutaneous collagenoma*) (Chapter 18).

Collagen naevi

See Chapter 18.

Albopapuloid form of epidermolysis bullosa

Synonym
- Pasini's syndrome

This rare form of epidermolysis bullosa is characterized by the development of ivory-white papules on the trunk, which histologically show connective tissue hyperplasia. Epidermolysis bullosa is discussed in Chapter 39.

Buschke–Ollendorf syndrome

Extensive nodular fibrosis may occur in the Buschke–Ollendorf syndrome (Chapter 18), in association with juvenile elastoma and osteopoikilosis.

Fibrous digital nodules

In addition to giant cell synovioma and infantile digital fibromatosis, fibrous nodules in the digits may be due to acquired digital fibrokeratoma, fibrous papule of the finger, dermatofibroma (Chapter 56) or the Koenen tumour (Chapter 15).

Infantile stiff-skin syndromes

Several rare syndromes have been described in which hard, stiff skin and joint contractures develop in early life.

Systemic hyalinosis

Infantile systemic hyalinosis is an autosomal recessive condition in which the skin becomes diffusely thickened and hard in the first few weeks of life, with limited joint mobility. Other characteristic features include small nodular thickenings of the perianal region, ears or lips, and gingival hypertrophy. There may also be hyperpigmentation, painful swollen joints with contractures, osteopenia, diarrhoea, frequent severe infections and growth failure. The prognosis is poor, and survival beyond the age of 2 years is unlikely [1].

The tissues show widespread deposits of hyaline material with the general staining properties of collagen.

Clinically, this syndrome shares many similarities with juvenile hyaline fibromatosis (see p. 45.49) [2,3]. Mutations in capillary morphogenic protein 2 (*CMG2*) have been found in both conditions, indicating that they are allelic [4,5].

Winchester's syndrome

Diffusely stiff, thickened skin may also occur in Winchester's syndrome [6–8]. This is a rare, autosomal recessive disease of infancy characterized by joint contractures, gingival hypertrophy, dwarfism, osteolysis, arthralgia, corneal opacities and hypertrichosis. The prognosis is relatively good, and many patients survive into adult life.

Previously, similar cases have been described as *hereditary contractures with sclerodermatoid changes of skin* and *stiff-skin syndrome* [9], with increased mucopolysaccharides in the skin.

The skin changes resemble those of scleredema of Buschke but are distinguished by their early onset. The condition must also be distinguished from sclerema neonatorum, but this is a disorder of subcutaneous fat rather than the skin.

Winchester's syndrome is caused by mutations in the matrix metalloproteinase 2 (*MMP2*) gene. The clinical and molecular findings suggest that Winchester's syndrome, nodulosis–arthropathy–osteolysis (NAO) syndrome and Torg (hereditary multicentric osteolysis) syndrome are allelic disorders that form a clinical spectrum [10].

Congenital fascial dystrophy

Synonym
- Stiff-skin syndrome

This hereditary connective tissue disorder is characterized by mild hirsutism, limitation of joint mobility affecting gait and localized areas of stony-hard skin, which are otherwise normal in appearance [11]. It appears in early infancy, and is only slowly progressive. The condition affects the deeper skin and fascia, which is

much thicker than normal, and tends to be most pronounced on the buttocks and legs, with a sharp demarcation of subcutaneous sclerosis at the inguinal canal. Unlike morphoea, no inflammatory changes are seen on histology. Electron microscopy of the skin shows large collagen fibres, and bundles of aggregated microfibrils [11]. Thickening of the thoracic fascia may cause hypoventilation due to thoracic underdevelopment, but there are no other systemic features of this disease.

The condition appears to be analogous to the tight-skin mouse [12].

Restrictive dermopathy

This very rare autosomal recessive laminopathy, also known as tight skin contracture syndrome, presents at birth with a taut, shiny skin, which restricts movement of the joints [13–15]. It is characterized by intrauterine growth retardation and premature birth, due to ruptured fetal membranes. The typical facies is a small, fixed, round, open mouth, micrognathia, small nose, low-set ears and widely spaced cranial sutures. The joints are all fixed in flexion, and gross restriction of the respiratory movements causes death within hours, or at most weeks. The epidermis shows hyperkeratosis and parakeratosis, and the keratohyaline granules are abnormal. The dermal–epidermal junction is flat, with a thin dermis, and a thick layer of subcutaneous fat. The eccrine and pilosebaceous glands are underdeveloped. The collagen bundles appear stretched, and orientated in parallel lines, as they are in a tendon [16].

Mutations have been found in the *LMNA* genes leading to synthesis of mutant prelamin A that cannot be processed into mature lamin A. Mutations in the prelamin A processing enzyme gene (*ZMPSTE24/FACE-1*) also cause abnormal accumulation of the precursor with deleterious effects on nuclear homeostasis [17,18].

Other causes of diffuse fibrosis

Environmental and drug-induced scleroderma

(see also Chapter 51)

A variety of environmental triggers may stimulate a localized or diffuse scleroderma-like reaction in a genetically susceptible host. Important causes are listed in Table 45.5. In most cases, the fibrotic process continues after withdrawal of the external stimulus. Sometimes, the ensuing clinical pattern resembles idiopathic forms of scleroderma (see Chapter 51).

Exposure to *vinyl chloride monomer* occurs in workers involved in polyvinyl chloride (PVC) production. One-third of male

Table 45.5 Cutaneous fibrosis due to chemical exposure.

Vinyl chloride
Silica dust
Organic solvents:
Aromatic hydrocarbons (e.g. toluene, benzene)
Aliphatic hydrocarbons:
Chlorinated (e.g. trichlorethylene, perchlorethylene)
Non-chlorinated (e.g. naphtha-*n*-hexane)
Epoxy resins
Toxic oil syndrome
Urea formaldehyde foam insulation
Breast augmentation (paraffin, silicone)
Drugs:
Reactions to local injection:
Phytomenadione
Pentazocine
Heparin
Reactions to systemic therapy:
Bleomycin
L-tryptophan (eosinophilia–myalgia syndrome)
Carbidopa and L-5-hydroxytryptophan
Penicillamine
Valproate sodium
Cocaine
Appetite suppressants (diethylpropion hydrochloride, amphetamine)
Diltiazem

Fig. 45.36 Vinyl chloride-induced osteolysis affecting fingertips.

Fig. 45.37 Scleroderma and scarring of the face due to porphyria cutanea tarda. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

operatives in a British factory developed a clinical syndrome that included Raynaud's phenomenon, dyspnoea, cutaneous sclerosis, pulp atrophy and radiological evidence of acro-osteolysis (Fig. 45.36) [1]. Genetic marker studies have demonstrated an increased incidence of human leukocyte antigen (HLA)-DR5 in affected individuals; severe disease is linked with B8 and DR3 [2]. A similar syndrome has been reported in gold miners exposed to silica dust [3], and in workers exposed to organic solvents, such as trichlorethylene [4] and perchlorethylene [5], which are structurally similar to vinyl chloride. Exposure to epoxy resin results in an acute syndrome of cutaneous sclerosis, muscle weakness, arthralgia, impotence, lung and oesophageal involvement [6]. The causative agent appears to be a cyclohexylamine. An increased prevalence of autoimmune disorders, including scleroderma, is reported in miners exposed to vermiculite contaminated with tremolite asbestos [7].

Toxic oil syndrome is a multisystem illness, reported in Spain in 1981. Acute fever, severe but transient pulmonary oedema, myalgia, and a pruritic exanthem and eosinophilia were followed after several months by widespread cutaneous sclerosis in 30% of cases [8,9]. The syndrome was probably due to ingestion of imported rapeseed oil mixed with an aniline denaturant, designed to make the oil unfit for human consumption. Toxic oil syndrome bears a striking resemblance to the *eosinophilia–myalgia syndrome* [10–12], linked with consumption of L-tryptophan; this is used as a 'food supplement' to treat insomnia and depression. The offending batches of L-tryptophan contained impurities similar to the contaminants in toxic oil [13,14].

In environmental fibrotic disorders, as in idiopathic scleroderma, subpopulations of fibroblasts appear to be activated to synthesize excess collagen; this property is perpetuated by fibroblasts *in vitro*, indicating that the elevated collagen gene expression is independent of extracellular stimuli [12]. Cytokines appear to stimulate the proliferation of these abnormal clones of fibroblasts; thus, transforming growth factor-β (TGF-β) and platelet-derived growth factor (PDGF) are elevated in the eosinophilia–myalgia syndrome [15].

Numerous drugs have been reported to induce cutaneous sclerosis. Lesions resembling morphoea may follow injections of pentazocine [16], heparin [17] and vitamin K_1 (phytomenadione) [18–20]; in the case of vitamin K_1, the trigger may be a solvent rather than vitamin K_1 itself [21]. Morphoea-like plaques have also been reported in patients taking penicillamine [22] and valproate [23].

Diffuse scleroderma-like changes have been reported following bleomycin therapy [24]. A combination of L-5-hydroxytryptophan and carbidopa induced lesions resembling eosinophilia–myalgia syndrome [25]. Phenytoin and diltiazem both induce gingival hypertrophy [26,27]. A patient on phenytoin developed florid hypertrophic retroauricular folds [28]. Thickened skin on the feet has been reported in a patient taking diltiazem [29].

Alcohol can provoke porphyria cutanea tarda, which can produce a sclerodermatous appearance (Fig. 45.37).

Nephrogenic systemic fibrosis

Synonyms
- Scleromyxoedema-like illness of renal disease
- Nephrogenic fibrosing dermopathy

Acute onset of skin thickening has been reported in patients with renal disease undergoing haemodialysis or renal transplant [1]. Irregular erythematous or brownish indurated plaques, with amoeba-like projections and islands of sparing, occur chiefly on the lower trunk and legs. Sometimes the skin has a *peau d'orange* texture, which can mimic carcinoma erysipelatoides [2]. Dermal mucin is detected with Alcian-blue staining, and increased collagen is laid down in haphazard bundles; there are increased numbers of $CD68^+$ histiocytes, dermal dendrocytes and fibroblasts. Inflammatory changes may predominate, including a septal panniculitis [3]. Although initially described as 'scleromyxoedema-like', the lesions have a different distribution and morphology, and there is no associated paraproteinaemia [4]. Initially thought to be restricted to the skin, there are several reports of involvement of internal organs including lungs, myocardium and striated muscle, which contribute to a high mortality [4].

The condition is strongly associated with the prior administration of gadolinium-based magnetic resonance contrast agents, particularly in patients with severe renal disease [5]. Gadolinium chelates stimulate fibroblast growth, synthesis and differentiation into myofibroblasts [6]. High-dose erythropoietin may also be implicated [7].

Usually, the condition is progressive, although it may remit spontaneously, particularly with the correction of renal abnormalities. No treatment is of proven benefit, but thalidomide [8], hydroxychloroquine [9], intravenous sodium thiosulphate and extracorporeal photopheresis [10] have been used empirically. Transient benefit has been reported with the use of the tyrosine kinase inhibitor imatinib mesylate [11].

GEMSS syndrome

This is an autosomal dominant condition, comprising *g*laucoma, lens *e*ctopia, *m*icrospherophakia (small, spherical lens), joint *s*tiffness and *s*hort stature [1]. Affected individuals have a stocky, 'pseudoathletic' build. Associated cutaneous sclerosis notably affects the upper back and limbs but spares the face. Skin histology is reminiscent of systemic sclerosis. Increased synthesis of collagen is reflected by markedly enhanced gene expression of $TGF\beta_1$ [2].

POEMS syndrome (see also Chapters 58 & 62)

Synonym
- Crow–Fukase–Takatsuki syndrome

This acronym is derived from *p*olyneuropathy, *o*rganomegaly (of liver, spleen or lymph nodes), *e*ndocrinopathy (often diabetes mellitus), *M* protein (a monoclonal gammopathy) and *s*kin lesions. The skin features include hyperpigmentation, hyperhidrosis, hypertrichosis and diffuse thickening resembling scleroderma [1–3]. Rarer features include angiomas, white fingernails and alopecia [3].

The syndrome appears to be a rare variant of myelomatosis [4], although skeletal X-rays show single or multiple osteosclerotic lesions with areas of bony proliferation rather than the lytic lesions that are more typical of myeloma [5].

Overproduction of vascular endothelial growth factor (VEGF) may explain the microangiopathy, neovascularization and accelerated vasopermeability that occur in this syndrome [6].

High-dose chemotherapy followed by autologous stem cell transplant is a successful treatment, although morbidity is high [7].

Keloids and hypertrophic scars

Both conditions represent an excessive connective tissue response to injury, which may be trivial. A keloid (cheloid, meaning 'crab claw') is a benign, well-demarcated area of fibrous tissue overgrowth that extends beyond the original defect. A hypertrophic scar is similar, but remains confined to the initial defect and tends to resolve with time [1].

Aetiology. The cause is unknown, although both local and constitutional factors are involved. A scar at any site has the potential to become hypertrophic or keloidal, although the earlobes, chin, neck, shoulders, upper trunk and lower legs are especially vulnerable. Ear piercing is an important cause of earlobe keloids. Burns or scalds and infected lesions predispose to hypertrophy. Another risk factor is the presence of foreign material, either exogenous (e.g. suture material) or endogenous (e.g. embedded hair). Some African tribes introduce foreign bodies into tribal marks to induce scar hypertrophy. Scarring acne, particularly on the trunk, may become keloid-like. Isotretinoin has been reported to delay wound healing and induce keloids in patients who received argon laser or dermabrasion for acne or rosacea [2,3].

Some races, notably Afro-Caribbeans, are more prone to develop keloids than others. A positive family history is obtained in 5–10% of Europeans with keloids, particularly severe lesions [4]. Family studies suggest an autosomal dominant inheritance with incomplete penetrance [5]. There is a genetic association with other 'fibromatoses' such as Dupuytren's contracture [6]. Keloids form readily in acromegalics, and after thyroidectomy in young patients. They have been reported in a boy with Dubowitz's syndrome [7]. Keloids are also recorded in association with EDS, pachydermoperiostosis and Rubinstein–Taybi syndrome [8]. Keloids are rare in infancy and old age, occurring chiefly between puberty and the age of 30 years. Women have a greater predisposition, and keloids may occur or enlarge during pregnancy [9].

Linear keloids have been reported to occur in athletes taking anabolic steroids [10].

Pathology [11–13]. Although the histology may be difficult to distinguish from normal wound healing in the early stages, hypertrophic scars and keloids typically exhibit increased cellularity. In keloids of recent onset, endothelial proliferation is surrounded by increased numbers of fibroblasts, which form large, irregular nodules or whorls of collagen with a peripheral capsule-like band [11]. Mast cells are increased in hypertrophic scars [12]. Mucinous material is deposited focally in keloids but not in hypertrophic scars. The epidermis is normal, or thinned by the underlying lesion.

On electron microscopy, the nodules contain stellate fibroblasts. It is uncertain whether these are [14] or are not [15] myofibroblasts. Scanning electron microscopy of keloids shows more haphazard organization of collagen bundles than in normal skin or mature scars. The collagen filaments are about half the diameter of those of normal skin.

Biochemical studies confirm that collagen and proteoglycan synthesis is increased in keloids and hypertrophic scars. Collagen degradation appears to be normal [16]. Synthesis of both types I and III collagen is increased [17], and hypertrophic scar collagen possesses the reducible keto cross-link, dehydrohydroxylysinonorleucine, normally associated with embryonic skin and granulation tissue [18]. Several growth factors have been studied using keloid fibroblasts *in vitro*. Keloid fibroblasts, unlike those from hypertrophic scar tissue, are hyperresponsive to both TGF-β, which is abundant in healing wounds [19], and PDGF [20]. Keloid fibroblasts also express increased levels of heat shock protein (HSP) 47, another stimulus to collagen synthesis [21].

Keloid fibroblasts secrete increased amounts of collagen and glycosaminoglycans for several passages in tissue culture [22]. It is unclear whether these cells represent a normal subgroup or have undergone transformation. Altered expression of proteoglycans in keloids may affect the three-dimensional organization of collagen fibres [23].

Immunohistochemical studies have shown that neuropeptide-containing nerves are present [24] and opioid receptors are upreg-

Fig. 45.38 Spontaneous keloids of the neck.

ulated [25] in hypertrophic scars but not in non-hypertrophic scars, and these may contribute to the symptoms of discomfort and itching in such scars.

Clinical features. Both hypertrophic scars and keloids become raised and thickened within 3–4 weeks of the provocative stimulus. The lesion becomes a firm, pink or red plaque, which may grow for months or years. Lesions often assume a 'dumb-bell' configuration, but sometimes become bizarre and irregular (Fig. 45.38). Usually, a hypertrophic scar shows signs of regression after a few months. The surface of a keloid becomes smoother and rounder, extending beyond the area of the original lesion. It is often irritable and hypersensitive, and sometimes exquisitely tender. Keloids tend to regress after several years; lesions on the beard area sometimes undergo central suppurative necrosis. Malignant degeneration has been reported [26], although a fibrosarcoma can mimic keloid clinically.

The diagnosis is usually simple if there is a history of trauma or an inflammatory skin lesion. Spontaneous keloids usually develop on the presternal region or upper chest. Lesions that can cause diagnostic difficulty include sclerotic basal cell carcinoma, scar sarcoid or malignancy developing in a scar, and dermatofibrosarcoma. In endemic areas, blastomycosis and lobomycosis cause keloidal reactions.

Prophylaxis and treatment. Although numerous treatments have been advocated with enthusiasm, a cure is rarely achieved [27]. Non-essential surgery should be avoided in the sites of predilection. If surgery is necessary, simple excision, ideally intralesional (core) excision, aiming to minimize skin tension and secondary infection, is preferable to electrocoagulation or caustic chemicals. In an individual at risk, preoperative radiotherapy to the excision site may be useful.

Keloids usually recur following simple excision, although adjuvant therapy, such as radiation, local compression with a custom-made pressure garment [28], particularly on the earlobe, or intralesional steroids may reduce the risk of recurrence. Some lesions respond to pressure alone, or to occlusion with a hydrocolloid dressing. Small keloids can respond to self-adherent silicone sheeting/silicone gel [29,30]. Silicone gel treatment is also effective for hypertrophic scars [29]. Promising results have been obtained using a cream made of 20% silicone oil, applied under occlusion; this may be beneficial for sites where it is impracticable to apply gel-sheeting [31].

Radiotherapy, including superficial X-rays, implantation with iridium-192 wires, or more recently with electron beam may prevent recurrence following surgery [32,33], but electron-beam therapy offers no advantage over orthovoltage [34]. Intralesional triamcinolone (10 mg/mL) is useful, especially in early lesions. Several injections may be necessary at intervals of 3–6 weeks. Prior freezing with liquid nitrogen before the injection causes oedema, which allows the triamcinolone to be injected more readily. Acne keloids respond moderately well to either intralesional triamcinolone or cryotherapy, but the response to the latter is better in early vascular lesions [35].

Topical retinoic acid, applied daily, may be helpful [36,37], although systemic retinoids may enhance keloid formation [3]. Intralesional lathyrogens, such as β-aminoproprionitrile, have been used, but systemic penicillamine is ineffective [38]. Intralesional cytotoxic drugs may cause ulceration, but intralesional 5-fluorouracil and 585-nm flashlamp-pumped pulsed dye laser produced comparable improvement in one study [39]. Flattening and reduced pruritus is claimed to follow intralesional bleomycin, administered through multiple superficial punctures [40]. A preliminary study suggests that topical mitomycin C reduces the risk of recurrence after shave biopsy of keloids [41].

Inhibitory cytokines, such as IFN-α and IFN-γ [42–44] perhaps in conjunction with intralesional triamcinolone [45], and TGF-β analogues [46], show promise. Interferons appear to reduce fibroblast collagen synthesis and increase collagenase activity by reducing the steady-state levels of mRNA [44]. Imiquimod cream can prevent recurrence of earlobe keloids after excision but is of limited value for presternal lesions [47]. Studies of keloid fibroblasts *in vitro* suggest a possible future role for gene therapy [48].

Different modes of laser treatment, for example the pulsed dye, Nd:YAG and carbon dioxide lasers, have a high recurrence rate.

Premature ageing syndromes [1,2]

Increasing age appears to cause many anatomical and functional changes in human skin, but some of these may be the result of cumulative damage due to sun exposure, etc. To date, no disease has been found to cause a true acceleration of the rate of ageing in all tissues. More than 150 diseases manifest one or more features of apparent premature ageing, but there are discrepancies between this process and true ageing. All the premature ageing syndromes are probably inherited, although the defect may not be obvious in the first few years of life. Cutaneous changes that may be a sign of a premature ageing syndrome include atrophy, loss of cutaneous fat, wrinkling, canities, hair loss, nail dystrophy, defective pigmentation, poikiloderma, sclerosis and ulceration.

The conditions associated with cutaneous signs of premature ageing are shown below.

1 Classical inherited premature ageing syndromes:
  (a) pangeria (Werner's syndrome)
  (b) progeria (Hutchinson–Gilford syndrome)
  (c) acrogeria (Gottron's syndrome)
2 Other congenital progeroid syndromes:
  (a) trisomy 21 (Down's syndrome)
  (b) neonatal pseudohydrocephalic progeroid syndrome (Wiedemann–Rauchenstrauch)
  (c) osteodysplastic geroderma
  (d) wrinkly skin syndrome
  (e) familial mandibulo-acral dysplasia
  (f) progeroid EDS
3 Excessive exposure to irradiation (usually UV)
4 Photosensitivity, especially congenital, for example poikiloderma congenitale, xeroderma pigmentosum, Cockayne's syndrome

5 Diseases causing elastolysis, for example cutis laxa
6 Thickened immobile skin, for example diabetic cheiroarthropathy
7 Fragile skin, for example prolidase deficiency
8 Loss of subcutaneous fat, for example generalized lipodystrophy.

Pangeria

Synonyms
- Werner's syndrome
- Adult premature ageing syndrome

Definition. An inherited disorder in which the ageing process is accelerated, starting after puberty. It is characterized by short stature, senile appearance, cataracts, joint contractures, early menopause, premature arteriosclerosis, various skin changes (including scleroderma-like features, premature canities, baldness and ulceration) and an increased risk of malignancy [1]. Werner's syndrome is considered one of the genomic instability syndromes [2].

Aetiology. The syndrome is due to an autosomal recessive gene, with a calculated gene frequency of 1–5 per 1000 population [3].

Numerous abnormalities have been described in this syndrome, including chromosomal aberrations (most noticeably translocations, inversions and deletions), altered connective tissue metabolism, and abnormalities in the immune and endocrine systems [4–14].

Causal mutations have been identified in the RecQ type DNA helicase gene (*RECQL2*, *WRN* gene) [15,16]. Recent biochemical and genetic studies indicate that the *WRN* gene plays significant roles in DNA replication and repair and telomere maintenance [17].

Pathology. Many tissues show premature ageing, but the changes are not uniform. Microsplanchnia and generalized atheroma are usually present. The epidermis is atrophic and some appendages are sparse. The dermis is thickened, with replacement of subcutaneous fat by hyalinized collagen, increased glycosaminoglycans, abnormal elastic fibres, disorganized nerves and vessel changes, which resemble those seen in diabetes mellitus. These abnormalities are more marked in the acral skin than on the trunk [4].

Clinical features [1]. The earliest manifestation of the syndrome is greying at the temples, which usually develops between the ages of 14 and 18 years but may rarely be present as early as 8 years. The greying rapidly becomes uniform and is sometimes associated with progressive alopecia. The first significant changes are usually noticed between 18 and 30 years but may begin earlier. The lower legs, feet, forearms and hands are most severely involved, the face and neck less so; atrophy of the skin and loss of subcutaneous fat results in a tense, shining and adherent appearance of the skin. Thin, spindly legs contrast with the normal or obese trunk, and there is a bird-like facies. The joints become fixed, and there may be sclerodactyly and acral gangrene. Mottled or diffuse pigmentation and telangiectasia are often conspicuous on the limbs, face and neck. Keratoses over pressure points on the feet and ankles separate to leave indolent ulcers. The voice may be high pitched and hoarse from thinning of the cords and fixation of the epiglottis. Intelligence is usually normal.

Most patients are of small stature and hypogonadal, with sparse or absent pubic and axillary hair, but some achieve normal stature and successful pregnancies. Other endocrine deficiencies are sometimes present; frank diabetes mellitus in at least 30% and abnormal glucose tolerance in many others. The diabetes is characterized by relatively low blood glucose levels and peripheral resistance to insulin [18,19].

Cataracts develop between the ages of 20 and 35 years in most cases and are usually posterior and subcapsular. Other ocular defects may occur [20].

The incidence of malignancy is high, especially fibrosarcomas, which occur in 10% of patients [21]. Carcinoma has developed in a chronic leg ulcer [22], but skin cancer is relatively rare. Generally, atheroma develops early. Abnormalities of metabolism are sometimes present but are not of uniform type. Death usually occurs in the fourth to sixth decade, due to myocardial infarction or malignancy [23].

The radiological changes [24] are often striking. There may be calcification of arteries, ligaments, tendons and subcutaneous tissues, with osteoporosis of the extremities, especially the legs.

Diagnosis. The prematurely aged appearance, the physical immaturity, the scleroderma-like changes and the cataracts, in combination, are unmistakable. In the Rothmund–Thomson syndrome, erythema, which is of early onset, is followed by poikilodermatous changes and, although the facies may be superficially similar, there is no sclerosis. In systemic sclerosis, the hands are involved more than the feet and there is no premature ageing; in some advanced cases, confusion is possible but can be resolved by biopsy.

Huriez syndrome may require exclusion (Chapter 19). The differentiation from some of the other ageing syndromes is indicated in Table 45.6.

Mutational analysis of the *WRN* gene is now possible, although diagnosis by immunoblot analysis using a monoclonal antibody directed against the *WRN* gene product is also feasible [25].

Treatment. Only symptomatic measures are available. The management of the recurrent, painful ulceration of the feet and legs is difficult, and amputation may be needed. Cataract surgery should be undertaken with special caution, for it is often complicated by severe degenerative changes of the cornea [20].

Table 45.6 Clinical features of the classical premature ageing syndromes.

	Pangeria (Werner's syndrome)	Progeria (Hutchinson-Gilford sndrome)	Acrogeria (Gottron's syndrome)
Stature	Small stature; cessation of growth at 12 years	Small stature	Normal
Facies	Beaked nose; skin of ears atrophic and tightly bound down	Mid-facial cyanosis; bird-like facies; glyphic nasal tip; prominent frontal tuberosities and scalp veins; chin recessed	Micrognathia; atrophy of skin on tip of nose
Skin	Dry atrophic skin; mottled hyperpigmentation; telangiectasia	Dry, thin and wrinkled with mottled pigmentation; may present with scleroderma-like changes on limbs	Atrophic with telangiectasia and mottled hyperpigmentation on extremities
Scalp hair	Premature greying at 20 years; loss of hair at 20–25 years	Hair lost in first 2 years of life	Normal
Eyes	Bilateral juvenile cataracts (20–30 years); keratopathy; glaucoma	Prominent eyes; otherwise normal	Normal
Nails	Normal	Thin and brittle	Dystrophic or thickened
Limbs	Lower limb ulcers; hyperkeratosis over bony prominences; generalized loss of subcutaneous fat	Prominent joints; coxa valga; generalized subcutaneous fat loss; poorly developed muscular system; no acrosclerosis or Raynaud's phenomenon	Atrophy of skin most marked on extremities; no leg ulcers

Progeria

Synonym
- Hutchinson–Gilford syndrome

Definition. This is a rare disorder characterized by retarded physical development and abnormal facies, skeletal abnormalities and the onset in early childhood of scleroderma. Although progressive senile degeneration occurs, many of the more common features of ageing, such as cataracts, presbyacusis and presbyopia, are not seen.

Aetiology. It occurs due to *de novo* mutations of the lamin A gene (*LMNA*) which encodes for a major constituent of the inner membrane lamina [1]. Reduced cell proliferation and altered DNA-damage responses are common causal mechanisms in the pathogenesis of both Werner and Hutchinson–Gilford syndromes [2]. Affected families have a high risk of spontaneous abortion.

Various abnormalities of mesodermal tissue have been identified [3]. In tissue culture, progeria fibroblasts have a decreased survival time [4]. The fibroblasts show a threefold increase in the production of hyaluronic acid, and the urinary excretion of hyaluronic acid is increased [4–7]. Animal studies suggest that increased hyaluronic acid in the tissues might produce a reduction in vascularity [5,8]. Tropoelastin production is increased [9], and it has also been suggested that type IV collagen may accumulate due to an interaction between activated T lymphocytes and fibroblasts [10,11]. A preliminary study of cultured fibroblasts from two affected patients suggests mitotic instability [12]. A polymorphism in the galactosyltransferase gene (*B4GALT1*) has been identified in affected cell lines [13].

Fewer than 100 cases have been reported to date, and 97% of patients have been white [8].

Pathology [14]. The major changes are in the skin, bone and cardiovascular tissues.

The skin shows atrophy of epidermis and dermis. There may be progressive hyalinization of dermal collagen and loss of subcutaneous fat. Scanning electron microscopy of hairs from one patient showed unusual longitudinal depressions with minor cuticular defects [11].

The cardiovascular system shows extensive atheroma, and there may be extensive myocardial fibrosis, with extensive lipofuscin ('age pigment') deposition characteristic of elderly adults [15,16].

The bones show a variety of changes including osteolysis, osteoporosis, necrosis, dislocations and poorly healing fractures [17,18].

Clinical features [19]. Affected children usually appear normal at birth, and growth may be only slightly retarded in the first year, but during the second year there is profound growth failure, with reduced subcutaneous fat on the face and limbs [8]. The facial appearance is reminiscent of a fledgling bird, with a disproportionately large cranium with patent fontanelles and frontal bossing, prominent eyes and scalp veins, very sparse, downy scalp hair, sparse or absent eyebrows and eyelashes, centrofacial cyanosis, micrognathia, thin lips and a 'beaked' nose. By the second year, the skin has become thin, taut and shiny in some areas but lax and finely wrinkled in others. Eccrine sweating is decreased. The veins are prominent and there may be easy bruising. After several years, progressive mottled hyperpigmentation develops, most marked on exposed sites, but there is no photosensitivity. Thickened sclerotic areas may be present on the lower trunk or thighs, and in one case multiple keloids developed on the hands and arms [11]. The nails are usually small, thin and dystrophic, and koilonychia and onychogryphosis may occur. Generalized alopecia often begins in the first year of life and the few remaining hairs are pale, fine and 'fuzzy'. The nipples may be hypoplastic.

The dentition is abnormal and delayed, and there may be skeletal abnormalities such as dystrophic clavicles and coxa valga, with joint contractures and a 'horse-riding' stance. Progressive bone resorption may lead to frequent fractures [18]. Sexual maturation is absent but intelligence is normal.

Death usually occurs in the second decade as a result of severe, generalized atheroma.

Diagnosis. The large, bald head with conspicuous veins, the bird-like facies and the well-proportioned little body are distinctive. Bird-headed dwarfism (Chapter 15) is distinguished by the absence of skin atrophy.

Cockayne's syndrome may cause confusion, but progeria is distinguished by the loss of hair, the lack of photosensitivity and ocular changes, and the absence of disproportionately large extremities.

In metageria, sexual maturation and skeletal growth are normal [20].

Acrogeria [1–4]

Synonym
- Gottron's syndrome

Definition. This disorder begins at birth or soon afterwards, and is characterized by cutaneous atrophy and loss of subcutaneous fat, particularly over the distal extremities, but with no tendency to atheroma, diabetes mellitus or decreased life expectancy. The term 'acrogeria' refers to premature ageing of the extremities.

Aetiology. Most cases occur without a family history, but presumed autosomal recessive as well as autosomal dominant inheritance has been reported [1,2]. Most patients have been female. *COL3A1* mutations cause variable phenotype, including Gottron-type acrogeria and vascular EDS [5,6].

Pathology. The subcutaneous fat is absent in the most severely affected regions. The dermis is atrophic, with sparse, thin collagen bundles, but there is abundant elastin, which appears clumped due to the deficiency of collagen.

Clinical features. The changes develop at or soon after birth. The skin becomes dry, thin, transparent and wrinkled, especially over the hands and feet, although the trunk and face may be affected

to a lesser extent. The veins are prominent, and there may be easy bruising, poikiloderma and telangiectasia. The nails may be atrophic or thickened. The face appears 'pinched', with a hollow-cheeked 'owl-eyed' appearance, a beaked nose and thin lips. Micrognathism may be present. The lack of subcutaneous fat accentuates the appearance of premature senility. Some patients have low birth weight and persistent short stature, but the general health and life expectancy are normal. The hands and feet may be very small.

Diagnosis. The normal hair and eyes help to distinguish the condition from progeria and pangeria. Cases are occasionally described which do not fit easily into any of the previously recognized categories and have been termed metageria and acrometageria [7,8]. It is not entirely clear whether these are separate entities.

Laboratory studies [1–3]

Fibroblasts from normal human skin have a limited lifespan in culture, which is inversely proportional to the age of the donor, and it seems that the *in vitro* ageing of fibroblasts may serve as a model for the *in vivo* ageing of the whole body. All the premature ageing syndromes studied to date have shown a marked reduction in fibroblast growth potential *in vitro*. These include Werner's syndrome, progeria, poikiloderma congenitale, trisomy 21 and diabetes mellitus. In addition, fibroblasts from progeria patients have shown a decrease in mitotic activity, rate of outgrowth from explants, DNA synthesis and cloning efficiency. Studies on fibroblasts from patients with progeria and Werner's syndrome have also shown enzyme changes consistent with an accelerated ageing process.

In the normal ageing process, there is a threefold increase in the affinity of surface insulin receptors for native insulin between the first and seventh decades. This accounts for the clinical finding of relative insulin resistance in the elderly. Patients with progeria also show increased insulin binding and relative insulin resistance.

Other cellular abnormalities in Werner's syndrome and progeria include a decrease in surface-membrane HLA antigens and a marked increase in the activity of a procoagulant, which may predispose to atheroma.

Post-irradiation DNA repair appears to be normal in progeria and pangeria, although the cultured fibroblasts may have reduced karyotype stability. A reduction in DNA stability might increase the rate of genomic deterioration, and this might accelerate cellular ageing.

Other associated conditions

Premature ageing with short stature and pigmented naevi

Synonym
- Mulvihill–Smith syndrome

This rare syndrome [1] is characterized by low birth weight, short stature and moderate mental retardation, associated with multiple pigmented naevi and a distinctive bird-like facies. There is a small chin, with broad forehead, and the lack of facial subcutaneous fat gives an appearance of premature ageing. Other features include hypospadias, a high-pitched voice, irregular dentition, fine hair, hepatomegaly and low IgG. The clinical features tend to become more noticeable with increasing age.

Neonatal pseudohydrocephalic progeroid syndrome of Wiedemann–Rautenstrauch [1–3]

This rare, autosomal recessive condition is characterized by mental and physical retardation and frontal and lateral bossing of the skull, with small facial bones, a small, beak-shaped nose, low-set ears, small mouth with dysodontia, and ectropion. The scalp hair and eyebrows are long and sparse, the extremities are thin, and the hands are large with long fingers and atrophic nails. The subcutaneous fat is decreased, the skin is thin and wrinkled, and the veins are prominent.

Gerodermia osteodysplastica [1]

Stunting of growth from early childhood is associated with senile changes in the skin, with normal scalp hair. Wrinkly, lax skin is

most prominent on the dorsa of the hands and feet. Generalized osteoporosis, multiple fractures, joint laxity and skeletal malformations, including Wormian bones, occur. The face appears sad, with drooping eyelids and jowls, malar hypoplasia and mandibular prognathism. Relatives presenting partial forms of the syndrome showed cutaneous ageing and osteodysplasia without dwarfism. Skin biopsy may show fragmented elastic fibres. Two reports of consanguineous Arabian families showed features overlapping both gerodermia osteodysplastica and wrinkly skin syndrome, suggesting that they may represent variable manifestations of the same disorder [2,3].

Wrinkly skin syndrome [1]

This rare, familial condition is characterized by the appearance at birth of dry, wrinkled skin of the hands, feet and ventral surfaces of the trunk. The veins are unduly prominent. There may also be mental retardation, ocular defects and poor muscle tone. The cause is unknown, and the dermal collagen and elastin appear normal on light microscopy. There is some phenotypic overlap with gerodermia osteodysplastica and autosomal recessive cutis laxa type II [2].

Poikiloderma congenitale

Synonym
- Rothmund–Thomson syndrome

This condition is fully described in Chapter 15. It may be considered as a premature ageing syndrome because of the atrophic hyperpigmented skin, the early onset of cataracts, and the premature greying and loss of hair. The striking poikiloderma is distinctive.

Cockayne's syndrome (Chapter 15)

The atrophic skin with mottled pigmentation and loss of subcutaneous fat on the face produce an appearance of premature senility, and the disease has often been confused with progeria.

Trisomy 21 (Chapter 15)

Synonym
- Down's syndrome

This disorder shows more features of true ageing than the classical premature ageing syndromes [1]. These features include progressive dementia with the neurofibrillary tangle seen in senile dementia, amyloid and lipofuscin deposition in many organs, diabetes mellitus, cataracts, cardiovascular disease, increased incidence of autoimmune disease and malignancy, and a decreased life expectancy [2].

The cutaneous features include dry, lax skin, and premature greying and loss of hair [2].

Familial mandibulo-acral dysplasia

Synonym
- Craniomandibular dermatodysostosis

The main features of this rare syndrome are mandibular hypoplasia, delayed cranial suture closure, dysplastic clavicles, abbreviated club-shaped terminal phalanges associated with acro-osteolysis and atrophy of the skin over the hands and feet [1] (Fig. 45.39). Other characteristics may include short stature, multiple Wormian bones, prominent eyes and a sharp nose [2,3]. In one family, the condition was also associated with loss of the lower teeth and alopecia [4]. Two types of body fat distribution patterns, both of which are associated with insulin resistance and its metabolic complications, may be evident; partial lipodystrophy of the extremities (type A) and generalized loss of subcutaneous fat (type B) [5]. Both are autosomal recessive, with mutations in the gene encoding lamin A/C; *LMNA* underlie type A and mutations in the zinc metalloproteinase STE24 gene (*ZMPSTE24*) give rise to type B [6,7].

Fig. 45.39 Familial mandibulo-acral dysplasia, showing the short, club-shaped terminal phalanges, the so-called 'tree-frog' appearance. (Courtesy of Dr A.M. Zina, Turin University, Turin, Italy.)

The cutaneous changes are a milder phenotype of progeria and some cases have been mistakenly diagnosed in the past as acrogeria or Werner's syndrome.

Diabetic thick skin [1,2]

Synonym
- Cheiroarthropathy

Diabetes may be classified as a premature ageing syndrome because of the predisposition to cataracts and atheroma and the reduced life expectancy [1,3].

Some patients with diabetes mellitus have thick, tight, waxy skin and limited joint mobility. This combination has been called *cheiroarthropathy* [4]. Affected patients are unable to bring their palms completely together, and their fingers will not bend backwards. The 'prayer sign', in which the patient tries to oppose the two palms, provides an easy screening test [5]. Skin and tendon sheath thickness has also been measured by ultrasound [6,7].

Cheiroarthropathy is present in 30–40% of insulin-dependent diabetics, and in non-insulin-dependent diabetics the figures have varied widely, from 4% to 70%. The changes may even precede the diagnosis of diabetes [8]. The changes are important because affected patients have an increased risk of retinal and renal disease due to microvascular damage [9]. Patients with diabetic cheiroarthropathy also have an increased incidence of frozen shoulder and Dupuytren's contracture [10]. There is often associated thickening of the plantar fascia [11].

The biochemical change is not fully understood, but it seems likely that non-enzymatic glycosylation in diabetic subjects might alter collagen metabolism [1,3]. The lysines in collagen are slowly glycosylated with increasing age, and during this process the glucose attaches to the lysine and undergoes an Amadori rearrangement, thus making the process irreversible [12]. Enzymatic digestion of tendon collagen from young patients who died from diabetes showed that their collagen behaved as if it was from patients who were 50–65 years older than their actual age [13].

Studies of viscoelastic ratio and skin extensibility in patients with type 1 diabetes have shown subclinical stiffness and loss of skin elasticity [14].

The histology of the skin changes resembles systemic sclerosis, but there is a subtle difference, with a predominance of large collagen fibres, thickening of the capillary basement membrane and increased mucin [15].

In some diabetic patients with thick skin, the extensor surfaces of the fingers develop a characteristic, minutely pebbled appearance over or near the knuckles (Huntley's papules). On histology, this shows a papillated epidermal hyperplasia with hyperkeratosis [16].

Because biochemical studies suggest that collagen is 'aged' by increased binding with glucose, it is desirable to maintain tight control of blood glucose levels in diabetic patients [17]. A patient improved with aminobenzoic acid, colchicine and DMSO gel [18].

Leprechaunism

Synonym
- Donohue's syndrome

Definition. Leprechaunism is a rare and poorly defined syndrome characterized by severe intrauterine and postnatal growth retardation, decreased subcutaneous tissue and muscle mass, and a characteristic facies [1]. Tissue resistance to insulin appears to be an important feature, as hyperinsulinaemia and pancreatic β-cell hyperplasia are frequently present [2,3].

Aetiology. The condition is inherited as an autosomal recessive trait. The basis for the insulin resistance is homozygous or compound heterozygous mutations in the extracellular domain of the insulin receptor, which leads to markedly impaired insulin binding [4]. Mutations that retain significant insulin binding activity cause the less severe phenotype of Rabson–Mendenhall syndrome.

The fibroblasts have a prolonged doubling time *in vitro*. They respond poorly to the metabolic actions of insulin, and to the actions of several other growth factors, such as epidermal growth factor.

Pathology [5]. In the skin, the elastic and collagen fibres are few and fragmented. On the extremities, the horny layer is markedly thickened. The muscles show a proliferation of abnormal connective tissue. In some cases, the ovaries are large and cystic, and there is β-cell hyperplasia of the pancreatic islets.

Clinical features [5–8]. The child is abnormal at birth, with low birth weight. The nose is broad, the ears low set and large, the eyes widely spaced. There is hypertrichosis of the forehead and cheeks. The skin appears too large for the body, is loosely folded at the flexures and may be corrugated, with gyrate folds on the hands and feet, which may be disproportionately large. Muscle wasting, often progressive, is usually present. The breasts and the penis or clitoris may be slightly hypertrophic. The bone age is retarded and there may be metaphyseal and epiphyseal dystrophy.

Growth is generally retarded, the nutritional status remains poor and susceptibility to infection is high. Death by the age of 1 year is usual.

Diagnosis. The cutaneous changes could be confused with cutis laxa, but in leprechaunism the skin, although folded, is thickened and not lax. The diagnosis is confirmed by the associated features and the finding of raised plasma insulin levels.

Lipoatrophy

The absence of subcutaneous fat may give the appearance of premature ageing if the face is affected. Lipoatrophy is fully discussed in Chapter 46.

Perforating dermatoses

Many dermatoses occasionally exhibit the phenomenon of transepithelial elimination (TEE), in which material from the dermis is extruded through the epidermis to the exterior with little or no disruption of the surrounding structures [1]. The extruded material may include inflammatory cells, red cells, microorganisms and extracellular substances, such as mucin or altered connective tissue components [2,3]. In most of these conditions, the TEE is secondary to some underlying disease, such as granuloma annulare or PXE, but there are four conditions that are regarded as *primary perforating disorders*: Kyrle's disease (Chapter 19), perforating folliculitis (Chapter 30), reactive perforating collagenosis and perforating serpiginous elastosis. It is possible that these primary perforating disorders might be due to defects in the epidermal keratinocytes, hair follicle, collagen and elastic fibres, respectively, with TEE being the final common pathway [2,3].

In acquired reactive perforating dermatosis (see below), the bulk of the coarse granular basophilic material that is extruded by TEE appears to derive from the nuclei of polymorphonuclear leukocytes [4]. It has been suggested that lysosomal enzymes derived from leukocytes might be responsible for the altered staining of collagen fibres, the degradation of elastic fibres and the impairment of keratinocyte adhesion, which allows TEE of dermal components [4].

Acquired reactive perforating dermatosis

Until recently, the four conditions mentioned above were thought to be unrelated, but there have now been numerous reports of these perforating dermatoses occurring in diabetes mellitus or in patients with chronic renal failure, many of whom were undergoing haemodialysis [2,5–9]. An incidence of 11% has been reported, with a particular association with long-standing diabetes [9]. The keratotic lesions in this condition develop on the trunk and limbs, and are usually pruritic, dome-shaped papules with central crusts (Fig. 45.40). They are not related to trauma.

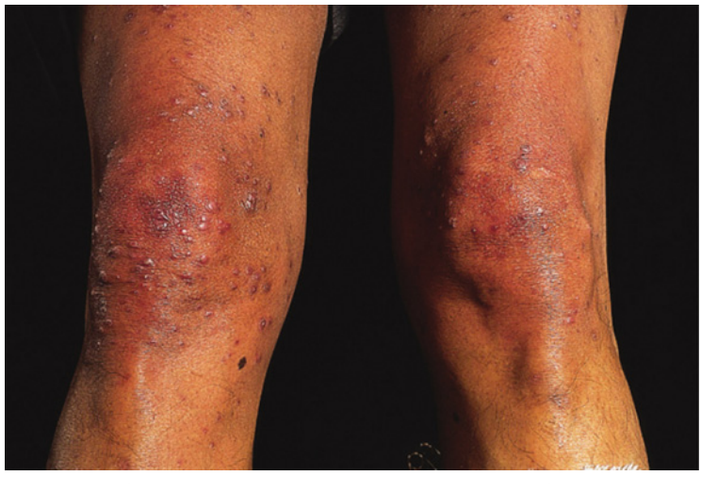

Fig. 45.40 Perforating dermatosis in a diabetic patient with renal failure. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

The distinction between the four dermatoses has not always been clear-cut, and the presence or absence of the Koebner reaction, and the presence or absence of collagen fibres in the epidermis, are not reliable distinguishing features [2,3]. Both collagen and elastic fibres can be extruded in the same patient [7], and it seems likely that at least in the case of haemodialysis patients these conditions may overlap. The name *acquired reactive perforating dermatosis* has been suggested for this skin problem. These four conditions, however, appear to be separate entities when they occur outside the setting of renal failure or diabetes mellitus.

Topical or intralesional steroids or topical retinoids may be helpful, but some patients improve spontaneously [9]. Other reported treatments include rifampicin and allopurinol [10].

Perforating disease due to exogenous agents

Occasionally, a chemical that has been applied to the skin topically or by intradermal injection can be eliminated by the transepidermal route to produce a perforating disorder. Eight cases have been reported following occupational exposure to a caustic drilling fluid used in the petrochemical industry [1]. Each patient noted skin irritation following exposure to the fluid, and 1 or 2 days later developed tender papules with central umbilication, which ulcerated and crusted. Histological examination of the lesions revealed TEE of altered collagen and debris which stained for calcium.

It is possible that the lesions were due to follicular penetration by the calcium present in the drilling mud. The drilling fluids contain many additives, but calcium carbonate or calcium chloride are often present in high concentrations in the mud. Similar cases have been reported following the use of calcium-containing electroencephalography paste [2].

TEE of altered collagen has also been reported following the use of intradermal steroid injections [3,4].

Reactive perforating collagenosis [1–4]

Definition. A rare inherited form of TEE in which collagen is extruded through the epidermis. It is usually precipitated by environmental cold or trauma. The commoner, acquired, form is often referred to as acquired perforating dermatosis (qv) which is typically associated with haemodialysis, although lesions have been recorded with internal neoplasia [4].

Aetiology. The cause is unknown, but the condition is often familial [5,6]. The basic defect seems to be a type of focal damage to collagen, which is then extruded as a result of necrolysis of the overlying epidermis [7].

Pathology [2,7,8]. The lesion originates in the papillary dermis, where collagen is surrounded and engulfed by focal epidermal proliferation. The collagen appears normal on electron microscopy, but gives an abnormal staining pattern with trichrome and phosphotungstic acid haematoxylin. The central crater which develops contains inflammatory cells and keratinous debris. Elastic tissue is typically absent, and the abnormal collagen is eliminated by transepithelial migration.

Clinical features [7]. The inherited form usually starts in early childhood as small papules on the extensor surface of the hands, the elbows and the knees following superficial trauma. Each skin-coloured papule increases to a size of about 6 mm over 3–5 weeks and then becomes umbilicated, with a keratinous plug. The lesions regress spontaneously in 6–8 weeks to leave a hypopigmented area or slight scar, but new lesions may appear. Lesions can be produced experimentally, and Koebner's phenomenon may be present, with linear lesions [9]. The papules can also be provoked by inflamed acne lesions, but deep incisions do not produce the lesions. The condition persists into adult life. In some cases, the disease is associated with intolerance to cold and improves in warm weather.

Diagnosis. The condition may be mistaken clinically for molluscum contagiosum, papular urticaria, perforating serpiginous elastoma, perforating folliculitis, perforating granuloma annulare and Kyrle's disease, but the histology is characteristic [6]. Verrucous perforating collagenoma must also be distinguished (see below). The nosological relationship between reactive perforating collagenosis and the acquired reactive perforating dermatosis of renal failure remains uncertain (see above) [4].

Treatment. Topical retinoic acid may reduce the number of lesions. Other treatments which may help include oral isotretinoin, methotrexate, emollient creams, topical steroids under occlusion [3,4] and PUVA [10].

Verrucous perforating collagenoma [1,2]

Synonym
- Collagenome perforant verruciforme

In this rare condition, severe (as opposed to superficial) trauma to the skin produces verrucous papules which show TEE of collagen. The eruption occurs as a single episode and is not familial.

Elastosis perforans serpiginosa

Synonyms
- Perforating elastoma
- Elastoma intrapapillare perforans

Definition. In this reactive perforating dermatosis, the material extruded through the epidermis is derived from elastic fibres in the upper dermis.

Aetiology. The cause is unknown, but a genetically determined defect of elastic tissue may be involved [1]. The altered elastin resembles that seen in experimental animals subjected to lathyrogens or copper deficiency.

It is probable that the primary abnormality is in the dermal elastin, which provokes a cellular response that ultimately leads to extrusion of the abnormal elastic tissue. It may be significant that the lesions are commonly seen in areas subjected to wear and tear. The lesions may follow an abrasion.

Some 40% of reported cases have been associated with connective tissue disorders, such as PXE, EDS, MFS, OI and acrogeria [2,3]. It has also been reported in otherwise healthy individuals and in mental deficiency, especially Down's syndrome [4–6].

It sometimes occurs in patients taking penicillamine, which is known to cause the production of abnormal elastin [7–10].

The relationship to perforating PXE and pseudo-PXE due to penicillamine is discussed on p. 45.25.

Pathology [4,11–13]. The earliest detectable change is the focal development of elastotic staining tissue and basophilic debris in the dermis. This is followed by a reaction of the overlying epidermis, which grows down to engulf the elastotic material. The epidermis surrounding the fully developed lesion is acanthotic and hyperkeratotic. The papule consists of a circumscribed area of epidermal hyperplasia traversed by a channel communicating directly with the dermis and containing a mass of tissue, which projects above the surface. This plug consists of horny material in its upper third and of amorphous debris derived from elastin in its lower two-thirds [11]. In the dermis beneath and around the lesion, there is a foreign-body giant cell reaction. The elastotic material is finally extruded, to leave irregular scarring and warty thickening. Electron microscopy shows an increase in elastic fibres, with fine filaments on the surface similar to those seen in normal embryos. In penicillamine-induced cases the elastic fibres have a characteristic 'bramble bush' or 'lumpy bumpy' morphology [9]. The hydroxylation of dermal collagen is similar to that of newborn skin [12].

Clinical features [14,15]. The age of onset ranges from 6 to 20 years. Males are predominantly affected. Small, horny or umbilicated papules are characteristically arranged in lines, circles or segments of circles in a serpiginous pattern. The individual papules may remain small or may enlarge slightly to assume a crateriform appearance with an elevated edge and a central plug, or further to leave an area of atrophic skin surrounded by smaller papules, each with a horny plug. The rings may reach a diameter of 15–20 cm but are usually smaller (Fig. 45.41). The back and sides of the neck are most commonly affected, but the lesions may also occur on the cheeks or on the arms or thighs, and are sometimes bilaterally symmetrical. They may persist for several years, but eventually involute spontaneously to leave reticulate atrophic scars. Biopsy scars readily become keloidal.

Fig. 45.41 Elastosis perforans serpiginosa in a patient with vascular Ehlers–Danlos syndrome.

Diagnosis. The annular or linear arrangements of the papules and their distribution suggest the diagnosis, which is confirmed by the characteristic histology. Conditions which may cause confusion include porokeratosis of Mibelli, reactive perforating collagenosis and perforating granuloma annulare.

A similar histological appearance can occur in the acquired reactive perforating dermatosis of renal failure (see above) [16].

Treatment. Careful removal of the nodules with a curette under local anaesthesia may give a reasonable cosmetic result. Freezing has been recommended [14,17]. Excision should be avoided, and dermabrasion may make the condition worse [4]. In a child with Down's syndrome and associated vitamin A deficiency, clinical improvement was observed with oral retinoid therapy, even though the treatment produced side effects [6]. Isotretinoin has been used successfully in a patient with penicillamine-induced disease [18]. There are reports of improvement following Sellotape stripping of the surface keratinous material [19], tazarotene [20], imiquimod [21], pulsed dye [22], ultrapulsed carbon dioxide [23] and Er:YAG [24] laser therapies.

Miscellaneous disorders

Colloid milium

Synonyms
- Colloid pseudomilium
- Colloid degeneration of the skin
- Elastosis colloidalis conglomerata

Definition. Colloid milium is a degenerative change characterized clinically by the development of yellowish, translucent papules or plaques on light-exposed skin, and histologically by the presence of colloid in the dermal papillae.

Aetiology. The cause is uncertain, and the condition may not represent a single entity. The rare juvenile form [1,2], beginning before puberty and often familial, can be distinguished from a non-familial form occurring in later life. Although light appears to play little part in provoking the lesions in the juvenile form, it is certainly implicated in older patients, among whom the incidence is highest in fair-skinned, outdoor workers in sunny climates [1,3,4]. Some authors consider the adult form to be a variant of actinic elastosis [5]. Cases among refinery workers in the tropics suggest that trauma and the photodynamic effects of phenols in oxide fuel (gas oil) may be contributory factors [6]. Cases have also been reported after the long-term application of strong hydroquinone bleaching creams. These patients also had ochronosis [7].

Pathology [7–13]. The earliest histological change is the appearance of colloid globules at the tips of the dermal papillae. Homogeneous fissured masses of colloid occupy the upper dermis, each surrounded by bands of collagen. The colloid is usually eosinophilic but may be basophilic. Within it, small blood vessels and the nuclei of fibroblasts are well preserved. In the larger, plaque-like lesions, the colloid change occurs diffusely throughout the dermis.

In the juvenile form, the colloid masses may also occur in the epidermis, and elastosis is not present, whereas in the adult form the colloid is separated from the epidermis by a band of elastin, and elastosis is present. In the juvenile form, 'immature' Civatte bodies occur in the epidermis.

The source of the colloid material is uncertain. It could be a protein synthesized by fibroblasts or it could be derived from degraded elastic fibres [1,3,9].

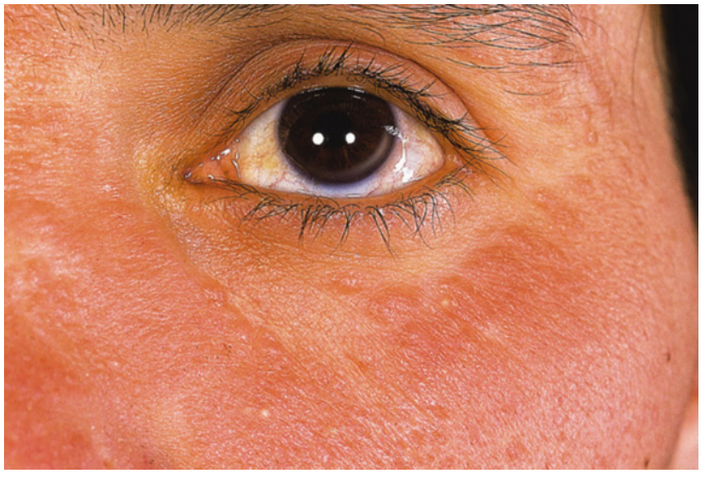

Fig. 45.42 Colloid milium of the infraorbital region. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

The histological changes may be difficult to distinguish from those of amyloidosis, especially lichen amyloid. Electron microscopy may be needed for definitive diagnosis [7,9,13]. In adult colloid milium, the colloid is amorphous, with wavy, branching filaments. In the juvenile form, it is composed of closely packed filaments, which are often in parallel rows, forming whorled fascicles [1,13].

Clinical features. Small dermal papules 1–2 mm in diameter, yellowish brown and sometimes translucent, develop slowly and more or less symmetrically in irregular groups in areas exposed to sunlight (Fig. 45.42). They feel soft and may release their gelatinous contents when punctured. The most frequently involved sites are the face, especially around the orbits, the dorsa of the hands, the back and sides of the neck and the ears. There is some variation in the clinical features according to the age of onset. In young children, the lesions are often confined to the face, with diffuse infiltration surmounted by innumerable small papules, which may appear vesicular. In older patients, the papules are often fewer and larger, and their potential distribution is much wider, although often only one or two sites are involved in each individual. The changes induced by prolonged light exposure are associated to varying degrees. Although colloid milium may become more severe and more extensive over the years, most cases reach their maximum development within 3 years and then remain unchanged.

The juvenile form may be associated with conjunctival and gingival deposits of an amyloid-like homogeneous material [11].

A nodular form has been described in which lesions may be 5–50 mm in size and may be single or multiple [14].

Diagnosis. The histological and clinical findings together are unmistakable, although the former alone may be difficult to differentiate from amyloidosis. Similar papular lesions are seen in severe actinic elastosis [15]. Trichoepithelioma, tuberous sclerosis and hidrocystoma are distinguished by biopsy.

Treatment. Treatments for actinic elastosis have been used in adult patients, including topical retinoids [5]. Improvement has been reported following dermabrasion [15] and ablation with the Er:YAG laser [16]. Destruction of the lesions with the diathermy or with cryotherapy has also been advocated, but the cosmetic result is seldom satisfactory.

White fibrous papulosis of the neck

Asymptomatic, small, white, fibrous papules around the neck have been described in several Japanese [1,2], Iranian and European patients [3,4]. The number of papules ranges from 10 to 100; middle-aged to elderly men are predominantly affected. The papules are round to oval, clearly marginated and non-follicular (Fig. 45.43). Histology is unremarkable, showing bundles of thickened collagen fibres in the mid-papillary dermis. Although lesions clinically resemble disorders of elastic tissue, such as anetoderma and dermatofibrosis lenticularis disseminata, elastic fibres are morphologically normal on histology. Acquired connective tissue naevi could exhibit similar features, although the late age of onset makes this diagnosis unlikely. The condition appears to have no prognostic significance, and may be under-reported. It may reflect intrinsic or photo-ageing [5].

Recently, it has been suggested that there may be a relationship between fibrous papulosis of the neck and acquired elastolysis of the papillary dermis [6]. These changes are attributed to ageing or photoageing [5,7].

Papular elastorrhexis

This is a rare variant of connective tissue naevus. Adolescents or young adults present with multiple, non-follicular oval white or yellowish papules on the trunk or limbs; dermal elastic fibres are decreased and fragmented on histology. Most reports are of sporadic cases, with no family history and no extracutaneous manifestations [1–3]. Similar lesions are seen in some patients with Buschke–Ollendorff syndrome (Chapter 18), in which osteopoikilosis is also a feature. To add to the confusion, abortive forms of Buschke–Ollendorff syndrome have been described, lacking osteopoikilosis [4]. A family has been described with this variant [5]. It is possible that papular elastorrhexis is not a separate entity [6]. Intralesional triamcinolone may be beneficial [7].

Progressive osseous heteroplasia [1,2]

This rare condition typically affects female infants and is characterized by ossification of skin and soft tissues. Ossification begins in the dermis, progressing to deeper tissues and to adjacent areas of skin. It is not associated with trauma or infection [3]. Skin lesions begin as groups of small, firm papules resembling rice grains; later, larger ossified nodules may develop. A skin biopsy should include subcutaneous fat. Cancellous and even mature intra-membranous bone is found in the dermis and subcutis. The differential diagnosis includes plate-like osteoma cutis (in which the lesion is solitary) (Chapter 56), Albright hereditary osteodystrophy (which is associated with dysmorphic features, including brachydactyly and short stature, and less severe ossification) and fibrodysplasia ossificans progressiva, in which ossification initially affects muscle or fascia and the great toes are malformed. The disorder is caused by a paternally inherited, inactivating *GNASI* mutation, which is also found in Albright hereditary osteodystrophy [4]. This gene encodes for guanine nucleotide-binding protein Gs alpha, which couples receptors to adenyl cyclases, generating cAMP. Studies in mice indicate that Gs alpha directly regulates the differentiation of growth plate cartilage and suppresses ectopic ossification, without affecting renal function [5,6].

The condition is progressive, and the morbidity depends on the site and the severity of the ossification. There is no effective treatment to prevent the ossification, but lesions that disrupt function or impair movement can sometimes be removed surgically.

Fascial hernias of the legs [1,2]

Small fascial hernias of the lower legs are not uncommon in athletes and heavy manual workers, and may present a problem in differential diagnosis. Herniation of muscle takes place through the hiatus in the deep fascia where it is perforated by communicating veins.

The hernias develop suddenly as nodules on the anterolateral aspect of the lower leg and are usually about 15 cm above the lateral malleolus. The nodules are soft, compressible and 1.5–2.0 cm in diameter. If bilateral, they are strictly symmetrical. No treatment is required, although minimally invasive fasciotomy is claimed to give symptomatic benefit [3].

Constricting bands of the extremities

Synonym
- Ainhum and pseudo-ainhum

Definition. This is a constricting band around a digit or limb. The band may be shallow, involving only the skin, or it may be deeper, involving fascia or bone, and in some cases amputation may result. The term *ainhum* (an African word meaning 'to saw' [1]) is applied to a specific type in which a painful constriction of the fifth toe occurs in adults, with eventual spontaneous amputation. *Pseudo-ainhum* is the term applied to other constricting bands which are congenital or secondary to another disease.

Ainhum

Synonym
- Dactylolysis spontanea

Aetiology. The condition appears to be due to an abnormal blood supply to the foot in some patients, as arteriography has shown that in these patients the posterior tibial artery is attenuated at the ankle, and the plantar arch and its branches are absent [2]. Mechanical factors, including trauma from walking barefoot, may then precipitate the development of a groove in the ischaemic toe. Chronic fissuring in hyperkeratotic skin also seems to be an important factor. A family history is common, and the disease is more common in certain races. Ainhum is most common in black Africans, but many cases have been reported in black Americans, and it can also occur in other races.

Various tropical infections, including leprosy, tuberculosis and yaws, have been suggested as possible contributory factors, but these conditions are probably coexistent rather than causative [2,3].

Pathology [4]. Fissuring and hyperkeratosis on the medial aspect of the digit is followed by fibrosis, distal degeneration and osteoporosis, ultimately leading to spontaneous amputation. There may be secondary infection and osteomyelitis.

Clinical features. The condition is most common between the ages of 30 and 50 years, but the earliest stages may be seen in childhood. The presenting symptom is usually a painful fissure.

Fig. 45.44 Ainhum, just before shedding of the fifth digit. (Courtesy of Dr D. Burley, Princess Margaret Hospital, Swindon, UK.)

The toe is held dorsiflexed at the metatarsophalangeal joint, and gradually becomes clawed. Rest pain, coolness and cyanosis of the digit distal to the groove suggest that ischaemia is present. Once the constricting band has encircled the toe, the condition tends to progress rapidly. The toe becomes globular, hangs by a thread of fibrous tissue and is eventually shed (Fig. 45.44).

Diagnosis. The condition must be distinguished from pseudo-ainhum.

Treatment. Control of secondary infection and protection from trauma may prevent extension of the scarring process. If symptoms are severe, or the dangling digit is a disability, amputation is indicated.

Pseudo-ainhum

Congenital. Congenital pseudo-ainhum may involve a digit, a limb or even the trunk, and it ranges in severity from a superficial groove to amputation *in utero* [5–8]. The cause is unknown, but familial cases have been reported. Some cases of pseudo-ainhum may be due to amniotic bands [9] or adhesions *in utero*, which may arise as a result of tearing of the amnion some time after the 45th day of pregnancy [10]. Cases have occurred in EDS and after amniocentesis [10,11]. Several cases are reported where raised limb bands develop in the postnatal period, not always associated with amniotic tears; other possible causes include an early teratogenic insult [1,12].

Histology of the affected digit or limb reveals broad, finger-like projections of collagen, and coarse elastic bundles that penetrate deep into the subcutaneous fat [8].

Congenital pseudo-ainhum must be distinguished from: *aplasia* of the limbs with rudimentary digits; *acromelia* (in which part of the limb does not develop); and *hypoplasia* (in which the parts, although formed, are poorly developed).

Fig. 45.45 Vohwinkel's disease with pseudo-ainhum of the fifth digit of the left hand. (Courtesy of Dr F.A. Ive, Durham, UK.)

Acquired. Pseudo-ainhum may be acquired as a result of infection (particularly leprosy), trauma, cold injury, neuropathy (especially congenital sensory neuropathy), systemic sclerosis, etc. [13] and chronic psoriasis [14], and it may occur in association with other hereditary diseases such as palmoplantar keratoderma (particularly Vohwinkel's disease) (Fig. 45.45), pachyonychia congenita, erythropoietic protoporphyria [15,16], and Olmsted's syndrome (Chapter 19). Factitial pseudo-ainhum has also been reported due to the self-application of a rubber tourniquet.

Multiple skin creases resembling constrictions may be seen in the Michelin baby syndrome (Chapter 18) and in 'multiple benign annular creases of the extremity' (Chapter 19).

Treatment. Staged Z-plasty sometimes gives an excellent result [17].

Heberden's and Bouchard's nodes

Heberden's nodes [1] are posterolateral bony outgrowths affecting one or more *distal* interphalangeal joints. Similar changes, affecting the *proximal* interphalangeal joints, are termed Bouchard's nodes. Both Heberden's and Bouchard's nodes are strongly associated with osteoarthritis, although they may be inherited independently as an autosomal dominant trait [2,3]. Characteristically, they are asymptomatic and of insidious onset, although tender nodes may develop acutely with a red, swollen joint. The association of multiple symmetrical nodes with distal interphalangeal joint arthritis has been termed 'primary generalized osteoarthritis'. Because this is associated with the tissue types HLA-A1 and B8 and shows a marked female preponderance, it has been postulated to be an autoimmune disorder; increased amounts of immune complexes can be detected in cartilage and synovium [4].

Introduction

Subcutaneous fat (subcutis) occurs almost universally over the body surface between the skin and the deep fascia, but it is absent from the eyelids and the male genitalia. It varies in thickness with the race, age, sex, endocrine and nutritional status of the individual.

Subcutaneous fat acts as an insulating layer and a protective cushion; it also has an important role in thermogenesis, and as a store of readily available energy. In a normal person, fat constitutes about 10% of body weight, and provides about 40 days' reserve energy [1]. Brown fat has a very important thermoregulatory role and acts by increasing the basal metabolic rate [2]. This is particularly important in infancy, and heat production in response to cold exposure is maximal in neonates, who have large quantities of brown fat.

Fat also provides support and has a cosmetic function, for example in the contours of the face. It also has great social importance. Fat children may be bullied or ostracized at school [3], fat adults may find it harder to get certain jobs, and the contribution of fat to the shape of the breasts and buttocks as a secondary sexual development in the female has been known to influence social behaviour.

In addition to the above functions, the obesity epidemic and the metabolic consequences of abnormal fat distribution have underlined the fact that the subcutaneous fat, comprising as it does innumerable adipocytes secreting a large variety of enzymes, hormones and cytokines, is also a major endocrine organ [4].

Embryology [5,6]

The first fat-containing cell, the pre-adipocyte, appears in the mesenchyme around the 14th week of fetal life. The primitive mesenchymal cell that forms the determined pre-adipocyte is also capable of maturing to form a fibrocyte, a myocyte, a chondrocyte or an osteoblast. Pre-adipocytes can terminally differentiate into either brown adipocytes or white adipocytes.

Brown fat is a special type of granular fat that differs from white fat in its distribution, histology and function. It is multilocular and is metabolically very active with many mitochondria so that it is capable of transferring energy from food to produce heat. As it has a much greater capillary network surrounding it compared to white fat (which is partly responsible for the brown colour), heat can be rapidly transferred into the circulation. It is most prominent in the neck and upper thorax of the fetus, and it may be homologous to the hibernating gland fat found in some animals [7]. Brown fat is now known to persist into adult life [8], and it may have a role in preventing obesity [8]. Warm patches develop in the skin 1 hour after taking ephedrine orally, and these warm patches may indicate the site of thermogenic brown fat. Brown fat adipocyte mitochondria uniquely express uncoupling protein-1 (UCP-1), allowing confirmation that brown fat is present in adult white fat depots in variable amounts, and that transdifferentiation from white to brown adipocytes can occur. Development of brown fat begins at the 20th week of gestation, reaches its maximum at birth and then diminishes so that there are no large collections of brown fat in the adult, though fluorodeoxyglucose positron emission tomography (FDG PET) suggests that some adults have supraclavicular areas of brown fat [9]. Evidence for cold induction of brown fat as an adaptive response in humans is at present equivocal [9].

Histology

White fat adipocytes are the largest connective tissue cells in the body, with a diameter of up to 100 µm. Much of their differentiation occurs soon after birth. The mature fat cell has a characteristic signet-ring appearance, because the flat oval nucleus is displaced to the side by a single, large, intracellular, fat-containing vacuole,

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

which is surrounded by perilipin. Originally thought of as an inert store for emergency supplies of energy when necessary, it is now realized that the white adipocyte has a huge array of functions, secreting factors (adipokines) that affect lipid and glucose metabolism, endocrine functions, blood pressure control, coagulation, fibrinolysis, angiogenesis and inflammation. For a full review the reader is referred to Frühbeck [6]. Groups of lipocytes are arranged in lobules, which are separated by interlobular septa composed of collagen and reticulin fibres. The adipocytes may comprise only 25% of the total cell population of a lobule; the remainder, the stromavascular tissue, being macrophages, fibroblasts, mast cells, pericytes, endothelial cells and pre-adipocytes, allowing for considerable cross-talk between cells with even more factors being produced.

Fat tissue has an abundant blood supply, each individual lobule being supplied by a terminal arteriole from the vascular supply running along the septa, which then breaks up to form capillaries which come into close apposition with the individual fat cells. The subcutaneous fat also contains a rich lymphatic plexus, which receives vessels from the dermis. These lymph vessels traverse the subcutaneous layer parallel to the skin surface for some distance, before eventually penetrating the deep fascia and draining into the regional lymph nodes. The nature of the lipocyte and its relationship to blood vessels and lymphatics has been reviewed in detail by Ryan and Curri [10]. Both white fat and brown fat are innervated by noradrenergic fibres of the sympathetic nervous system and para-sympathetic fibres.

The fat tissue and the fat organ. All fat tissue is composed of lobules of fat cells with their supporting connective and stromavascular tissue. In addition to the subcutaneous fat, approximately 20% of fat tissue occurs internally, in the mediastinal and retroperitoneal tissues, the mesentery and the bone marrow and in and around individual organs, including blood vessels. This tissue, although it is widely scattered throughout the body, forms a true organ as regards both structure and function [1] but in which depot-specific differences occur [11]. For example, increases in subcutaneous upper body and visceral fat are associated with an increased cardiovascular and metabolic risk but increases in gluteofemoral subcutaneous fat are not [12]. In addition, perivascular adipose tissue shows increased angiogenesis compared to subcutaneous fat [13]. The fact that some genetic lipodystrophy patients lose peripheral fat but fat padding for absorption of mechanical pressure is maintained, is further evidence for depot-specific differences.

The combination of the obesity epidemic and the advent of liposuction has rekindled interest in the structure of subcutaneous fat with MRI scanning as the investigative tool [14]. Subcutaneous fat is divided by the superficial fascia into two compartments, superficial and deep. The fat mass in the superficial (areolar) layer is compartmentalized into lobules by vertical and oblique fibrous septal planes and bands, whilst that of the deeper (lamellar) layer has its septae more horizontally positioned. The superficial layer is fairly constant, but the deeper is more variable, with an increase in fat mass accumulating between split horizontal septae. In females, subcutaneous fat is most abundant in the gluteofemoral region and breasts, resulting in the so-called gynoid distribution, whereas in males the android distribution of shoulders and upper arms, neck and lumbosacral area predominates.

Physiology [5,6,15–18]

Traditionally, adipose tissue was regarded as an inert energy store with insulating and padding properties. Whilst storage is still a major function, there is now an appreciation that adipocytes and their stromavascular tissue have many other highly complex and dynamic actions, including energy homeostasis, adipogenesis, insulin sensitivity and influences on immune and inflammatory responses.

Energy homeostasis. A major function of white adipose tissue is to store energy at times of calorie excess and release it when needed, such as during exercise or starvation. The synthesis (anabolism) and catabolism of fat in the subcutaneous depot depends on many factors, including nourishment, endocrine and nervous activity. The role of the autonomic nervous system in regulating fat metabolism is now well established [19], being particularly important for rapid energy need compared to the slower control exerted by neuroendocrine factors [20]. A decrease in parasympathetic activity results in increased lipolysis, as does an increase in sympathetic activity, with the opposites stimulating lipogenesis [21]. Hormones that may affect the energy metabolism of fat cells include insulin, cortisol, norepinephrine (noradrenaline) and several pituitary hormones, including somatotrophin, adrenocorticotrophic hormone (ACTH), thyrotrophin, lipotrophin and natruretic peptide [22].

The fats contained within the lipocytes are predominantly triglycerides (triacylglycerols), especially those of palmitic and stearic acids and the unsaturated oleic acid. All the fatty acids have an even number of carbon atoms, predominantly C16 and C18, with a few C14 and C12. Adipose tissue contains 10–30% of water with a small proportion of lipochromes, and less than 2% cholesterol. Fat-soluble substances are also present in varying amounts. These include fat-soluble vitamins and traces of chlorinated hydrocarbons (e.g. aldrin, dieldrin) ingested with the diet, as well as drugs such as acitretin. Adipose tissue *in vitro* has a metabolic rate similar to that of kidney tissue, and approximately half that of liver. Approximately half the triglyceride in the adipose tissue of rats and mice is catabolized and reconstituted in the course of a week or so.

The fat for storage enters the lipocyte as fatty acids, having been converted from lipoproteins by the extracellular enzyme lipoprotein lipase (Fig. 46.1). The fatty acids combine with coenzyme A, using the energy of adenosine triphosphate (ATP), to form the corresponding acyl coenzyme A compounds. Some of these are then oxidized to provide energy for the regeneration of ATP, but most are converted to triglyceride by combination with glycerol-3-phosphate derived from glucose.

The adipocyte is one of the few cells to express the insulin-dependent glucose transporter receptor 4 (GLUT-4), which mediates the passage of glucose into the cell, as well as leading to further triglyceride formation via *de novo* lipogenesis, the latter providing only a small contribution to the pool. At the same time, insulin inhibits hydrolysis and breakdown of triglyceride, conserving the energy store.

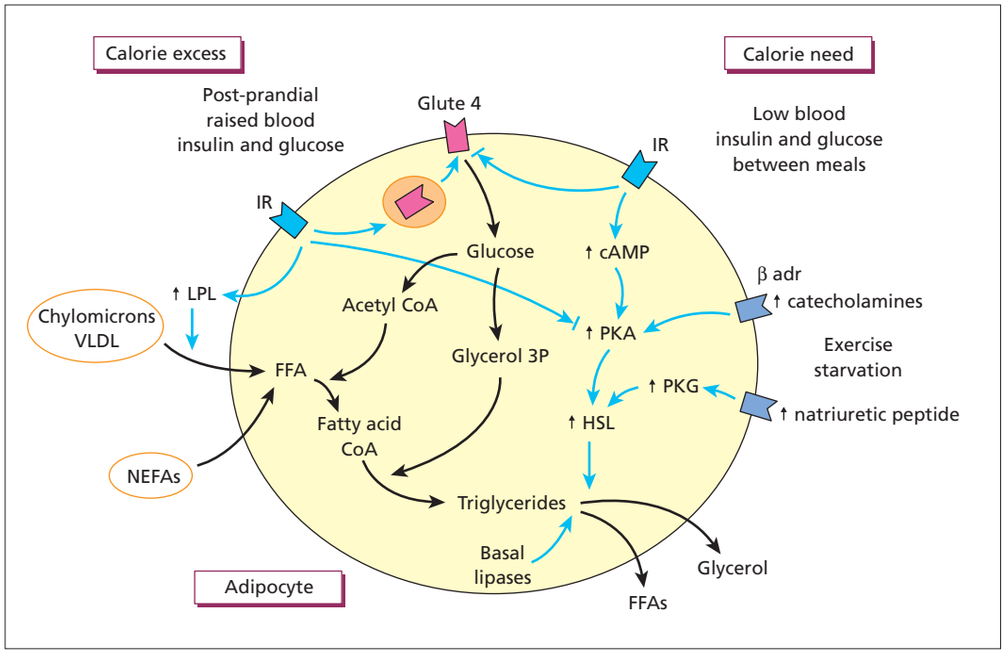

Fig. 46.1 Simplified outline of lipogenesis in an adipocyte during energy excess and lipolysis during calorie need. Effects of hormones and enzymes are in blue. β adr, β-adrenoceptor; cAMP, cyclic andenosine monophosphate; FFA, free fatty acid; Glute 4, insulin-sensitive glucose transporter; HSL, hormone-sensitive lipase; IR, insulin receptor; LPL, lipoprotein lipase; NEFAs, non-esterified fatty acids; PKA, protein kinase A; PKG, protein kinase G; VLDL, very low density lipoproteins.

When the body requires energy, lipolysis occurs. Triglyceride is hydrolysed in the adipocyte, converted to non-esterified fatty acids (NEFA) and glycerol, the rate-limiting enzyme being hormone-sensitive lipase (HSL). The NEFAs are conveyed in the blood to tissues such as liver and muscle, in which fatty acid oxidation readily takes place. In both tissues, the essential part of the process consists of the oxidation in the mitochondria of the long-chain fatty acids. The glycerol of the triglyceride molecule reacts with ATP to form glycerol phosphate, which is oxidized to glyceraldehyde-3-phosphate. This in turn may either be converted to glycogen by reversal of glycolysis, or it may be converted to pyruvate. Skeletal muscle readily oxidizes fatty acids but glucose, if available, is preferentially used. In cardiac muscle, fatty acids are a major source of energy. Lipolysis is regulated predominantly through insulin and catecholamines. The latter, elevated during a sudden energy demand, bind to β-adrenergic receptors on the adipocyte and activate HSL through the classic adenosine monophosphate-protein kinase A (AMP-PKA) pathway.

Leptin [23]. Leptin is an adipokine involved in energy homeostasis which may have evolved to help adaption from the starved to the adequately nourished state rather than to prevent obesity. Leptin, a product of the *ob* gene, is a 16-kDa polypeptide comprising 167 amino acids with a structural homology similar to other cytokine proteins such as TNF-α and interleukin-6. It is secreted by adipocytes predominantly, but also by the stomach, aiding immediate appetite control. Leptin receptors are present in the hypothalamus, on adipocytes, skeletal muscle, liver, pancreatic β-cells, ovary and endometrium. The main effect of leptin is via the satiety centres in the hypothalamus. If excess energy is being stored, rising leptin levels stimulate satiety centres to reduce appetite. Conversely, during starvation low leptin levels stimulate appetite. Circulating levels of leptin correlate with increasing body mass index (BMI), but have little effect on satiety centres, indicating an apparent leptin resistance. Leptin also influences several other functions, including neuroendocrine and reproductive functions, insulin secretion and blood pressure. Patients with congenital leptin deficiency have gross obesity, hyperphagia, delayed pubertal development, abnormal T-cell number and function, and altered thyroid and growth hormone function [24]. In addition, leptin has a role in immune function and inflammation [25]. There is increased expression in chondrocytes and leptin may have a part to play in articular degenerative disease.

Adipogenesis. Adipogenesis refers to the recruitment from multipotent stem cells in the mesenchyme and stromavascular tissue, and proliferation of pre-adipocytes followed by their differentiation into mature fat cells. Culture of cell lines has led to the elucidation of many of the transcriptional factors involved in adipogenesis, the major ones being peroxisome proliferator-activated receptor-γ (PPARγ) and the CCAAT-enhancer-binding proteins (C/EBPs). The precise contribution of adipogenesis towards enlargement of the fat organ at different stages of human development and life changes is uncertain, but it seems maximal before and around birth before diminishing, then possibly continuing at a low rate throughout adult life. Glucocorticoids, growth hormone and insulin stimulate cells to terminal differentiation, but when mature fat cells reach a certain size, recruitment occurs so that the fat organ enlarges through hyperplasia (increased numbers of cells) rather than hypertrophy (increase in size of cells). Control of this hyperplastic response may come from the local adipocyte through paracrine effects involving local growth factors. During adipogenesis the local extracellular matrix also changes, the effects of which might play their own role in differentiation. This is supported by the fact that fat tissue repair is improved if elements of this matrix are included with the donor adipocytes.

Insulin sensitivity. Insulin secretion, stimulated by raised blood glucose levels after meals to reverse hyperglycaemia, has two major effects. It facilitates glucose uptake into most of the body's cells (liver, skeletal muscle and adipocytes) and it suppresses glucose output by the liver. Insulin resistance occurs when a target organ fails to respond normally to insulin, resulting in hyperinsulinaemia. The effect may be incomplete suppression of hepatic glucose output in the liver and/or impaired insulin-mediated glucose uptake in peripheral tissues, including adipocytes. If increased insulin secretion cannot prevent hyperglycaemia, type 2 diabetes mellitus results. Adipocytes secrete many factors, some of which have direct and indirect effects on insulin sensitivity. The effects of dysregulation of some of these factors are discussed under obesity, below.

Adiponectin [26–28]. Adiponectin is a 30-kDa protein comprised of 244 amino acids with some structural similarity to both collagen and complement C_1q. It is thought, at the moment, to be secreted exclusively by adipocytes and has autocrine/paracrine effects within the local adipose tissue and endocrine effects distantly. Locally, it can promote preadipocytes to become mature fat cells which, with increasing size, down-regulate their adiponectin secretion to exert some feedback control. Adiponectin receptors are present in many tissues as well as adipocytes. It is likely that adiponectin receptor-activated AMPK (AMP-activated protein kinase) leads to enhanced insulin signalling and therefore insulin sensitivity. Adiponectin expression is lower in visceral adipose tissue (VAT) adipocytes compared to subcutaneous depots (SAT) if BMI is increased. Serum adiponectin levels are lower with weight gain and higher with weight loss.

Adiponectin also exerts protective anti-inflammatory effects both locally, by inhibiting secretion of interleukin-6, interleukin-8, macrophage inflammatory protein-1 and monocyte chemotactic protein-1, and distantly on monocyte/macrophages, endothelial cells, hepatic and muscle cells directly, and via inhibition of TNF-α production and action. There is an, as yet unexplained, paradox concerning adiponectin and its anti-inflammatory effects. Obesity is associated with macrophages in the visceral adipose tissue that generate factors, particularly TNF-α, that suppress adiponectin secretion. However, low levels of adiponectin promote inflammation, generating a self-sustaining loop; thus in obesity low adiponectin levels negatively correlate with inflammatory markers. In autoimmune states, such as rheumatoid arthritis and systemic lupus erythematosus, adiponectin levels are raised, the level positively correlating with inflammatory markers. To explain this, it has been suggested that the adiponectin system has evolved as a mechanism for adaptation to starvation, a catabolic state [29]. It is therefore raised in other catabolic states such as autoimmune disease and inflammatory bowel disease, and it did not evolve as a protective device against insulin resistance.

Many other adipokines have been described [6,18] and most are still being evaluated for their relevance to human biology. The stromavascular tissue itself is also responsible for a variety of cytokines. Macrophages secrete TNF-α, interleukins 1, 6, 8 and 10, monocyte chemoattractant protein 1, macrophage migration inhibitory factor, angiotensinogen, and endothelial and vascular growth factors. Therefore, as well as affecting energy homeostasis, insulin sensitivity and adipocyte differentiation, the fat organ has influences on inflammation, immune function, vascular inflammation and neo-angiogenesis. All of this lends credence to the concept of the fat organ being an endocrine organ in its own right. Whilst these discoveries are of the utmost importance for worldwide obesity-associated morbidity and mortality, except for lipodystrophy patients, their relevance has not provided much insight about the causation and treatment of classical skin panniculitides.

Obesity

Obesity is variously defined. Originally it was simply a condition in which there is excessive fat in the body. This has been modified slightly to the more subjective, an unhealthy excess of body fat that leads to an impaired quality of life, or the more specific, an unhealthy excess of body fat that increases the risk of morbidity and premature mortality.

Epidemiology. Body mass index (BMI: body weight in kilograms divided by height in metres squared) is used as a surrogate marker of adiposity. Both the World Health Organization (WHO) and the National Institutes of Health (NIH) classify adults with a BMI 25–29.9 kg/m^2 as overweight, above 30 kg/m^2 as obese and above 40 kg/m^2 as extremely obese [1,2]. For children and adolescents (under 20 years of age) the term obese is not used. 'At risk of overweight' is defined as a BMI for age at or above the sex-specific 85th centile and 'overweight' above the 95th centile. Being overweight as a child is of special significance, because many overweight children are obese as adults. Observations indicate that the prevalence of being overweight in childhood is high where adult obesity is common [3,4].

For adults, morbidity and mortality from hypertension, stroke, coronary artery disease and type 2 diabetes increase as the body mass index rises above 25 kg/m^2 [5], with more of an increase above 30 kg/m^2. These parameters were deduced from data on individuals under 50 years of age and they may not be true for individuals over 65 years with a BMI 25–27 kg/m^2 [6]. Nor does BMI take into account ethnicity [7]. BMI is an index of excess weight rather than excess body fat relative to height. More accurate measurements reveal that, for equivalent BMI levels, Asian people have more body fat, and Black people have less body fat, than do White people. To account for these differences in body fatness, it has been suggested that BMI cut-off points for overweight and obesity be lowered among Asian and increased among Black people. The same is true, but to a lesser extent, for children [7]. The other criticism of BMI is that it measures fatness as a whole and does not distinguish between visceral and subcutaneous adiposity. Visceral adiposity correlates better with morbidity and mortality and also correlates with body trunk measurements [8]. Waist circumference divided by hip circumference (WHR) can be used for this purpose. The waist is measured, after an overnight fast, halfway between the lower costal margin and the iliac crest, and hip circumference is measured over the widest part of the gluteal region [9]. WHR should not exceed 1.0 in men and 0.85 in women—cut-offs based on Scandinavian data [10]. Waist circumference is another reasonable way of assessing obesity. Circumference values that indicate a significant increased relative risk are more than 88 cm for women and more than 102 cm for men [10].

Measurement of skinfold thickness with callipers is another alternative technique, but there are possible variations in the distribution of fat between subcutaneous areas and deep body fat [11]. Computed tomography (CT), magnetic resonance imaging (MRI) and dual-energy X-ray absorptiometry (DEXA) are reserved for the more precise measurement during research rather than routine clinical practice.

The advantage of BMI is that it can be used easily for population screening. In the United States in 2003–4, among children and adolescents aged 2 to 19 years, 17.1% were overweight (above the 95th centile) and 32.2% of adults aged 20 years or older were obese. Sixty-five percent of all adults had a BMI above 25 kg/m^2. The prevalence of extreme obesity among adults was 4.8%. Between 1980 and 2002, obesity prevalence doubled in adults and overweight prevalence tripled in children and adolescents [12]. Between 1999 and 2004, the prevalence of overweight among children and adolescents and obesity among men continued to increase significantly, but no increase was observed among women over this 6-year period. Ethnicity differences remained. Among women, almost 58% of non-Hispanic black women aged 40 to 59 years were obese in 2003–2004 compared with about 38% of non-Hispanic white women of the same age. Among men, however, the prevalence of obesity did not differ by racial/ethnic group [12].

In England in 2006, 14% of 11 year olds were between the 85th and 95th centile and 17% were above the 95th centile [13]. In adults, the prevalence of obesity is much the same as the rest of Europe, with rates of around 20% [13]. Developing countries are now seeing serious increases in obesity, for example in the Caribbean, South America and South-East Asia [14,15], while in Australian Aborigines and Polynesia, figures approaching 80% have been recorded. China, except in poor rural areas, now has similar problems with childhood overweight and obesity approaching the epidemic levels of the USA [16]. It is estimated that globally there are 1 billion adults overweight of which 300 million are obese [17], a medical problem of a size beyond the capacity of even the best health-care system [1].

Obesity is accompanied by complications such as hypertension, non-insulin-dependent diabetes mellitus and atherosclerosis, which in turn cause ischaemic heart disease, stroke and premature death [18–20]. Other complications include hepatic steatosis, polycystic ovary syndrome, sleep apnoea, osteoarthritis, depression and certain malignancies such as prostate cancer. The alarming increase in diabetes is most probably a consequence of the current rapid rise in the prevalence of obesity.

Aetiology [21,22]. Very rarely obesity is monogenic [23]. It may be classified into three groups: due to gene mutations that affect the leptin–melanocortin system, mutations affecting hypothalamic development, or associated with a pleiotropic developmental syndrome such as Prader–Willi syndrome. Typically, these patients present with hyperphagia and very early onset obesity. Therapy

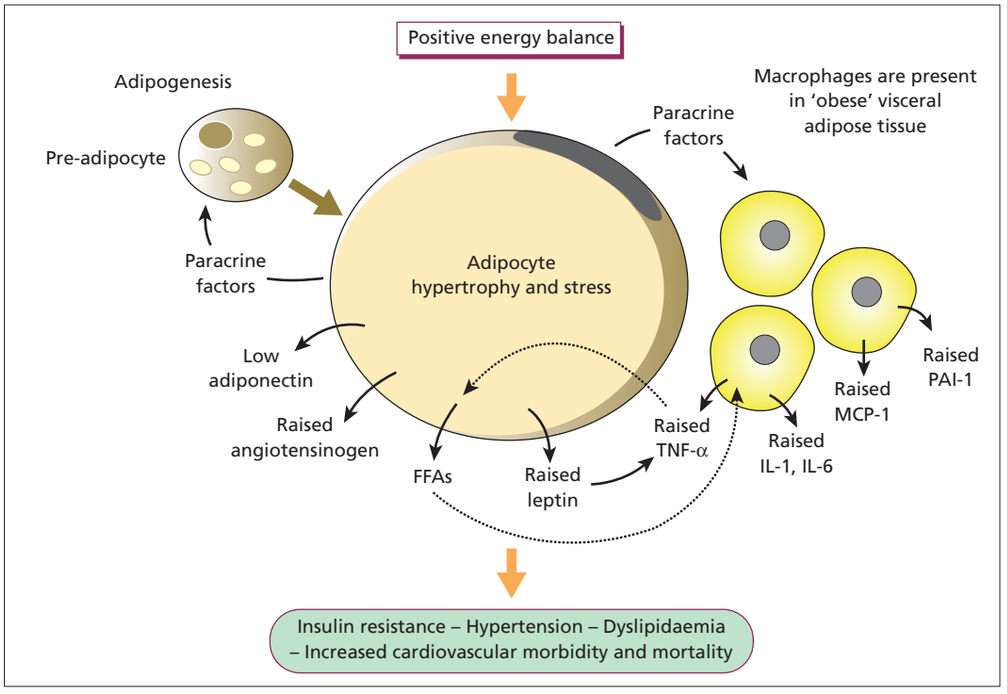

Fig. 46.2 Simplified outline of visceral adipocyte dysfunction in obesity leading to metabolic syndrome. FFAs, free fatty acids; IL-1, interleukin 1; IL-6, interleukin 6; MCP-1, monocyte chemoattractant protein-1; PAI-1, plasminogen activation inhibitor-1; TNF-α, tumour necrosis factor-α.

with leptin has transformed those with leptin deficiency. More frequently, obesity is associated with underlying disease such as polycystic ovary syndrome, hypothyroidism, Cushing's disease and hypothalamic injury, as well as corticosteroid and other drug therapy. By far and away the most frequent cause is common obesity—the result of genetic, behavioural, environmental, physiological, social, psychosocial and cultural factors that cause energy imbalance and promote excessive fat deposition. It has been suggested that inheritable factors contribute 45–75% to obesity. Bouchard *et al*. [24] demonstrated that the amount of body weight and fat gained, as well as the distribution of fat gained in response to overfeeding, had greater similarity within identical twin pairs. It is likely that genetic polymorphisms modify individual susceptibility to environmental factors [25,26]. Nutritional variability during fetal development is one such factor [27]. Maternal underweight before pregnancy [28], fetal under-nourishment and over-nourishment are all predictive of adult obesity, as is rapid weight gain in the first week of life. The pre-pubertal growth phase of early adolescence may be another susceptible time [29].

Obesity is the result of a positive energy balance input that exceeds output. The World Health Organization consultation on obesity [15] concluded that behavioural and environmental factors, such as sedentary lifestyles combined with excessive energy intake, are primarily responsible for the dramatic increase in obesity in the last 10–20 years. Food consumption has changed drastically over the last 30 years [30]. More calories are available to be consumed with a higher proportion of fats and sugar, often through increased snacking and soft drinks as well as increased portion sizes. Disordered eating behaviours, from missing meals such as breakfast, eating outside the home to binge eating, peer pressure and altered mental health may all contribute to an excessive intake. An increase in sedentary behaviour means that this increase in energy intake is not burnt off. Only a small amount of excess daily calorie intake is needed to lead to obesity [31].

Chronic positive energy balance leads to increased storage of triglycerides into fat cells. The increase in fat mass occurs due to adipocyte hypertrophy and hyperplasia. It has been suggested that increased storage occurs at first in the superficial and deep components of subcutaneous tissue until the maximal capacity has been reached [32]. At that time the secondary fat depots, including visceral fat, are filled. The subcutaneous fat shows both hypertrophy and hyperplasia but the visceral depot shows hypertrophy alone [32].

In obese subjects, macrophages are present in subcutaneous fat and they diminish in number after surgery-induced weight loss [33]. They are more numerous in omental than subcutaneous fat [34]. Inflammation associated with these macrophages, whether triggered by dysregulated adipogenesis, excess adipocyte hypertrophy or adipocyte endoplasmic reticulum and mitochondrial stress [22], results in adipocyte insulin resistance and dysfunction (Fig. 46.2). Free fatty acids and triglycerides are released into the circulation, and there is an altered secreted adipokine profile and release of inflammatory mediators. Higher concentrations of circulating free fatty acids and triglycerides are associated with lipid accumulation in multiple tissues, including liver, skeletal muscle, heart, pancreatic β-cells and blood vessels. With the portal vein draining visceral fat tissue products directly into the liver, the effect is accentuated in this organ. Perivascular lipid deposits have a role in atherogenesis [35]. Although the adipocyte secretes many adipokines, leptin and adiponectin have been the best evaluated. Circulating leptin levels correlate with increasing BMI, but the chronic high levels in obesity seem to generate leptin resistance at the hypothalamic level, in that the satiety centres do not respond

by diminishing appetite. Raised leptin levels contribute to hypertension as well as being independently moderately associated with coronary disease. In contrast, circulating adiponectin levels are low in obesity and therefore insulin sensitivity is blunted. TNF-α is an inflammatory marker associated with adiposity and cardiovascular risk factors. It inhibits lipoprotein lipase activity and increases lipolysis and also induces adipocyte apoptosis [36], as well as blunting insulin responsiveness. Increased angiotensinogen from the hypertrophied adipocyte contributes to hypertension. Monocyte chemoattractant protein 1 (MCP-1) plays an important role in atherogenesis, and plasminogen activation inhibitor-1 (PAI-1), a regulator of fibrinolysis, might be important in cardiac events [37]. Both MCP-1 and PAI-1 are produced by the stromavascular tissue.

Metabolic syndrome. The disease consequences of increasing amounts of fat tissue merits the fat being labelled as pathogenic. The traditional label for this has been the metabolic syndrome, though others prefer adiposopathy [38]. Adiposopathy is pathogenic adipose tissue that is promoted by a positive caloric balance and sedentary lifestyle in genetically and environmentally susceptible individuals. Diagnostic criteria for metabolic syndrome include glucose intolerance, elevated blood pressure, dyslipidaemia and measures of central obesity, and increased waist circumference or waist-to-hip ratio. Whilst metabolic syndrome is a convenient key for remembering its components, it may be no better as a predictor of future metabolic disease than assessment of its individual components. Also, there are five slightly different definitions of metabolic syndrome, of which three are given in Table 46.1; the use of these can blur the distinction between health and disease and exclude some individuals from preventive programmes [39,40]. Using the National Cholesterol Education Program (NCEP) metabolic syndrome criteria, the prevalence in adults in the USA is 35%, but it is 40% using criteria of the International Diabetes Federation (IDF) [41]. The prevalence in adolescents (with the IDF criteria) was 4.5% [42]. A global prevalence has been calculated at 16% [43].

Because obesity is associated with hyperinsulinaemia and diabetes, it is difficult to decide whether the skin manifestations seen in these conditions are due to obesity or its effects. Obesity impedes lymphatic flow with consequent lymphoedema. Acanthosis nigricans, the effects of hyperandrogenism, including hirsutism, hidradenitis suppurativa, striae distensae, venous hypertension, intertrigo and skin infections, are all seen more frequently in obese patients [44], as is plantar hyperkeratosis.

Prevention and treatment. The aim of obesity treatment is to achieve and then maintain clinically meaningful weight loss, with the ultimate aim of reducing the risk for, or severity of, obesity-related diseases. Measures directed at improving public health awareness should be given high priority in national efforts. They include: information campaigns, providing opportunities for exercise at school and in the community, making exercise-sparing devices such as escalators less readily available, and establishing bicycle and walking lanes in cities. Despite an increased focus on nutrition, an increased awareness of the energy and fat content of foods, and the availability of various reduced-fat, fat-free and sugar-free food and beverages, obesity continues to increase [45].

Effective therapeutic regimens for treating obesity should incorporate multiple approaches to encourage behavioural change or modification and create strategies to facilitate consistent and long-term follow-through [46]. Numerous options are available [46,47], including reduced-energy diets, physical activity and exercise, behavioural modification, pharmacotherapy and surgery.

The principle for treatment, self-evidently, is to induce a negative energy balance. Short-term weight loss is easy, but long-term weight maintenance after that is unusual [44,48]. The body weight itself is often not the most important problem, unless it is affecting mobility. It is the morbidity associated with the

Table 46.1 Three commonly used sets of criteria for the metabolic syndrome, showing differences.

	WHO	NCEP ATP III	IDF
Required criteria	Insulin resistance or impaired fasting glucose or impaired glucose tolerance or type 2 diabetes plus any 2 of the following:	3 or more of the following:	Central obesity and any 2 of the following:
Central obesity	BMI >30 kg/m^2 or waist to hip ratio >0.9 (men), >0.85 (women)	Waist circumference ≥102 cm (men), ≥88 cm (women)	Waist circumference ≥94 cm (European men), ≥90 cm (Asian men), ≥80 cm (women)
Insulin resistance	Insulin sensitivity < lowest quartile		
Glucose intolerance	Fasting glucose ≥110 mg/dL (6.1 mmol/L) or impaired glucose tolerance or previously diagnosed type 2 diabetes	Fasting glucose ≥110 mg/dL (6.1 mmol/L)	Fasting glucose ≥100 mg/dL (5.6 mmol/L), or previously diagnosed type 2 diabetes
Blood pressure	140/90 or above	130/85 or above	130/85 or above
Triglyceride	Triglyceride >150 mg/dL OR	Triglyceride ≥150 mg/dL (1.7 mmol/L)	Triglyceride ≥150 mg/dL (1.7 mmol/L), or specific treatment for this lipid abnormality
HDL cholesterol	HDLc <35 mg/dL (men), and <39 mg/dL (women)	HDLc <40 mg/dL (men), and <50 mg/dL (women)	HDLc <40 mg/dL (1.03 mmol/L) in men and <50 mg/dL (1.29 mmol/L) in women, or specific treatment for this lipid abnormality

metabolic complications that is of major concern, and this can improve rapidly even after a limited loss of weight. A normal body weight is not necessary, and is often unrealistic in the long term.

Reduced energy intake must be individually tailored to allow normal activities. A deficit of 500–600 kcal (0.210–0.251 mJ) per day is usually well tolerated. Emphasis should be placed on fat intake and on the energy density of food. Involvement of the family is important [49]. A combination of exercise and diet is more effective than either alone [48], and long-term low-intensity exercise such as walking is as effective as high-intensity activities [50]. This is important because most obese patients are unaccustomed to sporting activities and will drop out of vigorous regimens.

Behaviour modification is an important component of all weight loss programmes [51,52]. Frequently, behavioural strategies are targeted toward identifying stimuli that signal unhealthy behaviours such as binge eating, learning about the role of readiness in initiating or continuing positive behaviours [53], and recognizing barriers that may compromise healthy pursuits.

Pharmacological agents may be used in conjunction with diet, exercise and behavioural strategies when non-pharmacological approaches have failed to produce a success. Several appetite-suppressant drugs are approved for weight loss and the reader is referred to authoritative sources on the subject [45]. In general, their use can achieve a weight loss of only 5 kg after 1 year [54]. For overweight children, medications and lifestyle interventions are similarly disappointing [55].

Surgery was once reserved for cases of extreme obesity (BMI over 40 kg/m^2) but is now also being recommended for a BMI over 35 kg/m^2 plus serious obesity-related co-morbid conditions [56]. Vertical gastric banding is the most common procedure. It is the best treatment for long-term weight loss and reduces mortality markedly for diabetes, heart disease and cancer [57].

An excellent review on the aetiology, prevalence and treatment of obesity is by Racette *et al*. [45] and on the particular problems for the adolescent by Jasik and Lustig [29]. With the elucidation of the neuroendocrine regulation of body weight it remains to be seen whether novel molecular compounds might become available in the future, but this should not be at the expense of simple dietary measures and exercise [58].

Cellulite

Cellulite is an alteration of the topography of the skin that occurs mainly in women in the pelvic region, the limbs and abdomen. It is characterized by a dimpled appearance if mild, and lumpy skin if severe, and affects 85% of post-pubescent females [1]. No formal quality of life study has been performed on this, probably normal, secondary sex characteristic but treatment improves self-esteem and the size of the anticellulite market attests to patients' concerns [2].

Many authors confuse cellulite with obesity. However, this is incorrect; in obesity only adipocyte hypertrophy and hyperplasia occurs [3], whereas in cellulite there are several structural alterations in the dermis, in the local microcirculation and within the adipocytes. These may result in further morphological, histochemical and biochemical modifications [4–7].

Cellulite may be classified in at least two ways. One classification divides cellulite into four stages according to the histopathological and clinical changes [3]:

Grade 1. The patient has no symptoms and there are no clinical alterations. Histologically, there may be an increased thickness of the areolar layer, increased capillary permeability and microhaemorrhages.

Grade 2. There are no obvious changes in the skin at rest, but after skin compression or muscular contraction small dimples, local pallor, decreased temperature and decreased elasticity may be evident.

Grade 3. A padded skin or an orange peel appearance is evident at rest, and there is a slight feeling of granularity in the deeper parts of the skin on palpation, which may be associated with some pain. At this stage, there is the beginning histologically of fatty tissue destruction and the formation of micronodules.

Grade 4. This stage is characterized by changes seen in grade 3 but with more visible palpable and painful nodules and an obvious wavy appearance of the skin surface. Histopathologically, the lobular structure of the fatty tissue has disappeared and some nodules are encapsulated by dense connective tissue and there may be much fibrosis.

Cellulite may also be classified by the consistency of the skin—being hard, flaccid, oedematous or mixed [8]. Hard cellulite is observed in young women who perform regular physical activity. The appearance is of compact, firm tissues and is not changed according to position. Flaccid cellulite is characteristically found in inactive women, especially if they have suddenly lost weight. In contrast, oedematous cellulite presents as an increased volume of the entire affected limb, and is associated with depression of the tissue to fingertip palpation, which persists when the finger is removed.

Aetiology. Just what precisely triggers the histopathological and clinical changes of cellulite is poorly understood. Hormonal factors may play a predisposing or aggravating part. Oestrogen is probably the most important hormone. Evidence for oestrogen involvement includes the fact that cellulite predominantly occurs in females, the onset of the disease after puberty, and aggravation of

the condition during pregnancy, menstruation and with oestrogen therapy [9].

A genetic predisposition may also be important. White women tend to be more prone to cellulite than Asian or Black women and Latin women develop cellulite on the hips while Anglo-Saxon women develop cellulite on the abdomen.

Sedentary lifestyle contributes to the aggravation of cellulite as a consequence of a decrease in muscle mass, and the consequent decreased muscular pumping mechanism in the lower limbs inhibiting venous return. Obesity contributes to the problem by increasing the fatty mass. Factors that act as a mechanical barrier to the venous return are also likely to be important; tight clothes and pregnancy may be important in this context.

Traditionally, three major theories have been put forward to explain the abnormalities: oedema in the fat lobules; alterations in the fat microcirculation; and a structural conformation of the subcutaneous tissue that is different in women compared to men. Whilst there is evidence for all three, it is uncertain if these are the effects or the cause. MRI scanning has provided support for the anatomical case [10,11]. 'Pseudoherniation' of fat pushing into the lower layers of dermis is more prevalent in cellulite, perhaps due to a thinner dermis in women compared to men. Women appear to have a different fibrous septal structure in the upper layers of subcutaneous fat, tending to have more vertical bands and pillars than the oblique criss-crossing bands seen in men, which contain smaller fat chambers. In cellulite there would appear to be fewer vertical septal bands with some bands and pillars appearing thickened and some thinned. The histology of some of these thinner bands has appeared similar to the elastic tissue changes seen in cutaneous stretch marks [12]. What is unknown is what role the multifunctioning adipocyte has played in the development of this apparent remodelling process [13].

Treatment. Because of the multifactorial pathogenesis of cellulite, there are numerous therapeutic approaches—especially because many of the treatments are much less than optimal in their success. Treatments include reduction in aggravating factors, pharmacological agents, and the use of physical and mechanical methods, ultrasound and lasers.

Attempts to reduce weight, regular exercise and the use of non-hormonal contraceptives need to be encouraged, but weight loss improves the appearance of cellulite only in those with a high starting BMI and aggravates the appearance in those with a low BMI [14]. Several pharmacological agents have been tried, both topical and injectable (mesotherapy), but adequate double-blind, placebo-controlled studies are lacking [15]. Physical therapies, including thermotherapy, pressotherapy and lymphatic massage, have similar drawbacks. Local surgery, so-called subcision, seems effective and works by destroying the thicker fibrous septal bands using the cutting edge of a needle under local anaesthesia [16]. Focused ultrasound is helpful in dissolving fat in body-contouring and may prove useful for cellulite [17].

More recently, radiofrequency devices, such as low-energy diode laser and infra-red systems, have been reported to be of benefit [18–20]. A unipolar radiofrequency device with the capacity to generate heat 15–20 mm into skin produced dermal fibrosis, which might be responsible for the observed good clinical benefit still present after 6 months [21].

General pathology of adipose tissue: panniculitis [1–11]

Inflammatory disorders of the subcutaneous fat present an important diagnostic challenge to the dermatologist, because the lesions

often develop as subcutaneous nodules or plaques. An adequate diagnostic biopsy is essential as a prerequisite to accurate diagnosis in almost all instances. A larger scalpel incisional biopsy is preferred, which obviously should extend deeply through the subcutis. Conventional punch biopsies (4 mm or smaller) are totally inadequate, as the tissue tapers down to leave little, if any, subcutaneous tissue. However, trephine punches are adequate and provide acceptable cosmetic results [10]. The pathologist may well need to cut serial sections, as some of the panniculitides are characterized by rather focal or even scattered pathological changes, and to look for evidence of damage to larger blood vessels.

Most panniculitides are persistent, lasting for weeks or months. For diagnostic purposes, the biopsy should be taken from an active earlier lesion: erythematous, indurated and usually tender. Although the fat lobules have a rich capillary blood supply closely applied to fat cells, there are no lymphatics and very little intervening connective tissue [11]. Furthermore, the vasculature in the subcutis area is slow flowing. This renders the subcutaneous fat vulnerable to a variety of noxious insults [9]; for example, cold injury or enzymatic damage.

The sequence of cellular events following injury to the subcutis may take weeks or months to fully evolve, and is usually as follows [1,2]:

Neutrophils (eosinophils)
↓
Lymphocytes
↓
Histiocytes (granulomatous 'foamy macrophages')
↓
Fibroblasts (fibrosis)

The histological changes of the granulomatous stage are not necessarily diagnostic. When fat cells are damaged, the liberated lipid undergoes hydrolysis to glycerol and fatty acids, which usually provoke a foreign-body-type granulomatous reaction. Macrophages are attracted and foam cells are produced. After the phase of reaction to released lipocyte products, there is a period of reconstitution, the ease of repair depending on the extent of the initial lipocyte damage and the efficiency of the local circulation.

Atrophy of subcutaneous tissue (lipoatrophy) is a consequence of some types of inflammation in the fat lobules. In other instances, extensive fibrosis is inevitable after damage to subcutis, resulting in the formation of chronic subcutaneous fibrotic nodules.

In certain types of panniculitis, an ongoing slow chain reaction is set up, in which small foci of fat necrosis provoke a peripheral inflammatory reaction, which in itself leads to further peripheral fat necrosis, thus allowing the lesion to spread centrifugally. It is therefore clear that the histological findings will differ, depending on the age of the lesion biopsied.

In difficult cases of panniculitis, it is helpful to submit more than one biopsy from lesions at different stages of their clinical evolution. Polarization of sections should be routinely performed to look for crystalline material, and in certain clinical situations extra tissue should be submitted for bacterial or fungal culture.

Panniculitis may be classified histologically according to whether it is predominantly septal, mixed, or associated with vasculitis, as in the following [1–4]:

1 Septal panniculitis:
- (a) erythema nodosum (see Chapter 50)
- (b) erythema nodosum migrans (see Chapter 50); (subacute nodular migratory paniniculitis)
- (c) eosinophilic panniculitis (this condition may overlap with lobular or mixed panniculitis)

2 Lobular panniculitis:
- (a) relapsing febrile nodular panniculitis (Weber–Christian syndrome)
- (b) idiopathic nodular panniculitis
- (c) lipoatrophic panniculitis (formerly Rothman–Makai syndrome)
- (d) panniculitis associated with crystal deposition—sclerema neonatorum (see Chapter 17), subcutaneous fat necrosis of newborn (see Chapter 17), gout or factitial panniculitis, poststeroid panniculitis, calciphylaxis
- (e) enzymic (pancreatic) panniculitis
- (f) α_1-antitrypsin deficiency panniculitis
- (g) fat necrosis—cold injury, nodular cystic fat necrosis, lipomembranous
- (h) lymphomatous panniculitis
- (i) cytophagic histiocytic panniculitis

3 Mixed panniculitis:
- (a) lupus erythematosus profundus
- (b) scleroderma (fasciitis with eosinophilia, see Chapter 51)
- (c) connective-tissue panniculitis (overlaps with lipoatrophic panniculitis)
- (d) subcutaneous sarcoidosis (see Chapter 61)
- (e) subcutaneous granuloma annulare (see Chapter 60)
- (f) necrobiosis lipoidica (see Chapter 60)
- (g) infective panniculitis (e.g. opportunistic bacterial or fungal infections)
- (h) physical and factitious panniculitis (e.g. sclerosing lipogranuloma, oil granulomas, eosinophilic sclerosing lipogranuloma)
- (i) sclerosing panniculitis (lipodermatosclerosis)
- (j) fasciitis—panniculitis syndromes

4 Panniculitis with vasculitis (see Chapters 49 and 50):
- (a) small-vessel vasculitis—leukocytoclastic vasculitis
- (b) large-vessel vasculitis—polyarteritis nodosa, thrombophlebitis, nodular vasculitis (erythema induratum)
- (c) neutrophilic panniculitis
- (d) oedematous scarring vasculitic panniculitis: hydroa-like lymphoma.

Inflammatory disorders of subcutaneous fat

Septal panniculitis

Erythema nodosum (see Chapter 50)

Although erythema nodosum is the prototype of a septal panniculitis, the inflammatory changes always involve the overlying dermis. In acute lesions, there is oedema of the septae with transudation of neutrophils, and sometimes eosinophils, into the septae and adjacent margin of fat lobules. In older lesions, the infiltrate becomes lymphohistiocytic and finally granulomatous, before the septae became thickened and finally fibrotic. Radial granulomas (Miescher) are often found in the interlobular septae in erythema nodosum [1]. There is still some debate as to whether *erythema nodosum migrans* (subacute nodular migratory panniculitis) [2–4] and the chronic and granulomatous forms of erythema nodosum [5] are variants of the same pathological process. Erythema nodosum migrans tends to be characterized by markedly thickened and fibrotic septae, marked capillary proliferation and a massive granulomatous reaction (with giant cells) along the borders of the widened septae [6].

Eosinophilic panniculitis

Eosinophilic panniculitis is characterized by a prominent infiltration of subcutaneous fat with eosinophils, and has been identified in patients presenting with a variety of associated clinical conditions [7–14].

The inflammatory infiltrate, including eosinophils, occurs principally within the septae but can involve the lobules. The overlying dermis is often involved, closely resembling eosinophilic cellulitis (Wells' syndrome) [9]. Fragmented eosinophilic granules (flame figures) are occasionally seen (Fig. 46.3). The current view of eosinophilic panniculitis is that it is not a disease entity, but it can be principally considered as a reactive process, often associated with a systemic condition [8].

More common causes of eosinophilic panniculitis include arthropod bites, atopic eczema, erythema nodosum, infectious causes (*Gnathostoma*, *Streptococcus*, *Toxocara*) and leukocytoclastic vasculitis [8]. The condition has also been associated with chronic recurrent parotitis [11], lupus panniculitis, morphoea profundus [12] and *Fasciola hepatica* infection [13]. Fortunately, only very rarely is eosinophilic panniculitis associated with malignancy, either leukaemia [14] or a solid tumour [9]. It has been seen in association with trauma and autoinoculation with farm products [15] but may also arise spontaneously [16]. In a case of subcutaneous fat necrosis of the newborn, eosinophilic granules were seen inside giant cells [17].

Lobular panniculitis

Relapsing febrile nodular panniculitis

Synonym
- Weber–Christian syndrome

Relapsing febrile nodular panniculitis was first described by Pfeifer in 1892 [1]. The term Weber–Christian syndrome came to be used following the cases reported by Weber [2] and Christian [3]. Weber–Christian syndrome encompasses a febrile disease, characterized by the recurrent formation of single or multiple crops of tender inflammatory nodules in the subcutaneous fat. Because the range of clinical features differed, and the extent of systemic involvement varied, the concept of Weber–Christian syndrome never became popular and the view was put forward that it should not be considered to be a distinct entity [4–6]. The term nodular panniculitis was preferred [5]. Nodular panniculitis is essentially a lobular panniculitis in which fat necrosis develops in the absence of overt vasculitis.

Macrophages ingest fat released from damaged lipocytes, thus producing a characteristic foamy appearance. In some cases, liquefactive nodules appear, which ulcerate and discharge an oily yellow liquid [7]. In others, there is more systemic involvement, which may affect visceral fat or even the myocardium [8].

Nodular panniculitis can affect both adults and children, when it can occur in early infancy [9,10]. However, it must be stressed that nodular panniculitis or Weber–Christian syndrome may not be a distinct disease entity. On further investigation, many cases of nodular panniculitis can be subsequently reclassified depending on their cause; for example, pancreatic panniculitis, α_1-antitrypsin deficiency or cytophagic panniculitis. However, there are undoubtedly some cases of nodular panniculitis, in both children and adults, in which the aetiology remains to be determined.

Idiopathic nodular panniculitis

An idiopathic condition characterized by recurrent crops of nodular panniculitis. Some cases are accompanied by fever, malaise, abdominal pain and arthritis. As indicated above, the term Weber–Christian syndrome is best avoided. Many cases of nodular panniculitis can now be attributed to specific causes (see below).

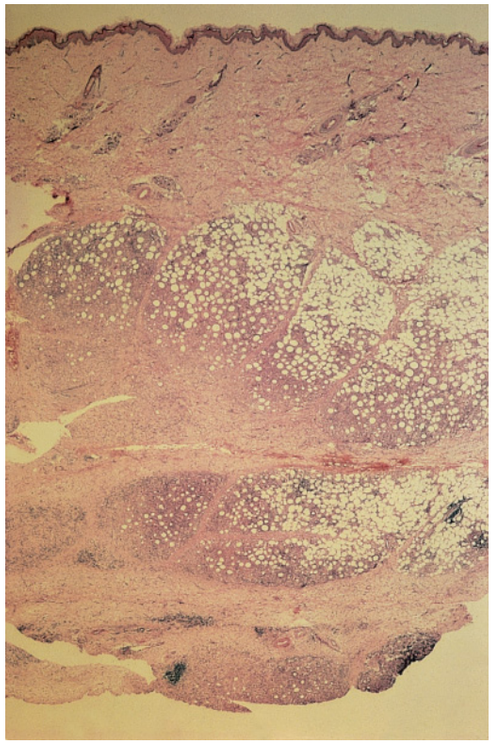

Fig. 46.4 Idiopathic nodular panniculitis. Low-power view showing lobular pattern of panniculitis. H&E, × 2.5.

Pathology. The histological changes are non-specific but the panniculitis is mainly lobular [1] (Fig. 46.4). In the early stages, the fat lobules are infiltrated with acute inflammatory cells, producing a pseudopyogenic reaction. Later, lymphocytes and macrophages appear to ingest the fat released from damaged lipocytes. These lipophages develop a characteristic foamy cytoplasm, producing the typical appearance of a lipophagic granuloma (Fig. 46.5). Healing is by fibrosis, the fibrocytes invading the lobules from the fibrous septae and ultimately producing complete lobular fibrosis.

Clinical features. Approximately 50% of cases of nodular panniculitis are idiopathic [2]. All ages may be affected, but the condition is very rare in childhood [3,4]. The majority of cases are young adult females who develop crops of dull-red, tender, subcutaneous nodules, usually about 1–2 cm in diameter. The lesions tend to be maximal on the lower limbs (Fig. 46.6), although the trunk and face can be affected.

Systemic features including fever, malaise, myalgia, arthralgia and weight loss are often present when there are multiple lesions. Many of the nodules eventually resolve, leaving a pigmented area or an atrophic depression. In a few cases, there may be overlying necrosis with drainage of oily, brownish, serous fluid (Fig. 46.7),

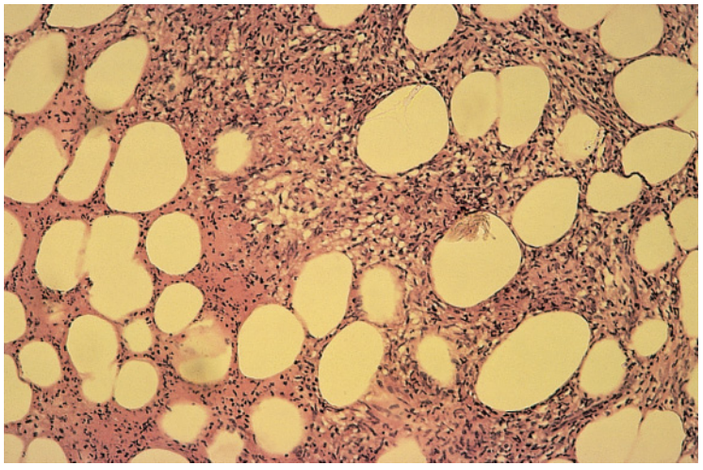

Fig. 46.5 Idiopathic nodular panniculitis: typical appearances of a lipophagic granuloma. H&E, × 40.

Fig. 46.6 Idiopathic nodular panniculitis.

eventually leading to scarring. Rarely, there may be involvement of visceral fat, including the heart, lungs, liver and kidneys, which may lead to death [5]. MRI scanning may disclose inflammation in an internal fat depot such as the retroperitoneum [6].

The laboratory features are non-specific, but there may be anaemia, leukocytosis or leukopenia, thrombocytopenia and a raised erythrocyte sedimentation rate.

Diagnosis. Idiopathic nodular panniculitis has to be distinguished from other forms of panniculitis (see below). It is important to perform repeated laboratory tests for pancreatic disease, autoimmune disease, complement deficiency, α_1-antitrypsin deficiency, and to exclude cytophagic histiocytic panniculitis. The possibility of factitial or infective panniculitis must also be considered.

Fig. 46.7 Idiopathic nodular panniculitis: drainage of serous fluid.

Prognosis. When only subcutaneous fat is involved, the prognosis is good [2]. Some cases recover after a few months, and permanent remission within 2–5 years is usual. Rarely, recurrences may continue for 10 years or longer, but without serious deterioration of the general condition. Exceptionally, the condition can be fatal if there is visceral involvement [5].

Treatment. Once the possibility of systemic disease has been excluded, the treatment is mainly symptomatic. Analgesics may be needed to alleviate pain, and ulceration may need bland aseptic dressings. In severe cases, systemic corticosteroids may be effective, provided adequate dosage (up to 80 mg/day prednisolone) is used for 7–10 days. The dosage should then be slowly tapered over a period of 4–6 weeks. Other treatments that have helped in some cases include antimalarials [7] and thalidomide [8].

Unusual causes of lobular panniculitis resembling idiopathic nodular panniculitis

Increasing numbers of case reports, usually isolated, are appearing that link nodular panniculitis to other illnesses or events. Autoimmune diseases such as Sjögren's syndrome have been linked to a lobular plasma cell panniculitis [9], and ulcerative colitis and myopathy with nodular panniculitis [10].

Infections, for example hepatitis A [11], *Borrelia burgdorferi* [12,13] and brucellosis [14], have also been implicated in the causation of nodular panniculitis. Granulomatous panniculitis has been associated with crescentic glomerulonephritis [15]. Lobular panniculitis has been reported to develop at the site of interleukin-2 injections for treatment of metastatic carcinoma, and to be exacerbated by intravenous use of the same treatment [16]. Delayed expression of an octopus bite [17] and local reaction to glatiramer acetate injection for multiple sclerosis [18] are other causes. Oral administration of the low-calorie artificial sweetener aspartame (Nutra-Sweet®) has been implicated in the causation of lobular panniculitis [19].

Lipoatrophic panniculitis

Synonyms
- Connective tissue panniculitis
- Autoimmune panniculitis

As the name implies, lipoatrophic panniculitis denotes the findings of prominent lipoatrophy. However, the development of lipoatrophy should be considered to be an 'end-stage' process, which is preceded by inflammation in the fat lobules and sometimes the fibrous septae. In the earlier literature, many cases of lipoatrophic panniculitis were considered to have Weber–Christian syndrome or Rothman–Makai syndrome [1]. As the aetiology of lipoatrophic panniculitis is unknown, it is perhaps not surprising that the nomenclature remains confused, and almost certainly there is considerable overlap in these clinical entities. 'Primary' lipophagic panniculitis has been described in adults (Fig. 46.8) [2] and children [3,4], either as an acute benign condition or as a chronic recurrent disabling disease. In children, a granulomatous histopathology can be seen prior to the development of lipoatrophy, for which the term lipophagic panniculitis is used [4]. Connective tissue panniculitis is a rare form of panniculitis, affecting septae and lobules, and leading to prominent lipoatrophy [5] (Fig. 46.9). The condition has been described in female adults and children [6]. Episodes of intense lymphocytic panniculitis lead to lipoatrophy. At various times in the illness, a circulating antinuclear antibody and/or SSB (La) antibodies may be detected [5,6]. The clinical spectrum of lipoatrophic panniculitis is thought to encompass connective tissue panniculitis [7]. Histologically, in connective tissue panniculitis there is no evidence of hyalinization of fat and collagen, which is typical of lupus erythematosus profundus [8]. Various other autoimmune diseases have been reported in association with lipoatrophic panniculitis, including diabetes mellitus, rheumatoid arthritis and Hashimoto's thyroiditis [3]. Lipoatrophic panniculitis has been reported in a very young child with a chromosomal abnormality on chromosome 10q26 [9].

Fig. 46.8 Lipoatrophic panniculitis: recurrent episodes of panniculitis have resolved to leave prominent lipoatrophy on the outer thigh. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

Treatment. Systemic corticosteroids are effective, but usually only in higher doses. Antimalarial therapy, hydroxychloroquine or chloroquine, is the most effective acceptable treatment [10], but may not be sufficient alone [5,7]. Reconstructive surgery, in the form of vascular pedicles or alloplastic implants, has been successfully used in severe cases of lipoatrophic panniculitis [7].

Panniculitis associated with crystal deposition

Polarization of skin histology is important in the assessment of any inflammatory or granulomatous type of panniculitis, as it may be the only way to identify crystals readily [1].

Lipid-containing crystals are dissolved out during formalin fixation, but usually leave cleft-like spaces, which often produce a characteristic histology. Needle-shaped clefts are characteristically seen in subcutaneous fat necrosis of the newborn (see Chapter 17), sclerema neonatorum (see Chapter 17) and post-steroid panniculitis. Cholesterol crystals may cause panniculitis, but the crystals are only found in the lumen of smaller blood vessels.

Post-steroid panniculitis [2–5]

Post-steroid panniculitis is now undoubtedly very rare. All the reported cases have been in children, in whom subcutaneous nodules developed 1–13 days after stopping high doses of systemic corticosteroids quickly. The nodules vary in size from 0.5 to 4 cm, and tend to localize in those areas where there is the greatest accumulation of fat from steroid therapy, but typically on the cheeks [6]. Although the nodules appear after the rapid discontinuation of steroids, they are not associated with systemic manifestations of the steroid-withdrawal syndrome. Resolution of the nodules is gradual, occurring over several weeks or months. There is no effective treatment.

The histology of post-steroid panniculitis is very similar to that of subcutaneous fat necrosis of the newborn, in that needle-shaped crystals may be found within lipocytes and histiocytes.

Calcifying panniculitis with renal failure [7]

In patients with chronic renal failure, a chronic alteration of calcium and phosphate metabolism often exists, and secondarily causes hyperparathyroidism. This combination leads to the processes of calciphylaxis and metastatic calcification [8,9]. Whilst calciphylaxis is almost always associated with chronic renal failure patients, many of whom are on long-term dialysis, it is seen in patients with normal renal function [10–12]. Some have, or have had, parathyroid problems, but it has also been reported in association with alcoholic cirrhosis [13] and malignancy, breast cancer and cholangiocarcinoma [14]. The calcification is principally present within smaller and medium-sized arteries. Weenig has suggested that vascular calcification results from the dysregulation of many factors, in particular nuclear factor κ-B (NFκ-B), a key transcription factor in bone mineral homeostasis, activation of which results in bone mineral loss [15]. If this local damage slows blood flow and contributes with other factors such as TNF-α to a local procoagulant state, the addition of a systemic hypercoagulable state, often present in these patients, would result in thrombosis.

Clinical features. The process begins with erythematous tender nodules or plaques that progress to violaceous livedo-like areas, usually located on the thighs (Fig. 46.10), abdomen or buttocks. These lesions tend to increase rapidly in size, progressing to large necrotic ulcers. In the acute stage a necrotic livedo pattern on the upper anterior thigh or lower abdomen in a patient with acute or chronic renal failure is a strong clinical pointer. Any long-term dialysis or chronic renal failure patient with a persisting leg ulcer should be assumed to have calciphylaxis until proved otherwise (Fig. 46.11). One clue is the really severe pain experienced, so extreme that patients cannot keep still. Parathyroid hormone levels are no different from dialysis patients without calciphylaxis, but are often high [16]. Sometimes repeated biopsy is required to find the calcified small vessels. Calcification in vessels is not pathognomonic, as it can be seen incidentally or in arteriopaths. Cutaneous necrosis mimicking calciphylaxis in renal failure has been reported, resulting from oxalate crystal deposition in the vessel wall [17]. Crystals from calcinosis in the fat induced by local heparin injection in renal patients and others are not in the vessel wall [18,19].

Treatment. Treatment should be aimed at preventing the hyperparathyroidism and secondary infection, but usually the disease has a high mortality, in one series only 46% surviving for a year [16]. Intravenous sodium thiosulphate [20] and biphosphonates

Fig. 46.10 Calciphylaxis of the upper thigh in a patient with renal failure.

Fig. 46.11 Calciphylaxis of the lower leg in a patient on long-term dialysis.

have been used with success [21,22] and may prevent the need for parathyroidectomy, which is not always successful in reversing the skin changes.

Gout

Urate crystals are inflammatory, and occasionally lobular panniculitis can be caused by deposition of crystals secondary to hyperuricaemia [23–25] though a raised urate is not always present [26]. Painful, ulcerating nodules on the lower legs is the usual presentation, though only four cases have been described. Crystals may be sampled directly from the chalky ulcer exudate and polarized. Large, pink, amorphous deposits surrounded by a giant cell reaction with little other inflammatory response is seen in the subcutis on histology. One case showed a neutrophilic lobular panniculitis [24]. Urate crystals can be distinguished by their fine, needle-like shape and tendency to form sheaves, but are usually only visible in ethanol-fixed sections.

In a unique case [27] urate crystals were seen intracellularly in adipocytes, mimicking subcutaneous fat necrosis of the newborn and post-steroid panniculitis. They were only visible as tissue had been processed through alcohol. The 6-month-old immunosuppressed patient had a large subcutaneous fungal infection on the cheek caused by fungi of the class *Zygomycetes*. The crystals appeared concomitant with the infection, much as oxalate crystals are seen with *Aspergillus* infections.

Drugs

Lobular panniculitis with crystals can occur following injection of drugs such as meperidine and pentazocine (Fig. 46.12) [28,29].

Crystal-storing histiocytosis

Crystal-storing histiocytosis is a rare condition in which tumorous deposits of histiocytes containing crystalline immunoglobulins are deposited in soft tissue. The condition has been reported to cause panniculitis of Weber–Christian type in a patient with lymphoblastic lymphoma [30].

Enzymic panniculitis

Synonym

- Pancreatic panniculitis [1]

Clinically, enzymic panniculitis overlaps closely with nodular panniculitis (Weber–Christian type) and leads to foci of subcutaneous fat necrosis. Systemic features are quite common, including arthritis, pleural effusions and ascites. The erythematous subcutaneous nodules tend to be present in the distal part of the extremities (often around periarticular areas). In milder cases, the nodule(s) can be single and resolve without ulcerating [2], mimicking erythema nodosum (Fig. 46.13), but usually they evolve into sterile necrotic abscesses, which spontaneously ulcerate and exude a thick, brown, oily material, which represents adipose tissue that has undergone liquefaction necrosis (Fig. 46.14).

Subcutaneous fat necrosis affects 2–3% of all patients with diseases of the pancreas [3]. It appears that all three pancreatic enzymes (lipase, trypsin and amylase) are needed to induce fat necrosis [4]. In 40% of cases associated with pancreatic-induced subcutaneous fat necrosis, the skin lesions were the presenting feature [5]. Monoarticular or oligoarticular arthritic symptoms are common, and may also precede diagnosis of pancreatic disease [6]. The nature of the pancreatic pathology can vary widely. Surgical correction of an anatomical ductal anomaly [7] or pancreatic pseudocyst [8] can result in complete resolution of panniculitis.

The syndrome has been described in post-traumatic pancreatitis [9], acute and chronic pancreatitis [10] and pancreatic carcinoma [1]. CT scanning can be useful in delineating the pancreatic lesion, as well as outlining areas of subcutaneous fat necrosis [11]. Rarely, acute panniculitis can be associated with a high urinary amylase excretion in the absence of overt pancreatic disease [12]. The association of subcutaneous fat necrosis with pancreatic disease has been reported in systemic lupus erythematosus [13].

Pancreatic panniculitis has been reported in association with primary human immunodeficiency virus (HIV) infection and a haemophagocytic syndrome [14], and in pancreatitis associated with hypertriglyceridaemia [15].

The histological changes of pancreatic panniculitis are unique but rarely encountered. Focal fat necrosis in the lobules occurs, which is probably initiated by circulating enzymes (Fig. 46.15). A characteristic coagulative necrosis of lipocytes ensues, which leads to ghosts of lipocytes and varying degrees of calcification [1]. In older lesions, fat necrosis and 'ghost' lipocytes become less prominent, and are replaced by a granulomatous infiltrate with Langhans' giant cells [1] (Fig. 46.16). In the very early stages of pancreatic panniculitis, a septal pattern of inflammatory involvement has been described [16].

The treatment of pancreatic panniculitis is primarily supportive and dependent on the underlying pancreatic pathology. Occasionally, complete resolution of symptoms occurs when gallstones are removed [17] or when an anatomical ductal anomaly has been divided [7]. Usually, the prognosis is gloomy. In a review of 27 patients with pancreatic panniculitis, all eight cases with pancreatic carcinoma and 42% of the 19 patients with pancreatitis died of their disease [18].

α_1-Antitrypsin-deficiency panniculitis (MIM +107400)

Subcutaneous panniculitis simulating Weber–Christian syndrome may be associated with deficiency of α_1-protease inhibitor (α_1-antitrypsin) [1].

Aetiology. Severe deficiency of this important inhibitor in the blood is inherited as the ZZ phenotype, which occurs in about 1 in 2500 people [2]. Severe deficiencies of α_1-antitrypsin can be associated with emphysema, hepatitis, cirrhosis, vasculitis, urticaria, angio-oedema and panniculitis.

The alleles of the gene involved are measured by electrophoretic ability and divided into medium (M), slow (S) and very slow (Z). MM is normal. Homozygous deficiency with phenotype ZZ is most commonly associated with panniculitis, although heterozygous deficiency with phenotype MZ has also been implicated [2,3] as has SS [4]. Patients with the MM phenotype have normal α_1-antitrypsin blood levels, whilst those with ZZ have the lowest.

α_1-Antitrypsin inhibits trypsin activity, but it is also active against neutrophil elastase, pancreatic elastase, serine proteases, collagenase, factor VIII and kallikrein [5].

The exact pathogenesis of the panniculitis is obscure, but deficiency of α_1-antitrypsin could accelerate the activation of lymphocytes and phagocytes, thus producing severe inflammation as well as tissue necrosis secondary to protease action.

Fig. 46.17 Severe suppurative panniculitis secondary to deficiency of α_1-antitrypsin. (Courtesy of Dr M.R. Pittelkow, Mayo Clinic, Rochester, MN, USA.)

Pathology. Characteristically, the panniculitis is severely necrotic and suppurative, involving lobules and septae. Vasculitis, haemorrhage or phlebothrombosis can occur in areas of severe inflammation. The end result can be extensive liquefactive necrosis of the dermis and fibrous septae in the subcutis, leading to transepidermal elimination of necrotic material. Even so, large areas of normal fat can be found adjacent to necrotic lobular and septal areas, which contain abundant polymorphonuclear leukocytes and macrophages [6]. In the earliest stage of inflammation, splaying of neutrophils between collagen bundles in the reticular dermis has been noted [7].

Clinical features. The age of onset of the panniculitis ranges from infancy to old age. Early lesions may resemble a cellulitis, as has been described in Marshall's syndrome (Sweet's syndrome leading to acquired cutis laxa), which has been reported to be associated with α_1-antitrypsin deficiency, and may represent part of the disease spectrum [8]. A clue to the diagnosis of α_1-antitrypsin deficiency is that the ulcerative lesions occur predominantly on the trunk and proximal extremities [2] (Fig. 46.17). The clinical findings of ulcerative panniculitis, combined with the histological findings of acute inflammation, necrosis and haemorrhage, certainly justify investigation of α_1-antitrypsin blood levels. Some of the lesions may be precipitated by trauma, and can be exacerbated by surgical debridement [6]. Even cryosurgery has been implicated [9].

Treatment. Dapsone [10] or doxycycline [11] can be very effective in controlling panniculitis [2,10], while systemic steroids, antimalarials and immunosuppressive drugs often give an inconsistent response. For patients with more severe manifestations of disease (e.g. emphysema, lung fibrosis and liver failure), replacement with weekly intravenous α_1-antitrypsin (Prolastin®) offers a valuable treatment [2]. Each patient requires approximately 10 g/month; the treatment is expensive and not licensed everywhere [12], but may be life-saving even for patients with panniculitis [13].

Fat necrosis

Fat necrosis is often an important accompanying feature in panniculitis, and can be prominent enough and sufficiently distinctive to merit separate description. Insults to the fat, including cold injury [1] or trauma [2], are well known to cause fat necrosis, often when there is accompanying venous insufficiency in the lower legs.

Cold panniculitis

Synonym
- Adiponecrosis e frigore (Haxthausen's disease) [1]

Cold panniculitis is a form of localized panniculitis that results from cold injury to subcutaneous fat.

Aetiology. The condition has been reported in neonates [2], children [1,3] and adults, notably as a consequence of ice cubes [4], ice packs [2] or exposure to mountain rivers [4,5] or freezing air temperatures, particularly in adults with a chilblain-type of circulation [6]. Cold panniculitis of the thighs or buttocks may occur in skiers or horse riders who wear inadequate clothing [6], although in this situation perniosis is more common than true panniculitis histologically [7]. Children sucking ice lollies (popsicles) can induce cold panniculitis in the facial subcutaneous tissues [8].

Fig. 46.18 Cold panniculitis: erythematous nodular area on the malar region of a 6-month-old infant which developed after exposure to a very cold wind. (Courtesy of Dr D.J. Atherton, St John's Institute of Dermatology, King's College London, UK.)

Pathology. The early features show a perivascular lymphohistiocytic infiltrate at the dermal–subcutaneous junction with established lesions showing a lobular panniculitis with a mixed infiltrate [5].

Clinical features. Some 48–72 h after cold exposure, the affected areas become indurated with an ill-defined margin. The inflamed skin may be red or bluish, but the diagnostic test is that the area is cold to the touch (Fig. 46.18). The subject may complain of a cold sensation or a dull ache. If the area is kept warm, the subcutaneous plaques slowly soften and resolve over weeks without scarring.

Differential diagnosis. The clinical appearances may resemble other forms of panniculitis (especially erythema induratum) but can usually be distinguished by the location, history of prior cold exposure and being cold to the touch.

Treatment. Cold panniculitis resolves spontaneously if further exposure to cold injury is avoided. In horse riders, tight jeans should be replaced by several layers of looser and thicker clothing. If the limb becomes thoroughly chilled, rapid rewarming should be avoided. Vasodilators tend not to be helpful [9]. One case had a dramatic response to tetracycline which was also effective prophylactically [10].

Nodular cystic fat necrosis [1]

Synonym
- Encapsulated fat necrosis [2]

The term denotes a characteristic form of encapsulated subcutaneous fat necrosis that presents as solitary or multiple subcutaneous nodules.

Aetiology. Early lesions begin as lobules of adipose tissue, which, because of compromised blood supply, often following trauma, become separated from the surrounding tissue [3]. These lobules subsequently become surrounded by thin fibrous tissue, and remain as encapsulated necrotic tissue or later undergo dystrophic calcification.

Pathology. The lesions are totally or nearly totally encapsulated, showing massive fat necrosis with preservation of the outlines of non-nucleated adipocytes, usually with little in the way of inflammatory changes. Fibrous septae within the lesion, and dystrophic calcification, tend to be seen in older lesions. Focal or extensive lipomembranous changes may coexist [4,5].

Clinical features. The painless lesions occur often on the lower legs of healthy adolescent boys or middle-aged women. The lesions can be solitary or multiple, often mobile, and varying from 2 to 35 mm in diameter, though 'giant-sized' cases 15–18 cm have been reported [4,6]. Multiple lesions have been described in both systemic lupus erythematosus and systemic sclerosis [7,8]. Preceding trauma is present in about 30% of cases. The nodules may be present for several weeks to years before excision. During surgical removal, a smooth-walled cyst within the subcutaneous fat containing solitary or multiple, free-floating or attached nodules is usually found. Nodular cystic fat necrosis is probably not uncommon, but not readily recognized. Similar changes in the fat have been reported within the abdominal cavity [9] or within the abdominal wall [10]. Some authors take the view that encapsulated angiolipomas and encapsulated lipomas are variants of nodular cystic fat necrosis, with a variable degree of vascularity [2,11].

Differential diagnosis. This includes lipoma, angiolipoma, pancreatic fat necrosis and membranous fat necrosis.

Lipomembranous fat necrosis [1]

Synonym
- Membranocystic fat necrosis

Lipomembranous fat necrosis is a striking and distinctive alteration in adipose tissue that was first described in Nasu–Hakola disease, a genetic disorder characterized by profound membranocystic degeneration of long bones and systemic adipose tissue, with associated progressive sudanophilic leukodystrophy of the brain [2]. Cystic areas of fat necrosis are lined by wavy hyaline acidophilic membranes (Fig. 46.19). Convoluted projections and arabesques of the membranes into the interior of the cysts are prominent [3]. The membranous structures stain brightly with periodic acid–Schiff but are resistant to diastase. Ultrastructurally, the membranes consist of two layers [4].

Changes of lipomembranous fat necrosis can occur as a non-specific reaction pattern in a wide range of autoimmune diseases, including lupus erythematosus [3], diabetes mellitus [3], morphoea [5] and dermatomyositis [6]. It may also be seen in panniculitis induced by chemotherapy [7]. In a clinical and pathological correlation of 1806 biopsies of panniculitis, lipomembranous fat necrosis was only identified in 13 cases [3]. It is now clear that venous stasis and ischaemia are important co-factors [1,3,8,9] in

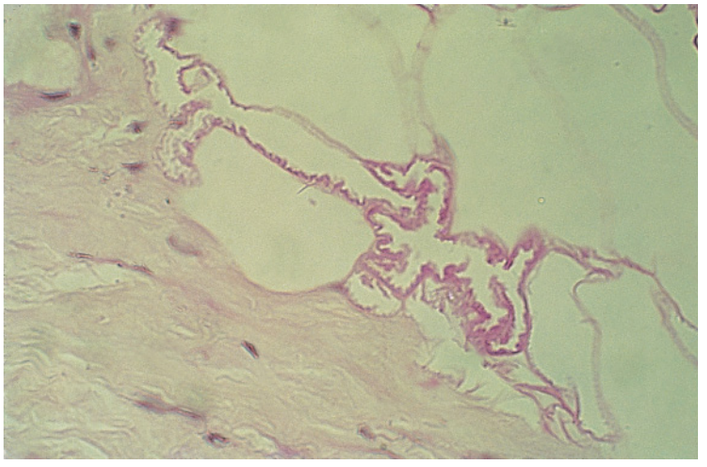

Fig. 46.19 Lipomembranous fat necrosis: the cystic areas are lined by wavy hyaline membranes. Periodic acid–Schiff (PAS) stain, × 25.

the development of lipomembranous fat necrosis. Most cases are seen in middle-aged, obese women who develop venous stasis-associated chronic sclerotic plaques on the lower legs and ankles [1]. The condition therefore overlaps with, or is a part of, sclerosing panniculitis [10], lipodermatosclerosis; some consider it to be a non-specific finding [11].

Panniculitis caused by cellular proliferative disease

Subcutaneous T-cell lymphoma is a rare type of peripheral T-cell lymphoma, which clinically and histologically may mimic benign forms of panniculitis [1]. Erythematous subcutaneous nodules localized to the extremities appear in crops, often accompanied by fever and malaise [1,2]. The lymphoma may behave indolently for months to years, but in most cases it enters an acute aggressive phase in which the majority of patients develop fatal haemophagocytic syndrome [3] or sometimes acute leukaemia [4].

Although low-power histological appearances may resemble benign panniculitis, high-power examination reveals cytological atypia of the malignant lymphoid cells, and immunochemistry studies confirm the T-cell lineage [5]. Angiocentric lymphoma can also cause lobular granulomatous panniculitis [6,7].

Cytophagic histiocytic panniculitis [1,2]

Cytophagic histiocytic panniculitis is the term commonly used to refer to the specific cutaneous manifestation of haemophagocytic syndrome (HPS) [3].

In HPS, there is a histiocytic proliferation throughout the reticuloendothelial system. The proliferation and phagocytic activity of histiocytes in HPS is associated with a proliferation of lymphocytes [3]. Indeed, the primary abnormality in cytophagic histiocytic panniculitis may be a clonal T-cell proliferation [8], though in familial HPS the genetic defect leads to an inability of natural killer cells to kill target cells, allowing lymphocytes and macrophages to proliferate [9].

Aetiology. The proliferation of lymphocytes and histiocytes in HPS may be secondary to microbial, particularly viral, infections (e.g. Epstein–Barr virus [10], cytomegalovirus), may be associated with autoimmune disease such as lupus erythematosus [11,12], or neoplastic in origin [2]. Cytophagic histiocytic panniculitis has been reported as a late complication of allogeneic bone marrow transplantation [13]. HPS has a higher rate of mortality when it is associated with a state of known immunosuppression, and has been reported in HIV-1 infections [2]. Indeed, lymphoma and infection may act as co-factors in the development of HPS. It has been postulated that in HPS cytokine production by the proliferating lymphocytes is important as a stimulus to activate macrophages [2]. In the light of a new classification of subcutaneous T-cell lymphoma [14], and case reviews [15], the histological picture of cytophagic histiocytic panniculitis may be thought of as occurring against a background of infection, in association with other diseases, particularly autoimmune, or in association with malignancy. Malignancy is further subdivided into subcutaneous panniculitis-like T-cell lymphoma of α/β T-cell phenotype (SPTL-AB) and SPTL with a γ/δ T-cell phenotype (SPTL-GD) [14]. Only 20% of SPTL-AB patients exhibit haemophagocytosis in the skin, compared to all SPTL-GD ones. Many SPTL-AB patients also have autoimmune diseases. SPTL-GD patients are now included in the cutaneous γ/δ T-cell lymphoma group (CGD-TCL) because of their poor prognosis.

Pathology [16]. Cytophagic histiocytic panniculitis may begin as a type of regional histiocytosis that primarily involves the subcutis. In most cases, the condition spreads to involve the bone marrow, lymph nodes and reticuloendothelial system. The affected tissues are gradually replaced by a syncytium of histiocytic cells with associated T lymphocytes and plasma cells. The histiocytes are actively cytophagic, so that they become stuffed with white blood cells, red cells, nuclear fragments and platelets, thus giving them a characteristic 'bean-bag' appearance (Fig. 46.20).

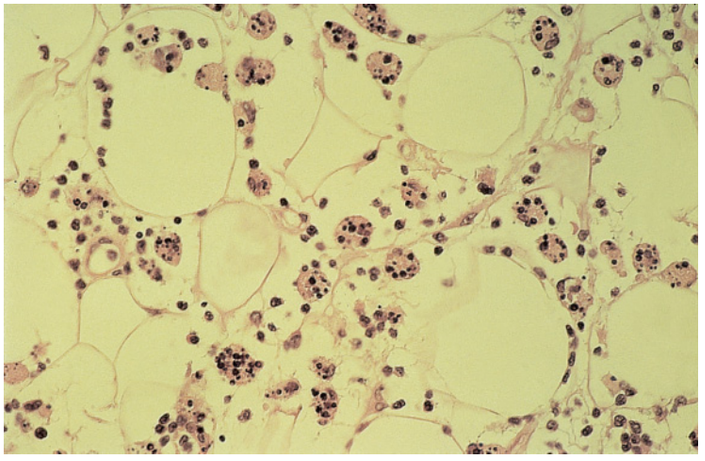

Fig. 46.20 Cytophagic histiocytic panniculitis: many histiocytes are present in the fat lobule, showing the characteristic 'bean-bag' appearance. H&E, × 25.

Fig. 46.21 Cytophagic histiocytic panniculitis: early stage with recurrent crops of lesions. (Courtesy of the Mayo Clinic, Rochester, MN, USA.)

Fig. 46.22 Cytophagic histiocytic panniculitis: note the haemorrhagic nature of this early lesion on the thigh. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

The histiocytic proliferation is accompanied by lobular panniculitis with areas of fat necrosis, together with massive hyaline necrosis, oedema and haemorrhage [16]. Immunohistochemical studies tend to show that the histiocytic population is benign, whereas the lymphoid element, whether benign or malignant, is composed primarily of T cells [2]. SPTL-AB lymphoma shows a lobular panniculitis with a lymphocytic infiltrate showing cells of variable size and irregularity. Rimming of individual adipocytes by neoplastic T cells is common. The presence of plasma cells points to the possibility of lupus erythematosus profundus being associated, whose gene rearrangement is polyclonal. The immunophenotype of SPTL-AB lymphoma is $CD3^+$, $CD8^+$ and $CD4^-$. Conversely, the infiltrate in SPTL-GD is more extensive and diffuse, and involves the overlying dermis as well as the lobules; there is less rimming, it is more angioinvasive, and is comprised of more medium–large, irregular lymphocytes. The immunophenotype is $CD3^+$, $CD8^-$ and $CD4^-$ and very often $CD56^+$. *In-situ* hybridization for Epstein–Barr virus is negative in both. The diagnosis is confirmed by the presence of the appropriate clonal gene rearrangement [14].

Clinical features. This is a rare condition, which in the past has probably been labelled as systemic nodular panniculitis (Weber–Christian syndrome) [17,18]. The condition begins with crops of red tender nodules, associated with fever (Fig. 46.21). The nodules often develop a purpuric or bruised appearance (Fig. 46.22). The condition can be acute, or chronic with a febrile course associated with anaemia and pancytopenia. More severe cases tend to display weight loss, thrombocytopenia, raised liver enzymes, serosal effusions and hepatosplenomegaly [17–19].

Most patients have a progressive form of the disease, which is ultimately fatal. The fatal progression is usually determined by the development of severe anaemia, thrombocytopenia and coagulation defects provoking bleeding, hypocalcaemia and liver failure [18,19]. At this stage, the development of terminal T-cell lymphoma [20,21], B-cell lymphoma [22,23], histiocytic lymphomas [24] or sinus histiocytosis with massive lymphadenopathy (Rosai–Dorfman) [25] may also be evident. The complex coagulation defects are not fully understood. There may be a combination of thrombocytopenia or thrombocytosis, decreased factor VIII and fibrinogen levels, and an increase in excretion of fibrin degradation products. It has been suggested that these abnormalities in coagulation may be caused by a circulating proteolytic enzyme other than thrombin, which may originate from proliferating lymphocytes [26].

However, prolonged survival after combination-type chemotherapy has been reported, even in cases where the clinical features indicate a poor prognosis [11,27]. Monitoring of phagocytic activity may be of value in assessing disease activity [11].

Treatment. Many cases are ultimately fatal, and for the progressive forms combination cytotoxic chemotherapy should be tried [10,19]. Prolonged survival or even complete remission have been reported with this type of treatment schedule [27,28]. Ciclosporin has been reported to be effective in cytophagic histiocytic panniculitis [29], presumably by suppression of the abnormal T-cell activation and proliferation. Combinations of systemic corticosteroids and azathioprine have been reported to be effective [30], as has the use of intravenous immunoglobulins [31]. The prognosis appears to depend on the presence or absence of systemic features of HPS and, if T-cell lymphoma is present, whether it is SPTL-AB or SPTL-GD in type. If systemic features of HPS are present (fever, unexplained cytopenia in two out of three lineages of the peripheral blood, hyperferritinaemia and histological evidence of

haemophagocytosis in bone marrow or lymph node), then treatment should be directed there, but prognosis is poor [9]. SPTL-AB lymphoma may need only systemic steroids or immunosuppressive agents, whereas SPTL-GD lymphoma needs aggressive chemotherapy [14].

Mixed (septal and lobular) panniculitis

Lupus panniculitis

Synonym
- Le profundus

Lupus panniculitis is a rare condition in which the inflammatory changes primarily affect the deep dermis and subcutaneous fat. The overlying skin may be associated with discoid lupus erythematosus (LE) in 20% of cases [1,2]. The serum antinuclear antibody is usually positive in approximately 70% of cases, but only 25–50% fulfil the American Rheumatism Association criteria for systemic LE [1,2]. However, there are a significant number of cases of lupus panniculitis that never meet the criteria for systemic LE, and some have no extracutaneous manifestations [3]. Many patients with lupus panniculitis tend to have a relatively mild but usually chronic disease course [3]. Lupus panniculitis is seen predominantly in females [1–4], usually young adults, though childhood [5–7] and neonatal [8] cases do occur. It arises spontaneously but can be triggered by injury such as immunization [7] (Fig. 46.23). Local injections of glatiramer acetate for multiple sclerosis have induced lupus panniculitis-like histology in some instances [9]. Hepatitis B vaccination has reactivated old lesions of lupus profundus [10], whilst interferon-beta has induced new ones [11]. Some cases have been associated with complement deficiencies [7] which might have made the disease more extensive [12].

Clinical features. The lesions begin with subcutaneous nodules or plaques, where the overlying skin may appear normal, erythematous or may show changes characteristic of discoid LE [2]. The lesions can be painful and may ulcerate, leading to atrophy and scarring after healing [13], even giving an anetoderma-like appearance [14].

Common sites for nodules include thighs, buttocks, arms, breasts and face (Fig. 46.24). When breast tissue is involved (lupus mastitis), there may be difficulty in distinguishing lupus mastitis from breast carcinoma, even on mammography [15]. Indeed, lupus mastitis may account for 10% of all patients with lupus

Fig. 46.23 Lupus panniculitis originally triggered by immunization. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

Fig. 46.24 Lupus panniculitis. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

panniculitis [16]. In black patients, peri-orbital oedema may be the initial presentation [4]. Many cases of lupus panniculitis may have only mild extracutaneous features, but the coexistence of photosensitivity, arthritis, pericarditis, renal involvement [3] and even neuropsychiatric manifestations has been reported [16].

Perhaps not surprisingly, lupus panniculitis can overlap with morphoea-like lesions [17], dermatomyositis [18] or other forms of connective tissue panniculitis [4]. Linear variants have been described [19,20].

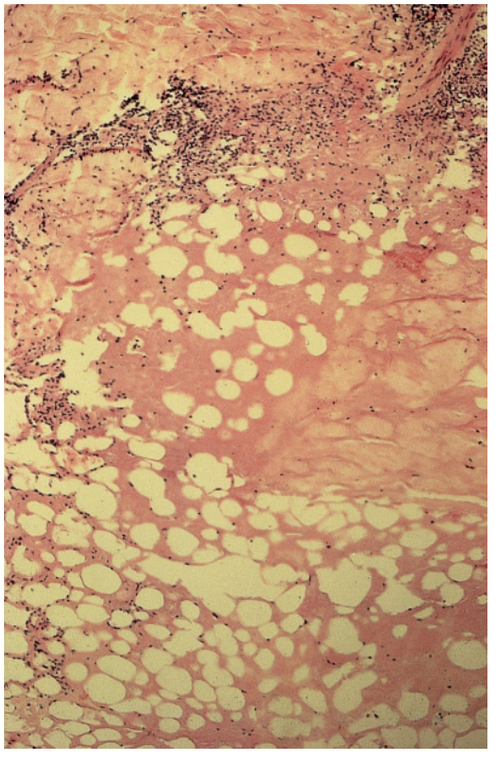

Fig. 46.25 Lupus panniculitis: extensive hyaline necrosis of fat with overlying lymphocytic aggregates are shown. H&E, × 4.

Pathology. The major histological criteria needed for a diagnosis of lupus panniculitis include hyaline necrosis of fat, lymphocytic aggregates or lymphoid follicle formation, periseptal or lobular lymphocytic panniculitis, and calcification [1] (Fig. 46.25). Minor changes (not necessary for diagnosis) include overlying changes of discoid LE, hyalinization of the subepidermal zone, mucin deposition, lymphocytic vascular inflammation and collections of plasma cells and eosinophils [21]. Karyorrhexis from lymphocyte nuclear dust is common and a strong pointer [1,22]. The main differential diagnosis is subcutaneous panniculitis-like T-cell lymphoma (SPTL), where the presence of atypical CD8+ve T lymphocytes and the absence of septal fibrosis, B-cell follicles, and plasma cells are major clues [22]. Rimming of adipocytes by lymphocytes is common in lupus profundus and not diagnostic of SPTL. A lupus band on immunofluorescence is positive in most cases, even in the absence of epidermal changes on routine histopathology [1].

Treatment. Treatment can be difficult in chronic forms of lupus panniculitis. Local treatment in the form of potent corticosteroids under hydrocolloid dressings [23] or intralesional triamcinolone can be of benefit. Dapsone [24], oral hydroxychloroquine [4,5] and corticosteroids [4,15] can be effective in the management of lupus panniculitis. Low-dose thalidomide can be effective for antimalarial drug-resistant cases of discoid LE and LE profundus [7,25].

Panniculitis with complement deficiency

Although complement deficiencies are perhaps better known for their association with lupus erythematosus and partial lipoatrophy syndromes [1], they have also been reported in lobular panniculitis. The association of an immunoglobulin E (IgE) paraproteinaemia and severe acquired depletion of C1-esterase inhibitor with episodes of nodular panniculitis and hepatitis has been reported [2]. Nodular panniculitis has also been associated with a low serum complement, together with a systemic LE-like disease and circulating IgM immune complexes [3].

Infective panniculitis

Infective panniculitis (either through direct inoculation or as a manifestation of sepsis) is becoming an increasingly important cause of panniculitis [1]. This is particularly so for any immunocompromised patient, either as a result of steroid or immunosuppressive therapy [2] or brought about by HIV infection [3]. An association of acquired immune deficiency syndrome (AIDS) with cutaneous aspergillosis is developing, and some patients present with subcutaneous nodules [4].

Granulomatous panniculitis on the legs caused by *Candida albicans* has been reported in a diabetic who had not received immunosuppressive treatment [5]. Other occasional cases with infective panniculitis are not overtly immunosuppressed [1].

Clinical features [1]. Most cases of infectious panniculitis appear as inflamed subcutaneous nodules, plaques or ulcers [4] on the lower extremities. Other sites include the shoulders, arms, fingers, abdominal wall and gluteal region. The differential diagnosis includes erythema nodosum, abscess or other type of panniculitis.

A wide variety of organisms have been identified in infective panniculitis. These particularly include Gram-negative [3] and Gram-positive [1] bacteria, *Histoplasma* [2,6], *Mycobacterium tuberculosis* [7], atypical mycobacteria [8,9], *Actinomyces* and *Nocardia* species [1], *Candida* [4] and various fungi [1]. Occasionally, the diagnosis of infective panniculitis has been missed because the infection has occurred in a clinical setting where a non-infective panniculitis was expected [10]. Conversely the situation whereby the patient's clinical setting has suggested that the panniculitis should be infective but tissue staining, culture or PCR was not confirmatory has been labelled panniculitic bacterid [11].

Histology. Classically, in infective panniculitis there is a mixed pattern of septal and lobular involvement. Neutrophilic involvement of the fibrous septae can occur [1], a feature that can rarely overlap with acute erythema nodosum [12]. Indeed, neutrophilic involvement in infective panniculitis can also overlap with other neutrophilic dermatoses (neutrophilic vasculitis and panniculitis) [13]. Certain morphological changes are found in infective panniculitis, whatever the identity of the infective organism. Epidermal involvement is common, as is papillary dermal oedema with diffuse neutrophilic infiltrate, vascular proliferation and haemorrhage [1]. Focal necrosis of sweat glands and discrete microabscess formation may be noted [1].

It is important to stress that infection should be suspected in virtually any case of panniculitis when it is known that the patient is immunocompromised. Extra biopsy material submitted for

tissue culture is highly desirable, if not essential [3], as special stains may fail to demonstrate the organisms [1].

Factitial panniculitis [1]

Factitial panniculitis is a rare condition in which the panniculitis is self-inflicted. Its importance lies in the fact that some cases may masquerade as systemic disease or idiopathic Weber–Christian syndrome. The causes and clinical features of factitial panniculitis may vary widely depending on the type of insult to the subcutaneous fat. Factitial panniculitis may result from blunt trauma to the skin, usually on the forearm and hand (l'oedème bleu) [2]. Histologically, such cases may show an organizing haematoma in the fat, together with haemosiderin and amorphous polysaccharide masses [2]. Cupping and acupuncture techniques for relief of pain may rarely lead to factitial panniculitis on the limbs [3]. More commonly, however, factitial panniculitis is induced by injected materials (e.g. drugs and silicone materials). Injected drugs such as morphine, pentazocine, meperidine or tetanus toxoid can all cause chronic ulcerative panniculitis on the thighs and buttocks, associated with 'woody-hard' fibrotic induration (see Fig. 46.12) [4,5]. Silicone injections (used by some patients to augment the size of breasts or genitalia) can cause panniculitis [6], as can the accidental injection of various oily vehicles for therapeutic agents. Povidine, a synthetic polymer used as a dispersing or suspending agent for drugs, has also been reported to cause panniculitis associated with fever [7]. The injection of mineral oil into tissues may induce a granulomatous foreign body reaction (sclerosing lipogranuloma) or 'paraffinoma' [8]. Histologically, paraffinomas show multiple 'Swiss-cheese-like' pseudocystic spaces (Fig. 46.26), which are surrounded by fibrosis and inflammation. Most paraffinomas occur on the head and neck area in women who have the injections for cosmetic reasons [9] (Fig. 46.27).

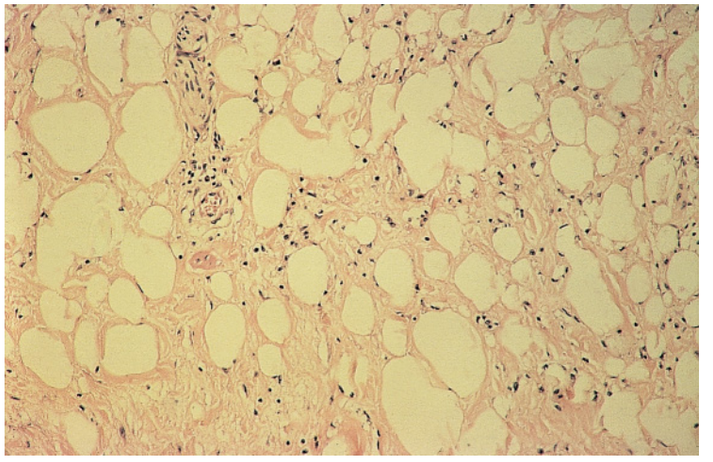

Fig. 46.26 Paraffinoma: showing typical 'Swiss-cheese'-like pseudocystic spaces. H&E, × 25.

Fig. 46.27 Paraffinoma: firm indurated areas present on the malar areas, following paraffin oil injections many years before for cosmetic purposes. (Courtesy of St John's Institute of Dermatology, King's College London, UK.)

Rarely, however, paraffinomas are not factitial in origin. The development of orbital and palpebral paraffinoma has been reported to ensue after ethmoidectomy for chronic sinusitis, when the nasal cavity was packed with gauze containing a petrolatum-based antibiotic ointment [10]. Mentally disturbed patients have been known to inject milk or faeces, which produces a severe cellulitis or suppurative panniculitis.

Factitial panniculitis simulating pyoderma gangrenosum has also been reported in Münchausen syndrome [11] and eosinophilic panniculitis was triggered by autoinjection of several farming products [12].

Histology. The histology will obviously vary according to the type of noxious injury to the fat. Blunt trauma tends to produce deeper haematomas [2]. Polarization is essential to reveal the possibility of injected crystals [4,5]. The presence of vacuoles or

pseudocystic spaces favours the injection of silicone [6] or paraffin [9,10].

The use of scanning electron microscopy or energy-dispersive spectroscopy techniques can aid in the identification of injected materials [6]. In general, factitial panniculitis is a mixed septal and lobular panniculitis that is associated with a prominent degree of inflammatory or granulomatous infiltrate, with fibrosis ensuing.

Differential diagnosis. The diagnosis may be suggested by the personality of the patient, the chronic and recurrent nature of the panniculitis and by its focal or bizarre site. In some cases, there may be fever or systemic symptoms and the condition may then be mistaken for systemic nodular panniculitis (Weber–Christian syndrome).

Oil granuloma

Synonyms
- Oleogranuloma
- Oleoma
- Paraffinoma
- Sclerosing lipogranuloma

Definition. A granulomatous reaction to the injection of a relatively bulky oily fluid into the tissues. In many cases the condition overlaps with that of factitial panniculitis, but in some cases it may represent an industrial injury.

Aetiology. Many years ago, mineral oils, particularly liquid paraffin and soft paraffin, were in vogue for improving the contour of the body (breasts, face, genitalia) [1]. Oil granulomas are now less common since the development of less toxic silicones and bovine collagen for tissue replacement, or the use of liposuction techniques, but they still occur [2–4].

Grease-gun injuries can cause sclerosing lipogranulomas [5].

Histology. A massive injection of oil tends to provoke an initial acute inflammatory response, but some mineral oils will remain in the tissue for a considerable time without producing any marked inflammatory reaction. Larger oil droplets become encysted by fibrosis ('onion-skin cysts'). The classical 'paraffinoma' shows multiple, small cystic areas ('Swiss-cheese effect') associated with very little inflammatory change but a prominent degree of fibrosis. Certain animal fats produce a tuberculoid granuloma, whereas vegetable oils, by virtue of irritant substances liberated by hydrolysis, often provoke inflammatory changes and lipophagic granuloma.

Differential diagnosis of a mineral oil granuloma from idiopathic sclerosing lipogranuloma may be very difficult, although the use of scanning electron microscopy and energy-dispersive spectroscopy techniques can be of help [6].

Clinical features. The nodules or plaques usually appear several months after injection, but their onset can be delayed for up to 42 years [7]. Once initiated, the lesions tend to persist indefinitely. Firm, non-tender nodules or plaques form, which may be fixed to both skin and deeper fascia. Ulceration occasionally occurs. The common sites following cosmetic procedures are the face and breasts of women. Nodules on the thighs and buttocks are the result of injections of therapeutic agents in oily vehicles. It is not rare for some patients to strenuously deny any history of earlier injections for cosmetic or therapeutic purposes.

The grease-gun injury characteristically affects the dorsum of the left hand and appears as a nodule, plaque or sinus [2,8]. The onset is more rapid, the patient usually being unaware of the injury, but there may be an anaesthetic period before the gradual onset of swelling, pain and ischaemia. Rapid referral to a plastic surgeon or hand specialist is necessary. Perianal oil granulomas have been reported to follow injections for haemorrhoids [9]. Factitial panniculitis (dermatitis artefacta) can be caused by self-injection of mineral oils or silicones. An analysis of the lipid content in 23 cases of sclerosing lipogranuloma of the male genitalia demonstrated the presence of paraffin hydrocarbons in all specimens [10].

Prognosis. In chronic cases, the lesions remain essentially unchanged almost indefinitely, although the coexistence of squamous cell carcinoma [11,12] and sarcoma has been reported [13]. With acute grease-gun injuries, ischaemic changes may rapidly develop.

Treatment. MRI scanning can be diagnostic and show the extent of the problem [14]. Decompression and clearing of the affected area are needed in grease-gun injuries [2]. Tetanus toxoid may be needed along with high-dose systemic steroids if there has been a delay in diagnosis of grease-gun injuries [2]. If there is any doubt about the diagnosis of chronic oil granuloma, a deep surgical biopsy should be performed. No effective treatment exists other than complete excision.

Idiopathic sclerosing lipogranuloma (eosinophilic sclerosing lipogranuloma)

An idiopathic form of sclerosing lipogranuloma has also been reported [15]. Whilst it is possible that this really represents an oil granuloma in which the history is concealed [8,9], it is a real entity in Japan specifically involving the male genitalia [16,17] and other cases continue to be reported where there is no history of injury or injection [18,19]. Idiopathic lesions are more likely to involve the scrotum rather than penis and to be painless rather than painful. On examination there is usually a Y-shaped, string-like mass in the scrotum at the base of the penis. Peripheral eosinophilia is often present and the histology is also characterized by an eosinophil-rich granulomatous infiltrate with some lipid vacuoles and lipomembranous changes. MRI scanning can contribute to the diagnosis. Spontaneous remission does occur. Trauma and cold injury have been implicated in causation, but eosinophilic sclerosing lipogranuloma is often spontaneous. The diagnostic clue is the tissue and peripheral eosinophilia, which seems not to occur in secondary lipogranulomas.

Sclerosing panniculitis [1–4]

Synonyms
- Lipodermatosclerosis [3]
- Hypodermatitis sclerodermaformis [3]

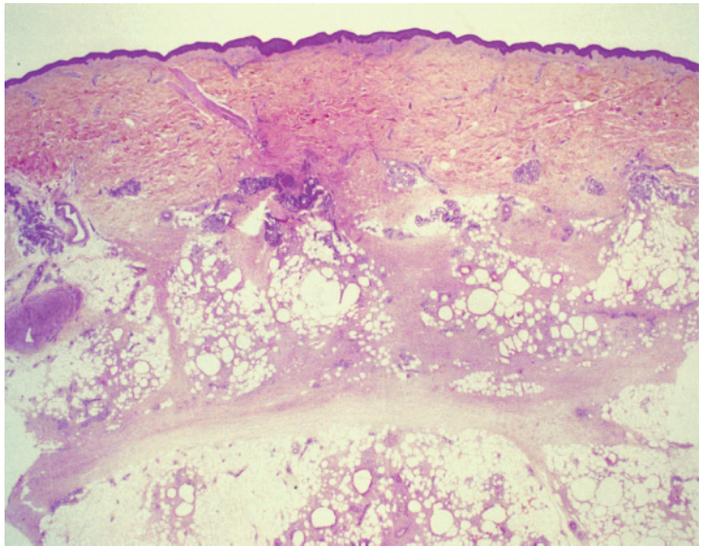

Fig. 46.28 Lipodermatosclerosis with thickened septa, lobular panniculitis and lipomembranous changes.

There is growing evidence that the term sclerosing panniculitis encompasses both lipodermatosclerosis and hypodermatitis sclerodermaformis, perhaps appearing in different stages [2]. The term lipodermatosclerosis was coined to describe the effects in the skin of chronic venous hypertension [5]. It is likely that its pathogenesis is multifactorial [6,7] but usually initiated by increased ambulatory venous pressure unrelieved by exercise. The original concept of physical obstruction to oxygen transport by pericapillary fibrin cuffs, slower capillary blood flow, white cell trapping and activation and highly convoluted capillaries, has been superseded by the realization that the changes probably result from highly complex interactions occurring in and around the endothelial cell, involving a huge variety of cytokines and growth factors [8] as well as matrix metalloproteinases [9]. The precise mechanism has yet to be elucidated. Not all cases are overtly associated with chronic venous hypertension [3]. It has been postulated that there may be overlap in the pathogenesis between lipodermatosclerosis and eosinophilic fasciitis [10] and that infective cellulitis may also have a role in exacerbating lipodermatosclerosis [11].

Histologically, there is a combination of fat necrosis and a lobular panniculitis, ultimately leading to fibrous thickening of the fascia and fibrous septae in the subcutis. Lipomembranous changes can coexist [12] (Fig. 46.28).

The patients, usually women in middle age with a high body mass index, gradually develop well-circumscribed, indurated plaques around the lower extremities, usually but not always on the medial aspect. In acute lipodermatosclerosis [3,13] (Fig. 46.29) the plaques are erythematous, painful and tender, simulating cellulitis. In the commoner chronic lipodermatosclerosis the indurated areas are skin coloured, with haemosiderin staining, eventually resulting in fibrotic narrowing of the lower leg.

Standard treatment is weight loss, elevation of legs and use of elastic compression stockings [2], but stockings cannot be tolerated in the acute situation. Stanazolol has been reported to be

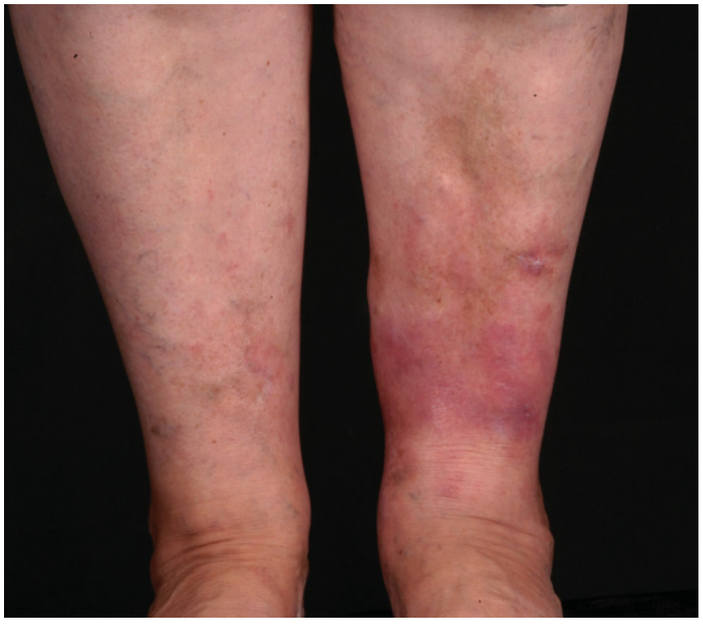

Fig. 46.29 Acute lipodermatosclerosis on the front of the left leg.

effective in both acute [14] and chronic stages [2]. Topical capsaicin is reported to have been of help in the acute stage [15].

Fasciitis–panniculitis syndromes [1]

In eosinophilic fasciitis and related syndromes, the inflammation often extends to involve the fibrous septae and fat lobules, the subcutaneous fascia which becomes thickened, and the underlying perimysium, resulting in thickened fascia around smaller muscle bundles [1]. It has become increasingly recognized that a histological picture similar to eosinophilic fasciitis, involving the subcutaneous fat, can occur in a variety of diseases, including morphoea profunda [1], lupus panniculitis [1], toxic oil syndrome [2], L-tryptophan-induced eosinophilia–myalgia syndrome [3], graft-versus-host reaction [4], post-irradiation injury [5], infections [6] and cancer-related (paraneoplastic) syndromes [7,8]. The term fasciitis–panniculitis syndromes [1] was coined to draw attention to the fact that any of the above diseases might present with either a plaque or, if on a limb, a sleeve of indurated bound-down skin, unilateral or bilateral, and which had the histology of chronic inflammation with extensive scarring.

Panniculitis in other connective tissue diseases

As already indicated, panniculitis in connective tissue diseases may overlap with lupus panniculitis [1] and also lipoatrophic panniculitis [2]. Deep morphoea (morphoea profunda) may show lipoatrophy, scleroderma-like lesions and deeper subcutaneous nodules or plaques. They may also share some histological features, notably lymphocytic panniculitis, lymphoid nodular areas in the fat, widening of the fibrous septae and lymphocytic vasculitis [3–5].

The association of panniculitis with dermatomyositis is very rare but well documented [6–9]. The parallel course of panniculitis and muscular involvement, and their response to treatment, suggest that panniculitis may be an inherent part of dermatomyositis [6–9]. Subcutaneous nodules or plaques develop on the arms, buttocks, thighs and abdomen, or features of multifocal lipoatrophy may be present [10]. Partial lipoatrophy may also coexist with

dermatomyositis [11,12]. The association of panniculitis and dermatomyositis has been reported to respond to a combination of low-dose methotrexate and prednisolone [10], or high-dose intravenous immunoglobulins [13].

Panniculitis with vasculitis

Because the vasculature of the subcutis is 'housed' in the fibrous septae that divide up fat lobules, it is obvious that most deep vasculitis syndromes (particularly large-vessel vasculitis) begin as a septal panniculitis and involve the fat lobules later.

Nearly all cases of leukocytoclastic vasculitis in the subcutis zone also affect the overlying dermis. Nodular forms of vasculitis affecting the fat are primarily dealt with in Chapter 50, together with larger vessel vasculitis syndromes (e.g. polyarteritis nodosa).

This section covers a series of miscellaneous entities that may overlap with vasculitis, or may in some way be associated with them.

Panniculitis has rarely been reported in association with relapsing polychondritis, and histologically was characterized by septal and lobular involvement with vasculitis [1,2]. The association of granulomatous lipophagic panniculitis with temporal arteritis and chronic active hepatitis has been reported, and perhaps represents three-organ manifestations of an underlying aberration of the immune defence mechanism [3].

Unusual forms of vasculitis-associated panniculitis include that resulting from the complications of jejunoileal bypass surgery for obesity (Fig. 46.30) [4,5].

Fig. 46.30 Scarring of lower abdominal folds secondary to panniculitis and/or vasculitis following jejunoileal bypass for gross obesity.

Neutrophilic panniculitis

Subcutaneous neutrophilic infiltrates are a rare accompaniment in atypical Sweet's syndrome and bullous pyoderma gangrenosum [6]. Recent case reports have highlighted the association of neutrophilic panniculitis with myelodysplastic syndromes [7,8] and sometimes administration of granulocyte colony-stimulating factor (GCSF) [9]. The neutrophilic infiltrates spread out from the septa to the lobules, without evidence of necrotizing panniculitis. It has been postulated that neutrophilic panniculitis belongs to the spectrum of atypical neutrophilic dermatoses associated with myelodysplastic syndromes [7] and inflammatory bowel disease. Septal forms of neutrophilic panniculitis can occur in classical Sweet's syndrome, and may present as erythema nodosum-like eruptions [10]. All-*trans*-retinoic acid chemotherapy triggered a pure lobular neutrophilic panniculitis in a patient with acute promyelocytic leukaemia [11].

A pustular neutrophilic form of panniculitis has been associated with rheumatoid arthritis, both adult [12] and juvenile [13]. Neutrophilic panniculitis is also seen in α_1-antitrypsin deficiency and factitious panniculitis, and it is necessary to exclude an infective organism, particularly in an immunocompromised patient [14]. Occasionally, a neutrophilic panniculitis is seen where infection is expected from the clinical setting but nothing found from the tissue. The term acute infectious id panniculitis or panniculitic bacterid has been coined for this situation [15].

Oedematous scarring vasculitic panniculitis: hydroa-like lymphoma

A condition termed oedematous scarring vasculitic panniculitis has been identified in children, which is described as a novel multisystemic disease with a mortality rate of 35.7% [16]. The cutaneous lesions may initially resemble hydroa vacciniforme, but later disfiguring involvement affects both covered and sun-exposed areas. The lesions develop as oedematous vesicles, which progress to deep ulcerations and varicelliform scars. Histologically, panniculitis and vasculitis coexist with a heavy nodular lymphohistiocytic infiltrate. In cases with systemic involvement, malaise, fever, failure to thrive, leukopenia, thrombocytopenia, hepatosplenomegaly and increased levels of serum C3 have been frequently observed [16]. Several of the patients ultimately developed cutaneous lymphoma, after an interval of 5–8 years, though

others wax and wane not unlike lymphomatoid papulosis. Other patients with 'hydroa vacciniforme' have also been reported to develop malignant lymphoma [17–19]. Thirty-one cases of this syndrome have now been reported, and it is likely that the entity is an evolutionary process in the development of malignant lymphoma in children, namely hydroa-like lymphoma. Most cases are CD4 or CD8 positive, but two cases with the natural killer cell phenotype CD56 have been reported [20].

Wells' syndrome [1–4]

Synonyms
- Eosinophilic cellulitis
- Recurrent granulomatous dermatitis with eosinophilia

Definition. This is a syndrome with an impressive and distinctive clinical picture resembling cellulitis, and with a typical histology characterized by tissue eosinophilia, oedema and 'flame' figures.

Aetiology. The syndrome can arise spontaneously or be apparently triggered by a particular stimulus, or be seen in association with other diseases. As such it may represent an allergic hypersensitivity response, with eosinophils playing a dominant role; the mechanism is unknown, but interleukin-5 may be involved [5,6]. Drugs [7] including cladribine for lymphoproliferative disease [8] and adalimumab [9], infection (HIV, herpetic, parasitic and fungal) and insect bites have all been incriminated. In one report, antiviral therapy led to a complete remission of the eosinophilic cellulitis associated with recurrent *Herpes simplex* virus type 2 infection [10]. Reactions to other triggers, such as thiomersal after immunization, can also occur [11]. More recently angioimmunoblastic lymphadenopathy, malignancy and inflammatory bowel disease have been added to the list [12–14]. Eosinophilic fasciitis [6], eosinophilic pustular folliculitis [15], Churg–Strauss syndrome [16] and immunobullous disease are other associations. Rarely, eosinophilic cellulitis is the first presentation of hypereosinophilic syndrome [17] and rarer still it is familial [18].

Pathology. Early on, there is an infiltrate of polymorphs and especially of eosinophils, with considerable oedema. Flame figures are noteworthy—clusters of eosinophils and histiocytes around a core of collagen and eosinophilic debris. The flame figures may disappear after the acute stage with the granulomatous infiltrate becoming more obvious. In bullous lesions, eosinophil-rich subepidermal and intraepidermal vesicles are found, but the dermal changes still dominate. Blood eosinophilia is usual but not invariable.

Clinical features. Wells' syndrome is rare. It can affect either sex, usually in adult life, but some congenital [18], neonatal [19] or childhood cases [20] have occurred. Any site may be involved, with single or multiple lesions. The disease evolves over a few weeks, and recurrences are common. Initially, the lesions are itchy erythematous plaques with features resembling both urticaria and cellulitis, sometimes evolving into a greenish morphoea-like plaque. Any pattern can occur, including unusual nodular variants [21] and lesions that follow the lines of Blaschko [22]. Vesicles and bullae may be dominant [15,16]. After a week or two, the lesions become flatter, and sometimes go through a greenish colour change before resolving without scarring. The general health is usually unimpaired, but fever has been reported, as has arthralgia and mild hepatic dysfunction.

Differential diagnosis. Clinically, erysipelas, cellulitis, urticaria and contact dermatitis are the main differential diagnoses. Multiple lesions in an atypical pattern far apart is a strong clinical pointer. *Toxocara* infections may be similar, both clinically and histologically. Infections such as ascariasis and onchocerciasis need to be excluded. Flame figures can be found in many other diseases, including insect-bite reactions, dermatophyte ide eruptions and pemphigoid; that is wherever the dermal infiltrate is

eosinophil rich. The histology in Sweet's syndrome is neutrophil rich, and extra-facial Kimura's disease shows lymphoid follicles. In general, the presence of systemic features, especially if severe, makes the diagnosis of Wells' syndrome unlikely and drug eruption with eosinophilia and systemic symptoms (DRESS) should be excluded, as should hypereosinophilic syndrome or other associated disease.

Treatment. Often no specific treatment is needed. Low-dose systemic steroids can provide symptomatic relief in severe cases [23]. Cetirizine, interferon-α and ciclosporin have all proved effective [24–26].

Lipodystrophy

The terms lipoatrophy and lipodystrophy are sometimes used interchangeably and without precise definition. Perhaps it is best to define lipodystrophy as an abnormality of fat that is usually associated with atrophy (lipoatrophy), or infrequently hypertrophy of the adipose tissue. Lipoatrophy refers specifically to loss of fat. However, the lipoatrophy may be part of a local panatrophy affecting all mesodermal layers [1]. Lipodystrophies are a rare and heterogeneous group of disorders characterized by selective and variable reduction in and, more often, loss of adipose tissue from different parts of the body; in all but the more very localized varieties they are often associated with metabolic complications of insulin resistance, in particular insulin-resistant diabetes mellitus [2]. Over the last 5 years, there has been a much better understanding of the aetiology of these disorders. The loss of adipose tissue can have a genetic, immunological, infectious or drug-associated aetiology [3]. The age of onset may also determine the nomenclature of the disease. Some patients may develop the disease very early on in life—such patients are then sometimes referred to as having congenital lipodystrophy. In other patients, the disease occurs later on in life—so-called acquired lipodystrophy. The lipodystrophies can also be classified according to the extent of the disease into three major clinical entities: localized, partial-body and whole-body distribution. The atrophy may be localized (e.g. to the thighs); it can be widespread, involving the upper part of the trunk (partial lipodystrophy); or it may affect the whole body (generalized lipodystrophy).

Nevertheless, the aetiology and clinical presentation are not always clear-cut. For example, cases of partial lipoatrophy have been reported that have evolved into generalized lipoatrophy, suggesting some common link between these uncommon disorders.

Localized lipoatrophy

Localized atrophy may be seen following injection of medications, for example in insulin-dependent diabetics, induced by insulin [1–9]; following certain inflammatory conditions, such as panniculitis and morphoea; or as primary idiopathic lipoatrophy. The list of medications inducing atrophy includes corticosteroids, antibiotics, heparin, growth hormone and glatiramer [10]. The

mechanism is uncertain and has been attributed directly to the medication, but localized lipoatrophy has been reported following acupuncture alone [11]. In many of these situations, spontaneous healing has occurred over the next month or two. Failure to perform a biopsy in the early phases of the atrophy may explain why some of the cases are labelled as idiopathic in origin. It has been suggested that many cases may be preceded by an inflammatory reaction in the fat (see also lipoatrophic panniculitis) [1].

Insulin lipodystrophies

This is a cosmetically distressing complication of insulin administration. Both atrophy and hypertrophy of the fat tissue can occur. It occurs in various degrees in up to 37% of insulin-dependent diabetics [2].

Aetiology. Insulin lipoatrophy is usually seen in women and children, rarely in men. The mechanism remains speculative but local changes induced by insulin or impurities are probably important [3] as are antibodies to insulin [4]. Most cases are associated with high levels of insulin requirement and/or an increased insulin-binding capacity.

Cross-reaction of insulin antibodies with cells thus changed could result in further damage [5]. It was thought that the introduction of highly purified insulin would make a significant impact in reducing the frequency of this disorder. There is evidence to support this view, because the subcutaneous damage is reduced if highly purified insulins are used, resulting in clinical improvement and a reduction in insulin requirements and insulin-binding capacity [5–7]. However, localized lipodystrophies in insulin-requiring patients are still very common, affecting up to 40% of patients.

A recent publication investigated a cross-sectional study of 112 children and adolescents with type 1 diabetes mellitus and related the presence of insulin antibodies to the clinical features of insulin lipodystrophies [4]. The antibodies against insulin increased significantly after diabetes manifestations and initiation of insulin treatment, while β-cell-specific antibodies did not. Severe lipohypertrophy was seen in four children, severe lipohypertrophy in 18 and moderate lipohypertrophy in 27 children. Among clinical and immunological parameters investigated, insulin antibodies were significantly associated with hypertrophy or atrophy of injection sites. It was concluded that lipodystrophies in diabetics are significantly associated with insulin antibodies, and that these may have a role in the development of the disease.

Histopathology. There is a loss of fat tissue and inflammatory changes are conspicuously absent. In lipohypertrophy, there may be replacement of mid-dermal collagen by hypertrophic fat cells.

Clinical features. Although both features can occur in the same patient, recent publications suggest that insulin fat hypertrophy is more common than atrophic changes [4]. Most cases present 6 months to 2 years after the start of insulin administration. Lesions may vary from only a small dimple to an extensive, disfiguring area with much local loss of fat or firm fatty induration. The changes are usually found only at the sites of injection, but loss of fat may occur elsewhere. There is a definite tendency to spontaneous recovery at the involved site when the site of injection is changed.

Treatment. A change to a purified insulin, particularly the new human insulin, is not necessarily curative [8]. Prevention is either by constant alteration of the site of injection, so that no two injections are given in exactly the same area more frequently than once a month, or by the use of the more purified insulins [5,9]. Alternatively, injection at the edge of the atrophy or combination with dexamethasone may help [12]. Liposuction may help the hypertrophic variety [13]. In one very resistant case of progressive lipoatrophy, continuous subcutaneous infusion with human insulin was required to control the atrophy [9] but continuous infusion itself may provoke the same reaction [14].

Localized lipohypertrophy has also been reported in a 51-year-old female patient with panhypopituitism during growth hormone replacement therapy [15].

Localized 'idiopathic' lipoatrophy

This group of disorders predominantly affects the thighs, ankles or abdomen, and all cases may possibly be variants of the same process.

Histopathology. Two histological subsets exist: involutional and inflammatory [1]. Sixty percent can be termed involutional; the adipocytes are small and embedded in hyaline connective tissue with many capillaries. Such patients usually have a single lesion,

Fig. 46.31 Extensive lipoatrophy of the legs.

and only one-third show immunoreactants. Forty per cent can be classed as inflammatory [2]; the lipocytes are normal and there is a sparse infiltrate of lymphocytes, histiocytes and plasma cells; all show immunoreactants [1]. The epidermis is normal. The appearance should not be confused with the striking lipomembranous (membranocystic) changes seen occasionally in morphoea, panniculitis and other inflammatory dermatoses.

Clinical features. Two clinical groups, based on the localization of the atrophy, have been described.

Lipoatrophia semicircularis [3–5]. These patients show lesions on the anterolateral aspects of the thighs, characterized by a band-like circular depression, 2–4 cm in width. Patients have also been described with lipoatrophy of the ankles which can extend up the legs (Fig. 46.31) [6]. The overlying skin is normal. An association with osteodystrophy of the hands and feet has also been reported [7].

The loss of fat develops rapidly within several weeks, usually without associated symptoms, although rheumatic-like pains within the involved areas were reported by two women. Trauma is a possible triggering mechanism—a series of seven cases has been reported in individuals working in the same office. The exact position of the indentations corresponding to the height of the desks strongly supports the hypothesis that in some patients this condition is caused by repetitive trauma to the upper thighs [8].

Primary inflammatory vascular changes in the subcutaneous tissue have been demonstrated in these patients, and also during the early period of other lipoatrophies [9]. There is no treatment, but considerable improvement may occur after the activity of the disease settles.

Centrifugal lipodystrophy. Lipodystrophia centrifugalis abdominalis infantalis is rare, and has been seen predominantly in Japanese children [10–14], affecting the subcutaneous fat, usually of the abdomen and upper groin. Patients of Chinese and English ancestry have been reported [15]. The condition spreads in a centrifugal fashion, with a central, large, bluish depressed area and slight erythema of the edge. Further experience has shown that the original name is inappropriate, because the condition may affect other areas, and may occur outside infancy and not affecting the abdomen [16,17]. The condition may be strikingly unilateral [18,19]. One case is reported to have lasted over 40 years, and was associated with angioblastoma, which occurred at the same site at the age of 46 years [11]. Regional lymphadenopathy may occur [13]. A 10-year-old boy with a centrifugal lipodystrophy also developed serpiginous erythema of the scalp with scarring alopecia [20]. Ulceration may also be a complication [21].

Histology shows a decrease in the subcutaneous fat, with an inflammatory infiltrate in the lower dermis and subcutis. Immunocytochemistry has more recently suggested the possible involvement of apoptosis as a factor responsible for fatty tissue degeneration [22]. A patient has been reported who showed characteristics of both centrifugal and progressive lipodystrophy [17].

Treatment. Treatment is disappointing, although after the disease activity has ceased there seems to be regrowth of fat in 75% of cases. Some improvement has been reported in most cases treated with oral and topical corticosteroids [10].

Partial or generalized lipoatrophies [1–3]

HIV-associated lipodystrophy syndrome has become by far and away the commonest. The remainder are rare syndromes where there is extensive absence, or progressive loss, of subcutaneous fat. Several syndromes are described: congenital generalized lipodystrophy, acquired generalized lipodystrophy, partial (cephalothoracic) lipodystrophy and partial face-sparing lipodystrophy [4]. Genetic explanations for these diseases are increasingly being reported [5].

Congenital generalized lipodystrophy

Synonyms
- Lipoatrophic diabetes
- Berardinelli–Seip syndrome (MIM 608694; MIM269700)

A rare congenital generalized lipoatrophy, autosomal recessive, with loss of the subcutaneous and visceral fat, hepatomegaly, increased bone growth, hyperlipaemia and, later, diabetes mellitus [1,3,6–8].

Aetiology. Two gene abnormalities on different chromosomes have been described, but some phenotypically similar pedigrees have an as yet undetermined genetic abnormality [9]. Congenital generalized lipodystrophy type I (CGL1) was mapped to chromosome 9q34 and CGL2 to chromosome 11q13. CGL1 is caused by mutations in the *AGPAT2* gene [10]. AGPAT enzymes are involved in triglyceride and glycerophospholipid biosynthesis. How the abnormality is converted into lipoatrophy is undetermined. CGL2 is caused by mutations in the *BSCL2* gene encoding a protein, seipin, expressed in neural tissue as well as adipocytes [11]. Again the effect of the abnormality is unknown. The phenotypic expression of both types is much the same, but CGL2 would appear to cause more morbidity than CGL1, with a higher incidence of premature death, more severe fat loss, including that in mechanical areas, more severe cardiomyopathy and more severe intellectual impairment [12]. CGL2 patients have higher insulin levels and earlier onset diabetes [13]. Lipodystrophy with cystic angiomatosis (Brunzell syndrome) demonstrates an *AGPAT2* mutation [14].

Histopathology. There is complete loss of subcutaneous and visceral fat.

Clinical features. There is complete loss of subcutaneous and other fat, present at birth or before the age of 2 years. As such, the musculature appears more defined and prominent. The children have an elevated metabolic rate accompanied by an excessive appetite and accelerated growth, sometimes producing an acromegaloid appearance. They are tall for their age; the somatic musculature is increased and the abdomen markedly protuberant, often with an umbilical hernia. There is often generalized hypertrichosis, even at birth, and the scalp hair becomes abundant and often curly with the onset of disease. Acanthosis nigricans starts in childhood, becoming more severe through adolescence. There is precocious enlargement of the genitalia, and in females marked enlargement of the clitoris. Affected men have normal fertility, but females are prone to oligomenorhoea, polycystic ovary and infertility. Hepatic steatosis leads to hepatomegaly, splenomegaly and cirrhosis. Younger patients show glycosuria only when given large amounts of glucose. Hyperglycaemia with excessive thirst and polyuria usually develop only after the age of 10 years, the evolving diabetes becoming markedly insulin resistant. Hypertriglyceridaemia, sometimes triggering pancreatitis, and low HDL cholesterol are other metabolic features.

Detailed metabolic and radiological studies have shown poor metabolically active adipose tissue, whereas mechanical adipose tissue may be well preserved [15]. X-rays show focal bone lesions which on MRI can be shown to be caused by absence of marrow fat [16].

Differential diagnosis. The main differential diagnosis of congenital generalized lipodystrophy is Donohue syndrome (leprechaunism) due to an insulin receptor defect [17]. Acanthosis nigricans and hypertrichosis may be present, as well as the generalized decrease in fat. However, the elfin facial appearance is a major difference. In SHORT syndrome (short stature, hyperextensibility of joints, ocular depression, Rieger anomaly and delay of dental eruption), an apparent autosomal dominant disorder, the lipodystrophy shows relative sparing on the legs [18]. Neonatal progeroid syndrome expresses fat loss confined to the face, distal extremities, and possibly the paravertebral and lateral gluteal regions [19]. Fat loss with mandibuloacral dysplasia is usually confined to the extremities though may be generalized [20].

Acquired generalized lipodystrophy [21]

Selective loss of body fat from large regions of the body occurs after birth, usually before adolescence.

Aetiology. The development of molecular genetics has allowed re-evaluation of the lipodystrophies, resulting in new diagnostic criteria for acquired generalized lipodystrophy (AGL), albeit still a heterogeneous mix. Individuals with a known or likely genetic abnormality are automatically excluded, as are patients with diminished subcutaneous fat in association with thyrotoxicosis, malabsorption, malnutrition and cachexia. Patients are then further divided into three groups: type 1, AGL with panniculitis

(25%); type 2, AGL with autoimmune disease (25%); and type 3, idiopathic (50%).

Histopathology. Type I AGL histology reveals a lobular panniculitis without vasculitis.

Clinical features. AGL is a disease of childhood and adolescence, with a female to male ratio of 3:1. The panniculitic type is expressed as a nodular inflammatory process occurring anywhere, but healing with a depressed area which might gradually enlarge without inflammation. More widespread, uninflamed fat loss might then occur, the whole evolving over several years. Some of these patients might have an autoimmune disease, but the true autoimmune AGL group do not have a clinical inflammatory panniculitis preceding the lipodystrophy. Juvenile dermatomyositis seems particularly associated with type 2 AGL [22]. The idiopathic group has neither of the features of type 1 or 2 AGL, and arises spontaneously or occasionally after a febrile illness. The degree of fat loss is less than the congenital counterpart; with variable preservation of visceral and mechanical fat pads but complete preservation of retro-orbital and bone marrow fat. Type 1 patients have less extensive fat loss, which may correlate with the less severe expression of anabolic and metabolic features. After fat loss, hepatomegaly from asteatosis is the commonest clinical feature, followed by acanthosis nigricans and hirsutism. Xanthomas are present in 50% of the type 3 group, but less in the other two. Excessive appetite and increased growth emphasize the overlap with the congenital type. Hyperinsulinaemia, diabetes mellitus, hypertriglyceridaemia, and low serum leptin and adiponectin levels are similarly present. Menstrual irregularities and polycystic ovary syndrome are less frequent than in the congenital type, as is hirsutism. Curly hair may still occur.

MRI imaging has provided a major advance in assessment of fat loss and fat hypertrophy, whether subcutaneous, visceral or mechanical [23]. Whether a simple MRI screening test of thigh fat will be a strong discriminator between normal and abnormal remains to be confirmed [23].

Patients with hepatomegaly may progress to cirrhosis, but the consequence of accelerated atherosclerosis seems a more important prognostic factor.

Differential diagnosis. In CGL fat loss is absent from birth. Other later-onset genetic lipodystrophies need to be excluded through clinical means, MRI scanning and confirmation of mutations. Cushing's syndrome, diabetes mellitus and thyrotoxicosis need to be excluded, as does any cachetic state such as HIV infection, malabsorption and malignancy. Localized lipoatrophy is focal and usually obvious from the history or distribution.

Treatment. Apart from genetic counselling, the management of CGL and AGL shows much overlap, with the emphasis placed on lessening the risk from glycaemic and dyslipidaemic metabolic consequences using standard management. If leptin deficiency and diabetes is present, CGL, AGL and partial lipodystrophic patients can have their insulin resistance and dyslipidaemia reversed if given continuing recombinant leptin therapy [24–27]. Diabetic complications and other features such as voracious appetite, hepatic steatosis, acanthosis nigricans and amenorrhoea can also be reversed, but not the subcutaneous fat loss. Surgical intervention for specific anatomical defects, such as the repair of severe buttock deformities with bilateral gluteus maximus muscle flap advancements [28], may be helpful.

Partial lipoatrophy [1,2]

Synonyms
- Partial lipodystrophy
- Barraquer–Simons disease
- Progressive lipodystrophy (MIM 608709)

This rare lipoatrophy occurs either in childhood or in young adults as an incidental part of a widespread mesodermal atrophy. The partial lipodystrophy locus has been mapped to chromosome 1q with no evidence of genetic heterogeneity [3].

Fig. 46.32 The typical cadaveric facies of a patient with partial lipodystrophy. She also has melasma.

Aetiology. Most patients are children or young adults when the disorder begins, but onset in the first year and in middle age is reported. Females are affected four or five times more frequently than males [4], and the condition is sometimes familial. It may follow an acute specific fever such as measles, but the common occurrence of non-specific fevers makes proof of this observation difficult. Facial hemiatrophy associated with loss of subcutaneous fat in borreliosis has been reported [5]. Partial lipodystrophy has followed damage to the region of the mid-brain or diencephalon [6]. The association of lipodystrophy with immunologically related renal disease [4,7–10], systemic sclerosis [11], systemic lupus erythematosus [12] and high titres of thyroid antibodies, supports the view of lipodystrophy being an immunological disorder in some patients [13], but one that requires more investigation.

It is difficult to explain the abnormal distribution of adipose tissue in partial lipodystrophy. Fatty tissue autotransplanted to an atrophic site lost fat, while atrophic tissue autotransplanted to a fatty site accumulated it, suggesting that local factors determine the distributions of fat [14]. The local factor may be neuronally mediated, as suggested by observations that there may be symmetrical segmental loss of fat, and the line demarcating dystrophic and normal tissue in partial lipodystrophy may correspond to a dermatome. Jensen [15] described increased adrenergic activity in a patient with partial lipodystrophy, and proposed that this was of significance, as adipocytes in the upper body are sensitive to the lipolytic effects of epinephrine (adrenaline) and those in the lower body are not. Alternatively, the pattern of disease may be related to complement factor D expression, a serine protease expressed in the kidney, but also by adipocytes. Activation of the alternative complement pathway by C3 nephritic factor (see below) however, could lead to complement-dependent lysis of adipocytes [16]. But the finding of mutations in the *LMNB2* gene in some patients with acquired partial lipodystrophy [17] suggests that a simple autoimmune process involving C3 nephritic factor is only part of the story.

Histopathology. There is usually complete loss of adipose tissue over the affected areas.

Clinical features. The disease is characterized by the relatively slow, symmetrical disappearance of the facial fat, producing a cadaverous appearance (Fig. 46.32) and complete loss of the subcutaneous fat in the upper half of the body (Weir–Mitchell type). In some cases, there is a coincidental hypertrophy of the subcutaneous fat of the lower part of the body (Laignel–Lavastine and Viard type) [3]. Ten per cent may have 'hemilipodystrophy' involving half of the face or body. Up to 90% can develop progressive membranous mesangiocapillary glomerulonephritis [3,18,19] and this can be precipitated by the contraceptive pill, pregnancy (especially in the third trimester) or the use of ergot derivatives [4]. A successful outcome in pregnancy is uncommon [20]. Thus, such patients should be observed by a renal physician during pregnancy, and oral contraceptives are prohibited.

The association of hypocomplementaemia and mesangiocapillary glomerulonephritis is now well established [7,8]. Approximately half of the patients with this form of glomerulonephritis have a persistently low plasma concentration of the third component of complement (C3), while the concentration of the fourth component (C4) is normal. This is accompanied by the presence

of a factor in serum that is capable of activating C3 without activation of the earlier components. This material has been termed 'C3 nephritic factor' or C3NeF [21,22]. Lupus, C3 nephritic factor and partial lipodystrophy are perhaps not as rare as previously thought [21,22]. Juvenile dermatomyositis is also a rare association [23].

The relationship between C3NeF, persistently low C3 and mesangiocapillary glomerulonephritis is not clear. It has been suggested that C3NeF predisposes the glomerulus to the development of mesangiocapillary glomerulonephritis in response to some other agent. In a series of 12 patients, four died from renal failure 10–25 years after the onset of the partial lipoatrophy [4]. Transplantation in one case resulted in normalization of C3 and the disappearance of C3NeF [18].

Insulin-dependent diabetes mellitus develops in one-third of patients with partial lipodystrophy. Retinitis pigmentosa, acanthosis nigricans and hepatomegaly are rare associated features [2]. Chronic purpura resulting from leukocytoclastic vasculitis has been reported [24]. This patient had extensive and moderate hypertrophy of the subcutaneous fatty tissue, macroglossia, polyarthralgia and mononeuritis. Myopathy associated with muscle weakness has rarely been reported, and is caused by fat droplets between the myofibrils [25]. Mammography in patients with partial lipodystrophy reveals unusually dense breasts with homogeneous opacities and ectopic fat depositions. These changes are possibly diagnostic, but confusing to the ill-informed radiologist [26]. Extrinsic allergic alveolitis has been reported in association with partial lipodystrophy, but with an acral distribution as opposed to the more usual facial involvement [27].

Treatment. There is little effective treatment, other than the prevention and treatment of kidney disease. New plastic surgical techniques, including free radial forearm adipofascial flaps, can markedly improve the facial appearance [28,29].

Partial face-sparing lipodystrophy

Synonym
- Kobberling–Dunnigan syndrome

This even rarer form is a genetically heterogeneous set of disorders characterized by a widespread but partial absence of subcutaneous fat usually sparing the face and neck; it can be easily missed because of the normal facial appearance [1]. Onset is usually during adolescence and the condition is often familial. With the development of molecular genetics this phenotype has been superseded by an evolving genetic classification into three groups: familial partial lipodystrophy (FPLD) one, two and three [2].

FPLD1. FPLD1 (Kobberling type; MIM 608600) at present has no known molecular genetic basis. Kobberling *et al.* described three patients [3], the proband, her mother and her sister, with the same clinical appearance of complete absence of subcutaneous fat of arms and legs but with well-developed adipose tissue on the trunk and face. His patient also had hyperlipidaemia, eruptive xanthoma and insulin-resistant diabetes. Herbst *et al.* [4] described a further 13 patients having this phenotype of peripheral lipodystrophy

with normal or increased central obesity and absence of the FDLP1 and FDLP2 genotype, emphasizing the benefit of measuring the ratio of skinfold thickness from abdomen to thigh, which was significantly higher than normal. Patients also had components of the metabolic syndrome, including hypertension, insulin resistance and severe hypertriglyceridaemia resulting in pancreatitis. Premature coronary artery disease was present in 31%.

FPLD2. FPLD2 (Dunnigan type; MIM 151660) results from heterozygous mutations in the *LMNA* gene encoding nuclear lamin A/C usually of an autosomal dominant pattern, but rarely sex-linked recessive. Lamins are a class of intermediate filaments forming the inner membrane of a nucleus. The precise mechanism, structural or otherwise, whereby the gene defect leads to lipodystrophy is unknown, but as lamins are ubiquitous in human cells, different mutations allow lipodystrophy to be associated with other phenotypes, including Hutchinson–Gilford progeria syndrome (HGPS), atypical Werner syndrome, Emery–Dreifuss muscular dystrophy, limb-girdle muscular dystrophy, mandibuloacral dysplasia (MAD), cardiomyopathies, cardiac conduction defects and Charcot–Marie–Tooth disease [2].

Dunnigan [5] described two families with an autosomal dominant disorder appearing in adolescence, and manifesting as loss of subcutaneous fat on the limbs so that the underlying musculature and superficial veins were more defined. The face appeared fuller than normal and moderate genital hypertrophy was noted. Acanthosis nigricans, tuberoeruptive xanthomata and insulin resistance were commonly associated. With increasing numbers of mutations being described, phenotypic heterogeneity is becoming apparent [6]. Patients with abnormalities in the lamin A gene only may demonstrate mild loss of limb fat, no gluteal loss and little of the features of insulin resistance. Those patients with lamin A/C abnormalities are more likely to express more extensive loss of fat, hypertriglyceridaemia, diabetes mellitus, insulin resistance, acanthosis nigricans, hirsutism and polycystic ovary syndrome. Individuals with *LMNA* mutations are recognized as having premature atherosclerosis and early coronary heart disease [7].

FPLD3. FPLD3 (MIM 604637) is associated with many different heterozygous mutations in the *PPARG* gene encoding peroxisome proliferator-activated receptor-γ (PPARγ). The PPAR protein is a nuclear transcription factor important in adipocyte differentiation, and the precise mechanism of effect for the gene abnormality is uncertain [2]. The peripheral fat loss is not as pronounced as FPLD2, but metabolic changes may be more severe. Severe hypertension is a feature [8].

Because the overall distribution of fat loss in FLPD is peripheral with facial sparing, the differential diagnosis includes Cushing's syndrome. Some patients have increased fat deposition on the chin, face and neck, and a buffalo hump, to confuse things further. Truncal obesity, lipomatosis and HIV lipodystrophy also need to be excluded.

Treatment. Management involves genetic counselling, attention to metabolic consequences and exclusion of associated syndromes. Treatment of the metabolic effects with thiazolidinediones, which attach to PPARγ, has been of some benefit in patients with and without defined gene defects [9]. They have increased subcutaneous fat in some subjects, but their use is of still uncertain benefit [10,11].

HIV-associated lipodystrophy syndrome

Patterns of fat atrophy and hypertrophy with metabolic changes in HIV patients taking highly active antiretroviral therapy (HAART) are described below [1–3].

Aetiology. Since the syndrome was described in 1998 [1], evolving research continues to uncover different patterns, mechanisms and risk factors [4]. Three patterns are described: lipoatrophy, lipohypertrophy and mixed (lipoatrophy and lipohypertrophy), though one group has found no association between peripheral lipoatrophy and visceral hypertrophy [5,6]. Lipoatrophy may be peripheral subcutaneous (face, limbs and buttocks), central subcutaneous (trunk and neck) and/or visceral (omental, mesenteric and perinephric). Lipohypertrophy may occur at central subcutaneous sites, especially dorsocervical (buffalo hump) and chin, and/or viscerally. Intrathoracic fat may also be increased [7]. Patients with lipohypertrophy are at present classed as having the HIV-associated adipose redistribution syndrome (HARS), which may or may not be associated with lipoatrophy [8]. The prevalence of lipodystrophy in HIV is difficult to ascertain because of problems with diagnostic criteria, but may be 17% in adults treated with protease inhibitor-containing therapy for less than 1 year, and around 40% in those treated for 1 year or more [2,9] though it may be as high as 53% [10]. Significant risk factors include

CD4-positive count, viral load, duration of therapy and age. Patients with fat loss are more likely to have taken an older thymidine analogue nucleoside reverse transcriptase inhibitor (NRTI), particularly stavudine or zidovudine, and be of white race. Patients showing hypertrophy are more likely to have taken an older protease inhibitor (PI) (indinavir or nelfinavir), and be of female sex [11]. Rarely, lipoatrophy is seen in patients who have not been exposed to HAART. The syndrome also occurs in children but less so if they received a lower dose of the protease inhibitor [12]. Another childhood study showed a prevalence of lipodystrophy of 9%, 47% and 65% at 48, 96 and 144 weeks after HAART initiation respectively [13]. At week 144, central lipohypertrophy (46%) was most frequent, with peripheral lipoatrophy (20%), and combined type (34%) less frequent. This variety of patterns of fat atrophy and hypertrophy suggests different mechanisms dependent on drug combinations, viral effects and host factors, such as genetic polymorphisms, interacting to result in a particular phenotype [4].

Pathogenesis. The mechanisms of HIV lipodystrophy are complex [11,14]. Lipoatrophy is associated with impaired adipocyte differentiation and increased apoptosis, insulin resistance and increased lipolysis, altered adipocyte cytokine expression and mitochondrial toxicity. Both PIs and NRTIs can inhibit adipocyte differentiation. Both alter adipocytokine secretion (reduced adiponectin and normal or increased leptin) and adipocyte TNF-α secretion (increased). NRTIs seem mainly responsible for mitochondrial toxicity. Buffalo hump lipohypertrophy [15] shows unaltered expression of marker genes of adipogenesis, but altered gene expression for enhanced cell proliferation plus features of a brown-versus-white fat phenotype. TNF-α secretion is not increased. Cortisol-induced new adipogenesis may be responsible for visceral fat hypertrophy combined with a need for disposal of free fatty acids, generated by lipolysis [11].

Histopathology. There is a diminution in the volume of subcutaneous fat, with the lobules containing adipocytes of varying size, interspersed with increased capillaries. Foci of lymphoid infiltrates and lipogranulomas are seen [3]. Scattered apoptotic adipocytes may also be present [16]. Ultrastructurally, buffalo hump lipohypertrophy shows adipocytes intermediate between those in brown and white fat [17].

Clinical features. Females (28%) are affected by lipoatrophy less than males (38%) [5,6]. The loss is most apparent in the face. Loss of buccal, parotid and pre-auricular fat pads produces a prominent cheekbone, and melolabial folds emphasized by the sunken cheeks and sometimes enlarged parotid glands. Loss of retro-orbital fat produces sunken eyes. Limb fat loss allows superficial veins and muscle to appear more defined. Central subcutaneous fat accumulation may be present on the upper back, neck (buffalo hump), on the breasts, suprapubic area [18], below the jaw, in the supraclavicular region or as multiple lipomas. Omental fat accumulation produces a protuberant abdomen and an increased waist to hip circumference ratio, sometimes provoking symptomatology such as abdominal distension, gastroesophageal reflux and sleep disturbances.

Lipoatrophy of the face is so recognizable that the altered appearance, indicating potential HIV-positivity, can be devastating for the patient [19]. Erosion of self-esteem, diminished desirability, attractiveness and sexual function, anxiety and depression may lead to discontinuation of therapy, though non-adherence is disputed [20]. Patients' subjective reporting of lipodystrophy correlates better with diminished quality of life than physician evaluation [19], and the absence of universally accepted clinical measurement criteria for lipodystrophy is still a handicap. Objective measurement of body fat may be performed with ultrasonography, dual-energy X-ray absorptiometry (DEXA), CT and MRI scanning, though DEXA scans do not distinguish between visceral fat compartments [21]. Anthropometry, such as waist and hip circumference and ratio [22], perhaps combined with ultrasonography [23], may provide the simplest and cheapest clinical method of evaluation, particularly for metabolic risk factors, with MRI remaining the gold standard [24].

Metabolic changes do not appear to be as severe in the HIV lipodystrophy group as in CGL [25], with acanthosis nigricans, hypertrichosis and PCOS almost never being seen. This may be related to the fact that insulin resistance is less frequent. Abnormalities in glucose homeostasis occur in 23%, and in hyperlipidaemia in 74%, of patients [26]. In a study of 614 patients, 20 months after initiation of protease inhibitor therapy, a cross-sectional study demonstrated that 23% had abnormal glucose metabolism, 20% had hypertriglyceridaemia and 57% hypercholesterolaemia [27]. In children at 144 weeks, fasting hypertriglyceridaemia was detected in 12%, hypercholesterolaemia in 11%, and increased plasma glucose in 4% [13]. Insulin resistance is related to increased fat in the liver rather than visceral adiposity [28]. Hyperlactataemia may be seen. However, the prevalence of the metabolic syndrome in HIV patients without lipodystrophy is disputed. One study from the USA found a prevalence of 14–18%, compared to a control prevalence of 24% for a non-HIV-positive adult population [29]. In another study of female HIV-positive patients only, prevalence was 33% versus 22% in controls [30], while a third study found no difference between HIV positive and negative patients [31]. Where obvious lipoatrophy and an increased waist circumference is present, patients often have insulin resistance [25].

Differential diagnosis. HIV lipodystrophy can be differentiated from HIV-wasting syndrome in that it is seen in patients responding to HAART, and lean body mass is preserved.

Management. Prevention and delay of progression/reversal of lipodystrophy, treatment of metabolic effects, and surgical interventions provide the mainstay of treatment [32]. Choosing the right combination of newer HAART drugs, and avoiding stavudine and zidovudine, reduces the risk of developing lipoatrophy. Delaying the timing of treatment, employing treatment interruptions, and treatment switching may all help. The addition of a thiazolidinedione (pioglitazone) may be beneficial in lipoatrophy. Diet and exercise may reduce visceral adiposity, as may the use of growth hormone and metformin; possibly at the cost of aggravating subcutaneous lipoatrophy. Management of traditional risk factors, rather than HIV treatment-associated ones, may be more important for lessening cardiovascular disease from the metabolic

syndrome [31]. Stopping smoking, diet and exercise to achieve an appropriate BMI should be the first line approaches. If lipid levels remain high after lifestyle changes and HAART switching, a statin, or fibrate if triglyceride levels are high as well as cholesterol, should be introduced. Likewise, if lifestyle changes have not achieved strict glycaemic control, metformin should be introduced for an overweight patient and pioglitazone for a lipoatrophic one. Hypertension, if present, should be addressed.

Surgical interventions for lipoatrophy include autologous fat injection, flaps and injection of fillers such as polylactic acid [33]. Fat injections may need to be repeated but can provide a satisfactory result [34], provided the source is not the brown fat in a buffalo hump. Polylactic acid, a synthetic polymer, may need to be injected repeatedly in severe facial wasting, but is safe, and effective, with good patient acceptance [35]. Liposuction is helpful for buffalo humps despite the fibrous septa and the high risk of recurrence [36]. Simple lipectomy treats gynaecomastia and lipomas.

Lipomas

Lipomas are benign tumours composed of mature fat cells. They are found in the subcutaneous tissue and less commonly in internal organs.

Aetiology. The metabolic changes associated with benign tumours are varied, but include fundamental defects responsible for the altered growth properties of the tumour. It has been demonstrated that loss of negative-feedback control regulatory enzymes (by citrate or phosphofructokinase) may be an early feature in the development of lipoma [1].

Histopathology. Fat cells in groups slightly larger than the normal lobule are typically enclosed within a capsule of connective tissue, but the capsule may be deficient and the tumour then appears locally invasive. Relatively large blood vessels are seen traversing the connective tissue septa. Primitive fat cells may be found in clinically benign lipomas in children [2]. Xanthomatous and mucinous changes appear in many lipomas. Lipomas exhibit, like many other solid tumours, distinctive cytogenic abnormalities (karyotypic aberrations affecting mainly 12q, 6p, 13q). Such distinctive changes may be of help in histologically borderline or difficult cases [3]. Variants of lipoma with large areas of normal fat cells such as spindle cell lipoma/pleomorphic lipoma and atypical lipomatous tumour are discussed in Chapter 56. For other rare lipomatous-like tumours the reader is referred to specialized texts [4].

Clinical features. A lipoma is a subcutaneous nodule, often lobulated, with a characteristic soft, putty-like consistency. The overlying skin is normal and moves freely over the tumour, and feels cooler than the surrounding skin. The tumour grows very slowly to reach a diameter that is usually between 2 and 10 cm but may be considerably greater. The most common sites are the neck, shoulders and upper arms, back and thighs. There are rarely any subjective symptoms, but pain from pressure on the nerves is sometimes experienced. Another rare event is infiltration of adjacent tissues, in a particular muscle [5]. In these patients, there is a high recurrence rate after surgical intervention because of its diffuse infiltration; thus complete surgical excision is often impossible [6]. Fat necrosis may cause enlargement, pain and tenderness. A large lipoma on the exposed skin of the lower legs is susceptible to nodular perniosis.

There may be only one lipoma, or large numbers [7] may develop at intervals over a period of years. Seven per cent of patients with lipoma have multiple lesions [8,9]. Such lipomas may be randomly distributed, or more or less confined to one region of the body. In most patients, the presence of multiple lipomas appears to have no special significance [2]. They may, however, be associated with neurofibromatosis, or with visceral lipomas in the respiratory, alimentary or genitourinary tract. Tendon sheath lipomas are rare and are usually associated with a mild discomfort [10]. They are an inconstant feature of Gardner's syndrome, in which they are associated with multiple sebaceous cysts, osteomas and polyposis of the colon. Multiple lipomas may also be a pointer to Proteus syndrome, Cowden's disease and Bannayan's syndrome. In addition to multiple lipomas, the latter exhibits macrocephaly, lymphangiomas and haemangiomas (see Congenital diffuse lipomatosis, below) [11].

Diagnosis. The diagnosis is usually easy, but in cases of doubt a biopsy should be performed. Angiolipomas are morphologically similar to lipomas, but are intermittently painful. Lipofascial herniae in the natal or perianal region simulate lipomas. Excision and suture are required to prevent recurrence. Mobile encapsulated lipomas are literally very mobile and can be moved from side to side over a range of up to 8 cm [12].

An epidermoid cyst can mimic a lipoma. However, the presence of the central punctum gives a clue to the correct diagnosis. The possibility of hibernoma should be considered when tumours appear in the thigh, neck and scapular region.

Treatment. This usually depends on the patient's desire for the lipoma to be surgically removed. Lipoma of the lumbar region may be associated with underlying spina bifida occulta, and removal of the tumour is dangerous without simultaneous exploration of the cauda equina. An MRI scan is essential in such patients; the spinal cord involvement is more frequent in girls than in boys, and is significantly associated with bladder dysfunction [13].

Angiolipoma

Angiolipomas are benign encapsulated lobulated tumours, differing from a lipoma in the excessive degree of vascular (capillary) proliferation histologically and in the possession of a normal karyotype cytogenetically. Approximately 10% of all lipomatous lesions examined pathologically are angiolipomas [1]. The degree of vascularity varies and there is no agreed parameter to distinguish between a lipoma and a poorly-vascularized angiolipoma. Fibrin thrombi are common. The age of onset is relatively young, and in one series of 288 patients averaged 17 years. Clinically, the lesions are from 0.5 to 5 cm in diameter and closely resemble lipomas. They are usually painful and tender and are sometimes bluish in colour [2]. The degree of pain varies with the degree of

vascularization. They occur most frequently on the arms, legs and abdomen, and are often multiple [3].

Angiolipomas are categorized into two groups: infiltrating and non-infiltrating [3]. The non-infiltrating angiolipoma is typically a soft, well-encapsulated, subcutaneous nodule. The non-infiltrating type occurs in younger individuals and is usually painful, often multiple and occasionally familial. Compression of nerve fibres that accompany the vascular channels may cause pain, which is usually dull. The infiltrating type, which is the less common type of angiolipoma, is solitary, has a more aggressive behaviour, and can infiltrate osseous, muscular, neural and fibrocollagenous tissues. It may cause signs and symptoms that can simulate malignant neoplasms. The infiltrating type has the propensity to recur following local surgical excision; therefore the treatment for infiltrating angiolipoma is wide excision to include normal tissue surrounding the tumour. Associated features are rare; the association of multiple angiolipomas, multiple cerebral aneurysms and multiple meningomas has been reported [4].

Three cases of HIV-1 infected patients have been described who developed symptomatic angiolipomas shortly after starting antiretroviral therapy, including protease inhibitors [5].

Painful lesions can be excised if single. Conventional analgesics usually do not help. Multiple lesions have been shown to respond to β-blockade with atenolol (50 mg/day). Pain relief was evident after 24 h. Therapy should be continued for a pain-free period of 2–3 months [6]. A double-blind study proved the benefit of intravenous lidocaine (lignocaine) (5 mg/kg) in saline given over 45 min. The pain disappeared after 1–2 days but reappeared 3 weeks later [7]. Infiltrating angiolipomas need wide excision [8]. Liposuction has been successfully used in one patient [9].

Frontalis-associated lipoma [1,2]

This is a deeply placed lipoma of the forehead, which deserves special mention because it is often mistaken for an epidermoid cyst. The lipoma presents a smooth, doughy, dome-shaped mass, which appears relatively immobile and the skin glides over it. It arises either within the frontalis muscle or between the undersurface of the muscle and its deep fascia, and its removal requires greater surgical skill than is required for removing an epidermoid cyst or lipoma. A layered closure is essential to repair the severed frontalis muscle, and a pressure dressing is advisable to close the 'dead space'.

Fat-storing hamartoma of dermal dendrocytes

One patient has been described with a congenital reddish-brown plaque over the lumbosacral area, which was composed of dermal dendrocytes that had phagocytosed lipid droplets [1]. There were no fat cells in the lesion and no associated metabolic abnormalities.

Hibernoma [1–4]

Synonym
- Granular cell lipoma

This is a rare benign tumour, comprising primitive fetal brown fat cells in which an increasing variety of structural abnormalities for the chromosomal band 11q13 are being found [5]. In the Armed Forces Institute of Pathology series of 170 cases [4] the mean age was 38 years, with the site of predilection being the thigh, then the shoulder, back and neck. The average size was 9.3 cm. Whilst the histology is characteristic, showing masses of distinctive cells with fine granules and a solitary central nucleus [1–3], myxoid, spindle cell and lipoma-like variants are also seen [4]. Hibernoma presents as a firm, non-tender nodule, with vascular dilatation of the overlying skin. CT and MRI imaging may be helpful but is not diagnostic [6,7]. Surgical excision is the only treatment. Local recurrence at excision is unusual, the tumour being multilobular but encapsulated [4,8].

Lipomatosis

Lipomatosis is diffuse infiltration of structures with non-encapsulated adipose tissue. Several different types of lipomatosis have been described.

1 Multiple symmetrical lipomatosis, characterized by a symmetric formation of fatty tumours, associated with signs of mediastinal location and neuropathy
2 Pelvic lipomatosis, characterized by fat accumulation in the pelvic cavity with vesical and ureteral displacement, compression and occlusion
3 Mediastinoabdominal lipomatosis, characterized by intrathoracic and intra-abdominal accumulation of fat, mimicking respiratory disease or ascites
4 Mediastinal lipomatosis, frequently associated with long-term oral steroid exposure
5 Renal sinus and perirenal lipomatosis, characterized by a tumour-like accumulation of fat in the renal and perirenal space inside the renal capsule
6 Adiposis dolorosa, or Dercum's disease, a disease affecting women, characterized by the formation of painful para-articular lipomatous masses.

The cutaneous lipomatoses [1,2] are well-defined but rare syndromes of which two major types are identified: the symmetrical and non-symmetrical varieties. Both produce marked disfigurement. Except in the rare cases when they compress a vital structure, they usually present no physical threat to the patient. Both are benign and non-encapsulated, and represent progressive growth and extension of mature adipose tissue far beyond its normal proportions. The fat accumulation is caused by an increase in cell number rather than cell size by a zonal differentiation of adipoblasts into mature adipocytes [3].

Non-symmetrical lipomatosis

The most common, albeit rare, form of localized lipomatosis is the non-symmetrical subcutaneous lipomatosis. It is a benign entity and normally has no clinical significance except for the cosmetic disability. A localized form affecting the shoulder girdle [4,5] may infiltrate the deeper structures and produce distal symptoms. A case has been reported with tuberous sclerosis, but the association may be fortuitous [6]. It is not usually the result of any metabolic disturbance, and is not usually associated with abnormalities of lipid metabolism; in one case there was familial hyperlipidaemia, the mode of inheritance suggesting an autosomal dominant trait [7]. Other associations include ipsilateral cranial and facial asymmetry, cranial and ocular manifestations, alopecia, spasticity and mental retardation. These associations occur with what is called encephalocraniocutaneous lipomatosis—a very rare syndrome [8,9]. It has been suggested that this syndrome is a variety of Proteus syndrome, in which such patients have hyperostoses of the skull, cutaneous lipomas outside the skull and visceral lipomatoses [10]. Co-occurrence with neurocutaneous melanosis has recently been described [11].

Multiple symmetrical lipomatosis

By contrast, multiple symmetrical lipomatosis (Fig. 46.33) is characterized by large, symmetrical masses of fat, mainly in the neck and shoulder region in a horse-collar distribution. MRI can be used to characterize the nature and extent of disease [12,13]. It may be associated with mild hypertriglyceridaemia, elevated high-density lipoprotein cholesterol [14], hyperuricaemia, impaired glucose tolerance and renal tubular acidosis. The lipomatous tissue in these patients has been shown to have enhanced lipoprotein lipase activity [15], a possible explanation for the elevated high-density lipoprotein cholesterol levels displayed by these patients. The inheritance in this type is autosomal dominant. Specific chromosomal abnormalities have been reported [16]. Mitochondrial dysfunction is common in multiple symmetrical lipomatosis and may be based on identifiable defects in the mitochondrial genome [17].

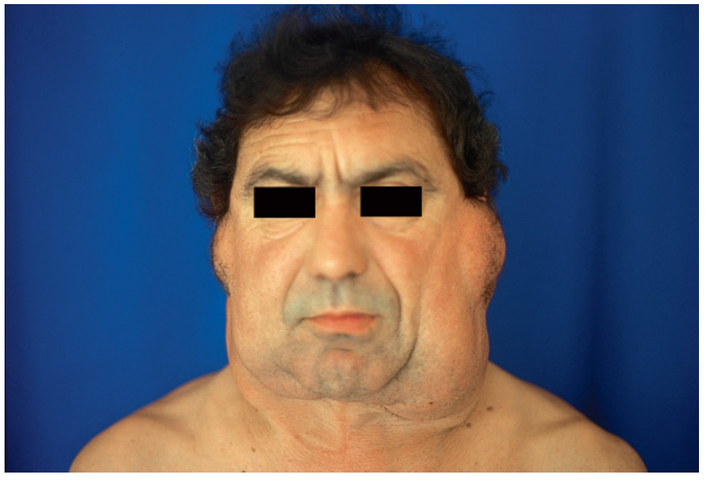

Fig. 46.33 Multiple symmetrical lipomatosis. (Courtesy of M.C. Rodrîguez-Cerdeira, R. Trillo and X.C. Brana, Meixoerio Hospital, Vigo, Spain.)

These patients may also have severe peripheral and autonomic neuropathies [18], often alcoholism, and mediastinal lipomas producing space-occupying symptoms [19]. Sebaceous naevus of Jadassohn has been reported in association with mediastinal lipomatosis [20]. Fifty per cent have a history of high alcohol intake with most of the remainder having a moderate intake or previous alcohol problems [2,21]. The male to female ratio is of the order of 6:1, with the distribution in female patients being proximal arms and legs and not the sub-mental neck pattern seen in men [21]. An unusual patient had benign symmetrical lipomatoses and giant rhinophyma producing a grotesque appearance [22]. Madelung's neck, probably the same condition, is a diffuse multilobular lipomatosis involving the back of the neck and the shoulders in a cape-like distribution. It classically afflicts wine porters and brewery workers. The disease may infrequently be sited in the upper thighs and lower abdomen [23]. Localization to the soles has been reported [24]. Localization of the symmetrical lipomatoses to the tongue results in macroglossia. Therapy is partial glossectomy [25].

The prominent fat deposits over the buttocks that constitute the steatopyga of the Bushmen and Hottentots may be regarded as a racial form of physiological lipomatosis. A distal form of acquired symmetrical lipomatosis of the hands has been reported in a chronic alcoholic Bantu male [26].

Treatment of lipomatosis is difficult. It includes classical lipectomy [27,28] but recurrence is common. Liposuction [29–31] has been reported to help considerably. Fenofibrate has been beneficial [32]. Unlike obesity there is no increase in cardiac mortality and the frequency of diabetes mellitus is the same as the normal population [33], but patients may have problems with autonomic neuropathy [34].

Congenital diffuse lipomatosis [1–4]

This has been infrequently recorded. Several syndromes that may involve a neuroectodermal defect have been described, in conjunction with various types of haemangioma or lymphangioma. Congenital lipomatosis may be associated with angiomatosis and macroencephalia (Bannayan's syndrome) [5]. The Proteus syndrome is very rare; the clinical features include hemihypertrophy, macrodactyly, exostoses, epidermal naevi, characteristic cerebriform masses involving the plantar or palmar surfaces, a variety of subcutaneous masses and scoliosis [6]. Histological examination of the subcutaneous masses has identified a variety of lipomatous and angiomatous tumours and hamartomas.

Treatment. Treatment is difficult but liposuction may help.

Dercum's disease

Synonym
- Adiposis dolorosa

Dercum's disease is a rare, progressive disease characterized by localized overgrowth of fat with painful subcutaneous plaques and ecchymoses.

Aetiology. The mechanism of Dercum's disease is not known [1]. It most commonly affects menopausal women; they are usually

Fig. 46.34 Dercum's disease. (Courtesy of Dr R. Motley, University of Wales College of Medicine, Cardiff, UK.)

obese at the time of onset of the disorder and severe emotional disturbance is common. A recent report implies that the disease is a severe expression of multiple painful lipomas [2] but clinical experience of patients in Sweden [3], where the disease appears to be more common, underlines the concept of, at present, a more heterogeneous group, divided into three types. In type I or juxta-articular type, painful folds of fat were seen on the inside of the knees and/or the hips. In type II, the diffuse type, there was widespread pain from increased fatty tissue. In type III, the nodular type, there was intense pain in and around multiple lipomas. In some families there is a dominant inheritance [4].

Histopathology. Histology in the nodular type reveals features of a lipoma or angiolipoma [1].

Clinical features [5,6]. Dercum [7] coined the term 'adiposis dolorosa' to describe three cases of a syndrome characterized by painful deposits of adipose tissue occurring over multiple areas of the body (Figs 46.34 & 46.35). Adiposis dolorosa occurs predominantly in postmenopausal women (female : male ratio of up to 30 : 1) and is associated with weakness, fatigue and, frequently, emotional disturbances. Obesity is almost always present initially, but patients may lose weight and become asthenic as the syndrome progresses. The painful areas of fat may occur as subcutaneous 'lumps', which feel like a 'bag of worms' on palpation, or may be diffuse in a localized or generalized pattern. The juxta-articular areas are the most commonly involved site [8], but painful areas have been described over virtually all areas of the body. The

Fig. 46.35 Dercum's disease showing much improvement after liposuction. (Courtesy of Dr R. Motley, University of Wales College of Medicine, Cardiff, UK.)

pain occurs with palpation of the involved fat, but may also occur spontaneously, often with a fibromyalgia pattern and quality. The disease usually begins gradually with only mild discomfort, but may progress to exquisite pain, particularly with movement, so that the patient is effectively immobilized. The pain tends to be cyclical with constant mild to moderate discomfort punctuated by episodes of severe pain, which is unresponsive to many or all analgesic agents.

Psychiatric disturbances are frequently observed, ranging from mild irritability to dementia. Depression, failure of memory and hypochondriacal complaints are quite common.

Diagnosis. This is not difficult when the classical triad is present: painful plaques, ecchymoses and obesity, appearing in women with amenorrhoea and neurotic symptoms.

Cushing's disease with diffuse deposition of fat, plethora and hirsutes must be distinguished from Dercum's disease. Amenorrhoea and ecchymoses are common to both disorders.

Treatment. Weight reduction and surgical excision of individual tumours may be helpful [8]. The pain is usually unresponsive to conventional therapy but several cases have been shown to respond to intravenous lidocaine [5,9–13]. Two studies were placebo controlled. The pain relief was from 3 to 52 weeks, and repeat therapy was associated with increasing duration of benefit [5,12]. The lidocaine effect is very specific, as other types of pain (e.g. headaches) continued; the mechanism of action is unknown. Topical lidocaine may be an adequate alternative [14]. Some response to mexiletine 150–750 mg orally has been reported [15].

Arterial and arteriolar disorders

Vasculogenesis, angiogenesis and arteriogenesis

Vasculogenesis is the first step in the development of blood vessels and is the process by which endothelial cells differentiate from their mesodermal precursors. Vasculogenesis leads to the formation of a primary capillary plexus and occurs mainly in embryonal development [1]. Angiogenesis is the process by which new capillaries are formed from existing vessels by sprouting, expanding and remodelling [2]. Vasculogenesis precedes angiogenesis but the two processes continue in parallel during early development. The skin, being of ectodermal origin, is vascularized mainly by angiogenesis. The establishment and remodelling of blood vessels requires a complex orchestration of molecular regulators. First, the extracellular matrix is degraded by local tissue proteases. This permits migration of budding endothelial cells under the influence of angiogenic stimuli, particularly the family of vascular endothelial growth factors (vascular endothelial growth factors A, B, C, D and E (viral homologues) plus placental growth factor) and their tyrosine kinase receptors, VEGFR-1, VEGFR-2 and VEGFR-3. Stabilization and maintenance of newly formed vessels occur mainly as a consequence of the angiopoietins and the tie-receptors [3].

Differentiation into arteries, veins and capillaries is the responsibility of angiogenesis. Neoangiogenesis is an important cause of recurrent varicose veins after stripping [4]. Arteriogenesis produces rapid circumferential growth in the pre-existing collateral vessels, which are less perfused under normal flow conditions. While local tissue ischaemia or hypoxia stimulates angiogenesis, arteriogenesis is mainly induced by inflammation and shear stress [5].

Arterial disease and peripheral ischaemic disorders

Arterial disease

Current concepts on the aetiology of arterial disease, atherosclerosis and peripheral ischaemia

The mechanisms that initiate arterial disease are still poorly understood. Recent research has shown that inflammation plays a key role in atherosclerosis [1]. Early atherosclerotic lesions are dominated by immune cells (macrophages) and their effector molecules accelerate the progression of the lesions. Evidence suggests that cardiovascular risk factors induce endothelial injury and endothelial dysfunction. Endothelial progenitor cells derived from circulating mononuclear cells may protect against atherosclerosis and cardiovascular disease [2]. Atherosclerosis is a patchy accumulation of lipid, mostly in the form of cholesterol, within the intima of the vessel wall. Atheromatous plaques eventually ulcerate through the endothelial lining, exposing a highly thrombogenic surface [3]. Platelets adhere to the ulcerated plaque and platelet

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

aggregates (platelet thrombi) may embolize distally or may initiate local thrombosis. Inadequate collaterals, or occlusion by thrombosis or embolism, will lead to tissue infarction (e.g. peripheral gangrene).

Atherosclerosis is responsible for more than 90% of all arterial disease in the Western world. It affects 5% of men over the age of 50 years, of which 10% may develop critical limb ischaemia; this increases to 20% if diabetic patients are included [4]. Apart from diabetes, tobacco smoking is one of the most important risk factors for arterial disease. A family history and hypercholesterolism are two other factors that are associated with atherosclerosis.

Atherosclerosis of the lower limb vessels

Many patients initially present with claudication (cramping pain on walking, which is usually experienced in the posterior calf muscles and is relieved by rest). The presence of persistent pain in the foot at night indicates the onset of critical ischaemia, which will lead to gangrene or ulceration if left untreated.

In the past, arteriosclerosis (hardening of the vessels) had been classified as a disease, but most authorities would now regard this as a physiological response to ageing. Thickening of the arterial wall, with an increase in collagen and calcium deposition, causes loss of elasticity and increased tortuosity of the vessels in the elderly [3]. Similar changes are seen in the vessels of younger patients with hypertension.

Clinical features [3–6]. All aspects of the patient's history and lifestyle are relevant, with particular attention being paid to risk factors such as cigarette smoking, hypertension, diabetes, diet, dyslipidaemia, hyperhomocysteinaemia, lack of exercise, obesity, occupation and a family history of cardiovascular disease [7]. In 1992, an examination of WHO epidemiological data from Toulouse (France) indicated that in spite of the population having a high saturated fat consumption, comparable serum cholesterol levels and other similar risks, there was a considerably lower incidence of death from coronary heart disease compared with other Western countries. Although the specific mechanism behind this 'French paradox' has not been identified, the flavonoid components in red wine are thought to have antioxidant activity which could contribute to cardiovascular benefits [8].

Most patients present with intermittent claudication, but ischaemic ulceration and skin infarction are more likely to be the presenting features in patients sent to the dermatologist (Fig. 47.1). Rest pain occurs if the disease progresses. This is experienced in the foot, and occurs predominantly at night. Altered skin colour (pallor or deep erythema) indicates ischaemia, and may be accompanied by other trophic skin changes such as dryness, scaling, loss of hair and thickened nails (Fig. 47.2).

A full general examination is essential. Particular attention should be paid to signs of anaemia, polycythaemia, xanthelasma and other xanthomatous deposits. Genetic disorders such as pseudoxanthoma elasticum, Ehlers–Danlos syndrome and Marfan's syndrome should be considered if an aneurysm is present. Cardiac examination should focus on dysrhythmias, particularly atrial fibrillation, murmurs and signs of heart failure.

Abdominal examination should detect the presence of a pulsatile mass, indicative of an abdominal aortic aneurysm. The fundi

Fig. 47.1 An ischaemic hallux with pregangrene; the rest of the foot has an ischaemic erythema.

Fig. 47.2 An ischaemic foot showing patchy areas of gangrene and rubor. The skin is flaky and the nails are brittle.

should be examined for evidence of diabetic and hypertensive retinopathy. The blood pressure should be taken in both arms; a marked difference suggesting a stenosis or occlusion of the subclavian artery (although ischaemic disorders of the upper limbs are unusual).

The skin of the legs may have an erythematous or dusky mottled hue. When the ischaemia is marked, limb elevation causes pallor of the foot while dependency results in delayed but exaggerated hyperaemia, best observed on the dorsum of the foot (Buerger's sign) (Fig. 47.3) [9]. Inspection may reveal ulceration at sites of pressure (Fig. 47.4); small cracks may appear over the sole of the foot or heel (Fig. 47.5). Platelet emboli lodging in the plantar and digital vessels cause areas of discoloration, which are often present over many toes or on the sole of the foot (Fig. 47.6). They often look like ecchymoses initially and may be confused with vasculitis. The aortic, femoral, popliteal, dorsalis pedis and posterior tibial pulses must be carefully palpated. Abnormally situated pulsations may indicate a collateral circulation or a congenital arteriovenous fistula. Auscultation over the course of the arteries may reveal the presence of a bruit indicative of turbulent flow. This is

Fig. 47.3 Buerger's test showing postural colour change in an ischaemic foot—white when the foot is elevated (right) and red when lowered (left).

Fig. 47.4 An ischaemic ulcer on the dorsum of the foot with an ulcer arising in the first interdigital space. Pressure between the toes is a common consequence of tight bandages or footwear.

commonly caused by an up-stream stenosis or by an arteriovenous fistula (which usually causes a 'machinery' murmur, present throughout systole and diastole). It should be noted that significant arterial disease demanding further investigation is uncommon when the foot pulses are easily palpable.

Investigations. Confirmation of the arterial disease of the lower limb can be obtained by measuring the ankle–brachial Doppler pressure index if peripheral pulses are reduced or absent or a bruit is heard [10]. After the Doppler ultrasound probe has been used to locate the dorsalis pedis or posterior tibial vessel a sphygmomanometer cuff is placed around the limb above the ankle and inflated (Fig. 47.7). The red cells flowing past the tip of the ultrasound probe deflect the beam, creating an audible noise. As the cuff is inflated above systolic pressure, flow in the artery ceases and the noise disappears. This ankle–brachial systolic gradient is normally unity, that is 1.0. A fall in ankle pressure results in a reduction of the pressure index: a ratio of 0.71 to 0.90 indicates the presence of mild peripheral arterial disease, an ankle–brachial index of 0.41 to 0.70 indicates moderate disease, and a ratio of 0.40 or less indicates severe disease. Pain at rest or severe occlusive disease typically occurs when an ankle–brachial index is less than 0.50. Ischaemic or gangrenous extremities are associated with an index of less than 0.20 [11]. Falsely high indices may be obtained in some limbs if the vessels are very calcified and fail to compress at systolic pressure. This is especially true for diabetic limbs. In such circumstances a more accurate means of assessment is to measure the Doppler pressures at the toe. Measurement of the transcutaneous Po_2 using a heated (Clark's) electrode applied to the skin of the lower limbs and compared with a reference site on

Fig. 47.5 An ischaemic 'crack' developing as a consequence of nutritional changes seen in hyperkeratosis and loss of suppleness of the skin of the heel.

the chest wall [12,13] can also be used to assess limb ischaemia. This usually fails to increase with inhalation of oxygen. Patients with severe venous incompetence can also have hypoxic extremities [14]. Isotope washout studies (which estimate clearance of an inert isotope from a tissue injection) can also be obtained [15].

Investigations in patients suspected of having peripheral arterial disease or critical leg ischaemia [4] should include: a full blood count to exclude anaemia or polycythaemia; electrolytes and creatinine to monitor renal function; and an electrocardiogram (often repeated after exercise) to detect rhythm abnormalities or cardiac ischaemia. A chest radiograph provides an assessment of cardiac size and excludes a coincidental bronchogenic carcinoma, which is common in smokers. Diabetes should be excluded, and plasma cholesterol, homocysteine and fasting triglycerides should be measured. Markers of inflammation, particularly C-reactive protein, have been associated with peripheral arterial disease. Raised haematocrit levels and hyperviscosity have all been reported in patients with peripheral arterial disease [7].

When surgery is contemplated, a detailed assessment of the anatomy of the arterial tree is also required. Duplex ultrasound scanning is often the initial investigation, and is used as a screening test to confirm the major sites of stenosis or occlusion in the vascular tree [16,17]. A duplex ultrasound scan provides both a B-mode image of the artery and a measurement of blood velocity; these can be combined to provide a map of stenoses and occlusions within the arterial tree from the aorta to the crural (calf) vessels. The greater the velocity, the tighter the stenosis. Most surgeons also obtain an arteriogram before angioplasty or bypass surgery is performed. Arteriography is performed by injection of non-ionic contrast media into the vascular tree, usually through a retrograde catheter inserted into the common femoral artery at the groin over a guide wire (Seldinger-type retrograde aortography), or from an intravenous or intra-arterial injection using digital subtraction equipment or computed tomography to enhance picture quality [18]. Each of these methods has its proponents, but retrograde aortography performed as an outpatient, or a combination of intravenous digital subtraction arteriography of the aorta, iliac and femoral vessels with femoral arteriography of the distal vessels, provide equivalent information. Thus invasive digital subtraction angiography remains the final investigation which is used if endovascular intervention is planned. Magnetic resonance angiography (MRA) of the extremities is sometimes useful to diagnose the anatomic location and degree of stenosis in peripheral arterial disease if patients are allergic to contrast. Computed tomography angiography is an alternative if patients have contraindications for MRA [7].

The further management of arterial disease is discussed under the heading of the individual diseases, and usually requires referral to an appropriately experienced surgeon and interventional radiologist.

Differential diagnosis. Thromboangiitis obliterans (Buerger's disease, p. 47.6–7) may be very difficult to distinguish from atherosclerosis. Preservation of the proximal femoral and popliteal pulses and the early age at first presentation usually indicates the possibility of this condition. Associated venous thromboses and

characteristic histological changes on vessel biopsy make the diagnosis more secure. A skin biopsy can sometimes be helpful in diagnosing Buerger's disease [1]. Arteriography in Buerger's disease shows characteristic 'corkscrew collaterals' [1].

In patients with acute limb ischaemia it is important to exclude the possibility of embolism, which may be suggested by a recent myocardial infarction or the presence of atrial fibrillation. Transthoracic or transoesophageal echocardiography can demonstrate intracardiac thrombus and structural abnormalities, especially of the valves and, in the case of transoesophageal echocardiography, with great accuracy [2].

Rarer causes of ischaemia include external arterial compression (popliteal entrapment or a cervical rib), dissecting or thrombosed aneurysms, ergot alkaloid poisoning, intra-arterial injections of noxious substances, traumatic disruption of the arterial wall, coagulation disorders, particularly polycythaemia and thrombocytosis, and various forms of vasculitis. Diabetes must always be considered as a potentiating condition, even in patients with atherosclerotic disease.

Claudication pain may be mimicked by arthritic conditions of the hip, such as osteoarthritis or rheumatoid arthritis. Pain in the leg may also result from referred pain arising in the lumbosacral spine, and spinal claudication is sometimes very difficult to differentiate from arterial claudication. Occasionally, venous claudication may also be misdiagnosed. Ischaemic rest pain may have to be differentiated from other painful conditions of the feet and toes, such as gout, interdigital neuromas, glomangiomas, ingrowing toenails, flat feet, calcanial bursitis and plantar fasciitis. Other causes of gangrene may need to be excluded (e.g. clostridial infection, diabetes, other causes of vascular obstruction, vasculitis and coagulation disorders).

Prognosis. Patients with atherosclerotic disease of the lower limb vessels usually have other arteries affected. Coronary artery disease was found to be present in 90% of a group of patients with peripheral arterial disease [3]. The extent of the atheroma in the coronary and carotid arteries determines the life expectancy of the patient, although antiplatelet agents [4], lipid-lowering agents and bypass surgery may improve the patient's prognosis as well as their symptoms of ischaemia. Silent myocardial infarction is present in about one-third of those who presented with intermittent claudication.

Treatment. Treatment options differ for patients presenting with claudication, rest pain or gangrene and acute limb ischaemia.

Claudication. The indications for intervention in a patient with claudication are always relative and must be weighed against the risks of the procedure and the fact that the condition normally has a very benign course [5]. Only 5% of all patients with claudication progress each year to develop rest pain or gangrene; a far greater proportion die every year from other causes, such as myocardial infarction. Patients with intermittent claudication are therefore usually managed conservatively at first, as collateral vessels may develop with an associated improvement in the symptoms.

Smoking cessation has been shown to reduce the risk of progression in patients with lower extremity peripheral arterial disease presenting with claudication. Nicotine replacement has been shown to be a safe and effective method of aiding smoking cessation [6].

Patients should be encouraged to walk through the pain as this tends to stimulate the development of a collateral circulation, to recruit capillaries and to increase the claudication distance. There are a number of studies demonstrating that supervised exercise programmes are as effective as therapeutic intervention in alleviating claudication, although the benefits of supervised exercise may not persist [7].

Patients with peripheral arterial disease should have their blood pressure maintained below 130/85 mmHg [8], but antihypertensive treatment should not be instituted in patients with claudication whose lower limb systolic pressures are lower than 80 mmHg.

Pharmacological interventions comprise the following. Antiplatelet agents must be considered in patients with claudication. Based on the available evidence, the first-line antiplatelet therapy should be aspirin or clopidogrel [6]. Aspirin has not been shown to improve claudication itself, but patients with claudication treated by antiplatelet agents have a 25% reduction in subsequent serious cardiovascular events. Statins modify lipid levels and reduce the risks of disease progression. Statins reduce LDL-cholesterol levels causing a significant reduction in the all-cause mortality [6,8]. Diabetes mellitus is closely associated with peripheral arterial disease and its progression, and rigorous control of blood glucose in patients with diabetes reduces microvascular complications. Although intensive therapy (achieving a HbA_{1c} of below 7%) had no effect on the risk of death or amputation in patients with peripheral arterial disease, there was a trend in favour of a reduced risk of non-fatal cardiovascular events [6,8].

Further investigation is indicated if the claudication distance remains unacceptable despite the patient having stopped smoking and after a reasonable period of conservative treatment. Stenotic lesions confirmed by arteriography can be treated by balloon dilatation (angioplasty), using specially designed coaxial balloon catheters that are constructed to withstand high external pressures [9]. This technique works best on stenoses in large proximal vessels, and least well on long occlusions of the distal arterial tree. Potential complications include arterial rupture, aneurysm formation, thrombosis and dissection. Additionally, the results of angioplasty in the femoropopliteal segment remain disappointing with a 30% restenosis rate at 1 year. The role of primary stent placement in revascularization of the superficial femoral artery remains controversial, mainly because of the high restenosis rate. Chemically treated slow-release stents may overcome 'restenosis' in the future, although so far several randomized trials have failed to confirm this. Stents placed in the superficial femoral artery can undergo fracture, which has been linked to restenosis. A randomized trial by Schillinger *et al.*, involving 104 patients with severe claudication, showed significantly higher patency rates at 1 year for lesions in the superficial femoral artery that were treated with stent placement than for lesions treated with angioplasty with a stent only being placed if there was a suboptimal result [10]. Long-term results are not, however, available.

Surgical endarterectomy or bypass remains the treatment of choice for extensive occlusions longer than 10 cm, or for occlusion of the popliteal or tibial–peroneal vessels [11]. Aortofemoral

bypass has an excellent 5-year patency (90–95%), but the operative mortality varies between 1 and 5% [10]. Femoropopliteal vein bypass grafting has a lower 5-year patency (60–70%) but a lower operative mortality (usually less than 1%) [12]. Distal bypass surgery (the lower anastomoses being below the popliteal artery into one of the three crural vessels) has no part to play in the treatment of claudication, although this procedure is of considerable value in patients with rest pain and early gangrene (see below) [13]. Operative or chemical lumbar sympathectomy do not help to relieve claudication [14] and are mainly of value in patients with ischaemic ulcers or Buerger's disease.

Rest pain or gangrene. Once rest pain or early gangrene has developed the situation changes, for if this state is left untreated amputation will be necessary to relieve pain and preserve life. Patients with rest pain or gangrene must be rapidly admitted and investigated, because successful revascularization can avert limb loss [7]. Any anaemia or polycythaemia should be corrected, and if diabetes is found this should be brought under control. Dehydration and infection must be treated.

The increasing use of more distal surgery with bypasses to the dorsal pedis, posterior tibial, peroneal and even plantar vessels has saved many limbs that in the past would have been amputated [13,15]. Angioplasty, stenting and surgery to the proximal vessels are, of course, still of value as these arteries are the main sites of disease.

In patients without evidence of frank ischaemia, chemical sympathectomy may alleviate rest pain [16]. Prostacyclin, prostaglandin E_1 and prostacyclin analogues, such as iloprost, are being tried in patients in whom a bypass cannot be constructed. These compounds may preserve a small proportion of threatened limbs [17]. A meta-analysis of seven randomized trials involving 643 patients with ischaemic limbs showed a small but significant effect of prostaglandin E_1 on ulcer healing and/or pain reduction and on the combined end points of major amputation or death [18].

Therapeutic angiogenesis using gene therapy has been tried but clinical trials have not shown any benefit to date. A phase 1 study on plasmid transfer of vascular endothelial growth factor in nine patients with severe peripheral arterial disease has, however, shown that this technology is possible. Many other studies are under way to assess the utility of gene therapy in patients with severe peripheral arterial disease [18].

The immediate amputation rate can be lowered by a policy of aggressive reconstruction, but this probably comes at the cost of a few higher amputations and some increased loss of life when graft failure is associated with a continued ischaemia and consequent amputation [19].

Acute limb ischaemia. Patients presenting with acute limb ischaemia should be rapidly assessed and, unless there is unequivocal evidence of an embolus (suggested, for example, by normal vessels in the other limb, atrial fibrillation or recent myocardial infarction), the patient should have urgent angiography to confirm the diagnosis and to assess the cause of the occlusion. This should be followed by infusion of a tissue plasminogen activator into the thrombus or embolus via the catheter unless the state of the limb demands urgent revascularization or amputation [20]. Repeat angiography, to confirm continuing or successful thrombolysis, is required at frequent intervals, and residual stenoses responsible for the thrombosis may require angioplasty, stenting or surgery. When vessel patency has been restored by thrombolysis, patients must remain on anticoagulants.

Balloon-catheter embolectomy should be reserved for embolic occlusions. When platelet emboli are suspected, antiplatelet agents may be prescribed before a definitive surgical or radiological intervention to remove the source of the emboli.

Amputation remains the final option in all types of ischaemic disease of the lower limbs where revascularization is impossible or ineffective. The value of preserving the knee joint for subsequent mobility is well recognized. The mortality of amputation stays stubbornly high (15–20%).

Thromboangiitis obliterans [1,2]

Synonym
- Buerger's disease

Definition. This appears to be a distinct condition separate from other forms of vascular occlusion [2,3], with differences in the pathological appearance of the vessel wall, and in the population affected, compared with other arterial diseases [2].

This condition was first recognized as an obliterative disorder of peripheral arteries of young males by Leo Buerger in New York [1]. The affected young men were all heavy smokers and the disorder involved the small vessels of the upper limb much more commonly than in atherosclerosis. While originally thought to occur only in men, there are increased reports of women with thromboangiitis obliterans, possibly as a consequence of the increasing use of cigarettes among women in the 20th century [4]. It is common in the Middle and Far East, and in the Indian subcontinent.

Aetiology [2]. The aetiology of the condition is unknown, although tobacco addiction is invariably a major contributing factor, and a failure to overcome this addiction is associated with progressive occlusion of the vessels. Autoantibodies have been found within the blood [5]. In particular, antiendothelial cell antibodies are present in high titre in active disease. They may be used to monitor disease activity and may have a pathogenic role [2].

Pathology [2,6]. The full thickness of the vessel wall is invaded by lymphocytes, eosinophils, plasma cells and monocytes, especially disrupting the internal elastic lamina, and there is luminal occlusion as a result of highly cellular thrombosis. Accompanying nerves and veins may become involved in the inflammatory process. All changes are segmental or focal. At a later stage in the disease, fibrosis occurs, which spreads to involve surrounding structures.

Clinical features. Pain is the main presenting symptom and may be of several types: intermittent claudication; rest pain, more severe at night; pain associated with ischaemic neuropathy, ulceration or superficial venous thrombosis. Sensitivity to cold is a frequent complaint. Claudication in the arch of the foot is especially characteristic [7].

Ulceration or gangrene may develop early in the disease, particularly following trauma, and often starts around the sides of the nails or tips of the digits (Fig. 47.8). Trophic changes, superficial venous thrombosis and oedema are also often present. Red or cyanotic acral colour changes are often unilateral, asymmetrical and may affect isolated digits.

Recurrent venous thrombosis is a frequent problem and may take the form of superficial red streaks and cords of 0.5–3 cm [2] or deep-vein thrombosis presenting with pain and swelling. Erythema nodosum may also develop.

Ischaemic areas are found on the tips of the fingers and toes and may initially present as chronic painful paronychia. The proximal pulses are usually present, but the dorsalis pedis, posterior tibial and brachial pulses are lost at an early stage.

Diagnosis. There are no specific laboratory tests to aid in the diagnosis of thromboangiitis obliterans [4]. The erythrocyte sedimentation rate (ESR) is often elevated and antiendothelial cell autoantibodies may be detected. An arteriogram should be obtained and may suggest the diagnosis, if there are many 'corkscrew' collaterals [8] (Fig. 47.9). The proximal vessels are usually entirely normal while the distal arteries are diffusely affected with multiple stenoses and occlusions.

Fig. 47.8 Ischaemic toes in Buerger's disease.

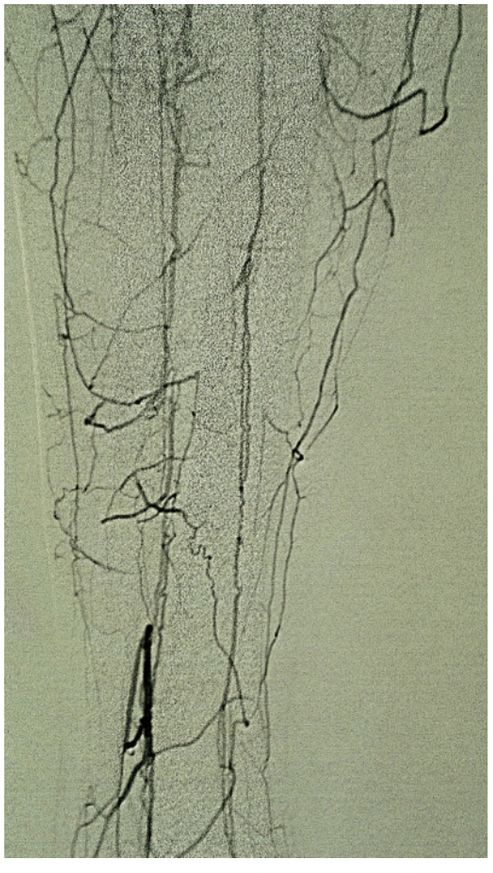

Fig. 47.9 An arteriogram in a patient with Buerger's disease. No major vessels are seen, just multiple collateral arteries.

The differential diagnosis is wide. It includes atypical 'young onset' atherosclerosis, diabetic vasculopathy and rheumatoid arthritis. Collagen-vascular diseases, such as scleroderma and systemic lupus erythematosus, must also be considered in the differential diagnosis. Multiple emboli derived from a proximal source may pose real diagnostic difficulty, and ergotism, abuse of cocaine, amphetamines and cannabis must not be forgotten. Hypercoagulable states (Chapter 49) should be excluded. In mild cases, acrocyanosis, livedo reticularis and erythromelalgia may be considered.

Treatment and prognosis. The dermatologist may be faced with the problem of a patient referred for ulceration or erythema of the foot and toes. Once the diagnosis is established, the matter is best dealt with by the vascular surgeon, whose advice should be sought. Collateral development can be expected to occur during phases of inactivity of the disease. The essential requirement for successful outcome is the complete discontinuation of tobacco use. Bed rest and antibiotics are other facets of conservative treatment. Surgical or chemical sympathectomy is usually helpful and prostacyclin infusions may buy time and minimize ablative surgery [9]. In a double-blind study of a chemically stable prostacyclin analogue, 85% of patients treated showed ulcer healing or relief of pain compared with 17% of an aspirin-treated group [10].

Arterial reconstructive surgery has little part to play in the management of this condition because of the distal nature of the disease. After sympathectomy, every effort should be made to avoid major amputations by the use of antibiotics and, when necessary, toe excisions. Below-knee amputation may eventually be required, particularly if gangrene extends to the foot. It should not be unreasonably delayed. There are an increasing number of reports on the use of an implantable spinal cord stimulator in patients with Buerger's disease; this can produce a marked improvement in regional perfusion, thereby avoiding amputation. The limb survival rate was 93.1% [11].

The prognosis is poor in patients who continue to smoke; hands and feet may be lost.

Fig. 47.10 Ulceration associated with calcification of arteries in secondary hyperparathyroidism.

Small vessel calcification and calcific uraemic arteriolopathy (calciphylaxis) [1,2]

Arterial calcification is a common and usually asymptomatic complication of chronic renal failure. Occasionally, especially when associated with hyperparathyroidism, it can cause complete vascular occlusion and infarction of the skin. This condition, calcific uraemic arteriolopathy (previously termed calciphylaxis), may begin as a small area of redness and tenderness or with a broad livedo reticularis pattern, evolving into intense erythema. This may progress to violaceous indurated plaques and nodules in the skin, attributable to fat necrosis [3]. The sites of predilection are the proximal extremities, especially the thighs, abdomen and buttocks (Fig. 47.10) [4]. Plain radiographs demonstrate small and large vessel calcification. The pathogenesis is unknown, and the condition is probably the result of a number of comorbid factors. The condition occurs in an estimated 1–4% of patients with terminal renal insufficiency and is much more common in women [3]. Uraemia and hyperphosphataemia are often more obvious than hypercalcaemia. The exact role of hyperparathyroidism is debated, but an elevated serum parathyroid hormone level is noted in most patients. The role of protein C and S remains to be determined, but a relative hypercoagulable state is present [3,4]. Histology usually confirms arterial medial calcification, intimal hyperplasia, fibrosis and vascular thrombosis and necrosis of the overlying epidermis [3].

The differential diagnosis of calcific uraemic arteriolopathy is extensive (Table 47.1) [3,4]. Treatment is unsatisfactory and the prognosis is poor, with sepsis as the main cause of death. Uraemia, and a raised serum calcium and phosphorus may be treated by dialysis; the mechanisms of the process, and medical treatments, are discussed in more detail in Chapter 49. Other important measures include pain control, wound management, sepsis prevention and avoidance of certain medications [3,4]. Parathyroidectomy is only indicated when there is evidence of hyperparathyroidism.

Neurovascular disorders of the extremities

Erythromelalgia [1]

Definition [2]. This is a condition of painful, red extremities in which a sensation of burning is associated with small vessel vasodilatation in the affected skin. The synonyms erythermalgia [3] and erythralgia are confusing. There are three types of erythromelalgia:

Type 1: This is associated with thrombocythaemia and is relieved by aspirin.

Type 2 (Weir Mitchell's disease): This is a primary or idiopathic disorder which is usually congenital and is provoked by exercise or exposure to warmth.

Type 3: This is secondary to inflammatory or degenerative peripheral vascular disease.

However, the simpler division into primary (type 2) and secondary erythromelalgia may be preferred.

Pathogenesis. Type 1 is the result of thrombocythaemia and is seen in polycythaemia and myelofibrosis. It may be unilateral or even affect one finger or toe [4–7]. There is fibromuscular proliferation of the intima which leads to occlusive thrombosis of the digital arterioles and arteries [8].

Type 2 is confined to the lower legs and does not progress to ischaemia [9]. Primary erythromelalgia is often familial and is inherited in an autosomal dominant manner with the causative gene being located at chromosome 2q24 [10–12]. A prospective study by Davis *et al*. showed that most patients with erythromelalgia had a small-fibre neuropathy [13]. Primary erythromelalgia is the first inherited painful neuropathy to be understood at a molecular level, being due to mutations in the gene *SCN9A*, which encodes the voltage-gated channel Nav 1.7. *SCN9A* is preferentially expressed in most nocicepetive neurones and in sympathetic ganglia. Mutations cause a gain of function and a lower threshold for the influx of sodium ions in response to a stimulus such as increased temperature. Consequently, pain signalling increases in response to heat [14]. Families with erythromelalgia have been described in which inheritance is dominant although heterozygous mutations in Nav 1.7 are not always found. Mice homozygous for the mutation do not appear to feel pain. Nav 1.7 might not have a major role in post-traumatic neuropathic pain, but it does appear to have a role in inflammatory pain [12].

Pain has a direct relationship to the temperature of the limb; when this reaches a 'critical point', which normally lies between 32 and 36°C and which is constant for each individual, then pain will occur [14]. Pain is not a direct result of vasodilatation as it can be induced or maintained by warming the limb while its blood supply is occluded by a cuff. The pain is made worse by making the limb dependent, irrespective of its temperature. Pain may also be induced by obstructing the venous return. The involvement of small nerve fibres in primary erythromelalgia is likely as such manoeuvres do not cause pain or distress in normal subjects [15,16].

Type 3 erythromelalgia can occur in patients with connective tissue disorders and other inflammatory states. Certain drugs and peripheral vascular disease can also give rise to erythromelalgia and this can involve acral sites other than the hands and feet. Females are more often affected [17–22]. In types 1 and 3, the hands and feet are usually involved but sometimes only a part of one extremity is affected. The principal feature of erythromelalgia of all types is that attacks are precipitated by exercise or heat, such as a warm bed, and are relieved by rapid cooling, such as immersion in iced water. The patient complains of intense burning associated with erythema and increased warmth of the extremity. Attacks last from a few minutes to several hours. A warm climate and fever may increase the distress. Ulceration and trophic changes may result from cold immersion injury produced by attempts to relieve pain.

Diagnosis. The fully developed characteristics of the syndrome and the description given by the patient seldom leave doubt about the correct diagnosis. However, there are some important differential diagnoses and disease associations. Complex regional pain syndrome (reflex sympathetic dystrophy) following trauma can produce a similar clinical pattern. The effect of dependency, and the bizarre measures by which the patient may attempt to obtain relief, are also indicative of the diagnosis.

Disease associations include hypertension, diabetes, rheumatoid arthritis, lupus erythematosus, thromboangiitis obliterans, gout and vasculitis. The most important association of secondary erythromelalgia is with myeloproliferative disorders, for example polycythaemia rubra vera or thrombocythaemia. It may be a presenting and premonitory symptom of these conditions, often being present several years before they develop. Vasoactive drugs, such as nicardipine, have been incriminated as a cause [21].

Treatment and prognosis. No treatment is consistently effective and there is a dearth of adequate clinical trials. There is a significant decrease in survival compared to the general population, and most cases get worse over time [20].

Management consists of avoiding exacerbating factors, and controlling secondary and underlying factors [23]. Thrombocythaemia, or causes of inflammatory vascular disease, must be treated where possible. Small doses of aspirin give considerable relief in some patients—presumably by preventing platelet aggregation—and clopidogrel may be the most effective antiplatelet agent [5,24]. Patients with vasodilatation and warmth in their affected painful extremities prefer immersion in cold water. Elevation also provides some relief by decreasing oedema. Some have claimed relief of erythromelalgia with benoxybenzamine hydrochloride or propranolol [25]. Amitriptyline and neuropathic pain treatments such as gabapentin can help, and selective serotonin reuptake inhibitors have been used with success. Pain has been totally controlled by inserting an epidural block for up to 3 weeks, which allows healing of ulceration. The response of one family to pizotifen has been reported as spectacular [26]. Recombinant growth hormone therapy immediately relieved pain and healed cutaneous ulcers in a child with erythromelalgia and a growth hormone deficiency [27]. More recently, relief of pain was achieved in 18 out of 33 patients using a 5% lidocaine patch [28].

Complex regional pain syndrome

Synonyms
- Complex regional pain syndrome types I and II
- Reflex sympathetic dystrophy
- Causalgia
- Sudeck's atrophy

Definition. Complex regional pain syndrome (CRPS) is the name now given to a syndrome of chronic pain and hyperalgesia, associated with sensory, motor, autonomic and dystrophic disturbances, usually in a limb. Two types can be distinguished:

CRPS 1: also known as reflex sympathetic dystrophy, typically develops after minor trauma with no obvious small nerve lesion

CRPS 2: also known as causalgia, in which there is clear evidence of nerve injury [1].

Pathogenesis. There is evidence to suggest that CRPS represents a spectrum of changes in the inflammatory, neural, vascular and musculoskeletal systems. Several mechanisms have been suggested, but none of them has so far explained the exact pathophysiology of this disease. Peripheral nerves or C and A-δ fibre terminals are injured in the autonomic and motor systems as well as in the pain fibres [2].

Clinical features. Patients typically describe pain, swelling and difficulty in using the affected limb. The pain has a burning or deep aching quality and is aggravated by movement. Consequently there is a tendency to avoid using the limb, and hyperalgesia encourages limb protection. The skin takes on a deep red to blue colour, suggesting that vasodilatation is occurring, and is initially warmer than the unaffected contralateral limb becoming cooler in the latter stages. Oedema may result from disuse and dependency, and the muscles atrophy (Sudeck's atrophy).

Diagnosis. CRPS is a clinical diagnosis and there is no simple diagnostic test. In 20% of the patients there are changes in the skin and less commonly in the nails and hair. There is a temperature and colour asymmetry in half the patients. Early hyperhidrosis, and later anhidrosis, may be demonstrated by starch-iodine testing. A decreased range of motion, weakness, dystonia and tremor may also be noted [3]. Increased blood flow is an important diagnostic feature of early CRPS [4]. It is clearly demonstrated by a three-phase bone scan [5]; the delayed phase of this scan is very sensitive, and a segmental diffuse increase in the uptake of radionuclide is very specific. Later the bone scan returns to normal and there are radiographic features of rapid bone loss including visible demineralization with patchy, subchondral or periosteal osteoporosis, metaphyseal banding and profound bone loss [6].

Treatment. The aim of treatment is to reduce pain and restore function of the affected limb as soon as possible. First-line treatment consists of physical therapy in combination with drugs. Medications that may improve neuropathic pain, including tricyclic antidepressants, anticonvulsants and opioid analgesia, are commonly used to treat patients with CRPS [7]. Although not well tolerated by most patients, compression bandaging is one of the mainstays of complex regional pain syndrome treatment, especially in reducing oedema and enhancing the circulation.

Free radical scavengers have been used in both the treatment and prevention of complex regional pain syndrome, based on the assumption that complex regional pain syndrome is induced by an exaggerated inflammatory response to tissue injury, mediated by excessive production of toxic oxygen radicals [8]. Promising results have been reported with dimethylsulfoxide and *N*-acetylcysteine [9].

Severe cases may require regional anaesthetic blockade. A meta-analysis by Hassantash *et al.* [10] found that 88% of 822 patients with CRPS 2 had a beneficial response to sympathetic blocks of the involved extremity. The same literature review demonstrated that 91% of 791 patients who were treated by sympathectomy had a relief of their symptoms after one procedure and 94% after a second procedure. In selected patients with severe chronic pain, electrical spinal cord stimulation can induce pain relief and improve the patient's quality of life.

Angiodyskinesia

Paraesthesiae, painful burning sensations combined with redness or pallor of the legs after prolonged walking or dancing, has been described in young people [1,2] and it has been suggested that these were a consequence of abnormal functioning of the arteriovenous communications. The term 'angiodyskinesia' has been applied to this condition [3].

Under this title, Ryan and Wilkinson described a blotchy erythema of the legs in a 14-year-old boy [4]. His condition developed at the same time as osteochondritis dissecans. The erythematous areas were 2–3°C warmer than the adjoining skin, and disappeared when the patient was recumbent, reappearing and becoming uncomfortable when he was standing. These features suggest failure of the normal vasoconstriction that occurs when a limb is lowered. The condition was more marked in warmer conditions and after a bath.

Restless legs syndrome

Definition. Restless legs syndrome is a sensorimotor disorder characterized by an uncomfortable feeling in the legs that urges movement [1].

Pathophysiology. Restless legs syndrome can occur as a primary or a secondary disorder.

In the primary form there is no apparent cause other than a possible genetic predisposition [2]. Under the assumption of a recessive and dominant mode of inheritance, three loci for restless legs have been found on chromosomes 9p, 12q and 14q [3].

Restless legs syndrome occurring as a secondary condition is related to iron deficiency, pregnancy and end-stage renal disease. Clinical evidence suggests that restless legs syndrome is associated with decreased dopaminergic neurotransmission. The symptoms are worse at night when dopamine levels fall [2]. Restless legs syndrome is not associated with chronic venous insufficiency.

Clinical features. The core feature of this syndrome is a distressing, irresistible urge to move the legs (akathisia). This often coexists with an uncomfortable, hard to describe, sensation deep within the legs. The prevalence in the general population lies between 2.5–15%, increasing with age and being more common in women. A family history is often present in patients whose symptoms appear before 40 years of age [4].

Four essential criteria have been established for the diagnosis to be upheld:

1. An urge to move legs that is usually accompanied or caused by uncomfortable or unpleasant sensations in the legs
2. An urge to move or an unpleasant sensation that begins or worsens during periods of rest or inactivity
3. An urge to move or an unpleasant sensation that is partially or totally relieved by movement as long as the activity continues
4. An urge to move or an unpleasant sensation that is worse in the evening or at night rather than during the day or that only occurs during the evening or at night [1].

Diagnosis. The diagnosis is made from the criteria listed above; the most important aspect is to identify any treatable underlying cause and to exclude other disorders that have some clinical similarities. End-stage renal failure is probably the most obvious and best investigated secondary condition associated with restless legs syndrome. Several studies have shown an association between restless legs syndrome and pregnancy. After delivery, the prevalence of restless legs syndrome decreases to values found in the normal population. Disorders in iron regulation may be involved in primary forms of restless legs syndrome. Correcting iron status in patients with iron deficiency has been found to reduce symptoms in patients with restless legs syndrome. An association between Parkinson's disease and restless legs syndrome has been made because of the response to dopaminergic treatment in both disorders [5].

The differential diagnosis of restless legs syndrome includes both movement and sleep disorders. Most of these conditions typically do not have a circadian pattern, nor does movement relieve the symptoms [1]. Although restless legs syndrome may be triggered by radiculopathy, neuropathic pain syndromes or peripheral neuropathy, a distinction should be made between these conditions [6]. Restless legs syndrome should be differentiated from drug-induced akathisia (e.g. antiemetics, neuroleptics, antipsychotics, serotonin reuptake inhibitors and tricyclic antidepressants), positional discomfort and arthritis. Other disorders such as nocturnal leg cramps, restless insomnia and vascular insufficiency should also be distinguished from restless legs syndrome.

Treatment. Treatment of restless legs syndrome begins with an assessment of potential factors that may aggravate the symptoms. Medications that can aggravate the symptoms of restless legs syndrome, such as dopamine-blocking agents, antiemetics, antihistamines and antidepressants, should be avoided. Other non-pharmacologic approaches consist of good sleep 'hygiene', behavioural interventions (for example a brief walk before bedtime and a hot bath) and avoidance of alcohol, nicotine and caffeine, especially in the evening [7].

Iron deficiency, confirmed by a low ferritin level, should be treated, as it has been reported that iron supplementation improves the symptoms of restless legs syndrome [4]. When drug management is required, dopaminergic agents are considered the first line of treatment in idiopathic restless legs syndrome. Other agents that have been shown to improve the symptoms of restless legs syndrome are opiates, benzodiazepines and anticonvulsant agents.

Telangiectases

Definition. Telangiectases (Latin: tel, end + Greek: angos, vessel + ectasis from Greek: ektasis, expansion) are chronically dilated capillaries or venules. They appear on the skin and mucous membranes as small, dull red, linear, stellate or punctate markings. Telangiectases (telangiectasia) represent dilatations (expansion, stretching) of pre-existing vessels without any apparently new vessel growth (angiogenesis) occurring. As such, telangiectases can be bracketed with spider angioma (spider naevi) and capillary aneurysm–venous lakes, whereas vascular malformations represent anomalies of embryological development (disturbances in vasculogenesis or angiogenesis). Hamartomas include proliferation of other tissue elements, for example melanocytic or eccrine cells, and are not solely vascular [1].

Telangiectasia can also be part of chronic venous insufficiency. The red lesions have a higher oxygen content than the blue lesions, suggesting a different origin in the capillary bed [2].

Development of telangiectasia [3]

The common telangiectases can be explained by abnormalities in the organization and ultrastructure of the small vessels rather than by neovascularization (angiogenesis) or random anastomoses.

The *macular telangiectases* seen in scleroderma, generalized essential telangiectasia and naevus flammeus are produced by dilatation of the postcapillary venules of the upper horizontal (subpapillary) plexus.

Cherry angiomas are produced by spherical and tubular dilatations of capillary loops in the dermal papillae with tortuous cross-connections between individual loops.

Telangiectasia macularis eruptiva perstans is a rare form of cutaneous mastocytosis. Clinically, there are tan-to-brown macules with patchy erythema associated with telangiectases that usually involve the trunk. Histologically, there may be only subtle alterations in mast cell numbers. The cells tend to be fusiform and loosely arranged around the dilated vessels of the superficial plexus. Eosinophils are usually absent [4].

Angiokeratomas of Fabry and Fordyce have the ultrastructure of collecting venules that contain valves and appear to represent the ectopic development of small valve-containing collecting veins.

The cutaneous lesions of hereditary haemorrhagic telangiectasia (HHT) represent microvascular arteriovenous anastomoses.

The development of telangiectases is a complex dynamic process with different mechanisms likely to be involved. In HHT, for example, where arteriovenous anastomoses cause focal dilatations of postcapillary venules, different genetic mutations (discussed on p. 47.17) interfere with integral membrane proteins on vascular endothelial cells responsible for binding transforming growth factor-β (TGF-β). TGF-β signalling mediates vascular remodelling through effects on extracellular matrix production [5]. Disruption of this latter maturation phase of angiogenesis seems to be important in the development of HHT [6].

Secondary telangiectasia and dilatation of pre-existing vessels

Telangiectases commonly represent the effect of wear and tear on the skin, and are particularly frequent in ageing, on light-exposed skin, or following trauma or X-irradiation, and in some skin diseases such as lupus erythematosus and dermatomyositis. In fact, they are found in most processes that cause atrophy of the skin, whatever their aetiology; they are prominent, for example, in poikiloderma. Smoking and UV-radiation are known to have a detrimental effect on human skin, characterized by elastosis and telangiectasia. The association between increasing age, sun exposure and the amount of telangiectasia is strong in men but less apparent in women. Similarly, smoking is associated with elastosis in both sexes but only with telangiectasia in men [1].

Prolonged vasodilatation may be followed by permanent telangiectases, for example, in rosacea. Varicose veins are frequently the cause of telangiectases on the legs, where they may produce a type of arborescent telangiectasia. Telangiectasias associated with chronic venous disease are assumed to be the result of a rise in venous pressure, which stretches the vulnerable venous end of the capillary or draining venule [2]. The significance of telangiectases of the lower limbs must not be underestimated. Considered a 'cosmetic' problem, their presence is often indicative of early or established abnormalities in the main leg veins. Telangiectases may be individual or they can arise in sheets or have an arborizing appearance. The colour of the telangiectasia depends on the calibre of the dilated venule. Large dilatations (<1 mm) are dark blue and often palpable. The smallest (0.1 mm), most superficial, telangiectases are red and barely empty when the leg is raised. Telangiectasias have been classified by Duffy (Table 47.2) [3]; some of the more important causes are listed in Table 47.3.

Table 47.2 Vessel classification (Duffy, 1988 [3]).

Type I	Spider veins, 0.1–1 mm diameter telangiectatic matting <0.2 mm diameter
Type II	Venulectasia 1–2 mm
Type III	Reticular veins 2–4 mm diameter feeder veins
Type IV	Non-saphenous varicose veins, 3–8 mm
Type V	Saphenous varicose veins

Table 47.3 Some causes of telangiectasia.

Secondary telangiectasia
Prolonged vasodilatation (rosacea, varicose veins)
Prolonged exposure to sunlight, tar, etc.
Post-traumatic
Radiodermatitis
Xeroderma pigmentosum
Atrophy, e.g. poikiloderma, topical corticosteroids
Raynaud's disease
Lupus erythematosus
Dermatomyositis
Systemic sclerosis
Morphoea
Mastocytosis (telangiectasia macularis eruptiva perstans)
Acquired immune deficiency syndrome
Primary telangiectasia
Vascular naevi
Angiomas and angiokeratomas
Angioma serpiginosum
Hereditary haemorrhagic telangiectasia
Ataxia–telangiectasia
Generalized essential telangiectasia
Unilateral naevoid telangiectasia syndrome
Hereditary benign telangiectasia
Spider telangiectases
Bloom's syndrome
Morquio's syndrome
Angiotropic lymphoma
Mycosis fungoides
Naevus anaemicus with telangiectatic vessels
Cutis marmorata telangiectatica
Solitary plaque-like telangiectatic glomangioma

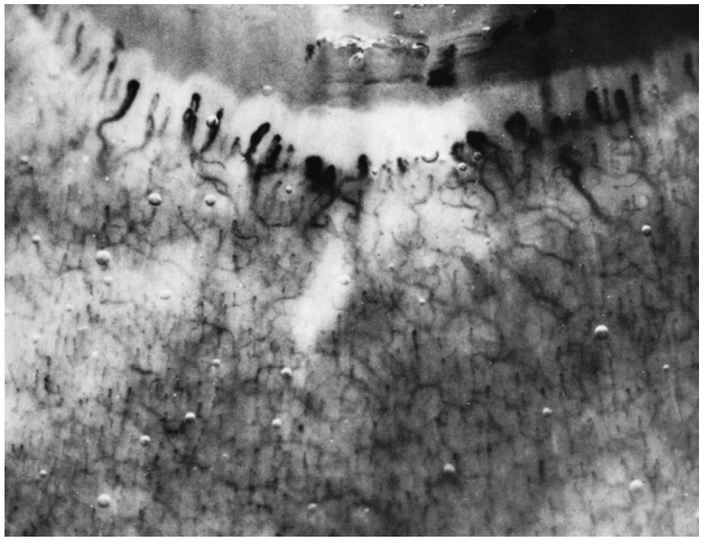

Fig. 47.12 Nail-fold capillaries in scleroderma. (Courtesy of Dr H.R. Maricq, Lyons, NJ, USA.)

The term *corona phlebectatica paraplantans* (venous ankle flare) [4] is used to describe perimalleolar and paraplantar venous telangiectasia that is always associated with venous hypertension. In contrast, telangiectases around the lower border of the ribs ('costal fringe') are virtually physiological in old age.

Telangiectases may be an important diagnostic sign in certain systemic disorders, especially in lupus erythematosus, dermatomyositis and scleroderma, or in association with Raynaud's phenomenon.

Capillary microscopy of nail-fold telangiectases may help in the differential diagnosis (Figs 47.11 & 47.12). Usually, the distribution and associated abnormalities leave little doubt about the diagnosis, but occasionally telangiectases may be the presenting or only sign, or may be the result of an otherwise burnt-out process. Patients with scleroderma, especially of the so-called Thibierge–Weissenbach or CREST type, may present with telangiectases that closely mimic HHT, and that may even cause severe bleeding. Patients with dermatomyositis may have telangiectases on the eyelids, hands or elsewhere. Localized areas of telangiectases on the face may be a manifestation of discoid lupus erythematosus. Telangiectases of the face and also of the mucous membranes are a common feature of Raynaud's phenomenon without other evidence of scleroderma. Telangiectases may be a manifestation of neonatal lupus erythematosus, with or without any other eruption [5].

Unusual mat-like telangiectases, especially on the upper back, have been reported in men working in an aluminium plant [6]. Telangiectases on the chest wall [7] and other sites [8] have been reported in patients with AIDS. Telangiectasias are also described in other conditions, including cutaneous mastocytosis (telangiectasia macularis eruptiva perstans) and angiotrophic (intravascular) lymphoma [9].

Spider telangiectases

Synonyms
- Arterial spider
- Spider naevus
- Naevus araneus
- Spider angioma

Aetiology and pathology. Spider telangiectases occur in up to 15% of completely normal persons, and more frequently in children [1,2]. They occur in large numbers during pregnancy—one or more spider naevi are found in two-thirds of all pregnant women [1]. They may appear in the first few months, but tend to increase in number until term; they usually disappear within 6 weeks of delivery but may persist or recur in the same sites in subsequent pregnancies. They are also characteristically found in patients with liver disease, when they can be a presenting sign [3]. A relationship to oestrogens has been suggested on this clinical evidence. Palmar erythema may be associated with spider naevi, with or without liver disease or pregnancy.

Fig. 47.13 Spider telangiectasis.

The main vessel of the spider telangiectasis is an arteriole. The blood flows from this to the periphery, and then passes into a capillary network [4]. The pressure in spider telangiectases rises to 40 mmHg. The lesions consist of a central, ascending, spiral, thick-walled arteriole which ends in a thin-walled ampulla just beneath the epidermis. From the ampulla, thin-walled branching channels radiate peripherally in the papillary dermis. Glomus cells have been described in the wall of the central arteriole [5]. Therefore these lesions actually resemble microarteriovenous malformations.

Clinical features. Spider naevi vary in size and shape, and may be up to 1.5 cm across. The central body may be raised, and is usually pulsatile on diascopy. The radiating vessels are just visible to the naked eye (Fig. 47.13). They occur on the upper half of the body, especially the face, neck and hands. They are frequently solitary, but may be multiple, even in health. Liver disease is seldom found, but should be suspected at any age when lesions are numerous. They may develop at sites of trauma and may be unilateral [6]. Similar lesions occur on the mucous membranes of the lips and nose. Here, the typical morphology is less apparent and the differentiation from HHT may be difficult.

The majority of lesions that occur in pregnancy disappear spontaneously, but some may persist. Lesions appearing in otherwise healthy children tend to persist indefinitely, but a small proportion regress spontaneously.

Diagnosis. The typical morphology, with a central pulsating vessel, does not occur in other conditions. In HHT, the telangiectases are macular, punctate or linear; when they are stellate they do not pulsate.

Cherry angiomas

Synonym
- Campbell de Morgan spots

These are particularly common on the trunk of middle-aged or elderly people. They disappear in extreme old age. Increased numbers have been recorded in diabetics [1], but this association is of doubtful significance. Ultrastructural examination has shown that they have reduplicated basement membranes with fenestrations of the endothelium [2,3].

When fully developed they are readily recognized. Tiny lesions, which may be very numerous (sometimes termed 'multiple minute Campbell de Morgan spots'), can resemble either petechiae or other types of telangiectases. They cannot always be made to blanch with pressure, and may need to be observed repeatedly to distinguish them from petechiae, although they are readily identifiable if magnified. Larger lesions can be excised or treated with a vascular laser under local anaesthetic if they are unsightly.

Angiokeratomas

Angiokeratomas are rare lesions that appear as dark red papules and plaques arranged either discretely or in clusters. Five different types can be distinguished from their morphology and location. Angiokeratomas are probably not vascular neoplasms but acquired telangiectases of pre-existing blood vessels of the papillary dermis, although some types of venular malformation cannot be excluded. All varieties of angiokeratomas are histologically similar and they possess the ultrastructure of collecting venules with valves [4].

Telangiectasia with calcium channel blocking drugs

There have been increasing numbers of reports associating telangiectasia with calcium channel blockers [1–3], particularly in sun-exposed sites. The aetiology of this disorder is not fully understood. Usually, the telangiectasias resolve within 3 to 6 months after discontinuation of the drug [4]. In a study of renal transplant recipients the grade of photodamage was strongly associated with the use of calcium channel blockers [5].

Venous lakes [1]

A form of senile angioma found on the face, lips and ears of elderly patients. Histologically, they consist of greatly dilated, thin-walled venules without the proliferation of vascular tissue found in the true angioma. There is degeneration of the supporting connective tissue [2]. Treatment consists of primary excision of the lesion rather than laser therapy.

Hand varices

Small varicosities of the palms and fingers, particularly on the palmar phalangeal creases, are much more common than generally is known in elderly people [1]. They can be treated, like other varicose veins, with sclerotherapy [2] or with the Müller technique of phlebectomy [3].

Primary telangiectasia

Angioma serpiginosum [1–4]

Angioma serpiginosum is a rare naevoid disorder affecting the small vessels of the upper dermis. Histology shows that the affected papillae are distended by a large, single, ectatic capillary, lined by flattened endothelial cells of normal appearance. Inflammatory changes are not present. The disease occurs predominantly in females (90%), and usually starts in childhood. Most cases are sporadic, but a family history suggesting X-linked dominant inheritance has been reported [5].

The commonly affected sites are the lower limbs and buttocks, but it can be more widespread (Fig. 47.14). It is often unilateral initially. Characteristically, there are red or purple puncta up to 1 mm in diameter. These are grouped in areas a few centimetres across, or sometimes form large sheets. Irregular lesions may arise, and commonly there is livedoid patterning of the puncta. Frequently, there is a background of more diffuse erythema. The lesions may not blanch completely on pressure, but, like multiple minute Campbell de Morgan angiomas, they have been confused with purpura [6]; that they consist of a cluster of small vessels rather than purpura can readily be distinguished by appropriate magnification [7].

(a)

(b)

Fig. 47.14 Angioma serpiginosum. (a) Grouped lesions. (b) Close-up appearance.

The condition starts as one or more small lesions, and usually ceases, but may recommence in adult life. Individual puncta often disappear spontaneously, and complete regression of the eruption may occur, or traces may persist indefinitely. There are no symptoms, and no other changes in the skin, although slight atrophy has been reported [8].

The dilated capillaries are easy to see under the capillary microscope. The background erythema is the result of dilatation of the subpapillary venous plexus. Epiluminescence microscopy can be helpful in diagnosis by demonstrating 'red lagoons'. Histologically, dilated and tortuous capillaries are observed in

the papillary dermis but without any inflammation or red cell extravasation.

The differential diagnosis includes angiokeratoma corporis diffusum, angiokeratoma circumscriptum naeviforme and forms of capillaritis. Treatment with vascular laser, such as pulsed dye laser and intense pulsed light source, improves the disorder, but is not always necessary [9].

Hereditary haemorrhagic telangiectasia [1]

Synonym
- Osler–Rendu–Weber syndrome

Hereditary haemorrhagic telangiectasia (HHT) is an autosomal dominant disorder characterized by epistaxis, cutaneous telangiectasia and visceral arteriovenous malformations (AVMs). HHT is more prevalent than previously estimated [1]. The clinical diagnosis is made on the basis of: (i) epistaxis—spontaneous, recurrent nose bleeds; (ii) telangiectases—multiple, at characteristic sites (lips, oral cavity, fingers, nose); (iii) visceral lesions—such as gastrointestinal telangiectasia (with or without bleeding), pulmonary AVMs, hepatic AVMs, cerebral AVMs, spinal AVMs; and (iv) a family history—a first-degree relative with HHT. Three criteria indicate a definite diagnosis of the disorder; two a possible or suspected case [2].

Aetiology and pathogenesis. HHT has an autosomal dominant inheritance pattern associated with mutations in at least two genes. Mutations in the endoglin (*ENG*) gene on chromosome 9q34 are responsible for HHT1, while mutations in the activin receptor-like kinase 1 (*ACVRL1*) gene on chromosome 12q are responsible for HHT2. The corresponding proteins, endoglin and ALK-1, are specific endothelial receptors of transforming growth factor β (TGF-β) [3]. TGF-β signalling is essential during angiogenesis and can activate ALK-1 and ALK-5 in endothelial cells, each one leading to opposite effects on endothelial cell proliferation and migration [4]. In HHT there is decreased endoglin expression and impaired ALK-1. HHT1 families have a higher prevalence of pulmonary AVMs than HHT2 families, who generally have a milder phenotype and later onset. Mice lacking the *ENG* or *ACVRL1* genes develop age-dependent vascular lesions of the skin of the extremities, oral cavity and internal organs in a phenotype very similar to the human condition [5].

Fig. 47.15 Hereditary haemorrhagic telangiectasia.

Clinical features. Recurrent epistaxis is usually the presenting symptom. It may begin in childhood or even in infancy, but far more commonly begins at puberty or in early adult life. Telangiectasia of the skin is not often seen before puberty, and usually appears in the third or fourth decade, but it may be extensive in early childhood. The individual lesions are punctate or linear. On the rare occasions when they are spider naevus-like, they do not pulsate. Nodular lesions may be present but are sparse in comparison with the smaller lesions, which may be numerous. Lesions may occur anywhere, but especially on the upper half of the body—face, lips, ears, conjunctivae, trunk, forearms, hands and fingers (Fig. 47.15). They are often conspicuous in the nail beds. The soles and toes may also be affected. The skin lesions seldom bleed.

The mucous membranes are almost invariably involved. Lesions occur on the nasal septum, in the mouth, nasopharynx, and throughout the gastrointestinal tract [2,6,7], where they may be demonstrated by endoscopy or arteriography. They may also be found in many other organs, including the retina. The lesions on the tongue have a characteristic and perhaps diagnostic appearance on capillary microscopy. Within a fungiform papilla there is a single, very dilated vessel, which may cause the papilla to be expanded [8]. Haemorrhages may occur from any site, and their severity and frequency determine the clinical manifestations and course of the disorder. Pulmonary arteriovenous fistulae are present in some cases, and occur particularly in some families [9,10]. They reveal their presence by dyspnoea, cyanosis and

clubbing of the fingers in adolescence. They can be demonstrated radiologically. Paradoxical embolization to the systemic circulation may occur. This disease is the commonest cause of pulmonary arteriovenous anastomoses. Cerebral vascular malformations occur in 10% of patients with HHT [11]. Hepatic arteriovenous anastomoses have been reported, and liver enlargement and cirrhosis also occur [9,11]. Aneurysms of other vessels, including the aortic arch and splenic artery [6], have been reported. Lesions of the eye [12] are uncommon.

Diagnosis. The history, family history and morphology of the individual lesions are usually sufficient to establish the diagnosis. The lesions do not have the characteristic morphology of a spider naevus. Other causes of telangiectasia have to be excluded. Epistaxis and the family history taken together usually permit the detection of patients potentially affected by HHT. The patients with known genetic mutations or clinically suspected familial HHT are then subjected to complete clinical screening. Screening programs are aimed at pre-symptomatic detection of AVMs in the brain or lung and should be recommended for all HHT patients and their relatives at risk [13].

It is recommended that patients with HHT have a complete blood count and haematocrit, evaluation of faeces for occult blood, brain MRI with and without gadolinium to screen for cerebral AVMs, and contrast echocardiography to screen for pulmonary shunting. Chest CT is done to characterize pulmonary AVMs if shunting is found. Screening for liver involvement is not currently performed on a routine basis [2].

Treatment. In mild cases, no treatment is needed. Anaemia from recurrent nosebleeds or gastrointestinal bleeding can be controlled with oral or parenteral iron, and sometimes blood transfusions are necessary for some patients. Laser therapy or intense pulsed light source (IPLS) treatment of telangiectasia of the skin and mucosae can be considered, if lesions bleed or for cosmetic reasons.

Epistaxis is the most common emergency, as it can be massive. Photocoagulation laser or septal mucosal dermoplasty is recommended if administration of tranexamic acid at high doses or combined oestrogen–progesterone preparations does not have any effect. Pulmonary AVMs are safely treated using transcatheter embolization. Although most neurological symptoms in HHT are treated by transcatheter embolization, stereotactic resection or stereotactic radiosurgery are occasionally necessary. Liver involvement may be silent, as the majority of patients remain symptomless throughout their lifetime. Organ transplant remains the treatment of choice when hepatic fistulae cause complications or if very severe liver insufficiency develops. Gastrointestinal bleeding can be treated medically by iron therapy and combined oestrogen–progesterone preparations [2,13].

The disease does not usually shorten life. The mortality rate is less than 10%.

Ataxia–telangiectasia

Synonym
- Louis–Bar syndrome

Ataxia–telangiectasia [1] is a rare, autosomal recessive disease with pleiotropic involvement of the nervous and lymphoid systems, caused by homozygous mutations in the ataxia–telangiectasia mutated (*ATM*) gene (OMIM: 208900, gene map locus 11q22.3) [2]. Defective repair of DNA damaged by UV-light, gamma or X-rays is responsible for its development. Most mutations are frameshift and nonsense mutations that are predicted to cause truncation of the ataxia–telangiectasia protein; the less common mutations are missense, splicing and there is one in-frame deletion [3]. Mutation of ATM causes defective cell cycle checkpoint activation, a reduced capacity for repair of DNA double strand breaks and abnormal apoptosis, all of which contribute to the major features of ataxia–telangiectasia, including genomic instability, increased cancer risk and neurodegeneration [4].

The syndrome manifests with telangiectases, progressive cerebellar ataxia, combined immunodeficiency and marked susceptibility to cancer, particularly lymphoma and leukaemia [2]. A diminished level of, or an absence of, IgA is characteristic of the condition but there may be a reduction in other immunoglobulins. Defects of T and B cell function may also be present.

Affected children, who are usually small, are apparently normal until the second year of life when they are noticed to be clumsy, and the ataxia becomes progressive, so that by the age of 12 years they are unable to walk without assistance. Other signs of cerebellar disease, such as nystagmus and slurred speech, and mental deterioration may be observed. Neurological symptoms may not begin before the age of 6 years. Telangiectases may be present as early as the second year of life, but usually develop between the ages of 3 and 5 years. They first appear on the bulbar conjunctiva, and subsequently involve the ears, eyelids and the butterfly area

Fig. 47.16 Ataxia–telangiectasia. (Courtesy of Dr P.W.M. Copeman.)

of the cheeks and limbs (Fig. 47.16). Not all sites are affected in every case and bleeding is very uncommon. There may be some associated skin atrophy and dryness. The hair goes prematurely grey. Disturbances of pigmentation and eczematous lesions may also be present [5], as may granulomas [6]. Recurrent sinus and pulmonary infections are frequent, and may dominate the clinical picture; they are not infrequently fatal. Ovarian agenesis is not uncommon.

Ataxia–telangiectasia needs to be distinguished from other neurological disorders with similar features, including the ataxia–telangiectasia-like disorders ataxia oculomotor apraxia 1 and 2 [7].

The laboratory diagnosis currently relies on the measurement of serum alphafetoprotein (AFP), which is elevated in patients with ataxia–telangiectasia, and on demonstrating cellular sensitivity to ionizing radiation. Improved diagnostic testing by immunoblotting of nuclear lysates from lymphoid cell lines for ATM has been described [8]. After the age of 10 years, magnetic resonance imaging (MRI) shows cerebellar atrophy. These patients should have as few ionizing radiological investigations as possible.

Management is discussed in Chapter 15.

Generalized essential telangiectasia

Generalized essential telangiectasia [1–3] is a condition that is not as rare as the paucity of reported cases suggests. Many cases may be misdiagnosed as atypical HHT. The heading 'essential telangiectasia' probably includes more than one disease.

The condition occurs more frequently in females, and commonly starts in late childhood or early adult life. Generalized essential telangiectasia is characterized by a widespread cutaneous distribution with extensive sheets of telangiectases on the limbs or body (Fig. 47.17). The lesions may progress and become permanent when they are accentuated by dependency. There is an absence of coexisting epidermal or dermal changes [4]. The telangiectases are usually linear, but small angiomas may be present. Recurrent haemorrhages from the skin and mucous membranes or into the eye may produce incapacity, but in the majority of cases, the disease is only of cosmetic importance.

The diagnosis is made by excluding other causes of telangiectases. HHT is distinguished clinically by the distribution of the lesions, their presence in large and sometimes asymmetrical sheets, and by the absence of haemorrhages associated with generalized essential telangiectasia. High-energy, long-pulsed, frequency-doubled Nd:YAG laser treatment may be helpful but lesions tend to recur [5].

Unilateral naevoid telangiectasia syndrome

Unilateral naevoid telangiectasia can be congenital or acquired. There have been reports that suggest an increase in oestrogen and progesterone receptors in the skin. When this syndrome is acquired, it arises almost exclusively during periods of relatively increased oestrogen levels such as during pregnancy or puberty or in association with alcoholic cirrhosis or hepatitis C infection [1]. Polymorphic light eruption has been described confined to an area of acquired naevoid telangiectasia [2].

Hereditary benign telangiectasia

This disorder probably has a dominant inheritance [1] and is characterized by the presence of extensive telangiectases resembling generalized essential telangiectasia, starting in childhood and without other systemic lesions [2,3]. Less commonly, the telangiectases may be present at birth [4]. They tend to occur more in light-exposed skin. Histology and electron microscopy have been used to distinguish this condition from HHT [5]. Distinction from HHT is dependent on the lack of bleeding, although lesions do appear related to arteriovenous anastomoses as in HHT [6].

Naevus anaemicus with telangiectatic vessels [1]

Following dermabrasion of the epidermis over a naevus anaemicus, enlarged telangiectatic vessels were observed within the previously pale area. The area was transplanted with thin epidermal grafts but 1 year later the naevus anaemicus looked the same as before grafting. The explanation proposed for a naevus anaemicus and port-wine stain coexisting was vascular twin spotting, but the primary abnormality could be telangiectasia with surrounding skin blanched through a 'steal' effect of blood flow.

Treatment of telangiectasia [1,2]

The central vessel of a spider naevus can be destroyed with electrolysis or pin-point 'hyfrecation' without anaesthetic. A significant proportion of such lesions recur, which may be related to the origin of the lesions; that is mini-arteriolovenular malformations with relative high pressure. Larger, isolated angiomas can be treated by complete excision. Treatment of extensive small lesions is unsatisfactory. Various types of lasers have been recommended [3]. (Long-)pulsed Nd:YAG laser at 1064 nm, intense pulsed light source (IPLS) and the 585 nm flashlamp pulsed dye laser (PDL) all have shown a beneficial effect on telangiectasia [4–6]. IPLS is preferred because of the excellent cosmetic results without scarring. Spider naevi are also well treated by IPLS [5]. Cryotherapy is disappointing. Injection with sclerosants is a good treatment for venous telangiectasia [1–3,7]. Cosmetic camouflage is possible if no intervention is desired.

Malformations

It is convenient to consider the following separately:
1 Arteriovenous shunts
2 Arteriovenous aneurysms ('fistulae')
  i congenital
  ii acquired
3 Arteriovenous malformations.

Arteriovenous shunts

Arteriovenous shunts form an alternative peripheral system of blood flow and are an integral part of a compensating mechanism at times of capillary stress and injury. Although the pathophysiology of arteriovenous shunting has not been entirely elucidated, prolonged and diffuse patency of arteriovenous shunts may result in a syndrome of local venous dilatation and some degree of tissue ischaemia [1]. Their presence can be demonstrated by finding high oxygen saturation in venous blood and a reduced circulation time [2]. They are active in venous hypertension, varicose veins [3] and in leg ulcers [4]. They can be found in association with atherosclerosis [5] and perhaps with the hormonal changes of pregnancy [6]. Arteriovenous shunting in varicose veins appears to be a secondary rather than an initiating cause [7]. They are also active in psoriasis, in neoplasms [8] and in skin flaps. They may be responsible for the postural changes seen in angiodyskinesia, and are a feature of arborizing telangiectasia [8].

Arteriovenous fistulae

Arteriovenous fistulae [9] consist of direct connections between larger arteries and veins and are always pathological. Their various congenital and acquired forms have been given a large number of descriptive titles (cirsoid aneurysm, aneurysmal varix, pulsating angioma, etc.) but are best described here simply as congenital and acquired. Localized and pulsating, they may present as red nodules with overlying telangiectasis, like a giant spider naevus. While most common on acral sites, they also occur in the head and neck and on the trunk.

Congenital. These are discussed fully elsewhere (Chapter 18). They result from failure of embryological differentiation into an artery and vein [9]. The many clinical varieties that affect the skin and visceral organs have been grouped together under the term congenital dysplastic angiopathy [6]. When such congenital fistulae involve the limb vessels they often give rise to distinctive physical signs, described below.

Acquired. Apart from iatrogenic arteriovenous fistulae (usually for haemodialysis), acquired fistulae are almost always traumatic; they are often large, and may therefore cause significant cardiovascular effects. Early diagnosis is important. Treatment is entirely within the province of the interventional surgeon or radiologist, who should be consulted if there is suspicion of the existence of such a fistula. Treatment is by inserting a covered stent to close off the opening from 'within', or by open surgical closure.

Signs and effects of arteriovenous fistulae [10,11]

Traumatic fistulae following penetrating wounds (classically a shell splinter, or occasionally an operation) can occur anywhere in the body. They should be suspected whenever venous varicosity is unilateral or when signs of venous insufficiency develop unexpectedly after an injury. Increased warmth of a limb and the finding of a machinery-like constant murmur or a palpable thrill establish the diagnosis.

Congenital fistulae commonly affect the limbs and are often multiple. They should be suspected when unilateral varicosities present early in life without a genetic background. The limb is warmer and may be larger than the contralateral limb. Slowing of the pulse produced by inflation of a proximal tourniquet at the root (Branham's sign) is indicative of a large shunt. Duplex ultrasound or arteriography confirms the site of the fistula and indicates the size of the communications.

The effects of arteriovenous aneurysms depend on their size and the volume of blood flow through the fistula rather than its site. No cardiovascular changes may be evident when small, although there will inevitably be some permanent diversion of blood from the capillary bed. Larger fistulae cause dilatation in the superficial veins distal to the site, with a varying degree of impairment of the arterial circulation. The cardiac output increases, often considerably; the heart is dilated and the diastolic blood pressure is reduced, increasing the pulse pressure.

Embolization under angiographic control is the most effective therapy. An alternative is to mobilize the vessel and ligate all the branches (skeletonization). It is also possible to insert a covered stent to block off a localized fistula and this is the treatment of choice in a traumatic fistula in an inaccessible location. Amputation may occasionally be necessary if congestive cardiac failure is a problem.

Arteriovenous malformations

Definition. Arteriovenous malformations are fast-flow vascular lesions composed of malformed arterial and venous vessels connected directly to one another without an intervening capillary bed [12].

Pathogenesis. Arteriovenous malformations may arise during early fetal development because of a failure of regression of arteriovenous channels in the primitive plexus. Although most cases of arteriovenous malformations are sporadic, there are a few inherited syndromes whose molecular genetics have been elucidated. A mutation in the gene *RASA1* has been identified on chromosome 5q in families with capillary malformations associated with arteriovenous malformations [13]. Although the pathogenesis of sporadic lesions still has to be clarified, it may involve an aberration in the TGF-β signalling pathway [14].

Clinical features. In patients with arteriovenous malformations, 40–60% are visible at birth and a further 30% become apparent during childhood. The lesions are more common in the head and neck area than in other locations. Excessive warmth, unusual pain and bleeding episodes provide clues but can occur in other conditions. Auscultation of the lesion should detect a machinery murmur. Duplex scans are helpful screening tools. Arteriovenous malformations may progress through four different stages [15,16].

Stage I. These lesions are in the quiescent phase, are asymptomatic and usually last from birth until adolescence. During this stage, the arteriovenous malformation may either not be apparent, or may have the appearance of a port-wine stain or involuting haemangioma.

Stage II. This is the progressive stage and most commonly begins during adolescence. In this stage, which is characterized by expansion, the vascular lesions enlarge, and darken, deforming the integument and invading deep structures. On examination, the local temperature is increased, a pulse or thrill can be palpated, and a continuous murmur is heard on auscultation. Puberty, trauma and pregnancy induce progression to this stage.

Stage III. This mimics stage II; deep destruction occurs with spontaneous necrosis, chronic ulceration, pain and haemorrhage.

Stage IV. This is defined by cardiac decompensation. High-output cardiac failure may result from increased blood flow through large arteriovenous malformations.

Diagnosis. Arteriovenous malformations are diagnosed by the clinical findings and confirmed by duplex ultrasound, which also allows assessment of the flow characteristics [12]. Other vascular malformations, vascular neoplasms and other neoplasms should be excluded. Radiological evaluation is needed to confirm the diagnosis, and angiography is used to assess the extent of the lesions.

Treatment. The treatment of arteriovenous malformations can be difficult. Extreme pain, ulceration, bleeding and extensive enlargement of the malformations are indications for treatment. Multimodal treatment, including preoperative embolization and complete surgical resection, is usually necessary for the management of localized arteriovenous malformations. Complete surgical resection of the lesions may be difficult, because of their widespread nature and the risk of bleeding. Palliative embolization may be used to treat symptomatic lesions when combination treatment cannot be performed [17]. This can be repeated on many occasions.

Acroangiodermatitis of Mali (pseudo-Kaposi's sarcoma)

A pigmented, purpuric eruption occurring around the malleolae and in the skin of the dorsal forefoot (particularly the base of the second toe) suggests acroangiodermatitis. Brown to plum-red papules coalescing into plaques resemble Kaposi's sarcoma clinically. The term acroangiodermatitis was introduced by Mali *et al*. in 1965 [1]. Histologically, there is marked benign capillary proliferation, plump endothelium and red cell extravasation. Rashkovsky *et al*. [2] described five possible causes:

1 Chronic venous hypertension
2 Arteriovenous malformations
3 Iatrogenic arteriovenous shunts in haemodialysis patients
4 Paralysed limbs
5 Amputation stumps.

Stewart–Bluefarb syndrome

In 1967, Stewart [3] and Bluefarb and Adams [4] independently described similar lesions on the legs of patients with arteriovenous malformations; in these cases the findings are usually unilateral and a palpable thrill may be noted. The condition can lead to ulceration of the toes and forefoot, in which case an arteriovenous shunt is the more likely underlying cause.

Venous malformations

Solitary venous malformations

Definition. Venous malformations are slow-flow, non-proliferating vascular birthmarks. They are composed of anomalous ectatic venous channels [1].

Pathogenesis. The histopathology of venous malformations reveals poorly circumscribed lesions composed of irregular, endothelial-lined vascular channels, with thin lumen walls that are deficient in smooth muscle cells [2]. This supports the theory that vascular malformations result from aberrant vascular development. Most cases of venous malformations are sporadic, but familial venous malformations can occur and are inherited in an autosomal dominant manner [3,4].

Clinical features. Venous malformations are present at birth, but typically become more prominent as the patient ages. The lesions usually present as soft, compressible blue masses that enlarge when the affected area is in a dependent position or with physical activity. The blue colour is pathognomonic and is caused by the presence of ectatic anomalous venous channels within the dermis. Venous malformations on the extremities are usually localized or segmental, although extensive deep involvement is common. Extensive, pure venous malformations of the extremities may extend into the skeletal muscles and joints and may be associated with either diminished girth or slight hypertrophy of the affected limb. Pain is a common complaint in extremity lesions and other complications include bleeding and phlebolith formation [1].

Diagnosis. The diagnosis of a venous malformation can be confirmed with MRI, which is also helpful in delineating the extent of the involvement of the lesion using the STIR sequence [5]. A coagulation profile, including D-dimer and fibrin, should be obtained to exclude an underlying coagulopathy. Localized intravascular coagulation within a venous malformation may result in abnormal coagulation profiles (consumptive coagulopathy) and may lead to episodes of bleeding and/or thrombosis.

Treatment. A multidisciplinary approach is essential for management of venous malformations. The general goals of therapy are to limit or avoid distortion of the facial features, limit bone deformation, preserve function and minimize painful swelling. Venous malformations may be treated with foam sclerotherapy [6] or surgery, or a combination of both. Large lesions, especially those extending into muscles and joints, are usually treated conservatively. Compression helps to decrease the discomfort caused by the venous malformations by reducing the volume, protecting the overlying skin, limiting swelling and improving localized intravascular coagulation.

Disorders associated with venous malformations

Klippel–Trenaunay syndrome

Definition. Klippel–Trenaunay syndrome (KTS) was first described in 1900, when Maurice Klippel and Paul Trenaunay reported two patients with a capillary malformation, varicosities and hypertrophy of soft tissue and bone in their lower limb [7]. In 1907, Frederick Parkes-Weber independently reported several cases similar to those described by Klippel and Trenaunay, though his cases were caused by multiple congenital arteriovenous malformations [7]. KTS is characterized by a capillary malformation (port-wine stain) of the skin associated with a soft tissue and bone overgrowth hypertrophy of the affected limb, in combination with varicose veins with or without deep venous and lymphatic abnormalities [8].

Pathogenesis. There are many theories on the aetiology of KTS and the genetic component is being defined. The disease may be best explained by either a paradominant disorder with autosomal lethal genes surviving only in the mosaic state, or as an autosomal dominant condition with incomplete penetrance (OMIM: gene map locus 8q22.3) [9,10]. KTS may be caused by a somatic mutation in a factor critical to vasculogenesis and angiogenesis during embryonic development [9].

Clinical features. The condition is characterized by the triad of: capillary malformations (port-wine stain/naevus flammeus), venous malformations (abnormal varicosities, persistent embryonal veins, and sometimes agenesis of deep veins or avalvulosis), with disproportionate limb growth of soft tissue and/or bone. It usually presents soon after birth. The naevus usually appears first; 95% of KTS patients exhibit a capillary malformation (port-wine stain), usually involving only the affected limb but sometimes extending beyond [11]. It usually has a metameric distribution. Limb hypertrophy develops later in childhood. Venous abnormalities may not be evident until adolescence. Lymphatic abnormalities frequently coexist, and affected children may present with a swollen limb. The surface veins are large and extensive with an abnormal distribution. A characteristic feature is a large ectatic 'primitive' vein in the lateral thigh. Varicosities may extend into the pelvis as well as down the leg. Superficial and deep-vein thrombosis is not uncommon, even in children. The bones may overgrow, resulting in increased leg length. Soft-tissue hypertrophy often occurs but may be difficult to distinguish from swelling caused by oedema or engorged veins or lymphatics. Pain is a significant and debilitating problem in KTS patients and has various causes [12].

Skin changes occur because of venous hypertension and abnormalities of lymphatic drainage. Other abnormalities associated with the syndrome include lymphangiectasia (cutaneous vesicles that leak lymph).

The abnormal veins (varicosity) lead to a significant increase in venous volume with age. As a consequence, the flow diminishes and the risk of deep and/or superficial thrombosis rises. There is also some evidence for a coexisting coagulopathy. These factors explain the high incidence of thrombosis in KTS patients. An acquired post-thrombotic syndrome aggravates the severity of KTS.

Diagnosis. The diagnosis is largely clinical. Physical examination should include auscultation and palpation of the involved area to assess for the presence of an arteriovenous malformation to rule out Parkes-Weber syndrome [8]. Duplex ultrasound scanning is the study of choice to evaluate for superficial and deep venous anomalies, and can also be used in differentiating vascular tumours from vascular malformations and arteriovenous fistulae [8,9]. MRI scans are effective for visualizing the extent of tissue overgrowth of lesions and infiltration of deeper tissues. X-rays may show increased thickness or abnormal density of the affected soft tissue as well as phleboliths [9]. Venograms may be required to delineate the venous abnormality and to exclude deep vein agenesis.

The differential diagnosis consists of other diseases associated with limb enlargement combined with a vascular lesion, for example Proteus syndrome, Parkes-Weber syndrome, Servelle–Martorell syndrome and hemihypertrophy with multiple lipomas. Other disorders that should be excluded are infantile haemangioma, kaposiform haemangioendothelioma and tufted angioma [8].

Treatment. Most patients with KTS can be managed conservatively with medical elastic compression stockings (MECS) to control venous hypertension, although patients with atresia of the deep venous system may complain of pain with compression [8]. Anticoagulants are administered to adults with thrombosis and anticoagulant prophylaxis is recommended after surgery, but long-term prophylaxis is not normally necessary, unless the patient is exposed to long periods of immobilization, for example long-term bed rest or air travel. Oral contraceptives should be avoided in women with KTS [9]. In treating varicose veins, (echo-guided) sclerotherapy is the treatment of first choice. Venous stripping, ligation or sclerosis can result in favourable outcomes in carefully evaluated and selected patients with symptomatic superficial varicose veins. If necessary, cutaneous lesions can be treated with vascular lasers or IPLS. Large limb-length discrepancies have been treated by osteotomy or epiphyseodesis as well as by epiphyseal stapling (which can be removed if further growth is required) [9,13].

Parkes-Weber syndrome

This syndrome was first described by Sir Fredrick Parkes-Weber in 1907. He reported a case involving arteriovenous fistula, together with varicosities and hypertrophy of the affected extremity. This syndrome is caused by congenital multiple arteriovenous fistulae, but can manifest with varicose veins and limb overgrowth as in KTS. There is no associated vascular naevus. Limb overgrowth gets progressively worse in Parkes-Weber syndrome, whereas in KTS leg-length disparity rarely increases after the age of 10 years [14]. Parkes-Weber syndrome more commonly affects the lower extremities, and lymphatic anomalies and lymphoedema can be present [8]. An obvious pulsatile swelling may be visible with discoloration of the overlying skin and large veins radiating from it. Duplex ultrasound demonstrates high blood flow and abnormal enlargement of the arteries [14]. During childhood, duplex ultrasound often shows enlarged arteries and patchy areas of hypervascularization; arteriovenous fistulae usually develop around puberty or after trauma. This disease may be complicated by cardiac enlargement and high-output congestive cardiac failure [8].

Conservative management consists of medical elastic compression stockings to prevent venous hypertension. Congestive cardiac failure requires active treatment. Repeated embolization under angiographic control is the most effective therapy. An alternative is to mobilize the vessel and ligate all the branches (skeletonization). Very occasionally, amputation may be necessary.

Genuine diffuse phlebectasia

Synonym
- Bockenheimer's syndrome

Phlebectasia is the term used to describe enlarged and irregular, superficial and deep veins. Histology of the phlebectasia shows a decrease in elastin in the wall of the ectatic veins. Thrombosis and calcification are often present [15]. Phlebangiomatosis involves cavernous angiomas, which manifest with cutaneous angiomas that extend into deeper layers including bone. Both conditions resemble KTS and Parkes-Weber syndrome but without an associated vascular naevus, bone overgrowth and arteriovenous fistula.

Servelle–Martorell syndrome [16]

This syndrome describes the association of a venous, and rarely arterial, malformation with skeletal abnormalities. Unlike KTS and Parkes-Weber syndrome, the intraosseous involvement leads to hypotrophy and therefore shortening of the limb bones. Deformation of the medullary cavity and thinning of the bone cortex can result in joint destruction. Otherwise the syndrome is similar, with ectasia and aneurysmal dilatation of superficial veins resulting in gross deformity of the extremity. The deep veins may be abnormally located or be hypoplastic with absent valves. Servelle–Martorell syndrome is considered to be an inverse form of KTS [17].

Capillary malformations

Capillary malformations are among the most common vascular malformations of the skin. They include telangiectases (p. 47.12) and port-wine stains (p. 47.23).

Venous disorders

Anatomy [1–7]

Most veins contain semilunar valves; these are usually in pairs, but some veins only contain one valve leaflet and sometimes three (tricuspid) valve leaflets are present. These valves are lined by endothelium and are found especially in the smaller veins and at the junction of these veins with larger branches. They prevent the reflux of blood and are particularly important in the leg, where their integrity, and that of the calf muscle pump (the venous heart), counters the gravitational hydrostatic pressure.

There are three systems: the deep veins, the superficial veins, and the perforating veins (or perforators). The perforating veins are numerous and inconstant, and connect the other two systems. During muscular activity, blood is directed from the superficial to the deep system, up from the foot to the thigh and thence to the abdomen, before venous blood returns towards the heart. Bicuspid valves are found in all three systems. The smallest veins to contain valves lie at the dermal subcutaneous junctions [4] and the valves are extremely variable. Valves may become damaged, thickened or degenerate with age [5]. Thrombosis also causes valvular destruction and a re-canalized post-thrombotic vein is valveless, anatomically distorted and functionally inefficient [5]. The most important perforating veins are considered to be on the medial side of the calf. Incompetence of the valves in these veins has been thought to be important in the causation of venous ulceration [5].

The superficial venous system of the leg begins from the veins on the dorsum of the foot, which join the greater saphenous vein (GSV) (originally called the long saphenous vein) and the short saphenous vein (SSV). They form a dorsal arch, which connects the territory of the SSV with that of the GSV. On the plantar side of the foot the same venous network joins to a plantar venous arch that also joins both saphenous veins [6,7].

Physiology/pathophysiology

The venous macrocirculation [1,2]

Veins act as the capacitance vessels of the circulation. The 'venous return' is the blood returning to the heart via the great veins. Venous return from the lower limbs is achieved by the pumping action of the foot and calf muscles associated with competent valves that prevent backflow [1].

The venous system of the legs contains a volume of 300 to 350 mL in a healthy standing subject. The venous wall contracts in response to filling, and its function is called 'venous tone'. This acts as counter-pressure and automatically changes to attempt to maintain venous pressure at a constant level. The superficial veins drain through the communicating (perforating) veins into the deep system, and only 10% of the venous blood flow from the lower limb passes through the saphenofemoral junction (SFJ).

The deep veins are compressed by each muscle contraction shifting the blood column towards the heart against the pressure of gravity. The venous valves prevent backflow during muscle relaxation. This mechanism is the 'calf muscle pump'. Other muscle groups such as those of the foot also compress veins and aid venous return, but the calf muscle pump is the most important muscle pump of the leg.

Venous reflux

Venous reflux is thought to be the major cause of venous disorders [1]. Reflux is the presence of retrograde flow in a vein in response to a stimulus such as a calf squeeze. It occurs during standing when the valves are incompetent [2]. It can occur in the superficial, deep and perforating veins of the lower extremity.

Venous pressure falls during calf muscle pump activity in healthy subjects and is known as normal lowering of ambulatory venous pressure [3,4]. An elevated and sustained ambulatory venous pressure (venous hypertension) is indicative of chronic

venous insufficiency (CVI). This may be caused by valvular incompetence or venous outflow obstruction [5]. Venous outflow obstruction occurs in some patients after a deep-vein thrombosis (DVT), a situation known as the post-thrombotic leg. Obstruction is more serious than reflux and more difficult to treat. In this situation, when the leg muscles contract the venous pressure increases, rather than the usual lowering of venous pressure that occurs during ambulation when the vein is not obstructed. Such heightened pressure is transmitted distally as far as the capillary system of the skin, causing capillary hypertension, and eventually leading to destruction of the nutritive capillaries [6].

The venous microcirculation

Disturbances of the venous microcirculation account for almost all the clinical signs of chronic venous disease. The raised ambulatory venous pressure is transmitted directly to the venular side of the capillary bed. The capillaries in the skin of the lower leg are the most affected. Five theories have been developed to explain the mechanism for the microcirculatory disturbances in venous disease.

1 Capillary stasis. Homans postulated that 'stasis' of venous blood in patients with post-thrombotic syndrome gave rise to the development of anoxia which he thought caused venous ulcers [1]. Initially, when the oxygen content of blood samples taken from varicose veins was measured, lower values were found than in blood taken from healthy individuals [2]. One year later, however, Blalock produced completely different results. He reported that the oxygen content of the femoral venous blood of patients with varicose veins was higher than in healthy persons [3]. He concluded that the blood flow through the leg of patients with a venous ulcer was higher than that of healthy persons. Blalock's findings were subsequently confirmed by several investigators [4]. Only one study carried out in 1971 produced conflicting results [5].

When a contrast agent was injected into the femoral artery of patients with varicose veins it entered their veins faster than the veins of healthy controls [6,7]. The flow velocity may, however, be markedly decreased in certain locations in the venous system, for example in certain capillary beds. This decreased flow might be responsible for focal hypoxia [8], despite the overall increase in venous flow through the whole system.

It was shown that the transcutaneous oxygen tension ($tcPO_2$) was significantly lower in patients with CVI [9–11]. Low $tcPO_2$ values in patients with CVI cannot be fully explained at present. Morphological changes develop in the microcirculation in response to prolonged CVI and these may also play a role in the lower $tcPO_2$ value.

Microangiopathy is a prominent sign of CVI [12] and was first reported by Bollinger *et al*., who combined intravital capillaroscopy and fluorescence angiography with videodensitometry [13]. Bollinger's group measured the transcapillary and interstitial diffusion of a colorant (Na-fluorescein) into the skin of healthy volunteers. These results were then compared to results from patients with CVI. Reduced diffusion was present in the skin areas of patients with CVI that had a reduced capillary density. The density of fluorescein does not, of course, equate to oxygen diffusion. The capillary microscopy showed stagnant blood flow in some capillaries, leading to intracapillary coagulation. It was felt that capillary thrombosis might account for the disappearance of capillaries. The $tcPO_2$ value and cutaneous capillary density appear to be related [14]. The $tcPO_2$ value in capillary plexi with a low density approaches 0 mmHg at a distance of 100 µm or more between the capillaries.

2 Fibrin cuff-theory. Browse and Burnand postulated that venous ulceration could be the result of deposition of pericapillary fibrin [1]. This theory was later named the 'fibrin cuff-theory' [2]. The leakage of large molecules such as fibrinogen through the pericapillary space was caused by the high venous pressure associated with CVI. Fibrinogen was thought to polymerize to insoluble fibrin in the interstitium to form a pericapillary fibrin 'cuff'. This cuff might then function as a oxygen diffusion barrier. A signifi-

cant increase in the collagen IV layer has also been found in and around the capillaries [3]. The authors suggested that fibrin could function as a matrix for collagen formation. The role of fibrin as a diffusion barrier was never conclusively proven and theoretical objections were put forward to its ability to reduce oxygen transfer [4]. In porphyria cutanea tarda (PCT) patients, where pericapillary fibrin deposits (cuffs) are present, normal tcPO_2 values exist [5]. The fibrin deposition appears to be an indicator of microcirculatory disturbance rather than the cause of a lower tcPO_2 value.

3 White cell trapping. In patients with lipodermatosclerosis, white blood cells disappear from the venous blood when the leg is in a dependent position [1]. Coleridge Smith *et al.* formulated a new theory for the aetiology of venous ulcers on the basis of these observations [2]. They suggested that the leukocytes may become trapped in the capillaries, obstructing flow and thereby leading to ischaemic ulceration. Adhesion molecules are over expressed and may play an important role by causing continuous leukocyte migration to the dermis [3,4].

4 Trapping growth factors. Falanga and Eaglestein hypothesized that the pericapillary fibrin cuffs, which included α2-macroglobulin, interfere with growth factor transport, making them biologically unavailable in patients with severe CVI. They felt that this might also account for delayed healing of ulcers [1]. The lack of availability of growth factors is controversial. Clinical research using topical epidermal growth factor (EGF), TGF-β and fibroblast growth factor (FGF) has failed to improve the healing of venous ulcers. The addition of a single growth factor has therefore not been able to restore the process of disturbed wound healing in patients with chronic venous ulcers.

5 Multicausal model: the Maastricht model. A dynamic conceptual model has been proposed by researchers at the University Hospital of Maastricht in the Netherlands [1,2]. They suggest that a raised pressure in the capillaries acts mainly on the venular side of the dermal microcirculation. The raised microcirculatory pressure is a consequence of elevated ambulatory venous pressure. The continuously elevated pressure leads to alterations in the structure of the capillary wall, in which the interendothelial space broadens and the collagen IV layer disintegrates. The capillary wall becomes thicker [3], and the structural changes interfere with capillary exchange [4]. Collagen IV disintegrates and the interendothelial space enlarges, in turn increasing the capillary filtration fraction.

In the first instance water diffusion is affected, causing oedema [5]; later, larger molecules escape into the tissues. Accumulation of these molecules leads to halo formation [6–8]. The fibrin/fibrinogen cuffs demonstrated by immunofluorescence studies are a sensitive sign of decompensating capillaries in the skin. The fibrin cuffs do not act simply as a diffusion barrier for oxygen; the presence of fibrin also serves as a stimulus for collagen formation. Collagen IV is laid down around the capillaries and collagens I and III in the dermis. α2-macroglobulin is also laid down and this binds molecules such as TGF-β, leading to decreased biological availability of various growth factors.

Widened capillaries have a lower flow velocity. White cells marginate and adhere to the capillary walls, sometimes blocking the circulation and leading to the formation of microthrombi. The escape of plasma proteins into the tissues enhances the inflammatory response, while the escape of leukocytes into the tissues releases proteolytic enzymes causing free radical damage. This is seen clinically as the changes of lipodermatosclerosis (LDS) [9].

There is evidence of continuous collagen degradation resulting from the increased action of the proteolytically active matrix metalloproteinase-1 (MMP-1) and matrix metalloproteinase-2 (MMP-2). Evidence of increased proteolytic activity has been found in patients with LDS who have decreased fibrinolytic activity [10]. It is attractive to assume that elevated proteolytic MMP-2 expression is a consequence of plasminogen activation in LDS which might cause an elevated matrix turnover [9]. This would be responsible for structural changes in the dermis and subcutaneous tissue which could then easily ulcerate.

Clotting and fibrinolytic disturbances play a role in the development of atrophie blanche [11]. The capillaries are obliterated in the affected areas leading to local hypoxia. Minimal trauma then leads to ulceration.

Venous thrombosis

Deep-vein thrombosis

Epidemiology. Deep-vein thrombosis (DVT) has an annual incidence of 0.2% in the urban population [1]. The disease is rare in children under 15 years old, but its frequency increases with age, with an incidence of 1.8 per 1000 person-years between 65 and 69 years and 3.1 per 1000 person-years between 85 and 89 years of age [2]. First episodes of DVT account for two-thirds of cases. The prevalence of DVT is highest in Caucasian adults and is low in Asian populations. The risk of a DVT seems to be slightly higher in men than in women, and the risk of recurrent venous thromboembolism is about 60% greater in men compared to women [3].

Aetiology and pathogenesis. In 1856, Virchow postulated that the main causes of thrombus formation were damage to the vessel wall, alterations in blood flow and hypercoagulability [2]. This is called 'Virchow's triad' and is still valid today. Risk factors for DVT include cancer, immobility, surgery and thrombophlebitis.

The maintenance of the fluidity and circulation of the blood and its ability to thrombose are essential for the maintenance of life and are governed by extremely complex homeostatic mechanisms. Thrombosis is a protective mechanism which prevents loss of blood and seals off damaged blood vessels. Fibrinolysis counteracts or stabilizes the thrombosis. Alterations in blood coagulability and platelet numbers, with associated changes in blood flow and endothelial damage, are the precursors of deep-vein thrombosis. The loss of normal vascular endothelial function is probably of primary importance [4].

Factor V Leiden, a pro-coagulant mutation, is present in 8% of patients with thrombosis. Anticardiolipin antibodies are also now recognized as an important cause of thrombosis [5,6]. A number of other hereditary and acquired conditions that predispose to thrombosis (thrombophilia) have also been recognized. These include protein C and S deficiency, antithrombin deficiency, the prothrombin 20210A gene mutation and activated protein C resistance (which is usually associated with the factor V Leiden genetic abnormality). Screening for thrombophilia, and for anticardiolipin antibodies, should be performed in patients presenting with a sporadic or recurrent thrombosis [7]. Surgical operations and pregnancy remain important triggers of thrombosis. Prolonged immobility (e.g. long-haul flights) and the contraceptive pill are also well-documented risk factors (Table 47.4).

Table 47.4 Risk factors for deep-vein thrombosis [2,8].

Advancing age
Obesity
Previous venous thromboembolism
Family history of venous thromboembolism
Surgery, especially procedures lasting more than 30 min.
Trauma, especially of the spine or legs
Malignant tumours
Acute medical illnesses, e.g. acute myocardial infarction, heart failure, respiratory failure, infection
Inflammatory bowel disease
Antiphospholipid syndrome
Dyslipoproteinaemia
Nephrotic syndrome
Paroxysmal nocturnal haemoglobinuria
Myeloproliferative diseases
Behçet's syndrome
Varicose veins
Superficial vein thrombosis
Congenital venous malformation
Pulmonary embolism
May–Thurner syndrome
Long-distance travel
Prolonged bed rest or sitting
Immobilization
Hospitalization
Limb paralysis
Pregnancy/puerperium
Oral contraceptives
Hormone replacement therapy
Other drugs
Chemotherapy
Tamoxifen
Thalidomide
Antipsychotics
Central venous catheter
Vena cava filter
Intravenous drug use

Clinical features. The onset of a deep-vein thrombosis is often 'silent' and may remain so. It commonly occurs about 7 to 10 days after a surgical operation, childbirth or the onset of an acute infection. It is often associated with a rise in the platelet count and an increase in young 'sticky' platelets. Between one-third and two-thirds of patients complain of some swelling and pain in the leg, usually in the calf [4]. An iliac thrombosis should be suspected if the whole leg is swollen and dusky. There may be a pink or

Table 47.5 Clinical score list for predicting pretest probability for having a proximal deep vein thrombosis [11].

Clinical feature:
Active cancer treatment ongoing or within previous 6 months or palliative
Paralysis, paresis, or recent plaster immobilization of the lower leg(s)
Recent immobilization for more than 3 days or major surgery within last 4 weeks
Localized tenderness/pain along the distribution of the deep venous system
Entire leg swollen
Calf swelling by more than 2 cm when compared with the asymptomatic leg (measured 10 cm below tibial tuberosity)
Pitting oedema greater in the symptomatic leg
Collateral superficial veins (non-varicose)

Each factor scores 1; maximum score 8; see text for grading of risk according to score.

cyanotic hue to the leg and evidence of superficial venous dilatation. The temperature of the leg may be raised, and pitting oedema of one ankle is an important physical sign.

Diagnosis. Pain and tenderness in the calf and popliteal fossa may occur in other conditions such as a ruptured Baker's cyst, a haematoma, or muscle tears or pulls. Infection (e.g. cellulitis) and lipodermatosclerosis should also be differentiated from a DVT. These can usually be distinguished clinically.

Assessment should include a clinical score and a D-dimer test, as a negative D-dimer test, in combination with a low-risk clinical score, avoids the need for compression ultrasound (CUS) in every patient with a painful or swollen leg [9]. The clinical score, based on medical history and physical examination, divides patients into low, moderate and high-risk categories for having a DVT (Table 47.5). A score of 0 (asymptomatic) means a low probability, a score of 1 or 2 a moderate probability, and a score of 3 or more a high probability, for DVT.

D-Dimer is a degradation product of a cross-linked fibrin clot. A negative test is useful for ruling out a DVT because the test has high sensitivity, but its specificity is low; it can be raised in various other conditions, such as post-surgery, inflammation of various causes, pregnancy and cancer. A moderate or high clinical probability, or a low clinical probability in combination with a high D-dimer, should therefore be followed by CUS of the legs (Fig. 47.18). The sensitivity of CUS is 97% for proximal and 73% for distal vein thrombosis compared with phlebography. CUS has many advantages over phlebography. It is non-invasive, simple, easy to repeat, relatively inexpensive and free of complications.

There are, however, two main disadvantages of CUS. Calf vein thrombosis can be missed, especially when the examination is limited to the popliteal and femoral veins, and small isolated thrombi in the iliac and superficial femoral veins or within the adductor canal can be difficult to detect and therefore easily overlooked [10].

CUS should be repeated after 1 week if the D-dimer is high and the CUS was negative but there is still a moderate or high probability of DVT on clinical grounds. The newer investigations of CT venography and MRI imaging appear to have advantages in certain circumstances, but at present their cost and availability limit their application.

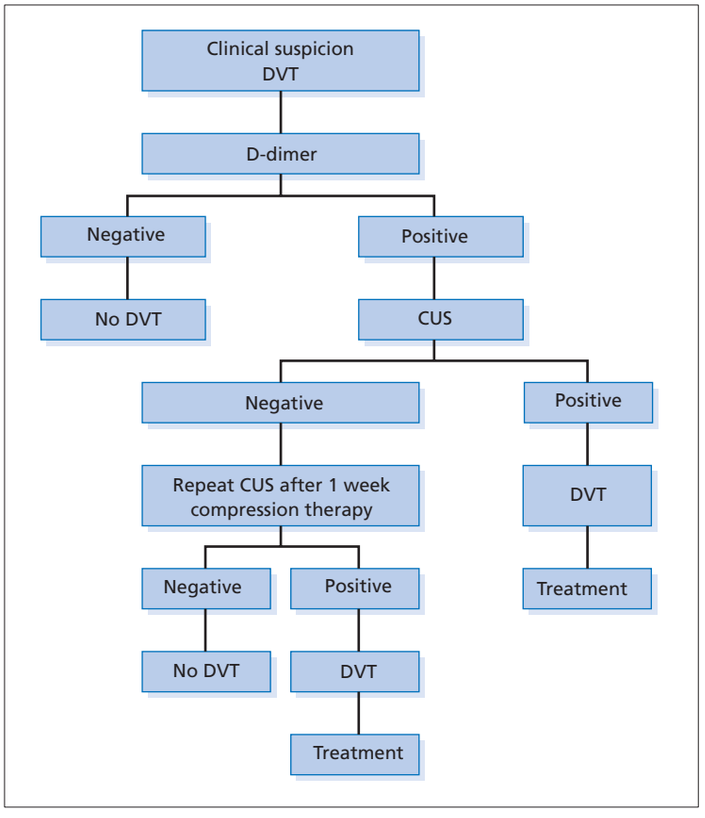

Fig. 47.18 Procedure to safely exclude deep vein thrombosis.

Treatment. Treatment includes the immediate therapy, awareness and prevention of complications and prevention of further episodes. Pulmonary embolism, post-thrombotic syndrome (PTS) and recurrent thrombosis are the main complications of DVT. About 10–30% of patients with DVT develop PTS. DVT has a recurrence rate of about 20% after 5 years, but the rate varies depending on the presence of risk factors [12]. Preventive measures should therefore be undertaken in every patient who has an increased risk of developing venous thromboembolism. Low-molecular-weight heparins (LMWH), intermittent pneumatic compression and medical elastic compression stockings (MECS) should be used as prophylaxis [13].

Active treatment is as follows. Initially a LMWH is given subcutaneously (150 to 200 IU/kg once daily). It can be given as an outpatient without the need for monitoring. It only needs to be given once daily and the risk of heparin-induced thrombocytopenia (Chapter 49) is negligible with LMWH compared with standard heparin preparations [2]. Vitamin K antagonists such as warfarin should be added to the LMWH at 24 or 48 hours unless contraindicated. Monitoring of anticoagulation is done by the prothrombin time, expressed in terms of the international normalized ratio (INR). A ratio between 2.0 and 3.0 should be achieved for adequate anticoagulation with a low risk of bleeding. LMWH can be discontinued when the correct INR has been attained [2]. Idiopathic venous thromboembolism is generally treated for 6 months, but anticoagulation may be for life if the condition recurs or a high risk exists [14].

LMWH and oral anticoagulants should be combined with compression stockings. Once oedema has reduced, class II MECS are prescribed to be worn for life. Class III MECS can be prescribed if the oedema remains a problem [15]. MECS significantly reduce the development of post-thrombotic syndrome.

Superficial venous thrombosis

Synonym
- Superficial thrombophlebitis

Incidence. Most studies report a female preponderance (female proportion between 55 and 70%) and a mean age of onset of 60 years [1].

Aetiology and pathogenesis. Several studies have described an association between superficial venous thrombosis and venous thromboembolism. Superficial venous thrombosis located in the main trunk of the saphenous vein has the strongest association with venous thromboembolism [2,3].

Predisposing risk factors for superficial venous thrombosis are similar to those for deep-vein thrombosis [3]. Superficial venous thrombosis usually develops in the lower limbs. In 60–80% of cases the greater saphenous vein (GSV) system is involved, and in 10–20% the short saphenous (SSV) system [4]. The main cause of superficial venous thrombosis of the lower limbs is varicose veins, which are present in 70% of cases [5]. The main cause of superficial venous thrombosis in the upper limb is iatrogenic, for example intravenous catheters or infusion of drugs such as chemotherapy or heroin. Mondor's disease may also be a form of superficial venous thrombosis.

Clinical features. The patient usually presents with pain and a reddened, warm, tender cord extending along the vein. The overlying skin may show signs of erythema and oedema. The differential diagnosis includes cellulitis, panniculitis, erythema nodosum, insect bites and lymphangitis [5].

Diagnosis. Duplex ultrasound can be used to confirm the diagnosis [1,4,5], and to exclude a coexisting deep-vein thrombosis. Patients should be further investigated if they have idiopathic or recurrent superficial venous thrombosis or if they have a superficial venous thrombosis without varicose veins [5].

Treatment. LMWH and non-steroidal anti-inflammatory drugs (NSAIDs) appear to be the best treatments for superficial venous thrombosis of the leg veins [3]. Sclerotherapy and stripping of any varicose veins should only be performed some months after the acute superficial venous thrombosis has settled. When a thrombus is found in or near the saphenofemoral junction or saphenopopliteal junction, especially if it extends as free-floating thrombus extending into the common femoral vein or popliteal veins, it should be treated by surgical removal, combined with ligation and stripping. The patient can receive a 3-month therapeutic course of LMWH [4]. The thrombus can be squeezed out of the vein through a needle puncture. This should be followed by application of compression bandages or stockings.

Thrombophlebitis migrans [1–4]

Recurrent migratory thrombophlebitis is an uncommon condition that affects large and small veins throughout the body. The superficial veins of the lower extremities, abdominal wall, flank, arms or elsewhere undergo segmental thrombosis, causing crops of tender, linear or oval subcutaneous lumps or streaks. This is a pattern seen in Behçet's disease (Chapter 50) [5,6]. Fazeli *et al.* [7] also found an association between thrombophlebitis migrans and Buerger's disease in 65.4% of 86 patients, though others have put this percentage lower.

Much of the literature regarding migratory thrombophlebitis is concerned with the link with underlying malignancy, termed

Trousseau's syndrome (Chapter 62). This association was carefully reviewed by Sack *et al.* [8] and by Samlaska *et al.* [9], who suggested that migratory thrombophlebitis is a chronic disorder of disseminated intravascular coagulation.

Clues to a primary hypercoagulable state include a family history, recurrent thrombosis, an unusual anatomical site, an early age of onset and resistance to conventional anticoagulation. Secondary hypercoagulable states are a consequence of malignancy, infection, pregnancy, the contraceptive pill, nephritis or liver disease [3,4,9].

A follow-up study of 4399 patients who had venography for suspected DVT recorded that 150 of 1383 with proven DVT and 182 of 2412 without thrombosis developed cancer; although the overall difference was not significant, there were significantly more cancers in the DVT group (66 cancers) than in the non-DVT group (37 cancers) in the first 6 months after the venography [10]. A more severe type of thrombophlebitis is associated with malignant disease. In 1500 cases of thrombophlebitis, 31 of 77 occurring in association with malignancy were of a migratory type [2]. Carcinomas of the lung and pancreas were the most common sites for the primary tumours, although carcinomas of the breast, colon and stomach were also reported.

Treatment. Malignancy must be carefully excluded in patients with migratory thrombophlebitis. It may be difficult to locate, especially if the patient has a pancreatic carcinoma. Computed tomography (CT) scanning, ultrasound, MRI and even positron emission tomographic (PET) scans of the abdomen may be necessary. Treatment is generally conservative, and patients should be treated with adequate anticoagulation. Lowering triglycerides may be advisable and exercise is good prophylaxis. Medical elastic compression stockings or bandages may alleviate symptoms. Stripping of the saphenous system has been advocated [1]. Earlier observations on the good effects of oral fibrinolytic agents [11,12] in Behçet's disease have not been substantiated by some later case reports [13].

Mondor's disease

The classic Mondor's disease is located in the chest wall and affects veins that include the lateral thoracic vein, the superior epigastric vein and the thoracoepigastric vein [1,2]. Similar cases have been reported in the antecubital fossa, inguinal area, axilla, penis [3], abdomen and lower limbs. The aetiology of the disorder is unknown.

Pathogenesis. A venous thrombosis which may partially or totally occlude the vein is followed by re-canalization. Fibromuscular hyperplasia develops in the vessel wall with infiltration and fibrosis of the surrounding subcutaneous cellular tissue [2]. Trauma or friction causes a sclerosing phlebitis of the affected vein and aggravates the course of the disease.

Clinical features. Women account for 75% of those affected, generally between the second and fifth decade of life [2]. Sudden, localized chest pain is the main presenting symptom, and is accompanied by the appearance of grooved, hardened 'cords' that are visible and palpable on the chest wall where they resemble wires. These cord-like structures attach to the overlying skin before retracting, with the formation of characteristic linear grooves. Patients may have fever and significant regional inflammation in the acute phase. As the disorder is self-limiting [2], relief of pain follows with complete resolution of the symptoms in about 2 to 8 weeks. Mondor's disease has been associated with primary or metastatic mammary carcinoma in up to 12% of cases [4].

Treatment. Mondor's disease is a self-limiting disease which nearly always resolves spontaneously. Anti-inflammatory agents (e.g. ibuprofen) and 75 mg salicylic acetic acid per day are recommended, plus local application of heat and physiotherapy involving gentle stretching of the cords where possible. Neither anticoagulation nor antibiotics are indicated. Resection of thrombotic vessels can be considered to treat the patient and confirm the diagnosis when symptoms are intractable.

Axillary web syndrome

Axillary web syndrome (AWS) follows axillary lymphadenectomy for breast cancer and manifests with palpable cords which

'bowstring' across the axilla, creating a web of skin [1,2]. The cords are painful and restrict shoulder movement. They can extend into the ipsilateral arm, even forearm, and can create a linear groove somewhat like those seen in Mondor's disease. Indeed, it is probably a site-specific variant of this condition, and probably has a traumatic cause; it has also been reported after skin surgery [3]. The cause is unclear but the condition usually resolves over 6 months.

Deep-vein obstruction [1]

The most common cause of chronic deep-vein obstruction is a previous DVT. Non-thrombotic causes include malignant disease or other pelvic masses compressing the iliac veins. Retroperitoneal fibrosis can obstruct the iliac veins and the inferior vena cava. The iliac compression syndrome (Cockett's or May–Thurner syndrome) is present when the left common iliac vein is compressed by the right common iliac artery crossing its course to the inferior vena cava [2]. Flow alterations do not usually cause problems unless thrombosis takes place. Large tumours (e.g. soft-tissue sarcomas) or aneurysms in the thigh may compress the deep femoral vein. In the popliteal fossa an aneurysm or a Baker's cyst can compress the popliteal vein. Primary tumours of the vein wall (leiomyosarcoma) are rare but are found more often in the lower limb. Ligation of deep veins may be unavoidable when removing a malignancy or when repairing vein damage from accidental trauma.

Chronic venous insufficiency

Classification

Several classifications have been used to describe the severity of chronic venous insufficiency (CVI), of which the classifications by Widmer *et al.* (Table 47.6) [1] and the CEAP classification (Clinical status, Etiology, Anatomy, Pathophysiology) (Table 47.7) [2,3] are the best known. The CEAP classification is a well-recognized classification for varicose veins, despite its deficiencies. In 2000, the Venous Clinical Severity Score (VCSS) was developed, which provides a slightly more detailed description of the factors contributing to CVI (Table 47.8) [4].

Chronic venous insufficiency/reflux

Chronic venous insufficiency may be classified anatomically into three categories (Fig. 47.19).

Superficial vein insufficiency. This is actually indicated by the presence of visible, tortuous, truncal varicose veins. It arises from

Table 47.6 The Widmer classification of chronic venous insufficiency [1].

Classification	Symptom
I	Corona phlebectatica paraplantaris, mild oedema
II	Hyperpigmentation, lipodermatosclerosis (LDS), atrophie blanche, oedema, eczema
III	Healed or active ulcer

Table 47.7 The CEAP (Clinical status, Etiology, Anatomy, Pathophysiology) classification [2,3].

C Clinical status	E Etiology	A Anatomy	P Pathophysiology
C0 no visible disorder			
C1 telangiectases or reticular veins	Ec congenital	As superficial	Pr reflux
C2 varicose veins	Ep primary	Ap perforating	Po obstruction
C3 oedema	Es secondary (post-thrombotic)	Ad deep	Pr,o combination
C4a pigmentation, oedema	En no known venous etiology	An no known venous location	Pn no known venous pathophysiology
C4b lipo- et dermatosclerosis, white atrophy			
C5 healed ulcer			
C6 active, venous ulcer			
S symptomatic			
A asymptomatic			

Table 47.8 The VCSS (Venous Clinical Severity Score) classification of factors contributing to chronic venous insufficiency [4].

Attribute	Absent = 0	Mild = 1	Moderate = 2	Severe = 3
Pain	None	Occasional, not restricting activity or requiring analgesics	Daily, moderate activity limitation, occasional analgesics	Daily, severe limiting activities or requiring regular use of analgesics
Varicose veins	None	Few, scattered: branch varicose veins	Multiple: GSV varicose veins confined to calf or thigh	Extensive: thigh and calf or GSV and SSV distribution
Venous oedema	None	Evening ankle oedema only	Afternoon oedema, above ankle	Morning oedema above ankle and requiring activity change, elevation
Skin pigmentation	None or focal, low intensity (tan)	Diffuse, but limited in area and old (brown)	Diffuse over most of gaiter distribution (lower 1/3) or recent pigmentation (purple)	Wider distribution (above lower 1/3) and recent pigmentation
Inflammation	None	Mild cellulitis, limited to marginal area around ulcer	Moderate cellulitis, involves most of gaiter area (lower 1/3)	Entire lower third of leg or more
No. of active ulcers	0	1	>2	>2
Active ulceration, duration	None	<3 months	>3 months, <1 year	Not healed >1 year
Active ulcer, size	None	<2 cm diameter	2 to 6 cm diameter	>6 cm diameter
Compressive therapy	Not used or not compliant	Intermittent use of stockings	Wears stockings most days	Full compliance: stockings + elevation

GSV, greater saphenous vein; SSV, short saphenous vein.

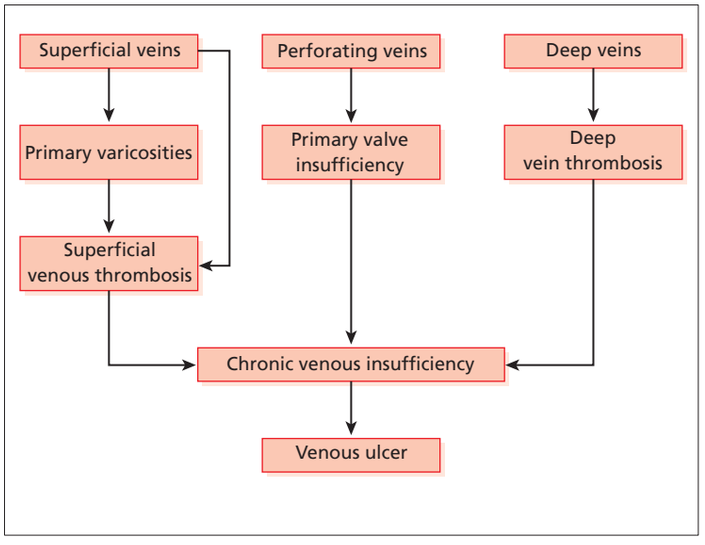

Fig. 47.19 Schematic presentation of the development of chronic venous insufficiency.

primary valve failure or when the superficial veins become distended, causing the valves to become secondarily incompetent.

Perforating vein insufficiency. This is a rare condition in isolation, when it is caused by primary valve insufficiency. Secondary perforating vein insufficiency often occurs in combination with deep vein insufficiency (post-thrombotic limb).

Deep vein insufficiency. Reflux is the most common type of abnormality, but in about 10% of cases a functional obstruction from thrombosis (non-recanalized thrombosis) will be present, in which case it is likely to be associated with the post-thrombotic syndrome. Avalvulosis is rare unless associated with a mutation of the *FOXC2* gene [1].

Reference

1 Mellor RH, Brice G, Stanton AW *et al*. Mutations in *FOXC2* are strongly associated with primary valve failure in veins of the lower limb. *Circulation* 2007; **115**: 1912–20.

Clinical signs of chronic venous insufficiency

Pitting oedema. Pitting oedema as a result of venous incompetence is worst at the end of the day and usually disappears at night. Patients may complain of a tight feeling in the oedematous leg and night cramps. The capillary filtration rate increases as a consequence of the increased ambulatory venous (and consequently capillary) pressure and overwhelms lymph drainage. This oedema always has a low protein content and pits easily, being mainly present around the ankle.

Corona phlebectatica paraplantaris (ankle flare). An ankle flare (the corona phlebectatica) is an early and important clinical sign of CVI and is a direct consequence of increased capillary pressure, which causes these vessels to expand.

Hyperpigmentation. Pigmentation in the 'gaiter skin' associated with CVI is invariably the result of haemosiderin accumulation after extravasation of erythrocytes (red cells). The pinpoint or patchy pigmentation may be minimal but may also extend over large indurated skin areas. In some cases pigmentation caused by melanin occurs as a secondary effect (post-inflammatory melanosis). Pigmentation begins modestly in the 'gaiter' area above the ankle and progresses to induration and inflammation, which indicates that lipodermatosclerosis has developed.

Pressure erythema. This is a direct result of elevated capillary pressure. Grouped, confluent, very small telangiectasiae develop. They are often found near incompetent perforating veins. Pressure erythema is often one of the first signs of evolving venous insufficiency.

Eczema. Several types can be recognized:

1 *Eczema as a result of venous disturbances* (synonyms: stasis dermatitis, hypostatic eczema, venous eczema, dermatitis venseuse). Usually this type of eczema starts round varicosities at the medial ankle, in the region of the Cockett perforating veins in the lower one-third of the leg. The eczema is relatively sharply demarcated and somewhat infiltrated with papules and vesicles, which may also extend beyond the main area of eczematous skin. Scaling and itching develops. Chronic lichenified eczema may develop with time. The aetiology is not completely clear. Homing of activated T-lymphocytes appears to be the most reasonable explanation.
2 *Allergic contact dermatitis*. This form of eczema is typically well demarcated but often with secondary involvement of adjacent or even distant non-contact sites. The most common sensitizing agents are locally applied drugs. Patch testing should be performed to exclude a contact allergic dermatitis. Patients with leg ulcers become more easily sensitized than healthy individuals [1,2], and therefore potential sensitizing agents should be avoided in these patients. Patients treated by MECS may develop an allergic contact dermatitis from the rubber constituents that provide elasticity, or from dyes that are used to give the stockings their colour.
3 *Asteatotic dermatitis* (synonym: eczema craquelé). Frequent washing may cause extreme dehydration of the skin. A morphologically similar eczema with a 'crazy paving' appearance occurs in some patients who develop rapid, lower leg oedema [3]. Patients who routinely wear MECS may develop an itching, dry and desquamating eczema. Application of a bland emollient at night will usually improve their symptoms.
4 *Impetiginization of eczematous dermatitis* (synonym: infected dermatitis). Wet eczema of the lower leg is often extensively colonized with bacteria, yeasts and fungi. Even after the infectious agent has been treated, an eczematous dermatitis may persist.
5 *Secondary spread ('id' eruption, 'autosensitization' eczema)*. Varicose dermatitis and allergic contact dermatitis may cause secondary spread onto adjacent and distant non-contact sites. Itching may develop at any site including the palms and soles.

Lipodermatosclerosis (LDS). This is a specific skin disorder that is pathognomonic of venous and lymphatic hypertension. It is a consequence of an increased matrix turnover caused by a chronic inflammatory reaction in response to escaped plasma constituents. LDS is known to be associated with an increased risk of leg ulcer development [4]. As a rule, the skin and subcutaneous tissues feel hard on palpation. At an early stage LDS may feel a little indurated and often has an inflamed, erythematous appearance. It is also quite often tender and painful. It is often confused with erysipelas, superficial venous thrombosis or even deep-vein thrombosis. In long-standing LDS the skin surface becomes pigmented (Fig. 47.20). It is often found just above the medial malleolus, at the level of the Cockett perforating veins, which are usually incompetent, as is the great saphenous vein. When the small saphenous vein is incompetent, the lipodermatosclerosis often affects the lateral side of the calf. The most characteristic histological findings are dermal and subcutaneous fibrosis, with fat degeneration.

Fig. 47.20 A venous ulcer on the medial side of the leg surrounded by pigmented sclerotic skin (lipodermatosclerosis).

White atrophy (atrophie blanche). This is the result of decreased capillary density caused by microthrombi and matrix degradation causing hypoxia. White atrophy is seen as an atrophic, ivory-white, depressed skin lesion often located on the lower legs (Fig. 47.21). The lesions have a diameter that varies from 0.5 to 15 cm and are almost always multiple. The lesions often contain many centrally enlarged capillaries that are visible as red dots. White atrophy is characterized histologically by an atrophic epidermis and a thickened and scleroderma-like dermis with proliferative, dilated capillaries. One or more capillaries are often occluded with fibrinoid material [5]. White atrophy does not cause clinical symptoms, but the associated ulcers are very painful. White atrophy does not respond well to treatment but antiplatelet agents and fibrinolytic-enhancing drugs have been tried with some success. White atrophy may also be seen in association with other disorders including lupus erythematosus, scleroderma, vasculitides, cryoglobulinaemia, polycythaemia and leukaemia. Summer ulceration is an idiopathic form of white atrophy in which ulcers develop on legs that show no evidence of chronic venous disease. The pathogenesis is largely unknown. Probably, the capillaries occlude as a consequence of microthrombosis during the 'summer' months.

Livedoid vasculopathy (livedo vasculitis). Livedoid vasculopathy is an occlusive thrombotic disease that affects superficial small blood vessels of the lower extremities (see also p. 47.55 and Chapter 49).

Fig. 47.21 Atrophie blanche: white scars with a central ischaemic ulcer and telangiectasia at the edge of the white areas.

Varicosities. Varicosities represent dilated and tortuous veins. In about the half of the patients CVI is the result of primary varicosities. In the 'post-thrombotic syndrome', venous hypertension often induces incompetence of the superficial venous system, and may lead to secondary varicosities [6].

Venous ulcer (ulcus cruris). This is an end stage of CVI.

Secondary (high output) lymphoedema. This may develop in patients with long-lasting CVI. Secondary lymphoedema develops when the previously healthy local lymphatic system fails in the face of an overwhelming filtration load, with eventual structural obliteration of lymphatic routes.

Investigations of chronic venous insufficiency

Duplex ultrasound

Colour Doppler duplex ultrasound has become the first choice investigation for most venous problems. Duplex gives excellent information on venous anatomy and reflux. Reflux does not always indicate a functional defect, because muscle pump capacity can compensate for reflux. It is not easy to diagnose venous obstruction with Duplex scanning. Colour imaging allows the direction of flow to be clearly seen. Duplex ultrasound is very 'operator dependent' and requires considerable experience and a detailed knowledge of venous anatomy.

Technique. A 7.5-MHz high-frequency linear array transducer (probe) is usually satisfactory for venous examination. A probe of 7.5 to 13 MHz is appropriate to obtain good quality images of the superficial veins of the lower limbs. For very large or oedematous legs a curvilinear array transducer of 3.5 to 5 MHz may be useful [1].

Examination of the superficial veins should be performed with the patient standing erect as the detection of reflux and assessment of the vein diameter is inaccurate when the patient is supine. Both transverse and longitudinal views of the veins should be obtained. The investigation should be performed in a warm environment, to encourage venous dilatation.

When compression is applied distal to the probe antegrade (forward) flow is elicited. Reflux (backward or retrograde flow) may subsequently occur when the manual compression is abruptly released. This retrograde flow (reflux) is the result of gravity. A small amount of retrograde flow occurs in normal veins to produce valve closure. Venous reflux is considered to be normal when it lasts less than 0.5 s [2]. Reflux may be elicited by manual compression of varices, of the saphenous trunks or by squeezing the feet. It can also be stimulated by pneumatic calf cuff deflation [3], the Valsalva manoeuvre or by active foot dorsiflexion and relaxation.

Duplex ultrasound allows the communications between the deep and superficial veins to be directly assessed [4].

Indications. The most important indications for venous duplex are: (recurrent) varicose veins, signs of deep vein pathology, analyzing the veins of the popliteal fossa, analyzing the perforating veins, preoperative marking of varicose veins, assessing venous malformations, surveillance after treatment, duplex-guided sclerotherapy, evaluation before endovenous interventions, diagnosing (deep-vein) thrombosis and follow-up after treatment [2].

Venous pressure measurement

At the beginning of the 20th century, Von Recklinghausen (1906) measured the venous pressure, followed by Roulson (1911) and Beecher (1936) [1]. The technique that is still used, and remains the gold standard for investigation of venous hypertension, was introduced in 1925 by Barber and Shatara [2], who demonstrated that venous pressure decreases during calf movement. The venous pressure drop during walking is less in patients with varicosities than in healthy individuals [3,4]. Arnoldi demonstrated that the pressure in the superficial venous system and the deep venous system was similar [4]. A correlation exists between calf muscle function and venous pressure [5].

Technique. A vein in the foot is cannulated and the patient stands on tiptoe 10 times. The venous pressure drops and the pressure drop is measured. This is defined as the ambulatory venous pressure. The patient stands still until the pressure returns; the time taken for the pressure to return is defined as the venous refill time.

Interpretation. The venous pressure is between 5 and 10 mmHg in the supine position. During standing the venous pressure is defined by the hydrostatic pressure being dependent on the subject's height. The distance between the right atrium and the puncture location determine the standing venous pressure. This value is between 80 and 100 mmHg in the average European. During the exercise, the pressure should drop to below 40 mmHg (or reach at least 50% of the standing venous pressure). Healthy individuals usually reach an ambulant venous pressure of around 20 mmHg, with a venous refill time of over 25 s.

Plethysmography

Plethysmography records volume changes in the limb. It was first described by Brodie and Russel in 1905 [1].

Photoplethysmography. Photoplethysmography (PPG) is the most commonly used non-invasive technique. Hertzman in 1938 [2] was the first to describe a photoelectric plethysmographic method of measuring the skin circulation. The intensity of light reflected from the skin red cells correlated with the blood volume in the skin [3]. Venous refill time after a standardized exercise is obtained with the PPG. The venous refill time should not be confused with venous pressure, although there is a relationship between the two [4]. Bays *et al.* found a positive predictive value of venous refill time examined with PPG of 77% and a negative predictive value of 100% [5].

Light reflection rheography and digital photoplethysmography. The technique of light-reflection rheography (LRR) is based on the technique of PPG and was developed by Wienert and Blazek in the 1980s [1]. Digital photoplethysmography (DPPG) is a further development of LRR (second generation LRR) [2]. The results of LRR and DPPG have been compared and show a high degree of correlation, particularly in patients with venous disorders [3,4]. The correlation from LRR to ambulatory venous pressure is 0.73 for venous return and 0.93 for expelled volume [5].

Phlebography

Water-soluble contrast media have lowered the risk of causing DVT to nearly zero.

Ascending phlebography. The objective of the examination is to visualize the deep venous system from the foot to the lower inferior vena cava. Contrast injected into a foot vein is driven into the deep veins by an ankle tourniquet.

Varicography. This is a variant of ascending phlebography. Varicography is performed by directly injecting contrast into a varicose vein or veins. It determines the route of 'drainage' from the varicose veins through communicating veins in the deep venous system and defines the anatomical extent of the varicosities [1]. It indicates the major point of the origin of the reflux, and is very useful for investigating patients with recurrent varicose veins.

Descending phlebography. This has nowadays been replaced by duplex ultrasound.

Varicose veins

Synonym
- Venous varicosity

This is the name given when there is visible, tortuous elongation and dilatation of the larger superficial venous trunks and their tributaries. Leg varicosities seldom develop before adolescence in women. Other types of venous dilatation are often incorrectly included within the category of 'varicose veins'. Capillary telangiectasias (diameter 0.1–0.4 mm) are predominantly red and intradermal. The colour of telangiectasias depends upon the calibre of the dilated venule; large dilatations are dark blue and often palpable (although still less than 1 mm in diameter). Reticular varicose veins are subcutaneous (2–4 mm in diameter) and arise from a blue leash of small veins.

Prevalence. The prevalence of varicose veins in the Western population is estimated to be between 10 and 50% although the higher figure is of dubious validity. The prevalence of varicose veins increases with age. By 20 years it is 10%; by the age of 40 years it is 40% in women and 25% in men, and varicose veins are present in about 70% of 80-year-old women and 60% of 80-year-old men. Women that give birth to several children have an increased risk of developing varicose veins [1]. A population-based cross-sectional survey in Germany of 3072 participants found that the prevalence of varicose veins was twice as high in an urban population as in a rural population [2].

Classification. Varicose veins are either primary or secondary.

Primary varicose veins have no obvious underlying cause. The superficial veins dilate and become tortuous with an associated valvular incompetence. The mechanisms for these changes are still not clearly defined. Biochemical abnormalities in the vein wall, genetic predisposition and haemodynamic factors may all affect the development of varicose veins. Haemodynamic changes do not seem to be of major importance in reticular and branch varicosities. Disorders of the endothelium and the extracellular matrix may account for the development of these minor varicosities. The recent report of venous reflux in 100% of patients with mutations in the *FOXC2* gene strongly suggests that at least some forms of varicose veins have a genetic basis which is the result of primary venous valve failure [3]. Similarly, the presence of varicose veins in congenital syndromes such as Klippel–Trenaunay syndrome indicate a genetic basis, although the fault may be in the vein wall as much as the valve.

Secondary varicose veins are the result of raised endoluminal venous pressure (venous hypertension) for which post-thrombotic damage is the most important cause. The deep venous system should be evaluated in all patients in whom secondary varicose veins are suspected to avoid operating on surface veins unnecessarily when prescription of elastic support stockings would be preferable.

3 Mellor RH, Brice G, Stanton AW *et al*. Mutations in *FOXC2* are strongly associated with primary valve failure in veins of the lower limb. *Circulation* 2007; **115**: 1912–20.

Clinical features. Varicose veins may be a purely cosmetic problem but many patients also complain of aching pain, which tends to be worse on prolonged standing at the end of the day, and which is relieved by leg elevation or compression. Symptoms such as itching, ankle swelling, and ultimately the development of lipodermatosclerosis or ulceration indicate haemodynamic failure and the need for investigation.

Complications of varicose veins, such as haemorrhage and thrombophlebitis, result from the varicose veins themselves whereas oedema, haemosiderin pigmentation, varicose eczema, atrophie blanche, lipodermatosclerosis and venous ulceration result from venous hypertension.

Diagnosis. Colour duplex Doppler ultrasound scanning is increasingly being used to investigate all patients with varicose veins, and is the investigation of choice for detecting deep-vein reflux. Duplex scanning is also essential to investigate patients with skin changes attributed to venous hypertension. There is some evidence that the incidence of recurrent varicose veins is lower after duplex assessment has been used to plan surgery.

Treatment of truncal varicose veins. The recognition of the skin changes which are associated with varicose veins is important because of the likely risk of progression to venous ulceration. Causes of secondary varicose veins should be sought, including DVT and intra-abdominal pathology.

Only varicose veins (superficial venous reflux) that are associated with cutaneous complications demand treatment. Many patients, especially women, present for treatment of varicose veins or telangiectases for cosmetic reasons. At present there is no means of assessing which limbs will progress to develop chronic venous insufficiency.

Several types of treatment for varicose veins are discussed [1–7] and the most common complications of these treatments are shown in Table 47.9.

Table 47.9 Important complications of the treatment of varicose veins [1–7].

Treatment	Complications
Sclerotherapy	Skin necrosis, hyperpigmentation, DVT (rare), superficial venous thrombosis, arterial thrombosis (very rare), allergic reactions [1]
Surgical therapy	
Stripping	Nerve damage, haematoma, infection, DVT, lymphocele, hypertrophic scarring, lymphoedema
SEPS	DVT, haematoma [2]
Phlebectomy	DVT, neuralgia, haematoma, infection [3] Haematoma, phlebitis [4]
Endovascular treatment	
Laser	Vein perforation, DVT, ecchymoses, skin burns, superficial venous thrombosis [5]
Foam sclerosant	DVT, allergic reactions, stroke, transient blindness
Stenting	Thrombosis [6]
Lasers	
IPLS	(Temporary) hyperpigmentation [7]
Nd : YAG	(Temporary) hyperpigmentation, scar formation [7]

DVT, deep vein thrombosis. IPLS, intense pulsed light source. SEPS, subfascial endoscopic perforator surgery.

Sclerotherapy

Sclero (compression) therapy is indicated for leg telangiectasias (thread veins), reticular veins, minor tributary veins, varicosities, and recurrent varicose veins following surgery (see Telangiectasia, p. 47.20). The aim of treatment is to obliterate the lumen of the injected veins. The most frequently used sclerosants are sodium tetradecyl sulphate (STD), polidocanol (aethoxysclerol), 23.4% saline, and a combination of 25% dextrose with 10% saline [1]. Several randomized controlled trials have shown that sclerosant choice, dose, local pressure dressing, degree and length of compression have no significant effect on the efficacy of sclerotherapy for varicose veins [2].

Compression therapy

Graduated elastic compression stockings are classified by the European Standardization Commission into four categories, which have different uses [1,2]:

Class I, 15–21 mmHg: thrombosis prophylaxis

Class II, 23–32 mmHg: mild/moderate oedema, mild CVI, after sclerotherapy, pregnancy

Class III, 34–46 mmHg: severe CVI, severe oedema, lymphoedema, post-thrombotic syndrome

Class IV, >46 mmHg: severe lymphoedema.

Class II or III should be chosen, depending on the severity of the venous hypertension. It is of the utmost importance that stockings are carefully fitted and that patients are instructed about how to put them on and take them off. An applicator may need to be purchased. Hosiery is not usually worn overnight, but this may be ignored if patients find stockings difficult to apply. At least two pairs of stockings should be provided, to allow for daily changing and washing. Washing is necessary to retain the elastic property of Lycra-containing hosiery. Two stockings per leg should last 6 months before compression is lost and replacements are required [3]. Patients should be encouraged to wear elastic compression stockings for the rest of their lives. A healthy lifestyle with regular daily exercise, for example walking, and maintaining an ideal weight is to be encouraged.

Stockings can be below-knee (A–D stockings), thigh length (also named A–F), or tights. Graduated compression stockings may improve the short-term haemodynamics in patients with varicose veins, thereby relieving symptoms [4,5]. There are no data on their long-term benefits. Wearing class II stockings may reduce venous reflux but they do not appear to prevent the development of superficial varicose veins [6]. Wearing class II below-knee stockings is an alternative treatment for patients with severe varicose veins who do not wish to have invasive treatment.

Surgical therapy

Venous surgery is potentially curative for refluxing superficial veins when the deep veins are competent. Conversely, surgery should be avoided in patients in whom the superficial veins may be acting as collaterals, which are the major route for venous return, in a severely post-thrombotic limb.

Flush ligation and stripping. For more than 100 years saphenous incompetence has been treated by flush ligation and stripping [1]. Although the technique varies, the results are the same. Most surgeons no longer strip the great saphenous vein (GSV) to the ankle. Damage to the saphenous nerve is avoided if the vein is stripped to the knee The short strip appears to be as effective as the long strip, but it does not influence the venous haemodynamics in the lower leg. Veins in the calf can be subsequently treated with foam sclerotherapy [2]. The results of surgical stripping are slightly disappointing, with a success rate of only 79.7% 1 year after treatment [3]. The recurrence of varicose veins is often the result of neovascularization, which will occur in 20 to 30% [4]. However, high saphenous ligation with stripping of the GSV remains the most commonly performed intervention for varicose veins in the world.

Ligation and stripping of the short saphenous vein (SSV) is technically more demanding than stripping of the GSV, which explains why more and more incompetent SSVs are treated by endovenous techniques or by foam sclerotherapy.

Subfascial endoscopic perforator surgery (SEPS). Incompetent perforating veins of the lower limb have been correlated with leg ulceration. Linton's and Cockett's operations to ligate these veins became discredited partly because the post-operative complication rate was high [1], and there was little evidence that this form of surgery was efficacious in preventing recurrent ulceration. A minimally invasive approach (SEPS) was introduced by Hauer in 1985 [2], but in a prospective randomized controlled trial Van Gent *et al*. showed that this procedure did not prevent recurrent venous ulceration [3].

Phlebectomy (Muller technique). Removing tributary veins through small incisions has been around for many years, but in 1966 Robert Muller re-described a minimal invasive surgical technique [1]. He used stab avulsions (microincisions) and fine hooks to extract the varicose vein tributaries. This technique is time-consuming but gives excellent cosmetic results. This means of treating varicose tributaries is significantly better than sclerotherapy [2].

Endovascular treatment [1,2]

Endovascular treatments do not disconnect the GSV from the femoral vein, which may explain the absence of neovascularization. Endovascular laser treatment (EVLT) was introduced in the late 1990s and has become tremendously popular, especially for the treatment of GSV incompetence. Radiofrequency ablation (RFA) is probably equivalent to EVLT and both types of endovenous treatment appear to have early benefits in pain and return to work. The wavelengths of the laser can be varied in absorption spectra of haemoglobin (e.g. 840 or 940 nm) or water (1320 or 1499 nm). It is not yet known which is the best wavelength. Damage to the vein wall and surrounding tissues may lead to pain and pigmentation.

Foam sclerosant treatment. Tessari introduced a technique in which air and a sclerosing agent are mixed [1]. Both polidocanol and sodium tetradecyl sulphate (STD) are detergents, and mixing them with air results in a firm foam. This foam is stable for a couple of minutes and can be injected directly into the vein under Duplex imaging. The foam allows this to be visualized [2]. This is now being used to obliterate saphenous systems. Comparisons against other techniques are, however, essential.

Post-thrombotic syndrome

Synonym

- Post-phlebitic syndrome

Definition. The post-thrombotic syndrome (PTS) is a chronic condition of the deep venous system in patients with a documented history of deep-vein thrombosis (DVT) [1].

Incidence. DVT has an annual incidence of 0.2% and about one-third of affected patients develop PTS within 5 years [2,3]. The incidence of PTS is about 10% 1 year after an episode of DVT, and increases to about 50% over a period of 5 to 8 years. The only clear, identified risk factor is recurrent DVT, which increases the risk of PTS as much as six-fold [4].

Pathophysiology. Venous hypertension plays a key role in the pathophysiology of PTS [1,5] and is the result of valvular incompetence, outflow obstruction and dysfunction of the calf muscle pump. After the initial thrombosis, resolution of the thrombus may start but propagation of the thrombus can also occur. The two processes can also occur simultaneously.

Loss of valve function leads to overloading of the venous system, which in turn leads to dilatation of the veins and to an increase in the venous volume. If this surpasses the capacity of the calf muscle pump, ambulatory venous hypertension results; this in turn causes further distension of the veins, leading to more valvular incompetence and the development of secondary varicose veins. When there is residual venous obstruction, the venous resistance and the venous pressure increases, which also leads to an increase in venous volume. In general, reflux causes more problems if it occurs in the distal part of the venous system and obstruction causes more problems when it occurs proximally.

Clinical features. The clinical symptoms of PTS are similar to those of CVI. They are, however, often more pronounced but may vary considerably from scarcely visible skin changes to pigmentation, lipodermatosclerosis, venous dilatation, oedema and ulceration. In the early stages of PTS, clinical signs do not correlate with the severity of disturbed venous haemodynamics [1]. Patients experience pain, heaviness, swelling, cramps, itching or tingling in the affected limb. Symptoms may be present in various combinations and may be persistent or intermittent. Typically, symptoms are aggravated by standing or walking and improve with rest and leg elevation, particularly lying down [4,6].

Diagnosis. The severity of PTS is often scored by the Villalta–Prandoni scale [7], which combines objective and subjective assessments. The simple Widmer score is also useful for PTS [8]. Duplex ultrasound provides information on reflux in both the deep and superficial venous systems. Non- or partially recanalized veins can usually be detected using this technique, although considerable interobserver variability is present. Phlebography is still necessary when the duplex scan is equivocal or direct deep venous surgery is being considered.

The range of movement in the ankle and knee joints should be tested because impaired movement in the lower leg reduces the effectiveness of the calf muscle pump [1].

Treatment. Prevention is an important part of treatment. Patients diagnosed with a DVT should be treated with a LMWH and oral anticoagulants. Once the oedema has settled, class II graduated elastic compression stockings are prescribed [3,9]. Patients should be reviewed annually after a DVT. A stent [10] or a Palma procedure [11] can be considered when there is evidence of venous obstruction. Graduated compression stockings should be worn for life.

Deep vein incompetence

Secondary venous incompetence

All patients with varicose veins should have a colour Doppler duplex ultrasound of their deep venous system. DVT often permanently damages deep veins and their valves leading to deep vein incompetence with the superficial veins then acting as collateral drainage routes; for example, when the popliteal vein is occluded the superficial veins are the major outflow tracts from the limb. Because superficial varicose veins serve as necessary collateral drainage in these circumstances, surgery to ablate varicose veins is contraindicated and graduated compression stockings should be worn instead.

Primary deep vein incompetence

Congenital absence of venous valves is extremely rare [1]. It can affect only the lower limb veins or the whole body. Kistner has described a group of patients with floppy valves [2]. This abnormality is an enlarged valve cusp with a long, free edge that allows the cusp to prolapse when subjected to retrograde flow. Whether this is a congenital or an acquired abnormality is not known.

Mutations in the *FOXC2* gene, the cause of lymphoedema–distichiasis syndrome, has been shown to cause deep venous reflux in one-third of cases [3].

Leg ulcers

Leg ulceration

Definitions and epidemiology. Leg ulcers represent a break of the skin, sometimes extending through the dermis or deeper. Causes are listed in Table 47.10. A chronic ulcer is defined as one lasting more than 6 weeks [1]. Healed and active ulcers of the lower limb affect 1% of the adult population and 3.6% of people older than 65 years [2]. The main causes are venous hypertension, arterial disease and diabetes, but many factors may contribute (Table 47.10). Venous disease is the single most common cause, but gravitational and venous influences may contribute to the development of other pathologies in the lower leg (e.g. vasculitis).

Table 47.10 Causes of lower limb ulceration.

Venous hypertension	Varicose veins, deep-vein thrombosis, venous obstruction, congenital vascular malformations, Klippel–Trenaunay syndrome
Arterial disease	Atherosclerosis, diabetes, hypertension, embolism, calcific uraemic arteriolopathy (calciphylaxis)
Skin cancer	Basal and squamous cell carcinoma, melanoma or any fungating tumour
Vasculitis	Connective tissue diseases, e.g. systemic lupus erythematosus, rheumatoid disease, progressive systemic sclerosis, necrotizing leukocytoclastic vasculitis, ANCA-associated disorders, polyarteritis nodosa
	Livedoid vasculopathy, cryoglobulinaemia
Haematological disorders	Coagulation states, e.g. factor V Leiden, protein S or C deficiency, hyperhomocysteinaemia, antithrombin III deficiency, sickle cell disease, thalassaemia, spherocytosis, antiphospholipid syndrome, myeloproliferative disorders, e.g. polycythaemia rubra vera, thrombocythaemia
Emboli	Cholesterol, platelets, tumour cells, infective
Loss of sensation	Leprosy, diabetes, spina bifida
Infections	Diabetes, osteomyelitis, Buruli ulcer, fungal infections, syphilis, mycobacteria, leishmaniasis, acute 'desert' sore, necrotizing fasciitis and cellulitis
Trauma	Physical, e.g. pressure sore, chemical or thermal (e.g. burns or cold injury)
	Self-harm
	Intravenous drug use
Drugs/therapy	Radiation
	Hydroxycarbamide, ergotamine
	Iododerma
Skin conditions	Pyoderma gangrenosum
	Necrobiosis lipoidica
	Scleroderma
	Graft-versus-host disease
	Blistering disorders (e.g. pemphigoid)
	Bites and stings: insects, snake, scorpion
Genetic	Prolidase deficiency
	Klinefelter's syndrome

Venous ulceration of the leg [3,4]

Definition. Ulceration of the lower leg occurring as the result of persistently elevated venous pressure and its secondary effects on the microvascular system. Nearly half of all venous ulcers are associated with deep-vein valvular incompetence or post-thrombotic damage, while the remainder result from incompetence of the superficial or communicating veins.

Epidemiology [5–7]. Community surveys suggest an overall incidence of about 0.2% [5]. It is an age-related disease, mainly

affecting older women. Women are two to three times more often affected than men; 2% of all those over the age of 80 years suffer with ulceration. About half of the ulcers heal within 4 months but approximately 20% have not healed after 1 year and about 8% have not healed after 5 years. The annual recurrence rate is 6 to 15% and most ulcers recur more than once.

Venous ulceration is a common disease of all Western communities [7]. It appears to be associated with a sedentary and physiologically unnatural mode of life and is comparatively rare in African people, although the incidence may be underrated [8–10].

A study of 4422 healthy working adults in Basle found 'chronic venous insufficiency' in 19% of men and in 25% of women [11]. Ulceration was present in 1.1 and 1.4%, respectively. Figures from other surveys are similar. It has been emphasized that up to one-third of ulcers in elderly people have coexisting arterial insufficiency as one factor contributing to their failure to heal. A family history of leg ulcers is found in over half of those affected [12]; this applies about equally to those who have suffered a known thrombosis and to those who have not. The significance of this is not known, although inheritance of coagulation defects may be one factor.

Venous disease accounts for 1–2% of the health-care budgets of European countries [13].

Pathogenesis. Venous ulcers are the end result of superficial venous insufficiency or the post-thrombotic syndrome (PTS) described above. The consequent ambulatory venous hypertension causes alterations in the microvasculature and interstitium which make the skin more liable to break down, or to fail to repair, following minor episodes of trauma. The fundamental fault is a sustained capillary hypertension resulting from persistently raised venous pressure. A failure to reduce venous pressure satisfactorily when the lower limb is dependent is consequent upon a failure of venous valves (allowing reflux) and poor calf muscle pump function. The lack of skin viability must reflect local hypoxia but the exact mechanism is not understood. The pathogenesis of the microvascular damage from the venous hypertension is discussed on p. 47.26.

A history of deep leg-vein thrombosis is obtained from a significant proportion of patients. In Anning's carefully documented series [12], a story of prior thrombosis was obtained in 75% of the patients. Leg injuries, particularly fractures, are frequently followed by thrombosis [14]. Other relatively common causes include hip replacements, pelvic and lower abdominal operations, medical illnesses and prolonged recumbency from any cause. In one study, 12 of 46 patients admitted to hospital with leg ulcers demonstrated resistance to activated protein C [15], a finding that has been observed in 20–40% of patients known to have had a previous DVT. Patients with chronic venous ulcers have a 41% prevalence rate of thrombophilia, which is 30 times higher than the general population [16]. Interestingly, thrombophilia does not necessarily appear to be related to past DVT [17]. Subjects with Klinefelter's syndrome have an increased risk of leg ulceration through an abnormality in platelet aggregability and fibrinolysis associated with elevated levels of plasminogen activator inhibitor-1 [18].

Up to 60% of patients with venous ulcers have isolated superficial vein incompetence with normal deep veins [19]. The concept of a primary defect in collagen or elastic tissue has been revised by the recognition of ulceration consequent on prolidase deficiency (p. 47.54). Congenital absence of venous valves as a cause of leg ulcers is probably rare [20].

Clinical features. The ulcer may be preceded by patchy erythema or discoloration of an intense bluish red colour, in which ischaemia of the skin finally leads to necrosis, often following a minor episode of trauma. This intense bluish colour can be seen by capillary microscopy to be caused by capillary congestion [21].

The ulcer is characteristically situated on the medial lower aspect of the leg, the 'gaiter' region, which is drained on the medial side by three large pairs of perforating veins. Venous ulcers do not usually develop initially below the level of the malleoli or in the foot unless complicated by livedoid vasculitis or arterial disease.

Two events may lead to a break in the continuity of surface epithelium. The first is capillary thrombosis, when the complete outline of the capillary can be seen to be filled with broken-up thrombus, which does not disperse on pressure. The second is a small bleed from the peak of the capillary; this separates the epidermis from its blood supply. These changes in the capillaries supplying the epidermis are frequently induced by small knocks, scratching or epidermal pathology such as dermatitis. The skin around an ulcer is frequently irritated by exudate, and inflamed varicose or medicament dermatitis may contribute to preventing healing and extending the ulcer size. Other signs of venous hypertension are usually present, for example lipodermatosclerosis, varicose veins (corona phlebectasia), varicose eczema or oedema; sometimes a nearby perforator vein may be evident by a palpable depression in the subcutaneous fat.

Ulcers often show pseudoepitheliomatous hyperplasia at their edge, which may be mistaken for a squamous cell carcinoma. The ulcer is covered with yellowish exudate over granulation tissue [22].

Healing ulcers have a shallow sloping edge with healthy granulation in their base and little slough. Epithelial islands may become scattered over the surface of a well-vascularized bed, and quickly enlarge (Fig. 47.23). The pink lip of the epithelium at the edge of an ulcer is uniform and supplied by relatively uncongested capillaries. The overall appearance is like a normal nail fold and cuticle. By contrast, a non-healing ulcer resembles a severe paronychia, being boggy, undermined and congested from oedema. The base is often white and very fibrous.

The coexistence of arterial disease can contribute to the progression of a venous ulcer, so symptoms and signs of peripheral ischaemia should be sought in all patients with leg ulceration. Rest pain can occur in the absence of arterial disease. Patients develop typical ischaemic pain on elevation of the ulcerated leg, which is oedematous. To relieve this pain, the patient keeps the leg in a dependent position, especially at night; this exacerbates the underlying pathogenesis.

After excluding arterial disease, a period of enforced elevation, necessitating strong analgesia, results in disappearance of the oedema with subsequent relief of the venous rest pain. Occasion-

ally, venous ulceration occurs at other sites in the limb, but other aetiologies should be suspected in such instances, especially if ulcers are present over the foot or just below the knee. Hyperkeratosis and papillomatosis around an ulcerated area or along the border of the foot, particularly below the malleoli, is a result of impaired local lymphatic drainage.

Associations and complications of venous leg ulcers

The main conditions associated with venous ulceration are anaemia and malnutrition (especially in elderly people living alone), and these must be assessed and corrected as far as possible.

General disease [1–3]. Coincidental obesity and hypertension are common. The relationship of these to the presence of the ulcer is uncertain, but they are undoubtedly perpetuating causes. Increased intra-abdominal pressure, for example from obesity, can increase cardiac filling pressures, femoral venous pressures, renal vein pressure, systemic blood pressure and vascular resistance [4]. Cardiovascular disease is common and heart failure can be a major contributor to venous ulceration through its effect on: (i) further raising venous pressure; (ii) creating peripheral oedema; and (iii) encouraging long periods of sitting. Joint disease, peripheral arterial disease and neurological disease can obviously impair the already precarious nutrition of the skin and the action of the muscle pump. Severe rheumatoid disease or long-standing poliomyelitis also reduce the effectiveness of the muscle pump and encourage recurrence.

Anaemia and hypoproteinaemia. Sickle cell anaemia [5] can cause ulceration, and the presence of marked anaemia, for example due to iron-deficiency anaemia or thalassaemia, may prevent other ulcers from healing by reducing peripheral oxygenation. Repeated infection or chronic inflammation arising from the ulcer may itself cause a normochromic normocytic anaemia. A poor diet, combined with continuous seepage of protein and blood from an untreated ulcer, relatively commonly leads to anaemia and hypoalbuminaemia.

Diabetes. Diabetes is common, and will compound any venous ulcer through arterial disease, infection and neuropathy.

Personal attitudes and habits: sociology [6]. Patients with long-standing ulcers commonly develop a number of complications that stem from the personality, domestic and social situation of the patient. Walking has long been abandoned and substituted by more damaging motionless sitting. The ankle can become fixed in equinus and the foot inverted leading to an irreversible condition. The leg becomes transformed into a useless and deformed peg and the calf muscles atrophy. Apathy, often with depression and apparent acceptance of the condition, is frequent. Affected patients may become chairbound with decreasing mobility and malnourishment, but potentially receiving much attention and sympathy from family members. Many such patients never go to bed but sit motionless in the chair all night. In a few cases, it is clear that any real attempt to cure the ulcer will be resisted unless this can be

accompanied by a vigorous social and psychological rehabilitation. Lonely patients may find that an ulcer is their only means of obtaining a visitor, be it district nurse or doctor.

Zinc depletion. This has received considerable attention [7–14], following the observation that zinc deficiency in rats impairs wound healing. Low plasma zinc levels have been found in patients with venous ulceration, and accelerated healing of such ulcers after oral zinc sulphate therapy has been reported. It is, however, the tissue levels of zinc that are of most importance in ulcer healing, and these have never been shown to be low in patients with leg ulcers. Analysis of six randomized trials indicates that oral zinc does not aid healing of leg ulcers, except possibly in patients with low serum zinc [15].

Infection [1]. The role of antisepsis in the healing of leg ulcers is much debated [2–4]. Pathogenic organisms are commonly found in leg ulcers of all types [3]. The bacterial flora is often profuse and usually mixed, but *Staphylococcus aureus* predominates. There is still insufficient evidence to determine to what extent such a flora influences the rate of healing, but quantitative bacteriology has indicated that fewer than 100 000 organisms per square centimetre of surface area or per gram of tissue does not delay repair [5]. Certain pathogens are, however, traditionally taken seriously; for example, the group A β-haemolytic *Streptococcus* or a heavy growth of *Pseudomonas* spp. Unimpeded resolution of uncomplicated leg ulcers under occlusive compressive bandaging is frequently accompanied by considerable pus formation, but healing is not necessarily impaired. Sometimes lakes of pus develop in an atrophic skin that readily breaks down. Referred to as erosive pustular dermatosis of the leg, the pus is sterile and the condition responds to intermittent use of potent topical steroids [6].

Fungi vary in extent and importance. Some authors have found *Candida albicans* only rarely [7], but it can be a common commensal organism, perhaps because of the widespread use of specific antibiotics. Ointment-impregnated bandages without preservatives were blamed for candidal overgrowth in one study [8]. Moist wound healing using contemporary occlusive dressings seems not to encourage infection [9].

Penicillin- and tetracycline-resistant staphylococci, and *Pseudomonas aeruginosa*, are very common in hospital-treated patients, and cross-contamination is very common in leg ulcer clinics [10]. *Proteus vulgaris* and other Gram-negative organisms are probably of little importance. The role of non-clostridial anaerobic organisms such as *Bacteroides* spp. in delaying ulcer healing has probably been underestimated. As with other types of infection, large controlled trials are required to measure healing after the ulcer surface has been sterilized. This information is not currently available to provide advice on the value of infection control. Venous ulcers are less likely to develop infection than arterial or diabetic ulcers [11]. All the antibiotic trials on ulcer healing that have been carried out have failed to show benefit.

Contact dermatitis. The skin around an ulcer frequently becomes red and sore, caused predominantly by the irritant effect of exudate (Fig. 47.24). Small pustules and superficial ulcers may develop, especially in the presence of β-haemolytic streptococci. Eczema may be responsible for further compromising skin viability, and

Fig. 47.24 Redness caused by exudate localized to the site of an overlying dressing, often confused with a contact allergy to the dressing.

so increasing the size of an ulcer. In most cases, the eczema is the result of local treatment (Table 47.11) and sensitivity can be demonstrated by patch testing. Patients with venous ulcers appear to become sensitized easily (Fig. 47.25) [12], often to several medicaments including lanolin and rubber [13–15]. The components of paste bandages may be responsible [16]. True medicament sensitivity is a frequent complication of therapy (Fig. 47.26) [17].

It is unfortunately not widely appreciated that the effect of potent topical corticosteroids on leg ulcers may inhibit healing for several weeks by producing an indolent 'arterial-type' ulcer with a deep adherent slough, 'steroid ulcer' (p. 47.56).

Haemorrhage [18,19]. Spontaneous haemorrhage occasionally occurs, especially from large ulcers [19]. This may be severe and can cause death if the patient faints and is held in the vertical position. First-aid measures include immediately lying the patient on the floor and elevating the limb while applying firm direct pressure to the bleeding point in the base of the ulcer. Occasionally, a suture will be required, but a tight bandage and elevation usually prevents further bleeding.

Lymphoedema (Chapter 48). The superficial lymphatics are absent in and around ulcers and their distortion or obliteration contributes to hyperkeratosis, papillomatosis, dermal fibrosis and oedema. An inadequacy of the lymphatic drainage predisposes to attacks of cellulitis [20], and with each episode of infection damage is compounded and chronic lymphoedema delays ulcer healing.

Malignant change [21]. Primary malignancies of the leg presenting as ulcers are increasingly common in an ageing population or

Fig. 47.26 Patch testing: 72-h reading showing multiple sensitivities, typical of patients with a long history of ulcer therapy.

those with sun exposure or transplantation-associated immunosuppression. Malignant change in an established ulcer is much rarer but carries a worse prognosis. Squamous epitheliomas may be difficult to distinguish from pseudoepitheliomatous hyperplasia, but if missed because of a failed diagnosis will often metastasize [22]. Biopsy should be considered if the diagnosis is in doubt [23]; multiple biopsies have been recommended as features may vary throughout the ulcer-associated tumour [24]. The edge becomes progressively heaped up (Fig. 47.27), vegetating and cauliflower-like and does not flatten with compressive therapy. Basal cell carcinomas may remain quite flat and undetected (Fig. 47.28).

Fig. 47.27 Heaped-up squamous epithelioma.

Suspicion may be aroused when the ulcer fails to respond to compression therapy. A distinction should be made between the rarity of malignant change in a chronic ulcer associated with disorders of the venous system, and the common primary malignancy occurring in the skin of legs that have had prolonged exposure to sunlight.

Subcutaneous calcification (post-phlebitis subcutaneous calcinosis) [25]. This is often widespread. It occurs in up to 10% of patients with chronic venous insufficiency [25]. It may cause nonhealing of an ulcer or be found incidentally. The calcification, which is sometimes osteoid, occurs around areas of fat necrosis and fibrosis [26]. Radiography reveals a coarse network of calcification, the edges of individual plaques impinging on the dermis. Other causes of calcification include phleboliths, atherosclerotic calcification, cysticercosis and a heterotopic form of dystrophic calcification (in which the serum calcium and phosphorus levels are normal). Calcium deposits act as a foreign body nidus for organisms and delay healing, particularly when they are extruded through the skin as a foreign body.

Bone changes. Periostitis is commonly seen beneath a chronic ulcer. Osteoporosis is often present in the later stages because of disuse atrophy. Osteoarthritis is a common concomitant condition in the affected or unaffected leg, especially the knee. Fibrous ankylosis of the ankle occurs also from disuse.

Diagnosis of venous ulceration. This is essentially clinical; based on finding ulceration in the gaiter area with the presence of signs of venous hypertension (p. 47.33). A past history of venous thrombosis, treatment for varicose veins or a family history of venous disease is supportive evidence. Arterial disease must be excluded and the ulcer should respond to compression therapy. Colour Doppler duplex ultrasound should be performed, not just to confirm venous reflux but also to see if superficial venous incompetence is responsible, in which case venous surgery may be an option if the deep veins are competent [1]. The preference is to wait for ulceration to heal before fully assessing the venous system. Plethysmography may be useful to investigate calf muscle pump function when venous duplex ultrasound is normal [2].

An ankle–brachial pressure index should be performed if foot pulses are not easily palpable, although the diagnosis of arterial disease does not exclude the possibility of an ulcer predominantly caused by venous disease (mixed origin). Arterial duplex Doppler scanning or arteriography should be undertaken if doubts remain regarding the presence of arterial ischaemia. A skin biopsy does not help in the diagnosis and may not heal in the presence of venous hypertension but is indicated if alternative causes such as skin malignancy [3] or vasculitis are possibilities. Signs of a peripheral neuropathy should be excluded and the range of hip, knee and particularly ankle movement should be tested.

Management of venous ulcers [1–4]

General management

Most venous ulcers are cared for in the community by appropriately trained nurses and general practitioners. First-line therapy for venous ulcers is compression bandaging. The concept is to reduce venous pressure, particularly during walking, by improving calf muscle pump function and by opposing gravitational venous reflux. Exercise and movement are to be encouraged, while long periods spent sitting and standing should be discouraged. When resting, the legs should be elevated, ideally with the ulcer just above the level of the heart to ensure the maximum reduction in venous pressure. Thus, lying is always preferable to sitting with the leg elevated. Patients should always be instructed to sleep in a bed; this might sound obvious but it is remarkable how many patients with venous ulcers fall asleep and remain in chairs with dependent legs both day and night, so exacerbating venous ulcers (despite bandaging) because of limited reduction in venous pressure.

Obesity is often a problem that becomes worse with immobility, boredom and social isolation. Weight control is therefore essential, but malnourishment with anaemia and poor protein intake can coexist with obesity. Frail, elderly patients are at risk of malnutrition. Adequate intake of essential vitamins and minerals in a balanced diet is essential for wound healing [5]. The contribution of other medical conditions, particularly heart and chest problems, needs to be considered. Heart failure exacerbates venous hypertension, while the need to sit upright in bed or in a chair to alleviate dyspnoea will fail to reduce leg venous pressures. Smoking should be stopped and excessive alcohol intake should be curtailed as both compromise wound healing [6,7].

Intravenous drug users that have used lower limb veins are at increased risk of venous leg ulcers. Management must consider any HIV or hepatitis risk to both the patient and the health-care professional (through wound fluids).

Assessment. After taking a full and detailed history clinical examination should include identifying signs of venous disease, palpation of the peripheral pulses, testing for any loss of cutaneous sensation and for the range of hip, knee and particularly ankle movement. The patient should be observed walking to identify any reasons preventing a normal heel to toe gait. Signs of heart failure should be carefully looked for and any sleep-apnoea syndrome considered, particularly in the obese.

Investigations. Blood tests should seek to exclude significant anaemia (a mild normochromic normocytic anaemia is to expected secondary to the ulcer), infection (indicated by neutrophilia and raised CRP), and hypoalbuminaemia (which will discourage healing and exacerbate oedema). A fasting glucose (plus a HbA_{1c} level in known diabetic individuals), as well as renal and liver function, should be measured [8]. A sickle cell test should be undertaken when sickle cell disease is a possibility. Patients with a history of recurrent thrombosis or family history of thrombosis should be investigated for a thrombophilia [9].

An ankle–brachial pressure index should be performed if foot pulses are not easily palpable. Arterial duplex Doppler scanning or arteriography should be undertaken if doubts remain regarding the presence of arterial ischaemia. Colour duplex Doppler ultrasound should be performed at some stage to see if superficial venous incompetence is responsible, in which case surgery may be indicated.

Compression therapy [10]. Compression therapy is the mainstay of treatment. In addition to stimulating fibrinolytic activity and reducing discomfort and oedema, compression therapy counteracts venous hypertension by facilitating venous return, improving calf muscle pump function and lymph drainage [11]. Many methods of compression are available, for example non-elastic (short stretch) wraps, elastic (long stretch) wraps and pneumatic compression devices. Compression may be administered in the form of single layer bandages, multilayer bandages, compression stockings or a combination of stockings and bandages. Any of these should exert 30–40 mm Hg of pressure at the ankle for effective compression. Compression increases ulcer healing rates compared with no compression. Multilayered systems are more effective than single-layered systems. High compression is more effective than low compression but there are no clear differences

in the effectiveness of different types of high compression. Graduated multilayer high compression bandage regimens capable of sustaining compression for a week at a time should be the first line of treatment for uncomplicated venous ulcers with an ankle–brachial pressure index above 0.8 [12].

When leg ulcer clinics have promoted compression treatment, healing rates have generally improved when compared with usual care given by community nurses [13]. Enthusiasm by professionals and a defined strategy, however, may explain the improvement.

In the UK, elastic (long-stretch) bandages are mainly used, whereas in Europe short-stretch bandages are preferred. Elastic bandages sustain compression for longer, whereas short-stretch bandages produce high 'venous' pumping pressures during exercise but lower resting pressures [14]. Multilayer bandaging has gained popularity owing to the high healing rate success reported in one study [15]. Unfortunately, all large ulcers were excluded and grafted in this study, and others have had difficulty in reproducing these results. Nevertheless, multilayer bandaging provides good conforming properties for a graduated distribution and sustainability of pressures.

Adequate training is essential for good results [16]. Incorrectly applied bandages can be harmful. Although compression therapy for the treatment of leg ulcers is in general performed with bandages, new medical elastic compression stockings were recently introduced for this treatment. A comparative study shows that this type of medical elastic compression stocking is more effective in daily practice than standard compression therapy with bandages [17].

Dermatological assessment. The condition of the ulcer and of the surrounding skin influences treatment outcome. If eczema is present, exudation and scratching will jeopardize the integrity of the surrounding skin. Consideration must be given to the underlying cause of the eczema which may be: (i) varicose; (ii) contact allergy; or (iii) contact irritant (e.g. caused by maceration from soaked dressings, see p. 47.44). A topical steroid is indicated to treat eczema, whereas emollients alone are sufficient for non-inflamed skin. Fragile oedematous skin needs careful application of compression bandages (but not necessarily less compression).

Cleansing and debridement. Management of the leg ulcer itself is important but should only be addressed once the patient's general health and venous hypertension have been considered. Cleansing of the ulcer should be kept simple [17,18]. Irrigation of the ulcer with warmed tap water or sterile saline is usually sufficient [19,20].

Any dressing technique should be clean and aimed at preventing cross-infection. Strict antisepsis is unnecessary. It is customary to remove slough, eschar and bacterial biofilms from the ulcer bed by debridement, as this improves wound healing [21]. Sharp debridement using scalpel, scissors or curette is most rapid and precise [22–23]. Autolytic or enzymatic debridement can be undertaken using moisture-donating dressings or protease preparations, respectively, but both are slow [24]. Debridement can also be achieved by topical negative pressure or vacuum-assisted closure (V.A.C.®) [25]. Maggots are used in some clinics for debridement but have never been compared with surgical debridement [26]. An ultrasound debriding instrument was very acceptable to patients and has provided some promising early results [27].

Fig. 47.29 A hydrocolloid dressing applied to an ulcer provides comfort and stimulus to healing. The centre of the dressing dissolves and contributes to odour and exudates on removal.

Dressings and topical therapies [28–30]. Dressings should keep the ulcers moist but not wet. Dressings should be simple, low adherent, inexpensive and safe. There is no evidence that any particular dressing or dressing type is more effective in healing venous leg ulcers. 'It's not what you do with the ulcer that is important, it is what you do with the leg' is a good axiom, reflecting the fact that the most important aspect of treatment is reversing the venous hypertension, not the choice of wound dressing.

Ideally, a dressing should be left undisturbed for as long as possible so the ulcer can get on with the job of healing. Changes of dressing only disrupt new fragile epithelium. Conversely, a wet, soaked dressing and bandage tends to produce maceration of surrounding skin and encourage infection. 'Strike-through' of exudate to the outside of a bandage is usually an indication for a dressing change.

First-line primary dressings include a knitted viscose primary dressing (e.g. N-A Dressing®) with a superimposed absorbent pad (secondary dressing). Tulle dressings impregnated with paraffin (e.g. Jelonet®) can increase maceration; medicated tulle dressings are not generally recommended unless infection is likely [31]. An absorptive dressing may be valuable in a highly exuding wound (e.g. foam, alginate or hydrofibre). Hydrocolloid dressings can be helpful in dry, sloughy wounds to reduce pain but are not recommended if there is much exudate (Fig. 47.29). In malodorous wounds foam, alginate, hydrocolloid and charcoal are recommended [9]. Zinc paste bandages (e.g. Steripaste®) can be applied directly to the wound base and to the intact skin from the base of toes to knee, with a covering compression bandage in one or two layers (Fig. 47.30). These dressings have been shown to increase the speed of ulcer healing in one controlled study where four-layer bandages were used as the comparator [32]. Patients can develop allergies after using a product for some time [33]. Patch testing should be considered if dermatitis develops or is difficult to control.

(a)

(b)

Fig. 47.30 Applying a past bandage to an ulcer, avoiding a tourniquet effect by frequent: (a) cutting; (b) folding.

Skin and substitutes. Three different types of transplants can be used in ulcer management; these are autologous, donor skin and allogeneic transplants. The autologous transplants consist of three main techniques, namely split-skin grafts, punch grafts and cultured autologous keratinocytes. Donor skin may be cadaver or pig skin. Allogeneic techniques involve a bilayered skin substitute, which consists of allogeneic keratinocytes and fibroblasts in a collagen gel. The disadvantage of this technique is that it is expensive and has shown only minor improvements in healing in certain subgroups [34].

Microbiology [35]. Chronic leg ulcers are usually colonized by microorganisms but whether this affects healing is debatable [36,37]. Routine wound swabs for bacteriology are unnecessary unless there is evidence of clinical infection such as: (i) surrounding inflammation; (ii) increased pain; (iii) heavy or purulent exudate; (iv) a rapid deterioration of the ulcer; or (v) fever. The identification of group A haemolytic *Streptococcus* should prompt use of a course of penicillin, but otherwise antibiotics should not be used too readily. The use of topical antibiotics is discouraged because of the risks of contact allergy and antibiotic resistance.

Fig. 47.31 Tracing around the margins of an ulcer to ensure the healing is occurring.

Pain relief. Most patients with venous ulcers suffer moderate to severe pain [33]. Pain can result in reduced mobility, particularly of the range of joint movement, leading to a poor calf muscle pump. Pain may also indicate other pathology such as arterial insufficiency, malignancy or infection. Analgesia is recommended if compression and elevation fail to resolve pain from a venous ulcer. Opioids may be necessary in some cases. Some deep pain is mediated by the autonomic nervous system and may be helped by amitriptyline, gabapentin or a guanethidine block [38,39]. Quinine is a useful therapy for night cramp [40].

Measurement [41]. It is unwise to recommend any agent for the healing of ulcers that has not been subjected to a properly controlled trial. The only measurement that matters is the time taken for total healing of a large number of ulcers, which would, if possible, be stratified by initial ulcer size. The size influences the time taken for total healing to occur [42]. Large ulcers generally take significantly longer to heal than small ones. The healing rate is a poor measure; however, it is of value in monitoring the progress of individual ulcers (Fig. 47.31).

Systemic therapy. Systemic antibiotics have not been shown to improve the healing rates of venous ulcers and should be reserved for ulcers with clear evidence of infection [43].

The effectiveness of pentoxifylline in healing venous leg ulcers may be because of its fibrinolytic action and a reduction in leukocyte adhesion. Although randomized trials have reported both positive and negative results, a systematic review was positive [44]. A dose of 800 mg three times daily may be better than 400 mg three times daily as conventionally used.

An increased rate of venous ulcer healing with the use of oral enteric-coated aspirin (300 mg) daily was reported in one randomized trial [45]. Mixtures of flavonoid drugs (e.g. oxerutins) are licensed for use in venous disease. Daflon 500 accelerated healing of small ulcers in a randomized trial [46].

Stanozolol, an androgenic steroid with fibrinolytic properties, is helpful in improving lipodermatosclerosis [47] but no studies have demonstrated improved ulcer healing.

Complications. Cellulitis (erysipelas) frequently complicates leg ulcers and in deep, long-standing ulcers osteomyelitis has to be considered [48]. Malignant transformation in a non-healing ulcer is significant, with a relative risk of 5.80 in one study [49].

Recurrent ulcers and their prevention

Once their ulcer is healed, patients should be transferred from a bandage regimen to compression hosiery [1,2].

Many recurrences are the result of poor follow-up and inadequate or worn-out elastic stockings. Indeed, the 50% overall recurrence rate over 5–7 years has been shown to be higher in those prescribed stockings and is an indication of poor supervision [3]. Some recurrences are the result of superimposed arterial disease causing tissue ischaemia and skin necrosis. Many ulcers are precipitated by minor trauma, in which case a foam or felt pad should be worn over or under the stocking over vulnerable areas. Despite this, a considerable proportion of well-treated, formerly ulcerated limbs develop recurrences from time to time, often for no obvious

(a) (b)

Fig. 47.32 A large ulcer (a) before and (b) after skin grafting.

reason. These recurrences are more likely in post-thrombotic limbs. Obsessional attention to detail in stocking use, avoidance of minor trauma and early vigorous treatment of any breakdown should reduce the period of re-ulceration to a minimum.

Surgical ligation of the saphenous veins and of incompetent communicating veins appears no better than stanozolol and stockings in preventing ulcer breakdown. Ablation of venous reflux by conventional surgery or endovenous treatment (plus compression hosiery) can reduce the risk of ulcer recurrence [4].

Surgical treatment [1]

Surgical removal of the superficial incompetent varicose veins in patients with normal deep veins does not improve ulcer healing but significantly reduces the incidence of ulcer recurrence (Effects of Surgery and Compression on Healing and Recurrence (ESCHAR) trial) [2]. Recurrence rates of 30–50% after different surgical manoeuvres have been reported within 5 years [3–5]. Ligation and stripping of the saphenous veins and compressive sclerotherapy are the procedures most frequently undertaken, although with endovenous treatments the same results should be obtained. Complete extirpation of the communicating veins 'feeding' the ulcer is a logical approach but has failed to show any benefit in the only controlled trial that has been reported [6].

It would appear that surgical eradication of superficial incompetent veins is effective in preventing recurrence in patients without post-thrombotic damage but has little place in preventing recurrent ulceration in patients with damage to the deep venous system [7]. The newer procedures of deep-vein bypass, valvuloplasty and brachial valve transplant have still not been subjected to rigorous assessment by independent centres concerned with treating large numbers of patients with post-thrombotic limbs and venous ulcers. The value of these techniques in preventing ulcer recurrence in post-thrombotic limbs is therefore unknown. Elastic stockings must be worn for life and renewed at 6-monthly intervals if recurrence is to be prevented, and even these are not totally effective [8].

Shave therapy, a method of excision of ulcer and surrounding lipodermatosclerosis followed by meshed split-skin graft, healed 88% of ulcers in 18 patients [9]. The long-term results of this therapy show that 50% of the ulcers remain healed at 5 years [10].

Skin grafting on the lower legs is a means of considerably reducing the time taken for the ulcers to heal. It is usually performed on in-patients but can be carried out as an outpatient ambulatory procedure [11]. Pinch grafting provides small quantities of dermis as well as epidermis but leaves unsightly donor sites; large ulcers usually require split-skin grafts, which must be placed on surgically debrided beds. The application of mesh grafts has proved very effective when combined with ulcer excision (Fig. 47.32) [12,13]. Recurrence rates depend on patient selection. Those with many underlying medical or social problems are likely to have

ulcer recurrence within a few weeks or months of grafting. Many studies of skin grown *in vitro* have indicated that keratinocytes will stimulate healing with the repopulation of host tissues even though the grafts may not themselves survive. Mechanisms underlying growth stimulation by cytokines have led to a growth-factor industry [12]. No cytokine, however, can be relied upon to promote healing unless most of the above-mentioned management factors are first attended to. If the underlying causes of ulceration are well managed, healing rates are excellent and added cytokines are not necessary [14].

Surgical options to correct venous reflux, such as endovenous procedures (foam sclerotherapy and endovenous laser), perforator interruption (SEPS), deep venous reconstruction and ligation and stripping of incompetent superficial veins, have not been shown to improve ulcer healing [15,16]. A randomized, controlled trial demonstrated that compression therapy alone did not differ from surgical correction of superficial venous reflux in combination with compression therapy in healing of venous ulcers [2]. Correction of confirmed superficial vein incompetence should be considered once healing is complete.

Arterial ulceration

Death of the skin automatically follows occlusion of its arterial blood supply unless this occurs slowly enough to allow a collateral circulation to be established. Arterial or arteriolar occlusion, if present, also complicates the treatment and prognosis of ulcers that are primarily venous in origin. A study of 600 patients with leg ulcers in the Lothian and Forth Valley, Scotland, revealed evidence of arterial disease in slightly less than one-quarter of those affected [1].

Atheroma of the abdominal and limb vessels is the single most common cause of ischaemic ulceration likely to be seen by the dermatologist involved in the care of patients with leg ulcers. Many other pathological states may, however, cause arterial occlusion, and not all can be defined with accuracy on clinical grounds. A useful empirical approach to the diagnosis of clinically ischaemic ulcers is to consider the causes in three main groups:

1 Extramural 'strangulation'
2 Mural thickening or accretion
3 Intramural restriction of blood flow.

There is often considerable overlap, and the exact pathology cannot always be well defined.

Extramural causes. Scar tissue and radiodermatitis cause a fibrotic strangulation of the arterioles and may give rise to small but persistent ulcers. Ulceration occurs in a number of diseases associated with dermal sclerosis, including scleroderma and progeria (Werner's syndrome; Chapter 15). Compression by tumours may also obstruct arterial flow.

Mural causes. Ulceration depends on the speed with which changes take place in the vessel wall. In vasculitis this is often sudden, but in hypertension it is slower and is preceded by pain, erythema and tenderness. In atherosclerosis the accretion of intimal plaques may proceed with a reduced flow until thrombosis, embolism or infection precipitate complete closure.

Intramural causes. Microvascular occlusion caused by changes in blood viscosity and clotting mechanisms is discussed in Chapter 49.

Clinical features [2]. The general symptoms and signs exhibited by the patient with advancing ischaemic disease of the limbs have already been described (p. 47.1). Arterial ulcers frequently arise in the pretibial area, the foot or on the toes, whereas venous ulcers favour the gaiter region.

Severe pain is usual, but is not a reliable discriminator from venous ulceration, which can also be very painful. Pain is as marked in small ischaemic ulcers as in large ulcers. The edges of the ulcers are sharply defined and the ulcer itself is often punched out.

There is often no pigmentation or lipodermatosclerosis in the surrounding skin, unlike the changes around venous ulcers, but the two can coexist. Usually, exudation from arterial ulcers is minimal. The base is often pale and covered with a slough which may have bare tendons in its base (Fig. 47.33). When smaller arteries and arterioles are occluded, the ulceration may have an irregular outline with strands of infarction extending along a vascular pattern in the skin. The condition is often indolent, healing only when the blood supply is improved and the ulcer base is excised and grafted.

Fig. 47.33 An ischaemic ulcer with slough and exposed tendons.

Treatment. Legs with severe arterial disease (APBI < 0.5) should be considered for immediate revascularization after assessment by arterial duplex ultrasound or angiography. Those with moderate arterial compromise (APBI > 0.5 but < 0.85) should be treated with modified compression, for example short stretch bandages that convey low resting pressures. Revascularization should be considered in ulcers that do not heal [3,4]. Limb salvage can be achieved in most patients but those failing the interventions described above, or who are unsuitable for revascularization, may require amputation. There is weak evidence that intermittent pneumatic compression is of benefit [5]. There is insufficient evidence to determine whether the choice of a topical agent or dressing affects the healing of arterial leg ulcers [6].

Hypertensive ulcer

Synonym
- Martorell's ulcer

Hypertensive leg ulcers are a unique form of lower extremity ischaemic leg ulcer. First described by Martorell, and by Hines and Farber in the 1940s [1,2], these ulcers are defined by pain disproportionate to the size of the ulcer, specific location on the lower extremity, female-to-male predominance, association with long-standing, often poorly controlled, hypertension, and healing response to specific antihypertensive agents [3].

Hypertensive ulceration tends to be bilateral and produces superficial ulceration yet the peripheral pulses are always present, distinguishing the condition from atherosclerosis. It is often initiated by trauma, and the ischaemia may be a consequence of a failure to meet the demands for repair. Whether it truly represents a specific disease has been questioned [4].

On biopsy there is increased thickening of the arteriolar walls with luminal narrowing by subendothelial hyalin degeneration. Smooth-muscle hyperplasia is most marked in the media and is most easily recognized by an increase in the number of smooth-muscle nuclei. It is later replaced by collagen fibres.

The ulcer is initially preceded by a small macular cyanotic lesion present on the anterior external aspect of the leg at a point between the middle and lower thirds of the limb. It is usually extremely painful, and this may be alleviated by holding the leg in the dependent position. The livid edge is a characteristic feature (Fig. 47.34).

The blood pressure should be controlled, and the leg should be placed in a position to prevent oedema but not so high as to promote further ischaemia. A firm non-elastic (short stretch) support bandage, without compression, is the most helpful treatment. At this site on the leg, the blood supply is difficult to re-establish, and several weeks may pass before the ischaemic necrotic tissue separates and granulation tissue begins to form. Smoking should be stopped and β-blockers avoided. Excision of the ulcerated area with grafting has been advised.

Other causes of leg ulceration

Prolidase deficiency

Prolidase deficiency is transmitted as an autosomal recessive condition and has a European incidence of less than 5 : 10 000 people [1]. This rare disease is caused by a defect in the prolidase (PEPD, iminodipeptidase) gene on chromosome 19cen-q13.11. Prolidase is one of the enzymes that degrade collagen to iminodipeptides, it cleaves dipeptides with hydroxyproline or proline at the C-terminus [2]. Decreased activity of prolidase causes excretion of large amounts of proline and hydroxyproline, bound to amino acids as iminodipeptides in the urine, resulting in a depletion of the total pool of proline [3].

Prolidase deficiency is a multisystem disorder and the skin is its primary target organ. Clinical symptoms commence before the age of 12 years [3]. Ninety per cent of patients have dermatological features. Recurrent, multiple ulcers of the lower extremities are seen in over 50% of patients (Fig. 47.35). The development of a squamous cell carcinoma in the ulcer is an uncommon complication. Fragility of the skin, resulting in breakdown at the site of injury, is often preceded by purpura or bruising. Fine scarring, telangiectasia and eczematous lesions may be a feature. The facies are characteristic, consisting of hypertelorism with a saddle nose, and patients are mentally retarded. Other associations, not present in all cases, are dental caries, splenomegaly, hyperextensibility of ligaments, osteoporosis, respiratory infections, corneal opacities, amblyopia and optic atrophy. The skin may have a doughy consistency as in other collagen diseases [4].

The diagnosis is ascertained by iminodipeptiduria greater than 5 mmol/24 h [5]. In the blood a decreased prolidase activity is found. Laboratory abnormalities associated with prolidase deficiency consist of thrombocytopenia, hypergammaglobulinaemia and iron-deficiency anaemia [2]. Skin biopsy is almost normal in prolidase deficiency, although fragmentation of collagen fibres with impaired aggregation or a decrease in the size of collagen fibres may be found.

A characteristic feature of the disorder is absolute resistance to all forms of treatment, including rejection of skin grafts. Using topical antibiotics may control infections, and developing infections should be treated with oral or intravenous antibiotics [2]. Because co-factors of prolidase are ascorbic acid and manganese, these have been recommended therapies, as has diphenylhydantoin [6]. Japanese investigators recommend an ointment containing 5% glycine and 5% proline [7], and this was confirmed to be effective by Jemec and Moe [6]. Apheresis exchange was successful in two patients [8] and the combination of topical and systemic growth hormone resulted in transient healed recalcitrant leg ulcers in a 13-year-old boy [9].

Hydroxycarbamide (hydroxyurea) therapy

Hydroxycarbamide (formerly hydroxyurea) is a chemotherapeutic agent that acts during cellular replication and inhibits DNA synthesis without affecting RNA synthesis [1]. It is currently the drug of choice for treatment of chronic myelo- and certain lymphoproliferative disorders, for example chronic myeloid leukaemia, chronic lymphocytic leukaemia, polycythaemia vera and essential thrombocythaemia [2]. It is also used in the treatment of sickle cell anaemia. Dermatological adverse effects have been well documented. In a study by Vassallo *et al*., all 158 patients using

hydroxycarbamide for the treatment of chronic myeloid leukaemia suffered cutaneous xerosis and mild stomatitis [3]. Other adverse effects include hyperpigmentation, brown nail discoloration, acral erythema, scaling of the face, hands and feet, dermatomyositis-like eruptions, partial alopecia, atrophy of the skin and subcutaneous tissue, and leg ulcers.

In a prospective study, leg ulceration was reported to occur in 9% of patients taking hydroxycarbamide [4]. In three-quarters of patients, the ulcers are located on or near the malleoli [2]. The ulcers usually develop after at least 1 year of treatment. The lesions are generally very painful and resemble atrophie blanche. Hydroxycarbamide therapy is associated with leg ulceration in a dose-dependent fashion; with higher doses, wound size increases and healing is usually observed after withdrawal of hydroxycarbamide.

Several pathogenetic mechanisms have been postulated, but currently it is unclear how hydroxycarbamide induces leg ulcers. Histological examination shows non-specific changes [5].

Differential diagnosis includes cutaneous leukocytoclastic vasculitis, cryoglobulinaemia and pyoderma gangrenosum, and these diseases should be ruled out.

After withdrawal of hydroxycarbamide, 85% of ulcers spontaneously heal in 1–9 months [2]. In most other patients, a reduction in ulcer size is observed. A split skin graft, preceded by surgical debridement, may be performed in cases without spontaneous resolution. Many patients will develop new ulcers after restarting hydroxycarbamide therapy, so this should be avoided if an alternate agent can be prescribed.

Vasculitis/vasculopathy

Most acute forms of vasculitis, and some subacute and chronic forms, are likely to cause ulceration. Vasculitic lesions are usually, but not always, multiple. Palpable purpura is characteristic but vasculitis may be polymorphous, even pustular.

Rheumatoid disease [1]. Leg ulceration in rheumatoid arthritis is common and the causes can be multifactorial. Poor joint movement impairs the calf muscle pump and immobility increases the risk of DVT. True 'rheumatoid ulcers' occur as a manifestation of rheumatoid arteritis. Ulcers are often situated in the gaiter region and have a sloughy base with poor granulation. The absence of surrounding lipodermatosclerosis or of other signs of venous disease, the presence of a positive rheumatoid factor (particularly if at high titre) and demonstration of normal Doppler pressures and venous duplex studies suggest that the ulcer is truly 'rheumatoid'. Biopsy may be helpful but is not always confirmatory and the site may not heal. Ulceration of rheumatoid nodules is uncommon except at pressure sites in bedridden patients. Thinned skin because of long-term corticosteroid treatment, and the use of methotrexate, both increase the risk of ulceration. Healing can be very impaired, particularly in the presence of muscle atrophy, immobility and oedema but patients should be treated with immunosuppression to control the vasculitic component.

Other autoimmune disease. Leg ulceration in patients with lupus erythematosus is well recognized [2]. In Felty's syndrome and Still's disease, multiple painful ulcers occur on the legs and feet and are difficult to heal. Ulcers also occur in polyostotic fibrous dysplasia (Jaffe–Lichtenstein disease), in which a diffuse mesenchymal abnormality is present. Ulceration occurs over large areas of subcutaneous or muscular calcinosis, especially around the knee.

Sarcoidosis. Sarcoidosis can rarely result in leg ulceration due to granulomatous vasculitis [3].

Livedo reticularis. Livedo reticularis, a fixed but broken pattern of mottling, may result from vasculitis but also occurs with intravascular thrombosis caused by cryoproteinaemias [4], antiphospholipid syndrome and Sneddon's syndrome (Chapter 49).

Livedoid vasculopathy (livedo vasculitis). This condition is a more specific form of occlusive vasculopathy limited to the gaiter skin and often extending onto the dorsum of the foot. Ulcers are small, painful and heal with ivory-white scars (atrophie blanche). The mechanism appears to be more to do with hyalinization and thrombosis of the microvasculature with scarce inflammatory infiltrate unlike a leukocytoclastic vasculitis; therefore immunosuppression treatment is not so effective and consideration needs to be given to hypercoagulable states and their treatment [5]. Livedo with summer ulceration is a variant of the same condition (Chapter 49).

Cutaneous polyarteritis nodosa may rarely present with ulcerating atrophie blanche. Associated sensory loss (mononeuritis multiplex) and medium vessel vasculitis may be the only positive findings [6].

Treatment of leg ulceration secondary to vasculitis or vasculopathy involves control of any underlying condition combined with compression, as gravitational forces largely determine the localization of ulceration to the gaiter region.

Fig. 47.37 'Steroid ulcer' with totally suppressed granulation tissue.

Haematological disorders

Indolent non-healing ulcers on the leg are a feature of sickle cell anaemia (Fig. 47.36), hereditary spherocytosis and other haemolytic anaemias [1]. Sickle cell ulcers were reported in 2.5% of over 2000 patients with sickle cell anaemia aged 10 or over and were more common in patients with sickle cell anaemia and thalassaemia genotypes [2]. There is a high incidence of venous reflux in sickle cell disease, indicating the need for compression therapy as well as treatment for the sickle cell anaemia itself [3]. Other haemolytic anaemias also predispose to leg ulceration [4].

Myeloproliferative disorders may contribute to leg ulceration if cell size compromises capillary perfusion or if thrombosis develops, but it can be difficult to distinguish between disease-related and treatment-related (e.g. hydroxycarbamide) ulceration.

'Steroid ulcers'

Intralesional steroid injections, especially if made in areas with an already impoverished blood supply, may cause an indolent ulcer with a characteristic greyish slough (Fig. 47.37) [1]. This condition is most commonly seen when strong topical corticosteroids are applied to venous or other ulcers of the lower leg and ankle. Long-term use of potent topical steroids on the shins can also lead to poor wound healing after traumatic injury.

Fig. 47.38 Meleny's spreading gangrene.

Infection

Infection may lead to ulceration, which is often slow to heal because of associated oedema, cellulitis, thrombophlebitis, diabetes or underlying vascular disease. Primary uncomplicated pyococcal ulceration is rare; ecthyma is an example. Meleney's ulcer (bacterial synergistic gangrene) extends rapidly and has a burrowing, bluish, undermined and painful edge (Fig. 47.38). Tuberculous ulcers occur in erythema induratum (Bazin's disease) and are chronic, often on the back of the calves. They usually have undermined edges and considerable surrounding inflammation (Chapter 31). Other mycobacterial infections may be more common than suspected (Chapter 31). Ulcers in leprosy are usually on the foot, especially the dorsum, and on the proximal phalanx of the great toe, but can occur occasionally on the leg. The 'classical' appearances of the ulceronodular form of tertiary syphilis are well known, but this is extremely rare. Multiple tissue-paper scars on the legs occur typically in yaws (Chapter 34). The so-called 'desert' or 'veldt' sore is shallow and crusted; the role of *Corynebacterium*

diphtheriae is uncertain. The 'tropical' ulcer is a variety of phagedenic ulcer with a mixed symbiotic infection and rapid spread. Leishmaniasis, relatively uncommon on the legs, should be remembered as a possible cause of an indolent granulomatous ulcer. Among other uncommon infective causes of ulceration are glanders, tularaemia, brucellosis and cat scratch fever.

Pyoderma gangrenosum (Chapter 50)

This causes rapidly spreading and often bizarre and extensive ulceration, which may mimic an artefact, particularly when it precedes obvious ulcerative colitis. Underlying systemic disease such as inflammatory bowel disease, rheumatoid arthritis and haematological malignancies are found in some 70% of cases [1,2].

Necrobiosis lipoidica and granulomatous diseases

Necrobiosis lipoidica may ulcerate following trauma, is extremely indolent, and should be regarded as ischaemic. Similarly, any granulomatous lesion may ulcerate if its blood supply is inadequate or if the vessels are involved in the granulomatous process, as may occur in sarcoidosis.

Decubitus and neuropathic ulceration

Pressure sores occur easily and with little warning on the heels and ankles of elderly people, especially in those who are comatose or have neurological disease. Pressure, including from bandages, may cause ulceration in those with compromised blood supply or reduced cutaneous sensation. In all cases where ulceration is protracted in the absence of venous, arterial or other obvious disease, artefact must be considered; interference with ulcers already present may also occur, even through bandages [1].

Neuropathic ulceration of the foot benefits from protection from shearing forces [2] by the use of a plaster cast or 'Scotchcast boot'. If this fails to achieve healing, the pressure must be taken off the foot and the base of the ulcer excised before being grafted. Split skin, rotation flaps or pedicle flaps may be used to cure the defect. It may be simpler to excise the toe and most of the first metatarsal to achieve rapid healing if the ulcer is situated over the ball of the foot. Patient education is of prime importance to avoid recurrent, inadvertent self-trauma.

Diabetic foot ulcers

Diabetic foot ulceration is a common, yet in many cases an eminently preventable, complication that affects 1 in 20 patients with diabetes. Risk factors for ulceration include reduced sensation (secondary to somatic neuropathy), high foot pressures, callus formation (a consequence of sympathetic neuropathy and high foot pressures), deformities (such as claw feet, prominent metatarsal heads, etc.), peripheral vascular disease, and, most importantly, a past history of ulceration [1].

Fig. 47.39 Neuropathic–ischaemic ulcers over the base of the foot (diabetic).

The natural history in the development of the diabetic foot can be divided into five stages: stage 1, a normal foot; stage 2, a high risk foot; stage 3, an ulcerated foot; stage 4, an infected foot; and stage 5, a necrotic foot. This covers the entire spectrum of foot disease but emphasizes the development of the foot ulcer as a pivotal event in stage 3, which demands urgent and aggressive management. An important prelude to diabetic foot treatment is the differing diagnosis of neuropathic and neuroischaemic foot. In the neuropathic foot, ulcers commonly develop on the plantar surface of the foot and the toes (Fig. 47.39), and are associated with neglected callus and high plantar pressures. In the neuroischaemic foot, ulcers are commonly seen around the edges of the foot, including the tips of the toes and the back of the heel, and are associated with trauma or wearing unsuitable shoes. Ulcers in stage 3 need relief of pressure (mechanical control), sharp debridement and dressings (wound control), and neuroischaemic foot ulcers may need vascular intervention (vascular control). In stage 4, microbiological control is crucial; severe infections need intravenous antibacterial therapy, and urgent assessment of the need for surgical drainage and debridement. Without urgent treatment, severe infections will progress to necrosis. In stage 5, necrosis can be divided into wet and dry necrosis. Wet necrosis in neuropathic feet requires intravenous antibacterials and surgical debridement, and wet necrosis in neuroischaemic feet also needs vascular reconstruction [2].

Infection is most often a consequence of foot ulcerations, which typically follows trauma to a neuropathic foot. Tissue specimens are strongly preferred to wound swabs for wound cultures. Gram-positive bacteria are the sole causative pathogens for most mild and moderate infections. These infections can usually be treated with culture-based narrow-spectrum antibacterials along with appropriate surgical debridement in an outpatient setting. In contrast, severe infections are often polymicrobial, requiring hospitalization and treatment with broad-spectrum antibacterials along with appropriate medical and surgical interventions. The initial

empirical antibacterial regimen may be tailored based on the results of culture and sensitivity tests from properly obtained specimens [3].

Diabetic foot care in all stages needs multidisciplinary management to control mechanical, wound, microbiological, vascular, metabolic and educational aspects. Achieving good metabolic control of blood glucose, lipids and blood pressure is important in each stage, as is education to teach proper foot care appropriate for each stage. In the management of neuropathic ulcers, pressure relief is of the utmost importance, and total contact casting remains the 'gold standard' means of achieving such pressure redistribution. Alleviation of the mechanical load on ulcers (off-loading) should always be a part of treatment. Neuropathic ulcers typically heal in 6 weeks with total contact casting, because it effectively relieves pressure at the ulcer site and enforces patient compliance [4].

An ulcer that does not heal for many months has a high probability of leading to osteomyelitis, for which treatment with antibiotics is not useful and which usually requires a surgical procedure. Charcot neuroarthropathy is a particular complication of neuropathy, which may lead to fragmentation or destruction of joints and bones.

Osteomyelitic bones in the foot must be excised and diabetic ischaemic ulceration treated by revascularization and split skin grafting with mesh where appropriate.

Introduction

The lymphatic system comprises the lymph, lymphatic vessels, lymph nodes and other organs containing lymphoid tissue, especially the spleen and bone marrow. A close developmental and working relationship exists between the lymphatic vessels and the blood circulation, particularly the veins. Although not a true circulation like the blood vascular system, the lymphatic system does provide an important 'limb' to the microcirculation, particularly in the skin, and, with the blood vessels, caters for the constant recirculation of protein and cells. While lymph drainage serves a predominantly 'plumbing' role, the lymphatic system does possess important immunological responsibilities. The lymphatic vessels are essential for the continual drainage from the tissues of the body of both plasma proteins and lymph-borne cells, for example lymphocytes and macrophages [1].

While technology has advanced our knowledge of the lymphatic system at the cellular and molecular level, our understanding of whole-body physiology lags behind. Nevertheless, the importance of the lymphatic vessel in disease is demonstrated by recent evidence implicating it in the pathogenesis of several conditions including cancer metastasis [2], asthma and airways obstruction [3], atherosclerosis [4], Crohn's disease [5], arthritis [6] and renal transplant rejection [7].

Lymphatic development

The embryonic origin of the lymphatic system has long been uncertain, but its close development with the venous system is not in doubt. In 1902, Sabin proposed that early in fetal development isolated primitive lymph sacs originate by endothelial cell budding from embryonic veins [1,2] and that the skin lymphatic vessels develop by endothelial sprouting from these primary lymph sacs (centrifugal development). Alternatively, it has been suggested that initial lymph sacs develop from precursor cells, 'lymphangioblasts', in the mesenchyme (centripetal development)

[3]. Recent work indicates that lymphangioblasts are located in the confluence of the cranial and caudal cardinal veins, where the jugular lymph sac (JLS) forms. Cell lineage studies show that the JLS is of venous origin. In contrast, the lymphatic vessels of the dermis are derived from mesenchymal lymphangioblasts, suggesting a dual origin of lymphatic endothelial cells (LECs), both central and peripheral, although the primary source of embryonic LECs probably resides in specific embryonic veins [4].

Lymphvasculogenesis and lymphangiogenesis

Lymphvasculogenesis is the *de novo* production of LECs. It may occur in the embryo from specific veins and possibly in the adult from bone-marrow derived progenitor cells [5]. It is essential for establishing the lymphatic system initially.

Lymphangiogenesis is the production of new lymphatic vessels by splitting and splicing of existing LECs, and occurs both in the embryo and the adult.

Vascular endothelial growth factor (VEGF)

In 1995, the first specific growth factor receptor of lymphatic vessels was identified and termed FLT-4 [6]. It is now termed vascular endothelial growth factor receptor-3 (VEGFR-3). The family of vascular endothelial growth factor receptors and their ligands are central to the development of blood and lymph vessels [6]. In embryos, VEGFR-3 is initially expressed in all vasculature, but during development its expression in blood vessels (veins not arteries) becomes restricted to the developing lymphatic vessels. In embryos, therefore, VEGFR-3 is important for cardiovascular development, but in adults it is responsible for the regulation of the lymphatic vessels [7].

Lymphatic development requires the activation of the transcription factor PROX1 [8], which acts as the LEC master control gene and then regulates the expression of VEGFR-3, a receptor for VEGF-C and -D. LECs expressing VEGFR-3 bud off and migrate away from the embryonic cardinal vein in response to a gradient of VEGF-C produced by the nearby mesenchymal cells [9]. The migrating LECs assemble into lymph sacs which extend through sprouting to lay down the lymphatic network.

Post-natal lymphangiogenesis

Lymphatic vessel growth is regulated by several lymphangiogenic factors, including members of the vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), hepatocyte growth factor (HGF) and angiopoietin families. VEGF-C and -D are the main ligands for VEGFR-3, which is lymphatic-specific, and therefore specific for lymphangiogenesis. The most potent inducer of lymphatic sprouting is VEGF-C. Over-expression of VEGF-C in skin keratinocytes leads to dermal lymphatic hyperplasia [10].

While lymphangiogenesis is mediated mainly via VEGF-C and -D binding to VEGFR-3, lymphangiogenic responses can occur through VEGFR-2 and VEGFR-3. In addition to VEGF-C and -D, VEGF-A (also called vascular permeability factor) is able to stimulate lymphangiogenesis. VEGFR-2 has been detected on endothelial cells of the lymphatic vessels, suggesting its direct role in the stimulation of lymphangiogenesis [11]. Alternatively, VEGF-A might recruit inflammatory cells that indirectly stimulate lymphangiogenesis through the secretion of cytokines and growth factors [12].

Recently, VEGFR-1, in response to VEGF-A binding, has been shown to promote lymphangiogenesis, as well as angiogenesis, via bone marrow-derived macrophage recruitment, but probably only in pathological states. For example, progenitor cells have been shown to participate in lymphangiogenesis in chronic renal transplant rejection [13]. VEGFR-1 is expressed not only on vascular and lymphatic endothelium but also on monocytes/macrophages. VEGFR-1 could be involved in lymphangiogenesis in one of three ways: firstly, VEGFR-1 contributes to vascular permeability, and resulting exudates induce lymph vessel dilatation and lymphangiogenesis; secondly, VEGF-A recruits bone marrow-derived macrophages in a VEGFR-1 signal-dependent manner; and thirdly, recruited macrophages express VEGF-C which binds to VEGFR-3 [14]. It is still unclear how physiological lymphangiogenesis is regulated.

Vascular separation

The separation of lymphatic vessels from blood vessels is important for their independent functioning. Syk and SLP-76 deficiency leads to arteriovenous shunting and lymphovenous connections [15]. These proteins and those of the Spred/Sprouty family may have implications in mixed vascular malformations where blood-filled lymphatic vessels can occur.

Lymphatic remodelling

After the initial lymphatic vasculature is established, it is then remodelled into a functioning network comprising lymphatic capillaries/initial lymphatics and collecting lymphatics possessing smooth muscle. FOXC2, EphrinB2 and Angiopoietin-2 play important roles in the remodelling process, including recruitment of smooth muscle cells and formation of valves [16].

Anatomy

In the skin, lymphatic vessels form two horizontally running networks, a narrow-meshed, superficial network lying subepidermally and a deeper, wide-meshed network. The networks are connected to each other through obliquely-running vessels (Fig. 48.1). Although fewer in number than blood vessels, lymphatics are potentially larger at capillary level. Lymphatics are essentially of two types:

1 Smaller, non-contractile, initial lymphatics (these used to be called terminal lymphatics), which commence or 'initiate' the drainage process within the tissues
2 Larger, contractile, lymphatic collectors, into which the initial lymphatics drain [1].

Afferent collectors drain to lymph nodes and efferent collectors (trunks) drain from lymph nodes. Lymphatic capillaries originate as blind-ending, endothelial-lined tubes in the subpapillary region, and are rarely seen within dermal papillae except in certain disease states—for example, in psoriasis [2,3]. From the superficial lymphatic plexus in the upper dermis, lymph drains through a series of enlarging precollectors into the contractile collecting trunks close to the dermosubcutaneous junction [1]. The lobules of adipose tissue have lymphatics only in their periphery, and clearance of lymph from the centre of the lobule is slow [4].

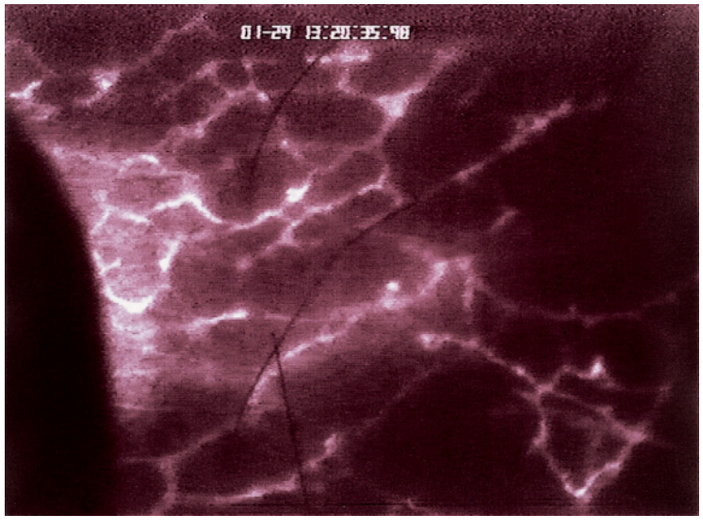

Fig. 48.2 Superficial network of dermal lymphatic vessels as viewed *in vivo* using fluorescence microlymphography.

Initial lymphatics in the skin are arranged in loosely constructed polygonal meshes (Fig. 48.2) high in the dermis [1,5]. Territories of skin are drained by these meshes into the vertically draining precollectors. A series of luminal valves ensure that flow is unidirectional. Such is the capacity of initial lymphatics for dilatation that the valves can become incompetent. Obstruction to deeper lymphatic routes leads to re-routing of lymph and results in 'dermal backflow', as witnessed both on conventional X-ray lymphography and lymphoscintigraphy. In this way, the initial lymphatic network of the skin provides collateralization by which lymph can escape to other (more) normally draining areas [6].

Structure and function

Description

Initial lymphatics/lymphatic capillaries

The lymphatic capillary is lined by a fine endothelium which is more attenuated than that of blood capillaries (Fig. 48.3). Potentially larger than blood capillaries, lymphatics are frequently not visualized in histological sections, because they are collapsed. A

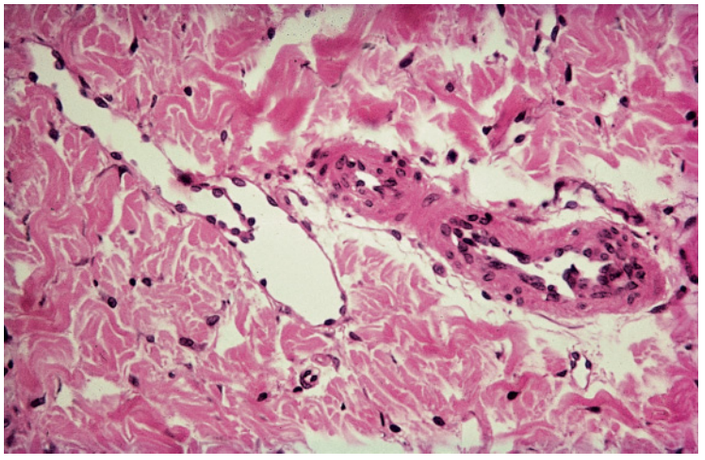

Fig. 48.3 Mid-dermal vessels showing the typical appearance of a mid-dermal blood capillary with plump endothelium compared with adjacent lymphatic vessels with attenuated endothelium and a valve. Such valves are not present in blood vessels high in the dermis.

distended lymphatic exhibits characteristically thin, attenuated walls with nuclei bulging into the lumen. On electron microscopy, the gaps between overlapping endothelial cells are much larger than in the blood capillary. These 'open junctions' act as primary (mural) valves and serve as the entry point for macromolecules [1]. Initial (dermal) lymphatics have little in the way of a basement membrane or pericytes [2]. The lymphatic endothelium contains very few pinocytotic vesicles and lacks Weibel–Palade bodies and fenestrae [3]. Attached to the outside of the endothelium are anchoring filaments which attach the lymphatic to surrounding collagen and elastic fibres [4]. The main molecular component of the anchoring filaments is fibrillin [5]. The elastic fibres form a partial envelope around the dermal lymphatics [6]. In addition to the flap valves in the lymphatic wall are bileaflet intraluminal valves [7].

Lymphatic–vasculature function critically depends on extracellular matrix (ECM) and on its connections with LECs. EMILIN1, an elastic microfibril-associated protein, is highly expressed by LECs *in vitro* and colocalizes with lymphatic vessels in several mouse tissues. The phenotype displayed by *Emilin1*(−/−) mice is the first abnormal lymphatic phenotype associated with the deficiency of an ECM protein and identifies EMILIN1 as a novel local regulator of lymphangiogenesis [8].

Contractile collecting lymphatics

Contractile lymphatics are endowed with a basement membrane and are covered by mural cells, both pericytes and smooth muscle cells. They contain a regularly spaced chain of lumenal valves that prevent retrograde flow even at high pressures. Segments of lymphatic collecting vessel, between one valve and the next, act as active pumps called lymphangions. They are innervated and respond to vasoactive mediators including nitric oxide [9].

Identification of skin lymphatics—molecular markers

The recent discovery of specific markers for lymphatic endothelium has contributed greatly to the identification of skin lymphatics in tissue sections. Previously, the only certain way of distinguishing a lymphatic from a blood vessel was by electron microscopy. Intramural valves between overlapping endothelial cells are pathognomonic of skin lymphatic vessels [1]. If large skin biopsies are fixed in an expanded condition by stretching the specimen in different directions, as would be the case *in vivo*, lymphatic vessels become visible for both light and transmission electron microscopy [2].

A number of markers are available for labelling endothelial cells, but the majority stain both blood and lymph vessels (e.g. factor VIII-related antigen, CD31 (PECAM-1)). Because initial lymphatics lack a continuous basement membrane, immunocytochemistry for the extracellular matrix components type IV collagen and laminin has been used to distinguish them from blood capillaries [3]. Pal-E monoclonal antibody is consistently negative in lymphatic vessels but positive in venules and small veins, the vessels most likely to be mistaken for lymphatics [4].

Of the newer molecular markers, VEGFR-3 was the first to be documented to be expressed in lymphatic endothelium, but it can also be found in a subset of blood vessels and in angiogenic vessels in certain pathological conditions. LYVE-1 (lymphatic vessel hyaluronan receptor-1) is a homolog of hyaluronan receptor CD44 [5] (Fig. 48.4). It is present in initial lymphatics but not in the larger contractile lymphatics. LYVE-1 is also present in activated macrophages in skin and is frequently down-regulated on lymphatics in inflammation.

Podoplanin is a glomerular podocyte membrane mucoprotein which is highly expressed in lymphatic endothelial cells [6]. It is also expressed in keratinocytes but is very specific for dermal lymphatics. Studies in cultured endothelial cells indicate that T1α/podoplanin promotes cell adhesion, migration and tube formation, whereas small interfering RNA-mediated inhibition of T1α/podoplanin expression decreased lymphatic endothelial cell adhesion [7].

Other markers reported to be positive in lymphatic, but not in blood, vessels include Prox-1 which is a nuclear stain [8]. CCL21 is produced by lymphatic endothelium and directs homing of cells such as lymphocytes possessing CC receptors [9]. It is unlikely that any one marker will be totally specific, particularly

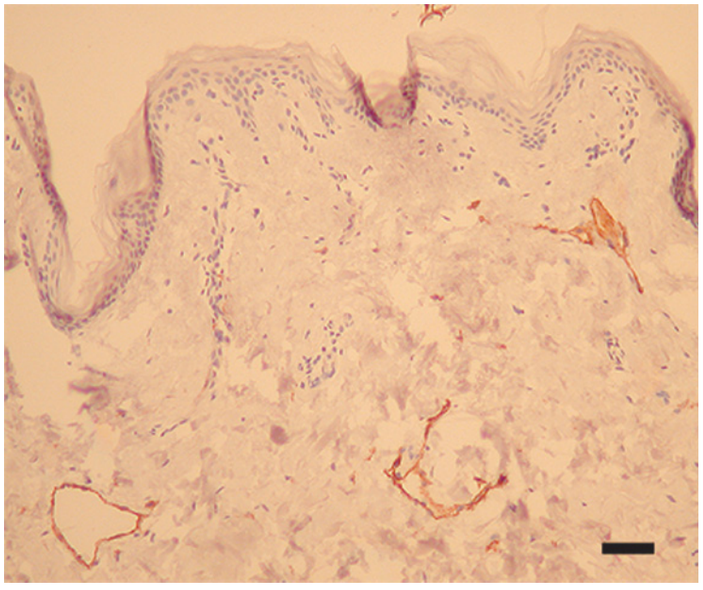

Fig. 48.4 LYVE-1 antibody marker for lymphatic endothelium. (Courtesy of Dr D.G. Jackson.)

Table 48.1 Markers for lymphatic vessels. (Adapted from [10].)

Molecule	Protein class	Biological effect
VEGFR-3	Receptor tyrosine kinase on endothelial cell	Lymphangiogenesis
LYVE-1	Receptor for extracellular matrix glycosaminoglycan	Transport of HA from tissues to lymph nodes
Prox-1	Transcription factor	Lymphvasculogenesis
Podoplanin (D2-40)	Integral membrane protein	Lymphatic morphogenesis
CCL21	Chemokine	T-cell trafficking

HA, hyaluronan; LYVE-1, lymphatic vessel endothelial HA receptor; VEGFR-3, vascular endothelial growth factor receptor-3; CC, chemokine with two adjacent cysteine residues.

in disease states, and the use of several markers is recommended (Table 48.1).

Purpose of lymphatics

Lymphatic vessels are primarily concerned with draining, from the tissue spaces, materials which cannot directly return to the bloodstream. While the bloodstream essentially supplies the tissues, the lymphatic system essentially drains them. This includes proteins as well as cells—extravasated erythrocytes, dendritic cells, macrophages, lymphocytes and, of course, malignant cells.

Contrary to traditional teaching, the lymphatic is the main drainage route for fluid. Only transiently is fluid reabsorbed by venous capillaries. It is important to understand this role of the lymphatic acting as a 'safety valve' or buffer against fluid overload, because it means that every form of oedema indicates some degree of lymphatic failure [1].

Lymphatics carry foreign material that has penetrated the dermis, including microorganisms, injected vaccines, solvents of skin cosmetics, inorganic material such as silica and stains from tattoos [2]. Bacterial and other microorganisms are channelled through lymphatics as a protective mechanism to prevent noxious agents from directly entering the bloodstream. Presumably this failure to 'police' infection is the reason why cellulitis/erysipelas can cause rapid systemic illness in lymphoedema before local signs are evident.

Snake envenomation causes a dose-dependent contraction of collecting lymphatic vessels, resulting in a reduction of their lumen and in a halting of lymph flow so venom remains contained within the lymphatics following a bite [3].

Lymph transport

After filtration from the microvasculature, interstitial fluid enters a series of passive initial lymphatics and is then propelled within the collecting trunks through a series of intervalvular pumping segments (lymph hearts) to the lymph nodes before eventually returning to the venous system at the thoracic duct. Transport of fluid and other materials (prelymph) across the interstitial space towards initial lymphatics is a passive process, dependent upon changes in local pressures (convective flow) [1,2]. Deformation or movement of the dermis by surface pressure and underlying muscle contractions and by dermal components, such as arterioles, causes expansion or compression of the initial lymphatics. The process of expansion is likely to result from pulling of the anchoring filaments on the abluminal surface of the lymphatic [3]. These probably act to prevent lymphatic collapse when interstitial

pressure is high, as in oedema [4]. Negative fluid pressure inside the initial lymphatics serves to open the interendothelial junctions (flap valves) and to permit inflow of interstitial fluid. After filling and equilibration of pressure the flap valves close. Compression of the filled lymphatic then moves lymph downstream, that is towards bigger lymphatics; the valves within the lymphatic vessels ensure that flow is in one direction. Recoil of the initial lymphatic occurs when the compression wave (squeezing) of the lymphatic ceases and the cycle repeats itself. Cardiac arrest leads to cessation of lymph flow, but lymph flow can be maintained with active skin massage even after the arrest of the heart.

Lymph does not passively 'drain downstream' through the collecting lymphatic vessels because the net pressure gradients oppose flow. Instead, the collecting vessels must act as both the conduits, that direct and regulate lymph flow, and the pumps that generate the lymph flow. The regulation of lymphatic muscle contractions is thought to occur via the interaction of cell calcium with regulatory and contractile proteins. This is almost certainly one of the mechanisms whereby calcium channel blocking agents cause peripheral oedema. However, our knowledge of this regulation of lymphatic contractile function is far from complete [5].

Immune functions

The principal immune function of the afferent lymphatics is to bear antigens and leukocytes from peripheral tissues to the draining lymph nodes. Recent research has shown that passage of leukocytes into the afferent lymphatic capillaries is far from an indolent process; rather it is carefully orchestrated by an array of adhesion molecules, as well as by chemokines and their receptors [1].

Lymphocytes and mononuclear phagocytes constantly patrol the skin, leaving via the afferent lymphatic vessels for the lymph nodes. Epidermal (e.g. Langerhans' cells) and dermal dendritic cells screen the skin for invading antigens. They migrate from the skin to regional nodes where a primary immune response is initiated [2]. Dendritic cells enter dermal lymphatics by transmigration through intercellular spaces of adjacent endothelial cells, frequently carrying material such as melanosomes and apoptotic bodies [3].

Under normal physiological conditions immature dendritic cells migrate constitutively and continuously from skin to lymph nodes via afferent lymphatics, undertaking immune surveillance [4]. Subsequent to inflammation the number of dendritic cells increases dramatically and they change from phagocytes into professional antigen-presenting cells [5]. Receptors on lymphatic endothelial cells facilitate migration of proteins and cells to, and within, lymphatics. CCL21 is a chemokine that is produced constitutively by lymphatic endothelial cells in the skin [6]. Disruption of the CCR7 gene, which prevents expression of CCL21, thereby prevents migration of dendritic cells from tissue to regional nodes. CCR7-deficient mice lack contact sensitivity due to a failure of translymphatic migration of epidermal dendritic cells [7]. CCR7 and its ligands (CCL21 and 19) are also important in regulating lymphatic trafficking of T cells [8].

Without intact lymphatics a primary immune response cannot develop. In the case of allogeneic skin grafts, removal of the lymph drainage channels causes cessation of the cellular reactions in the lymph nodes until lymphatic pathways are re-established [9,10]. Rejection is delayed in grafted skin sites where all draining lymphatics are severed [11]. Studies in lymphoedema following curative breast cancer treatment demonstrated an impaired response to dinitrochlorobenzene testing in the swollen limb but not in the contralateral control limb [12]. Similar results were reported in lymphoedema associated with Kaposi's sarcoma [13].

Bacteria, viruses, fungi and toxins which penetrate the skin are absorbed by lymphatics and not by blood capillaries [14,15]. Virulent haemolytic streptococci, tubercle bacilli and many types of soluble or particulate antigens injected intradermally readily reach the regional lymph node [9].

Table 48.2 Causes of oedema.

Increased capillary filtration
Increased capillary pressure
Increased venous pressure, e.g. right heart failure, DVT, obstructing malignancy, overtransfusion
Increased blood flow, e.g. inflammation, arteriovenous fistula
Reduced plasma proteins
Increased loss, e.g. nephrotic syndrome, protein-losing enteropathy
Reduced synthesis, e.g. cirrhosis, advanced cancer
Malabsorption, malnutrition
Increased capillary permeability
Inflammation, e.g. varicose eczema, psoriasis, urticaria and angioedema
Reduced lymph drainage
Primary lymphatic insufficiency
Genetic (and inherited)
Milroy's disease (onset at or soon after birth)
Lymphoedema, distichiasis (postpubertal)
Meige's disease (postpubertal)
Constitutive (presumed genetic)
Secondary lymphatic insufficiency
Iatrogenic interruption to drainage routes, e.g. surgery, radiotherapy
Cancer (particularly relapsed)
Infection, e.g. filariasis, cellulitis
Accidental trauma
Dysfunctional lymphatics
Dependency syndrome
Loss of mobility
High output failure, e.g. venous disease
Deep-vein thrombosis

Chronic oedema

Oedema is an excess of interstitial fluid. Interstitial fluid volume must increase by over 100% before oedema is clinically detectable. Dermal oedema manifests as 'peau d'orange' due to expansion of the interfollicular dermis, whereas subcutaneous oedema gives rise to pitting.

Any oedema, whatever the cause, is due to capillary filtration overwhelming the lymph drainage for a sufficient period of time [1]. Interstitial fluid is reabsorbed almost entirely by the lymphatics. Contrary to popular belief, venous reabsorption of interstitial fluid cannot be maintained for any length of time except in certain vascular beds, for example that of the kidney [1]. The causes of oedema formation are listed in Table 48.2. Most chronic oedemas arise from increased capillary filtration overwhelming lymph drainage. To some extent, therefore, any chronic oedema incriminates the lymphatic system through its failure to keep up with demand. Lymphoedema, however, is oedema arising principally from a failure in lymph drainage.

Therefore any chronic oedema indicates lymphatic failure. It is best not to approach a lower limb chronic oedema clinically by trying to pigeon-hole the diagnosis into 'heart failure', 'venous oedema', 'lymphoedema' etc. A far better approach is to consider if the oedema represents pure lymphatic failure, or, as is most common, lymphatic failure due to lymph drainage being overwhelmed by increased capillary filtration. Most cases of chronic oedema have more than one factor contributing to impaired lymph drainage and increased capillary filtration. Therefore terms such as lymphoedema (predominantly lymph drainage failure) or a filtration oedema (predominantly increased capillary filtration) are suggested [2] (Table 48.2).

Lymphoedema

Definition. Swelling due to the excess accumulation of lymph in the tissues caused by inadequate lymph drainage. Lymphoedema differs clinically from other forms of chronic oedema by its altered skin texture and the brawny quality of the subcutaneous tissues, which limit pitting. There may be no distinguishing features, particularly in the early stages of swelling. A more precise definition would be 'a swelling of soft tissues which is the result of accumulation of protein-rich interstitial fluid caused by a low output failure of lymph' [1].

Primary lymphoedema implies a genetic or constitutive cause whereby there is an intrinsic fault in lymph drainage determined by a lymphatic maldevelopment or functional weakness. Secondary lymphoedema implies an acquired failure of previously normal lymph drainage due to an identifiable cause extrinsic to the lymphatic system.

Epidemiology

Lymphoedema *per se* is perceived as uncommon, yet lymphatic insufficiency is a major contributing cause of chronic ankle oedema, which is considered common (particularly in the elderly) [2]. Because lymphoedema can be a difficult diagnosis, particularly if mild or in the early stages, it is frequently underdiagnosed. One survey, which determined the problem of chronic oedema (as a surrogate for lymphoedema) in the community, ascertained 823 patients in a catchment area of 619 000 in south-west London. This estimated the overall prevalence of chronic oedema as 1.33/1000 population; the prevalence increased with age and was 5.4/1000 in subjects aged over 65 years. In only a quarter did the oedema arise from cancer treatment. Twenty-nine per cent had experienced at least one attack of cellulitis over the previous year. Ten per cent of subjects had lost, or had had to change, employment as a result of their chronic oedema. Chronic oedema that was likely to be lymphatic in origin is common in the community and often goes unrecognized [3].

Primary types of lymphoedema tend to affect females more frequently (70–80% of patients are female). In less than 10% of cases is swelling present at birth; most cases present at or soon after puberty. It is estimated that 80% will present before the age of 35 years (lymphoedema praecox) and 10% after the age of 35 years (lymphoedema tarda) [4]. Data on prevalence of lymphoedema are few, and a figure for overall prevalence of primary lymphoedema is not available. However, a study of 1000 young

adults showed that 8% of women demonstrated signs of lymphoedema in the lower limb [5].

Secondary types of lymphoedema are more common than primary. In developed countries cancer treatment dominates as a cause whereas in tropical climates infection dominates [6].

Breast cancer-related lymphoedema (BCRL). The cumulative prevalence of swelling following breast cancer treatment in women is 28% [7]. The introduction of sentinel lymph node biopsy (SLNB), used as a staging investigation for cancer, has not necessarily reduced the incidence of lymphoedema as was hoped. While the incidence of BCRL following SLNB has reduced to 5–7%, the need for axillary clearance in the 30% who are node-positive can lead to an incidence of up to 45% in that group.

Pelvic malignancy. The incidence of lower limb lymphoedema following radical hysterectomy alone is estimated at 5–10% [8] but can be as high as 49% by 10 years of follow up in patients who have also received adjuvant radiation treatment [9]. The incidence after vulval cancer is reported at 28% [10]. Following prostate cancer the incidence has been reported at 3–8% [6], and after penile cancer 23–33% [11].

Melanoma. The incidence after lymphadenectomy can be up to 44% after therapeutic groin dissection for palpable disease [12], but the incidence following sentinel lymph node biopsy is much less [13]. Patients undergoing an inguinal lymph node dissection (ILND) for a positive SLN have a significantly lower risk of postoperative complication or lymphoedema than do patients undergoing ILND for clinically palpable disease [14].

Pathophysiology

Physiologically, there are only a limited number of ways lymphatics may fail. They may be reduced in number, obliterated, obstructed or simply fail to function. A lack of sensitive methods for investigation makes it difficult to distinguish between these mechanisms (Table 48.3).

A reduction in lymphatics may be due to hypoplasia such as the reduction of skin lymphatics in Milroy's disease. In the commonest form of primary lymphoedema, that presenting at or soon after puberty with distal leg swelling, lymphangiograms usually demonstrate a reduction in the size and number of superficial leg lymphatic collectors. It is often assumed that the lymphatics have been abnormal since birth but it is always possible that the lymph vessels have undergone an accelerated atrophy or ageing process. The congenitally determined abnormality may not therefore be an underdevelopment of lymphatics from birth, but rather a failure of growth/regeneration or function following damage or injury. This would explain the latent period before swelling manifests, particularly in those forms presenting later in life (lymphoedema tarda). In truth, we do not know and these possibilities are speculative.

An obliterative process, where there is permanent obliteration of the lymphatic lumen and consequently of the vessel itself, probably develops through lymphangiothrombosis or lymphangitis in the same way as for veins. Obliterative lymphangitis is probably the mechanism following infection or longstanding hand eczema.

Obstruction will cause increased outflow or downstream resistance and lead to re-routing via collateral pathways. Whether lymphoedema develops is dependent on the efficiency of such collaterals to accommodate the lymph load.

Reflux results from incompetence of intraluminal lymphatic valves. This is seen in lymphoedema–distichiasis syndrome, where there appears to be genetically-determined valve maldevelopment affecting both lymphatic and venous valves [15].

Table 48.3 Possible causes of lymph drainage failure.

Mechanism	Causes
Reduced lymph-conducting pathways	Hypoplasia of whole vessel, reduced numbers of vessels (initial or collecting) May be developmental failure or acquired obliteration of lymphatic lumen (e.g. lymphangiothrombosis, lymphangitis)
Poorly functioning lymphatics	May be physiological due to lack of movement or structural, e.g. pump (contractility) failure
Obstructed lymphatics	'Scarring' from lymphadenectomy, radiotherapy or infection
Lymph reflux	Megalymphatics, lymph vessel hyperplasia

Pathology. Decreased transport of lymph from the skin leads to an increase in protein-rich interstitial fluid. In circumstances other than where dermal lymphatics are congenitally absent (for example, Milroy's disease) or are destroyed (for example, post-erysipelas/cellulitis), interstitial pressure consequently rises and lymphatics dilate. Temporal changes observed in experimental lymphoedema indicate that the collagen fibres initially become swollen and separated [16]. Mononuclear cells are seen around the lymphatic and blood vessels [17]. Lymphatic walls thicken and fibrose. The muscular elements of the collecting trunks atrophy. Macrophages, fibroblasts and lymphocytes accumulate. Overgrowth of the interstitial connective tissue gradually transforms the soft stage of lymphoedema into the hard late-stage form [18]. The simple excess of protein seems to be the cause of the fibrosis [19,20]. The number of blood vessels greatly increases.

In human skin, the epidermis overlying an area of lymphoedema becomes acanthotic, with reduplication of the epidermodermal basement membrane. In the dermis, there is an increase in collagen, but the elastic fibres, including anchoring filaments, disappear. Ultrastructurally, the basal lamina of the dermal lymphatics thickens, but remains discontinuous, connective tissue microfilaments are increased, myofibroblasts appear and the connective tissue ground substance becomes hyalinized [21]. Inflammatory cells are conspicuous in the dermis. In the infiltrate, mast cells, macrophages, plasma cells and lymphocytes can be observed. Extravasated erythrocytes are often seen and large amounts of fibrin become deposited. Well-characterized morphological changes develop in the blood vessels (lymphostatic vasculopathy). In the upper dermis, numerous newly formed vessels can be seen. Angiogenesis results in a highly vascularized dermis.

Table 48.4 Causes of primary lymphoedema.

Congenital onset		Postpubertal onset	
Familial	**Sporadic**	**Familial**	**Sporadic**
Milroy's disease: below knee and bilateral	Turner's syndrome, Noonan's syndrome: can be transient; other phenotype abnormalities Neurofibromatosis, Proteus syndrome Pure or mixed vascular lymphatic malformations, lymphangiomatosis, Klippel–Trenaunay syndrome, Maffucci's syndrome: usually unilateral Amniotic bands: associated with autoamputation	Distichiasis–lymphoedema, Meige's disease: below knee and bilateral	Distal hypoplasia, lymph reflux: bilateral foot and lower leg swelling Ilioinguinal node sclerosis: whole limb and unilateral Yellow nail syndrome: bilateral, widespread oedema

Aetiology and classification

Lymphoedema may be primary (see Table 48.4), secondary (see Table 48.5), dysfunctional or cancer-related.

Primary lymphoedema

Lymphoedema arising from an intrinsic abnormality of the lymph-conducting pathways is referred to as primary lymphoedema [1] (Table 48.4). A simple classification by age of onset without reference to aetiology or other clinical features is into the following subdivisions: congenital (present at or very soon after birth), praecox (presenting before age 35 years) and tarda (presenting after age 35 years). The development of lymphangiography in the 1950s resulted in a radiological classification: aplasia (no formed lymph pathways found), hypoplasia (lymphatics smaller or fewer than normal) and hyperplasia (lymphatics larger and more numerous). Aplasia, hypoplasia and hyperplasia refer to abnormalities in the main (leg) conducting lymph vessels as opacified on lymphangiography, and not to the initial lymphatics, which are not imaged with this method. Further investigation revealed types of lymphoedema where few, if any, lymph conducting vessels could be identified in the foot, but vessels were found to be normal further up the limb [2].

An increasing understanding of the genetic basis of primary lymphoedema has further changed classification and to some extent made the praecox and tarda categories redundant. For example in lymphoedema–distichiasis syndrome (LDS), the onset of lower-limb oedema can range from puberty to 40 years old despite the same cause, namely a mutation in the *FOXC2* gene [3]. Conversely, LDS and Meige forms of primary lymphoedema can both present at puberty with similar lower lymphoedema but have different genotypes and different mechanisms; LDS is associated with hyperplasia and valve reflux of collecting lymphatics whereas Meige's disease is associated with hypoplasia of collecting vessels. In the future, classification of lymphoedema is likely to be based on phenotype, unless the genotype is known.

Inherited forms of lymphoedema where the gene is known

1 *Milroy's disease* (primary congenital lymphoedema, hereditary lymphoedema type 1; MIM 153100). Milroy first described the disease in 1892 but published definitively on it in 1928. He

described a large pedigree with lymphoedema beginning at or soon after birth [4]. Although the same condition was described earlier by Nonne [5], it was Milroy who gave the most complete description, and the eponym 'Milroy's disease' is universally accepted. Milroy's disease is often considered synonymous with primary lymphoedema, but the term should be restricted to cases of congenital lymphoedema with linkage to chromosome 5 or mutations in the *VEGFR-3* gene [6–8]. A failure of lymphangiogenesis due to inactivation of *VEGFR-3* appears to be responsible for the autosomal dominant inheritance of Milroy's disease [8]. Genotype–phenotype correlation demonstrates swelling which is confined to below the knee, and which is often brawny in the extreme with little pitting. Hydrocoele can be an additional feature, as can superficial vein incompetence but, much as Milroy described, there appear to be no other manifestations.

2 *Lymphoedema–distichiasis syndrome* (LDS; MIM 153400). Distichiasis is a congenital anomaly in which accessory eyelashes occur along the posterior border of the lid margins in the position of the Meibomian glands. It causes symptoms of corneal irritation, conjunctivitis and photophobia and occurs from birth. Lymphoedema in this syndrome, however, does not develop before puberty and may be delayed in onset until the fifth decade. Other features of this syndrome include ptosis, congenital heart defects and varicose veins [3]. The lymphatic abnormality appears to be lymph reflux with an increased number of lower-limb lymph vessels [9]. LDS shows an autosomal-dominant pattern of inheritance with variable expression and has been mapped to 16q24.3 [10]. Mutations in *FOXC2* (*MFH-1*), a forkhead family transcription factor, are now known to be responsible for this condition [11].

3 *Hypotrichosis–lymphoedema–telangiectasia syndrome* is a rare inherited disorder caused by mutations in *SOX18* transcription factor and manifesting with bilateral lymphoedema of the legs, hypotrichosis, telangiectases and angiomata limited to acral regions [12]. SOX18 acts as a molecular switch to induce differentiation of lymphatic endothelial cells early in development [13].

4 *Incontentia pigmenti* (MIM 308300). Incontentia pigmenti (IP) is not usually associated with lymphoedema in surviving females. The second liveborn male to be reported recently led to the identification of a *NEMO* (NFκB essential modulator) stop codon mutation in the affected child and in his mother, who had classical IP [14]. He had features of hypohidrotic ectodermal dysplasia with immune deficiency, recurrent infections and lower-limb lymphoedema which developed at a few weeks of age. A lymphoscintigram showed severe lymphatic obstruction. MRI suggested a lymphangiomatous malformation. Cutaneous capillary angiomas and possible mixed vascular/lymphatic malformations coexisted in the gut [15].

Other germline forms of lymphoedema

1 *Meige's disease* (Kinmonth's lymphoedema praecox, hereditary lymphoedema type II; MIM #153200). In 1898, Meige described the pedigree of a family with a distinct history of lymphoedema appearing at puberty [16]. The eponym Meige's disease has therefore come to be associated with this, the commonest variety of primary lymphoedema, which predominantly affects adolescent females. Swelling is usually mild, rarely extends above the knee and is generally bilateral. Lymphography demonstrates a reduced number of distal lymphatics (hypoplasia) with proximal collectors remaining patent. The term Meige's disease should be reserved for familial lymphoedema developing at or soon after puberty in which there are no associated abnormalities, for example distichiasis.

2 *Turner's syndrome.* This well-known abnormality is due to the absence of one X chromosome. Early spontaneous abortion occurs in over 95% of fetuses. Severely affected fetuses who survive to the second trimester can be detected on ultrasonography, which may reveal cystic hygroma, chylothorax, ascites and hydrops fetalis. The diagnosis may be suggested in the newborn by redundant neck skin and peripheral oedema. Surviving children have webbed necks and may exhibit peripheral oedema which often diminishes with age. Conversely oedema may present later in life. Chromosomal testing should always be undertaken in neonates or young children with primary lymphoedema.

3 *Noonan's syndrome* (MIM #163950). Noonan's syndrome is a multiple congenital anomaly syndrome for which mutations in *PTPN11* have been discovered to be the cause [17]. Lymphoedema is usually present at birth but the age of onset may vary from the prenatal period to adulthood. Phenotypic characteristics include short stature, ptosis, low-set ears and posterior hairline, neck webbing and congenital cardiac anomalies (typically pulmonary stenosis).

4 *Hennekam lymphangiectasia–lymphoedema syndrome* (MIM *235510). A syndrome of intestinal lymphangiectasia with severe lymphoedema of the limbs, genitalia and face, with mental retardation [18]. The intestinal lymphangiectasia causes hypoproteinaemia, hypogammaglobulinaemia and lymphopenia. Facial anomalies are characteristic and look somewhat oriental, with flat face, flat nasal bridge, epicanthic folds, hypertelorism, tooth abnormalities and small ears. Onset of lymphoedema is between birth and 12 years, with probable autosomal-recessive inheritance.

5 *Cholestasis–lymphoedema syndrome* (Aagenaes's syndrome; MIM *214900). Jaundice becomes evident soon after birth and recurs throughout life. Oedema of the leg, due to hypoplasia of the lymph vessels, begins at school age and progresses [19].

6 *Microcephaly lymphoedema–chorioretinal dysplasia* (MIM *152950). An autosomal dominant syndrome [20] in which microcephaly and lymphoedema are linked to chorioretinopathy.

7 *Pes cavus and lymphoedema.* Lymphangiography has revealed hypoplasia of leg lymphatics in this disease association [21].

8 *Yellow nail syndrome* (YNS; MIM #153300). The evidence that YNS is inherited is unsubstantiated, only one report describing YNS with familial primary hypoplasia of leg lymphatics [22].

Other genetic forms of lymphoedema

A number of sporadic forms of lymphoedema occur, usually presenting at birth or during childhood. The defect in such cases is likely to be due to a somatic rather than a germ-line mutation.

Klippel–Trenaunay syndrome (MIM 149000) is the commonest type, in which lymphoedema may be the presenting abnormality.

Subsequently, more characteristic features such as limb overgrowth, cutaneous angiomas and venous disease may develop.

Proteus syndrome (MIM 176920) is a very rare syndrome manifesting with many varied (protean) abnormalities. Characteristic features are asymmetrical overgrowth of almost any part of the body, macrodactyly, and rugose or cerebriform overgrowth of the palmar and plantar soft tissue. Verrucous epidermal naevi, angiomas and lymphangiomatous swelling also occur. Germ-line mutations in *PTEN* have been proposed but are not often found [23].

Amniotic bands: another poorly understood form of congenital lymphoedema is that associated with amniotic bands. These bands, which allegedly wrap around digits or limbs, cause circumferential fibrosis and scarring. This can lead to amputation of digits or lymphoedema distal to the band [24].

Maffucci's syndrome (dyschondroplasia with haemangioma, MIM #166000) usually manifests with venous cavernous malformations in infancy, but cavernous lymphangiomas are also often seen, and may be the sole manifestation, giving rise to limb swelling. Hard nodules arise from the bones, especially of the fingers and toes; these are pathologically enchondromas and are radiologically translucent. The malignant potential of the syndrome is high [25].

Fig. 48.5 The commonest form of primary lymphoedema: distal hypoplasia of peripheral lymphatic vessels presenting with asymmetrical but usually bilateral swelling of feet and lower legs.

Phenotypes of primary lymphoedema

Lower limb

1 *Distal hypoplasia.* The most common presentation, contributing about 80% of all cases of primary lymphoedema, is that of mild oedema of both feet and ankles. Patients are usually female with onset at puberty. The swelling is often asymmetrical and deteriorates slowly. Extension above the knee is uncommon and mild (Fig. 48.5). The cause is a paucity of distal lymph vessels.

2 *Proximal obstruction.* This variety is unilateral in 85% of cases. It usually involves the whole limb and develops rapidly. There is no family history. It is of paramount importance to exclude pelvic causes of venous or lymphatic obstruction—for example, tumour or thrombosis. The cause in primary lymphoedema is

fibrosis within ilioinguinal lymph nodes or obliteration of proximal lymph vessels [1].

3 *Bilateral whole-limb swelling*. Reflux of lymph due to gravitational forces and gross incompetence of valves leads to huge dilatation of lymphatic collectors (megalymphatics) in a manner similar to venous reflux and varicose veins. Chylous reflux may coexist.

Progressive distal failure of lymphatic collectors, the so-called 'die-back' phenomenon, occurs with time as a result of proximal obstruction or reflux [2].

Upper limb

Upper limb lymphoedema, if primary in type, usually presents at birth. It may be unisegmental, affecting one limb and the root of that limb, or may be multisegmental in which case it can be associated with lower limb, facial, genital or systemic involvement. Upper limb lymphoedema may form part of a syndrome with overgrowth, for example in Klippel–Trenaunay syndrome.

Genital lymphoedema

Lymphoedema is rarely confined just to the genitalia and is usually associated with intestinal lymphangiectasia/chylous reflux or lower limb swelling.

Facial lymphoedema

If primary facial lymphoedema occurs it is invariably present at birth and improves over time. It is usually asymmetrical and associated with lymphoedema elsewhere. Head and neck oedema occurring *in utero* may regress by birth but leave signs such as prominent medial epicanthic folds or neck webbing.

Secondary lymphoedema

Secondary lymphoedema refers to those forms of lymphoedema resulting from acquired obstruction or obliteration of lymph-conducting pathways due to some identifiable pathological process arising extrinsic to the lymphatic system (Table 48.5). These processes include infection, inflammation, trauma (including surgery and radiation) and malignant disease. No form of lymphoedema is mutually exclusive, and frequently a number of factors combine to produce swelling. For example, lymphoedema may become clinically obvious only when the lymphatic load is increased through higher fluid filtration exhausting lymph drainage capacity.

Intravenous drug abuse
Accident
Degloving injury
Burns

Lymphoedema associated with infection

Infection may cause progressive damage to lymph drainage routes by intraluminal obliteration of lymphatic vessels through processes such as lymphangitis and lymphangiothrombosis.

In recurrent cellulitis or erysipelas, the damage to lymphatics may ultimately lead to formation of lymphoedema, which itself predisposes to further episodes of infection, so exacerbating the lymphoedema [3,4].

Lymphatic filariasis is concentrated in the tropics and subtropics and is the most common cause of lymphoedema worldwide, with an estimated 90 million people affected [5]. Infection is transmitted by mosquitoes, which introduce microfilariae into the skin. These larvae migrate to the lymphatics, where they mature into adult worms. Progressive and permanent damage to the infested lymphatics causes lymphoedema. It has been established in animal studies that, within days of infection, vigorous movement by adult worms directly impacts on the endothelial lining of the lymphatic trunks and indirectly distorts the local lymph-node architecture. Dilated lymphatics with thickened walls and valves, thrombus formation and perilymphangitis result [6].

Lymphogranuloma inguinale and tuberculous node infection can cause lower limb lymphoedema [7]. Lymphoedema of the ear lobe has been described following infestation with head lice [8].

Lymphoedema associated with inflammation

Circumstances exist in which chronic inflammation without evidence of infection is associated with the development of lymph-

oedema. It is assumed that the inflammation progressively damages lymph drainage routes.

Facial lymphoedema may result from rosacea or even acne vulgaris. Skin or subcutaneous initial lymphatics fail rather than main regional collecting trunks. Telangiectasia and inflammation contribute to oedema through increased fluid filtration. In rosacea (Morbihan's disease, solid facial oedema) epithelioid granulomas are often seen with dilated dermal lymphatics [9].

Upper limb swelling may occur following chronic hand dermatitis, with or without documented episodes of lymphangitis [10]. Like other forms of lymphoedema, once established it tends to be permanent, irrespective of remission of the skin disease.

Podoconiosis (non-filarial elephantiasis) is a form of lymphoedema caused by particles of silica dust, present in certain soils, which penetrate the skin of the foot during barefoot walking. The microparticles are taken up by the lymphatics, causing damage. Soils rich in these substances determine the geographical distribution of the condition [11].

Studies with quantitative lymphoscintigraphy and fluorescence microlymphography have confirmed functional and structural changes to lymph drainage in pretibial myxoedema. It is likely that mucin deposition in the dermis impairs initial lymphatic function, resulting in the clinical appearance which resembles lymphoedema [12].

A small number of patients with rheumatoid arthritis develop lymphoedema, predominantly of the upper limbs. A study in rheumatoid arthritis found impaired lymph drainage only in patients with lymphoedema [13]. This suggested that inflammatory arthritis alone does not directly impair lymphatic drainage. Similar findings have been described in psoriatic arthritis [14].

Granulomatous diseases such as Crohn's disease, sarcoidosis, orofacial and anogenital granulomatosis and foreign body reactions from cosmetic procedures [15,16] cause inflammatory changes in local skin and subcutaneous lymphatics, leading to lymphoedematous swelling.

Panniculitis that is extensive enough to cause severe fibrosis may produce lymphoedema. This has been described following idiopathic retroperitoneal fibrosis [17].

Lymphoedema secondary to trauma

Trauma to lymphatics, either from elective surgery or by accident, usually needs to be extensive to induce lymphoedema. Indeed, the experimental production of lymphoedema is extremely difficult to achieve owing to the excellent regenerative powers of lymphatics [18]. It is possibly the failure of lymphatics to regenerate and re-anastomose satisfactorily through scarred or irradiated tissue which is responsible for lymphoedema following cancer treatment. Surgical excision of axillary or ilioinguinal lymph nodes will not uncommonly produce limb lymphoedema. The puzzles are why such intervention in animal models rarely produces chronic swelling and why there can be such a delay—up to 20 years—before lymphoedema manifests [19]. Radiotherapy to lymph nodes can be as much a risk factor towards lymphoedema as surgery [20]. The incidence of lymphoedema following varicose vein surgery is estimated to be 0.5% [21].

Fig. 48.6 Lymphoedema associated with chronic venous disease.

Accidental trauma, such as a degloving injury to a limb, will produce lymphoedema distal to the injury if widespread circumferential scarring occurs.

Self-inflicted injury, such as the repeated application of a tourniquet, will eventually cause permanent lymphatic damage and chronic swelling (Secrétan's syndrome) [22]. The abrupt termination of the swelling often coincides with a depression due to subcutaneous atrophy caused by a tight constricting band. Skin pigmentation may also coexist at the site.

Intravenous drug abuse may cause lymphoedema due to a combination of infection and associated venous damage.

Lymphoedema and venous disease (phlebolymphoedema)

Oedema is a common complication of venous insufficiency. It is assumed that venous oedema is the sole consequence of increased capillary filtration from venous hypertension. As lymph drainage is the main buffer against oedema, it is in fact the failure of local lymphatics to compensate for the increased lymph load from filtration that leads to oedema. Thrombosis of the major veins and deep vein incompetence does not generally affect the main collecting lymphatics but the small initial and precollecting lymphatics of the skin and subcutaneous tissues of the lower leg are damaged by prolonged venous hypertension. Lymphoedema develops with chronic lipodermatosclerosis, with or without venous ulceration. Lymphoscintigraphy has shown impaired limb lymph drainage [23] while fluorescence microlymphography has revealed damaged skin lymphatics [24]. Lymphoedema associated with venous disease can give rise to the most gross swelling and skin changes owing to the combined effect of impaired lymph drainage in the face of increased lymph load (capillary filtration) (Fig. 48.6).

Malignancy-related lymphoedema

Lymph flow is remarkably well maintained through malignant nodes, therefore cancer does not usually present with swelling. The few exceptions to this general rule are lymphophilic tumours, such as malignant eccrine poroma or Kaposi's sarcoma, as well as advanced cancers where other factors such as venous obstruction and hypoproteinaemia will contribute to oedema formation. Recurrent cancer, however, should always be considered as a cause of limb swelling, particularly if associated with pain. Full staging investigations should always be undertaken in such circumstances. Therefore, in general, malignancy-related lymphoedema usually results from cancer therapy, that is surgery, radiotherapy or a combination of the two, or from recurrent tumour directly infiltrating collateral drainage routes.

Kaposi's sarcoma may present with lymphoedema, sometimes years before tumour is evident. The association with lymphoedema [25] supports the view that in Kaposi's sarcoma the endothelial cell phenotype is lymphatic [26].

Lymphoedema arising from dysfunctional lymphatics

Lymph drainage, unlike blood flow, requires intermittent changes in local tissue pressure generated by movement and exercise in order to produce initial lymphatic transport. Consequently, immobility tends to encourage swelling, particularly if gravitational forces (dependency syndrome) encourage ongoing fluid filtration. A common scenario is 'armchair legs', a term coined by Sneddon and Church [27], where patients sit in a chair day and night with their legs dependent (otherwise known as elephantiasis verrucosis nostras, because of the severe lymphoedema skin changes that ensue). No premorbid abnormalities of lymphatics exist, but the immobility results in minimal lymph drainage and a functional lymphoedema due to a lack of movement or exercise to stimulate normal lymph drainage. Dependency of the limb compounds the problem by increasing capillary filtration. The syndrome is not confined to the legs, but can affect any chronically dependent and immobile part, as demonstrated in the pendulous abdomen [28]. With time, pathological changes within the failing lymphatics occur and an irreversible lymphoedema develops.

Clinical diagnosis of lymphoedema

Lymphoedema most commonly affects the extremities. This predilection for the limbs is due, at least in part, to the limited collateral drainage available at the root of a limb. Careful examination often reveals extension of the swelling to the associated quadrant of the trunk because the lymph drainage routes are shared with the limb.

The major clinical changes of lymphoedema take place in the skin and subcutaneous tissues; such changes are of value in diagnosis. Lymphoedema differs from all other oedemas (in which increased capillary filtration is the major factor) in that cells, proteins, lipids and debris accumulate in addition to water. This results in a 'solid' as well as a 'fluid' component to the swelling, so giving rise to the brawny nature of the oedema which does not readily pit [1]. The lack of pitting is an unreliable sign in lymphoedema, however, because easy displacement of tissue fluid on pressure can often be demonstrated, particularly in the early stages.

Fig. 48.7 The Kaposi–Stemmer sign: inability to pinch or pick up a fold of skin at the base of the second toe indicates lymphoedema.

Lymphoedema does not usually respond to elevation or diuretics, except in the early stages or when it is compounded by increased capillary filtration. Chronic oedema that does not reduce significantly after overnight elevation is likely to be lymphatic in origin. The symptoms accompanying uncomplicated lymphoedema are few. Swelling frequently develops rapidly, for example overnight. In the distal hypoplastic type, one ankle may swell. Pain may feature initially, prompting diagnoses including deep-vein thrombosis or soft-tissue injury. Oedema is often intermittent before becoming permanent, and is often painless although discomfort, aching and tightness are commonly reported symptoms. Eventually both legs swell. In proximal obstructive lymphoedema, swelling usually develops in the thigh and progresses distally.

Although swelling occurs most in the subcutaneous layer, the skin exhibits most changes. It becomes thicker, as demonstrated by the Kaposi–Stemmer sign (inability to pick or pinch a fold of skin at the base of the second toe) (Fig. 48.7) [2]. Skin creases become enhanced and hyperkeratosis develops. Dilatation of upper dermal lymphatics with consequent organization and fibrosis gives rise to papillomatosis. As dermal lymph stasis progresses these skin changes become more marked and are referred to as elephantiasis. Occasionally, the tissue fibrosis and thickening may become so marked in the later stages of lymphoedema that pitting is absent.

Complications

Complications of lymphoedema are mainly due to swelling and infection.

Swelling. Limb swelling leads to discomfort, limb heaviness, reduced mobility and, on occasions, impaired function. The size and weight of affected limbs can result in secondary musculoskeletal complications such as back pain and joint problems. Thickening of the skin causes pseudoscleroderma and consequently impairs small-joint mobility. The difficulty in finding clothes or shoes to fit creates social problems. Poor footwear will further compound the swelling by discouraging a normal gait or enough exercise.

Leakage of lymph through the skin (lymphorrhoea) may occur from engorged dermal lymphatics (lymphangiectasia).

Infection. Episodes of secondary infection, particularly cellulitis or erysipelas, are a characteristic feature of lymphoedema. Patients with lymphoedema irrespective of cause are liable to these attacks, which reflect a failure of immune surveillance. Constitutional symptoms such as fever, rigors, headache or vomiting can be profound and sudden in onset. Within 24 h, redness appears within the lymphoedematous area but without the advancing border. Pain and heat also feature. Recurrent episodes may be frequent and further impair lymph drainage, so exacerbating the lymphoedema. Thus, a vicious cycle is established. Haemolytic streptococci of group A, B or G have been demonstrated [3], although the bacterial aetiology has been brought into question [4]. Indeed, it is not unusual for patients to comment that attacks of cellulitis can be induced by strenuous exercise or long car journeys. This suggests a mechanism not dissimilar to herpes simplex where the microorganism is always present but becomes reactivated.

Fungal infections, particularly tinea pedis, are difficult to avoid because of web-space skin maceration from swollen toes. Local immune deficiency is likely to be a contributing factor, as illustrated by a case of cryptococcosis complicating congenital lymphoedema [5].

Malignancy. A rare but important complication of chronic lymphoedema is the development of cutaneous malignancy. Although the best-known associated malignancy is lymphangiosarcoma [6], other tumours have been recorded and include basal cell carcinoma [7], squamous cell carcinoma, lymphoma [8–11], melanoma [12,13], malignant fibrous histiocytoma [14] and Kaposi's sarcoma [15]. The Stewart–Treves syndrome describes lymphangiosarcoma developing from well-established postmastectomy oedema. However, lymphangiosarcoma is now described as occurring with lymphoedema of any cause. The favoured theory for these associations is altered immune surveillance in the lymphoedematous region [16].

Miscellaneous conditions. A range of other cutaneous conditions have been reported as occurring preferentially at sites of lymphoedematous involvement. These include xanthomatous deposits [17], atypical pemphigoid [18], toxic epidermal necrolysis [19], atypical neutrophilic dermatosis [20] and severe necrotizing fasciitis [21].

Midline lymphoedema

Lymphoedema localized to central regions such as the head and neck, trunk or external genitalia is uncommon, presumably because bilateral drainage routes operate and cross-flow from one region to another prevents swelling. Midline lymphoedema therefore usually develops when the lymphatics of the skin or subcutaneous tissue rather than the regional lymphatics fail.

Head and neck lymphoedema

Facial swelling can coexist with obvious primary lymphoedema of one or more limbs, suggesting that there is widespread congenitally determined lymphatic insufficiency. More commonly, the problem occurs later in life secondary to a variety of inflammatory or traumatic mechanisms. Rosacea, and less commonly acne [1,2], are the commonest causes of facial lymphoedema when it is known as Morbihan's disease or solid facial oedema. Swelling affects the central forehead, periocular skin and cheeks where it may be surprisingly asymmetrical. In rosacea, erythema is always present, but inflammatory pustules and papules may be conspicuous by their absence.

Chronic oedema of the eyelids is common and may be quite simply due to acquired lax skin from photo-ageing and other processes which have undermined tissue compliance, such as blepharochalasis [3]. Congenital eyelid lymphoedema may be associated with conjunctival oedema. Medical conditions to be considered with periocular oedema are dermatomyositis, thyroid or renal disease. Contact allergy or angio-oedema, if persistent or recurrent, may slowly compromise lymphatic function. Equally, one severe attack of facial erysipelas or cellulitis may damage lymphatics sufficiently to cause lymphoedema. Angiosarcoma or Kaposi's sarcoma may infiltrate local lymph drainage, and manifest with eyelid oedema.

Redness and swelling of one or both ears may indicate lymphoedema. Rosacea is the most frequent cause [4] but eczema, psoriasis, infection, pediculosis, trauma (cauliflower ears), pediculosis or congenital lymphoedema may also be responsible.

Oedema of the upper or lower lip (or both) may be congenital or result from recurrent angioedema, orofacial granulomatosis (OFG) or from administration of lip fillers for cosmetic purposes. OFG starts with intermittent bouts of swelling resembling angio-oedema, but with time the condition may become persistent. Extension of oedema within the mouth is common and is the reason for the rugose changes on buccal mucosae and tongue (scrotal tongue). Biopsy may or may not reveal the presence of granulomas. If present, a diagnosis of orofacial granulomatosis (granulomatous cheilitis, Melkersson–Rosenthal syndrome) is made, but it remains unclear if the granulomas are cause or effect [5]. It is possible that granulomatous inflammation in isolation can cause orofacial granulomatosis but a thorough search for gastrointestinal Crohn's or systemic sarcoidosis should be made. Despite negative investigations, Crohn's disease of the bowel can become apparent some time later.

Genital lymphoedema

Genital lymphoedema is more common in the male and may develop from lymphatic obstruction due to advanced pelvic/abdominal cancer or its treatment. Bilateral inguinal lymph node biopsy or infiltration of dermal lymphatics from tumour may also cause genital lymphoedema. Genital swelling may be precipitated by compression therapy to one or both lymphoedematous legs by forcing fluid into the adjoining trunk.

Infection may compromise local lymphatics. Recurrent cellulitis is frequently associated and may antedate the swelling.

Granulomatous inflammation from Crohn's disease, hidradenitis suppurativa or sarcoidosis may manifest only with oedema of the penis or scrotum. As with orofacial granulomatosis, anogenital granulomatosis may occur in isolation without associated granulomatous disease elsewhere.

Primary lymphoedema may involve the genitalia but usually in association with leg swelling. In these circumstances vulval lymphoedema may develop into a swollen fold which can extend from a pedicle and become a polyp [6].

Localized lymphoedema

Breast lymphoedema

As changes to breast cancer treatment have led to more breast-conserving surgery and increased use of therapeutic radiation, so the incidence of lymphoedema localized to the breast has risen [1]. The risk is higher in the obese and in women with larger breasts; the more pendulous the breast, the greater the risk. Inflammation is generally present, resulting in a red, painful swollen breast. Pitting and peau d'orange are most noticeable on the undersurface of the breast. Cellulitis can coexist and is difficult to distinguish from post-radiation changes, as often the only systemic sign of chronic infection is tiredness. Low-dose antibiotics, for example phenoxymethylpenicillin 1 g/day for 6 weeks, may be the only means of proving infection.

Massive localized lymphoedema

Lymphoedema typically affects a region such as a limb but uncommonly it can present as a localized mass resembling a tumour. It is not unusual for an area of lymphoedema on the lower inner thigh or inguinal region to hypertrophy into an enlarged fold and then, under the influence of gravity, progress into a pendulous swelling (Fig. 48.8). Solid or papillomatous plaques can mimic tumours but biopsy will reveal typical features of lymphoedema (elephantiasis), namely: oedema, dilated lymphatics, fibrosis, fat, epidermal acanthosis and hyperkeratosis, and inflammatory dermal infiltrate. Obesity and localized tissue damage increase risk [2,3].

Fig. 48.8 Massive localized lymphoedema.

Scar lymphoedema

Swelling within a scar and adjacent tissues, such as a flap, is common. Impaired lymph drainage contributes to raised and swollen tissues abutting a U-shaped scar because lymphatic pathways do not always re-establish drainage across scars [4].

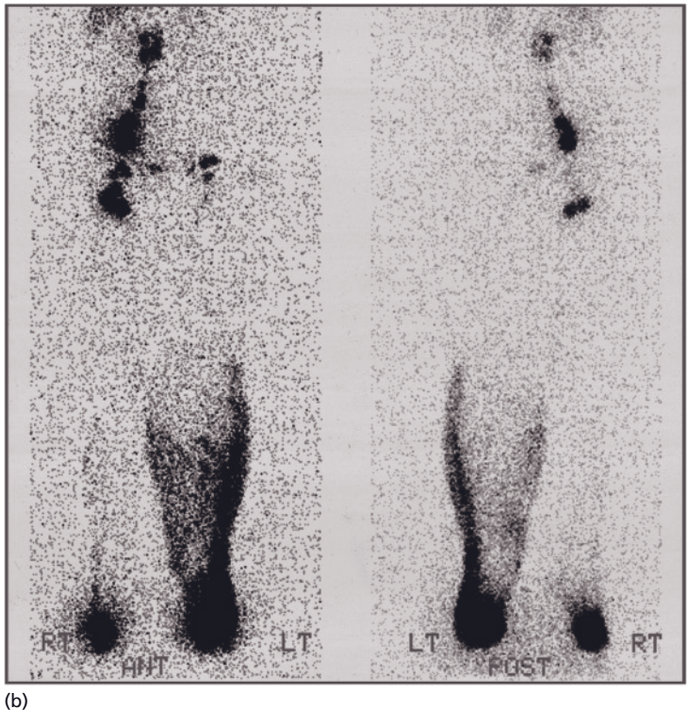
Investigations

Swollen limb



There are limited methods available that permit reliable investigation of lymphatics. Lymphoscintigraphy (isotope lymphography) involves the interstitial (dermis or subcutis) injection of a radiolabelled protein or colloid. Radioactivity, measured using a wide field-of-view γ-camera, is determined over the injection site depot and at regions of interest over vessels or nodes. Measurement of transit times and time activity curves permit quantitative analysis of lymph drainage [1]. Measurement of tracer uptake within axillary or inguinofemoral lymph nodes at a specified time following a standardized exercise routine will discriminate lymphoedema from oedema of non-lymphatic origin [2] (Fig. 48.9).

Computed tomography (CT) of lymphoedematous limbs has demonstrated a characteristic 'honeycomb' pattern in the subcutaneous compartment which other oedemas do not show [3]. CT not only provides information through cross-sectional area of volume change to a limb, but will also identify the compartment in which that change takes place. Whereas in post-thrombotic syndrome the muscle compartment deep to the fascia is enlarged, in lymphoedema it is unchanged or may even show some reduction in size. Thickening of the skin is also a characteristic feature of lymphoedema, although not specific. Magnetic resonance imaging (MRI) is potentially better than CT for distinguishing types of oedema [4].

X-ray contrast lymphography remains the gold standard for demonstrating lymphatic collecting trunks and nodes [5]. The technique is invasive and difficult to perform in the presence of oedema. It involves first of all the interstitial subcutaneous injection of a vital dye—for example, patent blue—to visualize the lymphatic for cannulation. The oily contrast medium Lipiodol is then administered directly into the peripheral lymphatic identified, usually on the dorsum of the foot. The failure to opacify subcutaneous collectors with the vital dye and its persistence in

the tissues for days afterwards are sufficient evidence for a diagnosis of lymphoedema. If there is lymphatic obstruction, the dye will often flow retrogradely into the dermal network—so-called 'dermal backflow'. Lymphography has been used to confirm lymphoedema less often since the advent of lymphoscintigraphy.

MR lymphangiography (MRL) has recently been introduced to overcome the invasive nature of X-ray lymphography. MRL involves the interstitial injection of paramagnetic contrast agent which delineates the collecting lymphatic vessels of the limb as well as regional lymph nodes and any re-routing such as collateral dermal backflow [6,7].

Initial lymphatics

In vivo visualization of lymphatic vessels (lymphangiography) was first achieved using vital dyes—for example, patent blue—to delineate intradermal and subcutaneous lymphatics. Some classic studies were undertaken in this way [8]. Fluorescence microlymphangiography enables the superficial lymphatic network of the skin to be seen under the vital microscope by means of fluorescing molecules (FITC-Dextran, Sigma) which, when injected subepidermally, are taken up by the initial lymphatics. Information regarding the morphology of functional initial lymphatics and the extent of tracer propagation within the dermal lymphatic network can be recorded on video for analysis [9].

Indirect lymphography involves the intracutaneous injection of a water-soluble contrast medium. Using an infusion pump, the contrast medium is administered over 10 min to create a depot of approximately 3 mL. Intradermal and subcutaneous lymphatics can be opacified by X-ray using the mammography film method, sometimes as far as the first lymph node [10,11]. The advantages over conventional lymphography are the convenience of the interstitial injection without recourse to direct access into the lymphatics, and the ease of application to multiple sites.

Skin biopsy

The distinction between lymphatic and blood vessels in skin biopsy sections has been made more straightforward by specific lymphatic markers. D2-40 (Podoplanin) is considered the most robust as it stains initial lymphatics, pre-collectors and collecting vessels but not blood vessels. LYVE-1 stains initial lymphatics but also macrophages and is down-regulated by inflammation. Prox-1 and VEGFR3 are also lymphatic-specific and stain larger vessels. A panel of markers is recommended, particularly in vascular malformations where differentiation between venous and lymphatic phenotypes may not be clear-cut [12].

CD31 and CD34 stain both lymphatic and blood vascular endothelium.

Differential diagnosis of the swollen limb (Table 48.6)

Swelling of a limb may be caused by oedema, in which case pitting should be evident to some degree, or it may be caused by an increase in volume of other tissue elements, for example bone, muscle or fat. MRI scanning is useful in circumstances where the nature of the swelling is uncertain. One must remember also that a patient may perceive one leg to be swollen when in fact the other leg has become smaller, for example through atrophy of muscle or fat.

Obvious lymphoedema with characteristic skin changes is not usually a difficult diagnosis but such cases are relatively uncommon. Milder cases frequently go unrecognized. Chronic non-inflammatory, and in particular asymmetrical, limb oedema should always suggest lymphoedema. In such cases lymphoscintigraphy is the investigation of choice.

Systemic causes of oedema including cardiac disease, renal disease or hypoproteinaemia should always be considered, particularly if bilateral leg swelling is present. Calcium channel blocking agents cause peripheral oedema in 50% of cases.

Lipoedema

A condition frequently misdiagnosed as lymphoedema is lipoedema (lipidosis, lipodystrophy) in which a 'fatty', non-pitting swelling is confined to the legs, thighs, hips and sometimes arms overlying the triceps [1,2]. Lipoedema is peculiar to females and is usually dismissed as a variant of normality in women with chunky legs and a 'bottom-heavy' weight distribution. Features of importance in recognition include: (i) onset at puberty or times of hormonal change, for example oral contraception, pregnancy or menopause; (ii) bilateral and symmetrical involvement of the lower limbs with sparing of the feet resulting in an 'inverse shouldering' effect at the malleoli (Fig. 48.10); (iii) tenderness and easy bruising; (iv) absence of pitting and lack of benefit from elevation; and (v) lack of benefit from dieting (dieting tends to result in weight loss from body sites other than those affected by lipoedema). Lymph drainage within main leg lymphatics is relatively normal [3] until the later stages when foot oedema develops—the so-called lipoedema–lymphoedema syndrome.

Fig. 48.10 Lipoedema.

Patients with lipoedema gain weight easily and often prefer to be fat than to diet furiously and suffer the embarrassment of thin torso, face and neck while retaining huge legs.

Liposuction performed with tumescent local anaesthesia and using vibrating microcannulae has proved to be a new effective treatment. A targeted and permanent reduction of the fat tissue leads to an increased quality of life due to an improved appearance, reduced tendency to swelling and less pain [4].

Males are very rarely involved and only when there is an underlying hormonal problem such as testosterone deficiency or oestrogen excess with chronic liver disease.

Dercum's disease (adiposis dolorosa, lipomatosis dolorosa, morbus Dercum) is a rare disorder resulting in painful fatty deposits around the upper legs, trunk and upper arms [5]. When pain is a significant symptom with lipoedema it is known as the painful fat syndrome and indistinguishable from Dercum's disease.

Obesity and lymphoedema

Obesity is a significant risk factor for lymphoedema in the arms as well as the legs. Obesity increases the risk of breast cancer-related lymphoedema [6]. Furthermore, dieting improves arm swelling beyond that possible through loss of subcutaneous fat from weight loss [7], irrespective of the diet used [8].

The pathophysiology of lower-limb lymphoedema can be complex. Increased abdominal girth and intra-abdominal pressure impair venous return, particularly when sitting, with the abdominal apron compressing the thighs. Higher venous pressures will increase fluid filtration into the legs so increasing lymph load. However, lymph drainage may also be compromised in the same sitting position, and is certainly decreased as a result of the reduced

exercise associated with obesity [9]. Severely obese patients suffering from sleep apnoea will tend to retain fluid for complex hormonal and autonomic reasons, while sleeping in a chair causes 'armchair legs' as described earlier.

Limb overgrowth (hypertrophy)

Limb hypertrophy (overgrowth) may be mistaken for lymphoedema but also be associated with it. Occasionally, lymphoedema coexists with complete hemihypertrophy, Klippel–Trenaunay syndrome, Parkes-Weber syndrome (multiple arteriovenous anastomoses) or proteus syndrome. Elephantiasis neurofibromatosa is a diffuse neurofibromatosis of nerve trunks with overgrowth of the subcutaneous tissue and of the skin, producing considerable enlargement of that region.

Yellow nail syndrome

YNS is associated with peripheral oedema, but the clinical features rarely resemble classical lymphoedema. Lymphangiogram abnormalities have been described [10], although a lymphoscintigraphic study demonstrated that a primary lymphatic abnormality is unlikely [11].

Management of lymphoedema

Lymphatic failure results in the accumulation of protein as well as water within the swollen tissues. Treatment is difficult because of the presence of the 'solid' component in the swelling. The management of lymphoedema varies greatly around the world. In developed countries, the emphasis is more on physical forms of therapy involving massage, exercise and compression designed to stimulate lymph drainage, whereas in poorer, hotter countries where hosiery and appropriate bandages are too costly and uncomfortable, surgery may be the mainstay of treatment. Two particular problems need to be overcome with lymphoedema: the swelling and the predisposition to infections, particularly recurrent cellulitis.

There is limited research to inform evidence-based guidelines on the treatment of lymphoedema. Nevertheless, robust guidelines developed through consensus by experts do exist [1, 2].

Assessment

Medical

Medical assessment aims to identify and exclude other causes of peripheral oedema. In circumstances where systemic causes for peripheral oedema, for example heart failure, have led to, or coexist with, the lymphoedema, then treatment of the internal medical condition must be undertaken before embarking on specific lymphoedema therapy. Where necessary, appropriate investigations should be performed to confirm lymphoedema and to identify treatable underlying causes (e.g. active cancer) or comorbidities (e.g. superficial venous incompetence).

Lymphoedema therapy

All patients with a diagnosis of lymphoedema should be referred to the local trained lymphoedema therapist. A list of trained therapists can usually be accessed through the national professional body for lymphoedema, for example the British Lymphology Society (http://www.thebls.com/directory); the National Lymphedema Network (USA) (http://www.lymphnet.org); and the Lymphoedema Association of Australia (http://www.lymphoedema.org.au).

Best practice for management will focus on the needs of each individual patient. This may include: (i) risk reduction, for example breast cancer patients; (ii) swelling reduction and improvement of shape; (iii) treatment and prevention of infection; (iv) treating skin problems such as elephantiasis, lymphorrhoea and wounds as well as discouraging tissue fibrosis; (v) restoring functional independence and correcting posture imbalance; and (vi) pain and psychosocial management. Therapy assessment will also include setting the benchmarks against which improvement can be judged, for example limb volume measurement, mobility and functional assessments. A treatment plan will depend on the site and severity of the lymphoedema and the need to engage other services, for example leg ulcer, oncology, vascular etc.

Physical therapy (decongestive lymphatic therapy, combined decongestive treatment)

Physical methods of treating lymphoedema have been practised in Europe for many years [1]. Therapy essentially aims to control lymph formation (capillary filtration), including treatment of inflammatory causes or of venous hypertension, and to improve lymph drainage through existing lymphatics and collateral routes by applying normal physiological procedures that stimulate lymph flow. Physical treatment can, in the majority of cases,

Fig. 48.11 Reduction of swelling in lymphoedema following 3 weeks' intensive therapy with multilayer bandaging and an exercise programme (the same patient as in Fig. 48.5).

improve quality of life considerably (Fig. 48.11). Central to management is getting patients to understand their condition and know what they can do for themselves [2]. Only then can a high level of motivation and compliance with treatment be generated.

It is important to explain to patients that, unlike the blood, which is propelled by the heart, lymph drainage relies on local changes in tissue pressure generated by exercise and movement. Physical treatment exploits these principles, enhancing lymph flow as much as possible within the limits of a compromised drainage. It should be appreciated that lymph flow still exists in lymphoedema, otherwise swelling would be a relentlessly progressive process.

Cornerstones of physical therapy

1 Care of the skin and prevention of infection

Elephantiasis skin changes are not only unsightly but lead to problems including infection, odour, lymphorrhoea, restricted movement from fibrosis (pseudoscleroderma) and possibly poor wound healing. Such problems can be particularly troublesome where fibrosis has become excessive—for example after trauma or surgery. Regular application of an emollient is important for hydrating the hardened skin so making it more supple and discouraging hyperkeratosis. Tinea pedis is almost invariable because of the closely apposed swollen toes, circumstances not improved by elastic hosiery. Modern antifungal creams unfortunately macerate skin further and therefore it is suggested that terbinafine cream is applied for 2 weeks followed by an alcohol wipe (assuming the skin is not broken). For deep cracks and crevices which bacteria may readily colonize, regular toilet is necessary followed by an antiseptic soak, for example potassium permanganate. Hyperkeratosis can often be improved through the regular application of 5% salicylic acid ointment, but the best treatment to reverse elephantiasis skin changes is long-term compression. Areas that constantly seep lymph should also respond to sustained compression.

Prevention of infection, particularly lymphangitis/cellulitis, is crucial to the control of lymphoedema. Care of the skin, good hygiene, control of tinea pedis and good antisepsis following abrasions and minor wounds are important to reduce risk of cellulitis.

2 Exercise

Exercise and movement are crucial to lymph drainage [3,4]. Dynamic muscle contractions (isotonic exercises) encourage both passive (movement of lymph along tissue planes or through non-contractile lymphatics) and active (increased contractility and therefore propulsion of lymph within contractile lymphatics) phases of lymph drainage. Overexertion and excessive static (isometric, e.g. gripping) exercise increase blood flow, which therefore tends to increase oedema.

3 External compression (hosiery, bandage or pneumatic compression)

External compression complements the exercise programme. Such compression is not intended to 'squeeze' oedema but to act as a counterforce to striated muscle activity and so generate higher tissue pressures during contractions. This provides the most powerful stimulus to lymph drainage. Compression also limits capillary filtration by opposing capillary pressure. Without exercise compression is much less effective.

Multilayer bandaging can be used for limb reduction, but also has the advantage of restoring limb shape so that subsequent use of compression garments (hosiery) is more effective at controlling swelling [5]. Bandaging may be the only method suitable for huge misshapen limbs and for controlling lymphorrhoea. Layers of strong, non-elastic (short-stretch) bandages are applied to generate a high pressure during muscular contractions but low pressure at rest. The use of foam or soft padding helps to distribute pressure more evenly and to protect the skin. The digits are also bandaged to control swelling of fingers and toes. The strategic positioning of rubber pads 'irons out' pockets of swelling and deep skin folds. Multilayer bandaging is a skill that takes time to learn and should not be undertaken by any professional without appropriate training. The compression administered may have to be modified in circumstances such as cancer requiring palliative treatment, moderate limb ischaemia, or if there is any neurological deficit.

Hosiery (below-knee or full-length stockings, half or full tights, sleeves) usually requires high compression and double hoses may occasionally be required. Most garments last no more than 6 months. Two garments (or pairs) should be provided, one to wear and one for the wash. Washing is necessary to maintain the compression properties of the garment. The patient's technique for application, removal and care of garments are crucial for a successful outcome.

Pneumatic compression therapy (intermittent/sequential pneumatic compression) should not be used in preference to exercise and compression but can be useful in mixed lympho-

venous oedema and in infirm patients [6]. An inflatable boot, legging or sleeve is connected to a motor-driven pump and lymph is displaced towards the root of the limb. If hosiery is not fitted immediately following compression therapy, the swelling readily recurs. Pneumatic compression softens the tissues and reduces limb volume during treatment, but it is doubtful that any long-term benefit is gained over hosiery and exercise alone.

4 Massage (manual lymphatic drainage therapy)
Massage is an important component of treatment, particularly for midline lymphoedema where there are few alternatives [1]. The problem is that there are different forms of massage, used mostly for increasing blood flow and therefore of vigorous nature. Tissue movement, if gentle, is a stimulus to lymph flow without increasing blood flow [7]. Indeed, in the absence of lymphatic contractility, massaging of filled lymphatics by muscle exercise or surface massage may be the major stimulus to lymph flow, just as it is with blood flow during cardiac arrest [4]. The skin lymphatic network is the likely route for collateral drainage to areas which have normal lymph drainage [8]. The practice that encourages such flow, referred to as manual lymphatic drainage therapy (MLD), is directed at normally draining lymph node regions; this 'siphons' or 'milks' lymph away from congested lymphoedematous areas, so complementing attempts to improve drainage 'upstream' by exercise and external compression. Continuous MLD delivered by a therapist is expensive and few health care providers will fund this long term. Simple lymphatic drainage (SLD) is a best alternative to MLD, and can be delivered by a partner or carer trained in the technique.

5 Breathing, postural exercise, elevation and rest
Breathing and postural exercises are also important, particularly for clearance of lymph from the thorax and abdomen. Without the dispersal of truncal lymph, more peripheral limb oedema will not drain. Elevation *per se* does nothing to improve lymph drainage, but lowering venous pressure (and therefore filtration) can help to reduce swelling. Rest and elevation alone, however, are not the correct treatment for lymphoedema!

Additional therapies

1 Weight loss. Many patients with lymphoedema are overweight, because of morbid obesity as well as fluid retention. Excessive weight gain is likely to impair lymph drainage in the same way as it impairs venous drainage, and obesity reduces mobility (and therefore exercise). Control of weight in combination with physical treatment may be sufficient to resolve oedema completely in some patients. Weight loss irrespective of type of diet has been shown to reduce arm volume over and above what would be expected from fat loss alone in breast cancer related lymphoedema [9,10].

2 Hyperbaric oxygen (HBO), low-level laser therapy (LLLT) and Kinesiotaping. There are some data recommending the use of HBO and LLLT independently in breast cancer related lymphoedema [11–13]. Kinesiotaping has been shown to increase lymph flow [14].

Intensive and maintenance treatment

Patients with mild limb lymphoedema, no fibrosis and no shape distortion can be started on maintenance treatment with compression hosiery. Intensive therapy, comprising a 2- to 4-week course of daily skin care, MLD, multi-layer bandaging and exercises, is indicated for patients with moderate to severe limb swelling, poor limb shape or tissue changes such as fibrosis, elephantiasis or lymphorrhoea. Once intensive treatment is complete, maintenance treatment is started.

Evidence of efficacy

While decongestive lymphatic therapy has become accepted first-line therapy [15], evidence for best treatment is weak. Using limb volume change as the main outcome measure, bandaging plus hosiery was significantly more effective at 6 months than hosiery alone [5]; hosiery was more effective than no hosiery [16]; MLD was more effective than SLD [17], although effects on total arm volume can be small [18]. Pneumatic compression therapy was no better than no treatment [19].

Management of midline lymphoedema

Management of lymphoedema of the head and neck, trunk, breast or genitalia can be challenging.

Truncal lymphoedema implies involvement of a body quadrant, for example a forequarter or hindquarter, and is usually associated with swelling of the adjoining limb. Lymphatic obstruction at the root of the limb, for example from tumour, should always be considered with truncal oedema. Clearance of the trunk, usually with MLD, is necessary before improvement of the limb can be expected.

Breast lymphoedema generally follows cancer treatment and is usually associated with inflammation from radiation or infection. Infection may be extremely difficult to control in these circumstances, requiring low-dose antibiotics, for example phenoxymethylpenicillin 500 mg twice daily for many weeks. Dependency is a contributing factor to oedema formation, particularly in a large breast, and a firm supportive bra, day and night, is recommended. Only then should MLD be introduced.

Genital lymphoedema can occur in the male or female but is more severe in the penis and scrotum due to a combination of dependency and limited drainage outlet routes. Genital lymphoedema is associated with lower-limb swelling when oedema creeps up to involve the lower trunk, such as following surgery or radiotherapy to ilioinguinal lymph nodes, in heart failure and sometimes with genetic forms of lymphoedema. Sadly, genital swelling may appear for the first time when lower limb oedema is forced up into the trunk by over-vigorous leg compression. When lymphoedema is limited to the male genitalia then underlying inflammation from granulomatous disease (Crohn's disease, sarcoidosis, hidradenitis suppurativa or anogenital granulomatosis) or due to infection have to be considered before embarking on specific lymphoedema treatment. MLD and innovative ways of applying compression [20] are most widely used but surgery can be considered at an early stage.

Lymphoedema of the head and neck is often a complication of cancer or its treatment. Facial lymphoedema (solid facial oedema) is most frequently caused by rosacea or acne but a differential diagnosis includes dermatomyositis, thyroid disease, lymphoma and (lymph)angiosarcoma. Periorbital oedema may result from loose eyelid skin, for example blepharochalasia (floppy eyelid

syndrome), where low compliance encourages oedema [21]. Once underlying conditions have been treated or excluded, MLD and SLD are introduced. Raising the head of the bed with blocks can be invaluable for preventing reaccumulation of oedema overnight.

Prevention and treatment of infection

Infections are common with lymphoedema because of the compromised immune status of the swollen tissues. The recommendations for management are born more out of consensus than robust research [1,2]. Skin care is the first priority as maintenance of skin integrity and an effective barrier will reduce entry of microorganisms.

Acute cellulitis (erysipelas)

Cellulitis is probably more likely to result from a pre-existent lymphatic insufficiency than to be a primary cause of lymphoedema. Nevertheless, it is not unusual for cellulitis to manifest lymphoedema without any prior knowledge of a lymph drainage weakness.

Administration of antibiotics at the time of an attack of cellulitis must be prompt, otherwise they do not significantly influence the course of the illness. Therefore, patients need to carry a supply of antibiotics—for example, co-amoxiclav or amoxicillin—with them at all times [3].

Recurrent cellulitis

For attacks recurring more than once a year, prophylactic antibiotics are the recommended treatment [3]. Phenoxymethyl penicillin 500 mg daily is as effective as any broad-spectrum antibiotic. Long-term prophylaxis is often necessary [4]. Control of the oedema and diabetic-type skin care may help reduce antibiotic requirements.

The only trials investigating prophylaxis against infection in lymphoedema were undertaken in filarial lymphoedema and compared the efficacy of diethylcarbamazine (DEC), ivermectin and skin care in preventing lymphangitis/adenitis [5]. The authors concluded that a foot care programme alone can drastically reduce the number of attacks of acute adenolymphangitis. In a second study [6], the same group compared oral penicillin, diethylcarbamazine and antibiotic cream. Both the penicillin group and the DEC group had significantly reduced frequency of attacks of lymphangitis compared with patients treated with placebo. The authors concluded that antifilarial drugs do not have a role in reducing acute inflammatory attacks (lymphangitis, cellulitis), but that penicillin does contribute significantly to a reduction in attacks when combined with foot care.

Drug therapy

Drug therapy is generally disappointing. Diuretics remain the most commonly used treatment because most doctors consider

oedema to be an indication for such drugs. Diuretics alone have little benefit in lymphoedema because their main mode of action is to limit capillary filtration by reducing circulating blood volume. Improvement with diuretics suggests that the predominant cause of the oedema is not lymphatic.

The benzopyrone group of drugs have been advocated as treatment for lymphoedema, but their clinical effect seems to be small. In the UK, the only available oral prescription medication in this class (although only actually licensed for venous disease) is oxerutins (Paroven®). Three randomized and placebo-controlled trials have been published, all demonstrating a marginal significant effect on limb volume but of little clinical benefit [1]. Other benzopyrone drugs investigated include Daflon® and coumarin (5,6-benzo-α-pyrone) and, while most trials claim significant volume reduction, the poor reporting means a meta-analysis is not possible. One robust trial concluded that there was no difference in effect between coumarin and placebo, and reported serious liver toxicity from coumarin [2].

Surgery

Surgery has a specific role in the management of lymphoedema [1]. It is of value in limb lymphoedema in a few patients in whom, even after conservative treatment, the size and weight of a limb inhibit its use or interfere with mobility. Surgery involves either removing excessive tissue or bypassing local lymphatic defects. Lifelong non-surgical measures—for example, hosiery—must be continued postoperatively.

Reduction (excisional) operations remove a longitudinal ellipse of skin and the underlying abnormal subcutaneous tissue down to the deep fascia in a 'melon slice' that permits primary closure of skin edges (Sistrunk procedure). Undercutting of the skin allows removal of additional tissue (Homans' procedure). This procedure is preferred to circumferential excision and skin grafting (Charles' procedure) or to the addition of in-rolling of a skin flap (Thompson buried dermis flap operation). Procedures involving surgery both above and below the knee or the elbow are usually undertaken one region at a time, because blood loss can be extensive.

A new, less invasive, form of debulking has been successfully employed using liposuction but necessitates compression garments 24 hours a day [2].

Reduction/debulking surgery is used sooner rather than later for genital [3] and eyelid lymphoedema.

Bypass operations involve either bridging an area of defective lymphatics with tissue containing lymphatics or with a vessel graft. If the lymphoedema results from excision of, or damage to, a local group of lymph nodes (e.g. in the axilla or groin) the area can be bridged with omentum or with an isolated and opened-out segment of gut. Lymph node-to-venous and direct lymph vessel-to-venous shunts have been undertaken but long-term patency is doubtful [4]. Lymph vessel transplantation, where autologous lymphatics are removed from an unaffected part of the body and anastomosed end-to-end with other unaffected collectors proximal and distal to the obstruction, has been shown to improve lymph transport [5]. Two to three microsurgical lymphaticovenous anastomoses (small subdermal venules joined to local lymphatics) are claimed to be sufficient to reduce limb volume [6].

Lymphatic malformations, lymphangioma and lymphangiectasia

The reclassification of vascular anomalies into vascular tumours and vascular malformations should apply to lymphangioma and lymphatic disorders [1].

Lymphatic malformations represent a failure of lymphatic development and often exist in isolation with no communication with otherwise normal lymph drainage pathways (extratruncular) or with some sort of communication as seen on lymphoscintigraphy (truncular) [2]. It is best to consider lymphatic malformations as genetically determined structural anomalies with normal endothelial cell turnover, rather than as tumours which are proliferative with endothelial hyperplasia. Malformations increase in size by distension or hypertrophy, not through increased cell division.

The term lymphangioma should only be used if progression through proliferation occurs, otherwise lymphatic malformation is to be preferred. Unfortunately, like haemangioma, the term lymphangioma, implying tumour, is often inappropriately used in clinical dermatology. Nevertheless some lymphatic malformations progress on a lethal, inexorably expanding, unalleviated course making distinction from lymphangioma (tumour process) impossible [1].

Acquired simple sustained dilatation of otherwise normal lymphatic vessels is referred to as lymphangiectasia [3].

Lymphatic malformations (lymphangioma)

Localized congenital lymphatic malformations (LMs) are frequently referred to as 'lymphangioma' and can be divided into

macrocystic, or deep, and microcystic, or superficial, lesions. Lymphatic malformations that appear microcystic, localized and superficial within the skin are called 'lymphangioma circumscriptum', but the term is a misnomer because there is frequently communication with a more extensive deeper malformation (particularly if the lesion is at the root of a limb). Macrocystic LMs are usually visible at birth in the neck and are referred to as cystic hygroma. Distinction between the two types is important because treatment and prognosis can differ [1]. Nevertheless, LMs can have both microcystic and macrocystic components.

The most important feature of congenital LMs is that they can be isolated from the normal lymph conducting system (extratruncal). When connected to the main collecting system they are referred to as truncal lymphatic malformations and can then be associated with lymphoedema. There have been attempts to classify LMs into localized or diffuse, with diffuse indicating that there will be associated lymphoedema, but lymphoedema in general is not due to LMs.

LMs are usually congenital but may not be apparent at birth. They may enlarge if infected or traumatized and only then become symptomatic. No evidence for inheritance exists, suggesting a somatic mutation in a restricted area of the lymphatic network as the mechanism for development [2].

LMs/lymphangiomas are classified according to their morphology as seen histologically or by imaging (e.g. using ultrasound), into macrocystic, microcystic and combined lymphangioma [3]. LMs/lymphangiomas have to be distinguished from true lymphatic neoplasms such as acquired progressive lymphangioma (lymphangioendothelioma) and lymphangiomatosis. LMs/lymphangiomas at least partially and temporarily depend on active lymphangiogenesis, and possibly on active angiogenesis, during the course of development or progression [4].

Lymphangioma circumscriptum

Lymphangioma circumscriptum is a term best reserved for a lymphatic malformation that is localized to an area of skin, subcutaneous tissue and sometimes muscle [1]. Clinically, the condition manifests with fluid-filled vesicles ('lymph blisters') which bulge on the skin surface (Fig. 48.12). The vesicles may be well defined and discrete, or may be grouped into structures resembling frogspawn. They may be translucent when the overlying epidermis is very thin, or they may vary in colour from red to blue-black when they contain blood, a frequent occurrence. The most common symptom is recurrent oozing, usually of clear fluid (lymph), known as lymphorrhoea. Alternatively, the surface of the lymphangiomas may appear extremely warty and the lesions may be mistaken for viral warts. Complications include ulceration, bleeding and secondary infection. Squamous cell carcinoma is described arising within lymphangioma circumscriptum [2].

Fig. 48.12 Lymphangioma circumscriptum: fluid-filled vesicles resembling frogspawn. At times the vesicles can contain blood, weep clear fluid (lymphorrhoea) or become warty.

There may or may not be swelling of the underlying tissues, depending on the presence and size of enlarged, abnormal, anastomosing lymphatic channels beneath the skin or how compromised lymph drainage is, that is where there is a contribution of lymphoedema. It has been postulated that the original malformation arises from deep contractile lymphatics which are malformed and not in continuity with the normal lymph-conducting pathways. Tissue drainage into these abnormal lymphatics results in their gradual dilatation into lymphatic cisterns, contraction of which results in retrograde flow into the skin initial lymphatics [3]. Only by identifying the limits of the subcutaneous cisterns prior to wide excision will there be any chance of cure.

Lymphangioma circumscriptum may present at any age but is usually noted at birth or appears during childhood. The commonest sites are the axillary folds, shoulders, flanks, proximal parts of the limbs and perineum. Doppler ultrasound will distinguish macrocystic from microcystic lesions as well as excluding any high flow and therefore vascular component. MRI is the best for delineating the extent of the lesion [4].

The treatment of choice for lymphangioma circumscriptum is radical surgery [5]. However, inadequate surgical excision of the visible lymphangioma frequently results in further development of surface vesicles, indicating the presence of a more widespread subcutaneous malformation. Therefore a stable, asymptomatic 'lymphangioma' may be better left alone. Bacterial superinfection is common, particularly with weeping lesions, and manifests with pain, systemic upset or cellulitis. Palliation for lymphorrhoea or to improve the appearance of vesicles can be achieved through intralesional administration of a sclerosant—for example, doxycycline [6], picibanil (OK-432) [7] or hypertonic saline [8]. Simple electrocautery and vaporization with carbon dioxide laser can be of palliative benefit, and superficial X-rays have been used successfully [9].

Macrocystic lymphatic malformations

Lymphangiomas with few but large macrocystic swellings containing clear lymph are called cystic hygromas (hygroma = moist

or watery tumour). Most occur in the neck, but they frequently extend into the upper mediastinum. The term tends to be reserved for those congenital lymphatic malformations that present at birth or are diagnosed by prenatal ultrasound. In the neck they presumably arise from an embryonic jugular lymph sac. Individuals with Turner's syndrome are particularly prone to both hydrops and cystic hygroma. Exceptionally, a cystic hygroma occurs in the groin, presumably from an embryonic iliac lymph sac. Fetal cystic hygroma can give rise to severe abnormalities, leading to fetal death [10].

Deeper, larger and cavernous lymphangiomas (LMs) are best called macrocystic LMs. Surface pressure with a digit will result in an indentation but a cavernous LM will rapidly refill, unlike the situation in pitting oedema where it takes many seconds for the interstitial fluid to redistribute when the pressure is released (like a sponge). They may be an isolated entity, part of a mixed vascular malformation (combined lymphatic–venous or capillary malformation) or associated with vascular syndromes such as Klippel–Trenaunay or proteus syndromes [11,12]. Cervicofacial LMs may cause airways obstruction, difficulty with feeding and speech development. Periorbital and skeletal hypertrophy are other complications of head and neck LMs [13].

Diffuse lymphangiomatosis

There is no clear distinction between lymphatic malformations and lymphangiomatosis. The difference may depend solely on the extent of the malformation. Most LMs are stable and run a completely benign course. Conversely, some visceral thoracic and abdominal LMs can relentlessly progress, infiltrating vital organs with fatal outcome and making distinction from frank neoplasia difficult; for example multifocal lymphangioendotheliomatosis with thrombocytopenia [1]. The CNS seems to be spared, presumably because of its lack of lymphatic vessels. Thoracic involvement leads to pleural and pericardial effusions and severe pulmonary infections [2]. Disseminated intravascular coagulation can give rise to thrombosis and haemorrhage [3]. Gorham's disease (Gorham–Stout disease; disappearing/vanishing bone disease) is characterized by proliferation of lymphatic vessels resulting in progressive destruction and resorption of osseous matrix. Skin 'lymphangiomas' may be the clue to the underlying diagnosis [1,4]. The outcome in diffuse lymphangiomatosis is poor, despite reports of successful use of interferon [5].

Chylous reflux, intestinal lymphangiectasia

Chyle is a 'milky lymph' which flows from the lacteals of the gut through the cisterna chyli and even through the thoracic duct. Incompetence of valves within main abdominal lymphatic trunks results in gross reflux of chyle. This can include reflux to the skin below the waist [1]; the most commonly affected sites are the genitalia, perineum and thigh. Chylous reflux is often associated with truncular lymphatic malformations in which case lymphoedema may be present, but the characteristic symptom is oozing of milky fluid through the skin, usually from visibly dilated chylous vesicles (chylous lymphangiectasia or 'lymphangioma'). Rupture of such vesicles may result in a spurt of chyle under pressure, or chronic leakage may give rise to warty plaques of a cream-yellow colour.

Chylous reflux is often associated with intestinal lymphangiectasia, which can lead to hypoalbuminaemia, hypogammaglobulinaemia and lymphopenia due to protein and cell loss through the gut. Capsule endoscopy is the investigation of choice [2]. Dietary replacement of fat with medium chain triglycerides (MCTs) is recommended as MCTs are absorbed and directed to the portal venous system rather than to the intestinal lacteals [3].

While intestinal lymphangiectasia is usually considered primary and therefore genetic in origin, for example Hennekam's syndrome [4], it can occur secondary to a range of gut pathologies where intestinal lymph drainage is altered [5].

Cutaneous lymphangiectasia (lymphangiectasis, acquired lymphangioma, benign lymphangiomatous papules)

The surface 'lymph blisters' seen in cutaneous lymphangiectasia are not necessarily structurally or histologically any different from those seen in 'lymphangioma'; both represent distended, otherwise normal, dermal lymphatics engorged with lymph due to a failure of downstream drainage.

Lymphangiectasia can be seen as translucent, almost flat, papules or vesicles in the skin, which may ooze lymph spontaneously or after trauma. Acquired or secondary lymphangioma is an alternative term, but confusing as there is no tumour or proliferative component. Benign lymphangiomatous papules represent the same process [1,2].

The clinical appearance of lymphangiectases/acquired lymphangiomas may vary greatly, ranging from clear fluid-filled blisters to smooth flesh-coloured papules or nodules.

Histologically, the latter show oedematous polypoid nodules within which are dilated lymphatics. Lesions may be solitary but scattered throughout a lymphoedematous limb, or they may be grouped, as seen in lymphangioma circumscriptum.

Lymphangiectases arise following damage to previously normal, deep lymphatic vessels [3]. The mechanism by which they form is identical to congenitally determined lymphatic malformations (lymphangiomas), that is obstruction to drainage leads to backpressure and dermal backflow, with subsequent dilatation of upper dermal lymphatics. Lymphangiectases are not true neoplasms or hamartomas, but represent simple expansion and engorgement (lymphangiectasia) of lymphatic vessels.

Lower-limb lesions usually arise in association with lymphoedema following either ilioinguinal block dissection or pelvic surgery and radiotherapy for gynaecological cancer. Lymphangiectasias/acquired lymphangiomas have been described in association with scarring processes, including recurrent or chronic infections (such as the scrofuloderma variant of tuberculosis), radiotherapy, scleroderma, keloid, tumour and repeated trauma [4]. They may also occur as a consequence of defective collagen or elastin, as documented in a report of penicillamine dermopathy [5].

Genital skin is particularly prone to lymphangiectasia. Lymph blisters of the penis or scrotum (and less commonly vulva), leaking lymph or chyle, may be seen in primary lymphoedema. In such circumstances the lymphangiectasia represents reflux of lymph or chyle from incompetent pelvic lymphatics and is usually associated with lymphoedema of one or both lower limbs.

Lymphangiectasia/acquired lymphangioma of the vulva or scrotum is described following cancer treatment, tuberculous inguinal lymphadenitis and genital involvement with Crohn's disease. Clinically, the most common pattern is that of circumscribed groups of tense, thin-walled vesicles. However, a hyperkeratotic appearance may make distinction from viral warts difficult [6] (Fig. 48.13). Recognition and appropriate treatment of vulval lymphangiectasia is important primarily because the lesions may act as portals of entry for infection. In addition, persistent leakage of lymphatic fluid may be mistaken for urinary incontinence.

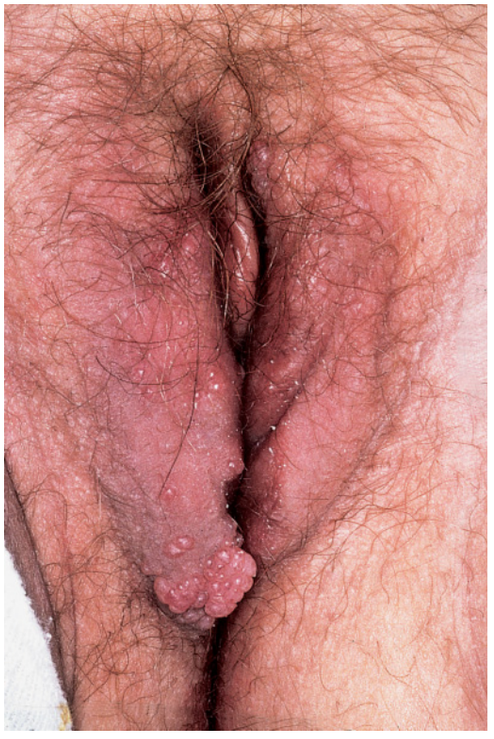

Fig. 48.13 Acquired lymphangiomas (lymphangiectasias) following cervical cancer treatment. The lymphangiomas were mistaken for genital warts.

Treatment of lymphangiectasia/acquired lymphangiomas is essentially the reduction of underlying lymphoedema and control of infection. This may be relatively straightforward on the leg, but is not so easy on the genitalia, where compression is not possible. Destruction of the 'lymph blisters' by laser or diathermy is helpful palliative treatment [7].

Lymphangiectasia/acquired lymphangiomas may be widespread and problematic in palliative circumstances where advanced cancer produces profound oedema of lower limbs, genitalia and lower trunk. In these circumstances copious lymph may weep. Opposing intralymphatic pressure with equivalent surface compression is the only way of controlling the lymphorrhoea unless the lymphatic obstruction can be relieved.

Acquired lymphatic abnormalities

Lymphangitis

In theory, the lymphatic system has evolved in humans as a host defence mechanism. Noxious agents and predators such as bacteria, if not dealt with at the point of entry to the host, access the lymphatic system. Lymphatic vessels, together with adjoining lymph nodes, effectively act as the second line of defence, hopefully preventing further onward spread and so limiting systemic involvement. In some circumstances, the inflammatory response may be profound, perhaps due to a heavy infection load, and either an overt lymphangitis or lymphadenitis, or both, arise. Lymphangitis represents inflammation of the lymphatic collectors and is clinically seen as tender red streaks up the limb corresponding to the inflamed vessels. In the lower limb, oedema is so often an accompanying feature that red streaks, such as are seen with lymphangitis of the arm, are rarely seen. A more diffuse erythema is seen extending up the medial side of the leg and thigh. Distinction from an ascending cellulitis becomes difficult.

Infection is usually limited by the lymph nodes, and in the lower limb lymphadenitis may give rise to painful swelling in the groin. Occasionally, infection bypasses a group of lymph nodes and affects those at a higher level. Constitutional upset can be severe and is greater the more proximally the infection has extended.

Lymphangitis may occur without any demonstrable inflammation or may be recurrent, for example following relapsing herpes simplex infection. Permanent obliteration of lymphatic collectors may follow severe or recurrent lymphangitis. In such cases, if reserve lymphatic capacity is limited, permanent swelling (lymphoedema) can result.

Recurrent cellulitis

Synonyms
- Recurrent inflammatory episodes
- Erysipelas
- Lymphangitis

Where lymphatic insufficiency exists and the local lymphoid tissue/lymphatic system fails in its host defence duty, recurrent infection can occur. Clinically, this manifests as recurrent cellulitis/erysipelas. Indeed, any patient who presents with even one attack of cellulitis in one leg may have a compromised lymph drainage in that leg, whether overt lymphoedema is present or not [1]. In most cases, however, subtle signs of lymphoedema are evident, particularly in the skin over the toes and forefoot. Because there is no localization of infection by the lymphatics, the first sign of illness will be constitutional upset with fever, rigors or vomiting. Only later may redness and tenderness appear in the leg and the diagnosis become clear.

Lymphangitis, as witnessed by red streaks up the leg, is generally not seen, presumably because the infection, uncontrolled by the lymphatic system, has spread through tissue planes (cellulitis) with rapid dissemination into the circulation. However, inflammation following the line of lymphatic channels can sometimes be apparent at the proximal border of a cellulitic area in patients with lymphoedema [2].

Treatment for recurrent cellulitis should first of all address predisposing factors such as tinea pedis, foot dermatitis, leg ulcers, etc. [3]. If no portal of entry or cause can be identified, then long-term prophylactic antibiotics may be necessary if the debilitating attacks are to be controlled but even that may fail to control attacks [4].

Lymphangiothrombosis

Lymph is capable of clotting, but the circumstances in which this happens, and what pathological effect lymph thrombosis has, are totally unknown. Extrapolating from knowledge about venous thrombosis would suggest that lymph thrombosis is likely to impair the function of lymphatic valves and the contractility of lymph-collecting vessels.

Mondor's disease, axillary web syndrome

Mondor's disease is alleged to be a superficial thrombophlebitis of the breast and chest wall [1] (see Chapter 47). A similar process, whereby cords or threads like violin strings extend down the inner arm, is frequently seen following axillary lymphadenectomy [2]. The manner in which the cords 'bowstring' across the axilla with the arm abducted, their diameter and the fact that the cords can snap between finger and thumb suggests that lymph thrombosis may be a more likely explanation than phlebothrombosis/thrombophlebitis. An equivalent condition may well exist in the lower limb but be mistaken for thrombophlebitis.

'Seroma'

Synonyms
- Lymphocoele
- Lymphocyst

Following lymphadenectomy, it is not unusual for a localized swelling containing clear fluid to develop. Often referred to as a

'seroma', the fluid is not serum, but lymph which has drained from the cut ends of the lymphatic collectors, so filling the space originally occupied by the nodes. The wall of lymphocoeles is 'false', in that no endothelial lining exists and instead a dense network of fibrin with lymphocytes is present [3]. Aspirated fluid is indistinguishable from lymph. Repeat aspiration is often necessary until a collateral lymph drainage forms. A 'seroma', particularly if infected, may herald the onset of lymphoedema if alternative drainage routes are not established.

Lymphatic tumours

Tumours of lymphatic vessels allegedly make up only a small group of vascular neoplasms but the use of specific lymphatic markers may change this view or make us realize that venous and lymphatic phenotypes can coexist within one tumour type, for example Kaposi's sarcoma and papillary intralymphatic angioendothelioma (Dabska's tumour) [1].

Acquired progressive lymphangioma

Synonym

- Benign lymphangioendothelioma

This benign tumour differs from simple 'acquired lymphangioma' or simple cutaneous lymphangiectasia by its clinical behaviour and histopathology [1]. Acquired progressive lymphangioma presents as reddish or bruise-like plaques which are usually located on the abdominal wall, thigh or calf. Typically, the condition affects young adolescents but may also arise in adults. It is usually localized, flat and grows slowly. Considered to originate from lymphatic endothelium, the histopathological appearance can mimic a low-grade sarcoma or Kaposi's sarcoma [2]. Anastomosing dilated channels, with a tendency to dissect the collagen bundles, are lined by swollen endothelial cells but without cellular atypia. It usually runs a long and benign course.

Lymphangiomyomatosis

Synonym

- Lymphangiopericytoma

This condition affects primarily pre-menopausal women, and presents with central lymphatic problems, typically progressive dyspnoea associated with chylous effusions and a chest X-ray which reveals honeycombing of the lungs [1]. Masses of spindle cells proliferate in and around the walls of lymph vessels, particularly in retroperitoneal tissues and in the mediastinum. These cells (lymphangiomyomatosis cells, LAMs) have a smooth muscle phenotype and have mutations in one of the tuberous sclerosis complex genes (*TSC1* or *TCS2*). Skin involvement, with facial angiofibromas, forehead plaques and periungual fibromas, can occur in lymphangiomyomatosis [2]. Lymphoedema of one or both legs can develop due to infiltration of LAM cells in the walls of main lymphatic trunks, and sometimes beyond this into surrounding adipose tissue. Suppression of mTOR signalling might constitute an ameliorative treatment in patients with the tuberous sclerosis complex or sporadic lymphangioleiomyomatosis [3].

Kaposi's sarcoma

There is increasing evidence that Kaposi's sarcoma (KS) may arise from lymphatic rather than from vascular endothelium, although its origins may lie with transdifferentiation from blood vascular to lymphatic phenotype [1,2].

The classical form of the disease, as described by Kaposi, presents with dark-blue or purple lesions, usually on the feet. Initially, lesions may be flat; when they become tumid, diascopy may produce partial blanching to reveal a brown tinge from extravasated blood. Individual tumours enlarge to a diameter of 10–30 mm and stop growing, whereupon adjacent areas fuse to form a plaque or tumour. New lesions appear proximally alongside a superficial vessel. Unlike the situation in patients with lymphangiosarcoma, lymphoedema may not be evident at the time the first lesions appear, but otherwise the morphology is similar. KS, however, is characteristically multifocal and, in time, symmetrical, affecting both lower limbs. Brawny oedema resembling lymphoedema develops with advanced KS.

In the African and Mediterranean types of KS, oedema is often the first sign with lymph nodes as the main tissue involved.

KS associated with immunodeficiency, whether HIV-induced or not, produces subtle lesions which are often widely scattered and quite dissimilar from the classical type.

KS can cause lymphoedema but can also follow lymphoedema. Presumably the local immunodeficiency derived from the lymphatic insufficiency promotes the development and progression

of KS in the same way that lymphoedema encourages infection and skin cancer.

Treatment is dependent on the type of KS. In AIDS-related KS, treatment of HIV is paramount and both KS and lymphoedema may regress. In endemic African-type KS, staging of nodal involvement is necessary before consideration of chemotherapy with or without radiotherapy. For localized disease, radiotherapy is the treatment of choice.

Maffucci's syndrome

Maffucci's syndrome consists of diffuse haemolymphangiomatosis accompanied by severe, widespread deformities of bone and cartilage, notably enchondromas of the digits [1]. The lymphangiomas do not appear, on lymphography, to communicate with the main lymphatic pathways and often possess both blood vascular and lymphatic elements. Bony deformity may be gross and slowly uniting pathological fractures are common. The disease has high malignant potential including lymphangiosarcoma.

Atypical post-radiation vascular proliferation

Cutaneous vascular proliferations that occur within the field of prior radiotherapy include angiosarcoma and small cutaneous solitary or multiple papules with a pseudosarcomatous pattern which resemble angiosarcoma (post-radiotherapy vascular proliferations, post-radiotherapy atypical vascular lesions). Clinical and histological distinction can be difficult but atypical vascular proliferations appear to have a benign prognosis [1].

Lymphangiosarcoma

This is a rare but well-recognized complication of any chronic lymphoedema, irrespective of cause. Red–brown or purple discoloration, like a bruise, appears in the skin of the lymphoedematous limb. Nodules or raised plaques may appear later. As the tumours proliferate, the oedema may increase and older lesions may ulcerate. The tumour metastasizes early and has a poor prognosis.

The tumour is best described in the upper limb following breast cancer treatment (Stewart–Treves syndrome) [1], but it is well reported in the lower limb in association with lymphoedema, usually of many years' duration [2]. Radical amputation, if performed early enough, may offer hope of cure. Isolated limb perfusion has been reported for non-resectable limb tumour [3].

Carcinoma erysipeloides

Synonym

- Carcinoma telangiectatica

Carcinoma erysipeloides manifests clinically with a fixed erythematous patch or plaque resembling cellulitis/erysipelas, but without fever [1]. The inflamed area may show a distinct raised periphery and oedema secondary to lymphatic obstruction. Histology reveals plugging of superficial and deep dermal lymphatics by adenocarcinoma, usually carcinoma of the breast, but the condition has been described with melanoma, lung, ovarian, colonic and pancreatic tumours [2]. The redness appears to be a consequence of the dermal lymphatic plugging with tumour, presumably through the release of cytokines. The term carcinoma telangiectatica refers to the presence of purpuric plaques, papules and vesicles where only the more superficial lymphatics are involved. 'Inflammatory breast carcinoma' has been suggested as an alternative term to 'carcinoma erysipeloides', but oncologists already classify inflammatory breast carcinoma as a subtype of cancer within the breast.

Introduction

Purpura and bruising, the main terms used to describe bleeding into the skin, may occur as isolated phenomena or as part of a systemic disorder. Purpura is the hallmark of vasculitis affecting the (usually smaller vessels of the) skin, and may be the dominant feature or a minor part of a systemic vasculitis (see Chapter 50). However, it may occur as a result of other non-vasculitic abnormalities of the blood vessel wall and, overall, much the commonest causes (although largely not seen by dermatologists) are haematological conditions due to platelet and coagulation disorders. Vasculitis typically causes other cutaneous lesions, including urticarial lesions, nodules, ulcers, livedo and frank necrosis, which have a purpuric component due to vessel wall damage. Several of these also occur in disorders in which vessels are occluded, as discussed later in this chapter. An appreciation of the morphology and associated features is of great value in the diagnostic approach [1].

Patients with purpura may require management involving one or more of several disciplines, including haematology, general medicine, nephrology and rheumatology, as well as dermatology; multidisciplinary management is often appropriate as each specialty sees a different range of clinical manifestations and has different areas of expertise.

Classification of purpura is difficult, as no single approach is satisfactory. The same clinical pattern may arise from many different causes, both vasculitic and non-vasculitic, and the aetiology of either purpura or vasculitis may be impossible to determine. Classifications based on morphology or aetiology therefore have limitations. For example, clinically non-specific capillaritis may be idiopathic, drug-induced or a manifestation of cutaneous T-cell lymphoma. Even within frank haematological causes of purpura, idiopathic thrombocytopenic purpura is not only viewed as a mixture of diseases but varies in its definitions and clinical descriptions [2]. Furthermore, intravascular events such as microvascular occlusion may give rise to palpable lesions and inflammation as a secondary component, thereby mimicking vasculitis and confusing both the clinical and histopathological picture.

Despite these limitations, as a practical matter the initial approach to a patient with purpura must typically start with a

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

differential diagnosis based on morphology [1], as few patients present with a known aetiology of their lesions. In practice, overt haematological causes (thrombocytopenia and clotting factor abnormalities) can be rapidly and easily evaluated by full blood count and laboratory measures of clotting times. Beyond this, diagnostically more complex haematological disorders (e.g. thrombophilias or abnormal platelet function), vessel wall defects (both structural and others) [3], infections, immunological disorders and thrombotic microvascular occlusion disorders may all need to be considered. The importance of trying to differentiate between disorders causing primarily inflammatory or non-inflammatory lesions is clear [4,5].

This chapter addresses purpura that is not primarily of vasculitic causation; Chapter 50 deals with disorders in which a primary vasculitis is involved.

Definition of purpura

Purpura is discoloration of the skin or mucous membranes due to extravasation of red blood cells. *Petechiae* are small purpuric lesions usually 1–2 mm (occasionally up to 4 mm) across, often occurring in crops. *Ecchymoses* or *bruises* are larger extravasations of blood. The many causes of petechiae and ecchymoses overlap, for example thrombocytopenia usually causes petechiae but more extensive bleeding may occur at lower levels of platelet count. In contrast, coagulation disorders usually cause ecchymoses rather than petechiae [1–4]. For example, haemophilias usually present as bleeding from the umbilical cord or gingivae, or as haematomas or haemarthroses—although dermatologists need to be aware that haemorrhagic subcutaneous nodules may be the first sign of an inherited haemophilia [5]. Gingival bleeding, epistaxis or internal bleeding may occur with platelet or coagulation disorders.

The sequence of colour changes in a bruise can help to identify it as such, should doubt exist, and can also help to establish its duration. Extravasated blood is broken down to various other pigments derived from haem, usually within 2 or 3 weeks. The characteristic colour changes [6–8] include red, blue and purple in the first 5 days (although these colours can occur at other times, particularly red), green after 5–7 days and yellow after 7–14 days (never less than 18 h). Many factors, both intrinsic to the individual (age, sex, skin colour, body site) and related to the injury (amount of blood extravasated, depth of bruising, medications that alter bruise dispersion), influence the timescale of colour changes [9]. In smaller and more superficial purpuric lesions, orange or brown colours due to residual haemosiderin may predominate. Assessment of traumatic ecchymotic lesions is not a major part of routine dermatological practice, but may be important in suspected child abuse [9].

Unlike purpura, increased intravascular blood in the skin, whether as diffuse erythema or within telangiectatic vessels, can be blanched by pressure, typically using the technique of diascopy (see Chapter 5). However, not all telangiectatic lesions can be emptied in this way. Small angiomas (e.g. in angioma serpiginosum or the multiple minute variant of Campbell de Morgan spots) and angiokeratomas may cause particular confusion [10]. Sometimes, observation over several days is necessary. Capillary microscopy or, more recently, dermoscopy may also be helpful in determining whether blood is intravascular or extravascular.

Classification and investigation of purpura

An aetiological classification of purpura is provided in Table 49.1. However, for clinical purposes, correlations can be made between the clinical features and the mechanism of purpura. Purpura occurs as a result of one or more of the following main mechanisms in cutaneous vessels:

1 Simple haemorrhage
2 Inflammatory haemorrhage
3 Occlusion/ischaemia.

Characteristics of lesions, including size, number, distribution pattern, and presence or absence of palpability and erythema, can be very useful in focusing on the most likely mechanisms of haemorrhage within these subsets.

In general, simple haemorrhage presents as macules without erythema (Table 49.2), although sufficient haemorrhage into subcutaneous tissue becomes palpable as a haematoma. The size of the macules has diagnostic importance. Inflammatory causes of haemorrhagic lesions usually evolve with increasing erythema in the first 24–36 h, along with increasing purpura. Such lesions are frequently, but not invariably, palpable. A subset of palpable purpura syndromes may uncommonly also produce lesions with retiform or stellate patterning, with accompanying early erythema

Table 49.1 Causes of purpura and ecchymosis.

Platelet disorders (see also Table 49.3)
Thrombocytopenia
Abnormal platelet function
Thrombocytosis

Coagulation disorders
Inherited, e.g. haemophilia or acquired factor deficiency or dysfunction (e.g. antibody inhibitor)
Drugs, e.g. anticoagulants
Localized, e.g. heparin injection sites, some insect bites
Metabolic, e.g. vitamin K deficiency, hepatic failure (decreased synthesis of clotting factors)
Thrombophilias, e.g. protein C deficiency, protein S deficiency
Disseminated intravascular coagulopathy and purpura fulminans
Secondary to systemic disease (often multifactorial, e.g. macrophage activation syndrome)

Other intravascular causes of purpura/microvascular occlusion
Dysproteinaemias, e.g. hypergammaglobulinaemic purpura (Waldenström), Sjögren's syndrome
Cryoproteinaemias
Emboli: crystal, fat, myxoma, infective

Mechanical vascular causes of purpura
Raised intravascular pressure
  Coughing, vomiting, Valsalva manoeuvre, tourniquet
  Stasis
Decreased support
  Actinic ('senile') purpura
  Corticosteroid purpura
  Scurvy
  Amyloidosis
Inherited disorders of connective tissue (pseudoxanthoma elasticum, Ehlers–Danlos syndromes)
Abnormal vasculature
Purpura around vascular lesions, e.g. targetoid haemosiderotic haemangioma, tufted angioma, aneurysmal fibrous histiocytoma

Purpura with inflammation
Non-thrombocytopenic toxin- and drug-induced purpura
Contact purpura
Purpura associated with infections
Capillaritis (pigmented purpuric dermatoses)
  Idiopathic
  Drug-induced
  Pre-mycotic
Inflammatory purpura/vasculitis (see Chapter 50), e.g. Henoch–Schönlein purpura, acute haemorrhagic oedema
Associated with other inflammatory dermatoses that are not usually purpuric
Solar purpura

External and other causes of purpura or ecchymosis
Physical and artefactual causes
Easy bruising syndrome and purpura simplex
Paroxysmal finger haematoma (Achenbach's syndrome)
Painful bruising (autoerythrocyte sensitization, Gardner–Diamond) syndrome
Stigmata

and palpability (inflammatory retiform purpura). By 48 h, erythema and palpability begin fading in both types of lesions, although the purpura may persist for several days. In contrast, lesions of occlusion/ischaemia usually begin with minimal or no erythema, and may show minimal palpability unless eschar forms, but may develop erythema if sufficient necrosis occurs to induce a wound healing response. Occlusive syndromes tend to manifest retiform or branching patterns of purpura (non-inflammatory retiform purpura), sometimes with accompanying localized livedo reticularis, or as necrotic plaques with minimal erythema.

Non-inflammatory purpura is generally due to haematological causes and detailed discussion is outside the remit of this chapter; specialized haematology texts [1–7] and online review resources [8] can be consulted. Similarly, structural and non-inflammatory

vessel wall changes that allow extravasation of blood are discussed in other chapters of this text, and reviewed elsewhere [9].

Diagnosis and pathophysiology of simple macular haemorrhage [1–6]

Purpura due to simple haemorrhage is suggested by the presence of purpura that is macular (non-palpable) and that has no blanching component in newly developed lesions (Table 49.2). Palpable lesions, or a blanching component, suggest that there is associated inflammation (which may occur as a secondary effect, hence the emphasis that evaluation must concentrate on new lesions). It should be noted that pale (not blanching) areas often appear in a perifollicular or blotchy pattern in older ecchymosis as extravasated blood is resorbed. The size of lesions, clinical patterns and body sites affected may all be diagnostically useful.

Size of lesions

Petechiae are often defined as lesions of 2 mm or less in diameter, although non-palpable, non-blanching lesions up to 4 mm usually suggest the same process. The main mechanisms of simple haemorrhage are:

1 Thrombocytopenia (platelet count always $<50 \times 10^9$/L, usually $<10 \times 10^9$/L)
2 Platelet dysfunction (uncommonly a cause of clinical purpura, although some degree of platelet dysfunction occurs in many systemic diseases or due to a variety of drugs)
3 Regional or localized increased intravascular pressure
4 Abnormal vascular support/vessel fragility
5 Many forms of capillaritis (pigmented purpura).

In contrast, macular lesions of 1 cm or greater in diameter (ecchymoses) usually result from disorders of the cascade coagulation system (especially acquired), platelet dysfunction or poor dermal vascular support. Such lesions are usually provoked by minor trauma. This results in two important clinical clues. The first is that lesions tend to localize to areas prone to frequent minor trauma, such as the extensor forearm and dorsal hand, lateral thigh and anterior lower leg. The second finding is a linear or geometric shape of individual lesions, because such lesions typically result from a frictional injury or extension of blunt trauma. Finally, as photodamage of fair skin is a very common cause of poor dermal support, ecchymotic haemorrhage is very commonly found on areas with chronic exposure to both sun and trauma, for example the extensor forearm and dorsal hand.

It is evident that some aetiologies can cause purpuric lesions of variable size. For example, scurvy (a disorder in which the collagen of vessels and dermis is altered) may cause small perifollicular petechiae or large sheets of bruising with significant induration. Drug-induced platelet dysfunction may cause small petechiae, capillaritis-type areas of discoloration, or frank bleeding. Moderately severe thrombocytopenia (platelet count around $10–20 \times 10^9$/L) may cause petechiae or broad ecchymoses.

Clinical patterns of purpura

The clinical pattern may help to determine which patients require investigation, and may suggest the most likely major pathophysiological mechanisms. Tiny purpuric spots on the lower legs, for example, are not uncommon in the elderly, in patients taking antiplatelet drugs, or in the context of an inflammatory dermatosis; investigation of such lesions in these settings is seldom needed. Similarly, larger lesions that are macular, purple, stellate or blotchy, and confined to photo-aged skin on the dorsum of hands or forearms are generally diagnosed clinically as a consequence of actinic damage (although the same process on the face may produce smaller or more linear lesions, clinically resembling amyloidosis, and more widely distributed lesions of this morphology occur in Cushing's syndrome). Some degree of purpura is not uncommon in inflammatory skin disease of several types, but investigation is likely to be aimed at the disease process rather than the purpuric component *per se*.

Features that suggest a need for further investigation include:

- Larger or variably sized lesions, particularly when not in sun-damaged skin
- Numerous or widespread lesions
- Lesions occurring in crops
- Palpable lesions
- Lesions forming reticulate patterns (livedo, retiform pattern)
- Associated features such as pustules, necrosis, nodules, splinter haemorrhages, etc.
- Evidence of bleeding from other sites, e.g. haematuria
- Associated general symptoms, e.g. fever, malaise, arthralgia.

Diagnosis of purpura at various body sites

Gravitational change has a major influence on the distribution of purpuric lesions, as discussed elsewhere in this section. Other body sites of specific importance include the following.

- Eyelids: purpura due to increased venous pressure—classically due to performing the Valsalva manoeuvre, but in practice more likely after severe coughing or vomiting, and also described after endoscopy, etc. (also affects the cheeks; Fig. 49.1); purpura or ecchymosis in amyloidosis (panda sign), due to abnormal vessels and supporting dermis; ecchymosis related to neuroblastoma.
- Ears: purpura due to cryoglobulinaemia and other hyperviscosity disorders; purpura due to some drugs, e.g. antineutrophil cytoplasm antibody (ANCA)-positive propylthiouracil reaction, levamisole
- Face, ears and acral: acute haemorrhagic oedema of childhood (Chapter 50); cryoglobulinaemia

Fig. 49.1 Purpura on the face due to the raised intravascular pressure that occurs during vomiting. The lesions are small, non-palpable and all of the same age.

- Acral: purpura due to cryoglobulinaemia and other hyperviscosity disorders; embolic causes of purpura; rickettsial infection
- Friction sites: clothing contact purpura; some cases of capillaritis; Henoch–Schönlein purpura and other small-vessel vasculitis; ecchymosis of Ehlers–Danlos syndrome
- Intraoral: thrombocytopenia; amyloidosis; myelomonocytic leukaemia; angina bullosa haemorrhagica.

Laboratory tests

Platelet count and function [1–4,7–9]

This is the most important investigation in patients with non-palpable petechiae. The normal count is 150–400 $\times$ 10^9/L. It varies greatly from person to person, and from time to time in the same person. It may be affected by numerous exogenous factors such as infections, and by internal factors such as hormonal changes. Purpura due to thrombocytopenia seldom occurs with a platelet count above 50 $\times$ 10^9/L, and significant spontaneous bleeding is unlikely unless the count is less than 20 $\times$ 10^9/L. Thrombocytosis may also be a cause of bleeding. As well as variation in number, variation in function of platelets may need to be assessed by specialized *in vitro* tests. A full blood count should always be undertaken in the investigation of purpura; in general, especially for milder bleeding problems, a staged approach to diagnostic testing is appropriate depending on the results of initial tests and the clinical suspicions [10].

Tests of occult bleeding

Simple tests to detect other sites of bleeding, whether in vasculitis or in haematological causes of purpura, include fundoscopy, urinalysis and faecal occult blood tests. Haematuria may occasionally occur in disorders that are felt to be essentially dermatological but non-vasculitic, such as drug-induced pigmented purpuric dermatoses [11,12].

Histology

Histological examination of non-palpable, non-blanching, small purpuric lesions is usually unhelpful; it is essential, however, to consider whether lesions are palpable or partially blanching. If there are palpable or partially blanching lesions, then vasculitis should be considered and biopsy is likely to be informative. If lesions are larger but not palpable, and platelet parameters are normal, then biopsy of the skin is appropriate, for example to assess disease of the vessel wall or surrounding tissues.

Capillary resistance and fragility [13–16]

If the pressure difference between the tissues and the capillaries is sufficiently increased, leakage of blood cells occurs. This is the basis of a variety of semi-quantitative tests for capillary fragility. However, the integrity of the capillary endothelium itself, and also the ability of platelets to fill any gaps which may arise in it, contribute to this type of bleeding. Abnormal results may therefore occur in conditions where there is thrombocytopenia, abnormal platelet function or intravascular coagulopathy, as well as in conditions where there is a vessel wall defect. Indeed, the precise aetiology may be mixed; for example, some types of Ehlers–Danlos syndrome (EDS IV) have abnormal vessel wall collagen, abnormal perivascular support, and may occasionally have associated platelet dysfunction, and several defects of haemostasis occur in hereditary haemorrhagic telangiectasia (HHT) as well as the vascular abnormalities [16].

Sometimes capillary leakage is discovered accidentally due to development of a shower of purpura on the arm distal to a blood pressure cuff immediately after the pressure has been released (Rumpel–Leede sign). More commonly, tests are performed to provoke purpura; the simplest clinical test, which essentially performs the same process, is the Hess test. A standardized increase in capillary pressure is produced by inflating a sphygmomanometer cuff around the upper arm to a constant pressure of 80 mmHg (or less if this approaches the systolic blood pressure) for 5 min. Petechiae develop over the next few minutes and can be counted in a measured area of 5 cm diameter just below the antecubital fossa; up to five may be considered normal. However, our experience is that the greatest density of purpura provoked by a Hess test is usually in the 'snuff-box' area over the space between the thumb and index finger metacarpals on the dorsum of the hand.

'Negative-pressure' tests require some simple apparatus to apply negative pressure to an area of skin usually 1–2 cm across. This technique is suitable for repeated tests in the same subject. The application of such a negative pressure at the rim of a cup may only be acting as a local venous tourniquet. Using these techniques capillary resistance is found to vary greatly, as does the platelet count, from individual to individual and with site and numerous other factors.

Bleeding time [4,17–20]

This is the time taken for bleeding to cease after a standardized tiny incision, usually in the skin of the forearm. This type of bleeding normally ceases because of contraction of the small vessels aided by production of a platelet plug. Techniques can be standardized in various ways, for example with a sphygmomanometer cuff at 40 mmHg the bleeding time is usually 4–10 min. The bleeding time is usually prolonged in thrombocytopenia where the platelet count is below 80 $\times$ 10^9/L and becomes progressively prolonged as the count falls, being 30 min at counts less than

10×10^9/L. It may be prolonged in von Willebrand's disease, other disorders of platelet function, severe anaemia, and in patients taking aspirin or receiving heparin, as well as being affected by age and skin laxity. Although often stated to be normal in disorders of coagulation, it may be prolonged in severe haemophilia. It is a rather insensitive test whose wide range of normal values makes it of limited use, even as a screening test. The bleeding time does not accurately predict internal surgical bleeding [19], although it has been used to investigate the effect of aspirin and non-steroidal anti-inflammatory drugs (NSAIDs), which may be relevant as a cause of bleeding during skin surgery [20].

Platelet function analysers (PFA), measuring the PFA closure time, may be more useful, but may vary in sensitivity and specificity according to the disorder being examined, the PFA being more accurate than the bleeding time for diagnosis of type I von Willebrand disease [21]. A study of the combined PFA closure times for ADP and epinephrine in normal subjects (the PFA-100) showed a false-positive rate of almost 16% and, of those who did have a platelet function abnormality, the specificity was 79% compared with 91% for the bleeding time [22]. Current techniques such as the PFA-100, even if less specific, do have the advantage of simplicity, are *in vitro* and therefore less invasive, and are more reproducible than the bleeding time. Although clinical experience with this technique is recent, this and similar methods (such as the Thrombostat 4000) are largely replacing the bleeding time in many clinical haematology laboratories.

Coagulation screen

Major coagulation defects can be excluded by a clotting screen including measurement of prothrombin time, kaolin cephalin clotting time, thrombin clotting time and fibrinogen levels. Clinical considerations and the results of the screening tests may suggest further laboratory tests, for example levels of individual clotting factors [10] or antiphospholipid antibodies. Discussion of how these tests are performed is beyond the scope of this book, but they are described in detail in other publications [23–25].

Capillary microscopy

Direct microscopic examination of capillaries is disappointing in the elucidation of haemorrhagic and purpuric diseases, although it is useful to determine whether small punctate lesions are actually petechial or small convoluted but intact capillaries. Purpura may at times be seen in the nail fold capillaries when not present elsewhere in the skin. Extravasation of blood may occur at the junction of the precapillary arteriole with the capillary, at the tip of the capillary or more usually at the venous end. Capillary microscopy is discussed further in Chapter 47 and, in relation to nailfolds in collagen vascular diseases, in Chapter 51.

Other haematological, biochemical and immunological tests

A number of other haematological tests may be indicated, depending on the likely diagnostic area. As a simple example, a blood film, bone marrow examination, and tests for antiplatelet antibodies may all contribute in distinguishing between thrombocytopenia due to decreased production versus peripheral destruction. This is the province of the haematologist, and is addressed in major haematological texts [1,2]. It is worth being aware that abnormalities predisposing to bleeding may coexist, and may require a wider range of tests than usual for the presumed diagnosis; examples include abnormal platelet function (relatively common), fibrinolytic defects and low-grade disseminated intravascular coagulopathy (DIC) (possibly in 50% of patients) in HHT [16], platelet dysfunction in Ehlers–Danlos syndrome [16], acquired factor X (sometimes IX and X) in systemic amyloidosis [16], bone marrow necrosis in antiphospholipid syndrome [26], thrombocythaemia with antiphospholipid syndrome [27], heparin-induced thrombocytopenia with the antiphospholipid syndrome [28], and the multiple causes of bleeding in acute promyelocytic leukaemia (DIC, fibrinolysis, and proteolysis of fibrinogen and von Willebrand factor) [29]. Some of these are discussed in more detail later in the chapter.

Hyperferritinaemia is a well documented feature of some inflammatory disorders. Ferritin is produced by phagocytic macrophages, and high levels occur in disorders where there is histiocytic proliferation and haemophagocytosis. This occurs in a little known disorder termed the *macrophage activation syndrome* (also termed autoimmune disease-associated reactive haemophagocytic lymphohistiocytosis), a complication mainly occurring in systemic onset juvenile idiopathic arthritis (Still's disease) and sometimes in juvenile systemic lupus erythematosus; it has also been documented in adult-onset Still's disease, and may be triggered by infections or by drugs. Purpura, bruising and mucosal bleeding occur due to a combination of thrombocytopenia and coagulopathy (prolonged prothrombin time and partial thromboplastin time, with fibrin degradation products and hypofibrinogenaemia) [30,31]. Other biochemical abnormalities include low sodium levels, and elevation of triglycerides, lactose dehydrogenase and transaminases.

Although not routinely performed, a variety of serological tests can give an indication of vascular damage; these include levels of thromboxane, endothelin, prostacyclin, soluble thrombomodulin, platelet activating factor, e-selectin and von Willebrand factor. Antibodies against platelets, clotting factors and others are sometimes measured. Emergent antibodies, but still of uncertain clinical application, include those against annexins II and V, which are important in fibrinolysis in acute promyelocytic leukaemia and in the antiphospholipid syndrome, respectively [32]. β_2-glycoprotein I is discussed later in relation to antiphospholipid syndrome.

Genetic tests

Although rarely the first approach, many causes of bleeding and thrombosis are now well characterized at a genetic level; appropriate tests may be used to confirm a diagnosis, and in some cases to estimate prognosis or suitability for specific treatment options. Some examples of relevance in evaluation of purpura and bleeding include cytogenetic testing (for example, demonstrating a high risk of bleeding in patients with acute promyelocytic leukaemia who have t(15:17) translocation), documentation of activated protein C resistance (factor V Leiden; pp. 49.38–39) and genetic tests such as identifying different types of Ehlers–Danlos syndrome (type IV, associated with severe bleeding due to vascular rupture, being due to mutations in the *COL3A1* gene), confirming different types and zygosity in homocystinaemia, distinguishing

between HHT I (endogulin gene mutations) versus HHT II (*ALK1* gene) in hereditary haemorrhagic telangiectasia, and demonstrating ADAMTS13 deficiency in thrombotic thrombocytopenic purpura [33].

Summary

To avoid performing every type of investigation in all cases of purpura, the following broad generalizations may be made.

1. Purpura of mild degree on the lower legs alone is commonly hydrostatic, especially in the elderly, in those with other evidence of venous disease, or in the distribution of other skin diseases, and seldom requires extensive investigation.
2. Coagulation defects usually present as large ecchymoses and external or internal bleeding but not as petechiae; inherited types may present as gingival bleeding. Capillary fragility tests are normal unless there is severe deficiency of clotting factors.
3. Thrombocytopenia is often associated with petechiae but there may also be external or internal haemorrhages and bruising.
4. External bleeding and large ecchymoses are due to coagulation or platelet defects, or to diseases of connective tissue such as Ehlers–Danlos syndrome.
5. Petechiae are due to platelet defects or capillary changes.
6. Dysproteinaemias may cause lesions of simple haemorrhage, inflammatory haemorrhage or occlusion, depending on the properties of individual abnormal proteins.
7. Thrombophilias may present with livedoid change, retiform purpura or usually non-inflammatory cutaneous necrosis.
8. An initial retiform pattern without blanchable erythema or palpable lesions is generally indicative of microvascular occlusion.
9. Inflammatory lesions of the vessels are seldom the cause of external bleeding or ecchymoses, but are the most common cause of persistent and localized purpura. A blanchable erythematous inflammatory component is often present in early lesions.
10. Inflammatory purpuric lesions are due to vascular changes rather than simple haemorrhage.
11. Splinter haemorrhages of the nails are due to purpura of the nail bed, are most commonly due to trauma and are not diagnostic of any one condition (see Chapter 65).

Purpura due to thrombocytopenia or platelet defects

Platelets are an essential component of the haemostatic process. Thrombocytopenia or abnormal platelet function from any cause may therefore produce purpura or a bleeding tendency, as discussed in the general haematology texts previously listed and in references listed below [1–7].

Table 49.3 Platelet disorders causing purpura.

Thrombocytopenia
Defective platelet production
  Bone marrow abnormality
    Aplasia: toxic, immunological, idiopathic
    Neoplasia: leukaemia, myeloma, carcinomatosis
    Replacement: myelofibrosis, radiation damage, sarcoidosis
Other impaired production: Wiskott–Aldrich syndrome, vitamin B_{12} or folate deficiency
  Metabolic: uraemia, alcohol, drugs
  Infections
Diminished platelet survival
  Platelet alloantibodies
    Neonatal
    Post-transfusion
    Antilymphocyte globulin
  Platelet autoantibodies
    Idiopathic (immune) thrombocytopenic purpura
    Marrow transplant
    Antiphospholipid antibodies
    Systemic lupus erythematosus
Mechanical: prosthetic heart valves
Drugs and vaccines
Infections, sepsis syndrome
Excessive platelet consumption
  Disseminated intravascular coagulation
  Haemangioma (Kasabach–Merritt)
  Hereditary haemorrhagic telangiectasia ('mini-Kasabach–Merritt')
  Thrombotic microangiopathies
    Haemolytic–uraemic syndrome
    Thrombotic thrombocytopenic purpura
Sequestration
  Splenomegaly
  Hypothermia

Abnormal platelet function
Inherited and congenital
  Von Willebrand disease and defects of the platelet von Willebrand factor receptor
  Hereditary haemorrhagic telangiectasia (often have platelet dysfunction also)
  Bernard–Soulier disease (GpIb/IX/V receptor defect with low platelet count)
  GpIa deficiency
  Glanzmann's thrombasthenia (GpIIb/IIIa deficiency)
  MYH9-related disorders (e.g. May–Hegglin abnormality)
  α-granule disorders
  Dense granule (δ-granule) disorders (Hermansky–Pudlak syndrome, Chediak–Higashi syndrome, storage pool disease)
  Abnormalities of signal-transduction pathways
  Membrane phospholipids abnormalities (e.g. Scott syndrome)
  Wiskott–Aldrich syndrome (δ-granule abnormality) and X-linked thrombocytopenia (WASP gene mutations)
Drug-induced
Uraemia
Cardiac bypass
Platelet antibodies
  Idiopathic (immune) thrombocytopenic purpura
  Systemic lupus erythematosus/antiphospholipid syndrome
Myeloproliferative disorders
Dysproteinaemias (especially IgA myeloma and macroglobulinaemia)
Cold-stored (blood bank) platelets

Thrombocytosis
Essential thrombocythaemia
Other myeloproliferative syndromes
Medical diseases and other causes
  Blood loss, trauma, burns
  Post-splenectomy
  Malignant disease
  Tuberculosis
  Sarcoidosis

Platelets exposed to damaged endothelium adhere to one another and to collagen and other subendothelial components. Numerous complex interactions occur, involving von Willebrand factor and its glycoprotein receptor, various integrin adhesion molecules, thrombospondin, fibronectin, laminin, phospholipases and ADP released from damaged cells, as well as collagen and platelets. Platelet activation causes release of serotonin and thromboxane A_2, both of which cause vasoconstriction, and increase platelet adhesiveness and aggregation leading to formation of a platelet plug. This process is aided further by the presence of plasma fibrinogen and by thrombin. Production of prostacyclin, a powerful vasodilator and inhibitor of platelet aggregation, is decreased as a result of endothelial damage. Developing platelet plugs are reinforced by fibrin strands formed as a result of activation of the plasma clotting system by platelet factor 3, when this is exposed by alterations in the surface characteristics of the aggregated platelets.

Purpura due to platelet defects can be divided into three groups:

- Thrombocytopenia, i.e. decreased platelet numbers
- Abnormalities of platelet function
- Thrombocytosis, i.e. increased platelet numbers.

Thrombocytopenia

The platelet count at which purpura occurs is extremely variable. Purpura due to platelet deficiency usually occurs with a count below 20×10^9/L and is seldom observed with a count above 50×10^9/L. The main causes of thrombocytopenia are listed in Table 49.3.

Idiopathic (immune) thrombocytopenic purpura [1–9]

Synonyms
- Autoimmune thrombocytopenic purpura (ATP)
- Werlhof's disease

Idiopathic immune thrombocytopenic purpura (ITP) results from immune destruction of platelets; transient ITP has been documented in children born to affected mothers, and passive transfer has been demonstrated. The prevalence is about 1/10 000 population per year, and it is about twice as common in women, except in childhood where males predominate [10]. Half of cases occur in children [4] (two-thirds before age 21 years), and it may occur in 0.1–0.2% of pregnancies. Familial and twin cases have occurred, some populations show an association with HLA-DRw2 or DRB1*0410 alleles, and a genetic predisposition appears likely [11]. There is an association with other autoimmune diseases, such as celiac disease [12] and thyroid disease [13]; other predisposing factors include certain immunodeficiencies, complement C2 or C4 deficiency, and abnormalities of the Fas pathway [1]. The onset may be gradual or, especially in children, acute, and the overall course may be self-limiting (especially in children) or long-term. Chronic ITP is usually autoimmune and apparently idiopathic.

The autoantibodies often show specificity for the platelet membrane glycoproteins IIb/IIIa (integrin αIIbβ3) and Ib/IX [5], and less often for Ia/IIa, IV or V. It is unclear why these develop but there is a Th1 cytokine profile and T cells may drive the process by stimulating antibody synthesis after being exposed to fragments of glycoprotein IIb/IIIa, but not to the intact native protein; such fragments may arise from destruction of platelets within antigen-presenting cells or by other mechanisms [5,8]. A current theory suggests that there is upregulation of CD40 ligand (CD40L, CD154) on T cells, which causes co-stimulatory B cell activation and ongoing antibody production. Viral antigen–antibody reactions may be demonstrated in acute forms of the disease, usually in children following an acute viral illness such as rubella, varicella, parvovirus B19, Epstein–Barr virus, echoviruses and others. Vaccines to prevent viral illness have also been implicated, including recently the combined measles, mumps and rubella (MMR) vaccine. Chronic infections that can provoke chronic (mainly adult) ITP include HIV, hepatitis C virus and possibly *Helicobacter pylori* [1,13].

Some cases are drug-induced (see later) or are associated with systemic lupus erythematosus (SLE) and other autoimmune connective tissue diseases, with agammaglobulinaemia, or with lymphoproliferative disease (e.g. chronic lymphocytic leukaemia, lymphomas) or with myelodysplasia. ITP may also coexist with other haematological abnormalities, for example the combination of ATP and neutrophilia, which presents as mucosal bleeding with infections; the platelet deficiency tends to be chronic. Of greater dermatological importance is Evans' syndrome, which comprises Coombs-positive haemolytic anaemia with ITP; this is also associated with collagen vascular disorders, usually SLE or scleroderma but occasionally dermatomyositis [14,15].

From the haematology perspective, the platelet count falls below 50×10^9/L and may even be zero. Usually the only symptom is a tendency to bleed from gingivae after brushing teeth, or into the skin to produce crops of petechiae or larger haemorrhages (Fig. 49.2). Bleeding may occur in any organ but joint involvement is unusual. The spleen may be slightly enlarged but gross splenomegaly should suggest an alternative diagnosis. Intracranial haemorrhage occurs in about 0.2% of children and is often fatal, but is very unlikely unless the platelet count is less than 10×10^9/L.

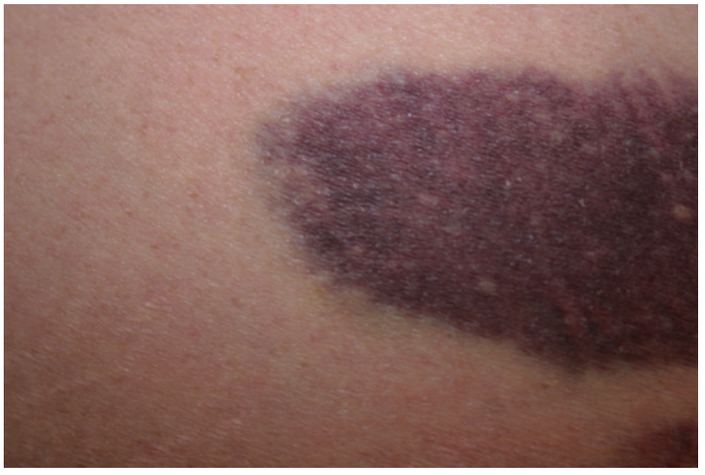

Fig. 49.2 Spontaneous bruising in drug-induced idiopathic thrombocytopenic purpura.

Lupus erythematosus develops in a small proportion of cases [16], although there are differences in immunopathogenesis between the thrombocytopenia of SLE and that of ITP [17]. About 20% of adult patients with immune thrombocytopenia have associated features of the primary antiphospholipid antibody syndrome (APLS), with a prolonged activated partial thromboplastin time (aPTT), lupus anticoagulant and anticardiolipin antibodies. The immune thrombocytopenia associated with APLS is rarely severe [18].

The diagnosis is established by the clinical picture, low platelet count, exclusion of other causes of thrombocytopenia and the mainly negative bone marrow findings (megakaryocytes are present in normal or increased numbers in the bone marrow, but bone marrow examination is not routinely performed, especially in younger subjects without other abnormal findings); ITP has historically been largely a diagnosis of exclusion. Various methods of demonstrating platelet antibodies have been used, but are largely of little help; they are sensitive but non-specific as they detect non-pathological antibodies. Antibodies bound to platelet glycoproteins have been felt to be pathological and more suitable for assay [19], with a positive predictive value of about 80% [4]. Their lack of specificity, and the variability of commercial assays, means that they are of limited value [1,8], although patients with antiplatelet glycoprotein antibodies tend to need more intensive therapy [8]. Elevated levels of caeruloplasmin may help to identify chronic ITP compared with other causes of thrombocytopenia [20]. New biomarkers of the autoimmune reaction (leptin, cell-bound antiplatelet antibodies, specific B cells) and of thrombopoiesis (thrombopoietin, glycocalicin, reticulated platelets) may advance diagnosis in the future [21]. The differential diagnosis is

wide but especially includes SLE, drug-induced purpura, disseminated intravascular coagulation (DIC) and renal failure.

Spontaneous remission often occurs in acute attacks (most children have spontaneous improvement within a month or two, and the disorder resolves in about two-thirds within 2–4 months [9]), but spontaneous remission is rare in chronic cases of more than 3 months' duration, where a continuous or fluctuating course may occur. A variety of treatments have been used [1,3–6,8,9,22–25], the aim being prevention of serious bleeding rather than normalization of the platelet count. In children, observation alone is often satisfactory unless there is bleeding, but in adults severe thrombocytopenia is an indication for treatment even in the absence of serious bleeding. A platelet count of below 30×10^9/L is usually the threshold for intervention. Corticosteroid therapy (prednisolone 1 mg/kg/day) is most commonly used but other regimens, such as a 4-day course of high-dose dexamethasone, may achieve better remission rates; about 50% of adults treated with corticosteroids achieve complete remission but platelet counts often fall as the treatment is tapered. Splenectomy is beneficial in at least two-thirds of chronic cases and in acute cases in which a spontaneous or steroid-induced remission cannot be achieved, but carries some risk. After splenectomy the platelet count tends to remain low but the purpura tends to cease. Immunosuppressive therapy or other treatments are indicated in cases that fail to respond to splenectomy and steroids, or where splenectomy is contraindicated; treatments that have been used in patients with refractory ITP include danazol, azathioprine, vincristine, interferon-α, ciclosporin, mycophenolate mofetil, Fc receptor blockade using intravenous immunoglobulin (IVIG) or intravenous anti-D antiserum (antiD), plasma exchange, various monoclonal antibodies and biological agents such as rituximab (anti-CD20), Campath-1-H (anti-CD52), second generation thrombopoietic agents [24,26,27], pegylated recombinant megakaryocyte-derived growth factor [8], and, rarely, autologous stem cell transplantation. AntiD only works in patients who are Rhesus D-positive and who have a spleen, but in such individuals there is typically a very rapid improvement in platelet count; IVIG is useful in achieving rapid responses, although its mechanism involves upregulation of FcRIIb rather than the competitive binding to FcRIII that occurs with antiD [1], and it also appears to be active in ITP caused by viruses such as parvovirus B19 and Epstein–Barr virus. In view of the possible link between *H. pylori* and ITP (especially in adults), appropriate testing and eradication, if indicated, would appear appropriate before using more toxic therapies. Similarly, hepatitis C infection should be treated if present. Beyond the standards of steroids and splenectomy, for rapid response, IVIG may be the best current agent, for remission rituximab (33% durable remission) and for the future non-thrombopoietin-like thrombopoietic agents and anti-CD154 antibodies.

Various measures have been used to predict and monitor outcome and treatment response in ITP, in addition to the platelet count [4,28–30]. Other than young age, which is associated with a shorter disease course (but which does not predict response to corticosteroids if used), the most useful clinical aspect is that splenectomy is most successful in those who responded initially to steroids, and who get a rapid improvement in platelet count after splenectomy. HLA-DRB1*14 and DRB1*0410 are associated with good prognosis and good response to common interventions, and HLA-DRB1*13 and DR4 with poor prognosis or therapeutic resistance. Serum IL-2 is a good prognostic marker in ITP, relapse is lower in children treated with corticosteroids, and platelet-associated IgGs are a useful monitoring parameter.

Secondary or symptomatic thrombocytopenia

Drugs and toxins [1]

Drug- or toxin-induced purpura may occur as a result of thrombocytopenia, altered platelet function or vascular damage. Each of these may be caused by many different mechanisms. The last two are considered later. The main causes of drug- or toxin-induced thrombocytopenia are:

- Direct bone marrow toxicity, e.g. benzol, nitrogen mustard, or general myelotoxicity (e.g. chemotherapeutic agents)
- Immunological bone marrow damage, e.g. chloramphenicol
- Destruction of formed platelets, via either immunological (e.g. apronalide (Sedormid), quinidine, quinine, sulphonamides) or non-immunological mechanisms (e.g. bleomycin).

The immunological mechanisms have been divided into [1]:

- Hapten-induced antibody (e.g. penicillins)
- Drug-dependent (compound or conformational) antibody (e.g. quinine, quinidine, NSAIDs, anticonvulsants, antibiotics and many others)
- Inhibitors of the platelet glycoprotein GIIb/IIIa—further divided into four known or probable mechanisms (ligand mimetic, drug-specific antibody, drug-induced antibody and immune complex-mediated).

Some of these are of interest as they relate to new types of drug, for example the chimeric Fab fragment of abciximab induces antibody specific for murine sequences that control GIIb/IIIa (with onset sometimes within hours of exposure). However, the most important mechanism, in that it is pertinent to most drug-induced thrombocytopenia, is that where a drug-specific antibody is created by the drug (or metabolite) binding to a platelet glycoprotein to create either an antibody-inducing drug–glycoprotein epitope or a conformational change elsewhere in the target glycoprotein for which the antibody is specific. The mechanisms for many drugs, and certainly the binding sites, are often uncertain; some drugs may cause thrombocytopenia by more than one mechanism (e.g. thiazides may cause selective inhibition of megakaryocyte production as well as immunological peripheral destruction).

It has been suggested that at least 200 drugs cause thrombocytopenia. The most common are cytotoxic/chemotherapeutic drugs, quinine, quinidine, gold salts, heparin, sulphonamides, penicillins, thiazides and furosemide (frusemide), procainamide, indometacin (indomethacin) and other NSAIDs, thiouracils and carbimazole, bismuth, arsenicals, rifampicin and isoniazid, acetazolamide, acetylsalicylic acid, imipramine, interferon, various sedatives, and anticonvulsants such as phenytoin, carbamazepine and sodium valproate [2–4]. Recently implicated drugs include tirofiban, roxifiban, eptifibatide and abciximab. Various biological agents used in dermatology, such as efalizumab [5], have also been implicated as a cause of drug-induced thrombocytopenia.

Onset of thrombocytopenia is usually after a week with first exposure but can be within 2–3 days on re-exposure [1]; improvement is usually within 10 days of stopping the culprit drug. However, the duration of thrombocytopenia after stopping the drug is too long to be explained on the basis of either drug clearance or platelet lifespan in some cases, particularly with quinidine or quinine, suggesting that true autoantibodies may be produced [6]. The severity of thrombocytopenia does not necessarily correlate with the implicated drug, mechanism, or specific glycoprotein to which the drug may bind.

Heparin-induced thrombocytopenia (HIT) [7–13] is discussed in more detail later. It may present as isolated thrombocytopenia (which may be severe but can be of modest severity compared with other drug-induced causes), but may also cause platelet-rich clot formation leading to venous thrombosis, limb ischaemia, injection site necrosis, adrenal crisis due to adrenal vein necrosis, and severe systemic post-bolus injection reactions. The risks are greater in females, in surgical settings and with unfractionated heparins; it occurs in about 2% of subjects exposed to heparin, but in up to 40% after cardiac surgery. It is important as it can be confused with post-transfusion purpura in early stages, but the greatest importance (which also helps to distinguish it from other drug-induced thrombocytopenias) is the association with arterial or venous thrombosis (heparin-associated thrombocytopenia and thrombosis syndrome), which occurs in about a third of patients with HIT, and with heparin-induced skin necrosis, as discussed later. A crucial issue in such instances is to avoid coumarins, which will not work (they may in fact worsen thrombosis by depleting protein C, and coumarin-induced thrombosis is about 100-fold more likely if HIT is present than if it is not). Treatment is therefore with agents that directly inhibit thrombin or its generation [11]. It is due to formation of antibodies against an immunogenic complex involving heparin and platelet factor 4 (PF4), the antibody reaction causing platelet aggregation; there are also high levels of thrombin–antithrombin complexes.

Other toxic causes of thrombocytopenia include alcohol, snake venoms and, rarely, foods and food additives.

Infections

Thrombocytopenia may occur with a wide variety of infections, often with associated capillary damage. Infections that may be associated with thrombocytopenia include septicaemia of many aetiologies, typhoid, typhus, tuberculosis, smallpox, chickenpox, vaccinia, scarlet fever, influenza, measles, rubella, cat-scratch disease, infective hepatitis, subacute bacterial endocarditis, glandular fever, malaria, dengue fever, human immunodeficiency virus (HIV), hepatitis C and other virus infections.

Bone marrow diseases

Bone marrow diseases, for example leukaemia or aplastic anaemia, are the commonest causes of thrombocytopenia (see Table 49.3). In addition to the abnormal platelet production, there may be platelet antibodies formed in patients with lymphoma or leukaemia. Splenomegaly of many different aetiologies causes

sequestration of platelets in the splenic sinuses but rarely produces a platelet count low enough to cause purpura. Purpura and ecchymosis are among the commoner cutaneous features of the haemophagocytic syndrome.

Pregnancy

Numerous reasons may explain thrombocytopenia in pregnancy [13]. The commonest cause is termed gestational or incidental thrombocytopenia, and accounts for three-quarters of cases, but does not cause platelet counts low enough to cause purpura. Thus, if purpura is present, other more significant disorders should be considered. ITP accounts for 5% of cases, occurring in 0.1% of pregnancies, and thrombotic thrombocytopenic purpura, drug-induced and infection-induced thrombocytopenia may all occur. The last-mentioned is of dermatological importance, as the likely infections include HIV and cytomegalovirus, both of which may cause congenital infection in the neonate. Pregnancy-specific thrombocytopenias include those due to pre-eclampsia, HELLP (haemolysis, elevated liver function tests, low platelets; discussed on p. 49.31) or fatty liver. There are also potential systemic disease associations, including SLE, antiphospholipid syndrome and disseminated intravascular coagulation, as well as various conditions of bone marrow failure and nutritional deficiencies.

Platelet consumption and the thrombotic microangiopathies (thrombotic thrombocytopenic purpura and haemolytic–uraemic syndrome)

Thrombocytopenia may be associated with haemangiomas (Kasabach–Merritt syndrome, see Chapter 18). This is caused by ongoing chronic consumption and there is often compensated subacute or chronic DIC. Relevant haemangiomas are usually large and have undergone an increase in size and become tender when the thrombocytopenia develops, but a low-grade version can occur in hereditary haemorrhagic telangiectasia.

Thrombotic thrombocytopenic purpura (TTP, Moschowitz's syndrome) [13–20] in adults and haemolytic–uraemic syndrome (HUS) in children are rare forms of thrombotic microangiopathy in which thrombocytopenic purpura and bleeding are associated with fever, haemolytic anaemia and renal and neurological symptoms. HUS has recently been shown to involve a severe prothrombotic coagulation disturbance before onset of clinical features; the main clinically apparent feature is bloody diarrhoea due to Shiga toxin from *Escherichia coli* (mainly serotype 0157:H7). TTP is multifactorial, and may occur due to neoplasia, drugs, infections or organ transplantation, but many cases are due to an acquired autoimmune deficiency of ADAMTS13 (a metalloprotease). Platelets adhere to 'ultra-large' von Willebrand factor (ULVWF) multimers that are secreted from endothelial cells, and are normally cleaved by ADAMTS13; failure of this control mechanism leads to platelet-rich thrombotic microvascular plugging. Schistocytes (fragmented erythrocytes) are seen on blood films. Microvascular injury and intraluminal platelet thrombosis, and platelet plugging in myeloproliferative disorders, are discussed in more detail on p. 49.27.

Abnormalities of platelet function

Several haemorrhagic syndromes have become recognized in which platelet function is abnormal although the total count may be normal [1–5] (Table 49.3). Such changes may be inherited, idiopathic or secondary to drugs or many other illnesses. These syndromes include thrombopathia, thrombasthenia, von Willebrand's disease, severe anaemia, chronic renal failure and fibrinogen defects. Hermansky–Pudlak syndrome consists of a bleeding disorder due to storage pool disorder, with oculocutaneous albinism and pigment-containing cells in the bone marrow (see Chapter 58). Laboratory testing of platelet function is of limited direct relevance to dermatologists but is reviewed in [6].

Drugs that may cause abnormal platelet function with clinical bleeding include aspirin, NSAIDs, some penicillin and β-lactam antibiotics (especially high-dose penicillin), alteplase and other antifibrinolytic drugs, prostacyclin, thienopyridines (ticlopidine and clopidogrel), glycoprotein IIb/IIIa antagonists (see below), cardiovascular drugs (nitrates, calcium channel blockers and quinidine), antidepressants and phenothiazines, and some chemotherapeutic agents such as mitomycin and daunorubicin [3–5]. Volume expanders such as dextran or hydroxyethylstarch, and radiocontrast media, are often forgotten as a cause of platelet dysfunction but can be particularly important in intensive care

Fig. 49.3 Purpura due to a calcium channel antagonist, an effect probably caused by platelet dysfunction.

situations, as can fibrinolytic agents such as streptokinase, and agents that increase platelet cAMP levels such as iloprost or prostacyclin. Natural and herbal remedy agents that can cause platelet dysfunction include fish oil, garlic, cumin, turmeric, *Gingko biloba* and black tree fungus [5]. In some instances, the mechanisms are well-understood but in others they are obscure. Aspirin causes irreversible acetylation of platelet cyclo-oxygenase-1 (COX-1), thereby inhibiting thromboxane A_2 (TXA_2) synthesis. NSAIDs also inhibit COX-1 but reversibly, such that platelet function recovers quickly once the agents are stopped [2]. COX-II inhibitors have no direct effect on platelets, which do not express COX-II; they may in fact increase thrombosis by an indirect effect as they block prostacyclin production, and prostacyclin has an inhibitory effect on platelet function. Clopidogrel (like ticlopidine) irreversibly binds to platelet purinergic receptor $P2Y_{12}$, blocking response to intrinsic platelet-generated and extrinsic ADP, with a biological half-life of about 3 days. Antagonists of the platelet glycoprotein IIb/IIIa (integrin αIIβ3), such as abciximab, tirofiban and eptifibatide, are strong inhibitors of platelet function, used in coronary artery surgery. Purpura, as provoked by Hess testing, sometimes with clinical bleeding but with normal platelet numbers, appears to be a class effect of calcium channel blockers [7] (Fig. 49.3); although the vasodilating action of such drugs cannot be excluded as a contributory cause, a platelet function abnormality seems most likely. Many other drugs may cause abnormal platelet aggregation *in vitro*, sometimes with abnormal bleeding time, but not necessarily with clinical bleeding [3–5].

Drug-induced platelet function abnormalities are of potential relevance to dermatologists because of issues regarding bleeding during skin surgery. Aspirin, NSAIDs, clopidogrel and calcium channel blockers have all been implicated in bleeding related to skin (and other) surgery, and whether to transiently discontinue such medications needs to be considered, as well as considering anticoagulant monitoring results, as part of the pre-operative management [7–11]. A questionnaire study suggested that stopping warfarin or aspirin before dermatological surgery might cause a thrombotic risk (1/6219 operations for warfarin and 1/21 448 operations for aspirin), but only a third of surveyed surgeons responded, there was no control population considered and no contemporaneous estimate of recalled significant bleeding [12]. Recent studies still conflict to some extent; some feel that the risks of operative bleeding due to aspirin [13], warfarin (with an international normalized ratio (INR) below 3.5) [14], or either drug [15], does not warrant stopping these treatments provided that careful attention is paid to haemostasis. However, there is some evidence that being on two or more different antithrombotic agents does increase the risk of bleeding after skin surgery [16], warfarin has been shown to increase risk of surgical bleeding in dermatology, an INR in the normal range being a poor predictor of this complication [17], and the combination of diltiazem and aspirin in normal subjects has a partially additive effect on platelet function (causing a bleeding time of over 15 min in two of five patients in one study [18]). These medications should probably be continued, but the risk of postoperative bleeding needs to be explained, particularly for difficult closures and body sites where application of pressure is awkward; the need for antithrombotic therapy (especially multiple therapies) and the risk to the patient of stopping treatment may need to be considered, and careful perioperative haemostasis should be performed.

Causes of abnormal platelet function may overlap with causes of thrombocytopenia. For example, both may occur in chronic renal failure (in which the abnormality of function is most important) or in myeloproliferative disorders (in which thrombocytopenia is usually paramount). Patients with Waldenström's macroglobulinaemia often have abnormal platelet function, less commonly those with IgA myeloma or benign monoclonal gammopathy, but bleeding in these conditions is usually due to hyperviscosity rather than to the platelet function defect. The platelet function defect is usually due to non-specific binding of immunoglobulin to platelets, but in some of these disorders other mechanisms may also be pertinent, including thrombocytopenia, inhibition or increased clearance of clotting factors and the hyperviscosity component.

Skin diseases in themselves may also alter platelet function in diverse ways, for example in eczemas, urticaria and psoriasis, potentially influencing expression of immune system inflammatory mediators [19].

Thrombocytosis

Abnormally high platelet counts may occur as a result of essential thrombocythaemia or other myeloproliferative disorders, or secondary to a variety of other disease processes (see Table 49.3). This may lead to a tendency to platelet plugging and thrombosis or, paradoxically, to a bleeding tendency (particularly when the platelet count exceeds 1000×10^9/L with a clonal platelet defect such as an acquired form of storage pool disease). Many cases of thrombocytosis do not achieve this high platelet count and are unlikely to cause purpura unless there are additional reasons related to the causative disorder (such as lymphoma or other malignant disease).

Dermatological manifestations and associations of thrombocythaemia include purpura with or without necrosis, livedo reticularis, acrocyanosis, purple (blue) toe syndrome, Raynaud's phenomenon, erythromelalgia, other vascular symptoms including gangrene, and associated disorders such as pyoderma gangrenosum [1–9]. The last-mentioned is relatively uncommon in pure thrombocythaemia [7] (the patient described in [7] subsequently developed further myeloproliferative features; cited in [8]). In one large study, 22% of patients with essential thrombocythaemia had skin lesions; 41% of these had haematomas, ecchymosis, petechiae or purpura, and 26% had erythromelalgia [9]. Many of these presentations are also seen in other hyperviscosity and dysproteinaemic conditions.

Platelet hyper-reactivity is not usually a dermatological consideration, but it is a factor in peripheral arterial disease and thrombotic emboli [10]. It is more common in females, linked with higher mean platelet volume and higher fibrinogen levels, and is partly genetically determined (especially associated with integrin α2 and β3 mutations that lead to high platelet glycoprotein IIb/IIIa levels).

Non-thrombocytopenic vascular causes of purpura and syndromes of primarily ecchymotic haemorrhage

A number of disorders cause purpura or ecchymosis due to vascular fragility/poor dermal support, intravascular pressure increase, platelet dysfunction (see also earlier), thrombocytosis (above) or coagulation cascade defects (Table 49.4). Minor trauma is often the precipitant of lesions. Disorders in which inflammation around vessels leads to purpura are discussed separately; these include the pigmented purpuric dermatoses and several conditions in which there is non-specific inflammation.

Purpura due to raised intravascular pressure

Raised intravascular pressure may cause purpura in the absence of any other disease. Crops of petechiae after prolonged coughing or vomiting occur, especially on the relatively loose tissues of the face and neck (see Fig. 49.1). They are of no significance other than causing concern if their cause is not appreciated.

Gravity and venous stasis are the most important causes of this type of purpura. Many purpuric eruptions are maximal on, or even restricted to, the lower leg. Likewise, many erythematous eruptions on the lower legs, especially in the elderly or those with leg oedema, show some degree of purpura that can usually be ignored. Bizarre patterns of purpura should always suggest the possibility of artefact.

Deaths from asphyxia are said to be associated with facial and conjunctival petechiae but the mechanism is probably due to vascular occlusion causing raised intravascular pressure rather than to hypoxia *per se* [1].

Purpura due to abnormal blood vessels or decreased support of blood vessels

Several disorders are associated with abnormal collagen, elastic or other structural proteins, leading to abnormal vessels or poor dermal support or both (Table 49.4). Conditions such as Ehlers–Danlos syndrome (collagen), pseudoxanthoma elasticum (elastic)

Table 49.4 Some dermatologically-relevant non-thrombocytopenic causes of purpura, easy bruising or cutaneous bleeding.

Type of disorder	Examples
Inherited defects affecting structural components of the dermis and/or vascular wall	Ehlers–Danlos syndrome*
	Marfan syndrome*
	Osteogenesis imperfecta
	Pseudoxanthoma elasticum
Acquired defects affecting structural components of the dermis and/or vascular wall	Deposition disorders, e.g. amyloidosis†
	Solar damage (solar/actinic purpura)
	Scurvy
Haemangiomatous disorders	Cavernous haemangioma†
	Hereditary haemorrhagic telangiectasia*†
Clotting factor and related inherited or acquired deficiencies	Haemophilias
	Von Willebrand disease
	Vitamin K deficiency
	Other nutritional deficiencies (often mixed)
Non-thrombocytopenic platelet abnormalities	See Table 49.3
Biochemical (congenital or acquired)	Homocystinuria
	Hyperhomocystinaemia*†
	Diabetes mellitus
	Cushing's syndrome
Collagen vascular disorders	Systemic sclerosis
	Dermatomyositis
Paraproteinaemias and hyperviscosity	Waldenström's macroglobulinaemia*
	Other paraproteinaemias*
Intra- or perivascular inflammation	Capillaropathies (see p. 49.22)
	Vasculitides (Chapter 50)
	Behçet's disease (Chapter 50)
	Many inflammatory dermatoses
Microvascular occlusion	See p. 49.26
Infection	See p. 49.20
Increased pressure within vessels	Valsalva manoeuvre
	Cough purpura
	Distal to a sphygmomanometer cuff
Physical	Simple trauma
	Venous rupture (Achenbach's syndrome)
	Artefactual
	Chemical and mechanical contact irritants (p. 49.21)
Drugs	Drugs altering vascular permeability or causing direct endothelial damage (p. 49.21)
	Antiangiogenic drugs
Others	Malignant hypertension
	Autoerythrocyte sensitization

* May also have platelet dysfunction.
† May also have clotting factor abnormalities.

and amyloidosis (abnormal protein) are discussed in more detail elsewhere. Facial or periorbital purpura ('panda sign') occurs in 15% of patients with primary amyloidosis [2]. In osteogenesis imperfecta, bruising tends to occur rather than purpura; both occur in Ehlers–Danlos and Marfan syndromes and in osteogenesis imperfecta [3] (as well as frank bleeding in Ehlers–Danlos syndrome and osteogenesis imperfecta). In hereditary haemorrhagic telangiectasia (Chapter 47) there may be bleeding from telangiectasias; the structural vascular defects may be accompanied by platelet and other haemostatic defects. Paraproteins act in various ways, causing coating of endothelial cells, occlusion of vasa vasora, and also causing platelet dysfunction as discussed earlier. In Cushing's syndrome, loss of dermal mucopolysaccharides that normally support the vessels, and of elastic tissue from the dermis and from vessels, may be the explanation for purpura; deposition of fibrin leading to thrombosis and 'downstream' capillary stasis is thought to explain purpura in malignant hypertension, diabetes mellitus and chronological ageing.

Scurvy is discussed in more detail in Chapter 59. Altered collagenous support for the blood vessels is manifest by either petechiae, especially on the legs, or by small or large bruises on the limbs following mild or inapparent trauma. Large deep bruises may lead to woody induration, usually of the legs. Perifollicular purpura is typical but is not diagnostic and is frequently absent. Diagnosis is established by the associated symptoms and signs (twisted 'corkscrew' hairs, gingival bleeding), dietary history, laboratory tests and therapeutic response.

Actinic purpura (*Bateman's purpura, 'senile' purpura*) and *corticosteroid purpura* [4,5] are the commonest patterns of purpura due to lack of support of the blood vessels. They occur most commonly in skin altered by both age and solar radiation, but may occur in premature ageing syndromes. Corticosteroid purpura has the same pattern whether due to topical, oral, endogenous (Cushing's syndrome) or even inhaled [6] corticosteroids. The precipitating factor is a shearing stress. Patients who develop this type of purpura with ageing, in association with rheumatoid arthritis or with corticosteroids, are more liable to develop osteoporosis of the spine than patients without this sign [7]. The purpura occurs mainly in atrophic skin on exposed parts of the hands and forearms, or on the legs. Lesions appear after minor trauma or apparently spontaneously. They are usually asymptomatic and vary in size from a few millimetres to several centimetres across. They are often arranged linearly, and may show a linear or geometric shape. The appearance of the lesions is characteristic, with irregular areas, usually not palpable, that show little inflammatory reaction and which are usually dark purple rather than having the sequential colour changes of a normal bruise. They may persist for several weeks. Treatment is usually not necessary or possible.

Easy bruising syndrome and purpura simplex

The term 'easy bruising syndrome' has been used in various ways, usually for a mild purpura for which no cause has been detected,

especially on the thighs of women ('devil's pinches'). It has been used to include those cases of a mild bleeding tendency in which changes in the morphology of capillaries may be seen by capillary microscopy, and in some of which variable but slight changes in coagulation factors have also been found. There are significant limitations in deciding what constitutes 'abnormal' or excessive bleeding [1]. The term 'purpura simplex' has also been used for any inflammatory purpura without vasculitis, including disorders with the morphology of the pigmented purpuric dermatoses [2,3], and this term is therefore also of uncertain value. Autosomal dominant inheritance of purpura simplex has been reported [4] and presumably represents a subtle haemostatic defect; in one family, purpura simplex was coinherited with ptosis [5].

Physical and artefactual causes of purpura

Bruising due to trauma seldom causes diagnostic problems, as there is usually a clear history, except when it occurs as an artefact or in child abuse. Bizarre patterns of purpura may be caused by suction, for example vacuum extractors in the neonate, electrocardiogram leads or around the mouth after sucking out the air from a glass [1]. Cultural remedies such as cupping, coin rubbing (Cao Gio) and spooning (Quat sha) may also produce unusual patterns of purpura that are usually obviously extrinsic in causation [2]. Black heel (talon noire) is a form of purpura due to frictional shearing of vessels, and is considered in Chapter 28.

Paroxysmal finger haematoma [3–5]

Synonym
- Achenbach's syndrome

In this syndrome there are recurrent episodes of painful bruising on the palms and palmar aspects of the fingers (Fig. 49.4). It seems likely that it represents venous rupture, as frictional trauma may be reported, such as turning on a tap or twisting the top off a jar. It is probably more common than the number of reported cases would suggest. Its importance is that it may be confused with Raynaud's phenomenon or acute connective tissue diseases and investigated unnecessarily.

Autoerythrocyte sensitization syndrome [6–9]

Synonyms
- Painful bruising syndrome
- Gardner–Diamond syndrome

Fig. 49.4 Achenbach's syndrome; acute bruising of the entire finger, presumably due to venous rupture after minor trauma.

This is a distinctive but rare clinical entity apparently due, in many cases, to allergic sensitivity to red cells in the tissues. Minor extravasations of blood, for example those so common on the thighs of women, are followed by an intense inflammatory reaction. The disease occurs most frequently in young adult and middle-aged females, who are nearly always psychiatrically abnormal. They present with recurrent, painful erythematous and purpuric lesions on the thighs and elsewhere. The diagnosis may be confirmed by intradermal injections of red cells or their washed stroma, or of phosphatidylcholine. This reaction occurs even in some subjects in whom a psychological cause is suspected and whose disease responds to psychological intervention [10,11].

Sensitivity to DNA [12,13] or to exogenous antigens attached to red cells [14] may present a similar picture. The condition is usually chronic, seldom disabling or associated with other abnormalities and is unresponsive to treatment. Plasmapheresis has been used successfully in isolated cases [15] and antimalarials are said to be effective in DNA sensitivity [16]. Dermatitis artefacta may produce a similar clinical picture, and is believed by some to account for all such cases [8,11,17].

Stigmata

In this very rare disorder there is exudation of apparently fresh blood through the unbroken skin of the hands, feet and side. The mechanism is obscure but, as with the previous syndrome, many if not all cases may have a traumatic origin [8,18].

Purpura in other dermatoses

Many eruptions on the lower leg, especially in the elderly, tend to become purpuric due to a combination of gravitational changes with vascular damage caused by the dermatosis. Rapid development of lower leg oedema may cause an eczematous eruption in which purpura may be prominent [1].

Even without the gravitational component, many dermatoses may be sufficiently intense to cause purpura. Sometimes this is physically due to scratching, but some disorders such as lichen planus, lichen nitidus and Langerhans' cell histiocytosis are not infrequently purpuric. Purpuric erythema annulare centrifugum, dermatitis herpetiformis, pemphigoid, pityriasis rosea and eczemas (especially of discoid type) may all occur. Purpura may be present in lymphomas and lupus erythematosus, either because of platelet deficiency or, more commonly, because of vascular abnormalities.

Lichen sclerosus often has a haemorrhagic component due to loss of collagenous support for the vessels.

Some insect bite reactions have a purpuric centre due to inoculation of the skin with anticoagulant chemicals in the bite (purpura pulicosa, maculae ceruleae).

Purpura may also occur around localized lesions with a strong vascular component if there are fragile vessels, for example targetoid haemosiderotic haemangioma or aneurysmal fibrous histiocytoma.

A rather characteristic disorder of children under the age of 1 year has been termed the *persistent acrovasculopathy syndrome*. Lesions occur on the ears, cheeks and extremities and are scaly and erosive; they may be purpuric, and there may be local lipoatrophy and distal phalangeal osteopenia.

Most of these conditions are discussed in more detail in other chapters; two disorders are specifically described here.

Solar purpura [2–5]

This condition is distinct from the actinic purpura discussed previously which is a manifestation of cumulative sunlight-induced ageing of the skin. The term 'solar purpura' is used to describe rapid development of purpuric lesions after exposure to sunlight. The precise nature of this disorder is uncertain. Some view it as a variant of polymorphic light eruption. It is distinct from erythropoietic protoporphyria, although purpura clearly occurs in this dermatosis in some patients (Fig. 49.5). Some cases may simply be a variation of purpura in dermatoses that are not usually purpuric, but where profound inflammation has allowed purpura to develop.

Fig. 49.5 Erythropoietic protoporphyria: marked purpura with sharp cut-off after sunlight exposure.

Acroangiodermatitis (of Mali) [6–8]

Synonyms
- Dermite ocre of Favre
- Gravitational purpura
- Pseudo-Kaposi's sarcoma

This chronic dermatosis is associated with venous insufficiency or with vascular anomalies such as Klippel–Trenaunay syndrome [9], and there are several reports of it occurring as a stump dermatosis in amputees [10]. It has been reported in a patient with a thrombophilic prothrombin mutation [11]. It may mimic a pigmented purpuric dermatosis (p. 49.22) but is discussed here as the purpura is due to abnormal vasculature rather than to capillaritis. It occurs more often in men than in women.

The lesions occur especially on the lower legs but may extend on to the dorsa of the feet and toes, and up the leg, especially over dilated varicosities. Individual lesions are minute purpuric macules that coalesce to form irregular plaques, which may be several centimetres in diameter. Follicular lesions may occur. The colour of the lesions is not usually the purple colour of fresh purpura but varying shades of yellow (ochre) and brown from haemosiderin and other breakdown products. The epidermis may be normal or show mild eczematous changes. Oedema, sclerosis, ulceration and other signs of venous insufficiency may be associated, but may be entirely absent even in cases of long duration.

Differential diagnosis includes ordinary gravitational dermatitis, Schamberg's disease and Kaposi's sarcoma; the last mentioned can be distinguished by the staining pattern with CD34 antigen, which stains perivascular spindle cells in Kaposi's sarcoma but only the endothelial cells in acroangiodermatitis [12]. Treatment is unsatisfactory but support hosiery seems logical.

Multifactorial purpura associated with systemic diseases

Non-thrombocytopenic purpura may be caused by a variety of systemic diseases. Many of these have already been discussed, but in some cases there may be mixed mechanisms of purpura or easy bruising. Of these, renal disease is perhaps the most important; petechiae, ecchymoses or mucosal bleeding are common in end-stage renal failure [1]. Platelet dysfunction is probably the major factor [2], but there may also be frank thrombocytopenia. Diabetes, severe anaemia, liver disease, haemochromatosis and carcinomatosis may also cause purpura.

In amyloidosis, with or without myelomatosis, purpura may be due to infiltration of the capillaries and perivascular tissue with amyloid, but platelet changes and liver disease may also contribute.

Purpura occurs in patients with malnutrition. It seems probable that changes in coagulation, platelets and capillaries all play their part. For example, in cystic fibrosis there may be dysproteinaemia, vasculitis and vitamin K deficiency.

Purpura has been associated with ovarian and other endocrine abnormalities [3], for example Cushing's disease, and may vary with the menstrual cycle.

Exercise-induced purpura/vasculitis

This is probably an underestimated condition, and histologically is a form of leukocytoclastic vasculitis [1,2]. It is therefore discussed in more detail in Chapter 50. The typical presentation is with purpuric lesions on the lower legs after prolonged walking (many descriptions are in golfers, marathon runners or long-distance walkers), usually in hot weather. Lesions may be urticarial. Patients are generally middle-aged, and otherwise well with no evidence of venous disease. Compression stockings may reduce its occurrence. It is discussed here as it can present as a pigmented purpuric dermatosis related to exercise [3], and has also been described in a child with recurrent purpura on the trunk after vigorous exercise [4].

Inflammatory haemorrhage: Henoch–Schönlein purpura and acute haemorrhagic oedema of childhood

Vessel damage with inflammation may lead to haemorrhage, typically manifest as palpable purpuric lesions. This is usually caused by one of the types of antigen–antibody reaction discussed in Chapter 13 but may be due to a direct toxic effect. The antigen in the allergic mechanism may be a component of the vessel itself or of surrounding tissues or, more commonly, an exogenous substance bound to the blood vessel or other tissues. Such substances include drugs, bacterial products and food additives; they may reach the blood vessel via the bloodstream or from the skin surface. The antigen–antibody reaction may occur on the surface of the endothelial cells or in adjacent tissues, or the vessels may be damaged by soluble complexes. The localization of many such lesions will be determined by local factors, for example changes due to gravity, cold and trauma. This inflammatory process is therefore a vasculitis, and is discussed in Chapter 50. Two conditions of this type are briefly discussed here, one because it carries the name purpura (Henoch–Schönlein purpura) and the other because it may present with striking haemorrhagic lesions (acute haemorrhagic oedema of childhood).

Henoch–Schönlein purpura (HSP, anaphylactoid purpura) is a vasculitic process due to IgA-immune complex deposition in the walls of arterioles and venules that gives rise to palpable inflammatory lesions; these are often purpuric as well as erythematous and may vary in size from 0.5 to 1 cm or more. However, minor lesions of HSP may sometimes be confused clinically with other types of purpura.

Acute haemorrhagic oedema of childhood is a small vessel cutaneous vasculitis; it has been proposed to be a variant of HSP, but IgA immune complexes often cannot be demonstrated. It has also been

described as cocarde purpura, Seidlmayer's syndrome and Finkelstein's disease. Most cases have been reported from continental Europe [1,2], but English [3] and American [4] cases are also reported. It may be overtly haemorrhagic, but can present as arciform or annular brown lesions that are of acute onset but which have some morphological similarity to pigmented purpuric dermatoses.

Fig. 49.6 Waldenström's hypergammaglobulinaemic purpura: lower leg lesions, in this patient usually provoked by prolonged standing or heat.

Dysproteinaemic purpura and Waldenström's hypergammaglobulinaemic purpura

Purpura may be the presenting and sometimes the only symptom of disturbances in plasma proteins. It may occur at exposed skin sites in cryoproteinaemia (see Chapter 28 and p. 49.32) and may occur due to monoclonal hypergammaglobulinaemia in myeloma. In such instances there may be platelet dysfunction, but clinical bleeding is usually related to the hyperviscosity syndrome rather than to the altered platelet function. Cutaneous features of paraproteinaemia include various patterns of vasculitis and neutrophilic dermatosis (see Chapter 50), cryoglobulinaemia (see below), urticaria and systemic capillary leak syndrome, abnormalities of lipid metabolism (notably diffuse plane xanthomatosis), subcorneal pustular dermatosis, lichen myxoedematosus and sclero-myxoedema, amyloidosis, and features due to hyperviscosity (purpura, mucous membrane bleeding, retinopathy and neurological disturbance) [1,2]. Haemorrhagic features are particularly seen in Waldenström's macroglobulinaemia.

Waldenström's hypergammaglobulinaemic purpura is generally taken to imply an idiopathic phenomenon but in fact two of Waldenström's three cases had sicca symptoms, one with sarcoidosis [3]. Hypergammaglobulinaemic purpura is usually a polyclonal disorder most commonly linked with sarcoidosis, lupus erythematosus, Sjögren's syndrome and other autoimmune conditions [4–10]. The majority of patients have positive antinuclear antibody and anti-SSA (Ro) or anti-SSB (La) antibodies [6–10]. Other features that have been associated include arthropathy (not uncommon), renal tubular acidosis, chest infections, lymphopenia and immune hypersensitivity pneumonitis. Most patients are female [11].

Clinically the pattern of purpura is often non-specific, usually consisting of crops of small erythematous macular or palpable purpuric spots on the lower leg (Fig. 49.6) [3–10], but unusual patterns with reticulate lesions may occur [12]. Prolonged walking, standing or sitting with the legs dependent, or other increase in venous pressure, may be an obvious provocative factor [9,10]. Itch or a burning sensation may occur. It is likely that this disorder is an immune complex vasculitis: immune complexes can be detected, histology may show vasculitic change, and direct immunofluorescence may show immunoglobulin in blood vessel walls [8,12,13]. Hyperviscosity leading to stasis and endothelial damage plays some part. There may be an abnormal ratio of IgG subclasses, with low IgG1/IgG2 ratio [14].

Lesions usually resolve in about a week but may become confluent and permanent. Treatment is often not required, although prednisolone, NSAIDs, hydroxychloroquine and etamsylate (ethamsylate) have been used.

A similar pattern has been reported in association with cystic fibrosis, due to either hypergammaglobulinaemia or cryoglobulinaemia [15,16]. It may appear suddenly, affects the lower legs mainly, and is exacerbated by prolonged standing or by tight garments or footwear. It is associated with severe lung disease and poor prognosis; a high antigenic load due to chronic lung infection may be the cause.

Purpura associated with infection

Purpuric skin lesions associated with infection [1] may be due to numerous mechanisms, more than one of which may be operative, including:

- Thrombocytopenia (discussed above)
- Localized or disseminated intravascular coagulation (discussed above)
- Direct vascular damage (invasion or occlusion by organisms)
- Vascular effects of toxins
- Immunological vascular damage (vasculitis, immune complex deposition)
- Emboli.

Purpura is a characteristic feature of certain bacterial infections, for example meningococcal or other septicaemias and bacterial endocarditis, and of many viral and rickettsial infections, for example typhus, Rocky Mountain spotted fever, dengue fever and the viral haemorrhagic fevers (see Chapters 30 and 33) [2–9]. Acral purpuric lesions are typical of Rocky Mountain spotted fever [3]; the histological features include a lymphohistiocytic capillaritis and venulitis with variable leukocytoclastic vasculitis, fibrin thrombi, capillary wall necrosis and immunofluorescent evidence of organisms within endothelial cells, suggesting that it is therefore a type of septic vasculitis. In typhus, however, acral sites are generally spared. Dengue fever has three subtypes, dengue fever, dengue haemorrhagic fever (DHF) and dengue septic shock (DSS); in DHF there may be petechiae of acral sites, face, soft palate and axillae, with larger purpuric lesions, epistaxis, gingival bleeding and more serious bleeding (gastrointestinal bleeding, menorrhagia) in some subjects, due to thrombocytopenia. Haemoconcentration is also a feature in DHS and DSS. In hantavirus infection, thrombocytopenia is a typical part of the hantavirus pulmonary syndrome (HPS); skin haemorrhages, gingival bleeding, epistaxis, haematuria and gastrointestinal bleeding are mainly due to thrombocytopenia, but coagulopathy can occur.

Skin lesions are the presenting feature in 70–90% of patients with meningococcaemia and are purpuric in 50%, often stellate in shape and tender. In some cases of meningococcal septicaemia, organisms can be seen on blood smears taken from scraped skin lesions [10]. There may be a leukocytoclastic vasculitis with thrombi and meningococci within endothelial cells or leukocytes, typically resulting in a clinical lesion of classical palpable purpura, ranging in size from 2 to 8 mm in diameter. Lesions may progress to purpura fulminans due to microvascular occlusion, with lesions typically enlarging and often developing stellate or retiform features with minimal to no erythema (discussed above). The mechanism of coagulopathy in severe meningococcal sepsis is probably multifactorial, sharing some features with other conditions of severe sepsis and potentially leading to large vessel thrombosis with digital or limb infarction. Levels of protein C, protein S and antithrombin antigen are reduced, thrombocytopenia and haemophagocytosis occur, and fibrinolysis is reduced. Critically, there is dysfunction of the protein C activation pathway such that the prothrombotic activity of thrombin escapes its usual regulation, and a procoagulant state results [11]; it is now routine for patients with severe sepsis, including that due to meningococcal disease, to be treated with activated protein C [12].

Various congenital infections may cause neonatal purpura (p. 49.49). Purpura may appear in the prodromal period of many infections, for example measles, in which case it is often a sign of a severe infection. When it occurs at the height of the infection it is of less serious importance. A large number of infections may cause purpuric lesions in children [13]. In neonates, congenital infections may cause 'blueberry muffin syndrome' with dermal erythropoiesis, originally described in congenital rubella with thrombocytopenia. There are several non-infectious causes, but the most important infections are those covered by the acronym TORCH (toxoplasmosis, other infections, rubella, cytomegalovirus and herpesviruses). The 'other infection' group that should be screened includes syphilis, coxsackieviruses (especially B2) and HIV [14].

The petechial gloves and socks syndrome, or papular–purpuric gloves and socks syndrome, is a distinctive syndrome that has been attributed to parvovirus B19 infection [15,16] or to other viruses such as measles, hepatitis B, coxsackievirus B6 and cytomegalovirus [13,17] (see also Chapter 33). Purpura may also occur in the laterothoracic eruption, which may have an infectious aetiology (often parvovirus B19), and a genital or 'bathing trunk' distribution of purpura has also been described due to parvovirus B19 [18].

Other infections may be associated with characteristic distributions of purpura, for example *Strongyloides* causes 'thumb-print' periumbilical purpuric lesions [19]. Based on six patients with cancer, immunosuppressed by disease or treatment, this feature was felt to be associated with septic shock and death [20].

Non-thrombocytopenic toxin- and drug-induced purpura [1–6]

Many agents may lead to purpura by causing thrombocytopenia (discussed above). There are also many substances capable of causing capillary damage with or without any change in platelets, either by direct toxicity or through an allergic reaction. The purpura varies in degree from a few petechiae to massive extravasation of blood. Sometimes there is obvious evidence of inflammatory lesions, as well as purpura, implying a frankly vasculitic process [7]. Exposure may be industrial, accidental or therapeutic. Some drugs may cause thrombocytopenia and either vascular purpura and/or frank vasculitis; the thrombocytopenia in such cases may be caused by a direct effect on platelets or by endothelial damage leading to platelet aggregation.

Substances capable of causing capillary damage include acetylsalicylic acid, allopurinol, *p*-aminosalicylic acid, arsenic, atropine, barbiturates, bismuth, carbimazole, carbromal, chloramphenicol, chlordiazepoxide, chlorothiazide, chlorpromazine, diethylstilbestrol, furosemide, gold, hair dye, indometacin, iodides, isoniazid, menthol, meprobamate, methyldopa, piperazine, quinidine, quinine, reserpine, snake venoms, sodium salicylate, sulphonamides, tartrazine and other food additives, thiouracil, tolbutamide and glyceryl trinitrate.

Carbromal is one of the few drugs that caused a rather distinctive pattern of purpura. The widespread areas of capillary leakage combined with erythema produced a picture which resembled itching purpura and Schamberg's disease. Drug-induced pigmented purpuric dermatoses are considered elsewhere.

Trimethoprim–sulfamethoxazole has been reported to cause an acral purpuric eruption, proven by rechallenge, that resembled the purpuric 'gloves and socks' syndrome more commonly caused by parvovirus B19 [8].

A diagnosis of toxin- and drug-induced purpura usually depends on circumstantial evidence. Unfortunately, laboratory tests are mainly unhelpful, although some drugs that cause purpuric reactions will produce a purpuric reaction when patch tested. Rechallenge may be dangerous; generally the diagnosis is made by careful history taking.

Drug-induced vasculitis or livedo are also discussed in Chapter 75; drugs that cause skin necrosis are considered later in the present chapter (see Table 49.9, p. 49.50).

Contact purpura [1]

Purpura may occur as an irritant reaction to mechanical friction from abrasive agents such as woollen clothing or fibreglass. Some topical medications may rarely cause purpura that appears to be of irritant or toxic causation, such as clioquinol (at flexural sites), benzoyl peroxide or EMLA local anaesthetic [2,3]. Textile and rubber chemicals [4–6] are particular causes of contact purpura that may have little or no eczematous component, although itch or lichenoid morphology may be prominent in some instances. Such reactions may be widespread, the distribution corresponding only approximately with the distribution of contact, and may therefore be confused with idiopathic pigmented purpuras.

Purpura around the acrosyringium may occur at patch-test sites to cobalt, and purpuric patch tests to apronalide and quinidine have been reported in subjects with a purpuric rash after systemic administration of these agents.

The main groups of chemicals that have been reported to cause contact purpura are:

- Dyes and textile agents: azo dyes, paraphenylenediamine, optical whiteners
- Rubber antioxidants: IPPD, isopropylaminodiphenylamine
- Resins: urea formaldehyde compounds, epoxy resin
- Plants: *Rhus*, *Agave*
- Others: topical medicaments, balsam of Peru, mercury.

Pigmented purpuric dermatoses

Synonyms
- Capillaritis
- Purpura progressiva pigmentosa

Capillaritis is the generic term for a variety of chronic conditions that share certain histological features. The term 'purpura simplex' has also been applied to this group of disorders, on the basis of the common histological aspects. However, the same term has been applied to other mild and unexplained but morphologically different patterns of purpura such as easy bruising, and it is therefore potentially confusing. The term 'pigmented purpuric dermatoses' may be preferred, at least at present, as it conveys the message of a component beyond simple transient purpura.

The sometimes striking morphological patterns of the pigmented purpuric dermatoses have given rise to a wide range of descriptive and eponymous names [1–8]. Typical examples of the various eponymous diseases are sufficiently distinctive to warrant separate description but in many cases the clinical features may not be characteristic of any one of the eponymous variants. As their aetiology is unknown, and no clear distinction has been established between the different patterns other than on clinical morphological grounds, classification remains clinical. Identification of pigmented purpuric dermatoses secondary to a systemic cause is potentially important and is discussed below. Gravity and increased venous pressure are important localizing factors in many cases. Exercise may be a provoking factor. Most are chronic but two-thirds may improve or clear eventually [5]. Adults are mainly affected but there are several series of cases in childhood [9,10].

Most authors would accept five different morphological variants of idiopathic pigmented purpuric dermatosis, each of which will be discussed separately, namely:

1 Schamberg's disease (about half of cases)
2 Itching purpura (eczematid-like purpura of Doucas and Kapetanakis) (about 10%)
3 Pigmented purpuric lichenoid dermatosis of Gougerot and Blum (about 5%)
4 Lichen aureus (about 10%)
5 Purpura annularis telangiectodes (Majocchi's disease) (about 5%).

A further variant, termed Favre-Chaix's purpura, occurs on the lower leg and comprises purpura and pigmentation associated with oedema, cyanosis and sclerosis; it would appear to be simply a manifestation of venous disease and is not considered further here. However, additional types (such as granulomatous), or subtypes (e.g. segmental variants of the above list) also warrant mention as they may in time prove to be aetiologically distinct; furthermore, about 20% of cases are unclassifiable [5] and many drugs, systemic diseases or local conditions of the skin may lead to localized, mild purpura with haemosiderin deposition and secondary melanin pigmentation [11]. These are summarized briefly before considering the idiopathic variants, and will be discussed in differential diagnosis of the named disorders in this group.

Pathologically, these disorders are characterized by narrowing of the lumen and endothelial swelling of superficial small vessels, accompanied by perivascular T-lymphocytic infiltration, extravasation of erythrocytes and haemosiderin deposits in macrophages. An appearance termed 'ectasizing endocapillaritis' has been reported, in a study in which the authors divided 22 cases into those that were papular (with an upper dermal band-like infiltrate), macular (with a perivascular infiltrate) or eczematous (with exocytosis and spongiosis) [11], but this has not led to any fundamental advance in understanding these diseases. The cellular infiltrate in all types contains $CD4^+$ T cells in close contact with $CD1a^+$ Langerhans' cells [12,13], suggesting that a cell-mediated immune reaction is operative. Strong expression of endothelial cell adhesion receptors ICAM-1 and ELAM-1 may determine the pattern of the infiltrate [13]. Immune complex deposition has also been reported but direct immunofluorescence is often negative. An IgA-associated lymphocytic vasculopathy has been described in eight patients, in six of whom the clinical and histological features were those of a pigmented purpuric dermatosis [14]; the significance of this is unclear but it is notable that many of the subjects had a preceding or associated condition, including viral infection, Henoch–Schönlein purpura, undifferentiated connective tissue disease, lupus erythematosus profundus, Degos' disease and Buerger's disease.

Secondary pigmented purpuric dermatoses and systemic causes

Many underlying causes have been proven or suggested for the various patterns of pigmented purpuric dermatosis, although with limited specificity [1,2]. Most cases in which a cause is found either resemble Schamberg's disease or are unclassifiable (similar to 70% of idiopathic cases) and drugs have been documented as a cause in all of the main clinical patterns. The apparently idiopathic variants of pigmented purpuric dermatosis, while much the commonest cause, are therefore a diagnosis made by exclusion. The most important underlying conditions are listed below.

Drugs and food additives [1,3–6]. Drugs caused 14% of cases in one large series [1]. Drugs reported to cause capillaritis resembling a pigmented purpuric dermatosis include calcium channel antagonists [6], β-blockers, angiotensin-converting enzyme inhibitors, nitrites, furosemide and other diuretics, antihistamines, antidepressants, chlordiazepoxide, carbamazepine, analgesics such as paracetamol, non-steroidal anti-inflammatory agents, glipizide, bezafibrate, medroxyprogesterone acetate, raloxifene, pseudoephedrine, vitamin B_1 derivatives, interferon-α (in hepatitis C infection), antibiotics including ampicillin and cotrimoxazole, polyvinyl pyrrolidone and topical 5-fluorouracil [2–6]. Amongst food additives and related agents, tartrazine and creatine supplements have been implicated. Minocycline has been reported to selectively pigment areas of pre-existing capillaritis [7], and minocycline-induced ITP has mimicked Schamberg's disease, but it does not seem to be a specific cause of pigmented purpuric dermatoses.

External contact agents. Both contact irritants and allergens, especially clothing dyes, have been implicated as a cause of pigmented purpuric dermatoses [8–10]; these are discussed separately above (p. 49.21). Patch testing at the lesional site has been suggested.

Infections. β-haemolytic streptococci, toxoplasma and rickettsiae have been linked to development of pigmented purpuric dermatoses. More recently, a case has been made for hepatitis viruses being associated with pigmented purpuric dermatoses; in a series of 10 patients, five had hepatitis C antibodies and two had hepatitis B antibodies, although no random controls were tested [11]. One case was reported in association with cryoglobulinaemia, hepatitis C and rheumatoid arthritis (which itself has been linked with pigmented purpuric dermatoses, below) and one with interferon treatment for hepatitis C (above). In five patients, a chronic pigmented purpuric dermatosis (Schamberg pattern in four and itching purpura in one) resolved after treatment of dental infections, either periodontitis or pulpitis [12].

Neoplasia. There are many reported instances in which an apparent pigmented purpuric dermatosis has been a manifestation (sometimes the only manifestation) of mycosis fungoides [4,13–15]. In one instance, pigmented purpuric dermatosis preceded the diagnosis of mycosis fungoides by 24 years [16]. Some have linked this subtle presentation of mycosis fungoides predominantly with the lichenoid patterns of pigmented purpuric dermatosis [17,18], but many cases are of lichen aureus, Schamberg or non-specific capillaritis pattern. Monoclonality, demonstrated by T-cell receptor-gamma [17,18] or beta [19,20] gene rearrangement studies, has been demonstrated in some cases, occurring in almost half of cases in one series [19], although it may also occur in collagen vascular disease and drug reactions as well as representing cutaneous T-cell lymphoma, and some reported cases with clonality have had a benign behaviour [18]. In one series of 23 cases of lichen aureus, half had T-cell monoclonality but none showed progression to mycosis fungoides and over half had no evidence of skin disease after a mean follow-up of over 8 years [21]. Cases with monoclonality thus account for a small minority of pigmented purpuric dermatoses, but it seems prudent to suggest a skin biopsy in cases that are atypical in age-group, site, extent or morphology, or that are progressive or recurrent in behaviour. Other malignancies have been linked with development of pigmented purpuric dermatoses, including neoplasms of breast, bladder, intestine and lung, as well as leukaemia and Hodgkin's disease, but the strength of such associations is unclear.

Collagen vascular disorders. Both lupus erythematosus and rheumatoid disease [22] have been reported in association with pigmented purpuric dermatoses.

Vascular and haematological diseases. Stasis dermatitis commonly includes a component of pigmented purpuric dermatosis, either around the ankle or overlying varicosities. There is a single case of association with spherocytosis. Apparent 'venous' pigmented purpuric dermatosis in younger patients, without overt varicosities, should raise suspicion of a thrombophilia (Fig. 49.7).

Fig. 49.7 A pigmented purpuric dermatosis suggestive of venous disease but occurring in a young male without varicose veins; thrombophilia screening documented a lupus anticoagulant.

Miscellaneous. Diabetes, thyroid disease, liver disease and obesity have all been reported in association with pigmented purpuric dermatoses although causative relationships are not clear in these cases.

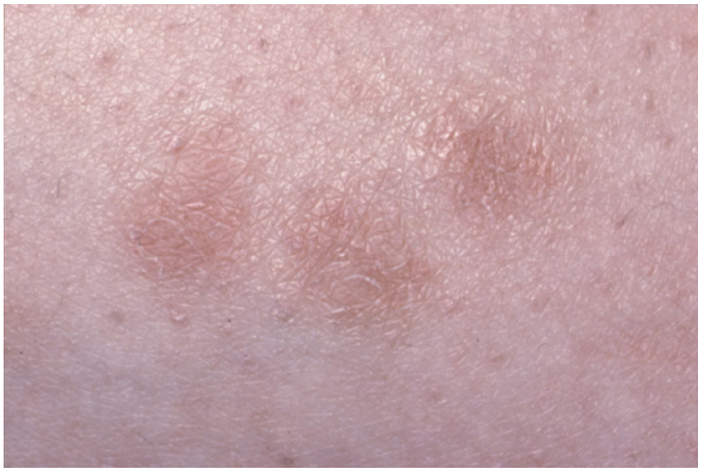

Fig. 49.8 Schamberg's disease.

Schamberg's disease [1,2]

Synonym
- Progressive pigmented purpuric dermatosis

This uncommon eruption is most common in young adult males but may occur at any age including childhood. Familial incidence has been reported [3]. The lesions are most frequent on the legs but may occur anywhere on the body, including the palms [4], and may be few in number or very extensive. They consist of irregular plaques of orange or brown pigmentation due to haemosiderin, with characteristic 'cayenne pepper' spots appearing within and at the edge of old lesions (Fig. 49.8). Slight changes in the epidermis may occur. There are usually no symptoms, although there may be some slight itching. The eruption is characteristically very chronic and may persist for many years. The pattern of the eruption changes, with slow extension and often some clearing of the original lesions. Spontaneous cure may occur eventually. Many patients have an eruption with features both of this disease and of the other pigmented purpuric dermatoses. An annular configuration may occur and there may be small lichenoid papules.

Itching purpura is a disorder that may be similar to Schamberg's disease, but the intensity of itch serves to distinguish the two.

Itching purpura [5–7]

Synonyms
- Eczematide-like purpura (of Doucas and Kapetanakis)
- Disseminated pruriginous angiodermatitis

This condition has many similarities to Schamberg's disease but is generally more extensive, develops more rapidly and is characterized by persistent, intense itch. It occurs most frequently in adult men and is of unknown aetiology. Purpuric lesions usually commence around the ankles and in a few weeks spread to involve the whole legs, sometimes the lower part of the body, and even elsewhere. They are more pronounced at sites of friction with clothing. The lesions consist of erythematous and purpuric macules that may become confluent. The eruption often has a

rather characteristic orange colour. The dermal perivascular changes are those seen generally in the pigmented purpuric dermatoses and there are variable changes in the overlying epidermis, including spongiosis. Spontaneous improvement after a few months is usual, but recurrences may occur and a fluctuating but chronic course is frequent. The itching may respond to topical corticosteroids and oral antihistamines.

An almost identical picture occurs with carbromal sensitivity, and less commonly with other drugs such as meprobamate, carbamazepine and perhaps even some foods. Clothing or rubber dermatitis may produce a similar picture, and may explain many cases of itching purpura.

Pigmented purpuric lichenoid dermatosis of Gougerot and Blum [8]

This eruption occurs especially in men aged between 40 and 60 years. It usually affects the legs, but lesions may occur elsewhere. The characteristic clinical feature of the dermatosis is the presence of lichenoid papules in association with purpuric lesions similar to those of Schamberg's disease, and this may simply be a variation of the same disorder. This clinical pattern has been found in association with porphyria [9] and a similar pattern of eruption may occur in the oral mucosa [10].

Lichen aureus [11,12]

Synonym
- Lichen purpuricus

This is a more localized, more intensely purpuric but often asymptomatic eruption that may have rather lichenoid morphology. Young adults and children are often affected, on body, limbs or even face. The lesions are often solitary and may be yellowish, golden, rust-coloured or purple. They may resemble a bruise, and hence must be distinguished from non-accidental injury in children, but may persist for a few years. Histologically, lichen aureus is distinguished from other pigmented purpuric dermatoses by a lack of epidermal component and in some cases a Grenz zone.

Purpura annularis telangiectodes [13,14]

Synonym
- Majocchi's disease

This eruption occurs especially in adolescents and young adults of either sex but may occur at any age, and may be familial [15]. Exercise may have been a provoking factor in one case [16]. The clinical features are distinctive and described in its name. Lesions occur at any site, often in the absence of venous stasis, and may be few in number or very numerous. They consist of small plaques 1–3 cm across that are usually annular from their onset (Fig. 49.9). Lesions consist of telangiectases and haemosiderin staining of the skin. They may be purple, yellow or brown, and may contain 'cayenne pepper' spots. Individual lesions persist unchanged for many months or years, or there may be slow centrifugal extension with development of slight central atrophy. Sometimes the lesions disappear and are replaced by similar lesions nearby. Treatment is usually ineffective. A variant termed *purpura telangiectatica arciformis (Touraine)* consists of fewer, larger and irregularly arciform lesions [17].

Fig. 49.9 Majocchi's purpura annularis telangiectodes.

Granulomatous pigmented purpuric dermatosis

An uncommon variant of pigmented purpuric dermatosis has been reported in which there is granulomatous histology [18,19]. In a series of four Asian cases, three had hyperlipidaemia, suggesting that this is worthy of evaluation in this rare variant of pigmented purpuric dermatosis [20].

Familial pigmented purpuric eruption

There are rare reported instances of the familial occurrence of Schamberg's disease [3,21] and of purpura annularis telangiectodes [14]. A distinctive pigmented purpuric eruption has been observed in several members of a family in which it was probably determined by an autosomal dominant gene [22]. Discrete reddish-brown spots developed in childhood or adolescence. The individual macules were larger than in Schamberg's disease and were arranged in a mosaic pattern. The lesions gradually covered a larger area and involved new sites, mainly on the limbs and in the larger flexures, but without any symptoms. Another family has been reported in which three generations were affected, supporting an autosomal dominant inheritance pattern [23].

Linear and quadrantic pigmented purpuric dermatoses

Various morphological types of pigmented purpuric eruption may occur in a linear or zosteriform distribution [24–28], or less commonly may diffusely involve a single quadrant of the body [29]. Linear lesions affect the legs more often than the arms. Individual lesions usually resemble lichen aureus or Schamberg's disease. In one case, trauma-induced linear pigmented purpuric dermatosis evolved into linear morphoea [30].

Treatment of pigmented purpuric dermatoses

These disorders may persist for many years [1–3] and are very resistant to any form of therapy; explanation without active intervention, or simply support hosiery, is often the most appropriate approach. Topical steroids may be of some help, especially for itch, but very prolonged use is best avoided. Emollients can be used as necessary. A rapid response of lichen aureus to topical pimecrolimus has been reported [4]. Psoralen and UVA (PUVA) [5–7] has proven effective in treating capillaritis of Schamberg, Gougerot–Blum and lichen aureus patterns, and TL01 UVB has been reported as effective in Schamberg's disease [8] and in Gougerot–Blum pigmented purpuric lichenoid dermatitis [9]. Ciclosporin [10] and griseofulvin [11] have also been effective in individual reports; calcium dobesilate has been suggested as first-line therapy as nine treated patients stopped developing new lesions within 2 weeks, but as the improvement at 12 months was graded as moderate in one patient, mild in six and none in two, it is not clear that this agent has much useful benefit [12].

Disorders of cutaneous microvascular occlusion

Numerous conditions may cause microvascular occlusion (Table 49.5). This process may involve abnormal coagulation (e.g. DIC, APLS), platelet plugging (e.g. heparin necrosis), emboli or crystal deposition (e.g. cholesterol emboli), abnormal erythrocytes (e.g. sickle cell disease) or abnormal proteins (e.g. cryoproteinaemia). Many of these conditions may cause purpura as one of their manifestations; many cause an initial non-inflammatory purpuric process that can be diagnostically helpful in differentiation from vasculitis. Morphological features that suggest this category of disease as an aetiology for early lesions include purpura without erythema, eschar without erythema, branching or fingering extension of the margins, or lesions that show purpuric, non-erythematous retiform, branching, or stellate configurations.

Table 49.5 Disorders of cutaneous microvascular occlusion: differential diagnosis by pathophysiological mechanism.*

Occlusion due to platelet plugs
Heparin-induced thrombocytopenia
Myeloproliferative disorders
Paroxysmal nocturnal haemoglobinuria
Thrombotic thrombocytopenic purpura (TTP)/haemolytic–uraemic syndrome (HUS)†

Occlusion due to cryogelling
Cryoglobulinaemia
Cryofibrinogenaemia
Cold-agglutinin-related occlusion

Occlusion due to vessel-invasive organisms
Ecthyma gangrenosum
Lucio phenomenon
Vessel-invasive fungi
Disseminated strongyloidiasis

Occlusion due to embolus
Cholesterol embolus
Oxalate crystal embolus
Atrial myxoma
Cardiac sterile thrombi
Septic emboli
Fat emboli‡

Occlusion due to systemic coagulopathies with cutaneous manifestations
Protein C/S/thrombomodulin pathway anomalies
  Neonatal purpura fulminans
  Coumadin necrosis
  Sepsis-related purpura fulminans
  Post-infectious purpura fulminans
Antiphospholipid antibody syndrome

Occlusion due to vascular coagulopathies§
Sneddon's syndrome
Livedoid vasculopathy/atrophie blanche
Malignant atrophic papulosis

Occlusion due to reticulocyte occlusion¶
Sickle cell disease
Other severe haemolytic anaemias

Occlusion due to unknown or controversial mechanisms
Cutaneous calciphylaxis
Some insect bites, especially *Loxosceles* (brown recluse spider)
Some snake bite syndromes**

* Most of these disorders present with purpura or necrosis with minimal inflammation, and frequently show retiform (stellate, branching) morphologies.
† TTP/HUS is usually occlusive in visceral vessels, but skin lesions are most often non-palpable petechiae, and not due to occlusion.
‡ Fat emboli typically cause occlusion in viscera, especially lungs; cutaneous lesions are rare and typically petechial, due to minute fat particle occlusion.
§ Sneddon's syndrome typically presents with pathological livedo reticularis; livedoid vasculopathy may have retiform purpura morphologies, however, atrophie blanche and malignant atrophic papulosis are often not purpuric, but heal with a characteristic atrophic scar with surrounding telangiectasia.
¶ Syndromes involving reticulocyte occlusion often heal with lesions mimicking atrophie blanche, and are seldom purpuric or retiform.
** Most snake bites cause haemorrhage; if fulminant disseminated intravascular coagulation results, some lesions might be occlusive.

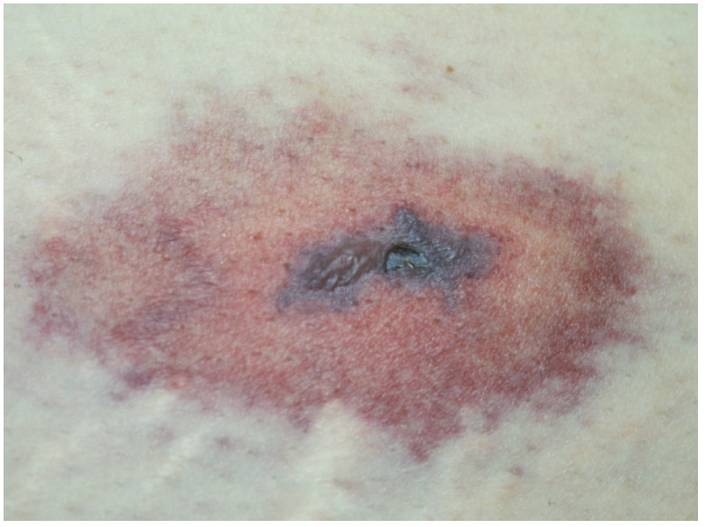
Occlusion due to platelet plugs

Heparin-induced thrombocytopenia and heparin necrosis [1,2]

Aetiology and pathogenesis. The syndrome of heparin-induced thrombocytopenia (HIT) is an uncommon paradoxical response to heparin, with some female predominance [1]. This syndrome can be defined as any clinical event best explained by PF4/heparin-reactive antibodies (HIT antibodies) in a patient who is receiving, or who has recently received, heparin [1]. Although IgA and IgM class antibodies may play a role, IgG antibody is most closely associated with this syndrome [3]. The antibody that causes HIT is not simply an antiheparin antibody. Heparin and certain other polyanions, when bound to PF4, can induce conformational changes in tetrameric PF4, exposing new epitopes on PF4. This may trigger antibody production to these newly exposed regions. When antiheparin/PF4 antibody binds with heparin/PF4 complexes on the surface of platelets, platelet activation and aggregation results. Not all heparin/PF4 antibodies appear to be pathogenic, and some antibodies responsible for HIT do not bind to heparin/PF4 complexes but to chemokines or cytokines, such as neutrophil activating peptide-2 (NAP-2) and interleukin-8, somehow activating platelets [1–3].

Unfractionated heparin is three times more likely to be associated with HIT following orthopaedic surgery compared with low-molecular-weight heparin [1]. HIT is more likely to be induced by bovine-derived unfractionated heparin than the porcine-derived variety, consistent with the hypothesis that longer and more flexible heparins bind to PF4 tetramers in ways that induce more conformational change and more exposure of neoepitopes. This may also explain the lower risk of HIT with low-molecular-weight heparins. HIT is even less likely to be triggered by fondaparinux, a pentasaccharide anticoagulant modelled after the antithrombin binding region of heparin [1]. The risk of HIT is highest in post-surgical patients, less so in medical patients requiring heparin and lowest in obstetric settings [1].

Clinical features. Patients with HIT usually develop absolute or relative thrombocytopenia (90%), often followed by evidence of venous or arterial thromboses or of heparin necrosis in the skin [1]. A proportional drop of over 50% in platelet number from the pre-treatment count may be a better indication of early heparin-induced platelet aggregation than an absolute thrombocytopenia of 100–150 $\times 10^9$/L [1]. This may occur immediately after heparin administration if the patient has been previously sensitized and has received heparin within the past 100 days. In two-thirds of patients, the fall in platelet count begins between days 5 and 10 of heparin administration, although significant thrombocytopenia may take 7–14 days to develop [1,4,5]. Uncommonly, patients may develop HIT several days after stopping heparin (delayed-onset HIT); this is attributed to the presence of high-titre antibodies that can recognize PF4 neoepitopes even in the absence of heparin binding, perhaps binding instead to chondroitin sulphate [1]. A history of HIT is not predictive of a second episode if the patient last received heparin more than 100 days previously. Although essential to thrombosis, HIT-IgG antibodies are not sufficient



alone to produce thrombosis. Only 5–30% of patients who form HIT-IgG will develop clinical HIT [1]. Only half of antibody-positive patients produce IgG class antibodies, and only half of the IgG class group show biological activity.

Accumulating reports of catastrophic thrombotic episodes, typically venous limb gangrene, suggest that there may be a synergistic thrombophilic state in patients with HIT also treated with warfarin, presumably through both HIT and protein C-depletion pathways [1].

Heparin administration commonly induces cutaneous findings of simple haemorrhage with ecchymoses, and occasionally triggers urticaria or infiltrated plaques [6–8]. Uncommonly, the syndrome of heparin necrosis results as a cutaneous microvascular occlusion subset of HIT. Purpuric, tender, sharply demarcated plaques develop; retiform extensions that sometimes develop at the lesional margins are characteristic of heparin necrosis. Erythema may sometimes accompany such lesions, and necrosis is frequent. Lesions are most common at subcutaneous injection sites but can occur elsewhere [9–11] (Fig. 49.10). Interestingly, as few as one-third of patients with skin lesions of heparin necrosis may develop absolute thrombocytopenia, even when HIT antibodies are detected [1]. Haemorrhagic adrenal infarction has been reported in such cases. Histological examination of lesions reveals 'white clots', representing platelet–fibrin thrombi, in the cutaneous microvasculature [5,12].

(a)

(b)

Fig. 49.10 (a) Heparin necrosis at sites of subcutaneous heparin injection. (b) Close-up of a 15-cm lesion on left abdomen. Lesion is a non-palpable haemorrhage with retiform margins, minimal erythema and central retiform intense haemorrhage, early necrosis and bullae formation. (From Robson K, Piette W. The presentation and differential diagnosis of cutaneous vascular occlusion syndromes. *Adv Dermatol* 1999; **15**: 153–82, with permission from Mosby.)

Treatment. Treatment of HIT and heparin necrosis continues to evolve. The correct diagnosis is important, because many patients on heparin develop thrombocytopenia for reasons other than the development of HIT antibodies; conversely, patients may develop the arterial or venous thromboses, or especially heparin necrosis, without manifesting thrombocytopenia [1]. Stopping heparin is important, although some patients do not worsen if heparin is continued whereas others may progress despite stopping heparin. Although replacing heparin with coumadin was previously thought to be effective in treating HIT and heparin necrosis, coumadin substitution is not only ineffective but may in fact induce venous limb gangrene [1]. Low-molecular-weight heparin is much less likely to cause HIT, but it is contraindicated for treatment of patients with HIT due to other types of heparin. Surprisingly, heparin is the appropriate treatment for cardiac surgery patients with a previous history of HIT, but whose antibodies have disappeared (beyond 100 days). The anticoagulants currently used to treat patients with HIT are danaparoid (a heparinoid) and two thrombin inhibitors, lepirudin and argatroban [1]. Even with treatment with one of these agents, there is a 5–20% frequency of new thromboses. Major bleeding in HIT patients has occurred in 3.1% of those treated with argatroban, and in 5.9–14.4% of those treated with lepirudin. Danaparoid is available in many countries, including the UK, but not currently in the United States.

Myeloproliferative disorders

Cutaneous lesions are common in thrombocythaemia and other myeloproliferative disorders (see also Chapter 62). Paradoxically, patients with myeloproliferative thrombocytosis may both bleed and clot abnormally. Skin lesions were documented in 22% of 268 patients with essential thrombocythaemia [1], and included urticaria, livedo reticularis, petechiae, ecchymoses, haematomas, erythromelalgia, Raynaud's phenomenon, recurrent superficial thrombophlebitis, necrotizing vasculitis, leg ulceration and gangrene. Biopsy findings were variable, but some livedo reticularis and acral infarcts were associated with evidence of microvascular occlusion. Additionally, tender erythematous facial plaques and palmar violet macules and papules were reported as manifestations of platelet plugging in a patient with atypical chronic myeloproliferative disease and a history of Budd–Chiari syndrome, another known thrombotic complication of myeloproliferative disease [2]. This patient's cutaneous lesions were unresponsive to coumadin, but cleared within 24 h of aspirin administration following identification of platelet plugs as the cause of previously identified microvascular occlusion.

Essential thrombocytosis and polycythaemia vera, although rare, are the first and second most common causes of elevated platelet counts, with an increased frequency of thrombotic events and of erythromelalgia [3]. A recent study of 605 patients with essential thrombocythaemia found a 10-year risk of thrombosis of 14% [4]. These diseases are more common at younger ages and in women. However, reactive or post-splenectomy thrombocytosis at any level is not associated with occlusion, suggesting that thrombosis in the setting of myeloproliferative disease is not a function of thrombocytosis alone. Multiple studies have shown that a specific mutation in the JAK2 tyrosine kinase (JAK2V617F) is found in many patients with essential thrombocytosis, polycythaemia vera, and primary myelofibrosis, and a gain-of-function mutation in the thrombopoietin receptor (MPL) in a subset of patients with essential thrombocytosis but who are JAK2V617-negative [5]. The mechanisms for ischaemic or occlusive syndromes in myeloproliferative disease must therefore depend on more than platelet number alone; the following factors may be relevant. Acquired von Willebrand factors in myeloproliferative disease have been associated with both bleeding and thrombotic complications. Anticardiolipin antibodies, factor V Leiden mutations, abnormal endothelial cell function, and decreased levels of protein C and protein S may be synergistic for thrombosis in chronic myeloproliferative diseases [6,7]. In addition to high platelet counts, abnormal platelet function occurs in myeloproliferative or myelodysplastic disease, although whether this can lead to vascular occlusion at platelet counts less than 1000×10^9/L is controversial. Thrombotic events have been reported at platelet counts below 600×10^9/L in patients with essential thrombocytosis, including some events at normal platelet counts [8]. In a study of 56 consecutive patients with essential thrombocytosis, 46 developed complications mostly related to thrombosis [8]. In these 46 patients, severe complications occurred in 22% at platelet counts lower than 600×10^9/L, in 15% at counts lower than 500×10^9/L, and in 4% at counts lower than 400×10^9/L. In a cohort of 1063 patients with essential thrombocythaemia, a paradoxical finding reported was that a platelet count greater than 1000×10^9/L was associated with a lower risk of thrombocytosis, and if combined with a leukocyte count less than 11×10^9/L pointed to a 'low-risk' category of thrombosis [9].

Erythromelalgia (erythralgia) can occur as a primary or secondary syndrome. This intensely uncomfortable burning associated with paroxysmal erythema of the distal extremities is frequently triggered by skin contact with a warm surface. Although erythromelalgia has been seen in many different settings, the association of purpuric or necrotic areas on hands and feet with the dysaesthetic erythema is exclusively seen with myeloproliferative or myelodysplastic thrombocytosis [10]. Because of the platelet origin of occlusion and vascular symptoms in the myeloproliferative subset of erythromelalgia, aspirin administration is notably effective in clearing lesions and alleviating symptoms, whereas it is much less effective in primary and other secondary forms of erythromelalgia.

Splenomegaly may be seen in all forms of myeloproliferative syndromes. Ruddy cyanosis is characteristic of polycythaemia vera, as is elevation of haemoglobin, haematocrit and red cell mass. All syndromes may show elevations in white count, but this is most characteristic of chronic granulocytic leukaemia, especially in association with elevated eosinophil and basophil counts. Anaemia and altered red cell morphology can occur over time in all patients, and all these diseases have some risk of transition to dyspoiesis and severe anaemia, leukaemia or myelofibrosis.

Many therapies previously used for myeloproliferative thrombocytosis increase the risk of leukaemic transformation and of complications in fertility and pregnancy. Low-dose aspirin has been widely accepted as effective thrombosis prophylaxis, although definitive proof of its efficacy is lacking. Its dramatic reversal of signs and symptoms in erythromelalgia provides some clinical evidence for its usefulness in thrombocythaemic complications. Hydroxycarbamide is the drug of choice for prevention of transient ischaemic attacks, but may not be effective in preventing venous thrombosis, and anagrelide treatment may reduce the risk of venous thrombosis but appears to dramatically increase the risk for arterial thrombosis and haemorrhage. Anagrelide has become an important therapeutic agent, acting to both inhibit platelet activity and decrease the platelet count [11,12]. The JAK2 mutations seem to correlate with leukocyte and platelet proliferation, but the role for the JAK2 and MPL mutations in enhancing thromboses is less clear [5,13]. Multiple studies suggest that the presence of the JAK2V617F mutation translates into activation of haemostasis, at least in part through increase in platelet-associated tissue factor microparticles and increased platelet–neutrophil aggregates [14].

Paroxysmal nocturnal haemoglobinuria

Paroxysmal nocturnal haemoglobinuria (PNH) is an acquired clonal blood disorder associated with deficient haematopoiesis, intravascular haemolysis and venous thrombosis [1,2]. Episodic haemoglobinuria is the characteristic result of nocturnal haemolysis, although it is the presenting feature in only 26% of patients [1,2]. The sleep-associated haemoglobinuria is secondary to an abnormally increased sensitivity of red blood cells to lysis by serum complement [1]. This increased sensitivity to complement lysis is related to abnormal regulation at two different points of the complement cascade, and this abnormal regulation is due in turn to the partial to complete deficiency of two membrane-associated inhibitors of the complement cascade, decay-accelerating factor (DAF) and membrane inhibitor of reactive lysis (MIRL, also known as CD59). DAF inhibits the activity of classic complement pathway C3 convertase and of alternative pathway C3 convertase, and MIRL/CD59 regulates the activity of the complement membrane attack complex on red cells. These two inhibitors are part of a group of roughly 20 red cell membrane proteins that share a common post-translational modification in the glycosylphosphatidylinositol (GPI) anchor. In PNH, a somatic mutation in the phosphatidylinositol glycan class A gene (*PIG-A*) on the X chromosome alters the ability of proteins sharing the GPI anchor to bind to the membrane [1–3]. Whereas previous diagnostic tests for PNH relied on the haemolytic sensitivity of PNH red blood cells, current tests rely on detection of loss of CD59 and/or CD55 on red cells, loss of CD59, CD24, CD16, or other GPI-anchored proteins on granulocytes, or lack of FLAER (Fluorescently Labelled inactive toxin AERolysin) binding to granulocytes, which also depends on binding to GPI anchors [4].

This complex pathophysiology explains the haemolysis and haemoglobinuria in PNH, but does not yet completely explain other manifestations of this disease such as thrombosis. Although 10–15% of patients may show spontaneous remission, the median survival is 10–15 years [4]. Thrombosis is a major morbidity; 40% of patients develop venous thrombosis [2], and this is the most frequent cause of death [4]. At least some of the thrombotic tendency may be related to complement-mediated activation of platelets or to platelet–leukocyte complexes, which share the defect in GPI-anchored proteins. Budd–Chiari syndrome (hepatic vein thrombosis) is common, as are thromboses in unusual sites such as cerebral, dermal, hepatic and portal, mesenteric and splanchnic veins [1]. This unusual localization may also favour a role of platelets in the thrombophilic state. The most likely pathway for this appears to be the development of microparticles from complement-damaged red cells and platelets, leading to an increase of phospholipid membrane surface area in blood. Episodes of thrombosis often follow haemolytic episodes, also suggesting that haemolysis-associated changes, such as nitric oxide depletion by released haemoglobin, may play an important role in thrombogenesis [4]. This same pathway is implicated in the vascular occlusion seen in sickle cell disease, another haemolytic anaemia. Clinical dermatological features of PNH include pyoderma gangrenosum, haemorrhagic bullae, cutaneous venous thrombosis and DIC [4,5].

Anticoagulants, corticosteroids and thrombolytic therapy may be effective in treating thrombotic episodes; the role of antiplatelet therapy is unclear [6]. More recently, the use of the humanized monoclonal antibody eculizumab, directed against the C5 component of complement, to reduce haemolysis, has also resulted in reduction in thromboses from 7.37 per 100 patient years to 1.07 per hundred patient years in PNH. This supports the hypothesis that haemolysis induces a thrombophilic state, either through nitric oxide reduction by free haemoglobin or inhibition of membrane damage which might otherwise lead to microparticle formation [7,8]. The only observed risk for infection from this therapy appears to be an increase in the risk of infection by *Neisseria meningitidis* or by *N. gonorrhoeae* (0.5 cases per 100 patient years with eculizumab). Although the antibody-induced equivalent of a late complement component deficiency may lead to an increased risk of infection, the complications from such an infection appear to be less than anticipated, as in patients with inherited terminal complement deficiency. The risk of infection can also be reduced by vaccination with tetravalent meningococcal vaccine, and by counselling of patients to promote early recognition and treatment of possible meningococcal infection [7].

Thrombotic thrombocytopenic purpura/haemolytic–uraemic syndrome

Thrombotic thrombocytopenic purpura (TTP) was first reported by Moschowitz in 1924 as an acquired syndrome, and subsequently as a congenital syndrome by Schulman (Upshaw–Schulman syndrome) in 1960 [1]. For many years, criteria for the diagnosis of TTP included thrombocytopenic purpura, microangiopathic haemolytic anaemia, renal dysfunction or failure, neurological abnormalities and fever, with a fatal outcome in 90% of patients [2]. Once plasma exchange proved at least sometimes effective in treating this disorder, criteria for diagnosis were pared to include only thrombocytopenia and microangiopathic haemolytic anaemia. Haemolytic–uraemic syndrome (HUS) was originally described in children with acute renal failure, microangiopathic haemolytic anaemia and, usually, thrombocytopenia, but no purpura, neurological findings or fever. Current diagnostic criteria do not distinguish between TTP and HUS. However, childhood HUS is distinguished clinically because most cases are related to enteric infection with *Escherichia coli* O157:H7, HUS developing about 1 week after diarrhoea due to this agent; most children survive without plasma exchange [2]. Epidemic forms of HUS are most common, associated with prodromal diarrhoea and with verotoxin (shigatoxin S1 or S2)-producing organisms, usually the *E. coli* strain mentioned previously, or enterococcus [3]. *Mycoplasma* can also provoke TTP. Pregnancy can induce TTP/HUS, as well as *HELLP* syndrome (haemolysis, elevated liver enzymes, low platelet count), as a complication of pre-eclampsia and eclampsia, and these may be difficult to distinguish [3]. TTP/HUS has been reported secondary to drugs (especially mitomycin C, ciclosporin, ticlopidine and quinine), after allogeneic bone marrow transplantation, and associated with autoimmune connective tissue disease (lupus erythematosus, scleroderma), vasculitis (polyarteritis nodosa), APLS [4], Sjögren's syndrome or metastatic carcinoma.

The molecular basis of TTP is a severe deficiency of a protease (ADAMTS13, 'A Disintegrin-like And Metalloprotease with Thrombospondin repeats' family of metalloproteases) that cleaves von Willebrand factor, resulting in persistence in plasma of ultralarge von Willebrand multimers secreted by endothelial cells [1–3]. Persistence of such large multimers in the circulation leads to formation of microvascular platelet thrombi. Congenital deficiency of ADAMTS13 leads to lifelong, recurrent episodes of TTP; mechanisms for acquired ADAMTS13 are still unclear, but can include acquired autoantibody. Some regard ADAMTS13 deficiency as a diagnostic feature of TTP (congenital and idiopathic), although ADAMTS13 levels are reported to be normal in most patients with secondary TTP/HUS [1,5,6]. Von Willebrand factor protease is deficient in hereditary, intermittent relapsing, intermittent acute, ticlodipine-induced and clopidogrel-induced TTP, but is normal in HUS and in transplantation-related thrombotic microangiopathy. However, not all patients with deficient von Willebrand factor protease have active TTP. ADAMTS13 deficiency rarely if ever occurs in the diarrhoea-associated HUS (D+ HUS) caused by shigatoxin-producing *E. coli*. HUS without antecedent diarrhoea is termed 'atypical HUS'; it also is typically not associated with ADAMTS13 deficiency, but frequently has alternate complement pathway abnormalities due to mutations in complement factor H, I, B, or in membrane cofactor protein [1].

Treatment options include plasma exchange with fresh frozen whole plasma or parts of plasma (e.g. cryoprecipitate-reduced plasma, high-molecular-weight fraction); corticosteroids, vincristine and antiplatelet drugs may also have a role. Outcome is usually good in childhood but less so in familial forms. As a practical matter, the response of patients to plasma exchange treatment in TTP or HUS is independent of whether they have deficient or normal levels of ADAMTS13 [7].

Microvascular platelet thrombi are characteristically seen in patients with TTP, especially in the renal and cerebral circulation [2]. Some have reported that HUS patients more often have fibrin-rich thrombi and more limited visceral vessel involvement [8]. Purpuric skin lesions are frequently mentioned in reports and reviews of TTP, but histological characterization of such cutaneous lesions is very sparse. Hyaline microthrombi composed of platelets and fibrin have been reported [9]. It seems likely from evaluation of lesional photographs that many, if not most, of the skin lesions in TTP are related to thrombocytopenia and simple haemorrhage rather than to microvascular platelet plugs as seen in the cerebral and renal vessels.

Occlusion due to cryogelling

Common clinical features

Occlusion syndromes triggered by cold exposure are suggested by an acral distribution of lesions of necrosis or purpura, often with retiform features, and sometimes associated with acral livedo reticularis. An acral distribution must be distinguished from a dependent distribution of lesions. Both patterns may involve hands and feet, but with a dependent pattern there are typically many more lesions on the feet and legs than on the hands. A dependent distribution of lesions suggests immune complex-mediated disease, and usually presents as classical palpable purpura or occasionally as inflammatory retiform purpura, not as bland or non-inflammatory purpura or pauci-erythematous necrosis. An acral distribution of lesions is also characteristic of erythema multiforme. However, erythema multiforme presents with target lesions, atypical target lesions or classical palpable purpura, rather than non-inflammatory retiform purpura or necrosis, and it is not associated with livedo reticularis. In addition, the acral distribution of cryo-occlusion syndromes often includes the ears and nose, sites usually unaffected by erythema multiforme. Although ill patients with immune complex vasculitis may develop dependent lesions on the posterior portions of the ears if supine due to their illness, their other lesions are typically in dependent areas as well, and there is usually no history of cold exposure as the precipitating factor. A biopsy of early lesions, before necrosis has had time to trigger a secondary vasculitic histology, should show non-inflammatory occlusion of dermal vessels with cryoprotein or agglutinated red cells.

Careful handling of serum and plasma is necessary to allow identification of cryogelling proteins, because those most likely to cause disease are those that gel at temperatures very close to normal body temperature. Likewise, identification of cryoproteins or cryoagglutinins does not prove a cryo-occlusion syndrome, because these may either gel at temperatures that are not relevant to typical cold exposure or may simply represent incidental findings. The latter is especially true of cryofibrinogens and cold agglutinins.

Cryoglobulins

Cryoglobulins, immunoglobulins that reversibly precipitate or gel in the cold, were first reported in 1933 and were named cryoglobulins in 1947 [1–4]. In 1974, Brouet *et al*. [1] proposed the now standard subset classification of cryoglobulins into types I, II and III. In the 1990s, a large proportion of cases were found to be associated with hepatitis C. Although precipitation of cryoglobulins is primarily related to reversible cold-induced denaturation of protein, other factors such as cryoglobulin concentration in the microvascular environment, pH and non-covalent binding factors also influence the likelihood and intensity of precipitation.

Type I (single molecule) cryoglobulins are single monoclonal immunoglobulins, usually IgG or IgM, less commonly IgA, and rarely Bence–Jones protein. Accounting for 10–15% of cryoglobulins, they are often associated with an underlying lymphoproliferative disorder, especially multiple myeloma or Waldenström's macroglobulinaemia [5]. As type I cryoglobulins are single proteins and are neither immune complexes nor proven to activate complement, if they are to cause vascular injury or occlusion they can do so only by cryogelling and not by immune complex vasculitis.

Types II and III, termed mixed cryoglobulins, are multiple molecule proteins, typically immune complexes, that gel under laboratory conditions (2–4°C). Unless they gel at temperatures close to body temperature, they are much more likely to cause disease as immune complexes than as cryoproteins, but they can cause disease through either or both mechanisms in any given patient. Rheumatoid factor activity (defined by anti-Fc binding) is detectable in the sera of 87–100% of patients with mixed cryoglobulinaemia [3]. Type II cryoglobulins are composed of monoclonal proteins of IgM, IgG or occasionally IgA class that bind to an antigen present in the blood, most commonly the Fc portion of polyclonal IgG molecules. Those that bind immunoglobulin (usually IgG) by anti-Fc affinity are also, by definition, rheumatoid factors, although only the IgM/anti-IgG rheumatoid factors are recognized by standard rheumatoid factor testing. In up to 95% of type II cryoglobulins with IgM as the antirheumatoid factor immunoglobulin, the IgM contains a κ light chain, which would not be expected by chance alone [3,6]. Type III mixed cryoglobulins are also most commonly rheumatoid factors, but the IgM, IgG or IgA anti-Fc antibodies in this group are polyclonal rather than monoclonal. In patients with mixed type II or III cryoglobulins, complement levels are usually reduced, especially the C4 component.

Antibodies to hepatitis C virus (HCV) have been found in more than 50% (42–98%) of patients with type II and III cryoglobulins [2–4]. Conversely, 13–54% of patients with HCV have mixed cryoglobulins detected in the laboratory, and the majority of these are type III cryoglobulins (67–91%). Of HCV-infected individuals with cryoglobulins, only 27% had clinical signs consistent with the syndrome of cryoglobulinaemia [2]. The reasons why only a fraction of HCV-infected and cryoglobulin-positive patients develop symptomatic cryoglobulinaemia are unknown.

In a multicentre Italian cooperative study of 913 patients with cryoglobulinaemia, 8.9% of all patients with symptomatic cryoglobulinaemia had lymphoproliferative disease at diagnosis [2]. Of this subset of patients, 27% had type I, 68% had type II and 5% had type III cryoglobulins. Although type I cryoglobulinaemia is usually associated with lymphoproliferative disease, it is a much less common type than types II and III; the latter two types therefore accounted for the majority of cryoglobulinaemia-associated lymphoproliferative disease in this study from a region with a high endemic rate of HCV and mixed cryoglobulinaemia.

Other syndromes are also associated with cryoglobulins detectable in serum. Patients with connective tissue disease also have higher rates of cryoglobulinaemia: it occurs in up to 25% of patients with SLE, 12.5% of patients with systemic sclerosis, 46% of patients with active rheumatoid arthritis and 17–37% of patients with Sjögren's syndrome [2]. In addition to HCV, other chronic infections such as Lyme disease, subacute bacterial endocarditis (up to 90%), Q fever, hepatitis A and B, hantavirus, cytomegalovirus, human T-cell leukaemia virus I and HIV have been reported [2,7]. Chronic inflammatory disease, such as liver cirrhosis from any cause, is also associated with a higher than expected rate of detectable cryoglobulins. The presence of cryoglobulins in serum does

not invariably predict disease; cryoglobulins were present at low titre in as high as 51% of normal individuals in one study [8]. In fact, despite detectable serum cryoglobulins in the patient groups mentioned, most will not develop symptomatic cryoglobulinaemia [2].

There are only two known ways in which cryoglobulins can result in disease. The first is by precipitation within the vascular lumen, typically cold-induced, with hyaline plug formation and minimal early-phase inflammation. Typical clinical lesions would be minimally inflammatory cutaneous infarction with or without associated livedo reticularis, or non-inflammatory retiform purpura. Since there is little evidence that cryogelling of monoclonal antibody induces complement activation, cryogelling is the only known mechanism for vascular lesions for type I cryoglobulins [5]. The second mechanism is that of immune complex vasculitis. As nearly all type II and III cryoglobulins are immune complexes, they should all be capable of inducing an immune complex vasculitis, although many do not. If they cryoprecipitate near body temperature, they could also cause vascular injury by simple occlusion, although most appear to gel at temperatures well below 37°C.

The median age at diagnosis of cryoglobulinaemia is early to middle sixth decade, with a female to male ratio of 2:1 [2]. Recurrent showers of dependent palpable purpura, sometimes with burning or itching, frequently associated with arthritis or arthralgia, is the classic presentation of mixed (type II and III) cryoglobulinaemia (the combination of purpura, asthenia and arthralgia has been termed Meltzer's triad). Patients with symptomatic cryoglobulinaemia of any type most often present with cutaneous lesions, usually purpura (in 55–100%, especially if HCV-associated) [2–4,9]. Ulceration, haemorrhagic crusts or cutaneous infarction are seen in 10–25% of patients, most often with type I cryoglobulins. Cold-induced acrocyanosis of acral areas, and non-inflammatory retiform purpura are also more typical of type I cryoglobulinaemia. Other reported cutaneous findings include acral cyanosis, Raynaud's phenomenon, urticarial lesions, ulceration and livedo reticularis [4,10,11]. Histological demonstration of non-inflammatory hyaline thrombosis is more common in patients with type I cryoglobulinaemia, but some such patients have also been reported to have cutaneous vasculitis [9]. A prospective study of biopsies of only new lesions (duration <48 h) of purpura in type I cryoglobulin patients has not been published. This leaves unresolved the issue of whether all reports of vasculitis in type I disease are those of vasculitis secondary to occlusive necrosis or ulceration. Non-cutaneous clinical findings most frequently include involvement of the joints (35–92%), peripheral nerves (17–56%), kidneys (21–29%) and liver [2–4].

Confirmation of cryoglobulins in sera requires careful handling of specimens to prevent cryoprecipitation before they can be detected. Collection of 10–20 mL of blood is suggested, and this must be kept warm and allowed to clot at 37°C for 30–60 min before centrifugation. The serum supernatant is left at 4°C for up to 7 days, with types I and II most likely to precipitate by 24 h [2,3,12]. A true cryoglobulin should once again be soluble if the sample is reheated to 37°C. Cryocrit measurements represent the percentage of the precipitate compared with the serum supernatant. Despite the presence of monoclonal protein, polyclonal gammopathy is the most frequent finding on serum protein electrophoresis of serum samples (not cryoprecipitate specimens) in patients with type II cryoglobulinaemia [2]. A more sensitive technique, such as immunofixation, is needed to identify the presence of a clonal protein.

Treatment of cryoglobulinaemia is often problematic, and prospective or controlled trials are rare [3,4]. If symptoms are mild, no treatment may be needed. If symptoms of acral lesions are precipitated by cold, then protection of affected areas may be sufficient. Measures to reduce the concentration of a type I cryoglobulin, such as plasmapheresis, plasma exchange or cytotoxic therapy, are occasionally effective, although unfortunately usually only in the short term. For immune complex-related disease, corticosteroids, cytotoxic agents or plasmapheresis may be effective, but relapse is typical once therapy is stopped. Interferon-α has been used to treat HCV-associated cryoglobulinaemia, with or without ribavarin [3,4,11]. Treatment with these agents has resulted in partial or complete remissions of vasculitic findings, but relapse often follows cessation of therapy. The therapy itself has occasionally been implicated in triggering the onset of vasculitis. In patients with mixed cryoglobulinaemia troubled primarily by recurrent cutaneous vasculitic lesions, colchicine or dapsone therapy may be of some help in reducing the frequency and severity of episodes.

Cryofibrinogenaemia

Cryofibrinogen deposits consist of a complex of fibrinogen, fibrin and fibronectin that forms on cold exposure [13]. Since cryofibrinogens can be cleaved to form fibrin, plasma rather than serum must be tested to detect these cryogelling proteins. Cryoglobulins should be present in both plasma and sera [13,14].

Cryofibrinogenaemia is common as a laboratory abnormality but is a rare cause of symptomatic clinical disease. One study found an incidence of 3% in a random sample of hospital patients, usually as an incidental finding [15]. Therefore, clinicopathological correlation is important. Cryofibrinogenaemia may be idiopathic or can be associated with malignant disorders (especially haematological), thromboembolic disease, IgA nephropathy or various inflammatory, connective tissue or infectious syndromes [16,17].

Acquired dysfibrinogenaemia very rarely may mimic a cryofibrinogen syndrome by acral occlusion, including gangrene. Interestingly, this subset of dysfibrinogenaemia appears to act by greatly increasing red cell aggregation, mimicking occlusion-inducing cold agglutinins. Blood smear preparations show marked rouleaux formation.

The most common cutaneous findings are cold intolerance, purpura, necrosis, livedo reticularis, gangrene and ulceration (Fig. 49.11) [14,16,17]. The purpura or necrosis typically has a non-inflammatory retiform purpura morphology. Biopsy specimens from skin lesions typically show thrombi in small vessels with dermal necrosis [16]. Leukocytoclastic vasculitis has been reported, but is probably due to ischaemic necrosis rather than being a cause [17]. Fibronectin may be a major component of vascular plugs in patients with cryofibrinogenaemia alone, whereas vascular occlusion in patients with both cryofibrinogens and cryoglobulins shows a predominance of cryoglobulin deposition [17]. Treatment

(a)

(b)

Fig. 49.11 Cold-induced lesions due to cryofibrinogenaemia, (a) on the ear and (b) on the foot. Acral location is typical for cryogelling. Foot lesion shows minimal erythema, retiform bullae and haemorrhage with necrosis.

of cryofibrinogenaemia should be aimed at the underlying disease, where possible, and at protecting areas from cold exposure [18]. Stanozolol, an androgenic steroid with fibrinolysis-enhancing effects, has also been used for treatment of cryofibrinogenaemia, as have other fibrinolytic agents [19].

Cold agglutinin-related cutaneous occlusion

Cold agglutinins are immunoglobulins that are able to agglutinate red blood cells below normal body temperatures. As agglutination of red blood cells depends on binding of antibody to more than one cell at a time, pentavalent IgM is almost exclusively responsible for this phenomenon. Just as with cryoglobulins, there are both monoclonal and polyclonal cold agglutinins, usually directed at I, i or Pr antigens of erythrocytes [20,21]. Monoclonal cold agglutinins are idiopathic or secondary to malignant lymphoproliferative diseases. Polyclonal cold agglutinins are usually associated with infection, especially due to *Mycoplasma pneumoniae*, less often HCV, parvovirus B19 or leptospiral infections.

Just as with many cryoglobulins and most cryofibrinogens, cold agglutinins are most likely to be asymptomatic. When responsible for disease, reversible acrocyanosis secondary to cold-induced acral agglutination is most common. Livedo reticularis, Raynaud's phenomenon, cold urticaria and rarely cutaneous necrosis may occur. In addition to acral lesions on environmental cold exposure, cold intravenous infusions can also trigger localized cutaneous necrosis [20]. Cold agglutinins can induce complement activation after cold-induced binding to red blood cells, followed by lysis and haemolytic anaemia, independent of occlusive syndromes from agglutination.

Patients with cold-induced agglutination syndromes must avoid cold exposure. Therapies such as corticosteroids, cytotoxic agents, danazol, rituxan or interferon-α have been occasionally beneficial [21].

Occlusion due to vessel-invasive organisms

Ecthyma gangrenosum

Ecthyma gangrenosum is a cutaneous syndrome characterized by usually painless, minimally erythematous macules or thin papules or plaques that typically progress to bullous lesions, followed by haemorrhage and necrosis, often with retiform extensions from lesional margins [1]. The anogenital area is a frequent site of involvement, but lesions can develop anywhere and at widespread

cutaneous sites [2,3]. Patients are almost invariably immunocompromised, and the infectious agent is usually *Pseudomonas aeruginosa*.

In a small series of cases of ecythma gangrenosum, all eight patients had haematological disease and were receiving immunosuppressive medications [4]. All had positive blood cultures, seven of which were *Ps. aeruginosa*. Biopsies of ecthyma gangrenosum reveal minimal vascular neutrophilic infiltration despite necrotizing vessel injury, and special stains show extensive bacillary infiltration of the perivascular region, the adventitia and the media of larger subcutaneous arterioles, with sparing of the lumen and intima [3–5]. Other bacterial-induced vasculitides tend to show bacterial invasion of the vessel lumen and fibrin thrombi.

Prompt recognition of this syndrome is critical, because prognosis correlates partly with delay in instituting effective intravenous antipseudomonal therapy. Other factors correlating with poor prognosis include multiple lesions and neutropenia [4]. Other organisms that may induce ecthyma gangrenosum-like lesions include *Ps. cepacia* and *Ps. maltophilia*, *Serratia marcescens*, *Aeromonas hydrophila*, *Klebsiella pneumoniae*, *E. coli*, *Vibrio vulnificus*, *Morganella morganii*, *Staphylococcus aureus*, *Mucor*, *Aspergillus fumigatus*, *Fusarium*, *Scytalidium dimidiatum*, *Candida albicans* and *Moraxella* [6,7].

Lucio's phenomenon

Lucio's phenomenon (erythema necroticans) is a rare syndrome almost exclusively limited to leprosy patients from Mexico and Central America, but is rarely reported from Cuba, South America, the USA, India, Polynesia, South Africa and South-East Asia [8–10]. It is a type 2 reaction that may be fatal, despite being the presenting feature of leprosy for many patients who develop this reaction. Lesions may be recurrent and sometimes cyclical over periods of 2 months to 10 years, most often on the legs, but occasionally on the arms and trunk [9]. Lesions usually begin as painful purpuric macules, plaques or vesicles, often ulcerate and heal with atrophic scars. Unlike erythema nodosum leprosum, it is restricted to patients with diffuse non-nodular lepromatous leprosy, is not associated with fever, leukocytosis or tenderness, and fails to respond to thalidomide.

At least in some reports, some lesions appear to induce non-inflammatory retiform purpura, eschar or ulceration [8,9]. Ulceration of lesions is common. Histological findings include either leukocytoclastic vasculitis or endothelial proliferation and thrombus formation in dermal or subcutaneous vessels, with a sparse lymphocytic infiltrate [8–10]. How often vasculitic change is secondary to necrosis or ulceration is unclear, but at least in some cases an occlusive mechanism for purpura and necrosis seems likely. Aggregates of bacilli within proliferating cells are evident on acid-fast stain of biopsy material [9,10].

Treatment includes the standard multidrug therapy for lepromatous leprosy (rifampicin, clofazimine and dapsone). Control of infection and attention to fluid and electrolyte balance are important. Prednisone, thalidomide and clofazimine may all be required to control the reaction. Response to treatment is often reported as poor, with severe morbidity and frequent deaths, but numbers of reported cases are small.

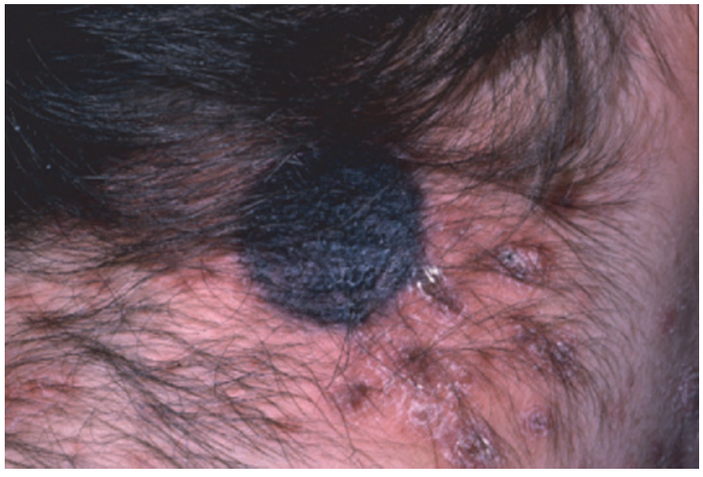

Fig. 49.12 Necrotic cutaneous lesion due to zygomycosis: invasion of vessel walls was apparent histologically.

Vessel-invasive fungi

As alluded to in the ecythema gangrenosum section, fungi may cause overwhelming infections in immunocompromised patients, often with cutaneous lesions, some of which may become purpuric or necrotic due to vessel-invasive organisms and thrombosis. *Aspergillus* and *Mucor* are two of the most commonly reported fungal groups to cause such vessel-invasive lesions.

Cutaneous lesions of *Aspergillus* may be either primary or secondary from haematogenous dissemination. Primary lesions typically occur at intravenous infusion sites, tubing sites secured by tape, or in skin in chronic contact with a colonized intravenous board [11,12]. Primary cutaneous aspergillosis can occur in immunocompetent patients, as well as in patients with burns or surgical wounds. Cutaneous lesions from systemic involvement have been divided into five categories: (i) a solitary necrotizing plaque; (ii) a subcutaneous abscess or granuloma; (iii) eruptive maculopapules with suppurative, vegetating or necrobiotic features; (iv) erythematous or exanthem-like reactions; and (v) progressive confluent granulomas [12,13]. Organisms in lesions appear as septate hyphae with acute-angle branching, invading blood vessels and surrounding tissues, often with minimal inflammation [13]. *Aspergillus fumigatus* is the most common cause of colonization and of disseminated infection by the *Aspergillus* group of fungi. *Fusarium* infections are increasing in frequency in patients with haematological malignancy; 72–91% of patients with this infection have skin lesions, which may be either metastatic or primary [14]. Metastatic skin lesions are described as either subcutaneous nodules, usually painful, or ecthyma gangrenosum-like.

The class Zygomycetes includes *Mucor*, *Absidia* and *Rhizopus* organisms, which can cause identical clinical manifestations (Fig. 49.12) [11]. Lesions may be either primary or secondary to disseminated disease, and include superficial vesiculopustules, ulcerating gangrenous lesions, purpuric nodules, cellulitis and necrotic ulcers. These organisms easily invade the epidermis and spread rapidly in the dermis, with vessel invasion by very large and long non-septate hyphae, resulting in thrombosis and infarction [15].

Response to therapy in these types of infection is relatively refractory. With *Fusarium* infections, for example, response rates are 30–48% with current therapies and support measures [14].

Disseminated strongyloidiasis

Strongyloides stercoralis is the nematode responsible for the human parasitic infestation known as strongyloidiasis. Affecting 100 million people worldwide, it is endemic in tropical or subtropical soil that is contaminated by faeces, in some temperate-zone areas such as the rural south-east and Appalachia of the USA, or in closed communities such as immigrant populations, close-quartered military personnel or institutions [16]. Filiform larvae from contaminated soil penetrate the skin, enter the blood vessels, exit through the lungs and migrate to the glottis, where they are swallowed [16–18]. They mature and reproduce in the upper small bowel, with hatching of non-infective (rhabditiform) larvae. Transformation of these into infective larvae can lead to autoinfection through penetration of intestinal mucosa or perianal skin [18]. Skin lesions with simple infection include papules or erythematous serpiginous tracts, which can extend several centimetres per hour and represent cutaneous migration of the larvae (larva currens).

In immunocompromised patients, including those on corticosteroids, hyperinfection and dissemination of organisms can occur [16]. In this setting, the diagnosis is usually made through examination of stool samples, and skin lesions are uncommon. However, with such overwhelming infection, petechiae, purpura and reticulated purpuric skin lesions have been described [16,17,19,20]. These lesions may be widespread but may cluster, particularly in the periumbilical region where they are said to have a thumb-print appearance. Biopsy of purpuric lesions has shown larvae within capillaries and between collagen bundles in the dermis, with extravasated red cells [20].

Mortality in disseminated strongyloidiasis is high, up to 70–90% [16]. Treatment is with oral thiabendazole, and may need to be prolonged in immunocompromised patients [17,18].

Occlusion due to embolus

Cholesterol embolus

Aetiology. The most commonly diagnosed cutaneous embolic syndrome is cholesterol embolus, which occurs secondary to fragmentation of ulcerated arteriosclerotic plaques, with distal cutaneous and visceral vessel obstruction. As it occurs secondary to atheromatous plaques, it is no surprise that cholesterol embolus is a syndrome reported primarily in men aged 50 years or older, and is associated with peripheral vascular disease and the known risk factors for atherosclerosis such as diabetes, hypertension and smoking [1,2]. Although cholesterol embolus may be spontaneous, known triggers include angiography, angioplasty, vascular surgery, intra-aortic pump placement, cardiopulmonary resuscitation (all inducing traumatic rupture of plaques, usually within hours or days), thrombolytic therapy (acute clot lysis in plaque with release of friable plaque within hours or days) and anticoagulation (slow reduction of clot with release of plaque fragments, usually after at least 2 months of therapy) [2,3]. Blue toe syndrome associated with coumadin use is a syndrome of cholesterol embolus and not of coumadin necrosis.

Clinical features. There are two 'classic' clinical triads of cholesterol embolus. The first comprises leg or foot pain, livedo reticularis and preservation of good peripheral pulses [3]. The second comprises livedo reticularis, renal insufficiency and eosinophilia [4]. Cutaneous findings are frequent in patients recognized as experiencing episodes of cholesterol embolus. Reported in 35% of patients in one series, findings include livedo reticularis (49%), gangrene (35%), cyanosis (28%), ulceration (17%), nodules (10%) and purpura (9%) [1]. Additional clinical findings include fever, myalgia, altered mental status, sudden-onset arterial hypertension, gastrointestinal ulceration and renal insufficiency that may progress to renal failure [3,4].

The incidence of cholesterol embolization syndrome (CES) following vascular procedures has ranged from 0.15% to 30%, with large retrospective studies reporting figures of 0.6–0.9% [5–7]. Autopsy studies have shown cholesterol emboli in 77% of patients who underwent aortic aneurysm resection [6]. A prospective study of 1786 consecutive patients aged over 40 years who underwent left-heart catheterization found an incidence of cholesterol embolus of 1.4%, with nearly half having definite CES and the remainder having possible CES with primarily renal abnormalities [5]. Patients with cutaneous findings (livedo reticularis, blue toe syndrome or digital gangrene) were considered to have definite CES and comprised 48% of the total. In-hospital mortality was 16% and was associated with progressive renal dysfunction.

Investigation. Eosinophilia is a frequent finding in CES, occurring in up to 80% of patients, and may be related to generation of the C5 component of complement [5,8]. Pre-procedure elevation in serum levels of C-reactive protein has been associated with an increased risk of post-procedure CES [5]. Additional laboratory findings may include leukocytosis, thrombocytopenia, pyuria, eosinophiluria, blood-positive urine or stool, elevated values of red cell sedimentation rate, creatinine, urea and amylase, and decreased serum levels of complement [1,2,8].

The traditional recommendation for cutaneous biopsy of livedo reticularis has been elliptical excisions centred on normal skin areas within rings of livedo reticularis, deep enough to include an ample specimen of subcutaneous fat. However, our experience is that careful examination of the livedo reticularis reveals that many patients will have retiform purpura, and such areas are high-yield biopsy sites for demonstrating the diagnostic cholesterol crystals on histological examination. On histological examination, the arteriole involved in the skin is usually at the dermosubcutaneous junction, with elongated clefts within small-vessel lumina along with thrombi [9]. The clefts result from fixation-related dissolving of cholesterol crystals. In experimentally produced cholesterol embolus, a mixed inflammatory infiltrate may be seen in arterial walls within 24–48 h, followed by multinucleated histiocytes within 3–6 days, and subsequent occasional intimal fibrosis.

Treatment. Treatment of cholesterol emboli involves trying to minimize the risk of further embolization (removal of remaining plaque or perhaps stenting of an atheromatous segment of a major vessel), minimizing damage to end organs, and preventive therapies aimed at slowing progression of atheromatous disease. Statins, iloprost (prostacyclin analogue), pentoxifylline (oxpentifylline) and steroids have been reported as having limited success in therapeutic interventions to minimize organ damage [6,10]. As anticoagulant use may precipitate cholesterol emboli, avoidance of these agents in patients with known CES seems prudent [3,7]. However, some types of cardiac surgery that may precipitate CES may also require post-operative anticoagulation, for example valvular prostheses [3,7].

Oxalate crystal embolus

Oxalate crystals are a rare cause of symptomatic emboli, but can mimic the cutaneous findings of cholesterol embolism. Although primary hyperoxaluria is rare, it is the most common cause of oxalate crystal embolus. Two enzyme defects are associated with primary hyperoxaluria: type I hyperoxaluria (glycolic aciduria) is due to deficiency of the hepatic peroxisomal enzyme alanine: glyoxylate aminotransferase; type II hyperoxaluria (L-glyceric aciduria) is due to diminished activity of D-glyceric acid dehydrogenase [11,12]. Absorptive hyperoxaluria is also reported due to idiopathic intestinal hyperabsorption of oxalate. Secondary hyperoxaluria can be due to excessive intake of oxalate or its precursors (ethylene glycol, methoxyflurane anaesthesia, very-high-dose ascorbic acid), pyridoxine deficiency, ileal resection, some intestinal diseases or long-term haemodialysis [11,13].

Type I hyperoxaluria is the most common and has three forms. The infantile form has no history of nephrolithiasis but has rapidly progressive renal failure. The juvenile form is the common type I subset. In this group, recurrent calcium oxalate nephrolithiasis precedes renal failure. Patients with the adult form typically present with renal failure and later develop complications of oxalate tissue deposition.

Cutaneous manifestations of primary hyperoxaluria are primarily those of oxalate crystal embolization: livedo reticularis, acrocyanosis, and peripheral gangrene, purpura or ulcerations [12,13]. Secondary hyperoxaluria, especially when due to long-term dialysis, is more likely to lead to extravascular cutaneous deposits of oxalate, producing calcified cutaneous nodules, or firm miliary papules that tend to form on the palmar aspect of the fingers [14].

Cardiac sources of embolization

Atrial myxomas, marantic endocarditis and septic endocarditis can be associated with cutaneous embolic phenomena. Although rare, atrial myxomas are the most common benign cardiac tumour, with an estimated incidence of 0.03% [15] and onset usually between the third and sixth decades [16]. The left atrium is the most frequent tumour site. Symptoms may partly mimic those of infectious endocarditis, connective tissue disease, vasculitis or rheumatic fever, with constitutional symptoms such as fever, malaise, arthralgia or weight loss. Obstruction of intracardiac blood flow mimicking valvular disease or embolic phenomena may also occur. Lentigines may be a cutaneous finding in the hereditary NAME or LAMB syndrome, which is associated with cardiac myxomas. Cutaneous findings of myxomatous emboli include livedo reticularis, splinter haemorrhages, Raynaud's phenomenon, an acral papular eruption with claudication, serpiginous or annular purpuric lesions of the fingertips, red–violet malar flush, petechiae of hands and feet, or toe necrosis [16–18]. Histology can confirm myxomatous emboli, but finding the emboli may require serial sectioning and multiple biopsies [16,19]. An echocardiogram is useful in evaluating patients with a history or physical examination compatible with emboli. Atrial myxomas require surgical treatment.

Marantic endocarditis results in the attachment of fibrin vegetations to heart valve leaflets, similar to those seen in acute rheumatic endocarditis and Libman–Sacks (APLS) valve disease, and these vegetations can embolize [19]. Infective endocarditis can also produce emboli from vegetations, but these are usually associated with acute bacterial endocarditis. Lesions in subacute bacterial

endocarditis may be from either emboli or immune complex-related vasculitis. Idiopathic hypereosinophilic syndrome is associated with intracardiac mural thrombi, which can also produce emboli [20,21]. Documentation of cutaneous emboli is limited, with clinical lesions described as splinter haemorrhages, non-blanching livedoid discoloration, or necrotic, blistering or purpuric lesions [22–24].

Crystal globulin vasculopathy is a rare syndrome, usually associated with IgG or light-chain paraproteins, that can produce intravascular occlusion by spontaneous crystallization [25,26]. This syndrome results in rapidly progressive renal failure, polyarthropathy, peripheral neuropathy and skin lesions. Cutaneous lesions include ulcerations, petechiae and ecchymoses, with intravascular thrombus and crystalline deposits [27].

Other emboli

Petechiae, which may be few or very numerous, are an important sign of fat embolism [28,29]. They occur particularly on the upper part of the body 2–3 days after a major injury and are an important clue to this diagnosis. Minute fat emboli have been found within the vessels at the sites of the petechiae.

Emboli may also occur from tumours at sites other than the cardiac myxomas discussed above.

Systemic coagulopathies with cutaneous predilection

There are several systemic coagulopathies that have a predilection for the cutaneous microvasculature. Cutaneous lesions may occasionally be a minor feature of a multiorgan syndrome, the most prominent findings of multiorgan involvement or sometimes the sole target of occlusion. The importance of recognizing these syndromes is critical in order to begin early, and sometimes syndrome-specific, therapy. There are two natural anticoagulant pathways that exist in humans. The most well known, the antithrombin III–heparin/heparan pathway, is important for primarily venous large-vessel thrombosis. The only cutaneous lesions related to antithrombin III disorders are stasis ulcers secondary to recurrent venous thrombosis with venous insufficiency. In contrast, disorders of the thrombomodulin–protein C/S anticoagulant pathway are important causes of severe cutaneous occlusion syndromes.

An understanding of this pathway is important in diagnosing and treating these syndromes. The end point of the coagulation cascade is conversion of prothrombin to thrombin, which rapidly catalyses the conversion of fibrinogen to fibrin and clot formation. The procoagulant role of thrombin is well known; less well known is its critical role in anticoagulation. When thrombin fails to bind to procoagulant sites on membranes and binds instead to the membrane protein receptor thrombomodulin, this powerful prothrombotic molecule undergoes a remarkable transformation. Bound to thrombomodulin, thrombin becomes ineffective at binding and activating clotting factors, and instead rapidly converts protein C in the plasma to activated protein C. Activated protein C, stabilized by certain phospholipids and by protein S, down-regulates clotting by cleaving circulating activated clotting factors, including factor VIIIa and most importantly factor Va. It thus exerts an anticoagulant effect; deficiency of protein C, or of its co-factor protein S, therefore creates a procoagulant tendency. The factor V Leiden mutation renders the factor V Leiden molecule much less sensitive to cleavage by activated protein C (APC

resistance); about 5% of the UK and Caucasian North American population are heterozygous for this mutation (reported incidence is highest in Cyprus, Sweden and Turkey at 10–15%, and lowest incidence in Asia and Africa, and in populations of those ethnicities). This protection from cleavage means that activated factor V Leiden remains longer in the plasma and continues to enhance coagulation. It would be expected then that factor V Leiden mutation should be synergistic with deficiencies in the thrombomodulin–protein C pathway. In fact, in some kindreds of protein C-deficient families, the presence of the factor V Leiden mutation appears to be an important predictor for who will develop large-vessel thrombosis in individuals with similar levels of protein C deficiency.

Another major cluster of systemic coagulopathies with cutaneous microvascular occlusion are those related to lupus anticoagulant activity and APLS. The mechanisms for clotting in this group are less well understood, and will be addressed following discussion of protein C/S-related syndromes.

Protein C/protein S-related disease

Neonatal purpura fulminans: homozygous protein C or protein S deficiency

Protein C and S deficiencies can be inherited autosomally with variable penetrance. Patients who are heterozygous for deficiency may develop repeated venous thrombosis or pulmonary embolism early in adult life, or may be asymptomatic [1,2]. One variable affecting the likelihood of thrombosis in these individuals is known—the previously mentioned co-inheritance of homozygous or heterozygous factor V Leiden mutations [3,4]. The frequency of homozygous protein C deficiency is estimated at 1 in 250 000–500 000 births [1]. Homozygous deficiency of either protein C or protein S is associated with neonatal purpura fulminans as well as with cerebral and ophthalmic vessel thrombosis. Retiform (stellate) purpura and necrosis is the most typical cutaneous finding that results from thrombosis within the cutaneous microvasculature. Skin lesions typically begin within a few hours to 5 days after birth, and are most commonly distributed on the extremities, abdomen, buttocks and scalp; they may localize to sites of pressure or previous trauma [1,5,6]. Laboratory findings are consistent with DIC, with evidence of consumption of clotting factors (prolonged partial thromboplastin time, PTT), clot lysis (elevated fibrin split products) and often thrombocytopenia. In the absence of appropriate therapy, lesions invariably progress to full-thickness cutaneous necrosis.

Traditional treatment included fresh frozen plasma to try to replace deficient protein C or S, or oral anticoagulants to reduce procoagulant factors. More recently, protein C and activated protein C concentrates have been used for treatment of both acute disease and as prophylaxis against subsequent episodes [7,8].

Coumadin (coumarin, warfarin) necrosis: severe acquired protein C dysfunction

Coumadin necrosis usually presents as the sudden onset of pain within affected areas 3–5 days after beginning coumadin therapy, followed by well-demarcated erythema progressing to haemorrhage, necrosis and often haemorrhagic bullae or eschar [9]. Although coumadin necrosis may rarely involve acral areas, acral cutaneous purpura in patients on coumadin is more likely to be due to cholesterol embolus—so-called purple (blue) toe syndrome. The risk of coumadin necrosis is increased if loading doses (10 mg or more) of warfarin are used and if a second form of anticoagulation such as heparin therapy is not used to cover the initial phase of anticoagulant therapy [10,11]. Warfarin (coumadin) necrosis is more likely to occur in areas with abundant fatty subcutis, such as breast, hip, buttocks and thigh [9,10]. The peak incidence is between the sixth and seventh decades, and is four times higher in women.

The therapeutic effect of coumadin is due to inhibition of γ-carboxylation of the vitamin K-dependent coagulant factors II, VII, IX and X. Although these factors are still produced and may be antigenically detected within the plasma, without γ-carboxylation they are dysfunctional. Importantly, protein C and protein S are also vitamin K-dependent plasma factors, and their inhibition can lead to a prothrombotic state. Protein C and factor VII, with half-lives of roughly 5 h, are particularly vulnerable to early inhibition, whereas protein S and the remaining procoagulant factors with much longer half-lives remain active for a considerably longer period [11,12]. There is thus a period, after the early inhibition phase, when the anticoagulant effect of protein C has been inhibited but there is an excess of uninhibited procoagulant clotting factors. Although up to one-third of patients with coumadin-induced skin necrosis may have partial protein C deficiency, the majority of cases appear unrelated to inherited deficiencies of protein C [10]. As coumadin action mimics that of vitamin K deficiency, it would be expected that depletion of vitamin K should result in coumadin necrosis-like findings, but this has not been documented.

Restoration of protein C activity can be accomplished through protein C concentrates, and presumably also through the use of activated protein C. If these are not available, heparin therapy has been recommended.

Sepsis-related purpura fulminans (bland retiform purpura) with DIC: acquired severe protein C deficiency

The term ‘purpura fulminans’ is used by physicians for many different situations. It was originally coined in 1887 to describe a syndrome occurring days to a few weeks after some preceding infection, especially varicella zoster or streptococcal infections (now termed ‘post-infectious purpura fulminans’) [13]. The term ‘purpura fulminans’ has subsequently been used for widespread cutaneous haemorrhage in patients with sepsis, including infection with *Neisseria meningitidis*, *Staphylococcus aureus*, groups A and B β-haemolytic streptococci, *Streptococcus pneumoniae*, *Haemophilus influenzae* and *Haemophilus aegyptius* [14]. However, haemorrhage in patients with DIC may be due to septic vasculitis, simple bleeding or microvascular thrombosis. The patterns of cutaneous haemorrhage for each of these different mechanisms are distinctive, and can be a guide to pathophysiology and therapy [15]. Cutaneous microvascular occlusion in sepsis with DIC presents clinically as non-inflammatory (bland) haemorrhage, usually with a retiform, stellate or branching configuration, with rapid transition to necrosis and eschar [16,17]. In a small study, early biopsy of retiform purpuric lesions showed microvascular occlusion with fibrin, and perivascular haemorrhage with minimal to

no inflammation; these findings correlated with severe protein C deficiency [17]. This was not true of other forms of purpura in sepsis with DIC. The protein C pathway is increasingly recognized as critically important in bacterial sepsis, acting to inhibit both coagulation and inflammation [18]. The use of activated protein C concentrate in sepsis appears to be beneficial, especially in severe cases, although whether all patients with sepsis should receive this is not clear [19–22]. In patients with sepsis, DIC and retiform (occlusion) purpura, it seems reasonable to assume severe protein C deficiency in the acute setting and to treat appropriately. Protein C concentrates and plasma exchange have also been successfully used to replace protein C in purpura fulminans [23].

Post-infectious purpura fulminans: acquired severe protein S dysfunction

As mentioned previously, post-infectious purpura fulminans occurs primarily in children as rapidly progressive purpura a few days to weeks after a febrile illness [14,24,25]. The most common associated infections are varicella zoster and streptococci. This syndrome has been associated with lupus anticoagulant activity and with autoantibodies to protein S [14,25,26]. Replacement of protein S activity is difficult, presumably because this condition is not due to simple clearing of protein S but rather to inhibition of protein S function by an antibody. Such antibody-mediated dysfunction is difficult to overcome by replacement of factor, and concentrated sources of protein S are unavailable.

Antiphospholipid antibody/lupus anticoagulant syndrome

From the original description as recurrent venous or arterial thrombosis, repeated fetal loss and thrombocytopenia to consensus statement criteria, APLS continues to be redefined [27–29], most recently by the addition of β_2-glycoprotein I (β_2-GPI) antibodies to the laboratory criteria for diagnosis (Table 49.6) [30].

A variety of serological markers exist, usually detected as antibody against phospholipids (especially cardiolipin) in combination with antigens from a co-factor molecule (e.g. β_2-GPI, prothrombin, annexin V, plasmin, tissue plasminogen activator, thrombin), or as an inhibitor of an *in vitro* coagulation test. Detection of antiphospholipid antibodies is roughly five times more common than detection of lupus anticoagulant [31].

APLS may occur as a primary or secondary disorder. In one large study, primary APLS comprised 53% of cases, lupus-associated APLS 36%, lupus-like APLS 5% and other disease associations with APLS 6%, with catastrophic APLS occurring in 0.8% [32]. Compared with primary syndrome patients, lupus patients with APLS were more likely to have arthritis, livedo reticularis, thrombocytopenia or leukopenia. The mean age was 42 ± 14 years at study entry, onset of symptoms was most often in young to middle-aged patients (2.8% before age 15 years, 12.7% after age 50), and there was a strong female predominance (82%).

Mechanisms of coagulation in APLS are only partially understood. These antibodies were first detected in 1906 in patients with syphilis, and measured as false-positive serological tests for syphilis in 1952 [29]. However, today they are most often detected as β_2-GPI antibodies, lupus anticoagulants or antiphospholipid antibodies. The lupus anticoagulant activity is detected, often incidentally, by prolongation of the activated partial thromboplastin time (aPTT), the dilute Russell's viper venom time (dRVVT), or the kaolin clotting time [33]. Both a test of activation of the intrinsic pathway (either aPTT or kaolin clotting time) and direct activation of Factor X (dRVVT) is recommended. The presence of an inhibitor is determined by 1 : 1 mixing studies with normal plasma. As such mixing guarantees at least 50% levels of all clotting factors, failure to correct the clotting test indicates the presence of an inhibitor. The proof of phospholipid dependency for this inhibitor is often done by the platelet neutralization procedure, in which washed platelets are used to provide enough phospholipid surface to bind the interfering antibodies while still providing excess phospholipid to support the clotting reaction. Although prolongation of these tests would seem to predict a tendency towards bleeding, individuals with lupus anticoagulant activity very rarely bleed abnormally, but may be paradoxically predisposed to clot formation.

Antiphospholipid antibody activity is detected by one of several antibody assays, the most common being ELISA screens for IgG or IgM antibody affinity for cardiolipin, a negatively charged phospholipid molecule found in mitochondrial membranes. Although anticardiolipin antibodies can be detected in the absence of binding to a co-factor such as β_2-GPI, antiphospholipid antibodies which bind to phospholipid alone without a coactor molecule are not usually physiologically relevant in inducing thrombosis. Studies have shown that in patients with both lupus anticoagulant activity and anticardiolipin activity, there may be little or no cross-reaction between antibodies which bind to each. Both the lupus anticoagulant test and the various antiphospholipid antibody assays can be positive in a great many patients who never develop any thrombosis. Likewise, until the mechanisms responsible for thrombosis in patients with these antibodies are understood, it is possible that some patients with thrombosis may test negative with current assays, and yet ultimately be found to have disease mediated by antibodies interfering with physiological pathways responsible for clinical APLS.

Table 49.6 International consensus statement preliminary criteria for antiphospholipid antibody syndrome (definitive diagnosis requires at least one clinical and one laboratory criterion) [30].

Clinical criteria
Vascular thrombosis
One or more clinical episodes of arterial, venous or small-vessel thrombosis
Complications of pregnancy
One or more unexplained deaths of morphologically normal fetuses at or after 10 weeks of pregnancy or
One or more premature births of morphologically normal neonates at or before 34 weeks of gestation or
Three or more unexplained consecutive spontaneous abortions before 10 weeks of gestation
Laboratory criteria
Anticardiolipin antibodies, IgG or IgM, present at moderate or high levels on two or more occasions at least 6 weeks apart
Lupus anticoagulant antibodies on two or more occasions at least 6 weeks apart
β_2-Glycoprotein I antibodies on two or more occasions at least 6 weeks apart

The most important autoantigen in APLS appears to be β_2-GPI (apolipoprotein H), which binds anionic phospholipids as part of physiological disposal of apoptotic cells [34]. β_2-GPI is composed of five complement control modules, domains I to V. Infections may trigger β_2-GPI antibodies (e.g. leprosy, leishmaniasis and leptospirosis), as may childhood atopic dermatitis. These antibodies may differ from those that trigger thrombosis by binding to domain V of the β_2-GPI molecule, rather than to the domain I region which appears to be characteristic of the thrombogenic subset [35]. Infection-related antibodies, especially in leprosy, are more often IgM than IgG type. In general, IgM β_2-GPI antibodies are seldom implicated in thrombotic events, except perhaps in cerebral stroke. IgG antibodies to β_2-GPI, especially the IgG_2 subset, are the most likely to be thrombogenic [33]. The binding of the glycoprotein to negatively-charged phospholipid or *in vitro* to an irradiated negatively-charged plastic plate induces a conformational change in β_2-GPI, leading to exposure of a cryptic epitope in domain I and, in some cases, to autoantibody formation. *In vivo*, the usual binding sites for β_2-GPI which induce the conformational change are membrane phospholipids, especially phosphatidyl serine, which is expressed by agonist stimulation of platelets, for example, with flipping of membrane bilayer phospholipids that are normally on the inner surface to the outer membrane layer [35].

Multiple pathways have been implicated by which antiphospholipid antibodies may promote thrombosis: promotion of procoagulant reactions (interfering with protective membrane proteins such as β_2-GPI or annexin V), interference with anticoagulant pathways (inhibition of protein C/S and antithrombin III pathways), activation of platelets by membrane binding, interference with prostacyclin production and release by endothelium, or interference with fibrinolytic pathways (inhibition of endothelial plasminogen activator or kallikrein activation) [29,36–38]. However, current investigation points to β_2-GPI antibodies being the likely prothrombotic pathway in most patients. The mechanism of thrombosis with antibody-bound β_2-GPI is thought to occur predominantly through disruption of a crystal shield of annexin V which covers the membrane and ordinarily prevents binding of procoagulant molecules [39]. An important physiological role for β_2-GPI is believed to be inhibition of atherosclerosis by preventing scavenger receptor-mediated uptake of oxLDL by macrophages, but β_2-GPI antibodies binding to β_2-GPI-oxLDL mediates atherosclerosis by promoting phagocytosis of the oxLDL complex by macrophages via Fc receptors. This suggests that in addition to potential thrombogenesis, β_2-GPI antibody complexes may also be atherogenic.

Although thrombocytopenia was frequently mentioned in early descriptions of the APLS, this is no longer a diagnostic criterion for the syndrome. Mechanisms for thrombocytopenia or a role for APL antibodies have been difficult to find, but recently it has been shown that β_2-GPI may inhibit both von Willebrand factor-mediated platelet aggregation and binding of platelets to a von Willebrand factor-coated surface, and that antibodies to β_2-GPI reduce the ability of β_2-GPI to inhibit these activities [40]. If this is true, then a role for platelet-mediated vascular occlusion may exist in some patients with antibodies to β_2-GPI.

Investigators have shown that β_2-GPI-oxLDL complexes can frequently be detected in sera from patients with APLS and/or systemic lupus erythematosus, but not in healthy individuals [41]. Furthermore, patients with APS have been shown to have autoreactive $CD4^+$ T cells responsive to β_2-GPI in patients with APLS, and which can promote pathogenic IgG anti-β_2-GPI antibody production by autologous B cells. These T cells do not respond to native β_2-GPI, but will respond to chemically reduced or bacterially expressed recombinant β_2-GPI, further supporting the hypothesis that it is a cryptic epitope that is responsible for pathological β_2-GPI antibodies. This insight leads to the possibility of future therapies targeted at depleting or blocking binding domain I-directed β_2-GPI antibodies, or inhibiting their production through elimination or inhibition of the pathological autoreactive $CD4^+$ T-cell subset [41].

Table 49.7 Cutaneous findings in antiphospholipid antibody syndrome.

Livedo reticularis, with or without retiform purpura or retiform necrosis
Sneddon's syndrome
Livedoid vasculopathy/atrophie blanche
Raynaud's phenomenon
Anetoderma-like lesions with thrombosis
Behçet's-like lesions
Nailfold ulcers
Widespread cutaneous necrosis (catastrophic antiphospholipid antibody syndrome)
Leg ulcers, secondary to recurrent thrombosis with stasis, or from conditions in this table
Cholesterol embolus-like proximal livedo reticularis, with or without distal retiform purpura
Acral livedo
Degos (malignant atrophic papulosis)-like lesions
Pseudo-Kaposi's sarcoma
Vasculitis-like lesions
Pyoderma gangrenosum-like ulcers
Splinter haemorrhages
Superficial thrombophlebitis migrans

Clinically, APLS can present with a variety of cutaneous findings (Table 49.7) [42]. Livedo is one of the most common, but least specific as this and retiform purpura or necrosis occur in other microvascular occlusion disorders [42]. In one large study the frequency of these findings was livedo reticularis 24%, leg ulcers 5.5%, pseudovasculitis 3.9%, digital gangrene 3.3%, cutaneous necrosis 2.1% and splinter haemorrhages 0.7% [32]. Catastrophic APLS is an uncommon but disastrous variant in which patients typically present with widespread cutaneous necrosis and multiorgan failure, especially renal and pulmonary. Precipitating factors include infections, surgical procedures, drugs and discontinuation of anticoagulation. The most common extracutaneous manifestations of non-catastrophic APLS include deep-vein thrombosis, pulmonary embolus and central nervous system abnormalities.

Specific therapy in APLS awaits an understanding of the mechanism by which thrombosis occurs in individual patients, and thus the capability to use tailored therapies to specifically oppose that pathway in a particular individual. As alluded to previously, investigation of the role of autoreactive $CD4^+$ T cells driving B-cell production of pathogenic β_2-GPI antibodies may provide more effective therapies in the future. For now, treatment is empirical. Antiplatelet therapy is of uncertain benefit; most therapy depends

on acute and often chronic anticoagulation, either with standard or low-molecular-weight heparin initially followed by coumadin [34]. Antimalarial therapy may be of some benefit for atrophie blanche-like or Degos-like syndromes in lupus patients; evidence suggests a protective effect in lupus patients against arterial or venous thromboses [29]. There is evidence that hydroxychloroquine may interfere with the binding of IgG-β_2-GPI complexes on phospholipid bilayers or to a line of cultured human monocytic leukaemia cells, which may provide some rationale for possible prophylactic benefit in APLS patients [43].

Occlusion due to vascular coagulopathies

Sneddon's syndrome

Definition. This syndrome comprises generalized livedo racemosa or livedo reticularis with cerebrovascular lesions that cause focal neurological symptoms or signs [1–5]. Livedo racemosa is usually the first manifestation, initially affecting the lower trunk and proximal part of the legs but becoming more generalized. It typically has a broad network pattern (Fig. 49.13). Associated Raynaud's phenomenon or acrocyanosis may occur, and may be the presenting feature.

Incidence. This has been estimated as four cases per million population per year [5]. Sneddon's syndrome is twice as common in

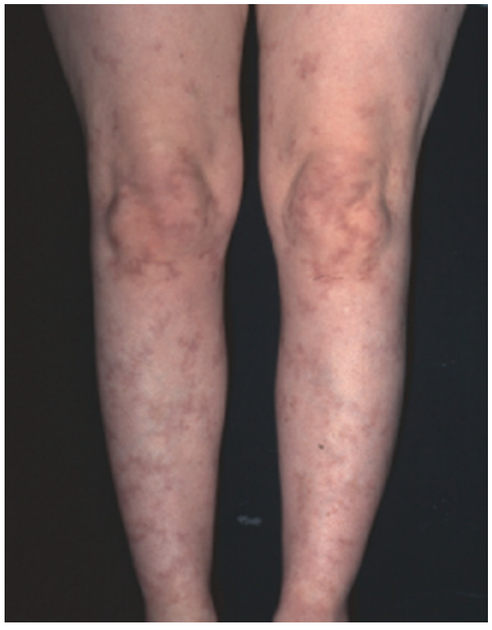

Fig. 49.13 Sneddon's syndrome showing a typical broad racemose livedo patterning.

women as in men, and typically presents in the fourth or fifth decade of life. It is usually sporadic, although familial Sneddon's syndrome has been reported.

Pathogenesis. Several authors have reported the presence of antinuclear antibodies or of antiphospholipid antibodies/lupus anticoagulant (reviewed in [6]), but others would only accept the diagnosis of Sneddon's syndrome if these antibodies were absent. Differences have been documented between the clinical features of patients with Sneddon's syndrome depending on the presence or absence of antiphospholipid antibodies; those without antiphospholipid antibodies typically have a larger-sized livedo pattern, whereas those with antiphospholipid antibodies have a higher risk of seizures, mitral regurgitation and thrombocytopenia [7]. It is likely that there is a spectrum of disease from APLS to SLE that includes the preferential arteriolar pattern of Sneddon's syndrome. Antiprothrombin antibodies were demonstrated in 57% of 46 patients in one series [8], and there are reports of platelet activation in a patient with persistently elevated levels of circulating PF4 [9], of increased levels of antithrombin III [10], of factor V Leiden mutation [11] and of activated protein C resistance [12].

Histopathology. Biopsies may show an endarteritis of dermal arterioles. It has been demonstrated that the most informative biopsies are from the clinically normal centre of any network area rather than from the peripheral 'watershed' area of livedo, and that taking multiple biopsies increases the sensitivity [13]. Initial changes are endothelial swelling with a mixed inflammatory infiltrate, progressing to vascular plugging, subendothelial proliferation and eventual vascular occlusion, fibrosis and disappearance of the inflammatory component [14]. It is possible, if not likely, that the histological findings in patients with antiphospholipid antibodies, especially in association with lupus or lupus-like disease, would be more typical of non-inflammatory occlusion.

Clinical features. In addition to the cutaneous livedo, there may be non-specific neurological prodromal symptoms such as headache, migraine, dizziness or vertigo. Later neurological features include focal paresis or hemiparesis, focal sensory or hemisensory symptoms, fits and visual defects, and later cognitive changes. Transient ischaemic attacks are commoner than completed stroke [15]. Peripheral nerves may also be affected. Hypertension may be present and confers a worse prognosis if untreated; hypertension and the neurological aspects are sometimes aggravated by pregnancy or use of oral contraceptives. There may be renal or cardiac involvement, including valve defects such as mitral regurgitation, although internal organ involvement other than neurological is often asymptomatic [5]. Other features such as shortened digits have rarely been reported.

The differential diagnosis is wide, from both the cutaneous and the neurological perspective. In particular, other causes of livedo and microvascular occlusion syndromes discussed in this chapter need to be considered as well as vasculitic causes (e.g. polyarteritis nodosa). However, it should be noted that other patterns of livedo with anticardiolipin antibodies may be associated with evidence of cerebral microthrombosis, for example livedo with summer ulceration or livedo with pyoderma gangrenosum-like lesions [16].

Magnetic resonance imaging (MRI), electroencephalography and arteriography may help to confirm the neurological component; skin biopsy (as above) and exclusion of other causes of livedo are necessary. Patients with positive antiphospholipid antibodies more commonly have infarcts in the distribution of the main cerebral arteries on MRI, whereas those with negative antibodies have small lacunar infarcts [17] and progressive leukoencephalopathy [15].

Treatment. There is generally no very effective treatment, reflecting the non-inflammatory nature of the disease. Corticosteroids may have some benefit but this is variable and often difficult to assess due to the intermittent nature of the neurological disease; other immunosuppressive agents are often disappointing. Avoidance of smoking and oral contraceptives, and treatment of hypertension and hyperlipidaemia (both of which are commonly present), are important. Thrombolytic agents and vasodilators have been used in the acute situation, and antiplatelet agents appear to be effective in the longer term [7]. In patients with antiphospholipid antibodies or lupus anticoagulants, maintenance of anticoagulation at an international normalized ratio (INR) of 2–3 seems warranted.

Livedoid vasculopathy; atrophie blanche

Synonyms
- Livedo reticularis with summer ulceration
- Segmental hyalinizing vasculitis

This syndrome is most common in young to middle-aged women as either an idiopathic or secondary syndrome [1]. One of the most commonly noted associations is with chronic venous hypertension and varicosities, although the atrophic scarring in this setting is not usually preceded by small painful ulcerations, nor with surrounding livedo reticularis. It would seem appropriate to separate venous stasis-related atrophie blanche from more typical forms of the syndrome.

Pathogenesis. The pathogenesis of livedoid vasculopathy is unknown. Clearly, APLS, with or without a lupus association, can produce this clinical syndrome [2]. Multiple pathophysiological abnormalities have been implicated, including platelet activation, factor V Leiden, altered fibrinolysis, antiphospholipid antibodies and hyperhomocystinaemia [1–4]. In one series of 32 patients, heterozygous factor V Leiden mutation was found in two of nine tested (22%), decreased protein C or protein S activity in two of 15 (13%), prothrombin G20210A mutation in one of 12 (8%), lupus anticoagulant in five of 28 (18%), anticardiolipin antibodies in eight of 29 (29%) and elevated homocysteine levels in three of 21 (14%) [5].

Histology. The most characteristic histological findings in this syndrome are some thickening or hyaline changes in the walls of superficial dermal vessels, and luminal fibrin deposition [1,6]. Red cell extravasation and perivascular lymphocytic infiltrates are expected findings. In a series of 45 skin biopsies from 32 patients, all but one showed intraluminal thrombus and direct immunofluorescence was positive in 86% [5].

Clinical features. Persistent, very painful and often punched-out ulcerations of the legs, especially around the malleoli, in women are typical of atrophie blanche [6]. The disease is bilateral in most cases. When accompanied by surrounding livedo reticularis, the term 'livedoid vasculitis' is more likely to be applied. Retiform or stellate purpura or ulcer extension can occur; healing results in a porcelain-white scar, frequently surrounded by telangiectasia. Besides venous hypertension and antiphospholipid antibody-related syndromes, sickle cell ulcers can show the same porcelain-white scar of atrophie blanche.

Treatment. Antiplatelet, anticoagulant and fibrinolytic therapies have been reported to be helpful in this syndrome, as well as anabolic steroids such as danazol and stanozolol [2]. PUVA therapy has been reported as effective in some cases [7]. In patients with lupus and atrophie blanche-like lesions, antimalarial therapy may be effective. Rapid relief of pain has been reported with use of intravenous immunoglobulins [8], postulated to be due to inhibition of the vasoconstrictor chemicals thromboxane A_2 and endothelin which thereby improves perfusion. Lipoprostaglandin E_1 has been used with good response in a patient with livedoid vasculitis and essential cryoglobulinaemia [9], but this may have been mediated by an effect on the cryoprotein levels, which fell dramatically; there are anecdotal reports of response to tetracyclines [10], and dapsone has also been used in patients with underlying myeloproliferative syndromes.

Malignant atrophic papulosis

Synonyms
- Degos' disease
- Kohlmeier–Degos' disease
- Lethal cutaneous and gastrointestinal arteriolar thrombosis

Definition. Malignant atrophic papulosis is a progressive vasculopathy causing occlusion of small and medium-sized arteries [1–6]. Originally reported separately by Kohlmeier [7] and Degos [8], it was also described as lethal cutaneous and gastrointestinal arteriolar thrombosis [9]. It is characterized by skin and gastrointestinal lesions, but neurological features are also frequent and post-mortem studies show widespread organ involvement. The skin lesions are usually the first feature, and may be the only manifestation over many years [2]; whether this represents a truly 'benign' variant is uncertain.

Incidence. It is rare; a review in 1995 suggested that about 120 cases had been reported [4]. It is mainly reported in white people, has a slight male predominance and is mainly a disease that presents in young adults, although it can affect any age group [3,5]. Familial cases have been reported [10].

Pathogenesis [3,5]. The pathogenesis probably involves abnormal coagulation, although the precise mechanism is uncertain. Platelet and fibrin thrombi are apparent in dermal, mesenteric and nervous system blood vessels, and both abnormal platelet aggregation and inhibition of fibrinolysis have been reported [3,5,11–14]. However, most patients have no clear evidence of a systemic coagulopathy, suggesting that the thrombotic tendency is at the microvascular level. Antiphospholipid antibodies have been documented in a small number of patients, usually in the context of SLE, although they may also occur even in the benign cutaneous variant [15].

There is also some support for a mechanism involving vascular inflammation. An autoimmune mechanism is suggested by the occurrence of lesions resembling malignant atrophic papulosis in some patients with SLE, rheumatoid arthritis, scleroderma or dermatomyositis [16–19]; antiendothelial antibodies have also been demonstrated but are probably not the cause of the disease [5]. Circulating immune complexes, or deposition of immune complexes or complement, are not usually demonstrated [2,20]. Although there can be a prominent lymphocytic infiltrate in later lesions, especially around venules, true arteritis and leukocytoclasis are not found [3,5,21].

Abnormal mucin deposits, which may be thrombogenic, occur even in early lesions although they tend to be more apparent in later lesions [3,5,21]. It is possible that they may be induced by activated T cells.

A viral aetiology was proposed on the basis of electron microscopic demonstration of interwoven tuboreticular structures resembling viral inclusions within endothelial cells [22], but these are seen in other disorders, including SLE, and can be induced by interferon [5]. Cases have been reported with HIV infection but a causal association is unproven.

Histopathology [2–6]. The histological picture in Degos' disease depends upon the duration of the lesion biopsied. Early lesions show a superficial and deep perivascular, perineural and periappendageal chronic inflammatory cell infiltrate [21]. Deep dermal vessels show endovascular inflammation, proliferation and thickening with thrombosis [23]. Mucin deposition is seen at all stages [2–4,21,24], and fibrin deposition may be demonstrated; fibrinoid necrosis of vessel walls may occur [23]. Immunofluorescence is occasionally positive for IgG or C3. From a histopathological perspective, the presence of lymphocytes, which may be seen within the damaged vessel wall, is viewed as abnormal and has led to classification of Degos' disease as a lymphocytic vasculitis [25] although it is not documented that this is a primary abnormality. Later lesions show a classical 'wedge-shaped' pattern of sclerotic change in the dermis, which is usually only sparsely cellular. Between these stages there is a phase with neutrophilic and eosinophilic infiltrate around adnexae and a dense perivascular lymphocytic infiltrate [21]. The epidermis, initially showing a mild vacuolar reaction, becomes atrophic with slight scaling, resembling that seen in lichen sclerosus and corresponding with the typical 'porcelain-white' colour seen clinically. There may be some associated pigmentary incontinence.

Panniculitis resembling that seen in lupus profundus has recently been reported [26]. Similar changes occur in the intestinal wall, particularly the submucosa. The muscularis mucosae is intact. Blood vessels are thickened and disorganized, with fibrinoid degeneration; platelet–fibrin thrombi are more prominent than in skin biopsy material.

Microaneurysms of the bulbar conjunctival vessels have been described. Renal changes include thickening of the afferent glomerular arterioles and of the capillary basement membrane.

Clinical features [1–8]. Cutaneous lesions usually precede systemic manifestations by months to years. They develop as crops over a period of time and are usually asymptomatic, although they may be preceded by slight burning. Skin lesions affect any site, mainly the trunk and proximal limbs; the face, palms and soles are generally spared. Although they may evolve gradually, and the number of lesions may vary considerably, about 30–40 active lesions are usually present [4]. Oral mucosal lesions are rare but penile lesions may occur [27]; the bulbar conjunctiva is often affected by lesions, which appear as sharply demarcated avascular areas [4]. Peristomal lesions have been reported.

Early skin lesions are pink or red, dome-shaped papules, usually 2–5 mm in size but sometimes up to about 15 mm. Papules soon become necrotic and umbilicated with central 'porcelain-white' pallor and scaling, and the pink oedematous border becomes telangiectatic. Most heal rather slowly to leave a small white scar, often surrounded by telangiectases as in atrophie blanche. Urticaria-like, ulceropustular and gumma-like nodules have been reported. New crops of lesions may continue for several years.

Similar lesions occur in many organs. Gastrointestinal lesions are the most important, as perforation of the gut is a cause of death. Neurological symptoms are also relatively common. The features in different systems include the following [4].

- Gastrointestinal: dyspepsia, abdominal pain or distension, bleeding, perforation, peritonitis, fistulae (enteroenteral or enterocutaneous), obstruction, pancreatitis
- Neurological: cerebral infarction (causing headache, aphasia, dementia, focal epilepsy, hemiparesis, pseudobulbar palsy), cord infarction (paraplegia/quadriplegia, transverse myelopathy), peripheral nerve (cauda equina syndrome, mononeuritis multiplex), various sites (sensory disturbance)
- Ocular: ptosis, diplopia, nystagmus, ophthalmoplegia, optic neuritis, papilloedema, visual field loss, pupillary reaction defects, conjunctival avascular lesions, posterior subcapsular cataract
- Cardiovascular: renal artery occlusion, pericardial effusion, constrictive pericarditis, ventricular wall defects
- Pulmonary: pleuritis.

Differential diagnosis. There is sometimes a resemblance to atrophie blanche or to guttate lichen sclerosus, although the evolution of lesions is different. Identical lesions have been described in cases of various connective tissue diseases [16–19] and in a patient with Crohn's disease [28]. The characteristic features can scarcely be confused. A disorder termed 'cutaneous–intestinal syndrome with oropharyngeal ulceration' [29] included a combination of macular, blistering and crusting lesions of the skin, with oropharyngeal ulceration and death from perforation of one of many intestinal ulcers. This differed both clinically and histologically from Degos' disease. Patients in whom systemic disease precedes skin lesions may cause particular diagnostic problems.

Prognosis [4]. Although possibly overestimated by reporting bias, and acknowledging that there does appear to be a benign cutaneous ('skin-limited') variant, mortality of 50–60% within 2–5 years is anticipated. Prognosis in males appears to be worse than in females.

Treatment. There is no consistently effective treatment [2–4]. Steroids do not help, although some benefit in neurological symptoms has been suggested. Aspirin, antiplatelet agents, fibrinolytic agents and pentoxifylline, alone or in combination, may lead to remission and are perhaps most effective in the cutaneous disease [2–6,11,15,30–32]; phenylbutazone has been reported to be effective. Heparin may produce short-term benefit. There is one report of a good response to transdermal nicotine patches [33]. Warfarin, dextrans, chloroquine, immunosuppressive agents and plasma exchange have all been tried. Surgery to treat intestinal perforation may resolve the acute situation but is difficult as there are usually multiple lesions, and there is no long-term benefit from this approach.

Occlusion due to reticulocytes

Patients with sickle cell anaemia may develop leg ulcers, which in tropical climates typically progress rapidly due to secondary bacterial infection [1]. However, in temperate climates the lesions are often perimalleolar, quite painful, and may heal with a porcelain-white scar, often mimicking atrophie blanche. Although this ulceration might be attributed solely to sickling of erythrocytes with microvascular occlusion, similar ulcers have been reported in other instances of severe chronic haemolytic anaemia, such as thalassaemia or antibody-mediated haemolysis, where sickling is not possible [2]. Multiple studies of possible occlusive mechanisms in sickle cell disease have shown that both young and old red cells have abnormally sticky membranes. In addition, abnormal leukocyte adhesion may initiate occlusion episodes, followed by adhesion of erythrocytes to these leukocytes, with a drop in tissue perfusion, followed by hypoxia and sickling with propagation of occlusion [3]. A number of platelet, procoagulant, anticoagulant and fibrinolytic abnormalities have been noted in sickle cell disease [3–5]. These might more properly be considered consequences of sickle cell disease vasculopathy [6]. A central mechanism for this vasculopathy seems to be haemolysis-associated reduction in the bioavailability of nitric oxide. Consequences of this reduction include endothelial cell activation, upregulation of the vasoconstrictor endothelin-1, vasoconstriction, platelet activation, increased tissue factor, and coagulation activation. Some of these mechanisms may be operative in other haemolytic anaemias, such as paroxysmal nocturnal haemoglobinuria (see previously) and thalassaemia [7]. Patients with sickle cell disease who are treated with hydroxycarbamide (hydroxyurea) appear to have a higher rate of ulcer development than other patients treated with hydroxycarbamide [7]. Although the mechanism is unclear, macroerythrocytes may play a role in initiation of hydoxyurea-induced leg ulcers and also in syndromes of severe haemolytic anaemia with high reticulocyte count and very early reticulocytes, but without sickling [2]. Whatever studies eventually prove, it seems that erythrocytes or their lysis may play an active role in some occlusive syndromes.

Occlusion due to other mechanisms

Calcific uraemic arteriolopathy

Synonym
- Cutaneous calciphylaxis

Calcific uraemic arteriolopathy is a rare, but increasingly frequent, complication of renal failure and dialysis [1–4]. It may very rarely occur in other situations, such as alcoholic liver disease, and occasionally after chemotherapy, in patients with normal renal function. Women are most at risk, accounting for over 80% of cases, mainly in the sixth decade, and even in non-dialysed subjects about a third have diabetes [2]. One large institutional study showed that, compared with other patients on dialysis, risk factors included obesity, liver disease, corticosteroid use, elevated calcium-phosphate product and elevated aluminium levels [2]. Hypoalbuminuria (or albumin infusions), recent rapid weight loss, protein C or protein S deficiency, warfarin treatment and hypotension have also been implicated as risk factors. The original term ‘calciphylaxis’ referred to an experimental situation of systemic necrosis in rats that were hypercalcaemic due to treatment with vitamin D or with parathyroid hormone, but did not specifically relate to vascular calcification, hence the change in terminology [3].

Early lesions tend to present as painful plaques, often with a retiform or stellate pattern, and may show central necrosis. They may resemble the lesions of hyperoxaluria. Some may become semiconfluent as a ‘broken’ livedo. The abdomen, thigh and hips are typical sites but the breasts may be involved, in some patients the disease is mainly acral, and uncommon sites include the penis and the tongue [5,6] as well as muscles and internal organs [3]. Woody induration with extending ulcer and eschar formation typically develops.

Pathologically, there is calcification in the medial layer of the wall of small subcutaneous vessels, with necrosis of overlying tissue [1–4]. Some calcification may occur in dermal vessels, in septae within the subcutaneous fat, and in adipocytes themselves. Thrombosed vessels are seen occasionally, presumably as a secondary effect as the calcification of small-vessel walls extends more widely than the thrombotic change or the extravascular calcification [4]. Dermal inflammation may occur without ulceration, and bullae sometimes occur.

Most patients have secondary or tertiary hyperparathyroidism, although the disorder can rarely occur in some with primary hyperparathyroidism. An elevated calcium–phosphorus product is generally expected, but some authors have suggested that this may be present in only a third of cases. Use of vitamin D, or of calcium carbonate (used as a phosphate binder in chronic renal failure), are risk factors. Relevant aspects of calcium homeostasis are discussed in [3]. Vascular calcification induces a phenotypic switch of the vascular myofibroblast to one of an osteoprogenitor. Local (paracrine) pro-mineralization chemicals that are involved include osteopontin (itself stimulated by high glucose levels), bone morphogenetic protein-2 (BMP-2) and Pit-1, as well as matrix metalloproteinases that are stimulated by a catabolic state.

Inhibitors of mineralization include parathormone-related peptide (which is inhibited by vitamin D) and matrix Gla protein (which is inhibited by warfarin); fetuin A inhibits calcification but is inhibited by vitamin D. Thus vitamin D, a commonly used treatment (often as the precursor alpha-calcidol) in chronic renal failure, and warfarin, may both provoke this process, although vitamin D is also used as therapy in patients with hyperparathyroidism who are not considered suitable for parathyroidectomy. It is felt that tensile stress and vascular stasis within calcified areas may also play a part by creating tissue ischaemia.

Parathyroidectomy has been cited as effective, but there is clearly bias in patient selection for this procedure towards those who can tolerate the procedure and are therefore a relatively healthy subgroup. Reduction of the calcium–phosphorus product when elevated is recommended (using low calcium dialysate fluids, and non-calcium oral phosphate binders), as is good wound care and attention to possible accompanying infection, which is a common cause of death. Hyperbaric oxygen, pamidronate, and tissue plasminogen activator have all been used in treatment. Newer treatments that may influence the outcome of this disorder include sodium thiosulphate [7,8], which increases solubility of calcium deposits and has an antioxidant function that may improve endothelial cell function, and cinacalcet hydrochloride [9], which is a calcimimetic therapy that suppresses levels of parathyroid hormone. Logically, cinacalcet should be most useful in patients with hyperparathyroidism and sodium thiosulphate in those without (or in whom it is controlled). Insufficient numbers of patients have been treated with these agents to determine their overall effect on outcome; the prognosis is generally considered poor, with mortality of 50–80%, although there are occasional reports of a more benign course [1,10].

Specific clinical presentations

This section briefly discusses clinical presentations that are common to a number of occlusive, embolic or vasculitis disorders, in order to allow an approach to the differential diagnosis.

Livedo [1,2]

Livedo describes a reticulate pattern of slow blood flow, with resultant desaturation of blood and bluish discoloration of the skin, which should be completely blanchable if vessels and the blood are normal. Livedo has been divided into two patterns.

Livedo reticularis tends to develop as a tight, net-like pattern of discoloration, often symmetrically distributed, and is more likely to be associated with general disturbances of blood flow such as cold-induced cutaneous vasoconstriction or vascular flow disturbances such as seen in polycythaemia or some cryogelling syndromes. Cutis marmorata in infancy is a perfect example of this pattern. Cutis marmorata telangiectatica congenita is a condition that causes a similar livid reticulate pattern because of telangiectasia.

Livedo racemosa typically has breaks in the tight, net-like pattern, resulting in larger, irregular rings ('broken livedo') than seen in livedo reticularis. It is seldom symmetrical. Livedo racemosa may be more indicative of focal impairment of blood flow, such as with vasculitis, and seems to be the pattern of livedo most often described in European cases of Sneddon's syndrome. The distinction between livedo reticularis and racemosa may be important, but frequently the term 'livedo reticularis' is used to describe both patterns, so careful documentation of the clinical usefulness of this distinction is limited. Finally, lesions of a variety of vascular occlusion syndromes have sometimes been described as lesions of livedo (as discussed above). Although livedo reticularis or racemosa may accompany or surround lesions of retiform purpura, the presence of purpura provides a more specific finding to aid in diagnosis. Whether such conditions frequently present with livedo alone is unclear as these terms have often been used interchangeably in the dermatological literature, and also because semiconfluent retiform lesions may sometimes resemble a broken livedo.

Localized lower extremity livedo (livedoid vasculopathy) is discussed further on p. 49.44.

Conditions that may present as livedo are listed in Table 49.8. It should be noted that more than one factor may apply in some patients, suggesting that a background abnormality has been 'exposed' by an additional event; examples include a patient with antiphospholipid syndrome and fibromuscular dysplasia of peripheral arteries, who developed livedo racemosa and digital necrosis [3]. The same applies in other retiform purpuras, such as phenylephedrine treatment causing microvascular occlusion syndrome in a patient with factor V Leiden [4], and the same applies in purpura fulminans (p. 49.39) in which, for example, meningococcal septicaemia causing thrombosis is strongly linked with background protein C or protein S abnormalities.

Table 49.8 Acquired livedo reticularis, non-physiological.

Vascular disease-associated
Vasculitis, especially microscopic polyangiitis, cutaneous periarteritis nodosa, rheumatic vasculitides, mixed cryoglobulinaemia, temporal arteritis, Sneddon's syndrome, livedoid vasculitis, arteriosclerosis
Rheumatic diseases
Lupus erythematosus, dermatomyositis, scleroderma, Sjögren's syndrome, antiphospholipid syndrome
Increased blood viscosity, decreased blood flow
Polycythaemia rubra vera, thrombocytosis, cryoglobulinaemia, cryofibrinogenaemia, cold agglutinaemia, monoclonal gammopathy, hypergammaglobulinaemia
Embolic and hypercoagulable disorders
Cholesterol emboli, thrombotic emboli (secondary to cardiac valvular disease, vascular stenosis or aneurysms, etc.), oxalate emboli, decompression sickness with nitrogen bubble embolization, ventilator gas embolization, antiphospholipid antibody syndrome, thrombophilias
Infection
Some reports of livedo with infection may be secondary to emboli (e.g. endocarditis), angiitis (rickettsial) or purpura fulminans-related occlusion (meningococcal); syphilis, tuberculosis and viral diseases are also important
Endocrine
Hyperparathyroidism, pseudohyperparathyroidism, hypothyroidism, Cushing's disease, carcinoid syndrome, phaeochromocytoma
Nutritional
Pellagra
Iatrogenic
Bismuth (intra-arterial), catecholamines/phenylephedrine, amantadine, quinidine (with drug-induced lupus syndrome), arsphenamine

Cutaneous necrosis

Necrosis of the skin occurs in numerous diverse conditions and may present a diagnostic and therapeutic dilemma. Many of the conditions leading to skin necrosis are discussed elsewhere in this chapter or in Chapter 50; vasculitis and vascular occlusion disorders comprise a significant proportion of such cases, but other disorders are briefly considered here [1–9]. Table 49.9 lists some of the more important causes of cutaneous necrosis. It is not intended to be comprehensive, and the disorders listed are those that either commonly cause cutaneous necrosis or in which cutaneous necrosis is a significant risk. The table therefore lists the most important diagnoses to consider, such as vasculitides or sepsis (Fig. 49.14). Not uncommonly, more than one cause may be present, for example in patients with HIV treated for HCV infection with interferon, or use of anticoagulants or chemotherapy in patients subsequently found to have protein C deficiency.

In some instances, the cause is uncertain; localized skin necrosis at injection or vaccination sites (embolia cutis medicamentosa, Nicolau syndrome) may in different cases be due to arterial spasm, thrombosis due to intra-arterial injection of the drug or arterial occlusion due to inflammation.

In some cases cutaneous necrosis may have predictive value, for example it has been suggested to be linked with the presence of underlying malignancy in patients with dermatomyositis [2].

Fig. 49.14 Acral necrosis due to sepsis; treatment with activated protein C may prevent vascular thrombosis in some patients.

Neonatal purpura [1]

The differential diagnosis of purpura or bleeding in neonates includes most of the causes of purpura. However, it is discussed as a separate entity due to the diagnostic dilemmas that may arise. The main causes are listed below.

- Deficiency of clotting factors and coagulation disorders (including purpura fulminans and vitamin K deficiency)
- Thrombocytopenia: congenital, maternal antibodies (ITP, SLE, others)
- Extramedullary erythropoiesis ('blueberry muffin' baby)
- Infections, e.g. TORCH syndrome, which comprises *t*oxoplasmosis, *o*ther infections (syphilis and viral), *r*ubella, *c*ytomegalovirus and *h*erpes simplex, may cause blueberry muffin baby; other infectious causes include HIV, parvovirus B19 and sepsis
- Congenital/inherited conditions, e.g. Wiskott–Aldrich syndrome
- Maternal antibody-mediated: autoimmune (ITP, SLE, drug) or alloimmune (isoimmune) due to fetomaternal incompatibility
- Associated with haemangiomas

Table 49.9 Some causes of cutaneous necrosis.

Coagulation defects [1]
Purpura fulminans, disseminated intravascular coagulopathy
Protein C or S deficiency, antithrombin III deficiency, prothrombin 20210A mutations

Vasculitis
Most vasculitides may cause skin necrosis, e.g. polyarteritis nodosa, Behçet's disease, Wegener's granulomatosis, Churg–Strauss disease, Henoch–Schönlein purpura (see Chapter 50)

Connective tissue disease (see Chapter 51)
Antiphospholipid syndrome/lupus anticoagulant, dermatomyositis [2], relapsing polychondritis, systemic lupus erythematosus, systemic sclerosis

Immunological
Shwartzmann reaction [3]

Hyperviscosity
Cryoglobulinaemia, cryofibrinogenaemia, cold agglutinins, paraproteinaemia, POEMS syndrome

Embolic
Cholesterol emboli, cardiac myxoma, bacterial endocarditis/septic emboli, emboli from arterial aneurysms, neoplasms, emboli through patent foramen ovale (thrombus, infective) from venous cannulae

Metabolic (see Chapter 59)
Diabetes, hyperhomocystinaemia, oxalosis, calciphylaxis [4], subcutaneous calcification

Arterial occlusion or spasm, neurovascular disease
Arteritis (e.g. temporal arteritis, Buerger's disease), Degos' disease, thrombosis, intra-arterial cocaine, aneurysm, anastomosis, compartment syndrome, embolia cutis medicamentosa (Nicolau syndrome), complex regional pain syndrome (reflex sympathetic dystrophy)

Infections (see Chapters 30–36)
Bacterial, e.g. necrotizing fasciitis, cellulitis, streptococci, clostridia, meningococcus, pseudomonas (ecthyma gangrenosum), leprosy (Lucio's reaction), sepsis (any cause) (Fig. 49.14)
Viral, e.g. HIV, cytomegalovirus, hepatitis B or C, herpes zoster
Fungal, e.g. deep/disseminated fungal infection (especially *Aspergillus*, *Mucor*, *Rhizopus, Histoplasma*)

Venoms
Snake bites, spider bites, stings (e.g. scorpion, stingray)

Drugs and toxins (see also Chapter 75) [5–8]
Systemic
- Anticoagulants, e.g. warfarin (coumadin), heparin
- Vasoactive drugs, e.g. vasopressin, norepinephrine, dopamine, metaraminol, β-blockers
- Chemotherapeutic drugs, e.g. methotrexate, bleomycin, cyclophosphamide, vincristine
- Cytokines and growth factors, e.g. tumour necrosis factor, interferons, interleukin-3, G-CSF, GM-CSF
- Antimicrobials, e.g. penicillins, sulphonamides, aciclovir, levamisole
- Antithyroid, e.g. thiouracils, carbimazole
- Toxins, e.g. carbon monoxide poisoning
- Illicit drugs, e.g. cocaine
- Miscellaneous, e.g. penicillamine, iodides, bromides, phenytoin

Topical
- Glutaraldehyde, cetrimide, calcium chloride, mustard gas, hydrofluoric acid, phosphorus

Injection sites
- Calcium salts, interferon, aminoglycosides, collagen, silicone, hydrocarbons, vaccines (DTP, BCG), iron dextran, chemotherapy extravasation, Depo-Provera, several illicit drugs, intra-arterial injections

Malignant disease
Leukaemia, lymphoma (especially angiotropic types), mycosis fungoides, lymphomatoid granulomatosis, hypereosinophilic syndrome, myelodysplastic syndrome, Langerhans' cell histiocytosis
Phaeochromocytoma (localized or acral necrosis)
Paraneoplastic thrombosis, paraneoplastic acral vasculopathy (Chapter 62)

Physical damage
Burns, radiation, trauma, factitious ulcer, sclerotherapy, liposuction

Inflammatory dermatoses
Sarcoidosis, pityriasis lichenoides acuta, febrile necrotic Mucha–Haberman disease, pyoderma gangrenosum and neutrophilic dermatoses, panniculitides

Miscellaneous
Intrauterine epidermal necrosis [9]

BCG, bacillus Calmette–Guérin; DTP, diphtheria–tetanus–pertussis; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte–macrophage colony-stimulating factor; HIV, human immunodeficiency virus; POEMS, polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes

- Traumatic: caput succedaneum and facial petechiae (prolonged vertex delivery)
- Others, e.g. vascular purpura, non-accidental injury (both rare in this age group).

The three most important groups for dermatologists are purpura fulminans, blueberry muffin baby and infections [1]. Purpura fulminans in the neonate is an important manifestation of protein S or protein C deficiency (discussed on p. 49.39). Skin lesions in blueberry muffin baby are distinguished from purpura as they are palpably firm and elevated, but non-palpable purpura may coexist. The TORCH group of infections may cause this condition, but haemolysis (such as rhesus incompatibility), hereditary spherocytosis and twin transfusion syndrome may also be associated with extramedullary erythropoiesis.

Haemorrhagic disease of the newborn is due to accentuation of the normal fall of prothrombin within the first week of life but is now uncommon due to routine vitamin K prophylaxis. An early form, within the first 24 h of life, may occur if there is maternal intake of drugs that interfere with vitamin K (such as oral anticoagulants), and a late form (1–12 months) occurs in children with impaired gastrointestinal absorption and may cause deep nodular ecchymoses. Haemophilia and other coagulation factor deficiencies only rarely cause bleeding at this age.

Of the many causes of purpura fulminans [2], the following are most likely in neonates or young infants:

- Acute infectious: usually bacterial sepsis [3], including meningococcus, streptococcus, *Haemophilus* and other infections
- Post-infectious: varicella, streptococcus and others (usually 7–10 days post-infection)
- Congenital protein C or S deficiency; factor V Leiden mutation
- Acquired protein C or S deficiency: coumarins, hepatic cholestasis, nephrotic syndrome, renal dialysis, marrow transplantation
- Heparin-induced skin necrosis (most cases are related to local skin injection).

In older children, additional causes include:

- Antiphospholipid syndrome
- Vasculitis: polyarteritis nodosa, Henoch–Schönlein purpura, others
- Thrombotic thrombocytopenic purpura/haemolytic uraemic syndrome, paroxysmal nocturnal haemoglobinuria
- Toxins and poisons: snake and spider bites (usually maximal purpura at the inoculation site).

Antiphospholipid syndrome (APLS) is rare in children although low-titre antiphospholipid antibodies, possibly provoked by infection, are relatively frequent (being found in about 10% of healthy children) [4]. Transplacental transfer of anticardiolipin antibodies occurs in neonates born to mothers with APLS but does not appear to result in thrombotic complications, despite the fact that antithrombin III levels are low in neonates and theoretically would represent a further risk factor. When APLS is associated with purpura fulminans, this is termed the 'catastrophic antiphospholipid antibody syndrome'; patients may have a preceding infection, rarely associated SLE, but do not tend to have protein C or protein S abnormalities [5].

It should be noted that the term purpura fulminans has been used either as a broad term for widespread cutaneous purpura of any type, or more specifically for disorders in which cutaneous microvascular occlusion is the known cause of widespread cutaneous purpura. Especially in neonates, in whom (in the absence of a clotting factor deficiency) infection and/or congenital thrombophilic states are the most likely associated causes of widespread purpura, it is prudent to assume that there may be a protein C or protein S abnormality.

Vasculitis

Introduction

Vasculitis is a term applied to inflammation and necrosis of blood vessels, whether they be arteries, veins or both. Vasculitis may be local or systemic, and may be primary or secondary to another disease process. Small vessels (such as capillaries, arterioles and venules), medium-sized vessels (such as visceral vasculature, including renal, coronary or hepatic arteries) and large vessels (the aorta and its great vessels) may be affected. Many vasculitides have a cutaneous component. A dermatologist can provide invaluable assistance in the clinicopathological diagnosis of vasculitis and by guiding patient evaluation and treatment.

Because of the wide range of organ systems affected by vasculitis of blood vessels of various sizes, the clinical presentation of the many vasculitides is varied. However, classic cutaneous manifestations, such as palpable purpura in dependent areas, typically the ankles and lower legs, characterizes smaller vessel involvement, whereas necrotizing livedo reticularis or multiple sites of peripheral gangrene characterize larger vessel vasculitis. It is also important to note that vasculitides may be present without any cutaneous signs or symptoms, especially in the case of cerebral vasculitis.

Infiltration of inflammatory cells with subsequent destruction of blood vessel walls is classically demonstrated in nearly all vasculitides. However, specific histopathological features are dependent on the type and size of the affected blood vessel.

Many vasculitides are triggered by various antigenic agents, such as infection or medication, or are related to underlying disease such as connective tissue, vascular or inflammatory bowel disease, myelodysplastic or other malignancies. However, a single trigger may be associated with several distinct vasculitides, implying that different and more specific mechanisms of inflammation apply in different disorders. Pathogenetic factors in vasculitis are discussed below.

Classification and nomenclature

The classification of vasculitides has been a confusing and debate-provoking topic over the last half century. The first attempt at a

1	Age at disease onset >16 years
2	Medication at disease onset
3	Palpable purpura
4	Maculopapular rash
5	Biopsy including arteriole and venule with histological changes showing granulocytes in a perivascular or extravascular location

At least three of the five criteria must be present. The presence of three criteria was associated with a specificity of 83.9% and a sensitivity of 71.0% [5].

classification was by Zeek in 1952 [1]. In her classification of necrotizing vasculitis, she incorporated a clinicopathological evaluation based on the size of the blood vessel involved in the inflammatory process. Zeek differentiated five types of necrotizing angiitis: periarteritis nodosa, hypersensitivity arteritis, rheumatic arteritis, allergic granulomatous angiitis and temporal arteritis [2].

Other factors that may be considered in the classification of vasculitis were discussed by Winkelmann [3]. He incorporated clinical classification, systemic versus cutaneous involvement, muscular vessel versus small vessel disease, and histopathological features in his schema. He also discussed 'laboratory vasculitis', which reviewed the laboratory findings of patients with vasculitis as part of a classification scheme, as well as aetiological factors of various vasculitides [3].

In 1976, James Gilliam [4] proposed a classification of necrotizing vasculitis as part of Medical Grand Rounds at the University of Texas Southwestern Medical Center.

The American College of Rheumatology published classification criteria for vasculitis in 1990 [5]. However, several problems exist with this classification scheme, which is shown in Table 50.1. Particular problems with the criteria include an attempt to codify histological findings of small vessel ('hypersensitivity') vasculitis using 14 biopsy criteria. Furthermore, the use of such terms as 'maculopapular rash', 'medication at onset' and 'eosinophils on biopsy', as well as the separate classification of Henoch–Schönlein purpura, seem inappropriate to most dermatologists.

In 1994, the Chapel Hill Consensus Conference [6] addressed the nomenclature problems relating to primary systemic vasculitides, aiming to create a standardized nomenclature (which is depicted in Table 50.2). This system divided the vasculitides into small, medium and large vessel types, but specifically did not aim to determine clinical criteria for classification or diagnosis of individual patients.

A further attempt to classify vasculitides based on an updated version of Gilliam's 1976 scheme is presented in Table 50.3.

Classifications based on histopathology features are described in [7,8]. Additional classifications have been proposed but have yet to stand the test of time; examples are described in [9–11] and discussed in [12]. Classifications that include, or are based on, serological markers such as antineutrophil cytoplasm antibodies (ANCA) are increasingly important, but the emphasis is often on primary systemic vasculitides and not all suggested classifications translate easily to understanding vasculitis of the skin. Thus, despite numerous attempts over 50 years, the development of a clinically relevant and easy-to-use classification system for vasculitis that incorporates clinical features, vessel size, histopathological and laboratory features, and aetiologies, is a goal that has not yet been fully achieved.

Despite the obstacles, various groups continue to incorporate current knowledge into revised classifications. As an example, the recent consensus criteria for the classification of childhood vasculitides produced by the European League against Rheumatism (EULAR) and the Paediatric Rheumatology European Society (PReS) have deleted the ACR age criterion for diagnosis of HSP, and have added the fact that skin or renal biopsy should show predominant IgA deposition [9] (the criteria state that there must be palpable purpura with at least one of four other criteria—

• Takayasu's arteritis
Larger vessel vasculitis with collagen vascular disease
Nodular vasculitis

diffuse abdominal pain, biopsy with predominant IgA deposition, acute arthritis or arthralgia and renal involvement).

The situation is further complicated by a number of disorders that appear to overlap with vasculitis, in that they may, in at least some cases, include vasculitis. A large group of 'neutrophilic dermatoses' come into this category; although we previously considered these as neutrophilic vascular reactions, the accepted spectrum of such disorders has widened, and histological evidence of vasculitis has been reported sufficiently often that, even though it may be a secondary effect, it is appropriate to discuss this group of conditions here (although epidermal neutrophilic dermatoses, such as neutrophilic IgA pemphigus, are discussed elsewhere). Indeed, in the case of Sweet's syndrome, one of the best accepted neutrophilic dermatoses, histological evidence of vasculitis was once considered inconsistent with the diagnosis but has recently been described as being present in 74% of 31 cases studied [13].

Similarly, the more aggressive forms of pityriasis lichenoides have a vasculitic component and are included here.

Between the extremes of pure vasculitis and pure neutrophilic dermatoses or vascular reactions, Behçet's disease may have pustules similar to bowel-associated dermatitis–arthritis syndrome, pathergy similar to pyoderma gangrenosum, and vasculitis of various sizes and types of blood vessel. The vasculitis of Behçet's disease arguably has features that separate it from other vasculitides, the associated aphthous ulceration of mucosae differs from the main vasculitides or neutrophilic dermatoses, and we have therefore discussed this as a separate entity with mixed features between vasculitis and neutrophilic dermatoses.

Pathogenesis of vasculitis

The pathogenesis of vasculitis is a complex subject, not least because there are likely to be many different pathogeneses reflecting the many different causes and pathological entities. This brief overview describes some of the major mechanisms and systems involved, with emphasis on those that have clinical importance (such as the diagnostic potential of ANCA). More detailed recent reviews can be consulted [1–9]; factors pertaining to specific vasculitides are summarized, with more specific references, in the relevant sections discussing specific types of vasculitis.

Histopathologically, cutaneous necrotizing vasculitis may be leukocytoclastic with a neutrophilic infiltrate and a presumed immune complex pathogenesis, or may be lymphomonocytic and pauci-immune; however, this is not always helpful diagnostically as the change from the former to the latter occurs as part of a dynamic sequence, leukocytoclastic vasculitis generating a secondary cell-mediated immune response. Factors that play a part in the pathogenesis of vasculitis include antigen–antibody related mechanisms (including autoantibodies and immune complex diseases), inflammatory cells and their lysosomal content, complement, cytokines, chemokines, adhesion molecules, vascular and cellular growth factors, genetic influences, pro-coagulant factors and the fibrinolytic system, as well as direct vessel wall damage (e.g. by some infectious organisms). Local blood flow influences the development of the vasculitis lesion, as evidenced by lesions occurring at areas of constriction by tight clothing, and local release of histamine also has a role. It is apparent that none of these factors operates in isolation—for example, endothelial damage will cause expression of cell-surface adhesion molecules, production of cytokines and influx of pro-inflammatory cells—so there is inevitably some overlap between the following sections, which address some of the more important and better documented factors involved in vasculitic inflammation.

Table 50.4 Theory of pathogenesis of cutaneous small vessel vasculitis. (Modified from [4].)

- Immune complexes interact with the complement system to generate C3a and C5a anaphylatoxins, which stimulate:
  - production of chemotactic factors which initiate chemotaxis of neutrophils
  - release of vasoactive amines (such as histamine), which cause endothelial cell retraction
  - release of proinflammatory cytokines (e.g. IL-1, TNF-α) which induce the expression of adhesion molecules (ICAM-1, VCAM-1, P- and E-selectin) in endothelial cells
  - adhesion molecules (ICAM-1, VCAM-1, P- and E-selectin) in endothelial cells
- Activation of the membrane attack complex of complement directly damages membrane integrity of endothelial cells
- Immune complexes deposit in vascular walls after histamine-induced endothelial retraction which increases selectin expression in endothelial cells
- Attracted neutrophils produce lysosomal enzymes in an attempt to engulf deposited immune complexes
- Neutrophils are activated through Fc binding and degranulate, and also produce reactive oxygen species
- Ultimate inflammation and 'bystander' fibrinoid necrosis of blood vessel wall

Antigens, immune complexes and complement

Antigenic triggers of immunological responses targeted at components of blood vessel walls elicit most vasculitides. The importance of circulating immune complexes has long been recognized in studies of serum sickness [1], and the deposition of immune complexes in blood vessel walls is the best characterized mechanism for the vascular injury associated with vasculitis [2]. This mechanism appears to be particularly important in leukocytoclastic necrotizing cutaneous small vessel vasculitis; potential antigens of relevance include bacteria, viruses, drugs and other chemicals. Most evidence for an immune complex-mediated pathogenesis is circumstantial (e.g. the demonstration of immunoglobulins in skin lesions) and is better documented for cutaneous small vessel vasculitis than for systemic vasculitides. It is generally accepted that immune complexes have a role in Henoch–Schönlein purpura (HSP), serum sickness, hepatitis B and C virus-induced vasculitis, urticarial vasculitis and cryoglobulinaemic vasculitis.

A theory about the pathogenesis of cutaneous small vessel vasculitis is described below and depicted in Table 50.4 [3,4]. The circulating immune complexes mediating vasculitis interact with the complement system to generate C3a and C5a anaphylatoxins which degranulate mast cells. They stimulate the production of chemotactic factors and subsequent chemotaxis, the release of vasoactive amines (such as histamine) and the release of proinflammatory cytokines which induce the subsequent expression of adhesion molecules. Circulating immune complexes may also be bound by myelomonocytic cells (via the Fcγ receptor) and by endothelial cells (via FcγRIIa (CD32)) [5]. Immune complexes with a sedimentation coefficient greater than 19S are deposited in vessel walls, a process that is strongly influenced by platelet-derived vasoactive amines. Endothelial cell retraction and detachment occur due to altered membrane integrity that is induced by vasoactive amines and probably by the membrane attack complex of complement [6]. Secreted cytokines, including interleukin-1 (IL-1), gamma-interferon (IFN-γ) and tumour necrosis factor-alpha (TNF-α), cause increased expression of adhesion molecules (ICAM-1, E-selectin and VCAM-1) and HLA-DR (the 'adhesion cascade') by endothelial cells, which recruit neutrophils [5]. The CD40 ligand, which is structurally similar to TNF-α and which is present on stimulated $CD4^+$ T cells, mast cells and platelets, may also activate secretion of cytokines and expression of adhesion molecules by endothelial cells. Neutrophils that are attracted to the site of immune complex deposition are activated *in situ* through binding of the fragment crystallizable (Fc) portion of the antibody, and release lysosomal enzymes in a teleological attempt to engulf the deposited immune complexes. This causes degranulation and destruction of the neutrophils (visible histologically as leukocytoclasis) with release of collagenase and elastase, and generation of reactive oxygen species, ultimately resulting in inflammation and 'bystander' fibrinoid necrosis of vessel walls. It is of practical importance to appreciate that neutrophils degrade immune complexes within 24–48 h after they are deposited [7], usually within 24 h; hence, direct immunofluorescence of vasculitis lesions older than 3–12 h will generally yield negative results [3,8]. Eosinophils are also attracted in some situations, and also contain cytotoxic lysosomal enzymes. Survival of neutrophils or eosinophils at sites of inflammation may be aided by the antiapoptotic effect of colony stimulating factors (this is discussed with relation to TNF-related apoptosis-induced ligand-3 (TRAIL3) and death receptors in the section on Churg–Strauss syndrome).

Immune complexes may also activate endothelial cells to produce tissue plasminogen activator (t-PA) and thus alter local fibrinolysis and vascular permeability [3]. There are therefore many complex and dynamic changes that occur.

Paraneoplastic vasculitis is thought to be caused by tumour antigens stimulating cell-mediated immunity or forming tumour antigen immune complexes, although direct vessel wall damage or occlusion can occur as a result of emboli. Haematological malignancies are the most common to be associated with vasculitis [9].

Antiphospholipid antibodies are important as a cause of microvascular thrombosis (Chapter 49). However, they also bind to endothelial cells and have numerous effects; they are proinflammatory, induce monocyte activation, stimulate cytokine and vascular adhesion factor expression, and result in a thrombophilic state [10]. In autoimmune conditions, binding requires plasma $\beta_2$glycoprotein-I (β_2-GP-I), which itself binds to endothelial cells and complexes with phospholipids.

Superantigens have also been implicated in development of vasculitis; this is discussed in more detail in the next section.

Complement activation leads to the adherence of C3b to immune complexes, such that they remain soluble and are cleared by macrophages. Immune complexes that have bound C3b also bind to erythrocytes via the complement receptor type 1 (CR1), about 90–95% of which is located on the surface of erythrocytes, leading to clearance of immune complexes from the reticuloendothelial system and preventing interaction with endothelial cells and other structures. Complement deposition is documented in skin lesions (e.g. in HSP) and genetic deficiency of complement is associated with immune complex diseases. However, IgA immune complexes in patients with HSP do not appear to activate the classical

complement pathway, although activation of the alternative pathway by IgA1 (the main IgA subclass in HSP) may allow complexes to be made soluble.

The role of infections [1–4]

Infections appear to provoke some vasculitides, particularly those relevant to dermatologists; the role of specific infections and the strength of such associations is discussed in sections relating to specific entities such as Henoch–Schönlein purpura (HSP) (in which a role for infective triggers is well documented) and large vessel vasculitides. Vaccinations have also been implicated in some vasculitides, notably acute haemorrhagic oedema of childhood and occasionally in cutaneous small vessel vasculitis. Conditions that mimic vasculitis, such as bacterial or fungal emboli, are not discussed here other than in terms of their potential to damage vessels. This section discusses mechanisms by which infections may be involved in pathogenesis of vasculitis, some of which may apply to other causes as well. There is evidence in most of the 'primary' vasculitides that at least some cases can be linked to one or another form of action of infective organisms [3]; the problems are that studies have produced conflicting evidence, that more than one infection may be linked with any particular pattern of vasculitis, and that the pathogenetic mechanisms have often not been elucidated. Several potential mechanisms, one or more of which may apply in some situations, have been proposed, as below. It must be stressed that this attempt to explain possible mechanisms is probably over-simplistic as they may not occur in isolation—for example, immune complexes may be formed in relation to an antigenic component of a circulating organism, to exposed antigens of an organism that has become intracellular, or to self antigens exposed by cellular infection. Equally, activation of cytokines may be a response to pathogens themselves, or be triggered by cellular damage consequent to an infection. Pathogens themselves may provoke a variety of different responses—for example, cytomegalovirus (a major cause of vascular morbidity in immunosuppressed individuals) infects and damages endothelial cells, causes ischaemia and thrombosis, and expresses antigens that may stimulate an immune response [5]. Thus, one or more of the following may occur as a result of infection:

1 Immune complex reactions (Gell and Coombs type 3 reaction): this has been discussed above as a major mechanism in vasculitis, due to several triggers (e.g. drugs) as well as in response to infections. Immune complexes may be formed between antibodies and an entire organism or specific antigenic components, and may become trapped in vessels, stimulating a cascade of reactions as described above. The pustular vasculitis of gonococcal infection and much of the vasculitis in subacute bacterial endocarditis probably occur due to immune complex formation, and circulating or tissue deposits of immune complexes have been found in hepatitis B, hepatitis C and human immunodeficiency virus (HIV) infections. Immune complexes related to infectious agents may be formed in the circulation or *in situ* in infected vascular cells.

2 Direct activation of complement by infectious organisms: as well as activating the classical complement pathway via formation of immune complexes, some microbial products directly activate the alternative pathway of complement. These include polysaccharides (e.g. from *Candida* spp.) as well as various parts of both Gram-positive and Gram-negative bacteria [1].

3 Direct activation of other pro-inflammatory mechanisms: bacterial lipopolysaccharides, as well as heat shock proteins from several organisms, induce tumour necrosis factor-alpha (TNF-α) production by macrophages, which in turn stimulates vascular endothelial cells to express cell adhesion molecules. Lipopolysaccharides and heat shock proteins also stimulate production of interleukins IL-1 and IL-6 from endothelial cells, and may directly stimulate secretion of matrix metalloproteinases.

4 Molecular mimicry hypothesis: if endothelial cells or other cells comprising vessel walls share epitopes with an infective organism, then humoral and cell-mediated responses to infection will also target the host cells that carry the same epitope. There is some evidence for this mechanism in, for example, renal involvement in HSP; group A β-haemolytic streptococci are implicated as a trigger in about a third of affected subjects, and renal glomerular vessels express nephritis-associated plasmin receptor (NAPlr) which is a streptococcal antigen [6]. Heat shock proteins, which are expressed by endothelial cells following stress, and which have considerable homology with some antigens of infective organisms, have been implicated in such a process but this is not a proven mechanism of autoimmunity in humans.

5 Superantigen hypothesis: superantigens directly activate T cells, without the need for antigen-presenting cells, by interaction with Vβ segments of the T cell receptor (TCR); they may also stimulate B cells. Analysis of Vβ sequences of the TCR of circulating T cells, or the V_H repertoire of B cells in lesional biopsies can be used to demonstrate patterns consistent with superantigen-induced proliferation. A role for superantigens of *Staphylococcus aureus* is a factor in atopic dermatitis (Chapter 24); in the vasculitides, most evidence for a role of staphylococcal superantigens has been documented in Kawasaki disease and in Wegener's granulomatosis (WG) [3]. In Kawasaki disease,

strains of *S. aureus* expressing the toxic shock syndrome toxin-1 (TSST-1) antigen have been implicated in causation. In WG, the evidence for a role of staphylococcal superantigens in disease perpetuation is better than for disease causation (and is supported by benefit from prophylactic treatment with cotrimoxazole). However, other infections have also been linked with both of these conditions [3], such as New Haven coronavirus in Kawasaki disease, so this hypothesis may not be the only pathogenetic factor.

6 Direct non-specific vessel wall or perivascular invasion and damage (also termed the bystander activation hypothesis), especially by vasculotropic viruses such as cytomegalovirus and human herpes-virus HHV-6; this causes both direct and indirect mechanisms of damage:
   i Direct damage: the infection may cause endothelial cell dysfunction, as well as generating cytokines and chemoattractants that augment the initial damage and attract pro-inflammatory cells that further extend the damage. Infected endothelial cells may express cell wall molecules that make them more procoagulant, more prone to oxidative damage, more able to bind inflammatory cells and less able to vasodilate. Infection may also alter other cells of the vessel wall, as discussed below.
   ii Indirect damage: it has been suggested that an additional effect of damage to the vascular cells is that it exposes sequestered autoantigens, thereby generating an autoimmune response. Additionally, some infections, via increased production of TNF-α and IL-1, may cause upregulation of cell surface expression of proteinase 3 (PR3) and myeloperoxidase (MPO) on endothelial cells and inflammatory cells. These proteins are the main targets for antineutrophil cytoplasm antibodies (ANCA), which, when bound to the PR3 or MPO, produce degranulation of neutrophils and a sequence of ongoing vascular damage and cytokine production. ANCA are discussed further below.

7 Altered self hypothesis: in this hypothesis the infective organism interacts directly with vessel proteins to create neo-antigens that in turn will activate the immune system.

8 Alterations of vessel wall components: various organisms may produce an increase in smooth muscle cells of the vessel walls, both by stimulation of the proliferation and migration of these cells and by inhibiting normal apoptosis [4]. Such processes may be important in medium and large vessel vasculitides.

9 Autoantigen complementarity hypothesis: this hypothesis has particularly been proposed in relation to ANCA-associated vasculitides [3,7]. In this hypothesis, the proposed immunogens are 'complementary' to parts of the PR3 and MPO ANCA autoantigens, that is are homologous with the amino acid sequence of the antisense RNA of the non-coding strand of the ANCA autoantigen gene. Such proteins could induce production of antibodies which react with the autoantigen. In support of this, many microbial and fungal proteins have sequences that show homology with the protein product of the middle portion of the antisense RNA of PR3. Thus, these infective agents could trigger production of ANCA-associated vasculitis.

Specific infections that have been implicated in individual vasculitis patterns or syndromes are discussed where appropriate in the relevant disease sections later, and a list of infections that have been documented as causes of vasculitis is provided on p. 50.55.

Effector cells: T lymphocytes and polymorphonuclear leukocytes

T lymphocytes are found in the inflammatory infiltrate in all vasculitis. In some types of vasculitis, lymphocytes and monocytes appear to be predominant, but this may also relate to the stage at which a biopsy is taken, many vasculitides characterized by neutrophils developing an increase in the proportion of mononuclears with the passage of time. $CD4^+$ T helper (T_H) cells secrete cytokines, notably IL-1, INF-γ and TNF-α, and cause recruitment of $CD8^+$ (cytotoxic) T cells, B cells and natural killer (NK) cells. The cytokines produced not only induce expression of major histocompatibility MHC 1 antigens, which can be presented to $CD8^+$ cells, but also upregulate expression of adhesion molecules by endothelial cells.

A role for γ/δ T lymphocytes ($CD3^+$, $CD4^-$, $CD8^-$) has been proposed in vasculitis. These cells are cytotoxic against various cells but also exhibit some T_H functions; they secrete many cytokines, including interleukins IL-2 and IL-4, granulocyte–monocyte colony stimulating factor (GMCSF) and INF-γ. They are thought to recognize portions of the major histocompatibility complex and peptide antigens within these structures, without the full antigen processing that is required to cause proliferation of α/β T cells, and also recognize human heat shock proteins, notably HSP65. They are found in significant numbers in the later stages of leukocytoclastic vasculitis, and are especially associated with infective causes of vasculitis [1,2].

A population of T lymphocytes that express CXCL8 appear to be important in chemoattraction of neutrophils in Behçet's disease and in pustular drug eruptions; their role in leukocytoclastic vasculitis and neutrophilic dermatoses is less certain [3].

Neutrophils and eosinophils are the predominant cells in many vasculitides, including most that are related to infections, drugs, foods, collagen vascular diseases, type II or III cryoglobulins, IgA-mediated, and many others [4,5]. They are recruited in response to infection; the other main pathogenetic processes that attract them to the skin have been summarized as vasculitis, antibody and complement, mast cell release and T-cell-mediated neutrophil

activation [6]. Neutrophil adhesion mainly occurs in small vessels, in a process that is induced by several factors, including stimulation by TNF-α or ANCA (MPO-ANCA being more potent than PR3-ANCA), although ANCA also accelerate polymorphonuclear cell apoptosis. The role of immune complexes has been discussed, but is still not fully understood. The interaction between ANCA, their antigens, and endothelial cells, in binding polymorphonuclear cells is discussed later, as ANCA play an important role in leukocyte–endothelial interaction. Binding and activation of neutrophils or eosinophils causes release of toxic enzymes and generation of reactive oxygen species, leading to tissue damage. This process seems to require the presence of CD18, as injected polymorphonuclear cells in CD18-deficient mice will gather around perivascular immune complexes but without causing vessel damage [7]. Interestingly, several single nucleotide polymorphisms (SNP) have been associated with MPO–ANCA+ vasculitis [8]. This suggests that some CD18 polymorphisms may facilitate polymorphonuclear cell adhesion, degranulation and respiratory burst, predisposing to vasculitis.

The mechanism by which leukocytoclasis occurs in vasculitis is also not fully understood; it also occurs in neutrophilic dermatoses in which vasculitis is an inconstant feature. The usual expectation would be for late apoptotic polymorphonuclear cells to be phagocytosed by macrophages; electron microscopy immuno-gold methods in anaphylactoid purpura have demonstrated that apoptotic polymorphonuclear cell removal may be incomplete, many polymorphonuclear cells in fully developed leukocytoclastic vasculitis having relatively intact nuclei but disintegration of plasma organelles and cell membrane [9]. One explanation for this relates to the prototypical tissue pentraxin PTX3, which inhibits the anticipated phagocytosis of late-stage apoptotic polymorphonuclear cells by macrophages. This has been demonstrated to be upregulated at sites of leukocytoclastic vasculitis infiltrates, with levels paralleling vasculitis activity; it may therefore permit accumulation of leukocytoclastic debris by inhibition of phagocytosis [10].

Antiendothelial cell antibodies and endothelial cell dysfunction in vessel wall injury

Antiendothelial cell antibodies (AECA) are of uncertain importance in the pathogenesis of vasculitis [1–4]. They can be identified at high titre in most patients with Takayasu's arteritis or with active thromboangiitis obliterans, and are variably demonstrated in patients with Wegener's granulomatosis (WG), microscopic polyangiitis, Kawasaki disease, hepatitis B-associated polyarteritis nodosa, Henoch–Schönlein purpura, Behçet's disease and systemic lupus erythematosus (SLE)-associated vasculitis. They are also found in several other connective tissue diseases and in haemolytic uraemic syndrome/thrombotic thrombocytopenic purpura, IgA nephropathy, ulcerative colitis and diabetes mellitus, as well as in some normal individuals. Some studies correlate their titre with disease activity in medium or large vessel arteritis, but whether this reflects a pathogenic role or vascular damage is unclear. The fact that they bind preferentially to endothelium of mesenteric vessels supports the possibility of a pathogenetic role in visceral arteritis [5].

Mechanisms by which AECA might have a pathogenetic role in vasculitis include those listed below [4], although it should be acknowledged that no target antigens of AECA are specifically expressed by endothelial cells, and also that endothelial cell-specific target antigens of AECA remain unidentified in systemic vasculitides [4]:

1 Direct activation, or indirect induction of activation, of endothelial cells: activation of endothelial cells leads to up-regulation of adhesion molecules such as intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1) and E-selectin [6,7]; this may be mediated by nuclear factor (NF)-κB [8]. Increased neutrophil cytotoxicity results. E-selectin is a promoter of endothelial cell activation and of leukocyte–endothelial cell interaction, being expressed on cytokine-activated endothelial cells, and might therefore have an active role in the pathogenesis of vasculitis; however, E-selectin levels in a variety of systemic vasculitides do not correlate with disease activity [9]. Identification of AECA with specificity for α-enolase, expressed by endothelial cells, and the possibility of this having an infectious trigger, is discussed in the section on pathogenesis of Behçet's disease. More recently, it has been shown that AECA upregulated expression of two inflammatory molecules, vascular adhesion protein-1 (VAP-1) and MHC class I-related antigen A (MICA) on renal endothelial cells in Wegener's granulomatosis, in turn leading to phosphorylation of stress activated protein kinase (SAPK)/c-Jun N-terminal kinase (JNK), activation of NFκB, and production of the chemoattractant cytokines monocyte chemoattractant protein-1 and granulocyte chemotactic protein-2; blocking SAPK/JNK significantly reduced the chemokine production and decreased expression of MICA, confirming that AECA have a role in generating pro-inflammatory endothelial cell responses [10].

2 Cytotoxicity, which may be direct, complement-dependent or indirect due to complement-independent antibody-dependent cytotoxicity: such cytotoxicity has been demonstrated in mice immunized with purified IgG AECA from a patient with Wegener's granulomatosis, and which subsequently developed

endogenous AECA with renal and pulmonary lymphoid infiltrates [11].

3 Induction of coagulation: von Willebrand factor, factor VIII and soluble thrombomodulin levels may all be increased in vasculitis, possibly due to AECA, although other evidence suggests that these changes are probably a secondary effect resulting from vascular damage. Soluble thrombomodulin levels have been shown to be related to disease activity in WG [9], although this is also increased in disseminated intravascular coagulopathy, thrombotic thrombocytopenic purpura, sepsis, malaria, diabetic microangiopathy and various other disorders in which there is damage to vessels.

4 Induction of apoptosis, for example by binding of phospholipids or of heat shock protein 60.

Several cytokines that may be involved in vasculitis are discussed later. Some cytokine events that are related to the interaction of endothelial cells and AECA have also been discussed above. Again, many of these effects are probably non-specific. For example, high levels of soluble VCAM-1 are found in Kawasaki disease but were even higher in febrile controls [6], and this finding is therefore presumably also a non-specific result of vascular injury. Similarly, nitric oxide production is also increased in some vasculitides but is not specific to an individual vasculitis syndrome; neutrophil-derived nitric oxide is known to be damaging to endothelial cells [12] (see above for a discussion of neutrophils).

Endothelial cell dysfunction has been recognized as a common event and active contributor in systemic vasculitis and connective tissue disease-associated vasculitis, rather than purely occurring as an uninvolved consequence of injury [13]. Endothelial cell dysfunction occurs at sites distant from active vasculitis in several primary small and medium vasculitides, independent of ANCA status or renal involvement (itself a cause of endothelial cell dysfunction), and with improvement correlating with disease suppression in some instances [13]. In Kawasaki disease, impaired endothelial cell function appears to persist for years after the clinical disease, with impaired fibrinolytic activity, and abnormal coronary blood flow, unrelated to the presence or absence of early-stage coronary artery aneurysms, after cold pressor testing [14]. Although this abnormality is prolonged in nature, it can be reversed by ascorbate. Circulating endothelial cell microparticles that can cause endothelial cell injury and apoptosis have been demonstrated in Kawasaki disease, as well as in some primary vasculitides, correlating with other markers of disease activity, and supporting a role of endothelial cell damage in the pathogenesis of these disorders [15]. Endothelial cell dysfunction has been related to either depressed release, or increased breakdown, of nitric oxide; polymorphisms of endothelial nitric oxide synthase (eNOS) have been related to risk of giant cell arteritis and Behçet's disease (discussed further in the section on Behçet's disease).

Antineutrophil cytoplasm antibodies

In comparison with other pathogenetic factors, many of which are either not routinely measurable or are of uncertain relevance to pathogenesis, antineutrophil cytoplasm antibodies (ANCA) have diagnostic value as well as an important role in the pathogenesis of vasculitis [1–13].

ANCA are classified, according to their indirect immunofluorescence (IIF) pattern on ethanol-fixed neutrophils, into C-ANCA (granular cytoplasmic staining with accentuation between the nuclear lobes), P-ANCA (perinuclear and/or nuclear staining) and atypical ANCA (various patterns, including diffuse cytoplasmic and 'very perinuclear'; atypical ANCA are also termed X-ANCA, snowdrift-ANCA or more recently a-ANCA) [3,7,9]. These patterns correlate with varying degrees of specificity to specific neutrophil granule contents (Table 50.5). ANCA are usually of IgG type but may be IgM or IgA. In addition to systemic vasculitides, ANCA may be positive in various infections (malaria, human immunodeficiency virus infection; HIV), connective tissue disorders (SLE, rheumatoid arthritis) and gastrointestinal diseases (inflammatory bowel disease, chronic autoimmune liver and biliary tract disease), as well as occasionally in some apparently healthy individuals.

In most disorders other than vasculitides, the types of ANCA identified are of P-ANCA or atypical ANCA type, and in most of these disorders there is no consistent ANCA specificity or correlation with disease activity. However, there are some exceptions, such as the association of cathepsin G-ANCA with malaria [14].

Table 50.5 Antigenic specificity and clinical correlates of antineutrophil cytoplasm antibodies.

Antigen	Usual ANCA pattern on IIF	Most commonly associated diseases
PR3	C-ANCA	WG, MPA, CSS, necrotizing and crescentic GN
MPO	P-ANCA	Idiopathic progressive GN, MPA, CSS, WG, SLE, ANCA-positive drug-induced systemic vasculitis, thromboangiitis obliterans
Cathepsin G	P-ANCA	IBD, especially ulcerative colitis, PSC, malaria
BPI (= CAP 57)	C-ANCA	Systemic vasculitis, SLE, IBD, PSC, cystic fibrosis, chronic airway infections, other chronic infections
Azurocidin (= CAP 37)	P-ANCA or C-ANCA	Systemic vasculitis, drug-induced systemic vasculitis
Lactoferrin	P-ANCA or atypical ANCA	Rheumatoid arthritis, SLE especially with serositis or livedo reticularis, systemic vasculitis, ulcerative colitis, PSC, hydralazine-related vasculitis, thromboangiitis obliterans
HLE	P-ANCA	WG, propylthiouracil-related systemic vasculitis, some other drug-induced vasculitides, HIV infection
β-glucuronidase	P-ANCA	IBD
Lysozyme	P-ANCA	SLE, IBD, HIV infection
h-lamp-2	P-ANCA	Necrotizing and crescentic GN, pyoderma gangrenosum
Others: actin, catalase, α-enolase, high mobility group protein	Anti-actin is C-ANCA, others P-ANCA or atypical	Mainly present in autoimmune hepatitis, primary biliary cirrhosis, inflammatory bowel disease

BPI, bactericidal permeability-increasing protein; C-ANCA, cytoplasmic antineutrophil cytoplasm antibody; CSS, Churg–Strauss syndrome; GN, glomerulonephritis; HIV, human immunodeficiency virus; h-lamp-2, human lysosome-associated membrane protein-2; HLE, human leukocyte elastase (also termed human neutrophil elastase, or simply elastase); IBD, inflammatory bowel disease; MPA, microscopic polyangiitis; MPO, myeloperoxidase; P-ANCA, perinuclear antineutrophil cytoplasm antibody; PBC, primary biliary cirrhosis; PR3, proteinase-3; PSC, primary sclerosing cholangitis; SLE, systemic lupus erythematosus; WG, Wegener's granulomatosis.

The presence of P-ANCA in SLE, although originally felt not to have any particular link with disease pattern [15], has been associated with serositis, livedo reticularis, venous thrombosis, anticardiolipin and anti-SSA/Ro positivity, and periodontal disease [16,17]; in particular, lactoferrin-ANCA is strongly linked with livedo reticularis [14]. Bactericidal/permeability increasing protein (BPI) ANCA and proteinase 3 (PR3) ANCA have also been linked with serositis in patients with SLE. Anti-dsDNA and anti-SSA/Ro antibodies may resemble P-ANCA, depending on fixation methods [18]. Human lysosome-associated membrane protein-2 (h-lamp-2) ANCA has been linked with pyoderma gangrenosum.

Generally, the P-ANCA pattern is relatively non-specific, having various (often undetermined) antigen specificities and often no link with disease activity. In contrast, the C-ANCA pattern almost always corresponds with antibodies against PR3, a 29-kDa neutral serine protease, and clinically with WG or other systemic vasculitis. In the context of systemic vasculitis, the important P-ANCA groups are those with antibodies against myeloperoxidase (MPO). It is therefore important to confirm MPO or PR3 antibodies, usually by enzyme-linked immunosorbent assay (ELISA), in the context of a positive ANCA test identified by IIF screening, and to refer to the more specific result where possible (e.g. as PR3-ANCA) [9]. Immunofluorescence is more sensitive, and ELISA more specific, so combining the two tests is most useful if clinical suspicion of an ANCA-associated systemic vasculitis is high. Other solid-phase assays such as immunodot and multiplex assay are also used.

A positive C-ANCA has a sensitivity of 66% (91% if only considering active disease) and specificity of 98% for WG [19], but may be positive in about one-third of patients with microscopic polyangiitis or with necrotizing crescentic glomerulonephritis, and in about 20% with Churg–Strauss syndrome (CSS). Patients with WG who are negative for C-ANCA/anti-PR3 usually have positive P-ANCA/anti-MPO. In addition, anti-MPO are found in about 65% with progressive idiopathic glomerulonephritis, in about 50% with microscopic polyangiitis or CSS, and may be found in SLE or in ANCA-associated drug reactions (notably to propylthiouracil or hydralazine). If ANCA are present in drug-induced systemic vasculitis the pattern is usually P-ANCA or atypical ANCA. It is important to be aware that 10–20% of patients with Wegener's granulomatosis, and 40–50% with Churg–Strauss syndrome, will have negative tests for ANCA (or may develop a positive test later in the disease). Of interest, patients with Churg–Strauss syndrome who are ANCA-positive are much more likely to have associated necrotizing vasculitis and, particularly, necrotizing and crescentic glomerulonephritis, than those who are ANCA-negative [20], suggesting the possibility that the vasculitic component of the disease may be ANCA mediated but that other manifestations may have a different pathogenesis [12]. A pathogenetic role for drug-induced ANCA is best documented in relation to propylthiouracil, but the ANCA response may be heterogeneous in comparison with the situation in primary vasculitides; of 19 patients with propylthiouracil-induced ANCA-positive vasculitis, all 15 with renal disease had MPO-ANCA but many other specificities were demonstrated in this group, over half of them having ANCA directed against cathepsin G and/or leukocyte elastase, and between a quarter and half having ANCA against one or more of lactoferrin, azurocidin and PR3 [21]. Production of ANCA requires competent T-cell and B-cell function; this may explain why anti-B cell treatments (such as the monoclonal antibody rituximab) can be effective in ANCA-associated systemic vasculitis such as Wegener's granulomatosis.

Numerous studies suggest a pathogenetic role for at least anti-PR3 and anti-MPO antibodies in systemic vasculitides. Both clinical and *in vitro* evidence for pathogenicity have been reviewed [12]. In particular, the IgG3 subclass of PR3 is implicated, a rise in titres in WG being predictive of relapse [3]; this subclass is a particularly strong activator of neutrophils. The role of ANCA in the

pathogenesis of vasculitis is multifactorial. ANCA cause activation of neutrophils primed by TNF-α (or by lipopolysaccharide), leading to production of reactive oxygen species, nitric oxide and cytokines such as IL-1 and IL-8 (a neutrophil chemoattractant), as well as enhancing degranulation with release of proteolytic enzymes. Neutrophils activated by ANCA up-regulate adhesion molecules, adhere to platelet monolayers or to TNF-activated endothelial cells *in vitro* rather than their usual behaviour of 'rolling', and develop pseudopodia [5]. ANCA also up-regulate expression of adhesion molecules (ICAM-1, E-selectin and VCAM-1; the adhesion cascade) and IL-6 production by endothelial cells, which in turn causes neutrophil adhesion, transmigration and tissue damage. The subject of endothelial cell adhesion and recruitment of neutrophils is discussed in detail in [22]. ANCA also stimulate monocytes to produce reactive oxygen species and to produce IL-8; monocyte activation may also be important in non-ANCA-associated vasculitides such as Behçet's disease [4].

Elastase is one of the main tissue-damaging enzymes released by neutrophil degranulation. It is potentially important that elastase stimulates release of tissue factor from cultured endothelial cells (human umbilical vein endothelial cells; HUVEC), as this may be relevant in development of microthrombi *in vivo* (PR3, but not MPO, also stimulates production of tissue factor from HUVEC) [23]. It is also of interest that autoantibodies to elastase enhance rather than decrease elastase activity, thus leading to tissue damage [24]; this might be a pathogenetic mechanism of injury by human leukocyte elastase (HLE)-ANCA.

Other cytokines and chemokines, and the cellular response [1–3]

Numerous cytokines have been implicated in vasculitis; some have already been discussed. Many are released as part of an acute phase response or because of upregulation of production by peripheral blood neutrophils or monocytes, such as IL-1, IL-2, IL-6, IL-8, interferon (IFN) and TNF-α. These may therefore be non-specifically elevated in vasculitis, but may play a part in ongoing damage. TNF-α is important for priming endothelial cells to express E- and P-selectin, ICAM-1 and 2, and VCAM-1 (see above), and also primes neutrophils to produce reactive oxygen species and to degranulate after exposure to ANCA. IL-8 is a potent neutrophil chemoattractant that is expressed by endothelial cells after stimulation by ANCA, and after non-cytotoxic binding of AECA. IL-6 has been studied especially in giant cell arteritis and Takayasu's arteritis, in which it appears to reflect disease activity. Increased levels of soluble TNF receptor have been demonstrated in ANCA-positive vasculitides.

Other chemokines that have enhanced tissue expression in vasculitis include monocyte chemotactic protein-1 (MCP-1), macrophage inflammatory protein-1α and -1β and RANTES (regulated upon activation, normal T-cell expressed and secreted) [4]. Expression of MAC-1 by neutrophils is up-regulated by ANCA.

Based on a mouse model in which genetic deficiency of IL-1 receptor antagonist (IL-1Ra) is associated with arterial inflammation, it has been suggested that IL-1Ra has a significant role in vasculitis and that a recombinant IL-1Ra might be a useful treatment [5].

T cells, monocytes and macrophages play a part in vasculitis injury, in addition to the role of neutrophils discussed above. Both $CD4^+$ and $CD8^+$ T cells accumulate at the site of injury. In WG there is a Th1 cytokine profile, with increased IFN-γ, TNF and IL-12 but

not IL-4, IL-5 or IL-10 [4], and CD28 expression; however, some studies have suggested a Th2 response in nasal mucosa, which may be of importance as nasal staphylococcal infection is associated with relapses in WG. Monocytes from patients with systemic necrotizing vasculitis produce more superoxide and MPO than monocytes from controls, and they can also be induced to express PR3 and to release IL-8 when exposed to ANCA [6]. However, monocyte activation also occurs in Behçet's disease, which is not ANCA-related. Defective macrophage apoptosis may lead to persistence and ongoing damage at the vasculitic site, as occurs with neutrophils [3].

Genetic factors

Familial clustering has been documented in some vasculitides such as WG, although this is uncommon [1,2]. Various explanations have been proposed, including the occurrence of TNF gene polymorphisms, genetic heterogeneity of ANCA antigens or their expression, and neutrophil Fcγ receptor polymorphisms. For example, expression of PR3 on resting neutrophils shows marked individual variation, the proportion of neutrophils expressing PR3 varying from approximately 10 to 80%, but being quite stable in any individual [1,3] This is now known to be genetically determined [4], and high expression has been associated with a higher risk of WG. Severe renal disease in WG has been linked with expression of the neutrophil receptor FcγRIIIb-NA1, although this is disputed [2,5]. The genetic region for elastase, azurocidin and PR3 is highly polymorphous, but no apparent associations with clinical disease have been identified [1]. Further polymorphisms are increasingly being documented; the association between some CD18 polymorphisms and Wegener's granulomatosis has been referred to earlier, and numerous polymorphisms have been linked with Behçet's disease (and are discussed in the relevant disease section). In particular, a predilection associated with various cytokine and inflammatory mediator alleles and polymorphisms, including polymorphisms in endothelial nitric oxide synthase (eNOS), in interleukin-10 (IL-10), IL-8, and CD28 genes, and presence of the antitumour necrosis factor-alpha (TNF-α) 1031C allele, are all associated with Behçet's disease susceptibility [6].

α_1-Antitrypsin (α_1AT) is a natural inhibitor of PR3 and elastase in neutrophil alpha-granules (as is caeruloplasmin for MPO). Deficiency of α_1AT may be genetic or may be acquired by the formation of α_1AT–PR3 complexes by anti-PR3 ANCA. An association between the α_1AT-deficient PiZZ phenotype and ANCA-positive vasculitis has been described, and PiZ heterozygosity has been linked with poor prognosis in ANCA-positive systemic vasculitis [7,8]. However, a large study of PiZZ-deficient sera showed an association with antibodies against elastase but not against PR3, MPO or lactoferrin, and α_1AT deficiency is not in itself sufficient to induce ANCA-associated vasculitis [5,9]. An α_1 protease inhibitor has been used with dramatic response in the treatment of chronic vasculitis in a patient with α_1AT deficiency [10].

In Kawasaki disease, the G2350A polymorphism in the angiotensin converting enzyme (ACE) gene has been associated with risk of the condition (but not with risk of coronary artery aneurysms) [11]; however, the itpkc_3 polymorphism in the inositol 1,4,5-triphosphate 3-kinase C (*IKPKC*) gene (a negative regulator of T cell activation) seems to be linked to immune hyper-reactivity and is associated with increased risk of Kawasaki disease itself and of coronary artery aneurysms [12]. There are also reported polymorphisms in chemokine receptor genes within the *CCR3-CCR2-CCR5* gene cluster, and polymorphisms in genes for some matrix metalloproteinases (a possible explanation for the variable risk of development of aneurysms).

In Henoch–Schönlein purpura (HSP), there have been reported associations with HLA class 1 alleles; HLA A2, A11 and B35 having an association with increased risk of HSP and HLA A1, B49 and B50 being associated with decreased risk [13]. These alleles did not appear to alter risk of renal disease, whereas some vascular endothelial growth factor polymorphisms may increase, or protect against, the risk of nephritis in HSP [14].

It is likely that advances in genetics will identify many polymorphisms that may alter susceptibility, severity or specific features of different vasculitides, quite possibly in a hierarchical or polygenic fashion [15].

Evaluation of the patient with suspected vasculitis

The essential aspects in the approach to a patient with suspected vasculitis, from a clinical dermatological perspective, have been described in various publications [1–14], some providing either flowchart [2,3,5,8,12] or algorithm approaches [7,11]. Additional approaches and classifications directed by histopathological features are also useful [15–17].

In broad terms, the evaluation of a patient with suspected vasculitis involves histopathological confirmation of the clinical diagnosis, an assessment of the extent of the disease (both the degree of skin damage, and the involvement of internal organs) and an attempt to establish an underlying aetiology. Clinical patterns that may suggest a vasculitis, other than the overtly vasculitic lesions discussed in this chapter, include cutaneous livedo, cutaneous necrosis, non-specific purpura and purple (blue) toe syndrome; these patterns can also occur in non-vasculitic microvascular occlusion disorders, and their significance and likely causes are discussed in Chapter 49.

Histopathological confirmation of suspected small vessel vasculitides is best performed by taking a punch biopsy of the lesions at the appropriate stage, recognizing that lesions represent various chronological stages of the disease process. Deeper, elliptical incisional biopsies should be performed for suspected larger vessel vasculitides. Processing part of the biopsy, or a separate biopsy, for direct immunofluorescence is potentially important. This initial investigative step usually confirms the presence of a vasculitis (or may show evidence of a vasculitis mimic, such as a vasculopathy). It also helps to define the type of vasculitis, based on vessel type and size, type of reaction (e.g. segmental arteritis in polyarteritis nodosa), infiltrating cells (e.g. prominently eosinophilic infiltrate in some drug-induced vasculitides), extent of infiltrate (e.g. pan-dermal small vessel disease in a patient with fever suggests possible sepsis) and may define a specific vasculitis process (e.g. CSVV with vascular IgA deposits in Henoch–Schönlein purpura).

In attempting to assess the extent of the disease, it is important to consider where circulating immune complexes may deposit. Specifically, the following systems should be evaluated, especially but not exclusively for the features listed:

- **General.** Myalgia, arthralgia, fever
- **Renal.** Proteinuria, haematuria
- **Nervous system.** Central or peripheral, diffuse or localized findings
- **Musculoskeletal.** Non-erosive polyarthritis
- **Gastrointestinal.** Abdominal pain, gastrointestinal bleeding
- **Pulmonary.** Pleural effusion, pleuritis, pneumonitis
- **Cardiac.** Pericardial effusion, pericarditis
- **Other systems.** Upper respiratory tract (larger vessel vasculitides), eyes (Behçet's disease, larger vessel vasculitides), larger vessels

The overall clinical pattern needs to be taken into account when evaluating internal disease, for example the combination of respiratory symptoms and mononeuritis multiplex would suggest possible Churg–Strauss syndrome.

Additional investigations should be performed to try to determine the aetiology of the vasculitis. It may be helpful to screen for medications, infections or diseases associated with immune complexes (connective tissue vascular diseases, malignancy, inflammatory bowel disease, etc.). Although 'directed' sequential blood tests are ideal, depending on the clinical picture and results of simpler tests, from a pragmatic perspective it is often the case that a 'vasculitis screen' is performed. Reasonable initial tests might include:

- Full blood count with differential white cell count
- Markers of inflammation: erythrocyte sedimentation rate (ESR), C-reactive protein (CRP)
- Electrolytes and hepatic transaminases, glucose
- Urinalysis for protein and blood
- Blood cultures (if pyrexial)
- Serology—ANA (+/− antibodies to extractable nuclear antigens; dsDNA if ANA positive), ANCA, complement C3 and C4, antistreptolysin-O titre, viral titres (e.g. hepatitis B and hepatitis C, possibly HIV, CMV, parvovirus B19 and others if recent infection), others if indicated or to exclude differentials (e.g. rheumatoid factor, electrophoresis, immune complexes)
- cryoglobulins
- chest radiograph (if symptoms, signs, ANCA-positive or suspected larger vessel disease)
- additional organ-directed investigations as necessary (renal, nerve, bone marrow biopsy; arteriography; etc.).

As well as being important for investigation of causes of vasculitis, blood tests requested should also include markers of severity (e.g. C-reactive protein, erythrocyte sedimentation rate), tests to determine the systemic effect of vasculitis (e.g. renal function) and baseline tests for possible corticosteroid or immunosuppressive therapy (glucose, thiopurine methylytransferase (azathioprine), G-6-PD status (dapsone), etc.).

The extent of additional investigation may depend on initial findings, severity of vasculitis and of general symptoms, and on response to therapy. It is important to remember, for example, that investigations for cutaneous small vessel vasculitis fail to demonstrate a cause in up to 50% of cases, and to consider the need for further investigation in a patient in whom the disorder is resolving. It is also often helpful to work with a colleague in internal medicine or paediatrics when evaluating the patient, particularly if larger vessel disease is suspected, as additional investigations might include biopsies of artery, kidney, lung or nerve, radiology studies such as arteriography of aortic arch or visceral vessels, etc. Even if the cutaneous vasculitis has resolved, it is appropriate to perform urinalysis and blood pressure monitoring subsequently (perhaps monthly and 3-monthly respectively, for 6 months) as delayed effects of concurrent renal involvement may become

apparent. In those who do have renal involvement, this may persist as renal impairment later in life [18] so there is an argument for annual tests of renal function in such individuals.

The information in the following sections discusses the definition, history, aetiology, pathogenesis, histopathology, clinical features, diagnosis and treatment of various vasculitides affecting small, medium and large blood vessels.

Cutaneous small vessel vasculitis

Synonyms

- Cutaneous leukocytoclastic vasculitis
- Hypersensitivity angiitis/vasculitis variants confined to skin
- Cutaneous necrotizing venulitis (necrotizing variant involving predominantly venules)

Definition. Affecting mainly cutaneous post-capillary venules, cutaneous small vessel vasculitis (CSVV) is the most common type of vasculitis in dermatology. Features of CSVV include palpable purpura, urticaria or ulcers on the legs. It affects both children and adults, and is seen more commonly in women. Extracutaneous manifestations of CSVV are by definition relatively uncommon and should prompt a search for other pathology such as Henoch–Schönlein purpura (HSP).

History and nomenclature. In the 1950s, Zeek described small vessel vasculitis related to drug exposure as a separate entity from large vessel vasculitis, and termed the small vessel vasculitis 'hypersensitivity angiitis'. Because of ambiguity, the term hypersensitivity angiitis was redefined by the Chapel Hill Consensus Conference in 1994 to describe patients with a small vessel vasculitis with primarily cutaneous involvement [1].

Aetiology and pathogenesis. A history of drug exposure or recent infection is frequently present in cases of CSVV, and circulating immune complexes can be identified in a large percentage of patients. It is important to be aware that CSVV can occur as part of microscopic polyangiitis or Wegener's granulomatosis, and that some patients with HSP may be erroneously thought to have 'simple' CSVV if renal involvement is delayed or if skin biopsy fails to show IgA deposits (as occurs in biopsy of older lesions). A detailed review suggested that about 50% of cases of cutaneous vasculitis are 'idiopathic', 15–20% due to infection, 15–20% related to inflammatory diseases (such as collagen vascular disorders), 10–15% due to medications and other drugs, and less than 5% are associated with malignancy [2]. CSVV is therefore a term delineating the extent of vasculitis, usually of leukocytoclastic type, but is really a diagnosis of exclusion, as discussed in more detail below.

Histopathology. Leukocytoclastic vasculitis with segmental inflammation in an angiocentric pattern, swelling of the endothelium, fibrinoid necrosis of vessel walls, extravasation of erythrocytes, and an infiltrate of neutrophils with karyorrhexis of nuclei (i.e. leukocytoclasia) are major features of CSVV (Figs 50.1 & 50.2).

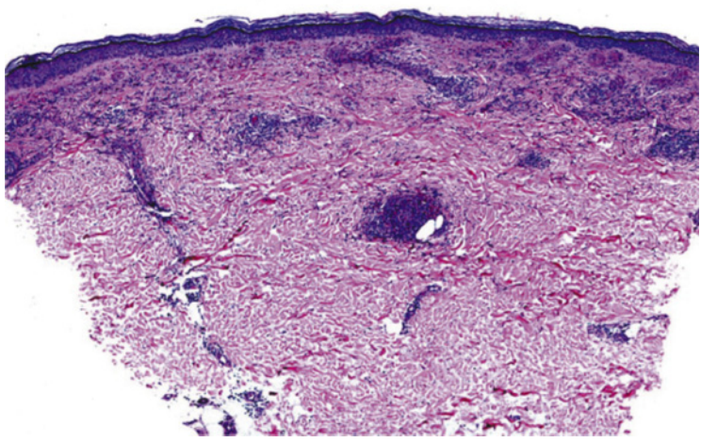

Fig. 50.1 Leukocytoclastic vasculitis. Low power photomicrograph showing perivascular infiltrates and fibrinoid deposits within the vessels of the upper dermis. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

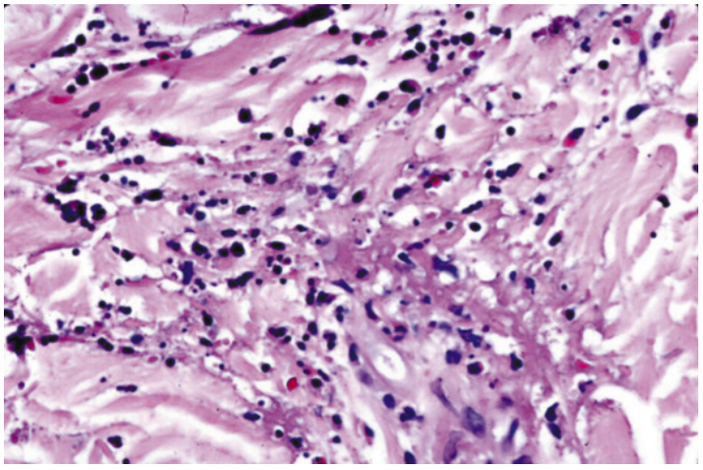

Fig. 50.2 Leukocytoclastic vasculitis. Higher magnification demonstrates nuclear dust, fibrinoid deposits, vascular alteration and collagen degeneration. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

In superficial dermal papillary vessels, IgM or complement C3 perivascular deposits are demonstrated in over 80% of fresh lesions [3]. Some studies state lower proportions, but this may depend on timing of biopsy and also because IgM is relatively poor at fixing complement. IgG is found less often.

Clinical features [2,4–13]. The skin lesions of CSVV typically arise as a simultaneous 'crop', resulting from the exposure to an inciting stimulus. They usually resolve within several weeks or a few months although, anecdotally, approximately 10% of patients will have recurrent disease at intervals up to years. In one retrospective analysis, a quarter of patients with cutaneous leukocytoclastic vasculitis had either a chronic course (over 3 months) or recurrent symptoms, including all those with hepatitis C-associated vasculitis and five of nine with a streptococcal aetiology [11]. The major cutaneous manifestation of CSVV is palpable purpura, ranging in size from 1 mm to several centimetres (Figs 50.3–50.5). Sometimes macular in the early stages, such purpura may progress to a wide array of lesions including papules, nodules, vesicles, plaques, bullae or pustules, with secondary findings of ulceration, necrosis and post-inflammatory hyperpigmentation. Other cutaneous findings include oedema, livedo reticularis and urticaria. The presence of the latter two should prompt consideration of cutaneous polyarteritis nodosa and urticarial vasculitis, respectively (see pp. 50.33 and 50.21). Lesions typically occur in areas prone to stasis, commonly including the ankles and lower legs [2,4–10], and typically sparing intertriginous regions. Although often asymptomatic, pruritus, pain or burning may be experienced, as well as systemic symptoms including fever, arthralgia, myalgia and anorexia. The presence of symptoms affecting other organ systems should raise the suspicion of other vasculitides such as HSP, mixed cryoglobulinaemia, or CSVV associated with polyarteritis nodosa (PAN) or with WG.

Diagnosis. A thorough history and physical examination is essential for correct diagnosis of CSVV, with screening for infections, connective tissue disease, medication usage and cancer. Vasculitides with systemic manifestations must be ruled out, as CSVV is diagnosed by exclusion. Table 50.6 describes the evaluation of a patient with a suspected CSVV (see also the preceding section 'Evaluation of the patient with suspected vasculitis', p. 50.12, and [2,8–10]). The differential diagnosis of CSVV includes many more specifically defined disorders, which are discussed in this chapter and listed in [2,3,9–13].

As indicated, a diagnosis of CSVV should be treated with some caution, not only because of the extensive differential diagnosis of the pathological features but also because other features may become apparent and make the diagnosis of CSVV, or of

Fig. 50.3 Cutaneous small vessel vasculitis on the thighs. There was similar involvement on the lower legs.

Fig. 50.4 Cutaneous small vessel vasculitis progressing to blistering.

(a)

(b)

Fig. 50.5 Vasculitis due to sepsis, in a patient with impaired level of consciousness. The necrotic lesion in (a) and the reticulate pattern on the leg in (b) are clues to involvement of deeper vessels. Histologically, vasculitis due to infection may involve vessels at all levels of the dermis.

Table 50.6 Evaluation of a patient with suspected cutaneous small vessel vasculitis.

Confirm the clinical diagnosis histopathologically
- Punch biopsy of lesion at the appropriate stage
- Direct immunofluorescence
- Incisional biopsy for suspected larger vessel vasculitis

Assess the extent of the disease

General
- Myalgia
- Arthralgia
- Fever

Renal involvement
- Proteinuria
- Haematuria

Nervous system
- Central or peripheral
- Diffuse or local findings

Musculoskeletal involvement
- Non-erosive polyarthritis

Gastrointestinal system
- Abdominal pain
- Gastrointestinal bleeding

Pulmonary involvement
- Pleural effusion
- Pleuritis

Pericardial involvement
- Pericardial effusion

Attempt to establish the aetiology (idiopathic in 50%)
- Drugs
- Infections
- Diseases associated with immune complexes
- Connective tissue vascular diseases
- Malignancy
- Inflammatory bowel disease
- Chronic active hepatitis

Idiopathic (50%)

idiopathic CSVV, insecure. The frequency of this occurrence is difficult to ascertain as some retrospective analyses exclude patients with associated collagen vascular disease, infection, etc. Two retrospective reviews of patients diagnosed as having cutaneous vasculitis or CSVV suggest that about a third of patients may have a more specific diagnosis or evidence of internal disease. In one study of 90 patients with CSVV, renal involvement was documented in 39 (43%); in 29 of these, renal biopsy was performed and led to reclassification as HSP (10 patients), microscopic polyangiitis (MPA) (13 patients) or WG (six patients) [14]. In a review of 93 patients, 57 were felt to have 'hypersensitivity vasculitis', the remainder having more specific diagnoses including HSP (11), urticarial vasculitis (six), types of polyangiitis (microscopic polyangiitis, five; classic PAN, one; cutaneous PAN, three), WG (two) and others; 20/93 had renal involvement, comprising six each with hypersensitivity vasculitis and HSP, and four each with microscopic polyangiitis and septic vasculitis [11]. In this study, 44% were classed as idiopathic.

Treatment. Treatment of CSVV is typically unnecessary, as the disease is usually self-limiting. The evidence for efficacy of any therapy in the management of vasculitis is derived from clinical experience rather than controlled trials. However, if any triggering agents are identified, such as a drug or infection, they should be removed or treated. Efforts to minimize stasis, such as use of compression hosiery and elevation of dependent areas, as well as the use of non-steroidal anti-inflammatory drugs (NSAIDs) and antihistamines, typically produce a decrease in symptoms [10], although there is little reason to suppose that they alter the course of the disease. Furthermore, oral corticosteroids at a dosage of 30–80 mg once daily, tapered over 2–3 weeks, often give effective symptom control, although no controlled trials have been carried out to evaluate the treatment of CSVV with oral corticosteroids. Corticosteroid use may be of particular benefit in cases with painful progressive cutaneous lesions, and they prevent glomerulonephritis in patients who actually have HSP. No data support

Table 50.7 Therapeutic ladder for patients with cutaneous small vessel vasculitis.

Symptomatic relief
Supportive therapy (3)
Antihistamines (3)
Non-steroidal anti-inflammatory drugs (2)
Skin lesions alone

Rituximab (3)

1, double-blind studies; 2, case series; 3, case reports.

the use of topical corticosteroids or antibiotics in CSVV, although such therapies are commonly used. Colchicine given at a dose of 0.6 mg twice daily has been shown to be of benefit by anecdotal evidence and open-label studies [15–17]. Similarly, the use of dapsone is based only on anecdotal or small case series, yet some believe that the use of dapsone along with colchicine may be advantageous in the treatment of CSVV [18–21]. In patients with disease refractory to the above therapies, cytotoxic agents may be considered. Such agents include azathioprine (typically at a dosage of 2 mg/kg/day; see also Chapter 74), methotrexate at a low dose of less than 25 mg/week, ciclosporin and cyclophosphamide [22–26]. Table 50.7 describes a therapeutic ladder for patients with CSVV. A therapeutic ladder based on individual diagnostic entities is provided in [2].

More recently, biological agents have shown some promise in the treatment of vasculitis, although they are rarely required for CSVV; infliximab, which blocks TNF-α, and rituximab, by blocking CD20 and thus inhibiting B-cell antibody production, appear to be the most promising [27,28]. Paradoxically, both of these agents have also been reported to cause vasculitis [29,30].

In some cases, ulceration, particularly of the lower legs, may prove difficult to heal despite apparently appropriate interventions. Although the cause(s) may be those that impair healing of the lower leg in any situation, such as obesity, diabetes, arterial disease, etc. (Chapter 47) (Fig. 50.6) it is also pertinent to note that hypercoagulability conditions (Chapter 49) may also impair healing; in a study of 13 patients with refractory leg ulcers following leukocytoclastic vasculitis, seven (53%) had either factor V Leiden or a lupus anticoagulant [31].

Fig. 50.6 Prolonged leg ulceration in a patient with cutaneous small vessel vasculitis, without systemic involvement; the main factor impairing healing was diabetic arterial disease.

Drug-induced vasculitis

Definition. Vasculitis of various morphological types can be caused by drug ingestion. This is briefly discussed as a discrete topic as it is always important to consider medications and other ingested drugs as a possible cause of vasculitis. The clinical pattern is usually that of a superficial small vessel cutaneous leukocytoclastic vasculitis but other patterns, including systemic vasculitis, occur. Drug-induced vasculitis is also considered in Chapter 75 with emphasis on causative agents.

Causes. Many drugs may cause vasculitis, and are listed in several reference sources [1–6]. The validity and importance of some reports of drug-induced vasculitis is uncertain as not all are histologically confirmed, the frequency in relation to the number of patients treated with any specific causative drug is often unknown, and most surveillance systems rely on spontaneous reporting. About 200 drug causes of vasculitis are listed by Litt [5]; even allowing for uncertainty in some cases, it seems likely that over 100 drugs are implicated as causes of drug-induced vasculitis or the closely related drug-induced lupus-like syndrome [7], although the actual frequency of drug-induced vasculitis is very low [6], possibly 1/100 000 people. However, it is also clear that, for any drug, vasculitis is one of the rarer reaction patterns that occurs (typically accounting for <1% of reactions to any individual drug). Some of the more important drugs that can cause vasculitis are also listed in Table 50.8. Those most frequently implicated are penicillins, sulphonamides, quinolones, analgesics (including non-steroidal anti-inflammatory drugs), thiazides and other diuretics, anticonvulsants, phenothiazines, allopurinol, and colony-stimulating factors [1–9]. Less commonly used drugs, but with a significant risk of causing vasculitis, include hydralazine, quinidine, thiouracils and various biological agents.

Drugs that may cause skin necrosis or drug-induced purpura are discussed in Chapter 49. It is important to be aware that illicit drugs (especially cocaine and sympathomimetics, such as ephedrine or amphetamines), drug excipients, vaccines (especially influenza and hepatitis B), herbal remedies [10] and food additives can all cause vasculitis, as these may otherwise be overlooked as possible triggers. Cannabis tends to cause an atherosclerosis-like arterial occlusion, mimicking severe peripheral arterial disease [11]. It has been suggested that routine influenza vaccination may lead to an increased number of cases of vasculitis in the target groups for immunization; when this does occur, the vasculitis may be cutaneous or systemic, usually occurs about 2 weeks after the vaccination, and is usually in patients who have had a previous uneventful influenza vaccination [12].

It is always important to consider the possibility of vasculitis in relation to newer drugs, as such reactions may only become apparent during wider use than in clinical trials. This is particularly difficult as some are used for systemic diseases where it may be difficult to distinguish drug-induced vasculitis from vasculitis due to the underlying disease or to other mechanisms (such as infection). Relatively new, or increasingly used, classes of drugs that can cause vasculitis include interferons, retinoids (mainly isotretinoin), leukotriene inhibitors, anti-TNF agents and other monoclonals, and colony stimulating factors. Bortezomib, a proteosome inhibitor used in treatment of haematological malignancies, has been associated with both a Sweet's syndrome-like neutrophilic dermatosis and with leukocytoclastic vasculitis [13]; occurrence of this eruption appears to be associated with a better treatment outcome than in patients who do not develop a rash. Dermatologists need to be aware that anti-TNF agents are not an uncommon cause of skin or systemic vasculitis; one study reported 39 cases during 1 year in France [14].

Mechanisms. Most drug-induced vasculitis is of hypersensitivity type and presumed to be immune complex-mediated; it probably accounts for 10–20% of small vessel cutaneous vasculitis [4]. The evidence for this assumption is often indirect, although sulphonamide crystals have been observed in blood vessel walls [15]. This pattern is provoked by various antibiotics, diuretics, NSAIDs, anticonvulsants, antipsychotics, cardiac drugs such as diltiazem, and others [3,4]. Relatively recent drugs that can cause this pattern include zidovudine, various haemopoietic growth factors and etanercept.

True serum sickness, originally related to use of hyperimmune sera, is rarely seen, although it does occur with protein drugs such as streptokinase and antithymocyte globulin; a serum sickness-like pattern of eruption is more commonly seen, occurring in relation to penicillins or sulphonamides, and less commonly with drugs such as thiouracil, phenytoin (hydantoin) or phenylbutazone.

Any of the other classical Gell and Coombs mechanisms for vasculitis may occur, although the mechanism by which drugs provoke systemic vasculitis is often less clear than in the immune complex pattern. In some instances, such as leukotriene antagonists administered for asthma 'causing' CSS (Chapter 62), there is

Table 50.8 Some causes of drug-induced vasculitis and the patterns of vasculitis they most commonly provoke.

Type of drug or organ targeted	Examples
Antibiotics/anti-infection	Penicillins, sulphonamides, quinolones, cephalosporins, minocycline, clindamycin, vancomycin, macrolides, rifampicin, isoniazid, imidazoles, griseofulvin, zidovudine, didanosine, efavirenz, mefloquine (all usually cause CLV ± SV; penicillins are also the commonest cause of SSLR; cephalosporins may also cause HSP or AASV; ciprofloxacin may also cause AASV; minocycline can cause CLV, AASV/C-PAN and LELS)
Antithyroid	Propylthiouracil; less frequently carbimazole or methimazole (LCV, AASV/MPA)
Rheumatological	NSAIDs (including cycloxygenase-2 inhibitors) (CLV, SV) Allopurinol (CLV, AASV) Penicillamine (AASV); sulphasalazine (CLV, AASV)
Cardiac	Anticoagulant/antiplatelet: aspirin (CLV); streptokinase (SS, CLV); warfarin (coumadin)(CLV ± SV); heparin (CLV) Diuretics (thiazides, furosemide, metolazone) (CLV ± SV; thiazides can cause AASV) Antiarrhythmics: amiodarone (CLV), quinidine (CLV ± SV) Antihypertensives: hydralazine (CLV, AASV, LELS); calcium channel blockers (CLV, SV); beta-blockers (CLV ± SV)
Neurological and psychiatry	Anticonvulsants: hydantoins, carbamazepine, most others (CLV ± SV; phenytoin reported to cause AASV) Phenothiazines, several antidepressants (CLV ± SV)
Oncology	Cytarabine, dacarbazine, gemcitabine, others (CLV ± SV)
Immunosuppressives and related agents	Ciclosporin (AASV, CV); azathioprine, methotrexate, busulphan, cyclophosphamide, melphalan, gold, tacrolimus, dapsone (all CLV ± SV)
Monoclonals	Anti-TNF agents (CLV, SV, HSP, AASV); rituximab (CVL,SV), bortezomib (CLV); colony stimulating factors (CLV); interferons (CLV, AASV, LELS); omalizumab (CSS)
Illicit drugs	Amphetamines/ecstasy, ephedrine, cocaine, heroin (CLV; cocaine causes AASV; cannabis causes atherosclerosis-like arterial occlusion; many may cause cerebral vasospasm or frank CV also)
Vaccines	Influenza (most cases), hepatitis B, hepatitis A, rubella, measles, MMR, pneumococcus, BCG, tetanus/DPT, rabies, smallpox (mostly CLV ± SV; influenza vaccine may also cause MPA; rabies vaccine may cause SS; hepatitis B vaccine may cause AASV/PAN/C-PAN, HSP, UV, CryoV, KD)
Miscellaneous	Warfarin (coumadin), quinine, potassium iodide and iodinated radiocontrast media (all CLV ± SV) Leukotriene inhibitors (AASV, CSS) Retinoids (CLV ± SV; PAN; AASV; pulmonary capillaritis)

AASV, ANCA-associated systemic vasculitis; CLV, cutaneous leukocytoclastic vasculitis; C-PAN, cutaneous polyarteritis nodosa; CryoV, cryoglobulinaemic vasculitis; CSS, Churg–Strauss syndrome; CV, cerebral vasculitis; DPT, diphtheria–pertussis–tetanus; HSP, Henoch–Schönlein purpura; KD, Kawasaki disease; LELS, LE-like syndrome; MMR, mumps–measles–rubella; MPA, microscopic polyangiitis; NSAIDs, non-steroidal anti-inflammatory drugs; PAN, polyarteritis nodosa; SS, serum sickness; SSLR, serum sickness-like reaction; SV, systemic vasculitis.

an argument that the asthma may simply have been an early feature of CSS and that the drug is not relevant. However, ANCA-positive (particularly MPO-positive) vasculitis has been convincingly linked with drugs such as hydralazine (which may also cause small vessel leukocytoclastic vasculitis) and thiouracils, and less commonly with penicillamine, allopurinol, minocycline and sulfasalazine [16–18]. Glomerulonephritis may occur related to propylthiouracil-induced ANCA-positive vasculitis, although in general internal involvement is relatively mild in ANCA-positive drug-induced vasculitis.

Drug-induced lupus erythematosus is discussed in Chapter 51; drug-induced neutrophilic dermatoses are discussed later in this chapter.

Pathology. A small vessel vasculitis with a lymphocytic infiltrate and little leukocytoclasia, or the presence of some degree of tissue eosinophilia, are suggestive of the possibility of drug-induced vasculitis. Although none of these is sensitive or specific, tissue eosinophilia was significantly greater in drug-induced cases of CSVV than in non-drug-related cases [19] and should arouse suspicion of a drug-induced vasculitis, especially in the absence of systemic symptoms and if ANCA are negative. Serum complement levels are generally normal. ANCA may be positive (see above).

Clinical features. Drug-induced leukocytoclastic vasculitis presents with palpable purpura, petechiae, necrosis and urticarial lesions, indistinguishable from other causes of this pattern of vasculitis.

In the serum sickness-like reaction, the initial rash may be acral, with urticaria or purpura, followed by more generalized annular urticarial lesions. There may be fever, arthralgia, haematuria or proteinuria, lymphadenopathy and decreased complement levels.

Medium and large vessel vasculitides mimic the patterns described elsewhere in this chapter, although there may be atypical features such as eosinophilia or the fact that all lesions appear to be of similar duration. Some drug-induced cases resembling CSS have relatively minor respiratory symptoms compared with the idiopathic condition.

Diagnosis. Generally, drug-induced vasculitis is indistinguishable clinically from the same clinical picture occurring due to other causes. This is particularly the case in CSVV or leukocytoclastic

vasculitis with systemic involvement. Timing of the eruption in relation to starting a new drug may be informative, especially if the drug is only administered once (such as vasculitis due to streptokinase, which occurs early after administration). However, in some instances, such as vasculitis due to diuretics, onset may be delayed for several months.

Eosinophilia may be a useful guide. Blood eosinophilia is found in almost 80% of patients with drug-induced systemic vasculitis, but in less than a quarter in whom the reaction is CSVV alone [20]; tissue eosinophilia is also more likely in drug-induced CSVV [19].

ANCA-associated vasculitides generally mimic the primary disease but with less systemic disease, although the differential diagnosis may be difficult, particularly if the cause is concealed, for example when illicit drugs are involved. Cocaine, in particular, is recognized as a cause of systemic vasculitis (notably including cerebral vasculitis), but may also cause facial midline destructive lesions that mimic WG and that cause particular diagnostic problems as over 80% have a positive ANCA (usually P-ANCA, but the pattern may vary even within one individual); a useful distinction is that most ANCA in Wegener's granulomatosis is directed against PR3 and sometimes MPO, whereas patients with cocaine-induced midline destructive lesions do not have MPO-ANCA, and even if they also have a PR3-ANCA, they have ANCA against human neutrophil elastase (human leukocyte elastase, HLE) which is not a specificity seen in WG [21,22]. Drug causes for ANCA-associated systemic vasculitides should be considered if there are multiple ANCA specificities or anti-HLE, rather than the more usual anti-MPO or anti-PR3 ANCA of the main differential diagnoses; for example, minocycline has been linked with MPO, HLE, cathepsin G, bactericidal permeability-increasing protein ANCA as well as with antihistone and anticardiolipin antibodies [7].

Treatment. Stopping any suspect drug is important and may be all that is required for cutaneous vasculitis. In cases with systemic disease, corticosteroids and even other immunosuppressive agents may be necessary. Supportive treatment such as compression hosiery may be required as in other forms of small vessel vasculitis. Renal function and urinalysis should be monitored.

In most instances, the causative drug should not be used again. It is also important to be aware of possible cross-reactions (notably between diuretics) when substituting a different drug.

Henoch–Schönlein purpura

Synonyms

- IgA immune complex vasculitis
- Anaphylactoid purpura
- Purpura rheumatoide

Definition. Originally described as a tetrad of palpable purpura, arthritis, gastrointestinal involvement and renal glomerular involvement [1,2], HSP is defined by the Chapel Hill Consensus Conference as a vasculitis affecting small vessels, involving deposition of IgA immune complexes, that characteristically involves the skin, gastrointestinal system and glomeruli with or without arthralgia or arthritis [3]. Unfortunately, many literature reports have previously assumed that all cutaneous small vessel vasculitis in children is HSP, rather than insisting on confirmed presence of IgA immune complexes, which causes great confusion. This has been addressed by the EULAR/PReS consensus [4], although some cases are acceptable in which IgA is not demonstrated (presumed to reflect delayed biopsy with destruction of immunoreactants). Although it can occur in adults, HSP is much more common in childhood; 75% of cases occur in children under 6 years old and 90% in children under 10 years old [5–9]. Furthermore, HSP occurs in various racial and ethnic groups [9–11].

History and nomenclature. Heberden first described HSP in 1801, in a young boy with abdominal pain, emesis, bloody stools,

arthritis and a purpuric eruption. The eponymous term Henoch–Schönlein purpura was later applied after Johann Schönlein and Eduard Henoch described features of the vasculitis in the mid-19th century.

Aetiology and pathogenesis [9,12]. Some infections, such as those caused by Group A β-haemolytic streptococci, are implicated in the cause of HSP, although evidence for streptococcal infection is only found in approximately 30% of children [8] (the range from different studies is about 20–50% [12]). Additionally, although other pathogens have been implicated (including *Bartonella henselae*, parvovirus B19, *Staphylococcus aureus*, coxsackieviruses, adenovirus, hepatitis A and B viruses), a triggering pathogen is not found in the majority of cases. Seasonal outbreaks have been described. The demonstration of nephritis-associated plasmin receptor NAPlr, a Group A streptococcal antigen, in renal mesangial vessels of children with HSP-associated nephritis (discussed earlier, p. 50.5) suggests a causative role for streptococci in at least some cases.

IgA is thought to play a pivotal part in the pathogenesis of HSP, as increased levels of IgA in the serum (in 50% with active disease), increased circulating immune complexes containing IgA, and increased deposition of IgA in blood vessel walls and in the renal mesangium are associated with HSP. In patients with HSP, IgA1 rather than IgA2 is the main IgA subclass deposited in the skin lesions [12,13]. Diminished glycosylation of the proline-rich hinge region of the IgA1 heavy chain is thought to be an important factor in allowing the IgA to be deposited in the mesangium and to activate the alternative pathway of complement in IgA, as it makes such IgA1 molecules more prone to forming macromolecular complexes [8,9].

Other IgA antibodies that occur in HSP include IgA ANCA, although this finding is very variable between studies. IgA rheumatoid factor and IgA anticardiolipin antibodies are also sometimes present, as are IgA AECA.

Activation of several cytokines is documented, although it is difficult to determine if any are a primary cause. TNF-α levels are increased, and TNF-α can be detected in skin lesions; IL-6, IL-8, transforming growth factor-beta (TGF-β) and vascular endothelial growth factor (VEGF) levels are all increased in active HSP. TGF-β is of particular interest as blood levels of T cells that produce this cytokine are increased in HSP, and it is known to enhance IgA1 responses. Neutrophil activation, elevated nitric oxide levels, reactive oxygen species and increased urinary leukotriene are all documented.

Familial clustering has been reported, which may support an infectious aetiology; however, various polymorphisms that either increase risk of HSP or are associated with more severe renal disease have been described and would also explain familial HSP (examples include polymorphisms in TGF-β, IL-1β, IL-8 and VEGF).

Histopathology. Biopsy specimens of the purpuric lesions demonstrate leukocytoclastic vasculitis affecting capillaries and post-capillary venules. Direct immunofluorescence microscopy of lesional and perilesional skin reveals deposition of IgA, C3 and fibrin in dermal blood vessel walls.

Fig. 50.7 Henoch-Schönlein purpura, with typical retiform pattern.

Clinical features. Most commonly, HSP manifests at the outset with the classic findings of purpura, arthralgia and abdominal pain [8–10]. The cutaneous findings are typically erythematous urticarial papules, which may evolve within 24 h into palpable purpura with haemorrhage. Furthermore, urticaria, vesicles, bullae and necrotic ulcers may develop. A retiform pattern within lesions is characteristic, but not necessarily present (Fig. 50.7). Typically involving the extensor aspects of the limbs (especially elbows and knees) and buttocks in a symmetrical fashion, HSP may also affect the trunk and face. Usually fading within 5–7 days, crops of lesions can recur for a few weeks to several months. Although HSP is chronic in 5–10% of patients, the cutaneous involvement usually lasts between 6 and 16 weeks and then subsides. Rarely, gastrointestinal involvement and arthritis can occur in the absence of skin disease. Renal involvement with HSP is common, occurring in approximately 40–50% of patients; 25% have gross haematuria and the remainder microscopic haematuria [9]. Proteinuria occurs in 60% of these, but is uncommon in the absence of haematuria. Only 1–3% of these patients progress to end-stage renal disease, although one-third to half of patients have renal abnormalities on long-term follow-up [9,14]. Furthermore, gastrointestinal involvement is common (65%), with frank gastrointestinal bleeding in 30% of patients with HSP [9]. Painful arthritis is seen in about 75% of patients, most frequently affecting the knees and ankles. Less common manifestations of HSP include orchitis (in 10–20% of boys), intussusception, pancreatitis, neurological abnormalities, uveitis, carditis and pulmonary haemorrhage [9].

Diagnosis. HSP is a clinical diagnosis, with confirmation by direct immunofluorescence and routine histology. Perivascular IgA deposits are characteristic of HSP and can help to distinguish it from other vasculitides including CSVV, WG, CSS and MPA. IgA immune complexes are not specific to HSP, but can be seen in a variety of patients including those with SLE, endocarditis, dermatitis herpetiformis, alcoholism, IgA nephropathy, inflammatory bowel disease, ankylosing spondylitis, Sjögren's syndrome,

rheumatoid arthritis, some cancers and in some drug hypersensitivity reactions [15–18]. No laboratory tests are specific for HSP.

Treatment. HSP is frequently self-limiting, the majority of patients fully recovering within several weeks or months, so treatment is mainly supportive. Although no data demonstrate the effectiveness of systemic corticosteroids in treating purpura, shortening the duration of HSP or decreasing the frequency of recurrences, they have been shown in a randomized controlled study to be effective in the treatment of abdominal pain and arthritis, and accelerated resolution of mild nephritis [19] (the dose was 1 mg/kg/day for 2 weeks, tapering over a further 2 weeks).

Dapsone (100 mg once daily) seems to shorten the duration of HSP as well as having a beneficial effect on the cutaneous lesions [6]. One trial proposed that factor XIII replacement may be useful in the treatment of abdominal pain and gastrointestinal bleeding associated with HSP [20], and another small trial demonstrated a decrease in the duration and severity of abdominal pain, as well as a decreased bleeding risk, with the use of ranitidine [21].

The presence of renal disease is the major factor determining the long-term morbidity and mortality associated with HSP [7,9]. Although no controlled trials have been conducted, data from several studies, as well as a case series, suggest a benefit from high-dose corticosteroids, either alone [19,22] or with cyclophosphamide and dipyridamole [23–25] in patients with progressive renal involvement associated with HSP. Ciclosporin and azathioprine have both been used [9], and case reports suggest that gastrointestinal involvement and cutaneous disease may be lessened, and rapidly progressive nephritis may be halted, by the use of intravenous immunoglobulin [26,27]. Patients with severe nephritis, including nephritic syndrome, have poor short-term and long-term outlook compared with those with milder disease; severe nephritis is typically treated with high-dose methylprednisolone at a dosage of 30 mg/kg once daily for 3 days followed by oral corticosteroids and an immunosuppressive drug such as azathioprine or cyclophosphamide [6]. NSAIDs have minimal, if any, benefit in the treatment of HSP, and should not be used in patients with renal involvement. For the cutaneous lesions, the therapeutic ladder presented for cutaneous small vessel vasculitis is also applicable for patients with HSP.

Urticarial vasculitis

Synonyms
- Chronic urticarial lesions as a manifestation of venulitis
- Unusual systemic lupus erythematosus-like syndrome
- Hypocomplementaemic vasculitis
- Hypocomplementaemic–urticaria–vasculitis syndrome (HUVS)

Definition. Of patients with chronic urticaria, roughly 5–10% have urticarial vasculitis (UV) [1,2]. This is a chronic disease, which presents as urticarial lesions that most often occur on the trunk or proximal limbs, frequently with associated angio-oedema

[3]. Lesions differ from those of simple urticaria in that individual lesions persist for greater than 24 h, often demonstrate purpura and post-inflammatory pigmentation, and cause symptoms of burning. Two types of UV have been described: UV associated with hypocomplementaemia, and UV without associated hypocomplementaemia (normocomplementaemic UV). Hypocomplementaemic UV is defined by the presence of anti-C1q precipitin and/or a decrease in the level of C1 [2,4]. Although all patients with hypocomplementaemic UV have these antibodies, this process must be distinguished from SLE, which can show similar laboratory findings [5,6]. Urticarial vasculitis may be described as a continuum starting with patients who have only skin lesions, progressing to patients with skin lesions and hypocomplementaemia, and finally to those who meet the criteria for SLE. UV without hypocomplementaemia has a slight female predominance, whereas hypocomplementaemic UV is seen almost exclusively in female patients.

Fig. 50.8 Urticarial vasculitis.

History and nomenclature. Agnello *et al*. [7] first discussed UV, which was later described as a syndrome consisting of hypocomplementaemia, cutaneous vasculitis and arthritis by McDuffie *et al*. [8].

Aetiology and pathogenesis. UV is strongly associated with some connective tissue diseases, having a prevalence of 32% in patients with Sjögren's syndrome and 20% in patients with SLE [1]. Other associations include physical urticarias, hepatitis B or C, IgM or IgA gammopathies, serum sickness, colonic cancer and drug ingestion. Some cases of UV have been reported in association with exercise or with exposure to ultraviolet light and cold. UV is thought to represent a type III hypersensitivity reaction, as circulating immune complexes may be demonstrated in up to 75% of patients [9]. Complement and immunoreactant deposition in vessel walls, with complement cascade activation in patients with UV [10], further supports this theory. Additionally, removal of immune complexes via plasmapheresis has been shown to briefly alleviate some symptoms of UV [11]. In hypocomplementaemic UV, autoantibodies are directed against the collagen-like region of C1q, resulting in a reduction of C1q in the serum with subsequent activation of the complement pathway [12].

Histopathology [13–16]. Lesions of UV are typically viewed as showing a leukocytoclastic vasculitis; hypocomplementaemic UV shows a large number of interstitial neutrophils, rather than eosinophils, and may therefore be distinguished from normocomplementaemic UV [13,14]. However, a recent prospective study of 22 patients suggested that a leukocytoclastic vasculitis was only present in the minority, most having a lymphocyte-predominant infiltrate with an admixture of eosinophils [17]. The neutrophilic group had more resistant disease, and had a statistical association with leukocytoclasis, fibrin deposition, hypocomplementaemia and anaemia. The significance of this is uncertain—many collagen vascular diseases (with which UV is associated) may cause cutaneous lymphocytic vasculitis (p. 50.47), and the general view that UV is characterized by leukocytoclastic vasculitis may reflect a group of patients with more systemic features and greater likelihood of having a skin biopsy. However, it appears that some cases, especially of normocomplementaemic type, may have a lymphocytic vasculitis.

Clinical features. Cutaneous lesions of both the hypocomplementaemic and normocomplementaemic forms of UV are erythematous indurated weals that may contain purpuric foci (Fig. 50.8). Angio-oedema and macular erythema may also occur; livedo reticularis, nodules and bullae may be evident, and may also contain purpuric foci. Patients with the hypocomplementaemic form may have constitutional symptoms such as fever, malaise and myalgia, as well as other symptoms and signs including lymphadenopathy, hepatosplenomegaly, abdominal pain with or without nausea and/or diarrhoea, laryngeal oedema, dyspnoea, chronic obstructive pulmonary disease (COPD), glomerulonephritis, conjunctivitis, uveitis and episcleritis. Although hypocomplementaemic UV has features similar to SLE, signs such as ocular inflammation, angio-oedema and COPD distinguish the two processes.

Diagnosis. If urticarial lesions last for longer than 24 h (which can be determined by drawing around their margin), then by definition they are not ordinary urticaria and a skin biopsy should be performed. Pain rather than itch, or the presence of purpura, also suggest UV. History, physical examination and laboratory studies, including C3, C4 and antinuclear antibody (ANA), should help to establish the extent of disease and to exclude underlying disease (e.g. hepatitis C), and to evaluate for SLE. Some patients may demonstrate an elevated erythrocyte sedimentation rate (ESR), hypocomplementaemia, a low-titre positive ANA and haematuria. A biopsy must be performed to confirm the diagnosis and to exclude other disorders such as atypical erythema multiforme.

Treatment. Although no single treatment is effective for all cases of UV, the majority of patients respond to systemic corticosteroids. However, other agents should be considered as steroid-sparing therapies [15,16,18]. Drugs that have been shown to be effective for the treatment of UV include dapsone (100–200 mg once daily),

colchicine (0.6 mg twice to three times daily) and hydroxychloroquine (200 mg once to twice daily) [19–23]. Dapsone plus pentoxifylline (400 mg three times daily) has been used in one patient [24], and mycophenolate mofetil (2 g once daily) has been successfully tried as a maintenance therapy in two other patients [25]. Some patients require oral antihistamines for control of angio-oedema and urticaria-like lesions, in addition to the aforementioned therapies directed at the vasculitis.

Exercise-induced vasculitis

This is probably an underestimated condition, several series of ten or more cases having been reported [1–3]. Although also described as exercise-induced purpura [4], the histological features are those of a leukocytoclastic vasculitis with variable deposition of IgM and complement C3 [1]. The typical presentation is with purpuric lesions on the lower legs after prolonged walking (many descriptions are in golfers, marathon runners or long-distance walkers), usually in hot weather. Lesions may be urticarial, plaques, palpable purpura or petechial. Compressed areas, such as the tops of socks, may be spared [4]. Patients are generally middle-aged, and otherwise well with no evidence of venous disease; there is a strong female predominance.

Extrinsic causes such as insect bites, reactions to socks or allergies to grass or ground plants may be suspected if the condition is not known. The disorder has a relapsing course, but patients may prevent it occurring as some know how much walking is likely to provoke the eruption. Treatments have included compression hosiery, manual lymphatic drainage, diuretics, or steroids (local or systemic) [4].

In cases with urticarial vasculitis provoked by exercise, eosinophils predominate in early lesions, with a neutrophilic infiltrate and leukocytoclastic vasculitis subsequently [5]. As CSVV of several aetiologies, and HSP, are often aggravated by exercise, it has been suggested that the pathogenesis of exercise-induced urticarial vasculitis lesions might be extrapolated to other leukocytoclastic vasculitides [6].

Cryoglobulinaemic vasculitis

Definition. A form of vasculitis due to cryoglobulins deposited as immune complexes in types II and III cryoglobulinaemia. Small and medium sized vessels are affected, mainly in skin and kidneys. Not all cryoglobulinaemia is associated with symptoms. Type I

cryoglobulinaemia is monoclonal rather than forming immune complexes (therefore causes cryogelling rather than vasculitis), and types II and III cryoglobulinaemia may cause cryogelling as well as an immune complex vasculitis; details of the history, aetiology and pathogenesis of cryoglobulin-associated disease are therefore provided in Chapter 49 and only a brief outline of these aspects is provided here.

Aetiology and pathogenesis. Cryoglobulinaemia as a cause of vasculitis and vascular occlusion is an increasingly recognized condition, largely due to the association between types II and III cryoglobulinaemia with hepatitis C virus infection. Cryoglobulins may be divided into three main subtypes:

I Monoclonal immunoglobulin, usually IgG or IgM, and usually associated with lymphoproliferative disease, especially multiple myeloma or Waldenström's macroglobulinaemia; accounts for about 10–25% of cases. This is discussed in Chapter 49 and is not considered further here.

II Mixed polyclonal (usually IgG) immunoglobulin and monoclonal (usually IgMκ) immunoglobulin, the latter having rheumatoid factor activity; accounts for about 25% of cases.

III Polyclonal IgM with rheumatoid factor activity and polyclonal IgG with antigenic activity; accounts for about 50–65% of cases.

The causes of cryoglobulinaemia include myeloproliferative disorders, systemic lupus erythematosus and chronic infections; all disease associations are discussed in more detail in Chapter 49, and a more detailed summary of the pathogenesis is provided in [1]. Immune complex vasculitis is limited to types II and III (together termed 'mixed' cryoglobulinaemia). The strongest aetiological factor in mixed cryoglobulinaemia is hepatitis C virus (HCV) infection, which accounts for about 80–90% of cases of what was previously termed 'essential' mixed cryoglobulinaemia; hepatitis G may coexist in about 30% of such cases [2]. However, although mixed cryoglobulinaemia can be detected in about 50% of subjects with HCV, immune complex vasculitis occurs in less than 5% [3]. There is also a strong link between mixed cryoglobulinaemia and connective tissue disorders, especially Sjögren's syndrome, in which cryocrit measurements of cryoglobulins may be indistinguishable from those of patients with HCV [1], and a 35-fold increased frequency of non-Hodgkin's lymphoma [3]. Chronic antigenic stimulation (by hepatitis C or other antigens) is felt to lead to B-cell proliferation, production of IgM with rheumatoid factor activity, mainly monoclonal cryoglobulin production and, in some cases, progression to B-cell non-Hodgkin's lymphoma [1–5]. Various factors are involved in the B-cell stimulation [1]. Especially in type II cryoglobulinaemia there may be t(14:18) translocations in peripheral blood lymphocytes; these activate the proto-oncogene Bcl-2, which increases B-cell survival by inhibiting apoptosis. Additionally, the E2 protein of the HCV envelope binds to CD81 on lymphocytes (and hepatocytes), complexing with CD21, CD19 and Leu 13, again causing B-cell activation [1].

HCV causes both cytotoxic and autoimmune hepatitis, and clonal B-cell expansion occurs in both blood and liver. HCV virions bind to IgG and are then complexed with monoclonal IgM which are deposited in vessel walls as an immune complex, causing complement-mediated vascular damage; HCV RNA sequences have been detected in vessel walls [2]. HCV-related mixed cryoglobulinaemia and/or vasculitis has been linked with HLA-B8, DR3 and DRB1*11 [1,4], and some HCV genotypes are predominant (1, 2, 2A/III) [2].

Histopathology [6]. Mixed cryoglobulinaemia affects capillaries, arterioles and venules, producing a pan-dermal leukocytoclastic vasculitis that may extend into the subcutis. Eosinophilic, PAS-positive, globular cryoglobulin deposits are seen, as well as (PAS-negative) intraluminal and fibrin deposition. More chronic lesions develop a mononuclear-predominant infiltrate and may become granulomatous. Changes in other organs include membranoproliferative glomerulonephritis (in a third of cases), and deposition of immune complexes in lung alveolar vessels (leading to lung fibrosis) and in vasa vasora of nerves (causing peripheral neuropathy).

In the liver, chronic HCV is one of several infections that cause a histological pattern termed a fibrin ring granuloma; it has been suggested that this may be a manifestation of endothelial injury related to immune complex deposition [7].

Clinical features [1,7,8]. Features of immune complex vasculitis predominate over those that relate mainly to cryogelling. Palpable purpura, especially of the lower legs but potentially including the buttocks and trunk, occurs in 60–90% and urticated lesions are common, reminiscent of the skin vasculitis seen in HSP. Worsening of skin lesions after prolonged standing is common, and symptoms are often intermittent initially. Polyarteritis-like dermal nodules may occur in 20%. Raynaud's phenomenon, and cold-aggravation of the vasculitis lesions, are each present in about a third of subjects. Livedo, bullae, necrosis and ulceration are all less common.

Associated glomerulonephritis is common and important. Arthralgia, or migratory myalgia, occurs in most patients. Overt lung involvement is uncommon, but may present as dyspnoea or haemoptysis. Peripheral neuropathy, if present, is predominantly sensory and usually mild.

Diagnosis. It is important to distinguish cryoglobulinaemic vasculitis from other causes of CSVV because corticosteroid therapy, although sometimes necessary short-term, will in the longer term worsen the underlying infection that is present in the majority of cases. Most other causes of leukocytoclastic vasculitis cause a more superficial vasculitis on biopsy specimens, and if cryoglobulin deposits are seen histologically then the diagnosis is usually suspected (although this is much commoner in type I cryoglobulinaemia).

Clinically, head and neck involvement, significant livedo, acrocyanosis, Raynaud's phenomenon or larger vessel occlusion, are all more suggestive of type I cryoglobulinaemia.

Blood tests may be helpful in suggesting this diagnosis [9]. A low complement C4 level is found in 90%, rheumatoid factor is positive in 70% and ANA in 20%, elevated transaminases are found in a third, and some patients (with type II cryoglobulinaemia) will have a monoclonal band on electrophoresis. Obtaining samples for identification of cryoproteins is discussed in Chapter 49. Testing for antibodies to HCV should always be performed.

These factors combined with the clinical picture have been gathered to create possible diagnostic criteria [1]; major criteria include mixed cryoglobulins, purpura and leukocytoclastic vasculitis, with minor clinical features including chronic hepatitis, membranoproliferative glomerulonephritis, peripheral neuropathy and skin ulcers, and minor pathology/serology features including positive rheumatoid factor, HCV or HBV, and clonal B-cell infiltrate of liver or bone marrow.

Treatment. Treatment will depend on the underlying cause. Although most cases of mixed cryoglobulinaemia are HCV-associated, SLE and other autoimmune conditions need to be considered and treated appropriately, and other infections need to be considered as alternative (or, especially in the case of HIV, as coexisting) infections that may also require specific therapy.

The treatment of HCV-associated mixed cryoglobulinaemic vasculitis has recently been reviewed [1,3]. Pegylated interferon-α with ribavirin is the usual initial choice for patients with relatively mild symptoms (purpura, arthralgia, proteinuria without haematuria or casts or abnormal renal function, mild neuropathy); in such patients, immunosuppressive agents can be avoided, or relatively non-aggressive therapy can be used (low-dose corticosteroids, or colchicine). There is some logic in also adding rituximab, as this combination targets the causative HCV infection and the cryoglobulin-producing B cells; using rituximab with antiviral therapy is recommended for those with more severe disease or those with an associated B-cell non-Hodgkin's lymphoma [1]. Treatments with corticosteroids, other immunosuppressive agents (cyclophosphamide, azathioprine, mycophenolate mofetil) and plasmapheresis all have a role in patients with severe membranoproliferative glomerulonephritis, severe (especially motor) neuropathy, significant skin necrosis, lung disease or, as occurs in some cases, widespread multiorgan life-threatening vasculitis. Plasmapheresis is recommended if there are features of hyperviscosity, although it also produces rapid response of other complications by removal of immune complexes and inflammatory mediators; if used for its speed of action in severe disease, it must be combined with immunosuppression in order to prevent a rebound flare of activity. Ciclosporin, melphalan and intravenous immunoglobulin have all been used with anecdotal success.

In general, the response of cutaneous vasculitis and arthralgia is quicker than that of renal or neurological disease, where (despite a rapid reduction in viral load) the response to antiviral therapy is slow; thus, immunosuppressives may need to be used whilst awaiting response to the antiviral regimen. Older age (especially age over 60 years), long duration of infection, high cryoglobulinaemia level and renal involvement all infer a poor prognosis, although the response of cryoglobulin levels does not always correlate with overall therapeutic benefit. Response of skin and joint symptoms is expected in over 80%, whereas response of nephropathy and cryoglobulinaemia may be less than 50% and 65% respectively, and mortality at 5 years may be as high as 50% in those with severe renal involvement. Antiviral treatment should be continued for at least 12 months [3]; some genotypes of HCV may be relatively resistant, but an early (3 months) complete virological response is associated with a better prognosis.

Erythema elevatum diutinum

Definition. Erythema elevatum diutinum (EED) is a rare, chronic, cutaneous eruption that is most commonly seen in the adult population. The first description of EED was by Hutchinson and Bury in the 1880s, and the condition was later named in 1894 by Radcliffe-Crocker and Williams. EED is characterized by fibrosing plaques with histological evidence of leukocytoclastic vasculitis. In addition to the characteristic polymorphonuclear fragmentation, endothelial swelling, extravasation of erythrocytes and fibrinoid necrosis of vessel walls, dermal nodules of EED contain spindle cells and fibrosis [1].

Aetiology and pathogenesis. Although EED is thought to be related to an Arthus-type reaction with immune complex deposition and subsequent inflammation, the exact aetiology is unknown. It has been associated with autoimmune diseases such as rheumatoid arthritis, coeliac disease, inflammatory bowel disease, and type I diabetes mellitus. Associations with infections, including streptococcus, hepatitis and syphilis, have also been suggested [2–11]. Lesions characteristic of EED have been induced by injection of streptococcal antigen into the dermis [12–15], and have occurred at sites of mosquito bites [10]. Erythema elevatum diutinum has also been associated with human immunodeficiency virus (HIV) infection, as lesions of EED have responded to antiretroviral and dapsone treatment in HIV-positive patients [16–22]. EED is now recognized as one of the defined reactive dermatoses associated with HIV [23]. In addition, EED has been associated with hypergammaglobulinaemia and IgA monoclonal gammopathies, as well as with myelodysplasia, pyoderma gangrenosum, and relapsing polychondritis. The association with haematological abnormalities, such as multiple myeloma, is strong; however, EED may precede the haematological disease by several years [24].

Histopathology (Figs 50.9 & 50.10). Acutely, lesions of EED demonstrate leukocytoclastic vasculitis, with little fibrin deposition. Eosinophils may also be present in the upper and mid-dermis.

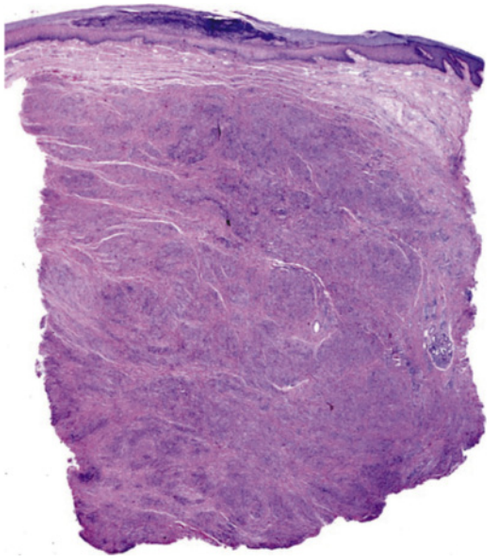

Fig. 50.9 Erythema elevatum diutinum. Low-power photomicrograph shows diffuse infiltrates throughout the entire dermis and areas of fibrosis. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

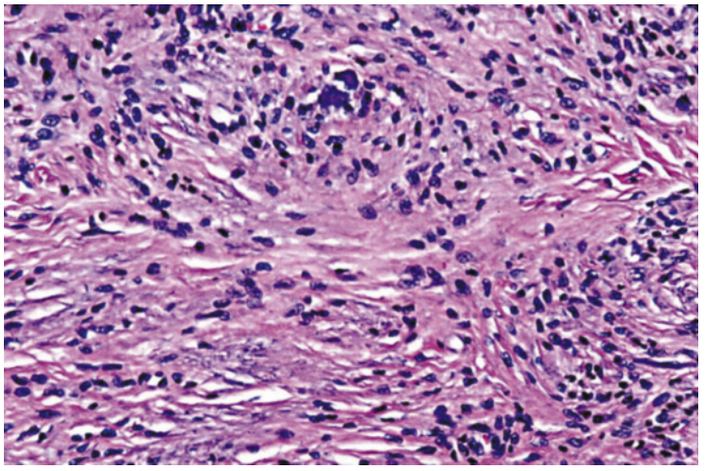

Fig. 50.10 Erythema elevatum diutinum. At higher magnification there is evidence of marked fibrosis and an inflammatory infiltrate composed of lymphocytes, histiocytes, neutrophils and nuclear dust. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

Depending on the degree of oedema and infiltration into the dermis, unaffected collagen may be present just under the epidermis. Chronically, lesions demonstrate angiocentric eosinophilic fibrosis, capillary proliferation, and infiltration of macrophages, plasma cells, and lymphocytes. Cholesterol deposits in histiocytes and in the extracellular tissue (the latter corresponding to a pattern that has been termed 'extracellular cholesterolosis') may be present in older lesions [25].

Clinical features. Patients are usually adult, although occasional childhood cases are reported [26]. Lesions of EED most commonly appear chronically in a symmetrical fashion over the dorsa of the hands, the knees, buttocks and Achilles tendons (Fig. 50.11). They

Fig. 50.11 Early non-fibrotic lesions of erythema elevatum diutinum at a typical site on the knee. This patient also had EED on the hands, and pyoderma gangrenosum.

are red-violaceous, red-brown or yellowish papules, plaques or nodules. Occasionally, the face and ears are also affected by EED. Initially, the lesions are soft, but eventually they fibrose, and later leave atrophic scars. Although they may be asymptomatic, the lesions of EED may also be painful. EED may last from 5 to 35 years, with crops of new lesions developing every few weeks to months.

Diagnosis. Although EED may be difficult to distinguish from cutaneous small vessel vasculitis histologically, the clinical presentation differs from that of other chronic small vessel vasculitis syndromes, allowing for an accurate diagnosis. EED and Sweet's syndrome are both described as neutrophilic dermatoses. However, EED differs from Sweet's syndrome by the character of the lesions and their distribution, as well as by histopathological features. The classic assumption that lesions from patients with Sweet's syndrome universally lack histopathological fibrinoid necrosis of vessel walls has been challenged; in one series, 29% of patients had biopsy specimens showing leukocytoclastic vasculitis [27], although it was felt that frank vasculitis was a consequence of neutrophil metabolites and occurred in older lesions. Clinically, the lesions in Sweet's syndrome are acute, more often asymmetrical and located on the arms, face and neck [28]. In contrast, EED lesions are chronic, symmetrical and classically located over the dorsum of the hands and knees, buttocks, and Achilles tendon. Although leukocytoclastic vasculitis has now been reported as a possible feature of Sweet's lesions [2], it is not always present and the fibrosis seen in lesions of EED correlates with the clinical chronicity.

The demonstration of IgA ANCA (with various specificities) in 6/10 cases of EED has been suggested to be of some diagnostic

value [29]; in this series, seven of the ten patients had raised IgA levels (monoclonal in three).

Treatment. Several medications have been used in the treatment of EED. Dapsone has a remarkable effect on EED [15], although stopping it is often followed by swift return of the lesions. Niacinamide has also been used with good effect [30]. High potency topical, or intralesional, corticosteroids may minimize the size of lesions in patients with limited disease. Treatment of an associated disorder such as HIV infection or paraproteinaemia [31] may be effective. Other therapies used for cutaneous small vessel vasculitis may also be effective in treating patients with EED.

Eosinophilic vasculitis

Synonym

- Recurrent cutaneous eosinophilic necrotizing vasculitis [1,2]

Definition. A relatively recently described and rare vasculitis consisting of a predominantly centripetal purpuric papular rash, angio-oedema, peripheral blood eosinophilia and an eosinophilic necrotizing vasculitis of small vessels.

History. This condition was recently distinguished from other eosinophilic vasculitides that affect medium to large vessels (CSS; see later in this chapter) and from eosinophilic disorders in which pruritic papules and/or angio-oedema may occur, such as hypereosinophilic syndrome, episodic angio-oedema with eosinophilia, dermatitis herpetiformis, Wells' syndrome, polymorphic eruption of pregnancy or drug eruptions. Association with connective tissue diseases and with rheumatoid arthritis has been reported [3,4].

Aetiology and pathogenesis. The cause is unknown. As in other strongly eosinophilic disorders, eosinophil cytokines such as IL-5, and toxic eosinophil granule proteins such as the major basic protein, have been demonstrated in serum and tissues, respectively, and presumably play a part in the tissue damage. Neutrophil elastase is prominent around vessels, and mast cell degranulation occurs. Eosinophilic vasculitis has also been reported in a patient with the hypereosinophilic syndrome; in this patient, CD40 (a glycoprotein of the TNF receptor family) was considered to be important in pathogenesis [5].

Histopathology. Shows fibrinoid deposition and necrosis of small dermal vessels with an infiltrate of eosinophils and absent or

minimal leukocytoclasis. Small epidermal vesicles containing eosinophils may be present. Immunoglobulin deposition is not a feature. This eosinophilic small vessel vasculitis is distinct from other vasculitides such as CSS, in which medium to large vessels are affected, and from most drug-induced vasculitis in which eosinophils are generally less prominent.

Clinical features. Recurrent pruritic papules and urticarial lesions occur at any site, especially the head and neck, with angio-oedema of the face and extremities. Either sex and any age group may be affected. The course is long and recurrent but fever, arthralgia and visceral involvement are absent. Digital occlusions manifest as Raynaud's phenomenon or digital gangrene have been reported in patients with cutaneous eosinophilic vasculitis associated with the hypereosinophilic syndrome [5,6], but they can also occur in the hypereosinophilic syndrome in the absence of cutaneous eosinophilic vasculitis [7,8].

An eosinophilic vasculitis, typically with hypocomplementaemia, also occurs in connective tissue diseases [9].

Treatment. Oral corticosteroids, intermittently or as prolonged maintenance therapy depending on response, appear to be effective.

Granuloma faciale

Definition. Granuloma faciale (GF) is an uncommon condition typified by asymptomatic cutaneous nodules occurring primarily on the face, with occasional extrafacial involvement. Granuloma faciale is limited to the skin, without any systemic manifestations. It is most common in males [1], typically in white people, although cases have been observed in populations of African or oriental ancestry [1,2]. Wigley [3] first described GF in 1945 as a type of eosinophilic granuloma, although it was distinguished from other eosinophilic granulomas by Lever and Leeper in 1950 [4]. Pinkus recommended the present name in 1952 [5].

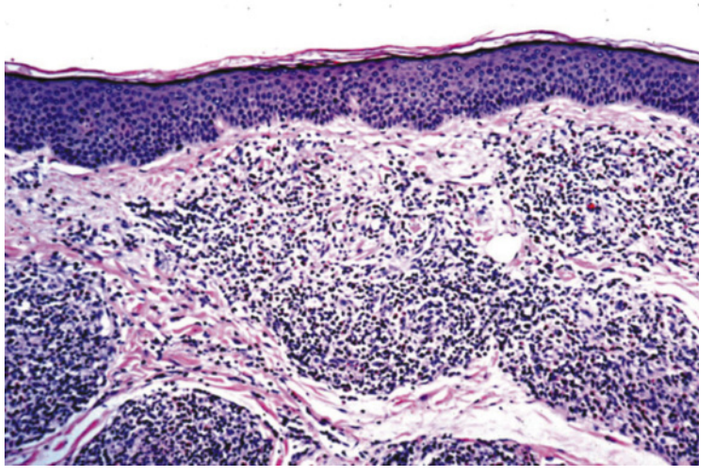

Fig. 50.12 Granuloma faciale. Low-power view shows perivascular nodular infiltrates within the dermis. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

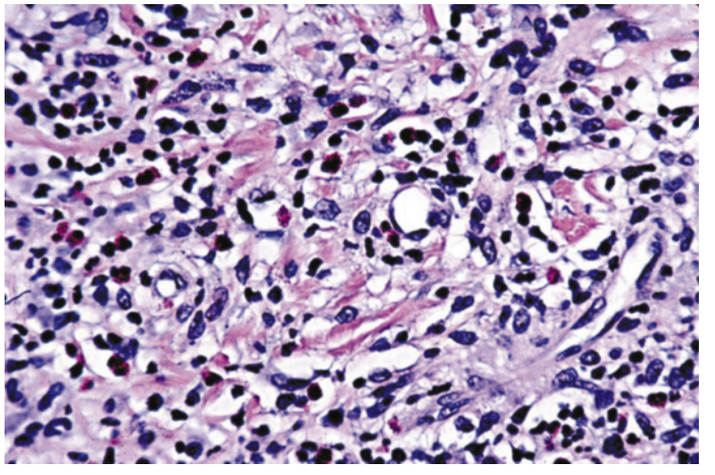

Fig. 50.13 Granuloma faciale. At higher magnification the infiltrate shows lymphocytes, eosinophils and a few neutrophils. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

Aetiology and pathogenesis. Although the aetiology is somewhat unclear, GF is considered to be a histological variant of leukocytoclastic vasculitis with a prominent eosinophilic infiltrate, and confined to the skin [6]. Deposition of IgG in and around dermal vasculature has been demonstrated, lending some support to the idea that GF is immune complex-mediated [7]. Clonal expansion of T cells producing IL-5, a powerful eosinophil chemoattractant, has been described within GF lesions [8].

Histopathology [9,10]. GF is characterized by a mixed inflammatory infiltrate with a predominance of neutrophils and eosinophils, although the latter is not constant [10], mainly in the upper half of the dermis but with occasional spread into the lower dermis and subcutaneous tissue (Figs 50.12 & 50.13). A band of normal

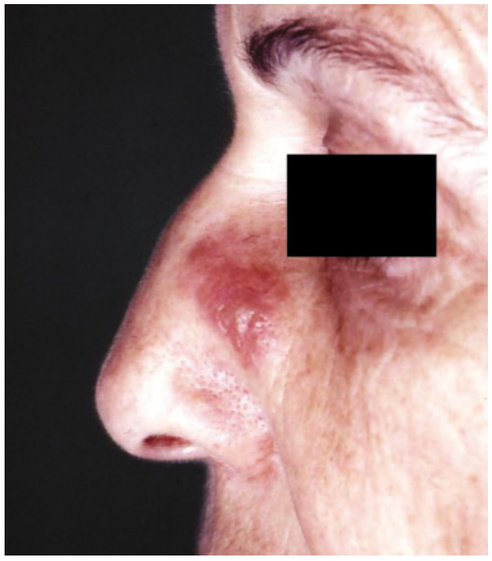

Fig. 50.14 Granuloma faciale. A reddish-brown plaque on the nose. (Courtesy of Dr G. Dawn, Monklands Hospital, UK.)

collagen referred to as a 'Grenz' zone typically separates the inflammatory infiltrate from the epidermis and pilosebaceous appendages. Nuclear dust (fragmented neutrophil nuclei) may be observed near capillaries. Vasculitis, with fibrinoid deposits near and within vessel walls, as well as haemorrhage, may be noted, and even frank vascular necrosis. Immune complexes have been documented either around vessels or at the dermoepidermal junction in several studies, but were lacking in many cases in a large series of patients [10].

Clinical features [10]. Lesions of GF are soft, brown-red nodules or plaques that most commonly occur on the face (Fig. 50.14); multiple lesions are present in about a third of cases but extrafacial involvement is uncommon, occurring in five of 66 patients in one study [10]. The nodules or plaques are smooth, with prominent follicular orifices and telangiectatic surface changes or scaling. Lesions of GF never ulcerate. They are almost always asymptomatic, although some patients may describe itching, burning or pain associated with the lesions [11].

In a review of 14 patients with extrafacial GF, nearly all lesions coexisted with facial lesions, mainly occurring after the facial lesions, and there was a male predominance [12].

An additional rare diagnosis in this category is eosinophilic angiocentric fibrosis, which is a mucosal variant of GF that may occur in nasal passages or upper airways, and which may be associated with skin lesions of GF [13,14].

Diagnosis. A definitive diagnosis of GF requires clinically consistent lesions and a confirmatory biopsy. Although most laboratory studies are normal, mild peripheral blood eosinophilia may be present [10].

Treatment. GF typically follows a chronic course with intermittent acute flares, and is often refractory to treatment. As a result, a wide variety of treatment methods, both surgical and medical, have been used to treat this condition. Examples include topical, intralesional or systemic corticosteroid, dermabrasion [15], laser treatments of various types [15–17], electrosurgery [15], cryosurgery [18], psoralen with ultraviolet A (PUVA) [19], and other systemic treatments including dapsone [11,20], clofazimine [21] and antimalarials [22]. Some cases have been treated with surgical excision [22]. More recently, topical tacrolimus has been reported to be effective, but in reports to date has required regular use for 2 months, then gradual reduction with ongoing once weekly use for many months to maintain remission [17,23]. A therapeutic ladder for GF is depicted in Table 50.9.

Table 50.9 Therapeutic ladder for granuloma faciale.

Topical corticosteroids
Topical tacrolimus (3)
Intralesional corticosteroids (3)
Cryosurgery ± intralesional corticosteroids (3)
Clofazimine (3)

Acute haemorrhagic oedema of childhood [1]

Synonyms
- Haemorrhagic oedema of childhood
- Acute haemorrhagic oedema of infancy
- Finkelstein's disease
- Seidlmayer's syndrome
- Purpura en cocarde avec oedeme
- Post-infectious cockade purpura

Definition. Acute haemorrhagic oedema of childhood (AHEC) is a rare disorder, whose manifestations are almost exclusively cutaneous. It occurs in children under 2 years old, and rarely outside this age group. There is often a history of a recent upper respiratory infection and/or treatment with antibiotics. Clinical features include petechiae and ecchymoses of the head and distal extremities. Snow first described AHEC in 1913 in the United States. In 1938 in Europe, Finkelstein published his paper on the disease.

Aetiology and pathogenesis. Infections (usually respiratory tract or urinary, e.g. streptococcal, staphylococcal, *Escherichia coli*, cytomegalovirus, adenovirus, coxsackievirus, or rotavirus infections), drugs, or vaccines may trigger AHEC, which may be a variant of childhood cutaneous small vessel vasculitis [1–4]. The age group, body sites affected, lesion morphology, rare renal or gastrointestinal involvement, and inconstant demonstration of IgA deposition in biopsies all serve to distinguish AHEC from HSP.

Histopathology. Leukocytoclastic vasculitis is evident in lesions of AHEC. As in cutaneous small vessel vasculitis (CSVV), the features include: karyorrhexis of neutrophils, endothelial swelling and extravasation of erythrocytes. Lesions of AHEC may show more prominent dermal oedema than lesions of CSVV.

Clinical features. Non-tender facial oedema may be the presenting sign of AHEC lesions, which are often asymmetrical. AHEC is characterized by sudden development of tender, oedematous lesions with petechiae and ecchymoses on the head and distal extremities. Large annular, arciform, coin-shaped or targetoid lesions (Fig. 50.15), that may later develop into bullae or necrotizing lesions, are typical. Lesions of AHEC start distally and progress proximally, sometimes involving the scrotum in males. Clinically, patients with AHEC are typically medically stable, although they may be febrile. Less dramatic presentations, in which the preceding infection and post-inflammatory pigmentation of annular and arciform skin lesions are dominant, may be mistaken for a drug rash or exanthem [5]. Although AHEC may rarely involve joints, the gastrointestinal tract, or the kidneys with vasculitic manifestations, it typically follows a benign course, lasting 1 to 3 weeks and with no persistent adverse effects following resolution [1–3]. Intussusception, classically associated with HSP, has also been reported with AHEC [6].

Fig. 50.15 Early discoid erythematosus lesions in acute haemorrhagic oedema of childhood.

Diagnosis. AHEC may be diagnosed only after meningococcaemia, erythema multiforme, UV, Sweet's syndrome, cutaneous small vessel vasculitis and Kawasaki disease have been ruled out.

Treatment. Supportive care is the only treatment usually necessary for patients with AHEC, although other treatments used in infants with CSVV or HSP may be appropriate in more severely affected patients.

Nodular vasculitis

Synonyms
- Lobular panniculitis with vasculitis
- Erythema induratum of Bazin and of Whitfield

Definition. Nodular vasculitis (NV) is a chronic relapsing lobular panniculitis with septal vasculitis. It is characterized by a vasculitis of subcutaneous arteries and veins, with subsequent ischaemia of subcutaneous tissue, which results in clinical suppuration. The cause may be a hypersensitivity reaction to an antigenic trigger such as a bacterial infection. It occurs primarily in middle-aged women, and is manifest as tender nodules or plaques on the legs that may later progress to ulceration.

History and nomenclature. Erythema induratum of Bazin was initially described by Bazin in 1861 as indurated plaques on the legs of women of middle age [1]. In 1900, French dermatologists described an association between erythema induratum and tuberculosis [2], although British physicians reported similar patients without evidence of tuberculosis at approximately the same time, a pattern which was later designated 'Whitfield's erythema induratum' [3–5]. In the middle of the 20th century, American physicians suggested the term nodular vasculitis for Whitfield's erythema induratum, which was thought to be distinct from erythema induratum of Bazin [6]. There remains controversy about whether erythema induratum of Bazin and nodular vasculitis should viewed as distinct, or as the same entity but with tuberculosis as just one cause. Many authors combine these entities [7], some view them as simply different names for the same condition [8], whereas others refer to them as nodular vasculitis/ erythema induratum (or vice versa) [9,10], reflecting some uncertainty. Others have used the term erythema induratum, but qualify it as Bazin-type if due to tuberculosis and Whitfield type if not [11]. A similar debate surrounds the putative role of tuberculosis as the cause; hyperreactivity to purified protein derivative, *Mycobacterium tuberculosis* DNA sequences in lesions, and response to antituberculous therapy all suggest that tuberculosis has a causal role in some cases, yet other convincing causative associations (medications, other infections) are recorded and negative results on investigation for tuberculosis in other cases. Even in terms of detection of *M. tuberculosis* DNA, studies differ; in one study 77% of 50 biopsy specimens were positive (with no obvious clinical or histopathological differences between those with positive or negative results) [10], whereas a more recent study found no positive results in 10 cases [9]. The latter study also had negative PCR results for DNA of several non-tuberculosis mycobacteria. Both studies used retrospective cases, so it is uncertain whether the archived diagnosis might have been influenced by the nosology of nodular vasculitis at the time the specimens were reported. We recommend using the term nodular vasculitis, as it then does not presuppose a single aetiology, but being aware that tuberculosis must be excluded in patients with lesions that fit this clinicopathological pattern, and that there are no histological features that reliably distinguish a tuberculous from a non-tuberculous aetiology.

Aetiology and pathogenesis. Several antigenic triggers have been implicated as the source for the hypersensitivity reactions with resultant subcutaneous vasculitis and lobular panniculitis in NV, as alluded to above. These include bacterial infections, such as streptococcal or mycobacterial infections, viral infections such as hepatitis C virus [12], and drugs such as propylthiouracil. NV has also been reported as occurring repeatedly in association with flares of autoimmune colitis [13], and related to colonic carcinoma [14]. The pathogenesis may be similar to that of cutaneous small vessel vasculitis, probably being immune complex-mediated, but causing a persistent delayed hypersensitivity or Arthus-type reaction [11] and with septal vessels in the panniculus as the target. Similar lesions may occur in rheumatoid disease.

Histopathology. Controversy exists as to whether arteries, veins or both are affected in NV. Regardless of the type of vessel involved, the early changes are of leukocytoclastic (sometimes lymphocytic or granulomatous [8]) vasculitis of vessels in the subcutaneous tissue leading to ischaemic changes, followed by inflammation and injury to lipocytes [7–11]. It has been suggested that the lesions can be classified on pathological grounds into type I (focal panniculitis with central neutrophilic muscular vasculitis, resembling PAN), and type II (diffuse panniculitis with multiple foci of neutrophilic small and muscular vessel vasculitis) [8]. C-PAN can usually be distinguished, as inflammation does not extend beyond the adventitia of arteries. In both histopathological types, there is coagulation and some caseation necrosis, the resulting occlusion leading to ischaemia and necrosis of fat lobules that may eventually involve the overlying dermis. Early in the disease process, the necrotic subcutaneous fat demonstrates fat cysts bordered by a finely granular eosinophilic substance with pyknotic nuclei. Later, foamy histiocytes encircle the necrotic areas, creating granulomatous inflammation (consistent with an additional name that has been used, lobular granulomatous panniculitis) (Figs 50.16 & 50.17).

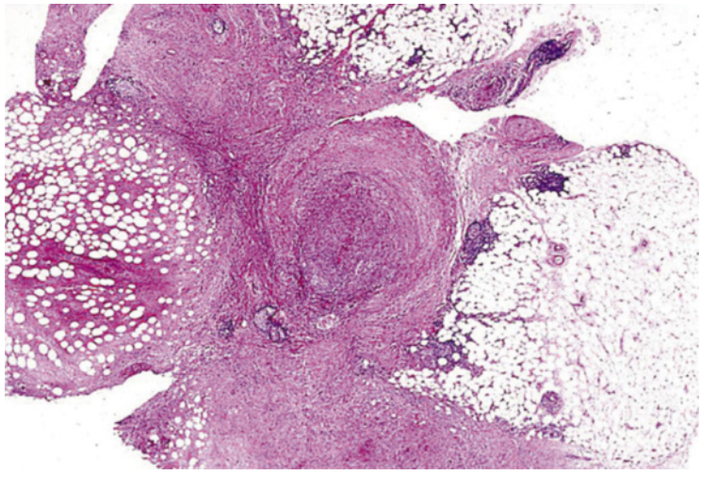

Fig. 50.16 Nodular vasculitis. Lobular panniculitis with prominent inflammation. Note the alteration of a vascular structure in the middle of the photograph. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

Fig. 50.18 Bazin's disease on the lower legs.

Clinical features. NV is manifest as tender, dusky, often suppurative, nodules or plaques on the posterolateral aspect of the legs (Fig. 50.18). It is typically seen in healthy, middle-aged, sometimes obese, women who may have venous stasis. Patients often have 'thick' calves with erythrocyanosis and perifollicular erythema. Lesions may be unilateral, are often inflamed and may progress to ulceration. The lesions of NV heal slowly, sometimes leaving an atrophic scar. The course of NV is chronic, with relapses typically occurring over several years. Nodular vasculitis may sometimes be seen in men, with unilateral nodules or plaques involving the anterior aspect of the thighs and legs, and other locations.

Lesions that have previously been termed 'erythrocyanosis with nodules' may have been examples of NV, or alternatively a pattern of perniosis.

Diagnosis. NV is a clinicopathological diagnosis, which requires deep incisional biopsy of active lesions. Lesions may resemble other panniculitides, erythema nodosum, perniosis, pyoderma gangrenosum, skin infections and the cutaneous lesions of polyarteritis nodosa (p. 50.33) or Takayasu's arteritis (p. 50.44). In cases where a tuberculous aetiology is suspected, a tuberculin skin test and chest X-ray should be performed. The recently developed ELISpot, which detects peripheral blood IFN-γ-secreting T cells, may also be useful [15]. Other tests for tuberculosis are discussed in Chapter 31. Evaluation is otherwise similar to that for patients with cutaneous small vessel vasculitis.

Table 50.10 Treatment of nodular vasculitis.

Tuberculosis present
Triple-agent antituberculosis therapy for a minimum of 9 months
Tuberculosis not present
Palliative treatments
• Compression hosiery
• Bed rest
• Non-steroidal anti-inflammatory drugs
Systemic corticosteroids
Potassium iodide
Other treatments used to treat patients with small vessel vasculitis (Table 50.7)

Treatment. In patients in whom tuberculosis is demonstrated, at least a 9-month course of triple-agent antituberculosis therapy should be given (Chapter 31) [16,17]. In non-tubercular cases, supportive measures, such as compression hosiery, bed rest and NSAIDs are recommended. Systemic corticosteroids may also be considered, as well as potassium iodide, which has been reported as an effective treatment of NV [18,19]. Other treatments outlined for patients with small vessel vasculitis might also be appropriate for patients with NV. Mycophenolate mofetil has been used in one case [20]. The treatment of NV is shown in Table 50.10.

Polyarteritis nodosa

Synonyms
- Classic polyarteritis nodosa
- Periarteritis nodosa

Definition. Polyarteritis nodosa (PAN) constitutes a necrotizing inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries or venules [1]. It was originally described by Kussmaul and Maier in 1866 [2] as 'periarteritis nodosa', and was renamed 'polyarteritis nodosa' in 1903 after Ferrari recognized its multivessel involvement as well as its transmural inflammation. Segmental involvement of medium-sized arteries is usual. Affected patients may have several signs and symptoms involving multiple organ systems. Ischaemia, infarcts and haemorrhage result from the vasculitis and lead to end-organ damage in patients with PAN. It has been described in all racial groups [3–5], with an incidence of 4.6–9 per million per year [6]; in populations with a low incidence of hepatitis B, its incidence is less than 5 per million population, but where hepatitis B is hyperendemic, the incidence rises dramatically (for example 77 per million in an Alaskan Eskimo population [7]). There may be an equal sex incidence or male predominance.

Aetiology and pathogenesis. Immune complexes are most commonly implicated in development of PAN. Immune complexes may activate complement with subsequent recruitment of neutrophils to the vessel wall. Progression of the inflammatory and immune response leads to recruitment of T lymphocytes, particularly $CD8^+$ T cells, and macrophages. Antiendothelial cell antibodies have also been proposed as a pathogenic mechanism, but specific antigens have not been identified and such antibodies are not specific to PAN [8]. The occurrence of nodose lesions and aneurysms at arterial branch points has also led to theories that the increased shear stress at these areas causes up-regulation of endothelial inflammatory factors [9–12], and that there may also be a greater number of macrophages in the tunica intima at these stress points [13,14], adding to the susceptibility of endothelial cells to inflammatory activity.

In cases of PAN associated with hepatitis B virus infection, HbsAg is thought to be the triggering antigen; typically this applies to 5–7% of patients with PAN, although incidences of associated hepatitis B as high as 10–54% have been reported [6]. Rarely, other viruses have been associated with PAN, including hepatitis C, parvovirus B19, human immunodeficiency virus and herpes zoster virus, as well as streptococcal infection. PAN has been described in association with malignancies, particularly hairy cell leukaemia [15], as well as with inflammatory conditions such as SLE, inflammatory bowel disease, familial Mediterranean fever and Cogan's syndrome. Minocycline has been implicated in a minority of individuals [16].

Histopathology. PAN affects small and medium-size muscular arteries and sometimes arterioles [6,17]. Lesions often develop at branch points, where there is a focal necrotizing arteritis; the inflammatory infiltrate is neutrophil-rich initially but subsequently mononuclear cells are predominant. There may be focal panniculitis; granulomata are absent. The vasculitis causes nodose swellings and may cause development of microaneurysms as blood vessel walls become weak and potentially necrotic. The most severely affected arterial branch points of vessels may rupture, leading to luminal thrombosis and obliteration, thus resulting in widespread distal tissue ischaemia and ultimately necrosis (Figs 50.19 & 50.20). Lesions heal by fibrosis. In patients with hepatitis B-associated PAN, HbsAg may be present within the lesions.

Clinical features. Patients with PAN usually have constitutional upset, including fever, weight loss, arthralgia and malaise. Organs commonly targeted comprise kidneys (infarctions and ischaemic nephropathy lead to hypertension and renal failure), heart (angina, myocardial infarction), gut (ischaemia, bleeding, perforation or infarction, presenting as abdominal pain) and peripheral nerves (mononeuritis multiplex) [8]. Rupture of an aneurysm may cause acute haemorrhage within the affected organ. In males, orchitis is a characteristic feature. Importantly for differential diagnosis, PAN does not affect the lung parenchyma and does not cause glomerulonephritis—patients in whom glomerulonephritis is a

Fig. 50.21 Polyarteritis nodosa. Note the location of the lesion on the patient's foot.

dominant feature are more likely to have microscopic polyangiitis. Patients with hepatitis B virus-associated PAN may have features of hepatitis.

Skin features of PAN are common, occurring in about half of patients depending on the series, although early reports included patients with microscopic polyangiitis where small vessel involvement with purpuric manifestations may have confused the picture [8]. In PAN, a subcutaneous nodule or group of nodules ranging from 0.5–2 cm (mostly 5–10 mm) may develop, predominantly on the lower limbs and often in proximity to vessels. Typical sites are around the knee, anterior lower leg and dorsum of the foot. Nodules may be tender, pulsatile or secondarily ulcerated, with either normal or erythematous overlying skin. Livedo reticularis may occur, with or without ulceration. Ulcers have a 'punched-out' appearance. Ulceration and gangrene of the digits or penis may develop. Cutaneous lesions in patients with PAN are depicted in Figs 50.21 and 50.22.

Fig. 50.22 Polyarteritis nodosa. Multiple lesions on the fingers.

Diagnosis. Conventional angiography of hepatitic, renal, splanchnic and splenic circulations remains the most reliable method of demonstrating the aneurysms, stenoses and abnormal vessels in PAN [18], although they are not specific to this disorder. Tissue biopsy of affected muscle or nerve may confirm the presence of vasculitic lesions [19]; sensitivities of muscle and sural nerve biopsy specimens are 60% and 70%, respectively, in cases of symptomatic muscle involvement and nerve involvement demonstrated electrophysiologically [20,21]. Renal biopsy specimens (when urinalysis is abnormal) and angiography and/or aortography demonstrating pathognomonic aneurysmal dilatation of vessel walls may also be used to help establish a diagnosis of PAN. Although very sensitive, skin biopsy is not specific, and is usually not sufficient to establish the diagnosis of PAN. A study of 29 patients with skin ulcers due to PAN (fulfilling both American College of Rheumatology and Chapel Hill Consensus Conference criteria) showed that the highest yield was achieved by biopsying both the peripheral area of the ulcer and the central area (the rationale being that the central area would represent the apex of a wedge-shaped infarct); 26 diagnoses were confirmed but biopsies needed to contain subcutaneous tissue, 9/26 confirmed cases required multiple biopsies and diagnosis could not be achieved from the skin ulcers in the other three [22].

During acute disease, the ESR and CRP will be elevated and there may be other non-specific laboratory abnormalities such as leukocytosis with neutrophilia, thrombocytosis, normocytic anaemia, hypergammaglobulinaemia and cryoglobulinaemia, as well as haematuria, proteinuria. Antineutrophil cytoplasm antibodies are negative; although P-ANCA has been said to be positive in 20% of cases of PAN, it is more commonly seen in MPA or CSS (suggesting that some cases may have been misclassified), whereas a positive C-ANCA is typically associated with WG, CSS or MPA but not with PAN. Patients who test positive for hepatitis B will all be HbsAg-positive and most will be hepatitis B early antigen-positive.

Treatment. Patients who do not have hepatitis B-associated disease benefit from high-dose corticosteroids, commencing at 1 mg/kg/day and tapering over 1 year to 5–10 mg/day; the ESR is useful for monitoring disease activity. Such treatment has improved the 5-year survival from about 10% to over 50% [23]. In patients with severe disease, three daily pulses of methylprednisolone, 500–1000 mg, may be considered although there is no evidence to suggest that this is any better than daily oral prednisolone. Severe disease is indicated by the presence of renal (renal insufficiency, proteinuria >1 g/day), gut, cardiac or central nervous system involvement [24].

It is possible that cyclophosphamide may be useful in achieving remission in patients with severe disease [22]; one recommendation is for 12 pulses of cyclophosphamide, given at 0.6 g/m^2 every 2 weeks for the first three pulses and thereafter monthly [25], although it is worth pointing out that the trial from which these recommendations stem included patients with both PAN and microscopic polyangiitis; patients with PAN were in the minority. Plasma exchange does not appear to have any additional benefit in patients with non-hepatitis B-associated PAN.

Patients with hepatitis B-associated PAN appear to benefit from a combination of antiviral and immune suppressing drugs [26]. Corticosteroids should only be used short-term because of the possibility of increased viral replication; one regimen involves corticosteroids for 2 weeks, followed by the antiviral lamivudine combined with plasma exchanges. Relapses are rare and do not occur once viral replication has ceased and seroconversion has been obtained.

Treatment for hypertension and pain are important. Surgery may be needed for complications.

Microscopic polyangiitis

Synonyms

- Microscopic polyarteritis nodosa
- Microscopic polyarteritis

Definition. Microscopic polyangiitis (MPA) is a systemic vasculitis affecting blood vessels ranging in size from capillaries to medium-sized arteries. In some instances, there is only venous involvement in histopathological specimens from lesions in patients with MPA. MPA is strongly associated with lung involvement (primarily alveolar haemorrhage) and with crescentic glomerulonephritis [1]. The incidence of MPA is six to eight per million per year [2].

Patients demonstrating signs of PAN without cutaneous nodules were first described by Wohlwill in 1923, and then by Arkin in 1930. In 1948, articles were published that distinguished MPA from PAN. In 1994, MPA was termed microscopic polyangiitis instead of microscopic polyarteritis by a consensus conference because of the lack of arterial involvement in some patients and the involvement of vessels other than arteries [1].

Aetiology and pathogenesis. The exact pathogenesis of MPA is poorly understood, although it is considered a pauci-immune vasculitis because of the relative absence of immunoglobulins or

complement in affected vessel walls [3–7]. P-ANCA may have a role in the aetiology by activating neutrophils and monocytes via interactions with enzymes on the surface of or directly around endothelial cells [8], initially causing direct injury to the vessel endothelium. This is demonstrated in early findings of pauci-immune small vessel vasculitides in which there is fibrin accumulation in the subendothelium [7,9] as well as lysis of leukocytes within the vascular space [9] associated with endothelial injury. Products from neutrophils and monocytes (such as serine proteinases and metalloproteinases) may be inactivated at distant sites [10], accounting for the large degree of local tissue injury in lesions of MPA. Direct interactions between these cells and the endothelium may also explain the predilection of the disease for small rather than larger sized vessels. In some patients, there is a relationship between MPA and infection with either hepatitis B or C viruses [11,12]. Recent evidence suggests that antimyeloperoxidase (MPO) antibodies, present in 70% of MPA patients, may play a role in the damage to blood vessels by activating an oxidative burst [13].

Histopathology. Histological specimens from MPA lesions demonstrate segmental vascular necrosis. Neutrophils and monocytes permeate vessel walls, causing leukocytoclasia, accumulation of fibrin and haemorrhage. Biopsy specimens from lesions of palpable purpura demonstrate leukocytoclastic vasculitis.

Clinical features. Many patients with MPA initially experience constitutional symptoms, including fever, weight loss, myalgia and arthralgia. These may be present for several years before the onset of the pulmonary and renal disease that often occurs in patients with MPA. Between 79 and 90% of patients with MPA have necrotizing glomerulonephritis, and 25–50% have lung involvement, sometimes leading to pulmonary–renal syndrome [14], and leading to pulmonary haemorrhage in up to 29% of patients [15–17]. Although less common than in patients with PAN, symmetrical peripheral neuropathies or mononeuritis multiplex may occur in patients with MPA. Gastrointestinal (GI) manifestations are present in half of MPA patients. Although GI disease in MPA is usually mild at presentation, there has been a report of initial presentation with extensive colonic ulcerations and haemorrhage, characterized by a crypt abscess [18]. Nearly half of patients have palpable purpura on dependent skin sites upon presentation [19], but the presence of nodules should raise the suspicion of PAN, Wegener's granulomatosis (WG), or Churg–Strauss syndrome (CSS).

Diagnosis. MPA must be clinically distinguished from other vasculitides such as WG, CSS, CSVV, or PAN. In patients with MPA, positive P-ANCA and rheumatoid factor tests are common, unlike in patients with PAN. Some authors claim that small vessel vasculitis in the skin can distinguish MPA from PAN, stating that cutaneous small vessel vasculitis lesions do not typically occur in patients with PAN, although this is controversial. When palpable purpuric lesions are present in the absence of constitutional symptoms or the systemic features of MPA, patients most probably have CSVV rather than MPA. Small vessel vasculitis in the absence of granulomatous inflammation or asthma suggests MPA instead of CSS or WG [1].

Treatment. The management of MPA has recently been reviewed [20]. The approaches needed for induction, maintenance and long-term follow-up all differ. A preceding 'identification' phase may be associated with delay in treatment, especially if renal disease is absent or ANCA is negative. Initially, patients with MPA should be treated with high-dose corticosteroids and immunosuppressive treatment; cyclophosphamide has been used for some decades and, although strong evidence-based support, such as that supporting its use in patients with WG, is lacking, this combination leads to remission in 75–90% of patients at 6 months [20]. This regimen remains the mainstay of treatment for MPA associated with pulmonary haemorrhage or rapidly progressive glomerulonephritis. Methotrexate achieves similar early results but with a much higher relapse rate. Plasma exchange, or plasma filtration, are used for those with severe renal disease and, although associated with high early disease-related mortality, does appear to reduce longer-term need for dialysis. Intravenous immunoglobulin has also been used with benefit. For those who may not tolerate a steroid–cyclophosphamide regimen, such as the elderly, gabexate mesilate has been employed as an alternative treatment [21]. Based on evidence of an anti-MPO antibody-mediated oxidative burst, a compound such as *N*-acetylcysteine (NAC) may show promise for future therapy; NAC is an antioxidant that blocks HOCl production during the oxidative burst and thus avoids endothelial lysis [13]. Anti-TNF agents have been used but have given rise to concerns about malignancy in the context of vasculitis; additionally, other damaging cytokines (such as IL-18) are not affected by TNF blockade [20]. Selective blockade of different TNF receptors in glomerular vessels may be future targets for therapy. Rituximab has been used in a small number of cases with good results, especially as those treated had refractory disease [20].

The course of MPA is characterized by relapses, in contrast with that of PAN [20,22]. The prognosis is worst in older age, in those with low glomerular filtration rate, and in those with more glomeruli affected, or with extra-glomerular arteritis, on renal biopsy. Long-term follow-up is necessary, with monitoring of renal parameters and ANCA.

Cutaneous polyarteritis nodosa

Synonym
- Benign cutaneous periarteritis nodosa

Definition. Cutaneous polyarteritis nodosa (C-PAN) is a variant of PAN that is limited primarily to the skin. It was first described by Lindberg in 1931 [1] as a more benign variant of systemic PAN that did not have visceral involvement, although controversy exists over whether or not it simply represents an early or more limited form of PAN [2,3]. Thus, C-PAN can only be diagnosed by exclusion of findings that would alter the diagnosis to that of classic PAN. The course of C-PAN is typically benign and relapsing, despite the presence of moderate constitutional symptoms and mild nerve and muscle involvement in some patients [4,5].

Aetiology and pathogenesis. Infections such as streptococcus (particularly in children), parvovirus B19, HIV, and hepatitis B, as well as inflammatory bowel disease (IBD), have been associated with C-PAN [6], although the exact aetiology is unknown. Medications including minocycline, prescribed for acne, have also been reported to induce C-PAN [7–9]. Immunological mechanisms are thought by some authors to be involved only in the pathogenesis of systemic polyarteritis nodosa, and not in the development of C-PAN [10]. Whether C-PAN is part of the disease progression of systemic polyarteritis nodosa or should remain a separate clinical entity remains a topic of debate. Evidence suggests that C-PAN should remain separate from PAN as it rarely progresses into PAN and, unlike PAN, it rarely exhibits systemic involvement and has a good prognosis [10–14].

Fig. 50.23 Cutaneous polyarteritis nodosa. Erythematous lesions on the leg.

Histopathology. Early in the course of C-PAN, there is a predominantly neutrophilic inflammatory infiltrate in the walls of medium-sized arteries and arterioles of septae in the upper portions of the subcutaneous fat. The involved vessels classically demonstrate a target-like appearance resulting from an eosinophilic ring of fibrinoid necrosis. Later in the disease process the infiltrate becomes less neutrophilic, consisting predominantly of lymphocytes and histiocytes. Complement and IgM deposits in vessel walls of lesions of C-PAN from some patients may be demonstrated by direct immunofluorescence [15]. Unlike those of systemic PAN, lesions of C-PAN do not typically involve arterial bifurcations.

Clinical features. Although some patients with C-PAN may report constitutional symptoms as well as chronic, mild involvement of both muscles and nerves [4,5], cutaneous manifestations are the most striking feature of the disease. Dermal or subcutaneous nodules are most commonly located on the distal lower extremities near the malleoli (Fig. 50.23) and may extend proximally to the thighs, buttock, arms or hands. Patients may report tenderness associated with the nodules, which may ulcerate (Fig. 50.24) or more commonly demonstrate necrotizing livedo reticularis, also referred to as retiform purpura. Gangrene of the digits can ultimately occur, most commonly in children with C-PAN, but this finding should trigger an aggressive search to exclude systemic PAN [16,17]. Recurrent spiking fevers, polyarthralgia and macular upper extremity cutaneous eruption, symptoms shared by both C-PAN and adult-onset Still's disease (AOSD), sometimes create a challenge when diagnosing C-PAN. The presence of livedo reticularis (Fig. 50.25) and the finding of a characteristic skin biopsy appearance with C-PAN help to differentiate it from AOSD [18].

Diagnosis. Patients with necrotizing lesions of livedo reticularis must be evaluated for vasculitis or vasculopathy (e.g.

Fig. 50.24 Cutaneous polyarteritis nodosa. Nodules and ulceration.

Fig. 50.25 Cutaneous polyarteritis nodosa. Livedo of legs.

antiphospholipid antibody syndrome, cholesterol emboli or other factors that can produce non-vasculitic vessel occlusion; see Chapter 49). If nodules are present, they should be biopsied by incisional biopsy methods to assess for a panarteritis of muscular arteries which would confirm a diagnosis of C-PAN. The distinction from systemic PAN requires patient evaluation by history, physical examination, screening laboratory tests and ongoing follow-up. In addition, rheumatological consultation is often appropriate.

Treatment. Although no double-blind prospective trials have been performed, several reports suggest that non-steroidal anti-inflammatory drugs and salicylates can be an effective treatment for symptoms of C-PAN [19]. High-dose corticosteroids followed by tapering of the dosage may occasionally be necessary for some patients [20,21]. Also without evidence from controlled trials, but based on the strong association with streptococcal infection, penicillin is often used for treatment and prophylaxis in children with C-PAN. Screening for recent streptococcal infection with anti-DNAse B or other tests may guide this decision. Other treatments documented in anecdotal reports include dipyridamole, sulfapyridine, pentoxifylline and dapsone in patients with C-PAN. Low-dose weekly methotrexate (7.5–20 mg/week) has been successful in some patients with skin lesions unresponsive to corticosteroids given topically, intralesionally and orally [22]. In addition, chronic leg ulcers resistant to treatment with high-dose corticosteroids have recently been successfully treated with granulocyte-macrophage colony stimulating factor (GM-CSF) which has been shown to improve wound healing [23]. GM-CSF improves the clearance of bacteria and debris through the local attraction of neutrophils, promotes neovascularization and enhancement of keratinization, and induces acceleration of the formation of new tissue [23]. However, low-dose weekly methotrexate therapy and gradient support hosiery are anecdotally adequate therapy for the majority of patients with C-PAN [22].

Wegener's granulomatosis

Definition. WG is classically described as a triad consisting of systemic small vessel vasculitis, necrotizing granulomatous inflammation of both the upper and lower respiratory tracts, and glomerulonephritis. The first description of a patient with WG was by Klinger in 1931, but the disease was later defined in 1936 by Wegener who described three patients. It is a potentially severe disease which, if not treated, can lead to end-organ damage and/or death. Affecting males and females equally, the incidence of WG is 5–10 per million per year, with the majority of cases occurring in Caucasians [1–3]. The average age at onset is 40 years [4].

Aetiology and pathogenesis. Although the pathogenesis of WG is not well understood, it is believed that it may involve an amplified immune response to an antigenic stimulus, such as an infection. Clinical observation points to *Staphylococcus aureus* as a potential trigger in some patients. The incidence of chronic nasal carriage of *S. aureus* is significantly higher in patients with Wegener's granulomatosis compared with healthy individuals [5]. One theory regarding the pathogenesis of WG is that neutrophils are activated via cytokines or apoptosis and degranulate, expressing cytosolic proteins on their surfaces and releasing harmful oxygen radicals as well as chemoattractants [6–9]. This enables ANCA to form against complementary peptide sequences to proteinase-3, otherwise known as the 'Wegener's autoantigen' [10,11]. Wegener's autoantigen may be introduced by a pathogen, specifically *S. aureus*, which exhibits a protein with a peptide sequence that mimics that of antisense PR3 [11]. The cytoplasmic antinuclear cytoplasmic antibodies (C-ANCA) are directed at antisense PR3 sequences which then cross-react with PR3 peptide sequences, thereby functioning as autoantibodies [11]. The perinuclear antineutrophil cytoplasmic antibodies (P-ANCA) are directed at myeloperoxidase (MPO). PR3 induces dendritic cell maturation via the protease activated receptor (PAR)-2, which in turn induces a strong Th1-type T-cell response. The PR3-induced T-cell response in WG is stronger than in healthy and disease controls [10,12]. In addition, activated neutrophils then attract additional neutrophils and damage vascular endothelium by attaching to blood vessel walls [13–15]. Another theory about the role of ANCA in the pathogenesis of WG is that activated neutrophils located at damaged blood vessels release antigens, causing a secondary ANCA response [16].

Histopathology. Although most biopsy specimens taken from patients with WG show perivascular lymphocytic infiltrates, such non-specific infiltrates may not be related to the pathogenesis of the disease [17]. More specific findings such as leukocytoclastic vasculitis and/or granulomatous inflammation may be present in up to 50% of skin biopsy specimens (Figs 50.26 & 50.27), although granulomatous inflammation around vessels or palisading necrotizing granulomas are uncommonly demonstrated in skin lesions.

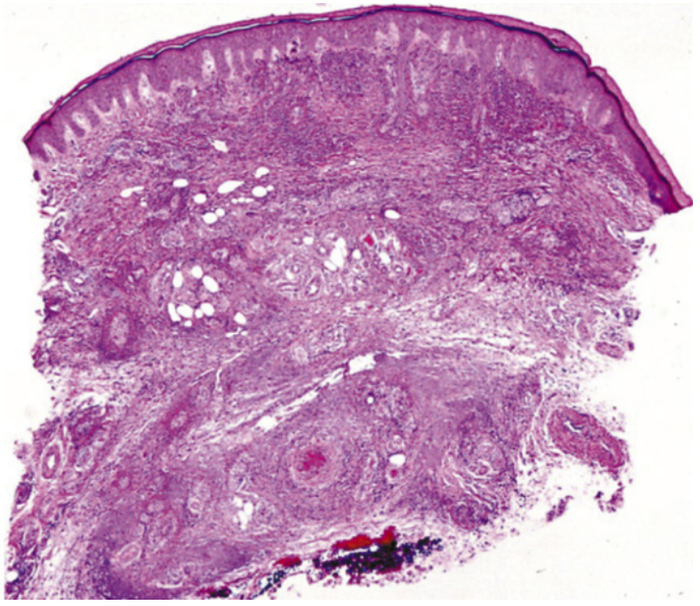

Fig. 50.26 Wegener's granulomatosis. There is extensive leukocytoclastic vasculitis involving the entire dermis. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

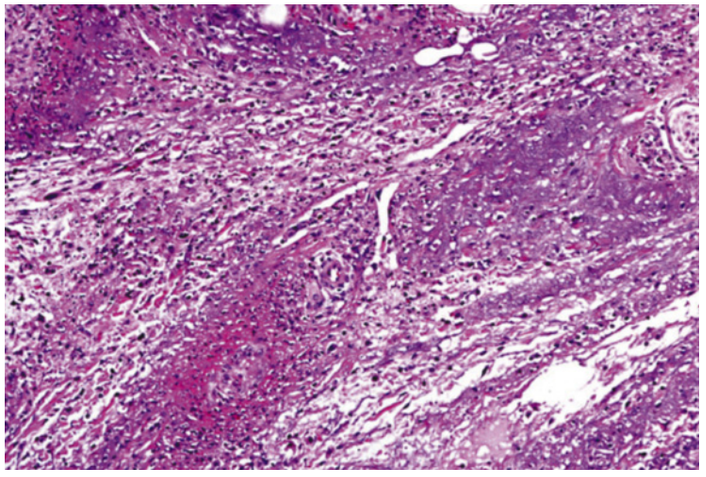

Fig. 50.27 Wegener's granulomatosis. Note the extensive area of collagen degeneration, destruction of vessels and mixed inflammatory infiltrate. (Courtesy of Dr Omar Sangueza, Wake Forest University School of Medicine, Winston-Salem, NC, USA.)

Clinical features. Features of the classic triad of WG are not always present early in the course of the disease, making the diagnosis sometimes difficult. Furthermore, presentation without involvement of the classical sites, including skin, respiratory tract

Fig. 50.28 Wegener's granulomatosis. Ulcerated lesions of cutaneous small vessel vasculitis.

Fig. 50.29 Wegener's granulomatosis. Larger ulcerated lesions with background vasculitis.

and kidneys, can occur. However, in up to 80% of patients, symptoms involving the upper or lower respiratory tract are present [18], and at presentation approximately 73% of patients will have nasal, sinus, tracheal or ear involvement. Less than half of all patients with WG present with pulmonary infiltrates or nodules. Renal disease is initially present in only 18% of patients, although approximately 77% will eventually develop glomerulonephritis [19]. Although 40% of patients with WG will eventually manifest skin findings, cutaneous manifestations and oral ulcers are only found in 13% and 6% of patients at initial presentation, respectively [19]. The most common cutaneous manifestation of WG is palpable purpura on dependent skin sites; other skin lesions include tender subcutaneous nodules, papules, vesicles and petechiae, as well as non-specific ulcers or pyoderma gangrenosum-like lesions. It is thought that patients previously diagnosed as having 'malignant pyoderma' may actually have had lesions secondary to WG. Nodular, or even papulonecrotic, lesions most commonly occur on the extremities but may also occur on the face and scalp. These non-specific lesions (also found in patients with CSS, rheumatoid arthritis, SLE, inflammatory bowel disease and some infectious states) may be differentiated from rheumatoid nodules in that they ulcerate, whereas rheumatoid nodules do not [20–22]. Oral ulcers are the second most common mucocutaneous sign of WG. The upper respiratory tract is most commonly affected by WG, with otitis, epistaxis, rhinorrhea and sinusitis as common presenting signs and symptoms. A saddle nose deformity may result from necrotizing granulomas of the nasal mucosa. Lower respiratory signs and symptoms include cough, dyspnoea, chest pain and haemoptysis. Ulcerative lesions in WG are shown in Figs 50.28–50.30.

Fig. 50.30 Wegener's granulomatosis, presenting with two deep skin ulcers and nasal symptoms.

Diagnosis. Wegener's granulomatosis must be differentiated from CSS. Important differences in these vasculitis syndromes are the lack of upper respiratory involvement and lack of severe glomerulonephritis in CSS, as well as the presence of asthma and eosinophilia in CSS but not in WG. Laboratory findings in WG include elevated ESR and CRP, anaemia, leukocytosis and positive rheumatoid factor [2,3]. Although a small percentage of patients will have a positive P-ANCA, or no ANCA reactivity, up to 80% of patients will have a positive C-ANCA (with anti-PR3 specificity) [23]. Those few patients with no ANCA reactivity may well have localized WG and a better prognosis when compared with those who are ANCA-positive [24,25]. Nodular densities from necrotizing granulomatous inflammation of lung tissue and pulmonary haemorrhage may be present on chest radiography; almost any chest X-ray change may represent WG, with the exception of hilar adenopathy [26].

Treatment. Inducing remission in patients with Wegener's granulomatosis is most successfully accomplished using a combination of corticosteroids and cytotoxic agents, such as cyclophosphamide. This combination of therapy results in a significant resolu-

tion of symptoms in greater than 90% of patients, with remission in 75%, and 87% surviving between 6 months and 24 years [19]. However, oral cyclophosphamide has significant toxicity and therefore other drugs, such as methotrexate, have been studied. Recent data suggest that, in patients with normal renal function, a methotrexate and prednisone regimen shows remission rates similar to the traditional cyclophosphamide and prednisone regimen. However, preliminary data suggest that the methotrexate plus prednisone regimen shows higher relapse rates, and therefore this regimen is suggested for inducing remission in a milder form of WG, such as head- and neck-limited disease [27]. The median survival for untreated WG remains only 5 months, and this prognosis is not appreciably altered by treatment with corticosteroids given as a monotherapy. Long-term treatment with trimethoprim–sulfamethoxazole (co-trimoxazole) has been documented to reduce the incidence of relapses, although side effects are relatively common [5]. Treatment options for refractory WG include anti-TNF-α agents such as infliximab or etanercept, and antilymphocyte antibodies such as rituximab. Rituximab is a monoclonal antibody that targets $CD20^+$ B-cells. It is currently used in the treatment of non-Hodgkin's lymphoma and rheumatoid arthritis but is also under investigation as a treatment option for refractory WG and other autoimmune diseases [28]. Impressive results can be seen, but development of antibodies to rituximab (due to its murine component) may limit long-term use.

Churg–Strauss syndrome

Synonyms
- Allergic granulomatosis
- Vasculitis of Churg and Strauss

Definition. CSS is a rare vasculitis affecting multiple organ systems. The majority of patients demonstrate cutaneous findings while in the active phase of the disease. The disease is characterized by asthma, peripheral blood eosinophilia and necrotizing vasculitis with extravascular granulomas. Originally described by Rackermann and Greene in 1939, as an allergic disease not classified as periarteritis nodosa, Churg and Strauss later described the syndrome and its histopathological characteristics in 1951.

Aetiology and pathogenesis. The aetiology of CSS is unknown, although vaccination, desensitization and rapid discontinuation of corticosteroids have been associated with the onset of symptoms of CSS [1]. In the past it was believed that leukotriene antagonists were associated with the onset of CSS; however, new research suggests that, after adjustment for other asthma drugs, there is not a strong association [2]. Leukotriene antagonists are a marker for more severe asthma and severe asthma is thought to be a risk factor for CSS [3]. The pathogenesis of CSS is not completely understood. Immune complex deposition was once thought to be the mechanism of vasculitis in CSS, although eosinophils, mediated by a Th-2 response, are now thought to be the effector cells in the disease [4].

There is growing evidence for increased eosinophil survival in blood and tissues in CSS [5], possibly due to decreased apoptosis. Recent research has documented increased expression of TRAIL receptor 3 on eosinophils in patients with CSS [6]. TRAIL is a member of the tumour necrosis factor superfamily (TNF-Related Apoptosis-Induced Ligand) that normally binds to two 'death receptors' and two decoy receptors (TRAIL receptors 3 and 4); these decoy receptors are expressed on eosinophils and have an antiapoptotic function, as they cannot transduce the death signal that is activated when TRAIL binds to death receptors. Thus increased expression of TRAIL receptor 3 would be expected to compete with death receptors for TRAIL binding, leading to prolonged eosinophil survival. Eosinophils secrete several highly toxic cytokines such as eosinophil major basic protein, eosinophil cationic protein (ECP), and eosinophil-derived neurotoxin, all of which cause tissue damage. Serum levels of ECP, which is a marker of eosinophil activation, often correspond with disease activity in CSS [7] and may be used to predict relapse [8].

Histopathology. Churg–Strauss syndrome is characterized by three key histopathological features: eosinophilic infiltration of tissue, formation of extravascular granulomas of the visceral and cutaneous tissue and vasculitis involving both arteries and veins. A biopsy specimen of a cutaneous lesion from a patient with CSS may demonstrate any one, if not all, of these features [9]. The granulomas of CSS contain necrotic polymorphonuclear leukocytes, eosinophils, severe fibrinoid and fibrillar collagen degeneration, and a proliferation of granulomatous tissue.

Clinical features [1,5,9]. Three phases of CSS have been described. The first phase, which may continue for years, consists of allergic rhinitis, nasal polyps, asthma and peripheral blood eosinophilia. The asthma component of this phase typically begins in adulthood, in contrast with allergic asthma. The second phase of CSS is vasculitis; this phase is characterized by disease affecting almost all organ systems, including cardiac, pulmonary, nervous, gastrointestinal, renal, genitourinary and musculoskeletal systems. Cardiac involvement is the primary cause of death in patients who do not respond to conventional corticosteroid therapy [10]. In this vasculitic phase, 70% of patients have skin lesions (Fig. 50.31). The third stage of CSS is characterized by allergic rhinitis, asthma, hypertension due to damage to the kidneys that occurred in the second phase, and peripheral neuropathies. There is typically complete resolution of damage to other organ systems. Nearly half of patients in all phases of the disease have cutaneous manifestations of the disease [1,9], with approximately 5% demonstrating cutaneous vasculitis [9]. Palpable purpura and infiltrated nodules (typically located on the scalp or limbs) [11] are the most common skin manifestations, but livedo reticularis, necrotizing livedo (i.e. retiform purpura), migratory erythema, new-onset Raynaud's phenomenon, aseptic pustules or vesicles, or infiltrated papules may also be present.

Diagnosis. The American College of Rheumatology 1990 criteria for the classification of Churg–Strauss syndrome are as follows: asthma, eosinophilia greater than 10% on differential white blood cell count, mononeuropathy (including multiplex) or polyneuropathy, non-fixed pulmonary infiltrates on roentgenography, paranasal sinus abnormality, and biopsy containing a blood vessel with extravascular eosinophils [12]. The manifestations of CSS may be easily confused with lesions of Wegener's granulomatosis (WG), although CSS is strongly associated with both asthma and involvement of the gastrointestinal tract, spleen and heart, in contrast with the strong association with renal disease in patients with WG. The triad of asthma, eosinophilia and extravascular granulomas may also be used to distinguish CSS from other disease processes.

Fig. 50.31 Relatively subtle vasculitis on the legs in Churg–Strauss syndrome; the patient also had eosinophilia and rapidly developed mononeuritis multiplex.

Treatment. Corticosteroids alone have been shown to be an effective treatment of CSS [5], with clinical remission achieved in over 90% of patients. However, the addition of cytotoxic agents, especially cyclophosphamide in severely affected patients, or therapy such as intravenous immunoglobulin (IVIG), may be useful in patients with recalcitrant disease or those with poor prognostic factors such as cardiac, GI, renal or CNS involvement [10], although no double-blind, prospective trials have been done to establish their use.

Giant cell arteritis

Synonyms
- Temporal arteritis
- Cranial arteritis

Definition. The definition provided by an International Consensus Conference for giant cell arteritis (GCA) was of a granulomatous arteritis of the aorta and its major branches, with a predilection for the extracranial branches of the carotid artery [1]. It often involves the temporal artery, usually occurs in patients older than 50 years and is often associated with polymyalgia rheumatica (PMR), a syndrome comprising aching and morning stiffness of the shoulder or pelvic girdle muscles that may precede or accompany GCA. However, the similar histopathological findings between GCA, PMR and Takayasu's arteritis have led some investigators to question whether they are separate entities or represent a continuum of disease [2,3]. The matter is not wholly settled.

Epidemiology. GCA is considered a disease that particularly targets Caucasians of European origin, being less common in African Americans, native Americans and Asians. The disease is about three times more common in women than men. The incidence appears to differ with geographical area, being commoner in more northern climes, but overall the worldwide incidence is about 1/50 000/year. The incidence may be increasing, particularly amongst women.

Aetiology and pathogenesis. Ethnic and geographical observations suggest that genetic factors probably contribute to development of GCA. Several studies have indicated an over-representation of HLA-DR4; recent associations have included HLA-class I and MICA and HLA-B polymorphisms [4]. It is suggested that the pathogenesis of GCA, as with many diseases, represents an aberrant response to an infectious agent and that the immune system appears to have a central role in the pathogenesis. The arterial adventitia contains dendritic cells, in close proximity with vasa vasorum, that are in an immature state in normal arterioles but that have a mature and activated phenotype in GCA, so that they are capable of triggering antigen-specific T cells [5]. Activated $CD4^+$ T cells that have undergone clonal expansion are also present in the adventitia and produce large quantities of IFN-γ [6]. In turn, IFN-γ can modify effector functions of macrophages and multinucleated giant cells that locate at the junction between the tunica intima and tunica media, setting up a vicious cycle with further production of proliferative and pro-inflammatory mediators. Distinct subsets of macrophages are present with non-overlapping functions that lead to production of proinflammatory cytokines, the release of reactive oxygen radicals, production of growth and angiogenic factors such as platelet-derived growth factor (PDGF) and vascular endothelial cell growth factor (VEGF), and production of nitric oxide synthase. The intimal hyperplasia and neovascularization that occurs in GCA, and which is largely responsible for the vascular occlusion and ischaemia, is probably driven by oxidative and nitrosactive stress within the medial smooth muscle cell layer. Intimal hyperplasia is also associated with the increased production of IFN-γ and formation of multinucleate giant cells.

Interestingly, in PMR, the arterial wall dendritic cells are in an activated state but there is aborted recruitment of $CD4^+$ T cells and macrophages, suggesting that PMR may be a *forme fruste* of GCA [6].

Histopathology. Almost any artery can be affected in GCA. Indeed, an exhaustive autopsy study by Ostberg in 1972, in which the entire aorta and its major branches were removed and sectioned, suggested that involvement of aortic branch vessels was common [7]. The affected artery demonstrates lymphocytic and macrophage infiltrates in the tunica media that can extend from the tunica intima to the adventitia. The internal elastic lamina is fragmented and concentric intimal thickening develops, leading to occlusion of the vessel lumen. Giant cells can be present but are not required for the diagnosis. Granulomas and fibrinoid necrosis are seen infrequently.

Clinical features. The symptoms and signs of GCA result from the inflammation and occlusion of affected arteries. The disease appears to target those arteries that contain an internal elastic lamina, that is extracranial vessels, sparing intracranial vessels.

Constitutional upset occurs in many patients with fever and weight loss, and GCA is associated with PMR in about half of individuals. Headache is common and may be localized to the area of the affected artery, that is temporal with temporal arteritis, or occipital with vertebrobasilar arteritis. The headache may start abruptly and may be associated with tender arteries that may be pulseless or nodular. Facial pain may occur on chewing due to claudication of jaw muscles. A feared complication is sudden, permanent visual loss related to ocular or orbital artery involvement. Transient monocular loss of vision (amaurosis fugax) may precede permanent loss in some individuals. Vertebrobasilar artery involvement may cause ataxia, vertigo or deafness.

Involvement of the aorta or of its main branches is common. In one longitudinal cohort study that used vascular imaging, 72% of patients had large artery involvement, usually of the aorta, axillary and subclavian arteries [8]. Aortic involvement can cause aortic arch syndrome with absent pulses and upper arm claudication, and aortic aneurysms can lead to life-threatening dissection.

Less common features include cerebrovascular accidents, neuropsychiatric manifestations, angina or myocardial infarction, bowel angina or infarction, leg claudication and renal

involvement. Unilateral or bilateral scalp ulceration, with or without necrosis, may occur. Rarely, tongue ulceration or infarction, or corneal ulceration, develops.

Diagnosis. The gold standard is histological diagnosis following biopsy of an affected artery, usually a temporal artery. The biopsy should ideally comprise a 2 cm length of vessel and, for the greatest chance of obtaining a tissue diagnosis, the biopsy should be performed within 24 h of commencing corticosteroid therapy. A negative biopsy does not exclude the diagnosis, because timing is important and the disease may be quite focal.

Imaging is playing an increasing role in diagnosis. Superficial temporal arteries and axillary arteries may be amenable to duplex ultrasound, and fluorodeoxy-glucose-positron emission tomography and magnetic resonance angiography are increasingly being used for evaluation of disease activity and extent [9,10].

The acute inflammatory response can be measured by C-reactive protein (CRP) levels and erythrocyte sedimentation rate (ESR). Interleukin-6 levels may be a more sensitive biomarker of disease activity than the ESR [11]. A normochromic, normocytic anaemia, thrombocytosis and raised alkaline phosphatase may all be present.

Treatment. Suspected PMR responds well to oral corticosteroids such as prednisolone, 15–20 mg daily. The dose can usually be reduced slowly in small steps every month, providing that the CRP/ESR levels remain controlled. Treatment is usually for 2–3 years. Higher doses of corticosteroids, for example prednisolone 40–60 mg daily, are needed for GCA. Treatment should be started as soon as the diagnosis is suspected in order to avoid the potential for the complications discussed earlier; if the diagnosis turns out to be incorrect, the corticosteroids can be quickly withdrawn. There is some evidence that initial high-dose methylprednisolone may allow for more rapid tapering of oral corticosteroids and may be associated with a greater number of patients experiencing long-term remission after discontinuation of treatment [12]. Intravenous methylprednisolone 500–1000 mg daily for 3 days, followed by oral prednisolone, may be particularly beneficial in those with visual loss. Unfortunately, if visual loss has already occurred, this may be permanent, but it is important to preserve residual vision and prevent further strokes. The dose of prednisolone can be reduced to 10–20 mg/day by 6 months, and then in small increments with discontinuation by 2–3 years, depending on ESR/CRP/interleukin-6 responses. Sometimes additional immunosuppressive therapy, such as azathioprine, mycophenolate mofetil or methotrexate, is required; some patients require treatment for many years. Aspirin is recommended providing there are no contraindications. Carotid artery stenoses may require angioplasty to improve perfusion.

Takayasu's arteritis

Synonyms

- Takayasu's disease
- Takayasu's syndrome
- Aortic arch syndrome
- Pulseless disease
- Occlusive thromboarteriopathy
- Aortitis syndrome

Definition. Takayasu's arteritis (TA) is a granulomatous inflammation of the aorta and its major branches that usually occurs in patients aged younger than 50 years [1]. Although it is most common in individuals less than 40–50 years of age, it may occasionally be diagnosed in older people.

Epidemiology. The disorder is often described as affecting young females of Oriental origin and, indeed, it appears to be a relatively common cause of renovascular hypertension in the Far East, although it does have a worldwide distribution and racial heterogeneity.

Aetiology and pathogenesis. TA is associated with an acute inflammatory response, and the histopathology of acute lesions is similar to that described in GCA, so inflammatory and immune mechanisms appear to be necessary for pathogenesis. Genetic, infectious and environmental triggers have been sought but none has been associated conclusively with the disease. Various HLA associations have been described depending on the population under study, and susceptibility has been linked to polymorphisms around the HLA-B and MICA genes [2]. Tubercle bacilli have been scrutinized as a possible precipitant, but patients generally respond to immunosuppression without development of overt tuberculosis.

Histopathology. The aorta and its branches are targeted and skip lesions can occur [3]. During the acute phase, a pan-arteritis is present. The inflammatory infiltrate may be predominantly around the vasa vasorum. Fibrosis gradually replaces inflammatory infiltrates. The vessel lumen may be narrowed secondary to the fibrosing stenotic lesions and/or by intraluminal thrombosis. In older patients there may be superimposed atherosclerosis, and calcification in the wall may occur as a late feature.

Clinical features. The symptoms and signs of TA result from inflammation, ischaemia and aneurysm formation within the aorta and its branches [4]. There may be overlap in features of TA with those of GCA [5]. Hypertension is a common presenting feature in Asian and Far Eastern patients and the blood pressure should be recorded in all four limbs. Renal artery stenosis, increased arterial stiffness and increased sensitivity of the carotid sinus reflex, all contribute to hypertension. Involvement of the renal arteries can also cause renal dysfunction, and abdominal pain, bleeding or perforation may result from ischaemia or infarction of a viscus. Involvement of the aortic arch and its branches can lead to 'aortic arch syndrome' with arm claudication, absent radial or brachial pulses (hence 'pulseless disease') or subclavian artery bruits. Aortic regurgitation, coronary artery ischaemia with angina or myocardial infarction, pulmonary hypertension, stroke, syncope and visual disturbances can occur.

Skin lesions have been reported in up to a third of cases and may comprise erythema nodosum, erythema induratum and pyoderma gangrenosum [6], as well as ulcerated subacute nodular lesions, papulonecrotic eruptions, papular erythematous lesions of the hands and fingers, facial lupus-like rashes and panniculitis [7]. Cutaneous necrotizing vasculitis has been described resembling nodular vasculitis/erythema induratum, suggesting that Takayasu's arteritis may occasionally involve small blood vessels [8]. The skin lesions do not appear to relate to the distribution of vascular involvement in any way.

Diagnosis. TA is best diagnosed using imaging techniques [9]. Angiography and magnetic resonance angiography may demonstrate stenotic lesions of the aorta or its branches. Increasingly, enhanced magnetic resonance perfusion imaging, duplex ultrasonography and positron emission tomography are being used [10].

In the early stages of the disease, inflammatory markers such as CRP and ESR may be elevated. However, if disease presentation occurs late, features of an acute inflammatory response may be absent. A normochromic normocytic anaemia is often present.

Treatment. The acute phase of TA is managed in a similar way to GCA. The response is usually less dramatic than in GCA and secondary immunosuppressant medication is often required. However, once arterial damage has occurred and the inflammatory component has settled, immunosuppression is unlikely to be helpful. Stenotic lesions may require treatment with angioplasty or stenting. Hypertension requires aggressive management. Smoking should be discouraged and, as there is an increased risk of premature atherosclerosis, cardiac risk factors should be sought and dealt with.

Other vasculitides and mimics of vasculitis

Kawasaki disease [1]

This eponymous disease is a mucocutaneous lymph node syndrome, predominantly affecting young children, although recurrent disease in adults and adult-onset disease can occur. It is discussed briefly here as the systemic component includes a multisystem vasculitis; however, the exanthem it causes is not vasculitic. It is discussed in more detail in Chapter 30 (Bacterial infections) because it occurs in epidemics and there is some evidence to suggest an infective aetiology, possibly involving *Staphylococcus aureus*, *Streptococcus pyogenes* or *Yersinia pseudotuberculosis*. Bacterial superantigens, notably staphylococcal toxic shock syndrome toxin type-1 (STSS-1) and streptococcal pyrogenic exotoxins B and C, have particularly been implicated, although evidence to support this is poor [2]. More recently, an IgA response to cytoplasmic inclusion bodies has been documented as a possible cause [3].

At a pathogenetic level, many factors common to medium and larger vessel vasculitides can be found, including activated T cells, B cells and monocyte/macrophages, as well as elevated TNF-α, IFN-γ, IL-1, IL-2, IL-6, IL-12 and ICAM-1 [1]; antiendothelial cell antibodies are also present. Elevated levels of anti-α-enolase antibodies have been demonstrated and suggested to have a pathogenetic role [4]. The elastolytic role of matrix metalloproteinases is also thought to be involved; MMP-1, MMP-2, MMP-9 and MMP-13 have all been implicated, but high circulating levels of MMP-2 and MMP-9 were shown not to be significantly associated with coronary outcome after adjusting for demographic, clinical and laboratory features in patients or in a mouse model [5]. However, a genetic polymorphism in MMP-13 has been proven to occur with a significant difference in frequency in patients with Kawasaki disease with coronary artery lesions than in those without such lesions [6].

The angiitis of Kawasaki disease affects nearly all organs, with a very high frequency of cardiac involvement, which follows four stages [1]. Initially, there is perivasculitis and vasculitis of small vessels (capillaries, small veins and arteries, including those of the vasa vasora of the main coronary arteries); as the stages progress there is a gradual decrease in the small vessel vasculitis but development of focal panvasculitis of medium-size arteries, especially of the heart, with a mixed inflammatory infiltrate. During this phase (stage 2), aneurysms, thrombosis and stenoses of medium-size arteries develop, with gradual scarring and loss of acute vasculitis by stage 4. Deaths may occur due to myocarditis, dysrhythmias, pericarditis, rupture of aneurysms and occlusion of coronary arteries; there is also an increased risk of atherosclerosis due to endothelial cell dysfunction. Coronary aneurysms are demonstrated in almost 20% of patients (and in 90% of those who die); some will regress (potentially with stenosis) but giant aneurysms (>8 mm) rarely regress, carry a high risk of death and may require bypass surgery. Clinical factors that predict a higher risk of coronary artery arteritic lesions or aneurysms, or that predict a poor response to treatment, include age below 1 year, low serum albumin, low haemoglobin, high CRP, abnormal liver function and, especially, duration of fever before treatment [7–10]; peripheral blood eosinophilia (>4%) after treatment is also associated with treatment resistance [10].

The angiitis of Kawasaki disease can be divided into that which affects medium- and large-size arteries outside organs (mainly the coronary arteries, in 90%, also the iliac and other arteries), arteritis within organs (also mainly cardiac, but also the skin, kidneys, gastrointestinal tract and others), and venulitis. Thrombotic disease, which may be triggered by tissue factor [11], is probably important as a cause of morbidity and mortality; gangrene of the legs and disseminated intravascular coagulopathy (DIC) have both been reported [12,13]. Clinically, the skin lesions are polymorphous, including urticarial, morbilliform, maculopapular, erythema-multiforme-like patterns, and less commonly aseptic pustules on knees or buttocks, or a scarlatina-like erythroderma. Hands and feet become swollen, with palmoplantar erythema and subsequent desquamation.

Treatment is with intravenous immunoglobulin (IVIG) and aspirin, which reduce fever and development of aneurysms. There is conflicting evidence regarding the benefits of additionally using pulsed corticosteroid therapy. Other cardiac medications or surgery may be required; formal high-dose anticoagulation is needed for those with large coronary aneurysms. In those in whom IVIG fails (based on echocardiological assessment for aneurysms), re-treatment may be tried, plasma exchange may be successful, and infliximab has also been used. Diagnosis and treatment, with an emphasis on long-term treatment and cardiac disease, have been documented in detail by an expert consensus committee [14].

Cerebral vasculitis and mimics

Some of the primary vasculitides discussed earlier have cerebral vasculitis as a possible component. There are also various infections, tumours, autoimmune disorders (such as antiphospholipid syndrome), collagen vascular disorders and other systemic diseases (such as sarcoidosis) that may combine neurological and cutaneous lesions and for which vasculitis might be considered in the differential diagnosis. Hypercoagulable states, sickle cell disease, thrombi (e.g. myxoma), Sneddon's syndrome (Chapter 49) and Fabry disease (Chapter 59) may all have both central nervous system and cutaneous features. Although vasculitides with predominantly cerebral features will not present to dermatologists, a few disorders warrant specific mention in the differential diagnosis of cerebral vasculitis as they may have skin manifestations that might suggest a vasculitis, thrombotic or microvascular occlusive process.

Intravascular lymphoma (intravascular lymphomatosis, angiotropic lymphoma, malignant angioendotheliomatosis) is caused by proliferation of clonal lymphocytes (usually B cells) within small vessels, and most commonly affects the central nervous system (CNS) and the skin. Cerebral vasculitis is often in the differential diagnosis of CNS involvement, both clinically and radiologically, and some of the cerebral pathology is due to thrombosis. Skin lesions occur in 40%, and may be the only site affected in 25%; they include localized or generalized telangiectasia, and tender indurated dermal or subcutaneous plaques or nodules with a blue to red colour, mainly on the lower legs, with associated painful swelling. The physical signs may mimic erythema nodosum, thrombophlebitis, adult Still's disease or cellulitis [1,2]. Gangrene of the lower extremities has been reported, and a vasculitis-like

illness with dementia [3]. One case has been reported with systemic lupus erythematosus (SLE) [4]; however, significantly raised serum ANA levels may be found in the absence of other features of SLE [3,5,6], erroneously suggesting a possible diagnosis of connective tissue disease-related vasculitis.

CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is a rare disorder that often presents as a form of dementia. It is due to a mutation in *NOTCH3* on chromosome 19 and is characterized histologically by granular osmiophilic material in the media of arterioles and small arteries, although this also occurs in non-muscular vessels including veins and capillaries [7]. Although the skin is not usually involved clinically, it is at a microscopic level, vessel walls being thickened by PAS-positive material. Additionally, haemorrhagic macular lesions with strong positive direct immunofluorescence for immunoglobulins, complement and fibrin, have been reported in CADASIL [8]. The neurological presentations include transient ischaemic attacks, which, if occurring in combination with haemorrhagic skin lesions, would mean that embolic or vasculitic processes might easily be suspected. Electron microscopy or NOTCH3 immunostaining [9] of skin biopsies may be useful, but gene analysis is more precise.

Leukoencephalopathies [10]. Two such disorders have particular relevance to dermatologists. *Progressive multifocal leukoencephalopathy* is caused by reactivation of the JC polyoma virus. It is particularly linked with systemic lupus erythematosus (SLE) and other collagen vascular diseases or vasculitides, even in patients on mild immunosuppressive regimens, suggesting that immune dysregulation may play a part in viral reactivation. It should be considered if cerebral symptoms are thought to be due to the underlying connective tissue disorder but fail to respond to increased immunosuppression; the importance is that it is progressive and usually fatal, and immunosuppressive treatment should be discontinued rather than increased. *Reversible posterior leukoencephalopathy syndrome* has also been associated with immunosuppressive therapy, usually more intensive treatment of renal disease or accelerated hypertension in SLE or Wegener's granulomatosis.

In tertiary referral practice, cerebral vasculitis occurs as a primary disorder (about 10% of cases), or is part of PAN (15%), MPA (10%), adult HSP (10–15%), WG (15–20%), SLE (15%) or cutaneous vasculitis (4%) [11]. The course and outcome of primary angiitis of the central nervous system (PACNS) appears to be related to the size of vessel involved, small-vessel disease being responsive to immunosuppression but having a relapsing recurrent course with severe brain injury, whereas medium-vessel disease tends to occur as isolated episodes with few relapses after treatment is discontinued. Therapy is recommended for at least 5 years for those with small-vessel disease, which may represent a limited form of PAN [11].

Lymphocytic vasculitis

Lymphocytic vasculitis does not neatly fit into classifications of vasculitis, except perhaps those based mainly on histopathological features [1–4]. Suggested classifications [3] have never really crossed from pathological to clinical practice, even though some skin disorders (e.g. graft-versus-host disease, Chapter 62) are good examples of lymphocytic vascular damage. To aid understanding of this area, the optimum terminology for lymphocytic vasculitis may need to be slightly different from that of leukocytoclastic vasculitides; for example, the use of terms such as lymphocytic endovasculitis, angiodestructive lymphocytic vasculitis, lichenoid lymphocytic vasculitis, lymphocytic granulomatous vasculitis and lichenoid dermatitis with granulomatous lymphocytic vasculitis, has been proposed [1,4].

It has been suggested that clinicians may try to adapt lymphocytic vasculitis into their working concept of neutrophilic vasculitis and its causes, possibly to the detriment of understanding of lymphocytic vasculitis. This perhaps occurs in part because many of the disorders already discussed may have a lymphocyte-predominant infiltrate at some point in their evolution (typically in more chronic lesions, thereby detracting from the possibility of acute lymphocytic vasculitis), partly because karyorrhexis (nuclear fragmentation) is more associated with polymorphonuclear cells (leukocytoclasis) than with lymphocytes, and also because other identifying features of vasculitis, such as fibrin deposition, are less constant in lymphocytic disease. Probably, some lymphocytic 'vasculopathies' actually represent lymphocytic vasculitis. Additionally, for the clinician, a histopathology report of a lymphocytic vasculitis often indicates that finding a cause will be difficult and that treatment may be difficult, even though lymphocytic vasculitis confined to the skin is often more indolent than its leukocytoclastic counterpart. An additional issue that makes lymphocytic vasculitis more difficult to understand is that, whereas neutrophils in vessel walls may be innocent (undergoing diapedesis) or harmful, lymphocytes in the wall of a muscular vessel are abnormal [3]. Fibrin deposition does occur, as with leukocytoclastic vasculitis, but in many respects the histopathological techniques necessary to understand lymphocytic vasculitis are less advanced than for leukocytoclastic disease. The benefits

of anti-TNF agents and of rituximab in vasculitides point to an important role of both T and B lymphocytes.

This section discusses some of the causes of vasculitis that are particularly associated with a lymphocyte-predominant (but not granulomatous) infiltrate. A histopathological classification (noting that different pathological patterns may coexist) can be summarized as [4]:

1 angiodestructive lymphocytic vasculitis—rare, usually seen in angiodestructive lymphomas or lymphomatoid granulomatosis, but occurs in some patterns of lupus erythematosus and in Behçet's disease
2 lichenoid lymphocytic vasculitis—the most common pattern, which may occur in viral infections, drug reactions, erythema multiforme, lupus erythematosus, graft-versus-host disease, pityriasis lichenoides, lymphomatoid papulosis, lichenoid mycosis fungoides and Degos' disease; a granulomatous component may also occur in some cases of lichenoid and granulomatous mycosis fungoides [5], as well as in mycobacterial infection and in patients with associated hepatobiliary disease [6]
3 lymphocytic endovasculitis—this affects medium size vessels causing intimal hyperplasia and vessel wall mucinosis, or causes segmental hyalinization of smaller vessels with thrombosis; examples include chronic graft-versus-host disease, scleroderma, lupus erythematosus profundus, some livedoid vasculopathy and Degos' disease.

A clinically orientated summary, based on aetiology, is suggested in Table 50.11; disorders discussed elsewhere in this section are cross-referenced from the table.

Leukocytoclastic vasculitis of many types may, in older lesions, have lymphocyte predominance. Examples include GF (in which the mononuclear infiltrate may appear pseudolymphomatous in late lesions, although plasma cells are also present as well as angiocentric fibrosis [1]), EED (although the infiltrate of older lesions also usually contains lipid-laden histiocytes and plasma cells, and exhibits fibrosis), C-PAN (histiocytes also present) and GCA (mixed infiltrate). In *urticarial vasculitis*, a recent study has suggested that the majority of cases have a lymphocyte-predominant infiltrate with an admixture of eosinophils, and that a neutrophilic infiltrate with leukocytoclasis is present in the minority [7], although in the past a leukocytoclastic vasculitis has usually been described; this issue is discussed on p. 50.22. *Macular arteritis* is discussed below (p. 50.51); its infiltrate is typically lymphocytic.

Collagen vascular disorders such as *systemic lupus erythematosus* (SLE), *rheumatoid disease*, *dermatomyositis* and *sclerodermas* may exhibit a type II immune response leading to either a pauci-inflammatory thrombogenic vasculopathy and/or a lymphocytic vasculitis [1], although SLE and rheumatoid disease in particular can also be associated with neutrophilic leukocytoclastic vasculitis. In rheumatoid disease, this may vary from superficial neutrophilic lesions (occasionally pustular or Sweet's syndrome-like) to palisaded neutrophilic granulomatous dermatitis (discussed below, p. 50.52). SLE is associated predominantly with thrombotic infarction, but a lymphocytic vasculitis may affect any organ; in the skin it is often pan-dermal rather than the more superficial leukocytoclastic pattern. Numerous skin lesions are associated with rheumatoid disease (Chapter 51), including various forms of vasculitis, but a thrombotic and lymphocytic vasculitis may affect vessels of all sizes. Less commonly, an eosinophilic vasculitis may also occur in collagen vascular diseases [8]. Vasculitis occurring with *relapsing polychondritis* is usually leukocytoclastic but in a small proportion of cases it may be lymphocytic. The vasculitis

Table 50.11 An aetiological classification of lymphocytic vasculitis*.

Type of process	Examples
Inherited	X-linked lymphoproliferative syndrome Autosomal dominant cutaneous small vessel lymphocytic vasculitis
Collagen vascular diseases	Systemic lupus erythematosus Rheumatoid disease Sclerodermas Dermatomyositis Sjögren's syndrome
Other autoimmune conditions	Lichen sclerosus Diabetic mastopathy
Vasculitides, vasculopathies and microvascular occlusion disorders	Older lesions of several leukocytoclastic vasculitides (see text) Urticarial vasculitis (some cases) (p. 50.21) Polyarteritis nodosa (classic and cutaneous types) Nodular vasculitis Behçet's disease (some lesions) (p. 50.56) Pyoderma gangrenosum (some cases) Degos' disease and Sneddon's syndrome (Chapter 49) Buerger's disease and Mondor's disease Macular arteritis (p. 50.51) Lymphocytic thrombophilic arteritis (p. 50.51) Pityriasis lichenoides et varioliformis acuta (p. 50.50) IgA-associated lymphocytic vasculitis Pigmented purpuric dermatosis (some) Kawasaki disease
Infections	Viral, especially: Epstein-Barr virus varicella-zoster virus (may also be granulomatous) cytomegalovirus Rickettsial
Drugs and vaccinations	Anti-TNF monoclonals Interferon Bortezomib Other systemic drugs, various Topical NSAIDs Imiquimod Various vaccines
Malignancy and paraneoplastic	Chronic lymphocytic leukaemia Lymphomas (especially angiocentric T-cell lymphomas) Myeloproliferative disorders and leukaemia (some) Paraneoplastic vasculitis (some)
Miscellaneous	Perniosis Graft-versus-host disease Some arthropod bites

* Note that other patterns of vasculitis, or thrombotic vasculopathy, may also occur in many of the disorders listed.

that may occur in *Sjögren's syndrome* is immune complex mediated, due to increased immunoglobulin production as a result of B-cell hyperreactivity, and is almost always neutrophilic.

Lupus erythematosus panniculitis may have features of lymphocytic vasculitis in a third of cases [9]; this, combined with the demographics (usually young females), site (usually upper arm or trunk), hyalinization of fat [4] and deposition of mucin in many cases, help to distinguish it from other causes of panniculitis. Similarly, scleroderma profunda is associated with a lymphocytic pattern of vasculitis [4,10].

Behçet's disease is discussed in detail later (p. 50.56). Numerous patterns of vascular injury occur including neutrophilic infiltrates with or without vasculitis, lymphocytic vasculitis, thrombotic lesions which may cause secondary vascular injury, histiocytic panniculitis (erythema nodosum-like lesions), and others [1,11]. Lymphocytic vasculitis is common in the erythema nodosum-like lesions [1,12,13], occurs in acral papular lesions, and is even present in nearly 30% of pustular lesions [14]. Lymphocytic vasculitis has also occasionally been reported in some cases of *pyoderma gangrenosum* [15,16], although leukocytoclastic vasculitis is more common in those cases that have a vasculitic component.

Viral and occasionally other infections are an important cause of lymphocytic vasculitis. Those most commonly implicated are Epstein–Barr virus (EBV), varicella-zoster virus and cytomegalovirus [17–21]. These viruses all have an affinity for endothelial cells, and can all generate clonal T-cell expansion, although the relationship between cutaneous and peripheral T-cell expansion does not appear to be straightforward [16]. EBV may also play a role in the lymphocytic vasculitis of X-linked lymphoproliferative disorder (discussed below). In some cases, viral inclusion bodies are seen in endothelial cells, but in others there is no PCR evidence of viral DNA in the infiltrating cells, so the precise mechanisms of the lymphocytic vasculitis are not fully explained. A lymphocytic vasculitis and perineuritis was documented in a case of parvovirus B19 infection [22]. Rickettsiae also infect endothelial cells and may cause lymphocytic vasculitis [2], and lymphocytic vasculitis has also been reported in dengue fever.

Drugs of many types may cause vasculitis of different types (see p. 50.17). Amongst the most important to recognize is the lymphocytic vasculitis that occurs due to *anti-TNF agents* [23,24]. This may be diagnostically difficult if the drugs are being used in patients with a vasculitis-prone disorder (such as rheumatoid disease), or indeed to treat vasculitis; notable features are that the vasculitis due to these drugs may be aggravated by a change to a different agent, and may relapse at intervals for several years after exposure [24]. Another new drug that can cause a cutaneous lymphocytic vasculitis is *bortezomib*, a proteosome inhibitor used in treatment of non-Hodgkin's lymphoma; patients who develop vasculitis also appear to have a better response to treatment [25]. Several drug causes of lichenoid and granulomatous dermatitis are listed in [6]; in some cases, granulomatous lymphocytic vasculitis was documented.

Topical drugs may also be associated with vasculitis; cases due to non-steroidal anti-inflammatory drugs may have a leukocytoclastic or a lymphocytic vasculitis [26], and lymphocytic vasculitis has been reported due to imiquimod [27]. Vaccination reactions may also cause lymphocytic vasculitis. This has been reported with anthrax vaccine [28] and with tetanus toxoid, the latter case progressing to membranous fat necrosis [29].

Vasculitis mimics such as Degos' disease (a form of microvascular occlusion; Chapter 49) [4] and pityriasis lichenoides may exhibit an element of lymphocytic vasculitis (in the latter case, in its pityriasis lichenoides et varioliformis acuta form; p. 50.50) [4]. Pigmented purpuric dermatoses typically have a mild capillaritis (Chapter 49) but in some instances a lymphocytic vasculitis has been suggested; one possible variant which clinically resembled a pigmented purpuric dermatosis was documented as *IgA-associated lymphocytic vasculitis* [30]. In the cases reported, preceding diseases included HSP, undifferentiated connective tissue disease (known to be associated with lymphocytic vasculitis [31]), lupus erythematosus profundus (see above), Degos' disease, Buerger's disease and viral infection. An immune complex pathogenesis was proposed.

Paraneoplastic vasculitis may sometimes cause a vasculitis of lymphocytic type. The most frequent is that associated with chronic lymphocytic leukaemia (CLL) [32,33] although other lymphomas, hairy cell leukaemia and myeloproliferative disorders may all be associated with a lymphocytic pattern of vasculitis. Rarely, CLL has been associated with an ANCA-positive systemic vasculitis.

Lichen sclerosus (LS; Chapters 51 and 71) is generally viewed as an autoimmune condition with a lymphocytic lichenoid infiltrate histologically. However, a large study of both vulval and penile LS biopsies found that both a perivascular lymphocytic infiltrate without vascular damage and a frank lymphocytic vasculitis were common; the latter had a concentric pattern around vascular adventitiae mainly in penile LS, and subendothelial infiltration with occasional fibrin deposition which was most common in vulval LS [34]. Larger muscular vessel wall infiltration was also documented in some cases, and a granulomatous component in some cases (including one patient with LS and hepatitis C, although the changes in this patient were superficial and lichenoid and not documented as prominently vasculitic [6]).

Diabetic mastopathy [35] is a rare condition but could present to dermatologists. It occurs mostly in type I diabetes, and presents as a unilateral (about 75%) or bilateral (25%) discrete mass or diffuse nodularity, predominantly of the subareolar region. Histologically there is a lymphocytic ductitis and lobulitis, with vasculitis in some cases. Recurrence, or involvement of the contralateral breast, occurs in a third of cases. The specificity of this disorder is uncertain as it also occurs in type 2 diabetes, occasionally in non-diabetic subjects, and in males.

Inherited lymphocytic vasculitis is rare [36,37]. In X-linked lymphoproliferative syndrome, the cause has been felt to be an abnormal response to EBV infection; however, a recent study failed to demonstrate EBV genomic sequences in lesions, so this pathogenetic mechanism is uncertain.

Pityriasis lichenoides (Chapter 57)

Although an overlap with vasculitis and an immune complex-mediated pathogenesis has been suggested, there is increasing evidence that the three entities that make up pityriasis lichenoides represent a cytotoxic $CD8^+$ T cell proliferation that may occur in different settings [1,2], at least some cases having convincing evidence of an infective trigger [3,4]. The clinically milder and smaller lesions of pityriasis lichenoides chronica (PLC) are unlikely to be confused with a vasculitis, but the more severe and sometimes necrotic lesions of pityriasis lichenoides et varioliformis acuta (PLEVA, Mucha–Habermann disease) may resemble a vasculitis, pyoderma gangrenosum or lymphomatoid papulosis. Vasculitic features are prominent in the much rarer and aggressive form, febrile ulceronecrotic Mucha–Habermann disease (FUMHD) [3–8] (Fig. 50.32). In contrast with PLC and PLEVA, which occur mainly in childhood and which may coexist, FUMHD usually occurs in

Fig. 50.32 Febrile ulcerative Mucha–Habermann disease, a disorder with pronounced systemic features that may mimic a vasculitis. (Courtesy of Drs I. Helbling and V. Yates, Hope Hospital, Salford, UK).

males in the second or third decade of life [3], and, although it can evolve from PLC or PLEVA [4], it usually occurs in isolation without more recognizable, milder pityriasis lichenoides lesions.

The lesions of PLEVA are oedematous papules and nodules that undergo central vesiculation (sometimes forming larger bullae) and haemorrhagic necrosis, eventually healing with varioliform scarring. In FUMHD, there are abundant, large necrotic lesions. Additional clinical features that might suggest a vasculitis include constitutional symptoms such as fever, headache, malaise and arthralgia that may precede or accompany the onset of PLEVA; in FUHMD there is high fever, general malaise, weakness, myalgia, neuropsychiatric symptoms and lymphadenopathy, with non-specific serological markers of inflammation such as raised ESR and C-reactive protein, and a fulminating course that may even be fatal [8].

Histological features that may suggest vasculitis in inflammatory or necrotic lesions include extravasation of erythrocytes and endothelial proliferation, although in PLEVA the infiltrate (comprised mainly of CD8 lymphocytes) may be deep, dense and wedge-shaped rather than predominantly perivascular. Immunofluorescence studies have variably demonstrated IgM, C3 or fibrin in vessel walls of fresh (usually purpuric) lesions, or at the dermoepidermal junction, and some studies have documented circulating immune complexes, all features that might be consistent with an immune complex-mediated vasculitic pathogenesis [3]. Indeed, in FUMHD there may be marked fibrinoid necrosis of deep vessels with luminal thrombi, partial necrosis of follicles and complete necrosis of eccrine glands [5], which may not be histologically distinguishable from other forms of acute necrosis of the skin.

Treatment options in aggressive PLEVA or FUMHD include systemic corticosteroids, methotrexate, dapsone, ciclosporin and intravenous immunoglobulin. Investigation for possible infection, with appropriate treatment, is also potentially important; serological evidence of associated herpes varicella-zoster [2] and cytomegalovirus [9] infections has been recorded in FUMHD.

Macular arteritis [1–3]

This recently described disorder is of uncertain causation. The clinical presentation is development of multiple asymptomatic or mildly pruritic, hyperpigmented macules on the trunk or, most commonly, the limbs; the lesions may have slight induration and sometimes have a degree of linearity or reticulation. Histology shows a deeply situated perivascular lymphocytic infiltrate or lymphocytic vasculitis affecting small arteries, which may be in the subcutaneous fat. An admixture of plasma cells is present in some cases. Fibrinoid necrosis of the vascular adventitia may occur, with luminal narrowing and eventual obliteration, but the tunica elastica is intact. There is no leukocytoclasis, no granuloma formation and no haemosiderin or melanin incontinence to explain the pigmentation (which is presumed to be epidermal). Patients are systemically well, do not have renal involvement, have negative ANCA and usually have no other serological abnormality.

Although earlier descriptions distinguished this disorder from C-PAN because the primary lesion is a pigmented macule, and there is no associated livedo, no ulceration, no non-pigmented dermal nodules and no tenderness of lesions [1,2], a recent pathological evaluation of biopsies from a patient with lesions on the instep of one foot led to the suggestion that this might be a latent, non-nodule forming variant of C-PAN [3].

Lymphocytic thrombophilic arteritis [1,2]

This is a very recently described, medium-size vessel arteritis, reported in five young women; all had gradually progressing patchy and reticulate pigmentation, subtle (more marked in one case) subcutaneous indurated areas, with livedo racemosa of the lower limbs [1]. Pain was a feature in one patient, and Raynaud's phenomenon in another. Histologically, there was a predominantly lymphocytic infiltrate in the muscular wall of small arteries of the deep dermis and superficial subcutis, with a ring of fibrin deposition concentrically situated at the periphery of all affected vascular lumina. Granulocytes were scanty or absent, and inflammation was tightly confined within the panniculus in the vicinity of affected vessels. Four of the patients had antiphospholipid antibodies, one also having factor V Leiden; three had positive antinuclear antibodies (but this was negative in two cases on retesting) and three had modestly elevated erythrocyte sedimentation rate. The combined features of lymphocytic vascular inflammation and thrombophilic endovasculitis suggested that the term lymphocytic thrombophilic arteritis was appropriate.

The nosology of this condition has been discussed by LeBoit [2], and it may represent the same condition as the macular arteritis described above. Clinically, polyarteritis nodosa is probably the most likely differential diagnosis, or collagen vascular diseases with livedo and antiphospholipid antibodies.

Palisaded neutrophilic and granulomatous dermatitis [1–4]

Churg–Strauss granulomas were originally described by Churg and Strauss as a histological feature of skin lesions in allergic granulomatosis, later known as Churg–Strauss syndrome. Winkelmann and colleagues described similar lesions in Wegener's granulomatosis, rheumatoid disease and systemic lupus erythematosus, and further delineated the histological features of what they termed the *cutaneous extravascular necrotizing granuloma* [2]. These lesions combine: (1) an interstitial (and variably perivascular) granuloma annulare-like or necrotizing extravascular granulomatous process with basophilic degenerate collagen; (2) intense tissue neutrophilia, leukocytoclasis, small vessel leukocytoclastic vasculitis (in about 50%) and sometimes an admixture with eosinophils; (3) positive direct immunofluorescence for complement, fibrin and immunoglobulins in vessel walls; and (4) associated circulating immune complexes in some cases [1–4]. Similar lesions were subsequently described as *rheumatoid papules*, and have also been documented in Behçet's disease, Takayasu's aortitis and other vasculitides, connective tissue, autoimmune and inflammatory disorders (including inflammatory bowel disease). LeBoit's group suggested that these features could be grouped together as '*palisaded neutrophilic and granulomatous dermatitis of immune complex diseases*' [3]. Other terms that have been applied include *interstitial granulomatous dermatitis with plaques*, *linear rheumatoid nodule*, and *interstitial granulomatous dermatitis with cutaneous cords and arthritis* [1,5–7]. Although it has been suggested that *palisaded neutrophilic granulomatous dermatitis* (PNGD) and interstitial granulomatous dermatitis (IGD) are separate, it is increasingly generally accepted that these are part of a spectrum (at least when associated with a connective tissue or immune complex-mediated disease); drug-induced IGD should probably be distinguished.

Clinical features include: erythematous urticated plaques or papules; firm, violaceous or waxy plaques; skin-coloured or erythematous papular or nodular lesions, sometimes annular and sometimes with ulceration or crusting; tender subcutaneous nodules; and firm linear subcutaneous cords or bands. The most typical presentation is as smooth, asymptomatic or tender papules, nodules or plaques on the forearms and dorsal hands, or on the buttocks and lower legs. Later lesions are usually more centripetal; cord-like lesions may be flexural. Sangueza and colleagues demonstrated a spectrum of clinical disease; earlier lesions are more urticated, whereas older lesions comprise firmer nodules and bands [7]. This would be consistent with the suggestion that the lesions start as leukocytoclastic vasculitis but progress to form palisaded granulomas and dermal fibrosis [1].

Treatment options may be dictated in part by the background disease (most commonly rheumatoid arthritis, in 40%), and include corticosteroids (topical or oral), colchicine, hydroxychloroquine, dapsone, ciclosporin and cyclophosphamide. It is important to be aware that TNF-α inhibitors, increasingly used in treatment of rheumatoid disease, can cause IGD [8]; distinction between disease-associated and drug-induced lesions may be difficult other than by withdrawal of treatment.

Other conditions that may rarely produce a cutaneous granulomatous vasculitis are herpes virus infections (herpes simplex and herpes varicella-zoster) and hepatitis C virus infection [9].

Vasculitis as a component of other systemic diseases

Vasculitis is a feature of many systemic diseases that are mainly discussed in other chapters; a representative list is given in Table 50.12. They include collagen vascular diseases (Chapter 51) and disorders such as sarcoidosis (Chapter 61) in which there may be either a large vessel granulomatous vasculitis or an immune complex-associated small vessel cutaneous vasculitis. *Necrotizing sarcoid granulomatosis* is a variant of nodular sarcoidosis that is in the differential diagnosis of Wegener's granulomatosis of the lung [1]; although it is unlikely to present to dermatologists, the occurrence of extrapulmonary lesions is common, and skin involvement has been reported [2].

Sjögren's syndrome is associated with purpuric lesions similar to those of Waldenström's hypergammaglobulinaemic purpura, and with vasculitis that often has an urticarial or urticated component and predominantly affects the lower limbs [3–5]. Pathologically, the vasculitis covers a wide spectrum; one study of 558 patients with Sjögren's syndrome documented 52 patients (51 being female) with vasculitis that was classified as urticarial in 11, cryoglobulinaemic in 14 and CSSV in the remainder. Of 38 patients biopsied, 36 had a leukocytoclastic vasculitis and two had a medium-size vessel necrotizing vasculitis [5]. Vasculitis in these patients had a statistically significant association with the presence of arthritis (occurring in 50%), peripheral neuropathy (31%), Raynaud's phenomenon (40%), renal involvement (10%), antinuclear antibodies (88%), anti-Ro/SSA antibodies (70%) and rheumatoid factor (78%) [5]. Cutaneous livedo, subacute cutaneous lupus erythematosus, erythema nodosum and cytopenias also occur; 10–20% have

Table 50.12 Some systemic diseases in which vasculitis may occur (excluding those in this chapter).

Type of disease	Examples
Collagen vascular and rheumatological diseases	Lupus erythematosus (including drug-induced) Rheumatoid disease Sjögren's disease Dermatomyositis Scleroderma/progressive systemic sclerosis Mixed connective tissue disease Relapsing polychondritis Still's disease Reiter's disease
Gastrointestinal	Inflammatory bowel disease Bowel bypass (see p. 50.87) Primary biliary cirrhosis Peritoneal fibrosis
Granulomatous	Sarcoidosis
Periodic fevers/ autoinflammatory syndromes	Familial Mediterranean fever Hyper-IgD syndrome PFAPA syndrome
Haematological and malignancy	Lymphomas Hairy cell leukaemia Other leukaemias and myeloproliferative disorders Myeloma Hypereosinophilic syndrome Autoerythrocyte sensitization syndrome Wiskott–Aldrich syndrome Solid organ-specific tumours (Chapter 62)
Miscellaneous	Goodpasture's syndrome Cystic fibrosis α_1-antitrypsin deficiency Kikuchi disease (necrotizing lymphadenitis)

PFAPA, periodic fever, aphthous stomatitis, pharyngitis, adenitis.

positive antiphospholipid antibodies or ANCA, but less than 10% of these have vasculitis [4]. High parotid scintigraphy scores and low complement C4 levels are both associated with vasculitis and are predictive that it is likely to occur [6]. Vasculitis, cryoglobulinaemia and hypocomplementaemia are all independently associated with risk of death [6]; 70% with Sjögren's syndrome and cutaneous vasculitis develop peripheral or central nervous system involvement, which is felt to be due to vasculopathy [3]. Hypocomplementaemia is associated with cryoglobulinaemia, systemic disease, lymphoma and death [7]. Less dramatic but of direct dermatological interest, dry skin is also a feature of Sjögren's syndrome; in one patient with cryoglobulinaemia, cutaneous vasculitis and generalized hypohidrosis, a skin biopsy showed dense peri-eccrine lymphocytic infiltration with glandular shrinkage [8], which was presumably distinct from the vasculitis process.

Cystic fibrosis is a cause of episodic vasculitis, especially in more severe cases; purpuric and vasculitis lesions may occur, most commonly on the lower limbs. Bullae and urticarial vasculitis have been reported, but the overall pattern in most cases suggests an immune complex-mediated leukocytoclastic vasculitis [9]. There is often associated arthralgia, and neurological and renal involvement occur. Immune complexes have been demonstrated in the circulation; skin biopsies show leukocytoclastic vasculitis, fibrin deposition and may have positive direct immunofluorescence for complement C3. The episodic nature (usually lasting about 2 weeks) and the link with respiratory symptoms suggests that the antigen in many cases may be from bacteria (or antibiotic treatments). However, cryoglobulins and positive rheumatoid factor have also been documented in some cases.

Hypereosinophilic syndrome (HES; Gleich syndrome; Chapter 62) is an uncommon entity, which may include more than one form of haematological malignancy [10]. In some instances, there is a clonal T-cell production of interleukin IL-5, a major controlling cytokine in production, release and differentiation of eosinophils. In other cases, there is clonal expansion of eosinophils with hepatosplenomegaly and thrombocytopenia; this condition appears to be due to a cytogenetic defect t(9;22)(q34;q11) in which there is chromosomal breakage and reciprocal exchange of chromosomal fragments that leads to formation of a fusion tyrosine kinase FIP1L1–PDGFRα. Various skin lesions have been reported in HES, including eosinophilic vasculitis with gangrene [11] and thrombotic damage with dense perivascular eosinophilic infiltrate but without vasculitis [12,13]. Although these cases were treated with steroids, newer treatments combined with identification of the causative abnormality may allow targeted therapy; imatinib mesylate, used mainly in treatment of chronic myelogenous leukaemia, targets the platelet-derived growth factor receptor (PDGFR) in the fusion tyrosine kinase of HES [14], described above, and mepolizumab, an anti-IL-5 monoclonal antibody, has also been used recently to treat HES [15].

Alpha$_1$-antitrypsin (AAT) deficiency is discussed in Chapter 46 in relation to panniculitis. It may also be associated with systemic necrotizing vasculitis; in a series of eight patients, six had an MPA pattern of vasculitis, one had WG and one had HSP [16]. These authors reviewed additional cases; all had cutaneous vasculitis and either renal or joint involvement, and two-thirds died (mainly due to renal failure).

Autoinflammatory diseases (including the disorders previously termed hereditary fever syndromes or periodic fevers, such as *familial Mediterranean fever* (FMF), *hyperimmunoglobulinaemia D with periodic fever syndrome* and others), are also a potential cause of vasculitis, as well as causing multiple other symptoms (see also Chapter 62). The evolution of understanding of this group of disorders, which also includes cryopyrin-associated periodic syndromes (CAPS), tumour necrosis factor receptor-associated periodic syndrome (TRAPS), PAPA (pyogenic arthritis, pyoderma gangrenosum and acne), Schnitzler syndrome (Chapter 22) and CINCA syndrome (chronic infantile neurologic, cutaneous, articular syndrome; also termed neonatal-onset multisystem inflammatory disease, NOMID), is summarized in recent reviews [17–19]. It is important to consider FMF as a cause of vasculitis in children with apparent HSP in areas where FMF is prevalent, as HSP is much more common in families with FMF compared with the general population [20]; diagnostic delay is common. Tests for faecal occult blood are often positive during acute attacks of FMF. Other vasculitic features in FMF include purpura, subcutaneous nodules and associated PAN (which occurs in about 1% of patients);

in particular, perirenal haematoma is usually associated with PAN secondary to FMF [20]. Both circulating IgD immune complexes and IgD deposits on direct immunofluorescence of the skin have been identified in hyperimmunoglobulinaemia D syndrome [21], and HSP has been reported in this condition [22]. Lymphocytic vasculitis was reported in a child with *PFAPA syndrome* (Periodic Fever, Aphthous stomatitis, Pharyngitis, Adenitis) [23].

Paraneoplastic vasculitis (Chapter 62) is particularly associated with haematological malignancies; mechanisms include vasculitis related to paraproteins, cryoglobulins or to the presence of antinuclear antibodies. Hairy cell leukaemia appears to be especially associated with vasculitis, which may be of leukocytoclastic, lymphocytic or polyarteritis nodosa pattern.

Vasculitis may also be a feature of *Wiskott–Aldrich syndrome* (Chapter 15), usually leukocytoclastic small vessel vasculitis but aortitis and mesenteric or renal arteritis may occur [24].

Several forms of vasculitis have been associated with *relapsing polychondritis*, discussed on p. 50.91.

Autoerythrocyte sensitization syndrome (Chapters 49 and 64) has also been reported with cutaneous vasculitis [25].

Microvascular occlusion disorders (Chapter 49)

It is important in the differential diagnosis of vasculitis to be aware of disorders that may present with livedo or infarcted lesions, such as *cryoglobulinaemic vasculitis*, *cholesterol embolization*, *cardiac myxoma emboli*, *Sneddon's disease* and *malignant atrophic papulosis* (*Degos' disease*). The major pathology in these is either initially occlusive, or is probably mediated by antiphospholipid antibodies (in Sneddon's syndrome), and so they are all discussed in the section on microvascular occlusion in Chapter 49. Other disorders associated with antiphospholipid antibodies are also discussed. In *calcific uraemic arteriolopathy* (*calciphylaxis)* (Chapter 49), the earliest event is vessel wall calcification [1], therefore this also is discussed in the section on microvascular occlusion rather than as a primarily vasculitic disorder. *Hyperoxaluria* may cause acrocyanosis, gangrene and livedo reticularis. *Hyperhomocysteinaemia*, typically in homozygotes for methyl tetrahydrofolate reductase mutation C677T, also predisposes to endothelial damage and vasculopathy. Vessel wall deposition disorders such as *amyloidosis*, or vessel leakage in *scurvy* or some *pigmented purpuric dermatoses*, may also mimic vasculitis, but histology demonstrates erythrocyte leakage without vasculitis. Thrombotic thrombocytopenic purpura, leukaemias and lymphomas may all occasionally mimic vasculitis.

Thromboangiitis obliterans (*Buerger's disease*) [2] is a disorder of small or medium-sized arteries (less commonly veins) in which there is an inflammatory non-suppurative panarteritis or panphlebitis with thrombosis. Antiendothelial cell antibodies may be significantly elevated in active disease and have a role in monitoring the disease [3]. This disorder is discussed in more detail in Chapter 47.

Other arterial thrombotic disorders that may mimic vasculitis include hypothenar hammer syndrome (Chapter 28), thrombosis resulting from polyvinyl chloride haemodialysis tubing [4], vessel wall invasion by tumour or organisms and sickle cell anaemia. Amyloid infiltration of the vessel wall may cause occlusion. Drugs such as ergot, amphetamines or epinephrine (adrenaline) typically

cause vasospasm but there may be histological evidence of vasculitis.

Infections [1–4]

Mechanisms by which infections may cause vasculitis have been discussed on p. 50.5. Several infections are implicated in the pathogenesis of vasculitides, such as streptococci in HSP, hepatitis C in mixed cryoglobulinaemic vasculitis (an immune complex-mediated process p. 50.23) or hepatitis B in PAN. These have been discussed in relation to specific vasculitides earlier. This brief section summarizes some of the preceding discussion of infections, and notes some infections that mimic vasculitis. Lists of infections linked with vasculitis are provided in many texts and references [3,4]; a summary of the most important is provided in Table 50.13.

Table 50.13 Some infections that have been documented to cause vasculitis.

Type of infection	Examples
Bacteria	Streptococci Staphylococci *Neisseria* spp.: *N. meningitidis, N. gonorrhoea* Spirochaetes: *Borrelia burgdorferi, Treponema pallidum* *Yersinia* *Salmonella* *Helicobacter pylori* *Pseudomonas* spp. *Mycobacterium* spp.
Viruses	Herpesviruses: herpes simplex, varicella-zoster, cytomegalovirus Hepatitis viruses: A, B and C Epstein–Barr virus Immune deficiency: HIV, HTLV-1 Parvovirus B19 Influenza and parainfluenza Other common viruses: adenovirus, rubella Hantavirus
Fungi	*Candida* *Aspergillus*
Others	Rickettsia *Mycoplasma* spp. *Toxoplasma* *Pneumocystis carinii* (in HIV infection)
Vaccinations (see Table 50.8)	Influenza Hepatitis B, hepatitis A Rubella/measles/mumps–measles–rubella (MMR) BCG

Kawasaki disease is discussed in Chapter 30, but a brief summary of the vasculitis-related aspects is provided below.

Vasculitis in patients with subacute bacterial endocarditis or with gonococcal infection is mainly immune complex-mediated, although bacterial emboli can also occur; this may also be a feature of mycotic aneurysms, which potentially mimic medium vessel vasculitis. Other infections may cause a vasculitis by direct infection of endothelial cells, notably in rickettsial or cytomegalovirus (CMV) infection. CMV has a particular affinity for endothelial cells, especially those of allografts, and may also provoke thrombosis; infections in immunocompromised patients may respond to intravenous ganciclovir but there is still significant mortality [5].

Some apparent associations, such as that of *Staphylococcus aureus* with Wegener's granulomatosis (p. 50.39) are less well understood. Herpesvirus infections and HIV may also cause or mimic vasculitis. HIV has been associated with numerous patterns of vasculitis including leukocytoclastic and necrotizing vasculitides, HSP, EED, C-PAN, CSS and eosinophilic vasculitis, cerebral vasculitis and others; however, in some instances, HIV-associated vasculitis may be due to therapy (especially zidovudine and didanosine) or to secondary infections such as cytomegalovirus [4].

Vaccines have been implicated as causes of vasculitis. The two that are most frequently reported as causes of different vasculitis syndromes are influenza and hepatitis B. Influenza vaccine has been linked with CSVV, systemic leukocytoclastic vasculitis (LCV), and MPA; hepatitis B vaccine has been linked with development of CSVV, LCV with systemic involvement, Kawasaki disease, HSP, CSS and Takayasu's arteritis.

However, infections may also mimic vasculitis, particularly by embolization or by direct invasion of vessel walls. Zygomycosis is an important cause, occurring especially in immunosuppressed subjects; cutaneous infarction by zygomycosis has been described as having a targetoid 'bull's-eye' appearance [6] but may just cause a necrotic discoid lesion (Chapter 49). Other important examples are *Salmonella* spp. causing aortitis, embolic lesions of *S. aureus* infections, and *Nocardia* infections mimicking Wegener's granulomatosis [7]. Disseminated candidosis has been reported as resembling leukocytoclastic vasculitis [8]. Such infections may occur in subjects who are being treated with immunosuppressive agents, and may be mistaken for a disease flare with the consequent risk of immunosuppressive treatment being increased. Even serological tests may be misleading in such situations—ANCA positivity has been documented in endocarditis, septic shock and others [9,10]. It is important to consider infection in the differential diagnosis of vasculitis (especially if clinically atypical) or as a cause of unexpected disease flares, to ensure that any pustular lesions are sterile, and to carefully investigate fever in patients with vasculitis.

Behçet's disease

Synonym
- Adamantiades–Behçet's disease

Definition. Behçet's disease, named after the Turkish dermatologist who first described the condition, is a multisystem disease that is defined by the presence of oral aphthosis with at least two of the following: genital aphthae, synovitis, posterior uveitis, cutaneous pustular vasculitis or meningoencephalitis, in the absence of IBD or autoimmune diseases [1–3]. With respect to classification, it is something of an enigma; it is viewed by some as a neutrophilic dermatosis [4], or as a neutrophilic dermatosis that can be associated with leukocytoclastic vasculitis [5], but by others as a true neutrophilic [6,7] or lymphocytic [8] vasculitis. It is also associated with thrombotic arterial or venous disease [9], and has been described as a pauci-inflammatory thrombogenic vasculopathy. Indeed, it has been suggested that it is unique in being a primary vasculitis with predominant venous involvement [10]. However, it has also been reported to occur in association with other 'classical' neutrophilic dermatoses such as pyoderma gangrenosum and Sweet's syndrome. These apparently conflicting or overlapping features are discussed in subsequent sections, but all of the above processes occur in different lesion types and stages.

Because of these classification difficulties, we have specifically discussed this entity between the sections on vasculitis and neutrophilic dermatoses, the two main groups of disorders comprising this chapter. As a generalization, skin and mucous membrane lesions in Behçet's disease mainly represent a neutrophilic dermatosis, cerebral involvement also represents a vasculopathy rather than vasculitis, but other lesions are vasculitic or thrombotic.

It typically affects young adults, but can occur in children [11]. It is uncommon in northern Europe and the USA, but is common in Middle Eastern and Japanese (i.e. 'silk route') populations [12]. In Arab populations, males are affected about four times as often as females, but in many other populations the sex ratio is approximately equal.

Aetiology and pathogenesis. Although the exact cause of Behçet's disease is unknown, a genetic component of the disease is suggested by its association with HLA-B51 [2,13]. However, this only accounts for a minority of sibling risk, and at least 16 genetic loci have been linked with Behçet's disease [10]. The HLA-B51 association is less strong in populations with a lower frequency of Behçet's disease, where a link with HLA-C*15 and HLA-C*16 may be more apparent. More recent studies have also shown a predilection associated with various cytokine and inflammatory mediator alleles and polymorphisms, including polymorphisms in endothelial nitric oxide synthase (eNOS), in interleukin-10 (IL-10), IL-8, and CD28 genes, and presence of the antitumour necrosis factor-alpha (TNF-α) 1031C allele are all associated with Behçet's disease susceptibility [14]. Several of these have only been found in certain ethnic groups, for example Glu298Asp polymorphisms of eNOS in Turks.

At least during disease flares, there is a Th1-predominant immune reaction. Specific triggering of certain subsets of γδT cells has been documented [15,16], for example Vγ9Vδ2 T cells in the intraocular fluid of patients with uveitis. The cytokine IL-12, serum levels of which correlate with disease activity, not only promotes a Th1 response, but also causes proliferation of γδT cells, suggesting that this is important in pathogenesis.

The possibility that infections may stimulate an abnormal immune response in persons susceptible to Behçet's disease has some support; IL-12B heterozygosity is associated with susceptibility, and plays a part in Th1 antistreptococcal activity [14], and demonstration of altered expression and function of Toll-like receptor 6 on granulocytes and monocytes in Behçet's disease (lower than in controls at basal levels, but enhanced after stimulation with heat shock protein or streptococcal extracts) support a role for microorganisms in the pathogenesis [17]. Further, antibodies to heat shock protein 60 (a streptococcal protein) have been demonstrated, increased serum levels of HSP60 occur but do not seem to correlate with disease activity [18], and the 336–351 sequence of HSP60 induces uveitis in a rat model. Antibodies against *Saccharomyces cerevisiae*, also found in Crohn's disease, are significantly more common in patients with intestinal Behçet's disease (and in their relatives) compared with those without gastrointestinal involvement [14], but a causal relationship has not been established. Parvovirus B19 DNA was detected significantly more often in skin of 40 patients with Behçet's disease than in controls [19].

Altered expression of various adhesion molecules, such as VCAM-1, CD44, CD86, CD58 and CD54, as well as changes in various cytokines and apoptotic markers, has been demonstrated in the oral ulcers in Behçet's disease [20], but, although relevant to cell and matrix interactions at the site of lesions, has not elucidated the pathogenesis. Serum VEGF is elevated, and may be a risk factor for ocular disease [18]. Increased levels of IL-23 p19 subunit (measured by RNA expression) have been demonstrated in the erythema nodosum-like lesions of Behçet's disease [21], but its role is unclear. Acting via CXCR-1 and CXCR-2 receptors, IL-8 is a neutrophil chemoattractant whose serum levels have some correlation with Behçet's disease activity [16]. IL-8 also activates endothelium, creating a pro-thrombotic environment [16].

Homozygosity of the T allele of the methylenetetrahydrofolate reductase (MTHFR) gene is more common in Behçet's disease; it is associated with low thiolactonase activity and high homocysteine levels, creating a pro-thrombotic situation [22]. Increased

platelet activation has also been suggested as an explanation for the thrombotic component of the disease. Neutrophil chemotaxis, activation and production of reactive oxygen species is also a feature; recent studies have shown that a subset of T cells producing CXCL8 may be relevant in this and other neutrophilic dermatoses [23], and also that patients with active Behçet's disease (and those with Sweet's syndrome) have elevated levels of granulocyte colony-stimulating factor (GCSF), which suppresses neutrophil apoptosis [24].

Autoantibodies such as ANCA and anticardiolipin antibodies do not appear to have a pathogenic role in Behçet's disease. Although anticardiolipin/antiphospholipid antibodies have been described in up to 50% of cases, most studies suggest that they are not present, or only in a small proportion, and their presence does not appear to correlate with specific events or overall disease activity [25], although higher serum levels have been reported in patients with thromboses [18]. Other antibodies that have been demonstrated include antiribosomal phosphoprotein and antiphosphatidylserine antibodies; the latter have a role in apoptosis and may be implicated in the development of vasculitis [26]. Antiendothelial cell antibodies (AECA), as in many vasculitides, are found but are of uncertain relevance; a more specific role is suggested by the identification of IgM AECA directed against α-enolase in the vascular wall [27]. Further supporting the possibility that an immune response to microorganisms may be involved in the aetiopathogenesis of Behçet's disease, α-enolase-like molecules are found in the cell wall of streptococci and many fungi [16]. Thus several microorganisms, rather than one specific infection, might cause the same complex immune response, generating anti-α-enolase antibodies that can bind to endothelium, thereby increasing IL-8 production and activating neutrophils.

High prevalences of procoagulant mutations such as factor V Leiden (factor V gene mutation G1691A) [28] and prothrombin gene mutation G20210A [29] have been reported in patients with Behçet's disease in whom thrombotic events occur; each was found in a third of patients with Behçet's disease and thrombosis, compared with those without thrombosis in whom the expected background prevalence (each about 1–5%) is observed. In a study of 64 patients with Behçet's disease (32 with thrombosis and 32 without), over half of those with thrombosis had one or both mutations [29]. Other prothrombotic tendencies therefore seem to augment the thrombotic tendency in this disease.

Histopathology. As discussed above, the type of reaction (vasculitic or not) and infiltrate (neutrophilic, lymphocytic or pauci-inflammatory) viewed as most characteristic of Behçet's disease is controversial. Even the predominant size of vessels involved (a frequently applied method to classify vasculitides) varies between authors, some classifying Behçet's disease as a primary vasculitis affecting predominantly large vessels (but may also involve small and medium vessels) [1], and others viewing it as predominantly a disease of small and medium-sized vessels [2].

It is probably best viewed as a systemic vasculitis that can affect any vessel size, any organ, and in which individual lesions may have vasculopathic/vasculitic or thrombogenic aetiology, with variable cellular infiltrate in both type and degree [3,4]. As a general rule, larger vessel involvement tends to be thrombotic or aneurysmal [3]. The mucosal and some skin lesions often have

features of a neutrophilic vascular reaction rather than of frank vasculitis, although a leukocytoclastic vasculitis can occur [3–9]; later lesions are lymphocytic, and primary lymphocytic vasculitis occurs in erythema nodosum-like lesions (described below). Pustular lesions are sterile and, even though they may be inflammatory and appear to have clinical features of pustular vasculitis, histologically they may have a neutrophilic infiltrate and leukocytoclasis without vasculitis, resembling the lesions of Sweet's syndrome, bowel-associated dermatitis-arthritis syndrome or rheumatoid neutrophilic dermatosis. Erythema nodosum-like lesions usually contain at least focal lymphocytic or neutrophilic vasculitis, unlike erythema nodosum from other causes, and may have microabscesses, phlebitis or arteriolitis [10]. The tendency of erythema nodosum-like lesions to develop necrosis may reflect a component of thrombophlebitis, coexistence with small vessel vasculitis, or indicate that the panniculitis is occurring due to a medium-size vessel vasculitis; these lesions also tend to scar or heal with hyperpigmentation; neither ulceration, pigmentation nor scarring are typical of 'ordinary' erythema nodosum.

Using pathergy reactions, the initial inflammatory response consists of neutrophils, monocyte/macrophages and $CD11c^+$ dendritic cells followed by an exaggerated Th1 immune response [11].

A review of the pathological features of vasculitides described three main types of reaction in Behçet's disease [4], namely:

1 Vascular, including:
   (a) a lymphocytic or granulomatous vasculitis with or without thrombosis, necrosis and fibrinoid deposition
   (b) a pauci-cellular thrombogenic vasculopathy
   (c) a neutrophilic vascular reaction that may affect capillaries as well as arteries or veins of any size, and that includes a leukocytoclastic vasculitis and a Sweet's syndrome-like reaction

2 Extravascular with or without vasculopathy, including a mononuclear cell- or neutrophil-predominant inflammation of the dermis and/or panniculus, or a histiocytic panniculitis

3 A suppurative or mixed suppurative/granulomatous folliculitis comprising acneiform lesions

According to these authors [4], additional patterns include acral purpuric papulonodules characterized by a lymphocytic interface and perivascular reaction, and the oral or genital aphthae which have a central dense neutrophilic infiltrate with necrosis, but a dense lymphocytic infiltrate in the submucosa.

The acneiform lesions are debated; other authors have described pustules as non-follicular and representing a neutrophilic pustular vasculitis. Non-follicular papulopustular lesions are useful for diagnosis, as they usually have features of a leukocytoclastic vasculitis (sometimes a neutrophilic infiltrate without vasculitis, occasionally a lymphocytic vasculitis), often with positive direct immunofluorescence (especially IgM in vessels) [12].

Clinical features. The clinical course of Behçet's disease is highly variable, although patients typically have oral aphthae with any combination of genital aphthae, cutaneous pustular vasculitis, ocular lesions or arthritis. The International Study Group criteria for the diagnosis of Behçet's disease [1] are depicted in Table 50.14. Two large series of 387 and 661 patients provide a basis for giving an approximate frequency of the various findings [2,3], although it should be noted that both were from areas with a high frequency of Behçet's disease, and some features may have a different incidence in other parts of the world.

Oral and genital lesions (Figs 50.33 & 50.34). Oral ulceration is a defining criterion for Behçet's disease, and therefore is present in 100%, but is not a very sensitive feature for diagnosis as it is common in the general population. Genital ulcers, present in about 90% of subjects [2,3], are possibly slightly more common in

Table 50.14 International Study Group criteria for the diagnosis of Behçet's disease [1] (applicable only in the absence of other explanations for the clinical findings).

Recurrent oral ulceration	Minor aphthous, major aphthous, or herpetiform ulceration observed by physician or patient that recurred at least 3 times in one 12-month period
Plus two of the following criteria:	
Recurrent genital ulceration	Aphthous ulceration or scarring observed by physician or patient
Eye lesions	Anterior uveitis, posterior uveitis, or cells in vitreous on slit-lamp examination; *or* retinal vasculitis observed by ophthalmologist
Skin lesions	Erythema nodosum observed by physician or patient, pseudofolliculitis or papulopustular lesions; *or* acneiform nodules observed by physician in post-adolescent patients not receiving corticosteroid treatment
Positive pathergy test	Read by physician at 24–48 h

Fig. 50.33 Behçet's disease. This patient demonstrates oral aphthosis.

Fig. 50.34 Behçet's disease. An aphtha is present on the penis.

Fig. 50.35 Behçet's disease. Non-follicular pustules on the upper arm.

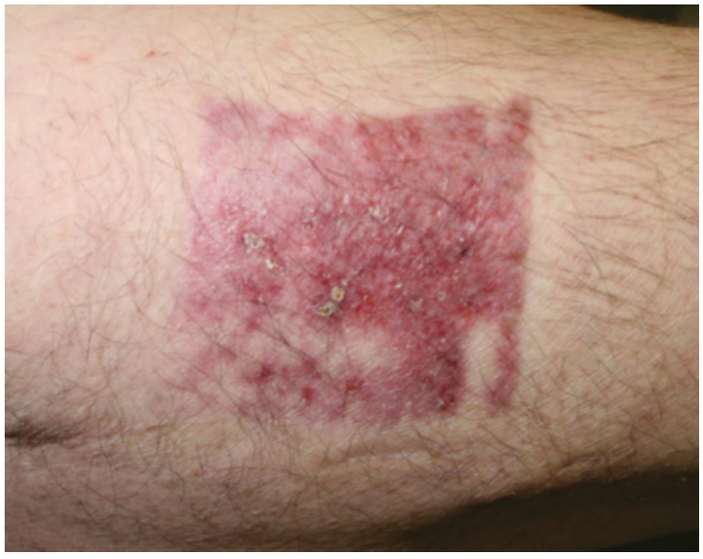

Fig. 50.36 Behçet's disease. An unusual manifestation—the patient had a skin graft site that had failed to heal after 9 months (pathergic pyoderma gangrenosum).

males than in females; they usually occur on the shaft of the penis or on the scrotum in males, and on the labia majora or minora in females. Residual scarring is common.

Skin lesions (Figs 50.35 & 50.36). Other than mucosal ulcers, skin lesions are the most common manifestation of Behçet's disease. Of the possible skin lesions, only pustular vasculitis (present in 55–83% of subjects, more often in males than in females [2,3]) and erythema nodosum-like nodules (44–62% of subjects, more common in females) should be used to satisfy diagnostic criteria when considering Behçet's disease. A wide range of additional cutaneous findings includes Sweet's syndrome-like and pyoderma gangrenosum-like lesions, abscesses, palpable purpura/leukocytoclastic vasculitis, acral purpuric papulonodules, and panniculitis [4–9].

Pathergy, the triggering of a significant inflammatory response by minor injuries such as venepuncture, is a feature of Behçet's disease that is sufficiently specific and frequent (occurring in about 40%, more often in males than females [3]) that it is considered to be a diagnostic criterion; however, it also occurs in several neutrophilic dermatoses, such as pyoderma gangrenosum. Several mechanisms may be involved, including HLA-B51-related hyperreactivity of neutrophils. It typically develops within 48 h, either after specific provocation by needle-prick [6] or following venepuncture or other venous access, and may evolve to form larger lesions inseparable from pyoderma gangrenosum [10].

Other organ systems. Uveitis (usually posterior or pan-uveitis) is the main ocular feature of Behçet's disease, occurring in about 30–45% of subjects, rather more common in males than in females.

The posterior uveitis observed in Behçet's disease is a consequence of retinal vasculitis and may result in blindness, a feared complication of Behçet's disease. Hypopyon uveitis is associated with severe retinal vasculitis and is very suggestive of Behçet's disease, although it is rare [6]. Episcleritis may occur but is not very specific.

Vascular involvement in Behçet's disease may affect arteries and veins, leading to aneurysms or occlusions that are sometimes fatal [6,11,12]. The frequency of vascular disease rises from about 30% at initial presentation, to approaching 50% during the course of the disease, and is most common in males. Venous thromboses are most frequent (seven times more common than arterial occlusion [13]), especially lower limb deep vein thrombosis or superficial thrombophlebitis of extremities. Patients with thrombophlebitis are at greater risk of developing deep venous thrombosis. Other sites of venous thrombosis include the vena cava, hepatic veins (Budd–Chiari syndrome), and cerebral venous sinuses. Arterial lesions include inflammatory stenoses, thrombosis, and, especially, true or false aneurysms of the abdominal aorta, pulmonary or peripheral arteries (with a strong male predominance), in contrast with large vessel vasculitides which tend to affect the aortic arch, renal or mesenteric vessels [6]. Vascular complications should always be borne in mind in patients with known Behçet's disease, particularly pulmonary artery aneurysm as a cause of haemoptysis (the presence of haemoptysis and deep-vein thrombosis may erroneously suggest pulmonary embolism, which is relatively uncommon in Behçet's disease); pulmonary artery aneurysm may occur in isolation (described as the Hughes–Stovin syndrome, but probably part of the spectrum of Behçet's disease). Vessels may show an arteritis, particularly of the vasa vasora, but the aneurysms and thrombosis are not necessarily a consequence of vasculitis, and therefore may not respond to medical therapies for vasculitis. Endovascular control of bleeding aneurysms has been described [13].

Many neurological manifestations may be present in patients with Behçet's disease, including parenchymal and dural sinus thromboses and meningoencephalitis [6,14], but only occur in about 3% of patients. A particular problem of this 'neuro-Behçet's disease' is distinguishing it from central nervous system involvement in Sweet's syndrome (neuro-Sweet's syndrome). Peripheral neuropathies are rare, although brainstem or spinal cord involvement may occur. An asymmetrical, migratory, non-erosive oligoarthritis that may mimic rheumatoid arthritis occurs in 30–40% [3,4,6,15]. Gastrointestinal involvement is uncommon; when it occurs, it consists of mucosal ulceration, especially in the terminal ileum or colon, mimicking inflammatory bowel disease. In contrast with Crohn's disease, which is the most frequent differential diagnosis, anal lesions are rare, and inflammatory markers such as CRP are usually modestly elevated in comparison with active Crohn's disease. Renal involvement is rare, a useful distinction from many vasculitides.

Diagnosis. The diagnosis of Behçet's disease should be suspected in any patient with recurrent and extensive oral aphthosis. However, in these persons, other causes of aphthosis such as inflammatory bowel disease, as well as lesions that mimic aphthae such as herpes simplex infection, must be excluded before a diagnosis of Behçet's disease can be made. Papulopustular lesions, especially outside the normal body site distribution for acne, and with a neutrophilic vascular reaction histologically, suggest Behçet's disease, as do erythema nodosum-like lesions with ulceration, scarring, residual pigmentation or a medium-size vessel vasculitis histologically. The diagnosis should be considered in young patients with deep-vein thrombosis, especially in males or in the absence of other risk factors or thrombophilia. Anterior chamber uveitis with severe retinal vasculitis is not a feature of other vasculitides [6] and therefore suggests a diagnosis of Behçet's disease; similarly, dural sinus thrombosis, aortic or peripheral arterial aneurysms in a young male, or aneurysm(s) of the pulmonary artery or its main branches, strongly suggest this diagnosis. A clinical picture suggesting a medium or large vessel vasculitis, but lacking supporting features such as renal or mesenteric involvement, a positive ANCA, peripheral neuropathy or granulomatous histology, suggests the possibility of Behçet's disease. A positive pathergy provocation test may further support the diagnosis. Ophthalmology, neurology and rheumatology consultations may be beneficial when evaluating a patient with suspected Behçet's disease.

Some patients are encountered in whom recurrent, severe aphthous ulceration dominates the clinical picture; although not fulfilling diagnostic criteria for Behçet's disease they may represent a *forme fruste* of the disorder [16]. Along similar lines, clinical experience also reveals some individuals with severe, non-infective genital ulceration, either in isolation or sometimes with a neutrophilic dermatosis or other features of Behçet's disease, but who deny oral ulceration, and in whom classification is difficult as they appear to have Behçet's disease but in the absence of the main disease-defining criterion. In general, the diagnostic criteria are most reliable in areas of higher prevalence.

Table 50.15 Medical treatments for Behçet's disease.

Palliative treatment of aphthae
Topical corticosteroids/corticosteroid mouthwash
Intralesional corticosteroids
Topical sucralfate
Topical tacrolimus
Nicotine patches
Topical viscous lidocaine (lignocaine)
Topical granulocyte colony-stimulating factor
Mucocutaneous manifestations
Colchicine
Dapsone
Dapsone and colchicine
Systemic involvement
Systemic corticosteroids
Immunosuppressants, cytokines and related agents for most severe disease
• Azathioprine
• Methotrexate
• Ciclosporin
• Cyclophosphamide
• Chlorambucil
• Thalidomide
• Interferon-α
• Anti-TNF agents (infliximab, etanercept)

Treatment (Table 50.15). Oral or genital ulcers may be treated symptomatically with topical or intralesional corticosteroids, topical sucralfate gel, topical tacrolimus and/or viscous lidocaine (lignocaine) applied to individual lesions [1,2]. Nicotine patches applied to oral aphthae have been reported to have rapid benefit [3]. Topical application of granulocyte colony-stimulating factor has been demonstrated to be effective but is expensive [4]. Betamethasone used as a mouthwash is a practical treatment if there are several ulcers. Rebamipide (a mucosal protective agent used in some countries) may also be useful for oral aphthae [5]. Colchicine (0.6 mg two to three times daily) may also be used to treat mucocutaneous manifestations, including aphthae, papulopustules and erythema nodosum-like lesions, although this treatment option is limited by gastrointestinal intolerance and requires monitoring for neutropenia [6–8]. Dapsone alone has demonstrated efficacy in treating Behçet's disease [9], and anecdotally has been effective in combination with colchicine.
