Accessory tragus

Synonyms
- Accessory auricle
- Ear tag
- Cartilage naevus

Aetiology. The tragus (the cartilaginous bump anterior to the external auditory meatus) is derived from the dorsal portion of the first branchial arch. During embryonic life, the first arches grow ventrally to join in the midline, and accessory tragi may be found anywhere along this migratory course, from tragus to sternoclavicular joint. Isolated accessory auricles may be inherited as an autosomal dominant trait [1], mapped to 14q11.2–12 [2].

Fig. 18.35 Accessory tragi.

Pathology. Numerous, tiny hair follicles and eccrine sweat glands are conspicuous in the dermal core of accessory tragi, which are covered by normal epidermis. There is a prominent connective tissue framework in the subcutaneous fat [3]. Cartilage is almost always present. They may be difficult to differentiate from hair follicle naevi [4].

Clinical features. Accessory tragi are small, skin-coloured tags or nodules, arising on or near the tragus, along a line between the tragus and the corner of the mouth, or on the neck (*cervical auricles* or *wattles*) along the anterior edge of the sternomastoid muscle [5]. Vellus hairs often protrude from the surface. They may be unilateral or bilateral, single or multiple (Fig. 18.35), and either soft or cartilaginous in consistency. Like pre-auricular cysts and sinuses, they most commonly occur as a solitary abnormality [6], present in about 1% of neonates [7]. They also occur with other malformations and syndromes of the first branchial arch, such as Treacher Collins, Goldenhar, Nager's acrofacial dysostosis, 4p-, oculocerebrocutaneous and Townes' syndromes.

Similar lesions have very occasionally been described at other sites on the face such as the glabella [8].

Treatment. Accessory tragi are best removed surgically, with careful dissection and excision of any associated cartilage that may extend more deeply [5,9].

Cervical tab

Synonyms
- Cervical auricle
- Wattle
- Congenital cartilaginous rests of the neck

Cervical tabs simply represent accessory tragi at the ventral end of the migratory path of the first branchial arch [1,2].

Histologically, they comprise lobules of mature cartilage embedded in dense collagen.

Clinically, cervical tabs take the form of an irregular, often pedunculated papule or nodule up to 15 mm in diameter, occurring on the neck along the line of the anterior border of the lower third of the sternomastoid muscle. They may be unilateral or bilateral, and are usually noted during infancy. These lesions are not associated with fistulous tracts or connections to deeper structures, but cartilage may extend deeply.

Branchial cysts, sinuses and fistulae

Synonyms
- Branchial cleft cyst
- Lateral cervical cyst
- Cervical cyst, sinus, fistula

Aetiology. During weeks 4 and 5 of human embryological development, complex tissue movements produce the facial structures [1–3]. A 35-day-old human embryo has four gill-like branchial clefts on the sides of the neck, separating the branchial arches. The first cleft persists as the external auditory meatus, the others normally disappear by fusion. The second branchial arch fuses with the fifth arch, enclosing the second, third and fourth arches and their respective clefts to form an ectodermal pocket, termed the cervical sinus. Incomplete fusion results in fistulae (tracts with two openings), sinuses (tracts with one opening), or cysts (tracts with no openings). Sinuses and fistulae communicate with skin or internal mucosa according to whether the anomaly affects, respectively, the branchial cleft (ectoderm) or branchial pouch (endoderm).

Pathology [4]. First branchial arch anomalies are lined by keratinizing stratified squamous epithelium, and may contain cartilage, reflecting their relationship to the external auditory meatus [3]. Second and third branchial remnants have either non-keratinizing squamous epithelium or mucus secreting respiratory-type ciliated, columnar epithelium. Beneath the epithelium there is usually lymphoid tissue, often with germinal centres and subcapsular lymph sinuses. Thymic or parathyroid tissue may be found in third arch remnants, and thymic or thyroid tissue in fourth arch remnants, reflecting the origin of these organs.

Clinical features [2,3]. Branchial anomalies usually present at birth or in early childhood, sinuses and fistulae earlier than cysts. They are sometimes bilateral. Girls and boys are affected equally. Familial occurrence has been recorded [5,6]. Most branchial anomalies are derived from the second branchial cleft; third and fourth branchial anomalies are rare. Sinuses are the most common type of branchial anomaly reported, and fistulae the least common.

Branchial sinuses opening externally are usually apparent from birth as pits or blind-ending tracts. Those derived from the first branchial cleft are found over the parotid gland, below the angle of the mandible and occasionally on the back of the earlobe [7]; second, third and fourth sinuses exit in the lower third of the neck along the anterior border of the sternomastoid muscle. The external opening may become more prominent later because of mucous secretion, inflammation, infection or granulation tissue. A skin tag, sometimes containing cartilage, may mark the site of the opening. The tract itself may be palpable, running upwards in the neck from the cutaneous opening. Branchial sinuses are features of several syndromes including Treacher Collins, Goldenhar, Townes–Brocks, branchio-oto-renal and branchio-oculo-facial.

Branchial fistulae share the same cutaneous distribution as branchial sinuses, but also open internally [2]. First branchial pouch anomalies open into the external auditory canal [8,9] or middle ear, and can present with discharge from the ear [8]. There may be a membranous band from ear drum to auditory canal. Second branchial pouch remnants open into the tonsillar fossa, and third and fourth pouch remnants into the pharynx at the pyriform fossa. Branchial fistula can occur as an isolated anomaly [9], but is also a characteristic component of the autosomal dominant branchio-oto-renal (BOR) syndrome due to *EYA1* mutations, in which it is associated with pre-auricular pits, deafness and renal anomalies [10]. Branchial fistulae also occur with pre-auricular pits, deafness, commissural lip pits and rib anomalies in the autosomal recessive branchio-oto-costal syndrome [11].

Branchial cyst may present any time up to the third decade, as a pre- or post-auricular swelling [12] or a lump in the neck. In some cases, the swelling is painful, usually because of secondary infection. Branchial cysts vary from less than 1 cm to about 10 cm in diameter. On palpation they may feel cystic or solid. Pressure symptoms may occur, for example fourth arch cysts can cause thyroiditis [13,14], or recurrent laryngeal nerve paralysis [13,15]. Rarely, squamous cell carcinoma develops in the wall of a

branchial cyst [16]. Thyroid carcinoma has been reported in ectopic thyroid tissue in a branchial cyst [17].

Diagnosis. Ultrasound examination, CT scanning with contrast, and fistulography with thin barium [3] can be used to define branchial cleft remnants. Direct laryngoscopy may be used to detect fistulae, which are sometimes missed on flexible nasal pharyngoscopy [14]. Otological and MRI examination are important to exclude associated anomalies [12]. The differential diagnosis of lateral neck swellings includes unilateral lymphadenopathy, particularly malignant and tuberculous [18], parotid and thyroid tumours, thymopharyngeal cyst, thyroglossal cyst, lymphoepithelial cyst, dermoid cyst, teratoma, carotid body tumour, infantile haemangioma and neurofibroma. Cystic hygroma occurs in the posterior triangle of the neck, that is posterior to the sternomastoid muscle, and is usually apparent from birth or shortly afterwards. Histologically, third and fourth branchial anomalies may resemble cysts derived from rests of thymic or parathyroid tissue [2].

Treatment. Branchial remnants are usually removed surgically under general anaesthesia [3,8], first arch remnants through a standard parotidectomy incision, dissecting out the facial nerve, and others via a lateral neck incision. Injection of methylene blue into the cutaneous opening of sinuses and fistulae, or cannulation with a suture can be used to guide surgical removal [2,9]. Recurrence is likely if excision is incomplete; branchial cysts are more likely to recur if no epithelial lining is identified in the surgical specimen [3]. Ideally, surgery should be carried out before infection distorts the anatomy and hinders complete excision. However, a period of watchful waiting may be reasonable for asymptomatic lesions. Fistulae can be tackled by avulsion through the mouth using a varicose vein stripper [19], or endoscopic diathermy to the internal opening [13]. Sclerotherapy with OK-432 has been used successfully for branchial cleft cysts in adults [20].

Midline cervical cleft

Aetiology. This rare anomaly probably results from imperfect first or second branchial arch fusion in the midline. The histology could be explained by mesodermal cells destined for the tongue being deposited in the anterior neck [1].

Clinical features [1–5]. This is commoner in females. This lesion takes the form of a vertically orientated atrophic area, several centimetres in length, and several millimetres in width, in the lower anterior midline of the neck. There may be a polypoid skin protruberance at the upper end and a sinus tract at the caudal end. Fibrous bands may connect the lesion with the underlying platysma, causing contractures of the neck and lower jaw. Traction on the growing mandible may produce a bony spur. It may be associated with labial or mandibular clefting, and with thyroglossal and other branchial cleft anomalies.

Pathology. There is an unusual mixture of skin, skeletal muscle, and fibrous and salivary tissue.

Treatment. Treatment is surgical [3], via a series of Z-plasty incisions, ideally in the first year of life. Deep fibrous remnants should also be removed to avoid contracture.

Thyroglossal cysts

Aetiology. The embryonic thyroglossal duct normally obliterates by week 5, remaining only as the foramen caecum at the base of

the tongue, and the pyramidal lobe of the thyroid [1]. Thyroglossal duct remnants take the form of fistulae, cysts or solid masses of ectopic thyroid tissue, and may occur anywhere along its length. Thyroglossal duct cyst is sometimes inherited as an autosomal dominant trait [2] sometimes manifesting as congenital hypothyroidism [3]. The cysts gradually enlarge because of internal secretions from the epithelial lining.

Pathology. Thyroglossal cysts are lined by stratified squamous or mucus-secreting columnar epithelium, and may contain ectopic thyroid tissue.

Clinical features [1,2]. Thyroglossal cyst usually presents during the first 5 years of life but may not be diagnosed until adult life [4]. It is the commonest cause of midline anterior neck swellings in children. It usually presents as a soft mass in the midline of the neck, 1–3 cm in diameter and close to the hyoid bone. It moves upwards on swallowing or on protrusion of the tongue. There may be an opening in the mouth at the foramen caecum, leading to fetor or an unpleasant taste. Occasionally, it drains externally, often as a result of previous surgical procedures. Thyroglossal cyst may present acutely as an infected neck mass, dysphagia, hoarseness, airway obstruction [5], and even fatal asphyxia if the mass is at the base of the tongue [6]. Infection tends to be recurrent. Very large thyroglossal cysts may be displaced laterally and not move on swallowing [7].

Ectopic thyroid tissue in the throglossal remnant may be the only thyroid tissue present. This is an important consideration before excising thyroglossal duct cysts. Such patients may already be hypothyroid. Malignant degeneration occurs in 1–2% of thyroglossal duct remnants, including children [8,9]. Generally this is associated with a good prognosis following excision. It is sometimes multifocal, affecting also the thyroid gland.

Diagnosis. The differential diagnosis includes enlarged lymph nodes, dermoid cyst, lymphoma [10] and haematoma [11]. Bronchogenic cysts may occur in the midline at the suprasternal notch, but are rare.

Treatment. Fine-needle aspiration may be needed for decompression, histology and microbiological sampling. Acute infection is treated initially with antibiotics. Solid masses, particularly in hypothyroid patients, are usually scintiscanned to identify distribution of thyroid tissue prior to surgical excision, since the thyroglossal remnant may contain the patient's only functioning thyroid tissue. Surgery is deferred until any infection and inflammation have completely settled [12]. Surgical treatment is by dissection of the cyst and tract, and removal of the hyoid bone and base of tongue musculature [13]. Ethanol sclerosis therapy has also been used [14]. If malignant cells are found on fine-needle aspiration, a pre-operative MRI scan and wide excision are required. The roles of ablative radio-iodine and thyroidectomy in thyroglossal duct carcinoma are debated [9].

Other defects of relevance to dermatology

Bronchogenic cyst

Synonym
- Presternal ciliated cyst

Definition. An isolated cyst lined with respiratory epithelium.

Aetiology. Bronchogenic cysts usually occur in the chest or mediastinum, but are very occasionally found in the skin [1–3]. They are assumed to develop from tracheal buds at the time of division of the foregut into its tracheal and oesophageal components. At this stage, the right and left mesenchymal bars of the sternum are still unfused. The characteristic suprasternal site may reflect pinching off of bronchogenic tissue by the closing sternal plates. The other locations may be reached by migration of this tissue [2]. Alternative explanations for bronchogenic cysts include lymphatic or haematogenous spread of respiratory tissue [4] and *in situ* anomalous tissue differentiation (heteroplasia) [5].

Pathology. The cysts occur in the dermis or subcutis. The mucosal lining comprises lamina propria and a pseudostratified columnar ciliated epithelium with goblet cells. The cyst wall frequently contains smooth muscle and mucous glands. Lymphoid tissue may be present, particularly when secondary infection has occurred. Cartilage is occasionally seen, in keeping with the bronchogenic origin of this lesion. Gastric mucosa was seen as well as respiratory and squamous epithelium in a lesion on the upper back [6]. There is no connection to underlying structures.

Clinical features. Bronchogenic cysts are solitary and four times more common in males [7]. They are apparent at birth or shortly afterwards, usually as a pinpoint orifice, or a soft, asymptomatic, mobile nodule that very slowly increases in size and may eventually discharge mucoid fluid through a small fistula. Other morphologies include a papillomatous nodule [8] and an area with the appearance of aplasia cutis, and linear, erythematous pruritic hyperkeratotic papules resembling ILVEN [7]. Cutaneous bronchogenic cysts are characteristically located close to the suprasternal notch or over the manubrium sterni [9,10]. Occasionally, they occur in the shoulder [11] and scapular area [4,12], or in the thyroid gland. Lesions have also been reported on the chin [13–15] and abdominal wall [16]. Malignant transformation has been reported in non-cutaneous bronchogenic cysts but not in cutaneous bronchogenic cysts [7,15], apart from a single report of malignant melanoma arising in a bronchogenic cyst on the scapular area of a middle-aged Japanese man [17].

Diagnosis. Differential diagnosis includes branchial cysts, sinuses and fistulae, thyroglossal cysts, teratomas and heterotopic salivary gland tissue.

Treatment. Treatment comprises surgical excision.

Cutaneous associations with sternal clefts

Sternal clefts are rare congenital anomalies, which are, however, frequently associated with a variety of cutaneous abnormalities, including fistulae [1,2], an area of ulceration or scarring [3–5], supra-umbilical midline raphe [6] and facial haemangiomas. Congenital aortic aneurysm is one of the more serious extracutaneous associations. Recognized syndromes include the PHACE association [7] and the sternal malformation/vascular dysplasia association [8], which may overlap [9].

Bifid sternum and incomplete fusion of the ribs in the midline are features of mice lacking glycogen synthase kinase-3beta (GSK-3beta) [10]. The mutant phenotype can be 'rescued' by administering GSK-3beta at two specific times in gestation. This model may shed light on sternal cleft and related anomalies.

Congenital dermoid cysts and sinuses

Aetiology and nomenclature [1]. A dermoid cyst is a *choristoma*, that is a benign tumour consisting of mature tissue derived from germ cell layers foreign to that site. The term 'dermoid' is sometimes used incorrectly for a benign cystic *teratoma*, that is a tumour with mature tissue derived from all three germ layers. Most cutaneous dermoid cysts develop from epithelium trapped along lines of embryonic fusion. There may be an associated sinus tract extending superficially or deeply or both. They are usually sporadic but there are several reports of familial dermoid cysts of the nose. Midline dermoids have occurred in a mother and daughter, external angular dermoids have been reported in siblings [2], and occipital dermoid sinuses in a mother and son [3].

Pathology. Cutaneous dermoid cysts are located in the subcutis; they are often adherent to periosteum, and may invade or erode underlying bone. The cysts are lined by keratinizing stratified squamous epithelium, complete with hair follicles, sebaceous and sweat glands. The lumen contains lipid, keratin and hair.

Fig. 18.36 Midline dermoid cyst on the bridge of the nose.

Clinical features. About 40% of dermoid cysts are present at birth, and about 70% by the age of 5 years. They enlarge because of the secretory activity of the epidermal lining. They typically appear as subcutaneous 'doughy' spherical nodules varying from around 0.5 to 6.0 cm in diameter, largely depending on site. Usually they are white, pearly or erythematous nodules, but occasionally appear as a yellow plaque [4]. A sinus opening, sometimes with projecting hairs, may be the only cutaneous sign of an intracranial dermoid [5]. They are usually found on the head and neck [6–8]. Predilection sites are the outer third of the eyebrow, the so-called *external angle dermoid*, the midline of the nose, usually near the bridge (Fig. 18.36), the scalp, the submental area, the anterior neck, the anterior chest wall and the occipital area.

Deep periorbital lesions derived from the orbital suture may displace the eyelid, cause proptosis, and erode the orbital bones, the intracranial extension sometimes creating an hour-glass shape [8]. In a series of 18 midline nasal dermoids, 12 had extensions to the septum and two to the skull base [9]. Recurrent infection may be a problem, and osteomyelitis and meningitis are occasional complications [10]. Pressure erosion of bone may also occur [1]. Dermoid cysts and sinuses of the head and neck require MRI and CT imaging prior to surgery, to reveal the anatomical extent of the tract and its relationship to the anterior cranial fossa [11]. Dermoids of the head and neck are usually isolated lesions but may be associated with other craniofacial anomalies [11].

Diagnosis. In the neck, the dermoid cyst is only slightly less common than the thyroglossal cyst and may be clinically indistinguishable. It must likewise be differentiated preoperatively from ectopic thyroid gland and branchial cyst.

Cysts at the bridge of the nose must particularly be distinguished from nasal gliomas, which present at birth as firm, reddish tumours at the side of the bridge, and meningoencephalocoeles which may pulsate and may be associated with an underlying skull defect [12]. Infected nasofrontal dermoid sinus may present as recurrent sinusitis [10].

It is essential to use MRI scanning [11–13] and/or high-resolution ultrasound [14] to evaluate midline facial masses, and thyroid function tests and ^{99m}Tc or ^{123}I scintillation scanning to identify any possible ectopic thyroid tissue prior to surgical excision of neck lesions [15].

Treatment. Surgical excision may be complicated by the presence of deep tracts adherent to underlying periosteum, or to the septum in the case of nasal lesions, or communicating intracranially. Failure to excise these tracts leads to recurrence, and treatment of these lesions is therefore best undertaken under general anaesthesia by a craniofacial, plastic or ENT surgeon after appropriate imaging [11,16].

Nasal glioma

Nasal gliomas are rare childhood lesions, not true gliomas but rather encephalocoeles that have lost their intracranial connection [1]. They comprise heterotopic neuroectoderm and derive from the nasofrontal dural diverticulum: failure to obliterate this embryonic connection between dura and skin results in a nasal glioma

or a midline nasal dermoid, depending, respectively, on whether dural elements are retained externally or cutaneous elements internally. The heterotopic neural tissue may be amputated by closure of the craniofrontal sutures, or a stalk of fibroglial tissue may remain. Most nasal gliomas are intranasal, but some appear externally.

Histology shows astrocytes and neuroglial fibres interspersed with dense connective tissue trabeculae, sometimes containing striated muscle fibres, within the dermis [2]. In one case all three components of neural tissue were present, that is leptomeninges, glia and neurones, as well as sweat duct hyperplasia [3].

External nasal gliomas are usually present at birth, and grow in proportion to the child. They are asymptomatic and appear as a firm, red or bluish, smooth, domed swelling on the bridge or side of the nose. Hypertelorism may be present. Unlike true encephalocoeles, they do not increase in size with crying or the Valsalva manoeuvre. Intranasal gliomas take the form of a polypoid mass in the nose or pharynx, causing upper respiratory tract obstruction. Of a surgical series of 10 cases, two were external [2].

Differential diagnosis includes the true nasal encephalocoele and meningoencephalocoele [4], other cutaneous neural and meningeal heterotopias [5], congenital dermoid cyst, lacrimal duct cyst, neuroblastoma and rhabdomyosarcoma, but nasal gliomas are probably most often confused with infantile haemangioma [6,7].

Treatment is surgical excision. Biopsy and fine-needle aspiration are contraindicated because of the possibility of intracranial extension. If preoperative imaging reveals an intracranial connection, neurosurgical collaboration is required.

Transverse nasal groove

Synonym
- Nasal crease

Definition. A horizontal crease across the nose where cartilage meets bone.

Aetiology. The appearance of this lesion may be explained by differential growth of the alar and septal cartilages of the nose during childhood or as a residual embryonic groove in the frontonasal cartilage [1,2]. It is probably not rare, but is seldom noticed. It is often hereditary [1], possibly determined by an autosomal dominant gene [3]. This is probably the same as the nasal crease associated with allergic rhinitis and thought to be caused by repeated upwards rubbing of the nose: the 'allergic salute' [4,5]. No studies have been reported that seek to determine whether this lesion is in fact more frequent in children with allergic rhinitis.

Clinical features. A reddish pink, transverse streak or a shallow groove appears at the junction of the middle and lower thirds of the nose, generally at about the age of 10 years and most often in girls. It is obliterated spontaneously during early adult life. The presence of milia and comedones along this nasal groove [1,6–9] has been termed pseudoacne of the nasal crease [9].

Lip pits and sinuses

There are three types of lip pits: commissural pits, sinuses of the upper lip and lower lip pits, also known as lip sinuses.

Commissural lip pits

These are the commonest type of lip pits, and are found in about 2% of neonates, the highest frequency being found in black neonates [1]. Pits are visible just within the oral cavity at the angle of the mouth. These pits are generally bilateral, and should be regarded as sinuses, ending blindly within a few millimetres of their openings. They probably arise as a result of locally incomplete fusion of the maxillary and mandibular prominences. Histologically, the sinuses comprise stratified squamous epithelium identical to that of the vermilion border. Ducts having a cuboidal epithelium have occasionally been noted to open into the main sinus lumen, but associated glands have not been identified. Commissural lip pits are frequently inherited as an autosomal dominant trait [2]. They may be associated with pre-auricular sinuses [3], and may rarely communicate with the parotid duct [4]. They have occasionally been reported in association with other defects particularly deafness, external ear anomaly [5–7], rib anomalies [8], with branchio-oto-renal (BOR) syndrome, and with a variant of BOR syndrome without renal anomalies which mapped to 1q31 rather than to the established BOR gene (*EYA1*) locus at 8q13 [6,7,9]. Van der Woude's syndrome also features lip pits and maps to 1q31, but the two loci are distinct [9].

Sinuses of the upper lip

Congenital sinuses of the upper lip are extremely rare. One-third are lateral, rarely symmetrical [10], while the rest occur in the midline above the vermilion border, between the philtrum and the frenulum [11–13]. The embryology of these sinuses is unclear. Lateral sinuses may represent a *forme fruste* of cleft lip due to failure of fusion of the maxillary processes, or aberrations in the normal mesodermal merging process [12]. However, cleft lip is more often lateral, whereas upper lip pit is more often medial [14]. The idea that upper lip sinuses arise from a burrowing process analogous to that which forms the nasal cavities [11] is supported by the facts that the upper lip and nasal cavities are formed at the same embryological stage, that both anterior nasal cavities and upper lip sinuses are lined by stratified squamous epithelium, and that the sinus never goes right through to the oral cavity [14].

Congenital midline sinus of the upper lip may present with recurrent swelling or cellulitis around the frenulum [14,15].

Occasionally, upper lip sinuses are associated with other developmental anomalies such as hypertelorism, nasal fistula and lip fistula [10,16,17].

Lower lip pits

Synonyms
- Congenital lip sinuses
- Congenital lip fistulae

These take the form of bilateral openings in the vermilion border, at the peaks of the lower lip convexities, and may be associated with nipple-like protruberances [18]. Secretions may be expelled from these sinuses under the same conditions that stimulate secretion of saliva, and there may be a fistulous link to the salivary gland [19,20]. Histologically, the pits are blind sinuses, about 2–15 mm in length, lined by stratified squamous epithelium identical to that of the lip [21]. At the blind end, mucous glands may be present.

Lower lip pits are a characteristic component of the Van der Woude syndrome, an autosomal dominant trait with very variable expression. When fully expressed, the syndrome comprises cleft lip, cleft palate and uvula, hypodontia and lower lip pits [22–24], but some patients and families have only lip pits [25–27]. Lower lip pits are also a characteristic feature of the popliteal pterygium syndrome, in which they are also associated with cleft lip and/or palate [28,29]. Van der Woude and popliteal pterygium syndromes share the facial phenotype and are in fact allelic variants, both caused by mutations in *IRF6* at 1q32 [30]. *IRF6* mutations can also cause non-syndromic cleft lip and palate: studies in mice and chick embryos suggest a role for *IRF6* during the fusion events that occur during development of the lip and palate [31]. A variety of other anomalies have occasionally been reported in association with lower lip pits [32,33], including type I orofaciodigital syndrome [34] and Kabuki syndrome [35].

Polydactyly

Synonyms
- Accessory digit
- Supernumerary digit

Polydactyly can occur as an isolated trait, but also occurs in many syndromes [1]. The genes for polydactyly provide remarkable insights into normal fetal development [2].

The commonest form of supernumerary digit is postaxial polydactyly (PAP), in which the additional digit, which may be well-formed (PAP-A) or rudimentary (PAP-B), arises from the ulnar border of the hand, at or near the base of the fifth digit. Isolated postaxial polydactyly is ten times more common in black people than in white people: the US estimates of incidence are 1/3300–1/630 live births in white people and 1/300–1/100 in black people. It is transmitted as an autosomal dominant trait, possibly modified by a sex-linked recessive modifier gene [3]. The prevalence is 44% in the offspring of affected black fathers and 31% in the offspring of black mothers. In the offspring of non-black fathers and mothers it is 34% and 33% respectively [1]. PAP-A is genetically heterogeneous, and can be caused by mutations in the *GLI3* gene (*PAPA1*) at 7p15 [4], *PAPA2* at 13q31-q32 and *PAPA3* at 19p13.1–13.2 [5]. PAP occurs in 75% of patients with trisomy 13 (particularly those involving q31–q34) [4] suggesting a locus on chromosome 13. There are several genes for polysyndactyly including *HOXD* [6].

Preaxial polydactyly, with accessory digits on the radial side of the hand, is also heterogeneous. It is a feature of 25 different syndromes and can occur in isolation [2]. Clinically it is divided into type 1 (thumb polydactyly), type 2 (triphalangeal thumb polydactyly), type 3 (polydactyly of index finger) and type 4 (polysyndactyly). Genes include *GLI3* and *LMBR3* [7]. Crossed polydactyly is when the polydactyly is preaxial in the hands and postaxial in the feet or vice versa.

Polydactyly is often bilateral. The rudimentary lesion is a small, skin-coloured, sometimes pedunculated nodule, which may contain cartilage or be capped by a vestigial nail. Sometimes the lesion is soft and globular, in other cases warty.

The presence of numerous nerve bundles is a histological feature [8], which may also be seen at sites from which supernumerary digits have been amputated spontaneously, or traumatically, in early life [9].

Solitary ectopic nails may occur on the palmar aspect of fingers, usually the little finger. This anomaly is distinct from supernumerary digits [10]. In adults, such lesions must be distinguished from acquired digital fibrokeratomas [11].

Treatment. Polydactyly may be the presenting or sole abnormality in the proband with a familial syndrome. Therefore a careful family history must be taken, and genetic referral may be indicated. Supernumerary digits may be excised on cosmetic grounds. Neonatal paediatricians commonly ligate rudimentary accessories that have a narrow pedicle [12].

Supernumerary nipples

Synonym
- Polythelia

Supernumerary areolae and nipples are very common, occurring in about 6% of a German population [1]. They usually occur along the embryonic milk line that runs from axilla to groin. There is some evidence that they are commoner in males than in females, and that they are commoner on the left side [1]. The supernumerary nipple can occur with or without an areola and glandular tissue; sometimes an areola with or without glandular tissue occurs without a nipple. About 6% of cases are familial, the condition being transmitted as an autosomal dominant trait with incomplete penetrance. There is an unresolved debate as to whether there is [2–5], or is not [6–8], an association between supernumerary nipples and urinary tract malformations. They may be associated with Becker's naevus [9], and have been reported in children with haematological disorders [10].

Supernumerary nipple often passes un-noticed, but is susceptible to hormonal changes, infection and malignancy, particularly if there is associated breast tissue.

Developmental anomalies of the umbilicus

Clinically significant developmental anomalies in the region of the umbilicus are rare but present important diagnostic problems for the dermatologist [1]. The commonest umbilical lesion in the neonate after detachment of the umbilical cord is umbilical granuloma (Fig. 18.37) [2,3]; this has become less common since the routine application of talc to the umbilical stump was discontinued. A persistent umbilical lump or discharge not responding to silver nitrate therapy may be connected to the gastrointestinal or urinary systems (Table 18.14) and requires investigation by ultrasonography or CT before considering surgical treatment [3–6]. A retrospective series of 130 umbilical lesions excised over a 10-year period at a children's hospital in Ohio showed 14 vitelline remnants, seven urachal remnants, and three cases where both were present [7].

Fig. 18.37 Umbilical granuloma.

Anomalies of the omphalomesenteric (vitelline) duct [8]

The omphalomesenteric (or vitelline) duct connects the yolk sac with the embryonic digestive tract via the umbilical cord. It is normally obliterated between the fourth and seventh weeks. Anomalies have been classified (Table 18.14) as: (i) complete patency; (ii) partial patency (enteric, intermediate or peripheral); (iii) mucosal remnant at the umbilicus (umbilical polyp); or (iv) congenital band due to a fibrous remnant of either the vitelline duct or artery which can cause intestinal obstruction.

Completely patent omphalomesenteric duct [8–10]. Complete patency is clinically apparent soon after birth. The base of the cord separates to leave a sinus or a red nodule at the opening of an umbilical enteric fistula, the faecal discharge from which irritates the surrounding skin. Very rarely, ileum may prolapse through the fistula [8,11]. Treatment of these ducts requires excision of the umbilicus and tract. Unusually the appendix may be present inside the vitelline duct and present at the umbilicus as an appendico-umbilical fistula [12] or mass [13].

Patency of the enteric portion of the duct [8]. Persisting patency of the proximal vitelline duct constitutes a Meckel's diverticulum. The duct may be patent throughout its length and closed peripherally only by skin or granulation tissue.

Patency of the mid-portion of the duct. A cyst along the course of a fibrosed vitelline cord presents as a periumbilical lump.

Patency of the peripheral portion of the duct [1,10,12]. This may present to dermatologists as a sinus 1.0–2.5 cm in depth intermittently discharging mucus, or a red, polypoid nodule (*umbilical polyp*) comprising ectopic gastrointestinal mucosa. Symptoms may be very slight, so that persistence of these lesions into adult life is not unusual. Occasionally the mucoid, serous or blood-stained discharge gives rise to troublesome dermatitis.

Omphalomesenteric umbilical polyp must be differentiated from umbilical granuloma (see above) and prolapsed urachal

Table 18.14 Developmental anomalies of the umbilicus.

	Gastrointestinal system	Urinary system
Embryonic structure	Omphalomesenteric (vitelline) duct	Urachus
Complete patency	Umbilicoenteric fistula	Patent urachus
Partial patency: enteric	Meckel's diverticulum	Vesicourachal diverticulum (normal)
Partial patency: intermediate	Vitelline cyst	Urachal cyst
Partial patency: peripheral	Umbilical sinus	Umbilical urachal sinus
Mucosal remnant at umbilicus	Umbilical polyp	Umbilical polyp
Fibrous band remnant	Fibrosed vitelline cord	Median umbilical ligament (normal)

mucosa (see below). Fibrous umbilical polyp presents in childhood, more commonly in boys, and is composed of fibrous tissue [14]. Treatment is by simple excision, having checked radiologically that there is no associated patent omphalomesenteric duct or urachus.

Anomalies of the urachus [4,5,15]
The elongation of the body stalk to form the umbilical cord obliterates the part of the allantoic cavity within it. The urachus is the residual intra-abdominal portion of the allantois, from the umbilicus to the vertex of the bladder. After birth it forms a fibrous cord, the median umbilical ligament. Persistence of epithelial remnants within the fibrous end is frequent. The urachus may remain patent throughout all or part of its length forming cysts, sinuses or fistulae leading from the umbilicus or bladder. Carcinoma may develop in a urachal remnant in adult life [16]. However, of a retrospective paediatric radiological series of 56 urachal anomalies, only 20 were symptomatic and 36 were found incidentally; nine anomalies (including two that were symptomatic) disappeared spontaneously during follow-up [15].

Complete patency of the urachus. This presents within days of birth by intermittent dribbling of urine from the umbilicus. The umbilicus may appear normal or the prolapsed distal portion of the urachal duct may form a globular nodule, covered partly by skin and partly by urachal epithelium. The surrounding skin may be irritated, but usually less severely than by a faecal fistula. The diagnosis may be confirmed radiologically. Surgical excision should be carried out as soon as possible, on account of the risk of urinary tract infection in the short term, and the risk of malignant change in adult life [16].

Partial patency of the urachus. This presents differently according to the site of the defect [4,5]. Peripheral patency (umbilical–urachal sinus) appears as a small opening or a granuloma-like lesion at the umbilicus. The lower portion of the urachus remains patent in about 33% of persons (vesico–urachal diverticulum), often involutes spontaneously and requires no treatment unless it is symptomatic [15]. Cysts are the commonest urachal anomaly and may form at any point along the course of the urachus; they may communicate with the umbilicus, the bladder or with neither. Unless they discharge their contents externally, they are seldom clinically evident unless large or infected. They may present at birth as a giant umbilical cord [5,6] or later as tender midline swellings between the umbilicus and the symphysis pubis. If they communicate with the umbilicus, the discharged contents may consist of urine or mucus, pus or blood. In one case an epithelial-lined umbilical cyst draining into the urachus was thought to have derived from the allantois [17].

Cutaneous urachal remnant must be differentiated from umbilical granuloma and omphalomesenteric polyp. Congenital clear-cell acanthoma has also occurred at this site [18].

Congenital sinuses and cysts of the genitoperineal raphe

Synonyms
- Mucous cysts of the penile skin
- Parameatal cysts

Median raphe cyst of the penis takes the form of a translucent or blue cyst, a tender nodule or an indurated cord at any site along the ventral midline between the urethral meatus and the anus, usually near the glans. Several theories have been proposed to explain their occurrence [1]. They may result from incomplete ventral fusion of the urethral or genital folds. Alternatively they may represent ectopic periurethral glands of Littre (*mucoid cysts*) [2,3], or separated outgrowths of urethral endoderm (*urethroid cysts*) [4].

Median raphe cysts of the penis are usually lined by pseudostratified columnar epithelium, except in the distal portion of the raphe where they are lined by squamous epithelium [5]. Ciliated epithelium, similar to that of a bronchogenic cyst, has been reported in some cases [6,7]. Melanocytes were found in the lining of multiple median raphe cysts in two unrelated Japanese boys [8]. Apocrine cystadenoma of the penis is sometimes considered to be the same as median raphe cyst, but can be distinguished by positive expression of human milk fat globulin 1, a marker for breast and apocrine tissue [9].

In most cases, median raphe cysts of the penis remain asymptomatic until after puberty [1], and present only when they become the site of staphylococcal or gonococcal infections [10]. Parameatal cysts can present because they obstruct or distort urine flow in either males [11] or females [12]. However, they may present incidentally as an asymptomatic papule at any age, in some cases as late as the seventh decade [5,13]. Surgery is indicated where infection is not controllable by antibiotics.

Mucous cysts occasionally develop in the retrorectal space and are probably derived from hind-gut remnants. These may discharge via a sinus along the posterior part of the raphe.

Anomalous anal papillae

Disturbance of the normal embryological development of the anus may rarely result in the appearance of one or more polypoid projections at the anus. These may be asymptomatic, but often become complicated by ulceration, faecal retention and constipation [1]. These can be distinguished from infantile perianal pyramidal protrusion, a transient lesion in infants possibly resulting from constipation [2]. The latter is always anterior to the anus and commoner in girls than boys.

Posterior midline cutaneous lesions associated with defects of the cranium, vertebrae and spinal cord

Dorsal midline birthmarks have great significance as markers of underlying neural tube and bone defects [1].

Aetiology. Failure of the caudal neuropore to close at the end of the fourth week of intrauterine life results in neural tube defects (*spinal dysraphism*), which may also involve tissues overlying the spinal cord, including the meninges, vertebral arch (*spina bifida*) and skin. Defective closure of the rostral neuropore, also during the fourth week, may result in analogous malformations in the occipital area. Genetic factors are undoubtedly involved, the recurrence risk of <25% suggesting multiple factors. Spina bifida is commoner in infants of obese mothers, where obesity is defined as body mass index (BMI) >29 kg/m^2 [2]. Folic acid supplementation before and during pregnancy reduces the risk of open neural tube defects [3].

Classification [4]. Neural tube defects can be classified according to whether the CNS is exposed (open or closed), whether neural tissue protrudes externally, and whether their position is caudal or cranial. Of 986 children referred to a spina bifida centre in Italy, 353 had open spinal dysraphism (OSD) and 633 had closed spinal dysraphism (CSD) [4]. The most common OSD was myelomeningocele, which was always accompanied by an Arnold–Chiari (Chiari II) malformation in which the cerebellum and fourth ventricle are displaced downwards. CSD was associated with a subcutaneous lipomatous mass, dural defects and meningoceles in 18.8% of cases. CSD without a mass was classified as simple (tight filum terminale, intradural lipoma) or complex (split cord malformations, caudal regression).

Clinical features.

Open lesions. A *myelomeningocoele* is an open defect of the caudal neural tube, with neural tissue widely exposed on the surface. This presents as a skin defect over the back, bordered laterally by the unfused dorsal portions of the vertebrae, and covered by a transparent membrane, which initially leaks cerebrospinal fluid. It soon dries and ceases to leak, the fluid accumulation causing the membrane to bulge. Spinal cord function is variably impaired, and there may be hydrocephalus due to the *Arnold–Chiari malformation*. An open defect at the cranial end of the neural tube (*cranium bifidum*) may similarly be associated with protrusion of meninges (*meningocoele*) or brain tissue (*meningoencephalocoele* or *encephalocoele*). *Meningocoeles* contain dura and arachnoid, but no neural tissue. Meningocoele can be identified by transilluminescence [5].

Islands of ectopic neural tissue may persist externally as 'rests' overlying intact bone [6]. In the occipital and parietal areas of the scalp they are sometimes termed 'atretic' meningocoeles or meningoencephalocoeles [6], 'meningiomas' [7] or meningothelial hamartomas [8]. Such lesions generally take the form of domed, hairless nodules with a collar of surrounding hypertrichosis (the 'hair collar' sign) [6,8], or sometimes just a tuft of hair [9], and sometimes an associated vascular stain [8]. They are not necessarily confined to the midline. They may look like areas of membranous aplasia cutis congenita. Ependymal rests may also be found in the sacrococcygeal area [10].

A *dorsal dermal sinus* is an open tract with no protrusion of neural or meningeal tissues. It appears as a deep dimple, the bottom of which cannot be seen. It may occur at any level from the occiput downwards, most commonly in the suboccipital and

lumbosacral areas [11,12], only 1% and 10% occurring in the cervical and thoracic areas, respectively [13]. The skin around the exit is often normal but may be dimpled, hairy or the site of a lipoma, abnormal pigmentation, port-wine stain or haemangioma [14–17]. Sometimes the cutaneous anomaly obscures the ostium of the sinus. In the occipital area, the exit site near the external protruberance of the occipital bone [12] is usually hidden by hair, which may be more luxuriant than elsewhere on the scalp. This insignificant dermatological anomaly is an important marker for serious associated complications including infection, underlying CNS anomaly and inclusion tumour. Entry of infection into the subarachnoid space may lead to meningitis, cerebellar abscess [18] or spinal abscess [15]. Spina bifida, spinal dysraphism or tethered cord may coexist with dorsal dermal sinus [13]. Congenital inclusion dermoid cysts are commonly associated [18] and may cause spinal cord compression [14,19]. In one case a dermal sinus opening over the lumbar spine communicated with the posterior mediastinum [16].

Closed lesions. In *spina bifida occulta* there is a defect in the vertebral arch but the lesion is closed and not associated with protrusion of the spinal cord or meninges. The cord may be normal, malformed or hypoplastic, or it may be damaged by transfixation by a bony spicule or fibrous septum arising from a vertebra, usually in the lumbar spine (*diastematomyelia*). Occult spinal dysraphism may occur in as many as 20% of cases, but only a small percentage of these will have a significant associated neurological defect. While most common in the lumbosacral area, spina bifida occulta may occur at any level of the vertebral column [20].

Closed defects with overlying cutaneous malformations are of particular importance to dermatologists to whom they may present first [5,21]. In a series of 1449 healthy American neonates, 70 (4.8%) had dorsal cutaneous stigmata [22]. In 207 infants with midline dorsal cutaneous stigmata, there was associated occult spinal dysraphism in 16 (8%) diagnosed on ultrasonography [22]. A Spanish study [23] reported minor midline dorsal cutaneous lesions in 7.2% of 2010 neonates, and of these 8% had underlying lesions on ultrasound examination, most commonly dermoid sinus. A retrospective French study of 54 children with congenital midline lumbosacral cutaneous lesions investigated by magnetic resonance imaging or ultrasound showed occult spinal dysraphism in three of 36 patients with an isolated lesion and 11 of 18 patients with two or more different skin lesions [1]. In about 50% of cases of spina bifida occulta there is an overlying cutaneous abnormality [11,24–26]. Cutaneous anomalies reported include dermal dimple or sinus, deviation of the gluteal cleft, lipoma [26,27], a tuft of long, soft, silky hair (often called a *faun-tail*) [28], small areas of atrophic or hypertrophic skin, pigmented or depigmented macule, skin tag, tail-like protrusion [29,30], dermoid cyst, macular vascular stain [31,32], 'twin' naevus of vascular stain and naevus anaemicus [33] and aplasia cutis congenita [34,35]. Infantile haemangioma [36,37] can be associated with tethered cord and other anomalies, in the so-called SACRAL [38] or PELVIS [39] syndrome, but the literature is confused by use of the term 'haemangioma' for macular capillary malformations [40,41]. Solitary haemangioma (strawberry naevus) may not be a marker of spinal dysraphism [42] but sometimes coexists with dermal sinus tract and associated haemangioma of the spinal cord [17]. Spinal lipoma is the commonest anomaly underlying a cutaneous mass lesion [5]. A *lipomyelomeningocoele* is a subcutaneous lipoma extending through the bony defect to the dura and attached to the cord. An association between cockade naevi at various body sites and spinal dysraphism has been suggested [43]. Rarely, intradermal ectopic renal tissue (nephrogenic rest) overlies spinal dysraphism [44]. There is some correlation between specific skin lesions and the nature of the underlying anomaly [5], but no clear rules [40].

Even without any bony defect, a dorsal midline anomaly may overlie a spinal abnormality, for example tethered cord with lumbosacral haemangioma, and vascular malformation of the spinal cord with an overlying port-wine stain (Cobb's syndrome).

A variety of other tumours and cysts, representing residual nonregressed distal cord and associated tissues, may occur in the retrorectal space, or subcutaneously over the sacrum [45,46]. They include hamartomas [47], teratomas [48], lipomas [27], ependymomas [10,49] and vestigial tails largely composed of adipose tissue [30,50,51]. Non-neoplastic perirectal inflammatory conditions and giant cell tumours of the sacrum also occur. These may occasionally be associated with overlying cutaneous lesions such as skin tags and epidermal naevi [24].

About 4% of all children have deep sacrococcygeal dimples and pits, or congenital pilonidal sinuses [52,53]. In the absence of other cutaneous anomalies or neurological signs such lesions within the gluteal cleft require no investigation [22,54]. Two patients with plexiform neurofibroma or mastocytoma overlying the lumbosacral spine did not have any underlying anomaly [55]. Collagenoma was found overlying occult spinal dysraphism in a child who also had lumosacral hypertrichosis and a sacral dimple [56], but has not been reported as an independent marker. However, a giant lumbosacral shagreen patch was associated with spina bifida occulta in a child with tuberous sclerosis and scoliosis [57]. An association of spina bifida with three pilomatricomas on the left side of the body was probably coincidental [58].

Diagnosis of occult spinal dysraphism. The likelihood of a spinal defect underlying a posterior midline skin lesion depends, firstly, on age at presentation; a neurologically normal child or adult is unlikely to have a functionally significant spinal defect but might still have a sinus with risk of infection. Secondly, it depends on the nature of the defect; small postanal dimples are very common and those <5 mm diameter or <2.5 cm from the anus are usually uncomplicated. It has been argued that ultrasound examination of such minor lesions only heightens parental anxiety unnecessarily [59]. True sinuses are more likely above the gluteal cleft. The following midline dorsal lesions warrant investigation: atypical dimples (>5 mm diameter or >2.5 cm from the anus), sinuses, masses, sacral hypertrichosis, two or more skin abnormalities, haemangioma, port-wine stain, and sacral telangiectasia even in an infant with an obvious naevus flammeus in the usual glabellar and occipital sites [22,32,40,60]. Ultrasound [61] or X-ray of the spine may be sufficient in the absence of a history of meningitis or neurological impairment. Ultrasound is most useful in neonates up to 3–4 months of age, before the posterior spinous elements ossify [23,59,61]. MRI is the investigation of choice for any suspicious lesions, allowing visualization of the tract and its termina-

tion as well as spinal anomalies and tumours compressing the cord [13,62].

Treatment. The treatment of large and open defects is beyond the scope of this book. Suspected dorsal dermal sinus should be investigated preoperatively with MRI to see whether it connects with the subarachnoid space. Probing and sinography are inadvisable and may lead to meningitis. Usually, no further action is required for asymptomatic single lesions in the lumbosacral area noted in infancy if the plain spine X-ray is normal. However, any suggestion of neurological deficit should be investigated with a spinal MRI.

Congenital absence of skin

Synonym
- Aplasia cutis congenita

The term 'aplasia cutis congenita' implies a failure of skin development, while the broader term 'congenital absence of skin' includes situations where the skin developed but has subsequently been lost. The appearance at birth is extremely variable, in terms of site, extent, depth, and degree of healing and scarring, and there are probably many different causes [1–3]. From careful review of the literature, a number of distinctive clinical disorders have emerged, many of which are genetic [2–5]. Frieden's classification has proved helpful [2] and a modified version will be used here. The term 'congenital absence of skin' is preferable to 'aplasia cutis' for Frieden types 5, 6 and 8, where skin was probably present at an early stage but was subsequently damaged and lost.

Few histological descriptions are available [1,6]. The epidermis is absent, and usually the dermis. Where the dermis remains, the connective tissue lacks appendages and elastic fibres. The subcutaneous fat may also be partly or wholly missing and there may be an underlying skull and dural defect. Where re-epithelialization has occurred the epidermis is flat, characteristically lacking appendages [7,8]; hypertrophic scarring may also occur [9].

Type 1: non-syndromic aplasia cutis congenita of the scalp

Non-syndromic aplasia cutis congenita of the scalp is the commonest pattern of congenital absence of skin. It sometimes shows autosomal dominant inheritance [1–9] with reports of concordant [10,11] and discordant [12] monozygotic twins. The usual position at or adjacent to the parietal hair whorl may be explained by this being the site of maximum scalp tension during the period of rapid brain growth from the 10th to the 18th week of gestation [7].

About 80% of all lesions of congenital absence of skin occur on the scalp [7,13]. Scalp lesions are single in about 70% of cases, double in about 20% and triple in about 5%. Lesions vary enormously in diameter (from 0.5 to over 10.0 cm), shape and depth. They may initially appear deeply ulcerated, superficially eroded, scarred or bullous, and sometimes heal with hypertrophic scarring [5,14]. The larger lesions are often the deeper ones, and may extend to the dura or even to the meninges [15–17]. Such deep lesions may be associated with haemorrhage, sagittal sinus thrombosis or meningitis [16,18–20]. Up to one-third of cases involve the underlying bone [6,9,17,21]. Locally dilated scalp veins reported in several cases [11,17,22,23] suggest that the scalp defect may result from a vascular developmental abnormality [23,24]. An isolated patch of congenital absence of scalp skin is often mistakenly attributed to birth trauma, particularly from fetal scalp electrodes [25].

Lesions of aplasia cutis congenita surrounded by a zone of hypertrichosis, the so-called hair-collar sign, particularly those with a bullous appearance, may be clinically and histologically indistinguishable from atretic meningocoele in which rests of neural tissue are left on the outside of the intact cranium [26,27].

Severe aplasia cutis congenita of the scalp regenerates spontaneously but has also been repaired with engineered skin [28] and bone grafts.

Type 2: congenital absence of skin on the scalp with limb reduction abnormalities

Synonym
- Adams–Oliver syndrome

Adams–Oliver syndrome is characterized by congenital midline scalp defects, asymmetrical distal limb reduction anomalies, cutis marmorata and cardiovascular anomalies. It is usually inherited as an autosomal dominant trait with highly variable penetrance and expression [1,2]. Autosomal recessive inheritance has also been described [3,4]. Many isolated cases have been reported [5]. The gene has not yet been identified [6].

Typically, the skin lesions are solitary or multiple bald scars near the vertex. They vary in diameter, from about 0.5 to 10.0 cm, larger lesions being disproportionately common. The lesions also vary considerably in depth, sometimes penetrating the skull to the dura. Dilated scalp veins [1] are frequently associated, and may be the sole abnormality [7]. Intellect is normal [1].

Hypoplastic or absent distal phalanges are the most common limb anomalies, but defects range from hypoplastic nails to absent hands or lower legs [1,5]. The lower limbs are generally more severely affected than the upper limbs.

Persistent cutis marmorata is reported in about 12% of cases [1,7,8] and may be the sole feature in an obligate gene carrier. Congenital heart disease affects about 8% of cases [9], and pulmonary hypertension occurs in some families [10,11]. A vascular aetiology seems likely [1,10–13], and an abnormality of pericyte recruitment has been postulated [11].

Incomplete forms of Adams–Oliver syndrome frequently occur, and any neonate presenting with a large area of scalp aplasia cutis congenita should be examined carefully for the associated anomalies, which may be limited to cutis marmorata [14] or coarctation of the aorta [2]. Sometimes there are no associated anomalies, only a familial aggregation of diverse cardiovascular anomalies [2]. Antenatal diagnosis has been achieved by ultrasound [4]. Adams–Oliver syndrome must be differentiated from focal dermal hypoplasia, trisomy 13 and the amniotic band sequence. Congenital absence of skin with split hand deformities [5,15], and congenital absence of skin with postaxial polydactyly [16,17] probably represent distinct genetic disorders.

Spontaneous osseous regeneration has been reported in a patient with a large skull and scalp defect due to the Adams–Oliver syndrome [18].

Type 3: congenital absence of skin on the scalp with epidermal naevi

Sebaceous naevi occasionally occur next to areas of congenital absence of skin in the scalp [1]. Multiple areas of bullous congenital absence of skin have also been reported in a child with extensive unilateral verrucous epidermal naevi on the trunk and limbs [2].

Some of these cases have had associated either ophthalmological or neurological abnormalities identical to those seen in the epidermal naevus syndrome [1,3–5]. Happle and Konig suggest that the co-occurrence of aplasia cutis congenita and nevus sebaceous is a twin spot phenomenon [4], as is the association of aplasia cutis congenita with a fatty scalp naevus (naevus psiloliparus) in encephalocraniocutaneous lipomatosis [6].

Type 4: congenital absence of skin overlying developmental malformations

Congenital absence of skin naturally occurs over large, open defects of the body wall such as spina bifida, meningomyelocoele and gastroschisis. However, it may also overlie smaller herniations or extracranial 'rests' of neural tissue, where it is sometimes the presenting feature. In the occipital and parietal areas of the scalp, heterotopic neural and/or meningeal tissue appears as a domed, hairless nodule with a collar of surrounding hypertrichosis (the 'hair collar' sign) [1,2]. The surface of the lesion is typically translucent and 'membranous' [3] and this diagnosis should always be considered in cases of 'membranous aplasia cutis congenita'. The lesion may be flat or depressed rather than raised, and will not always be sited in the midline. There may be an associated port-wine stain [1,4]. Ultrasound examination is essential to establish whether there is an underlying bony defect (as in meningoencephalocoele) or not (as in 'sequestrated' or 'atretic' meningocoele).

The skin is also characteristically absent or hypoplastic over a number of other developmental malformations, including spinal dysraphism [5,6], omphalocoele and sternal clefts [7–9]. Congenital absence of skin has also been reported over other cranial [10] and intracranial developmental anomalies, including arteriovenous fistula [11], leptomeningeal angiomatosis [12], congenital midline porencephaly [13] and cranial stenosis [14].

Type 5: congenital absence of skin associated with fetus papyraceus

Congenital absence of skin has been observed in a number of infants whose birth was accompanied by the delivery of a *fetus papyraceus*, that is a twin or triplet that had died *in utero* during the second trimester [1–5]. In these cases, multiple, mostly symmetrical, linear or stellate areas of congenital absence of skin were present on the limbs and trunk (Fig. 18.38). Some also showed fibrous constriction bands on the limbs [1].This type of congenital absence of skin may represent cutaneous infarction due to release

Fig. 18.38 Congenital absence of skin in an infant with a stillborn twin of fetus papyraceus type.

of thromboplastin into a shared placenta after an intrauterine death [6]. Symmetry of the skin lesions is hard to explain by this mechanism. Associated hyperechogenic areas diagnosed as haematomas in the liver of one patient were thought to support the idea of a vascular aetiology [3].

The practice of selective feticide in multiple pregnancies complicated by fetal or maternal disease creates an iatrogenic fetus papyraceus. As predicted [7], there are increasing numbers of reports of aplasia cutis congenita in surviving co-twins following selective feticide. Similar skin lesions in one of surviving twins [8], and in singletons with no fetus papyraceus [9–12] might reflect *in utero* death of an unrecognized twin or triplet. In other, similar cases without mention of a twin, placental infarction has occurred [13], or the placenta has been described as pale and large [14,15].

Type 6: congenital absence of skin with epidermolysis bullosa

Synonym
- Bart's syndrome

The term 'aplasia cutis congenita' is a misnomer for Type 6, which represents antenatal loss of skin rather than failure of skin development. Bart *et al.* [1] reported a dominantly inherited disorder in 26 members of a large kindred, characterized by congenital absence of skin on the lower legs, widespread blistering of skin and mucous membranes, and nail dystrophy. Further ultrastructural and genetic studies of this family confirmed dominant dystrophic epidermolysis bullosa due to a glycine substitution in type VII collagen [2,3]. We now recognize 'Bart's syndrome' as a non-specific feature of epidermolysis bullosa, not only the dominant dystrophic type, but also junctional epidermolysis bullosa (particularly the type associated with pyloric atresia) [4] and recessive EB simplex caused by plectin mutations [5]. In at least one family with dominant dystrophic epidermolysis bullosa, some affected members had 'Bart's syndrome' while others did not [6]. Where this pattern of congenital absence of skin has been reported without epidermolysis bullosa being diagnosed [7–9], it is possible that skin fragility was simply less apparent after birth than before.

The lesions usually present as extensive, well-defined, glistening, red ulcerations on the dorsum and medial aspect of the foot, often extending up the shin. They may be unilateral or, less frequently, bilateral and probably result from rubbing one shin and foot with the other heel, perhaps in response to pruritus. The idea that the lesions are determined by Blaschko's lines [10] seems less likely. Extensive aplasia cutis congenita affecting the trunk and neck has been reported in infants severely affected by junctional epidermolysis bullosa with pyloric atresia [11].

Type 7: isolated congenital absence of skin localized to the extremities

This is a diagnosis of exclusion: a careful family history and clinical examination may reveal epidermolysis bullosa or associated anomalies characteristic of other types [1]. Type 7 congenital absence of skin may be associated with amniotic band [2] or ischaemia, as in Volkmann's ischaemic contracture [3,4].

Type 8a: congenital absence of skin caused by specific teratogens

Several cases have been reported of congenital absence of midline scalp skin in children whose mothers took methimazole or carbimazole for treatment of hyperthyroidism during early pregnancy [1–5]. It is now regarded as highly likely that these drugs were responsible, although the risk appears to be low [3,4]. This defect was found in only one of monozygotic twins exposed to methimazole between weeks 11 and 17 [6]. Infants exposed to methimazole antenatally may have other anomalies including flared eyebrows, broad nasal bridge, choanal and oesophageal atresia, in the so-called 'methimazole embryopathy' [7]. There have been isolated reports of scalp aplasia cutis congenita following first trimester intake of the prostaglandin misoprostol, and in one case benzodiazepines [8]. Low molecular weight heparin has also been implicated [9].

Type 8b: congenital absence of skin following intrauterine infections

Congenital absence of skin may occur in neonates with intrauterine herpes simplex infection [1–4], but is a more characteristic finding in intrauterine varicella-zoster virus (VZV) infection [5–10], where it may be associated with other features of the 'congenital varicella syndrome'. The cutaneous ulceration or scarring is unilateral and linear, usually occurring in a zosteriform distribution. Such lesions are most often a sequel to maternal chickenpox during the first or second trimester [9,10]. Confirmation of the diagnosis rests on the persistence of VZV IgG antibodies beyond 7 months of age when maternal antibodies [9,10] should have disappeared. Maternal chickenpox in the last trimester may also result in congenital ulcerations in the neonate, usually multiple and no larger than about 1 cm in diameter [11].

Type 9: congenital absence of skin as a feature of malformation syndromes

This is a very heterogeneous group because congenital absence of the skin has been reported in numerous malformation syndromes, sometimes only in a single case [1,2]. The major disorders in which aplasia cutis congenita is a recognized feature are listed in Table 18.15. Those in which it is a characteristic feature include Adams–Oliver syndrome (see Type 2 above) and others described below.

Trisomy 13

Synonym
- Patau syndrome

Table 18.15 Major syndromes in which congenital absence of skin occurs.

Chromosomal disorders	Patau syndrome (trisomy 13)
	Wolf–Hirschhorn syndrome (4p-)
Autosomal dominant disorders	Adams–Oliver syndrome
	Focal facial dermal dysplasia
	Ectrodactyly, ectodermal defects, clefting (EEC) syndrome
	Ankyloblepharon, ectodermal defects, clefting (AEC) syndrome
Autosomal recessive disorders	Adams–Oliver syndrome (autosomal recessive type)
	Johanson–Blizzard syndrome
	Setleis syndrome
X-linked disorders	Goltz focal dermal dysplasia
	MIDAS syndrome
Possibly mosaic disorders	Delleman–Oorthuys (oculocerebrocutaneous) syndrome
	Epidermal naevus syndrome

Infants with this chromosomal abnormality rarely survive beyond their first year. Congenital absence of skin in the parietal or occipital scalp occurs in 38% of cases [3]. Other characteristic findings include holoprosencephaly (a developmental anomaly of the forebrain), microphthalmia, iris colobomas, cleft lip and/or palate, polydactyly, narrow and excessively convex nails, and a port-wine stain on the forehead. Interestingly, patients with mosaic trisomy 13 may present as hypomelanosis of Ito with a rather characteristic 'phylloid' pattern of hypopigmentation [4], together with mental retardation and other features of trisomy 13 syndrome. There are several pigment genes on chromosome 13 [5]; dyspigmentation has not been reported in full-blown trisomy 13, but might not have been noticed in the presence of other serious defects.

Deletion of the short arm of chromosome 4 (the 4p- syndrome)

Synonym
- Wolf–Hirschhorn syndrome

This syndrome is characterized by severe growth and mental retardation, seizures, craniofacial malformations and high childhood mortality. Congenital absence of skin in the posterior midline scalp is a frequent finding [6,7]. Other typical features include ocular hypertelorism, a beaked or broad nose, microcephaly, low-set, simple ears and pre-auricular tags or pits. Most patients have deletions involving large segments of 4p. Wolf–Hirschhorn syndrome is a contiguous gene syndrome [6,7], but exact genotype–phenotype correlations have not been established. A small critical region on 4p has been identified in patients with growth retardation and minor facial features but no aplasia cutis [6,8,9].

Focal facial dermal dysplasias

Symmetrical congenital atrophic lesions of the face resembling scars have been described under a number of different titles, including bitemporal aplasia cutis congenita, congenital ectodermal dysplasia of the face and hereditary symmetrical systemic aplastic naevi. The disorder may be isolated or associated with other facial anomalies. A review of published cases [10] suggested three distinct subgroups: (i) autosomal dominant focal facial dermal dysplasia without other facial anomalies; (ii) autosomal recessive focal facial dermal dysplasia without other facial anomalies; and (iii) focal facial dermal dysplasia with other facial anomalies (synonym Setleis' syndrome).

Autosomal dominant focal facial dermal dysplasia without other facial anomalies. A number of families have been reported in which the disorder is transmitted as an autosomal dominant trait [11–13]. The skin lesions appear to be the sole abnormality, and take the form of congenital, hairless, scarred areas on the face which are usually, but not always, oval in outline and symmetrical, and may be either hyper- or hypopigmented. These lesions may occur on the temple, or on the cheeks, where they tend to be disposed along a line that runs from the ear to the corners of the mouth. The size of the lesions is variable. There may be a surrounding rim of fine, lanugo-like hairs [14,15]. There may be a distinctly puckered appearance to the affected skin.

Histologically, there is atrophy of the dermis and subcutaneous fat, an absence of pilosebaceous follicles and eccrine glands but a normal epidermis. Striated muscle may be placed very close to the epidermis, and could be partly responsible for the occasionally reported puckering of the affected skin.

Autosomal recessive focal facial dermal dysplasia without other facial anomalies. Essentially identical skin lesions have been reported in other families in which inheritance appeared to be of autosomal recessive type [10]. There have been reports of clinically indistinguishable but sporadic cases whose pattern of inheritance is uncertain [15,16].

Focal facial dermal dysplasia with other facial anomalies (Setleis' syndrome). Since the first report by Setleis *et al.* [17], several families have been reported in which children demonstrated a leonine, aged facies with absent or abnormal eyelashes and eyebrows, puckered periorbital skin, a rubbery feel to the nose and chin, and scar-like defects on each temple [18–22]. While most reported patients have been Puerto-Rican, other ethnic groups have been affected [22–24]. Both autosomal recessive [23,25] and autosomal dominant inheritance with variable penetrance and expressivity [21,23,26,27] have been reported.

Rare, non-cutaneous manifestations include imperforate anus [22,28], megaureter [22], mental retardation [22], Fallot's tetralogy [17], iris coloboma, limb malformations and recurrent digital fibromas [28], and developmental delay [29].

Johanson–Blizzard syndrome

This rare, autosomal recessive disorder is characterized by pre- and postnatal growth deficiency, microcephaly, variable intellectual impairment, deafness, thyroid dysfunction, pancreatic insufficiency and rectourogenital abnormalities. Hypoplastic alae nasi are characteristic and congenital absence of skin in the posterior midline scalpis is seen in 76% [30]. It is caused by mutations in the ubiquitin ligase gene *UBR1* [31]. There are several features of ectodermal dysplasia, including sparse hair with a marked frontal upsweep, absent eyebrows and eyelashes [32], hypodontia of both dentitions, peg-like deformity of remaining teeth [33] and hypoplastic nipples and areolae. Café-au-lait macules and dilated scalp veins may be observed.

*MIDAS syndrome (**m**icrophthalmia, **d**ermal **a**plasia, **s**clerocornea) (MLS syndrome [**m**icrophthalmia with **l**inear **s**kin **d**efects])*

Since the first description in 1990 [34] several cases of this syndrome have been reported [35–38]. This X-linked dominant condition is associated with heterozygous deletions on the X chromosome at Xp22.31. This region contains the gene *HCCS*, which encodes human holocytochrome *c*-type synthetase. Mutations in *HCCS* cause MIDAS syndrome [39] and have been found in most patients with a normal karyotype [40]. There is considerable inter- and intrafamilial phenotypic variability, with in one case a mutation found in some cells of the asymptomatic mother of a typically affected daughter [41]. Rare affected males usually have an extra X chromosome [42,43]. The twin boys reported by Anguiano [42] were subsequently described by Cape [44].

Patients with this syndrome have ocular abnormalities with linear skin defects of face and neck, as well as variable brain, genital and cardiac anomalies. The skin defects comprise asymmetric erythematous atrophic lesions distributed in Blaschko's lines, similar to those seen in focal dermal hypoplasia but limited to the face, scalp, neck and upper trunk. Unlike in focal dermal hypoplasia, there are no exophytic fatty protrusions. With age they heal with pigmentation.

Ocular defects include microphthalmia and corneal opacities which may be bilateral, and sclerocornea which is usually unilateral [44]. Genital abnormalities [37] and cardiac anomalies occur, including life-threatening arrythmias [42,45]. Brain anomalies include corpus callosum agenesis.

Oculocerebrocutaneous syndrome

Synonym
- Delleman–Oorthuys syndrome

This distinctive malformation syndrome [46–57] occurs sporadically and in both sexes. Twenty eight cases had been reported by 2005 [51]. No familial cases have been reported, and the scattered, asymmetrical nature of the characteristic abnormalities suggests mosaicism for a mutant gene that would be lethal if the zygote were affected [52]. Linear dyspigmentation in one case supports the idea that this is a mosaic disorder [53]. The severity is variable [54].

Typical ocular manifestations include orbital cysts, eyelid colobomas, microphthalmia and anophthalmia [55]. There may be skull defects and dysmorphic facial features. CNS abnormalities include cerebral malformations, particularly cystic spaces (porencephaly), and agenesis of the corpus callosum, with developmental delay and seizures. The cutaneous features comprise a highly characteristic combination of areas of cutis aplasia and cutaneous appendages. The cutaneous appendages are usually around the eyes, nose and ear, and may take bizarre finger-like or tubular forms. They are histologically indistinguishable from striated muscle hamartomas [56]. Multiple focal skin defects occur mainly on the scalp, face, neck and lumbosacral area and comprise cutis aplasia, areas of atrophy and punched-out defects [49,54]. These usually appear hypopigmented, and, in one case, normal skin markings and lanugo hair within the lesions were regarded as evidence that they were not scars [49]. As well as hair within the atrophic lesions [54] a ring of more profuse hair growth around scalp lesions has also been noted [57].

Delleman's syndrome overlaps clinically with encephalocraniocutaneous lipomatosis (fatty naevi, with ocular and neurologic defects) [53,58–61]. It requires differentiation from focal dermal hypoplasia, and from Goldenhar syndrome [62], and oculoectodermal syndrome (aplasia cutis, epibulbar dermoids and cutaneous hyperpigmentation) [63].

Other disorders

Numerous other conditions have featured areas of absent skin at birth. Extensive symmetrical congenital erosions were reported in *congenital erosive and vesicular dermatosis healing with reticulate supple scarring* [64,65]. Aplasia cutis congenita can occur at any site in the amniotic band disruption sequence [66,67], and on the scalp in tricho-odonto-onychodermal ectodermal dysplasia [68]. Extensive congenital areas of absent skin resembling epidermolysis bullosa have been described in cases of ectodermal dysplasia with cleft lip and/or palate, in the EEC syndrome (*e*ctrodactyly, *e*ctodermal dysplasia, *c*lefting) [69], and in the AEC syndrome (*a*nkyloblepharon, *e*ctodermal defects, *c*left lip/palate) [70]. Areas of absent skin at birth have been recorded in a familial disorder featuring *lumpy scalp, odd ears and rudimentary nipples* [71]. Multiple scalp erosions at birth occurred in two phenotypic females with 46XY gonadal dysgenesis, associated with cleft lip and palate, ear deformity and pre-auricular pits [72].

Single families have been reported with conditions associated with congenital absence of skin. A disorder comprising congenital absence of skin, nipple and breast hypoplasia, nail dysplasia and delayed dental eruption has been described in a mother and her son [73]. Ear deformities and pre-auricular pits were also present in members of another family in association with unilateral facial paresis, dermal sinuses and congenital absence of skin [74]. Posterior midline scalp absence of skin and intestinal lymphangiectasia, leading to hypoproteinaemia and oedema, occurred in two siblings [75].

Single cases have been reported of a syndrome comprising bilateral scarring above the ears, linear submental scars, craniosynostosis, polydactyly, syndactyly, low-set, deformed ears, hypoplastic tibias and cardiac disease [76], and of a syndrome comprising extensive congenital erosions of the skin, anonychia and an atrophic lesion on the tongue [77]. Extensive aplasia cutis congenita occurred in a baby with an unbalanced translocation, being monosomic for distal 12q and trisomic for distal 1q [78]. Aplasia cutis congenita was associated with intestinal lymphangiectasia, skull defect and brain heterotopia [79]. In one fatal case with some features of very severe Johanson–Blizzard syndrome, almost complete congenital absence of skin was associated with absent ears, choanal atresia, syndactyly, imperforate anus, pulmonary hypoplasia and other anomalies [80]. A female with complete absence of skin died soon after birth with hypoplastic lungs, syndactyly, skull defect, oesophageal atresia, intestinal malrotation, calcifications of the hepatic capsule and other anomalies [81].

Differential diagnosis. In the neonatal period parents sometimes mistake congenital absence of skin for obstetric trauma due to forceps or scalp electrodes [1,2], a confusion which may have significant medicolegal repercussions [3].

During childhood, congenital absence of scalp skin may be confused with sebaceous naevus, traumatic scarring, cicatricial alopecia, the linear scarring alopecia seen in *en coup de sabre* morphoea, and the alopecia along scalp suture lines characteristic of the Hallermann–Streiff syndrome.

Cases have been described of congenital bald patches in the scalp with histologically normal skin apart from absent appendages [4]. These 'aplastic naevi' might represent the minimal end of the spectrum of congenital absence of skin.

Treatment. Most lesions will heal spontaneously from the margins, to leave a smooth, yellowish, hairless, papery scar. Underlying defects in the cranium generally resolve spontaneously during infancy even when large [1]. Occasionally, hypertrophic scarring occurs [2], and linear lesions on the limbs may lead to joint contracture. In the vast majority of cases, the prognosis is excellent if attention is paid to the prevention of both secondary infection and further trauma.

Small residual lesions can be treated by excision of the abnormal skin margins followed by primary closure [3]. Larger scalp defects are probably best treated by early grafting or flap rotation [4,5], as delayed closure may be complicated by infection or haemorrhage from the sagittal sinus, which may be lethal [6–8]. Composite ('engineered') skin grafts have been used successfully, using allogeneic keratinocytes [9], or autologous fibroblasts followed by keratinocytes a week later [10]. Bone grafts may be required to reconstruct large cranial defects [11,12]. However, some authors have recommended a conservative approach even for extensive lesions [1], with later excision of scars. Tissue expansion [12] has proved very valuable for this type of procedure.

Amniotic bands and adhesions

Synonyms
- Congenital ring constrictions
- Intrauterine amputation
- Adam complex syndrome (amniotic deformities adhesions mutilation)
- Raised limb bands

Definition. These are circumferential bands, appearing at birth or soon after, usually on limbs, and occasionally associated with other anomalies, particularly distal limb reductions.

Aetiology. Aetiology and classification of these disorders is confused [1–3]. Some undoubtedly result from antenatal rupture of the amniotic membrane: this produces tough bands which encircle developing limbs, resulting in annular constrictions [4,5], secondary syndactyly [6], and intrauterine amputations [7,8] in about one in 10 000 neonates. Amniotic bands may also result from amniotic membrane adhering to an abnormal fetal surface, particularly craniofacial defects [9] and cleft lip [10]. Occasionally, similar limb bands, appearing at birth or later, occur with an intact amnion, suggesting a localized abnormality in limb development rather than external constriction [1,2]. Tight socks have been suggested as a cause of bands appearing around the lower legs in infants [11–13]. Both ring constrictions [14] and congenital amputations [15] are occasionally familial.

Pathology. Biopsies of raised bands showed no specific abnormalities [2].

Clinical features. The most characteristic appearance is ring constrictions of digits, limbs, neck or trunk. The groove is usually about 1–3 mm wide and 2–4 mm deep. Beyond the constriction, there is often lymphoedema. Raised, narrow, scar-like bands can occur [16] and may coexist with the more typical grooves [1,2]. Distal limb deformities, such as syndactyly [6], polydactyly, talipes and distal limb reduction, not necessarily of the same limb, are also frequent, as is peripheral nerve palsy [17]. *In utero* amputation may also occur. Neonatal herpes simplex has been reported localized to an area of ulceration at the site of amniotic band compression [18].

Diagnosis. In the Michelin tyre baby syndrome there is abnormal limb enlargement with folds, rather than primary constrictions. Histology of the folds may show diffuse smooth muscle hamartoma or lipomatous naevus.

Treatment. Plastic surgery is indicated for residual constrictive grooves in a limb or digit, where there is interference with vascular or lymphatic circulation.

The molecular genetics of keratinizing disorders

Classification of keratinizing disorders

The term 'disorders of keratinization' refers to a broad spectrum of skin disorders where there is abnormal differentiation of the epidermis and/or appendages, often with aberrant formation of the cornified envelope [1]. These disorders may have associated epidermal fragility, and there is clinical and pathological overlap with inherited and acquired blistering disorders (see Chapters 39 and 40). Epidermal and/or adnexal defects may exist in isolation or can also be associated with additional extracutaneous features.

The pathogenesis of many of the acquired disorders included in this chapter is poorly understood and may prove to encompass a variety of infective, inflammatory or other causes. However, many disorders of keratinization are inherited as single-gene Mendelian traits, and understanding their aetiology has permitted re-evaluation of their classification. Traditionally, this group of diseases has been classified according to clinical, histological and ultrastructural findings. As the majority of the genetically determined disorders are uncommon in the population, the morphological approach has been beneficial to the practising clinician and offers a logical pathway to diagnosis when confronted with a patient with an unknown disorder. Remarkable advances have been made in molecular genetic technology during the past decade or so, stemming from the development of the polymerase chain reaction (PCR) technology and related techniques from the late 1980s onwards [2]. This technology facilitates rapid amplification and

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

DNA sequencing (decoding) of genes and parts thereof, using minute amounts of a patient's DNA as the starting material. This, coupled with the recent advances in the mapping and near-complete sequencing of the entire human genome, have led to a rapid increase in understanding the basic molecular defects responsible for inherited disorders of keratinization, and these advances have made possible a new, molecular mechanism-based approach to their classification, which complements the pre-existing morphological classification system (Table 19.1). These molecular genetic and biological insights have in many cases confirmed the accuracy of the original clinical distinctions. As knowledge increases, however, the association of mutations in one gene with a distinct phenotype has become more complicated, as illustrated below.

Genotype–phenotype correlation

A good example of phenotypic heterogeneity arising from mutations in a single gene is that of keratin K1. Heterozygous dominant negative mutations in suprabasal keratins K1 and K10 were initially reported to be the genetic basis of bullous ichthyosiform erythroderma of Brocq (BIE) [3,4]. These mutations were strongly clustered in parts of the keratin molecule that are known to be critical for keratin assembly and function (see Intermediate Filament Mutation database; http://www.interfil.org). In an early genetic study of a family with a quite typical BIE mutation in K1, there were mildly and severely affected persons within one family, all of whom had inherited the same mutation [5]. Later, in a family originally diagnosed by Brocq himself as having a consistently milder BIE phenotype, a mutation was found in a region of the K1 protein, linker L12, where mutations in other keratins produced milder phenotypes [6]. Later still, larger deletion and insertion mutations have been identified in K1 that produce primarily palmoplantar keratoderma [7,8]. The latter phenotype is easily confused with the Vörner form of epidermolytic palmoplantar keratoderma (EPPK) resulting from K9 mutations [9]. Certain mutations have also been associated with mild annular [10] and polycyclic erythematous forms of BIE [11]. More recently, a frameshift mutation affecting only the V2 domain of K1 was shown to consistently produce a phenotype closely resembling ichthyosis hystrix of Curth–Macklin in an African American kindred [12]. In contrast, an almost identical frameshift in K1 produced a very much milder, striate keratoderma phenotype in a British Caucasian kindred [13]. In each of the phenotypes associated with these K1 mutations, there is histological evidence of epidermolytic hyperkeratosis (EHK) and ultrastructural evidence of suprabasal tonofilament disruption; however, the tissue distribution and severity of EHK is quite variable. Similar complexity of genotype–phenotype correlation has been identified in disorders caused by mutations in desmosomal proteins and connexins.

There are a number of lessons from these studies. First, mutations affecting different parts of a gene (and thus specific protein domains) can lead to radically different phenotypes. Secondly, there can be phenotypic variation between families carrying similar mutations, and even within one family where all affected persons have the same mutation. The source of phenotypic variation is presumed to be a result of a combination of unknown genetic modifying factors and environmental influences. Thirdly, there can in some instances be ethnic variation in phenotypes resulting from similar or identical mutations. In this case, there is possibly a greater scope for variation in both genetic background and environmental factors. As time goes on and more cases are studied at the molecular level in close consultation with experienced clinicians, greater insights will be gained into the molecular basis and classification of these diseases, as well as the subtle functions not just of proteins but of individual protein domains in epithelial biology.

The biology of keratinization revealed through genetics

Over the last decade, a great deal has been learned about the basic cell biology of epidermal differentiation and keratinization through the study of genetic disorders of this biological system. The various classes of molecules shown to be involved in this system, along with their respective genetic diseases, are listed in Table 19.1. Some of the defective molecules have a mainly structural role in maintaining the mechanical integrity of the epidermis and its appendages in the face of persistent physical trauma. The keratin intermediate filament cytoskeleton has been shown to be a major player in providing mechanical strength for epithelial cells. To date, mutations in 18 keratin genes are linked to cell fragility syndromes affecting the epidermis, adnexae and other epithelia [14]. Similarly, mutations in keratin-associated proteins, such as desmosomal proteins and molecules involved in the cross-linking of keratins during cornification, such as loricrin, have been linked to other keratinizing disorders [15]. Defects in molecules involved in regulating the movement of ions and other small molecules between cells of the epidermis have also been linked to a range of keratinizing disorders, including gap junction proteins [16] and calcium pump molecules [17]. Calcium metabolism plays an important part in the control of epidermal differentiation [18], as evidenced by the phenotype of Darier's disease. Similarly, a range of enzymes is involved in lipid metabolism, which generates the epidermal lipid barrier and is integral to the production of the cornified cell envelope (a highly cross-linked protein–lipid barrier structure), during the terminal differentiation of the epidermis. These include transglutaminase-1, which cross-links keratins and other structural proteins [19], SPINK5, a protease inhibitor [20], and enzymes of lipid peroxidation [21]. Some unexpected molecules have been turned up by positional cloning, such as SLURP-1, a novel secreted protein whose absence leads to mal de Meleda [22]. The finding that deficiency of the cornified envelope protein filaggrin predisposes to atopic disease indicates the wider importance of integrity of the epidermal barrier [23].

In conclusion, the field of keratinizing disorders as it stands today represents a close marriage between clinical and morphological observations and molecular and cell biology. This union of medicine and science has led to improved classification and diagnosis, including first trimester prenatal genetic testing, accurate genetic counselling and, hopefully in the future, an informed mechanistic approach to the design of new therapeutic agents for this group of diseases.

Disorder	Genes affected	Further information
Keratin disorders		
Annular epidermolytic ichthyosis variant of BCIE and cyclic ichthyosis	*KRT10, KRT1*	Suprabasal keratin 10 (chr 17q12–q21) for annular variant; keratin 1 for cyclic ichthyosis (chr 12q11–q13)
Bullous congenital ichthyosiform erythroderma (BCIE)	*KRT1, KRT10*	Suprabasal keratins 1 and 10 (chr 12q11–q13 and 17q12–q21)
Diffuse non-epidermolytic palmoplantar keratoderma	*KRT1*	Keratin 1 (chr 12q11–q13)
Epidermolytic palmoplantar keratoderma	*KRT9*	Keratin 9 (type I keratin; chr 17q12–q21). Keratin specific for palm and sole skin
Focal non-epidermolytic palmoplantar keratoderma	*KRT16*	Keratin 16 (chr 17q12–q21). Constitutive expression in palm and sole epidermis and other sites
Pachyonychia congenita type 1 (PC-1; Jadassohn–Lewandowsky form)	*KRT6A, KRT16*	Dominant-negative mutations in differentiation-specific keratins K6a (chr 12q11–q13) or K16 (chr 17q12–q21)
Pachyonychia congenita type 2 (PC-2; Jackson–Lawler form)	*KRT6B, KRT17A*	Dominant-negative mutations in differentiation-specific keratins K6b (chr 12q11–q13) or K17 (chr 17q12–q21). Some cases are isolated steatocystoma multiplex
Ichthyosis bullosa of Siemens (IBS)	*KRT2E*	Epidermal keratin 2 (chr 12q11–q13). Expressed in late suprabasal cells of epidermis
Ichthyosis hystrix (Curth–Macklin)	*KRT1*	Frameshift mutation in V2 domain of keratin 1 (chr 12q11–q13)
Striate palmoplantar keratoderma	*KRT1*	Frameshift mutation in V2 domain of keratin 1, almost identical to IHCM defect, above (chr 12q11–q13)
Desmosome proteins		
Dilated cardiomyopathy with woolly hair and keratoderma	*DSP*	Desmoplakin 1 (chr 6p2)
Ectodermal dysplasia with skin fragility	*PKP1*	Plakophilin 1 (chr 1q)
Naxos disease	*JUP*	Plakoglobin, component of desmosome and adherens junction (chr 17q21)
Striate palmoplantar keratoderma	*DSG1, DSP, KRT1*	Desmoglein 1, a desmosomal cadherin (chr 18q12.1) Desmoplakin 1, role in attachment of intermediate filaments to the desmosome (chr 6p2)
Stratum corneum proteins		
Ichthyosis vulgaris	*FLG*	Filaggrin (1q21) crosslinks intermediate filaments
Loricrin keratoderma	*LOR*	Loricrin, component of cornified cell envelope (chr 1q21)
Gap junction proteins		
Clouston's syndrome (hidrotic ectodermal dysplasia 2)	*GJB6*	Connexin 30 (chr 13q12)
Erythrokeratoderma variabilis (EKV)	*GJB3*	Connexin 31 (chr 1p35.1)
EKV with erythema gyratum repens	*GJB4*	Connexin 30.3 (chr 1p35.1)
Keratitis, ichthyosis and deafness	*GJB2*	Connexin 26 (chr 13q11–q12)
Palmoplantar keratoderma and deafness (various)	*GJB2*	Connexin 26 (chr 13q11–q12)
Calcium pump defects		
Darier's disease	*ATP2A2*	Sarcoplasmic/endoplasmic reticulum calcium ATPase (SERCA2) (chr 12q24.1)
Hailey–Hailey disease	*ATP2C1*	Calcium transporting ATPase (chr 3q21–q24)
Metabolic and enzyme defects		
Autosomal recessive ichthyosiform erythroderma (Lamellar ichthyosis, Non-bullous ichthyosiform erythroderma)	*TGM1*	Transglutaminase (chr 14q 11.2), cross-linking enzyme in cornified envelope formation (mainly lamellar ichthyosis)
	ALOX12B	Arachidonate lipoxygenase (chr 17p13.1)
	ALOXE3	Arachidonate lipoxygenase (chr 17p13.1)
	ICHYN	Ichthyin (chr 5q33) possibly a receptor for peroxisomal lipids
	CYP4F22	Cytochrome P450 4F22 (chr 19p13.12)
	ABCA12	see Harlequin ichthyosis
Chanarin–Dorfman syndrome	*CGI-58*	CGI-58 (chr 3), CGI protein of the esterase/lipase/thioesterase subfamily
CHILD syndrome (congenital hemidysplasia, ichthyosis and limb defects)	*NSDHL, EBP*	3β-hydroxysteroid dehydrogenase, an enzyme in cholesterol biosynthesis (chr Xq28). Mouse mutant, bare patches Mutations also reported in 3β-hydroxysteroid-δ8, δ7 isomerase
Harlequin ichthyosis	*ABCA12*	ABCA12 (chr 2q35) is a membrane based lipid transporter
IBIDS/Trichothiodystrophy	*ERCC2/XPD; ERCC3/XPB*	DNA excision repair complex (chr 19q13.2–q13.3; 2q21)
Ichthyosis Prematurity syndrome	*SLC27A4*	Fatty acid transport protein 4 (chr 9q34)
Netherton's syndrome	*SPINK5*	Serine protease inhibitor LEKTI (chr 5q32)
Papillon–Léfèvre and Haim-Munk syndromes	*CTSC*	Cathepsin C, a lysosomal protease (chr 11q14.1–14.3)
Refsum's disease	*PAHX*	Phytanoyl-CoA hydroxylase (chr 10pter–p11.2), a PTS2 protein
Rhizomelic chondrodysplasia punctata type I	*PEX7*	Peroxisomal matrix protein with type 2 peroxisome targeting signal receptor (chr 6q22–q24)
Richner–Hanhart (tyrosine transaminase deficiency)	*TAT*	Tyrosine aminotransferase (chr 16q22)
Sjögren–Larsson syndrome	*FALDH (ALDH3A2)*	Fatty aldehyde dehydrogenase (chr 17p11.2). Catalyses medium and long-chain aliphatic aldehyde oxidation
X-linked ichthyosis (steroid sulphatase deficiency)	*STS*	Arylsulphatase C gene (chr Xp22.32)
X-linked recessive chondrodysplasia punctata	*ARSE*	Arylsulphatase E gene (chr Xp22.3) resulting in steroid sulphatase deficiency
X-linked dominant chondrodysplasia punctata (CDPX2) or Conradi–Hünermann syndrome	*EBP*	Emopamil binding protein, 3β-hydroxysteroid-δ8, δ7 isomerase. Role in cholesterol biosynthesis (chr Xp11.22–p11.23). Mouse model, tattered
Secreted protein		
Mal de Meleda	*ARSB*	Encodes SLURP-1 (chr 8q24.3)

Ichthyosis

Definition

Ichthyosis describes dry, rough skin with scaling over much of the body (Greek *ichthys/ikhthus*, fish -osis). The ichthyoses are a clinically and genetically heterogeneous group of skin disorders, characterized by a diffuse, generally uniform and persistent pattern of scaling without mucosal or extracutaneous (except in ichthyosiform syndromes) involvement. They are classified as disorders of keratinization or cornification. There are several congenital or genetic ichthyoses (with distinctive morphological features), a number of well-defined ichthyosiform or ichthyotic syndromes, rare cases that do not fit into either category, and acquired ichthyosis which is a complication of several systemic and malignant diseases (Table 19.2). They range in severity from mild ichthyosis vulgaris, to inflammatory and syndromic types and the often lethal harlequin ichthyosis.

Table 19.2 Congenital and acquired ichthyoses.

Congenital ichthyoses
Ichthyosis vulgaris (syn. autosomal dominant ichthyosis)
X-linked recessive ichthyosis (steroid sulphatase deficiency)
Non-bullous ichthyosiform erythroderma
Lamellar ichthyosis
Harlequin ichthyosis
Bullous ichthyosiform erythroderma (syn. epidermolytic hyperkeratosis)
Ichthyosis bullosa of Siemens
Ichthyosis hystrix
Ichthyosiform syndromes
Netherton's syndrome (syn. ichthyosis linearis circumflexa)
Sjögren–Larsson syndrome
Neutral lipid storage disease (syn. Chanarin–Dorfman syndrome)
Refsum's disease
Kallmann's syndrome
Multiple sulphatase deficiency syndrome
X-linked dominant ichthyosis (syn. Conradi–Hünermann-Happle syndrome)
IBIDS (syn. Tay syndrome, trichothiodystrophy, PIBIDS)
KID syndrome (keratitis, ichthyosis, deafness)
CHILD syndrome (congenital hemidysplasia, ichthyosiform erythroderma, unilateral limb defects)
Ichthyosis follicularis with alopecia and photophobia (IFAP)
Neu–Laxova syndrome
Congenital ichthyosis variants
Isolated genetic syndromes with ichthyosis (case reports)
Acquired ichthyosis
Drugs (e.g. nicotinic acid, hypocholesterolaemic agents, maprotiline)
Chronic hepatic disease, renal failure, thyroid and parathyroid disease
Malabsorption states
Sarcoidosis, leprosy
Acquired immune deficiency syndrome (AIDS)
Lymphoma and other malignancies

Ichthyoses result from abnormal epidermal differentiation or metabolism. Defective epidermal desquamation (retention) is a feature of some ichthyoses while a prominent inflammatory component occurs in others, usually associated with epidermal hyperproliferation. Epidermal fragility is a feature of some keratin mutations, while pruritus may complicate others.

History and classification

The first historic reference to ichthyosis appears in an Indian text in 250 BC, where there is mention of 'Ekakushtha, skin disease like scales of a fish' [1]. Detailed reports of 'Porcupine men' in the 1730s highlighted the severity and familial occurrence of hystrix-type ichthyosis [2]. The first account of a harlequin fetus

(ichthyosis) was in 1750 [3]. Willan, in his treatise *On Cutaneous Diseases*, classified ichthyosis as a 'squamous disease' [4] and attempts at genetic classifications followed. Brocq first used the label 'congenital ichthyosiform erythroderma', and distinguished between bullous and non-bullous ichthyosiform erythroderma [5]. The characteristic histological features of bullous ichthyosiform erythroderma were described by Lapiere [6], and subsequently termed epidermolytic hyperkeratosis [7]. Cockayne regarded sex-linked ichthyosis as a separate entity, and lamellar ichthyosis as a recessive condition [8]. Wells differentiated X-linked and autosomal dominant ichthyosis vulgaris in an epidemiological survey [9]. Recognition of ichthyosiform syndromes such as Refsum's disease, Netherton's and Sjögren–Larsson syndromes has come through astute clinical observation.

Early classifications depended on descriptive analogies, such as ichthyosis larvata, tarda, mitis and inversa. Wells and Kerr [9] defined groups of ichthyoses with autosomal recessive, sex-linked and autosomal dominant inheritance patterns, and clearly established X-linked recessive ichthyosis as a separate entity. Esterly [10] identified four categories of ichthyosis; major primary forms (ichthyosis vulgaris, recessive X-linked ichthyosis, bullous ichthyosis and congenital ichthyosiform erythroderma), ichthyosiform syndromes, related disorders of cornification and acquired ichthyoses.

Frost and van Scott [7] used epidermal kinetic data to characterize hyperproliferative (erythrodermic) and retention ichthyoses (ichthyosis vulgaris, X-linked ichthyosis). A numerical approach to 'disorders of cornification', lists 24 conditions (DOC 1–24), including the congenital ichthyoses and diverse diseases such as Darier's disease, peeling skin syndrome and the erythrokeratodermas [11]. Anton-Lamprecht and Schnyder [12] detailed subtle ultrastructural features of congenital ichthyosiform erythrodermas, and subdivided them into types 1–5. Traupe [13] identified four main categories: isolated vulgar ichthyoses, including ichthyosis vulgaris and X-linked recessive ichthyosis; associated ichthyoses of the vulgar type, such as Refsum's disease; isolated congenital ichthyoses, such as harlequin fetus, non-bullous ichthyosis and epidermolytic ichthyoses; and associated congenital ichthyoses, such as Sjögren–Larsson and Netherton's syndromes, IBIDS and X-linked dominant ichthyosis.

Elucidation of the underlying molecular abnormalities in many of these conditions now provides a more logical and mechanistic classification (Table 19.1) and reveals previously unsuspected heterogeneity.

The epidermis in health and ichthyosis

Epidermal differentiation is characterized by the synthesis and post-translational modification of many structural proteins, in particular, the proteins constituting the cornified cell envelope and enclosed aggregated keratin filaments, which are the major components of the stratum corneum. Envelope precursors, such as involucrin, loricrin, small proline-rich proteins and envoplakin, are synthesized late in stratification and then cross-linked by the action of transglutaminase enzymes, which are synthesized in the granular layer. The corneocyte protein envelope is linked covalently to an outer ceramide layer, the lipid envelope, which also contains a variety of membrane-associated glycoproteins such as the integrins. Desmosomes are modified in the stratum corneum to form an electron-dense plug, the corneosome. In normal skin, desmosome density and cohesion lessens in transit from the lower to upper stratum corneum, but in hyperkeratotic states this does not occur [1]. Keratin macrofibrils are aggregated by interaction with filaggrin (filament aggregating protein), a basic histidine-rich protein stored as profilaggrin in keratohyaline granules. Keratin intermediate filaments are the major stress-bearing cytoskeletal proteins of mammalian epithelial cells, the product of two gene families encoding type I (acidic) and type II (neutral-basic) polypeptides, which are co-expressed in particular pairs in a tissue-specific and differentiation-related manner.

The intercellular spaces of the stratum corneum contain lipid-rich multilayered lamellae, which are secreted by lamellar or Odland bodies, present in large numbers in the cytoplasm of granular layer keratinocytes. At the granular–corneal junction, the lamellar body gravitates to the apex of the granular cell, and secretes its disc-like contents into the intercellular spaces [2]. The lipid-rich layers are redistributed into multilayered lamellae, composed of alternating electron-dense and electron-lucent lipid bands. Evidence suggests that these structures are formed by the condensation of liposomes under the influence of ceramides (sphingolipids that contain the n6 essential fatty acid, linoleic acid), which span the layers acting as rivets. They are also rich in non-polar lipids, free sterols including cholesterol sulphate, free fatty acids and triglycerides, and contain hydrolytic enzymes [3,4]. Conversion to cholesterol by cholesterol sulphatase, present on the cell membrane surface, leads to breakdown of the intercellular lipid lamellae and resultant desquamation [5]. Stratum corneum barrier function is dependent on the intercellular lipid lamellae, and increased transepidermal water loss is a characteristic feature of ichthyosis [6].

The importance of lipid metabolism in epidermal structure and function was first noted in 1929, when an animal model

deprived of dietary essential fatty acids developed hyperkeratosis, abnormal desquamation and increased transepidermal water loss [7]. In the 1950s, the lipid-lowering drugs nicotinic acid and triparanol caused a reversible ichthyosis in some patients [8]. An inherited enzyme deficiency was identified in the 1960s as the cause of Refsum's disease [9] and cholesterol sulphatase deficiency in patients with X-linked recessive ichthyosis was reported in 1976 [10]. Sjögren–Larsson syndrome, another ichthyosiform disorder with neurological disease, is associated with fatty alcohol defects [11], while peroxisomal dysfunction, specifically abnormal sterol biosynthesis, has been identified in patients with Conradi–Hünermann and CHILD syndromes [12,13].

Disordered keratinization also results from alterations in structural proteins, including individual keratins, cornified envelope proteins and keratin-associated proteins (Table 19.1). Enzyme and metabolic defects (e.g. loss of transglutaminase activity in lamellar ichthyosis) and abnormalities in gap junction proteins (connexin mutations in the keratitis–ichthyosis–deafness (KID) syndrome) have been identified in diverse ichthyoses [14]. Several ichthyoses are associated with hyperproliferative and inflammatory features. Chronic barrier damage induces keratinocyte DNA synthesis and results in epidermal hyperplasia [15], with knock-on effects on the activity of cytokines, growth factors, calcium gradients, adhesion molecules and lytic enzymes. The identification of a serine protease inhibitor mutation in Netherton's syndrome and defects in lipoxygenase activity in an erythrodermic ichthyosis provide further insights into the occurrence of inflammatory changes [16].

Congenital ichthyoses

Ichthyosis vulgaris (MIM 146700)

Synonym
- Autosomal dominant ichthyosis

Ichthyosis vulgaris (IV) is the most common of the inherited ichthyoses, with a reported incidence of 1 in 250 in an English population study of 6051 healthy schoolchildren [1]. It is regarded as an autosomal dominant condition with variable penetrance. The majority of affected individuals have mild scaling which may clear in the summer months. It is more common in temperate climates and Caucasian populations and has an equal sex distribution. There is a close association between IV and atopic diseases; 37–50% of people who have ichthyosis vulgaris show features of atopic disease [1–3]. However, the difficulty in distinguishing IV from the xerosis of atopic eczema on clinical grounds may result in an overestimate of both its frequency and its correlation with atopic eczema [4].

Histopathology. Histology of affected skin shows a mild hyperkeratosis and, usually, a diminished or absent granular layer in the epidermis. The dermis is normal. Features of keratosis pilaris may be seen. Electron microscopy reveals scanty and fragmented keratohyaline granules in granular layer cells, whereas the keratin filaments appear normal [5]. The association between IV and atopic eczema has been questioned on histological grounds, as eczematous features are found in biopsies of atopic xerosis [6]. Furthermore, ultrastructural study of xerotic lesions in 49 patients with atopic eczema and dry skin showed typical features of ichthyosis vulgaris in only two [4].

Aetiology and pathogenesis. In the 1980s, biochemical studies on ichthyosis vulgaris skin showed that, in lesional skin only, uptake of radiolabelled histidine by the granular layer was reduced [7]. Histidine is necessary for the synthesis of profilaggrin, the high-molecular-weight, 400-kD precursor of filaggrin. Profilaggrin was virtually absent from the epidermis and cultured keratinocytes (in those IV patients with absent granular layer and keratohyaline granules) and filaggrin synthesis was defective [7]. Filaggrin (from *fil*ament *aggr*egating prote*in*) is a 37-kD peptide which is a major component of the keratohyaline granule in the granular layer. Filaggrin binds to keratin filaments causing their aggregation and leading to flattening of the stratum corneum keratinocytes (corneocytes). Their intracellular proteins are cross-linked by transglutaminases, forming the cornified envelope which contributes to epidermal barrier function. Cultured keratinocytes from unaffected skin formed thickened layers, with small keratohyaline bodies, which failed to react with monoclonal anti-

body to filaggrin [8]. Expression of filaggrin mRNA was reduced [9], keratin expression and markers were normal [10] and proliferative activity was reduced [11]. A mouse mutant, flaky tail mouse, lacking profilaggrin expression provides an animal model for IV [12].

In 2002, genetic studies confirmed linkage between IV (with absent granular layer) and the epidermal differentiation complex (EDC) of genes on chromosome 1q21 [13]. The EDC contains the genes for filaggrin and several other proteins integral to late epidermal maturation and barrier function. Identification of mutations in the filaggrin gene was delayed because of its complexity, but Smith *et al.* finally sequenced the critical terminal exon [14]. They went on to prove in a large genetic study of affected families that two common filaggrin loss-of-function mutations, R501X and 2282del4, cause ichthyosis vulgaris [14]. These same filaggrin mutations also predispose to atopic eczema [15,16], atopic asthma and possibly psoriasis. Even in patients with homozygous mutations, some filaggrin fragments may be produced which might account for phenotypic variation in IV.

Additional factors that may contribute to the severity of scaling in IV are a deficiency of the water-retentive amino-acid breakdown products of filaggrin (including urocanic acid and pyrrolidone carobxylic acids) in the outer stratum corneum [17] and a defect in serine proteases involved in the degradation of desmoglein 1, a transmembrane desmosomal protein [18].

Clinical features. The skin may appear dry and scaly in the neonatal period, but more usually scaling is obvious from 2 months onwards and may be further delayed. The scale is white or grey, small, flaky or branny, and semi-adherent with turned-up edges (Fig. 19.1). It is most pronounced on the extensor surfaces of the arms and lower legs, and characteristically spares the flexural creases. The trunk, especially the abdominal wall, is often mildly affected and the nappy (diaper) area is spared. Facial scaling, generally forehead and perioral, mild dandruff and involvement of the pinnae are seen in some patients. The palms and soles are usually free of scale, but palmoplantar hyperlinearity (linear grooves crossing perpendicularly to the thenar and hypothenar eminences), a reflection of mild hyperkeratosis, is a helpful feature in many ichthyosis vulgaris patients, whether they have coexistent eczema or not [19]. It also occurs in atopic eczema without ichthyosis [4,20]. Keratosis pilaris is a common associated feature of both atopic eczema and IV, and favours the extensor aspects of the upper arms and thighs.

Fig. 19.1 Ichthyosis vulgaris.

Symptoms of IV are few, mainly dryness or roughness of the skin and the cosmetic effect. In isolated IV, pruritus is not a problem, but in patients who also have eczema, pruritus, excoriation and lichenification are additional features. In these patients, atopic xerosis may mimic IV but the ichthyosis has a characteristic histology and persists after the eczema has settled.

There is a marked seasonal variation in most patients, with improvement in warm and sunny weather, with a degree of ambient humidity. Many sufferers (38% of 169 patients) report a gradual improvement in adolescence [1], although a small number worsen with age. Reports of ocular manifestations and testicular cancer in ichthyosis vulgaris have not been verified, and may have arisen from inclusion of X-linked ichthyosis cases [21,22].

Diagnosis. Ichthyosis vulgaris may be mistaken for atopic xerosis, irritant dermatitis, eczéma craquelé, acquired ichthyosis, Refsum's disease and a mild autosomal recessive ichthyosis variant reported in five of eight siblings [23].

Genetics. Ichthyosis vulgaris is regarded as an autosomal dominant disease with variable penetrance, such that disease severity can vary between generations, and affected siblings. Following the success in sequencing the filaggrin gene, recent extensive genetic studies, including IV families with linkage to the epidermal differentiation complex on chromosome 1, have uncovered two common filaggrin mutations, R501X and 2282del4, which result in loss-of-function, stop codons in the gene and absence of filaggrin in keratinocytes [14,24]. The carrier rate for filaggrin mutations in populations of European descent is around 10% (heterozygotes, clinically mildly affected), with 1% who are compound heterozygous or homozygous (moderate to severe IV). The combined allele frequency was estimated to be 4% [14]. This is referred to as semi-dominant inheritance and the common heterozygote state may confer a biological advantage. A recent Scottish study of the clinical effects of filaggrin mutations showed even higher rates of carriage with 1:8 heterozygous and 1:80 compound heterozygous or homozygous [25]. Different filaggrin mutations have been found in Japanese IV and atopic dermatitis patients [26].

Treatment. As a general measure, avoidance of low humidity environments and extremes of temperature is of benefit to all ichthyosis patients. Regular emollient application is recommended for those with ichthyosis vulgaris, and if provided with samples of a variety of suitable preparations, patients can make their own choice as to the most acceptable and appropriate for them in a given situation. Many do not require treatment in the summer as they spontaneously improve. In drier, colder seasons, mild and moderately affected individuals may opt to use a light emollient, such as aqueous cream, which can also be used as a soap substitute. More severe ichthyosis warrants concentrated paraffin containing (50/50 mixtures of white soft and liquid paraffin) or

cetostearyl alcohol-containing emollients, of which there are many proprietary brands. Glycerol may be added to improve lubrication. It should be borne in mind that greasy emollients such as emulsifying ointment have adverse effects on certain fabrics, the rubber seals of washing machines and drains. Open pots may become contaminated with bacteria as ointments do not contain preservatives.

Emollients need to be applied at regular intervals, but while morning and evening treatments are convenient for most patients, application during the day may not be possible for people with a busy work or school routine or shift workers. Assistance from carers and at school should be arranged for severely affected children. Emollient bath oils and a variety of soap substitutes are available. Cetomacrogol additives may enhance the antipruritic effect of bath oils. Bubble bath, astringent and other irritant products should be avoided.

Keratolytic agents, such as 1–5% salicylic acid, may be added to emollient cream bases, to encourage shedding of scale, but in practice they tend to be too irritant for regular usage. The risk of systemic toxicity (salicylism) precludes widespread application of salicylic acid-containing compounds, especially in young children who have a high surface area relative to body size. Alpha-hydroxy acids, such as lactic, glycollic, malic, mandelic, citric, pyruvic, gluconic and tartaric acids, 5–10% in an oil, lotion, cream or hydrophilic ointment base are said to enhance corneocyte shedding by virtue of their effect in breaking intercellular bonds [27]. They have become popular additives in many commercial skin-care products ('fruit acids') in recent years, and may be less irritant although more expensive than salicylic acid compounds. Toxicity has also been reported with topical lactic acid [28]. Beneficial effects from topical 12% ammonium lactate lotion have been reported [29]. Urea-containing (5–10%) emollients improve epidermal hydration, lyse keratin and are bacterostatic [30,31]. Topical retinoids are generally too irritant. The activity of keratolytic and urea treatments can be enhanced by occlusion under tubular dressings, sleep suits or bandages. In practice, they can be applied as tolerated to localized areas of the limbs for 1–2 weeks at a time to produce a mild exfoliation, which can then be maintained with less frequent application. Mechanical exfoliation can be achieved with a loofah while bathing. Dandruff is not a problem for most ichthyosis vulgaris sufferers, but if present can be controlled with a tar- or salicylic acid-containing shampoo.

Patients with both ichthyosis vulgaris and atopic eczema will need appropriate eczema therapy with the addition of topical anti-inflammatory or immunomodulatory preparations as required. Topical steroids and immunosuppressive agents do not benefit IV but oral evening primrose oil, which contains essential n6 fatty acids, produced a slight improvement in some [32]. Systemic retinoid therapy is not necessary or appropriate for IV, and in patients with associated atopic eczema would be likely to exacerbate the eczema.

X-linked recessive ichthyosis (MIM 308100)

Typically, X-linked recessive ichthyosis (XLRI) affects male offspring who inherit an X chromosome bearing a mutated steroid sulphatase gene from their asymptomatic carrier mother. Although the ichthyosis is rarely a significant problem, XLRI is an important disease for many reasons. It may be associated with extracutaneous manifestations and obstetric complications. The underlying lipid metabolic defect and the pathogenesis of the ichthyosis have been elucidated. The gene for steroid sulphatase (*STS*) is located at the distal end of the short arm of the X chromosome.

Incidence. Wells and Kerr [1], in a large epidemiological study in 1966, differentiated XLRI from ichthyosis vulgaris and defined clinical and genetic features. They estimated its incidence in the UK at 1 in 6190 males. A not dissimilar incidence has been reported in other countries, based on clinical diagnostic criteria. In a Danish population study of placental *STS* deficiency, a predicted incidence of XLRI of 1 in 2000 males was derived [2]. XLRI has a worldwide distribution in all ethnic groups.

Aetiology and pathogenesis. In the 1970s, *STS* deficiency was identified as the cause both of XLRI and placental sulphatase deficiency, confirming them as a single disease entity [3,4]. Fibroblasts, epidermal cells, leukocytes, nail, hair bulbs, amniocytes and testicular tissue can all be assayed for a functional and immunological enzyme deficiency. The enzyme substrate, cholesterol sulphate, is elevated in many tissues, including serum, red blood cell membranes, stratum corneum and nail matrix, but serum cholesterol levels are normal, as its main synthetic enzyme is hydroxymethylglutamyl-CoA reductase. Lipid analysis of normal epidermis shows a gradual decline in cholesterol sulphate (which stabilizes lipid bilayers) from 6% in the granular layer to 3% in the stratum corneum. A concomitant rise in epidermal cholesterol, which triggers stratum corneum intercellular lipid bilayer disintegration and desquamation, reflects the increasing activity of membrane-based steroid sulphatase at the corneal–granular layer junction. In XLRI, cholesterol sulphate accounts for 12–30% of stratum corneum lipids [5,6]. Calorimetric studies identified a failure of the normal liquid–crystalline transition phase of stratum corneum intercellular lipids in XLRI, presumably because of the polar subgroups of cholesterol sulphate [7]. The raised level of cholesterol sulphate in the stratum corneum also reduces the activity of serine proteases responsible for cleaving desmosomes [8].

Steroid or cholesterol sulphatase is one of the two isomers of aryl sulphatase C, a membrane-bound microsomal enzyme, and is responsible for hydrolysing sulphate groups from cholesterol sulphate and certain other steroids. The sulphated forms of some steroid sex hormones, such as 17-hydroxyprogesterone, oestrone and dehydroepiandosterone, are also increased in patients with XLRI [9]. Androstenedione and testosterone sulphate are reduced, but testosterone and dihydrotestosterone levels are normal, as synthesis can be mediated by a desaturase enzyme system. Pituitary gonadotrophins (with the possible exception of LH), prolactin and sex steroid binding globulin are normal. The altered sex hormone profile may, in part, explain the abnormal testicular development in some XLRI patients.

Evidence of a direct causal link between elevated cholesterol sulphate levels and scaling is compelling. Topical application of cholesterol sulphate in the hairless mouse induced a reversible retention ichthyosis, and a threefold increase in stratum corneum thickness after 1 week [10]. The scaling cleared within 3 days of stopping the treatment, and did not occur if other sulphated substrates of the enzyme were applied. Topical cholesterol prevented this effect, and also temporarily reduced the scaling of XLRI but not of other ichthyoses. Many cholesterol-lowering drugs have caused ichthyosis as a side effect [11].

Histopathology. Affected skin in XLRI shows an expanded stratum corneum without parakeratosis or acanthosis. The granular cell layer is usually normal, but may be mildly thickened or, rarely, diminished, making histological differentiation from ichthyosis vulgaris difficult. Ultrastructurally, the keratohyaline granules are normal or small, in contrast to ichthyosis vulgaris, and are numerous. Desmosomes are more persistent than normal, and corneal melanosomes more prominent [12,13]. Kinetic studies have shown normal rates of cell turnover.

Clinical features. In 75% of cases, scaling is evident within the first week of life [14], but 6% develop scaling after the age of 1 year [15]. A Danish study of 76 patients revealed onset of light, flaky scaling before 1 month of age, with more typical scale by 6 months in all but two children [16]. A prominent peeling episode at this stage was characteristic. The scaling tends to increase throughout childhood, often spreading up from the lower legs to the trunk. It stabilizes in the teens with little subsequent change, and in most patients scaling diminishes in the summer months. There is considerable variation in the severity of scaling between families, and even in some instances within affected kindred. Pruritus is unusual.

Scaling in XLRI is most prominent on the extensor surfaces of the upper arms, the abdomen, outer thighs and around the lower legs (Fig. 19.2). Typically, the scale is medium to large, polygonal, adherent, dull and light to dark brown, depending on skin type. The posterior and lateral neck, upper and lateral abdominal wall and pre-auricular facial skin are commonly affected with semi-adherent, grey scale and, in contrast to ichthyosis vulgaris, the flexures may be involved. The face, scalp, axillae, flexor aspects of the limbs and dorsal hands and feet may show light grey scaling but the palms and soles are spared. Rarely, a fine white or brown scaling is the predominant sign, and leads to a delay in diagnosis (Fig. 19.3). In one study the average age of diagnosis was 10.3 years [14].

Extracutaneous features of XLRI. Various extracutaneous abnormalities have been noted in some patients with an increased incidence of testicular maldescent, abnormalities of sperm count or

(a)

(b)

(c)

Fig. 19.2 X-linked recessive ichthyosis. (a) Scaling on the arm, (b) on the legs and (c) on the trunk.

Fig. 19.3 Mild X-linked recessive ichthyosis in a 3-year-old boy.

motility, and testicular cancer have been reported [16–19]. Of a group of 76 patients, nine had testicular maldescent and three developed testicular cancer in normally descended testes (one had bilateral cancer) [16,19]. Inguinal hernia appears to be more common, and unilateral renal agenesis was reported in half of those with cryptorchidism, all of whom had features of Kallmann's syndrome [14]. Male pattern baldness does occur in XLRI.

Corneal dot, thread-like or comma-shaped opacities, detected with the slit-lamp microscope, occur in 24–100% of adult patients [15,16,20,21], and to a lesser degree in 24% or more of female carriers [21]. They are usually of no functional significance but a minority suffer from mild keratitis. Corneal opacities in XLRI are thought to be a result of stromal deposits on the posterior surface of Desçemet's membrane [21].

Perinatal manifestations of steroid sulphatase deficiency. It was noted, in the 1970s, that low maternal urinary oestriol excretion in the third trimester of pregnancy was not invariably associated with intrauterine growth retardation. These pregnancies often ended in a prolonged labour, and the underlying defect, placental

STS deficiency, was identified. Coincidentally, *STS* deficiency was noted in boys with XLRI [2,3].

Prolonged labour may affect up to one-third of patients with XLRI, with a consequent risk of perinatal complications. In a group of 33 patients, four had a spastic paraplegia or paraparesis, apparently as a result of prolonged labour, requiring obstetric intervention [14]. In each case, a younger male sibling with XLRI was neurologically normal.

XLRI and contiguous gene defects. Kallmann's syndrome describes the association of XLRI with hypogonadotropic hypogonadism, anosmia and a variety of neurological defects, including nystagmus and mirror movements of the hands and feet (synkinesis) [22]. It is estimated to affect 1 in 60 000 of the population, and may be misdiagnosed as XLRI until adult life because of delayed recognition of hypogonadism. Adult patients develop obesity and osteoporosis. Renal anomalies and cleft palate have also been reported in Kallmann's syndrome. Developmental delay and spastic paraplegia appear to be more common in Kallmann's syndrome than in isolated XLRI. Kallmann's syndrome is caused by a large deletion of the short arm of the X chromosome proximal to and including the *STS* gene. The features of Rud's syndrome (X-linked ichthyosis, obesity, hypogonadism, mental retardation, epilepsy and endocrinopathies) can, in large part, be attributed to Kallmann's syndrome or to perinatal complications in patients with XLRI [23].

Larger X chromosome deletions distal to and including the *STS* gene may lead to XLRI associated with mild mental retardation, mild chondrodysplasia punctata and short stature [24]. Epiphyseal stippling of long bones, larynx and vertebrae can occur transiently in early childhood in the chondrodysplasia variant, while dysplastic features may be detected on X-rays later in life. Hypoplasia of cartilage and distal phalanges has been noted in affected males, and carrier females may also be of short stature. Sparse, brittle hair occurred in two patients with large X chromosome deletions [14].

Diagnosis. Raised serum cholesterol sulphate in patients with XLRI can be detected on serum lipoprotein electrophoresis [25]. Cholesterol sulphate carries a stronger electronegative charge than cholesterol, resulting in increased mobility of the β low-density lipoprotein fraction (a 'fast' band 2 mm or so beyond that of controls) towards the anode (Fig. 19.4). This simple screening test is not widely available. Equivocal results (1 mm difference) should be followed up with the definitive test, *STS* assay, which is available in regional laboratories. Enzyme activity can be measured in leukocytes (EDTA blood sample) or skin fibroblasts, and is much reduced or absent in XLRI [26]. Serum cholesterol levels are normal in XLRI.

Chromosomal analysis using high-resolution G-banding will detect and quantify significant Xp deletions where clinical evidence of contiguous gene defects exists. DNA-based techniques include fluorescent *in situ* hybridization (FISH) analysis which detects deletion of the *STS* gene, the most common cause of XLRI [27], and Southern blot analysis to identify specific gene deletions, or point mutations at and distal to the *STS* gene locus [28]. PCR amplified testing for exons in Kallmann's syndrome genes is the most sensitive test for this condition

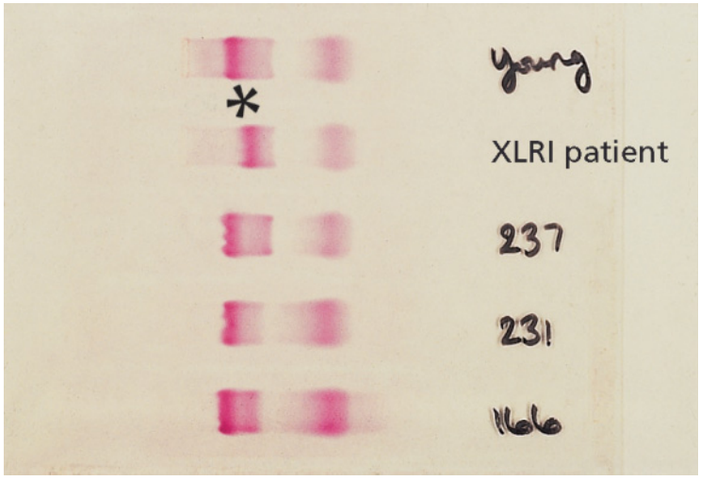

Fig. 19.4 Serum electrophoresis, showing 'fast' band in XLRI patient (compared to controls).

Clinically, XLRI may resemble ichthyosis vulgaris or mild lamellar ichthyosis. A Sardinian kindred with a phenotype suggestive of XLRI but normal *STS* activity has been reported [29]. XLRI has been reported in a female [30].

Genetics. Linkage of XLRI and the Xg red blood cell group in the 1960s was an early example of chromosome localization identified by tracking linked traits in family studies [31]. The association of XLRI with stunted growth, hypogonadism and anosmia has enabled mapping of the relevant genes on the short arm of the X chromosome (Xp). Gene mapping in families with X to Y translocations placed the *STS* gene at the Xp 22.3 locus [32]. The Kallmann's syndrome gene is proximal to this, while deletions distal to the *STS* gene (towards the pseudoautosomal region at the tip of the X chromosome) may cause mental retardation, chondrodysplasia punctata and short stature [24,33].

The virtual absence of immunoreactive *STS* in XLRI patients is matched by a complete deletion of the *STS* gene on Southern blot analysis of genomic DNA in up to 90% of cases [14,34]. Point mutations of the gene have also been identified [28,35]. There is considerable genetic heterogeneity in XLRI and contiguous gene syndromes, with sizeable DNA loss (3.4%, up to 2 megabases) detected by flow cytometry in some [36] and in others evidence of X–Y translocations [37].

Isolated XLRI is generally a mild disease and few families are interested in prenatal diagnosis. However, placental *STS* deficiency is a risk factor in affected pregnancies, and knowledge of their carrier status could reduce perinatal risk for mother and baby. Kallmann's and other contiguous gene defects are more serious conditions and affected families seeking genetic counselling and/or prenatal diagnosis first need genetic and molecular investigation, including heterozygote detection. Prenatal diagnosis of XLRI and associated conditions, previously suggested by low maternal urinary oestriol levels, can be confirmed by steroid sulphatase assay of a chorionic villus/amniocyte biopsy.

Southern blot analysis with PCR will detect *STS* gene deletion and mutations or contiguous gene defects while high-resolution G-banding identifies large Xp deletions. FISH analysis can also rapidly identify female carriers [2,27,28].

Carrier detection. Obligate carriers show no consistent cutaneous features but corneal stromal deposits are detected on slit-lamp examination in a proportion [20,21]. Lipoprotein electrophoresis is normal in obligatory female carriers. *STS* levels in leukocytes, fibroblasts or hair roots are higher in normal females than in normal males, because the Lyon effect (random inactivation of one X chromosome in normal female cells) does not apply to the *STS* gene [38]. Therefore, female carriers would be expected to have 50% of the *STS* values of non-carrier females. Indeed, 30 of 31 obligate carriers had a leukocyte *STS* level below the 2.5 percentile of normal females, indicating enzyme heterozygosity [38]. However, partial X inactivation was evident in other studies; enzyme values in the range of 40–86% in known carriers were obtained. Leukocyte *STS* assay, using oestrone sulphate as substrate, proved the most reliable biochemical test for heterozygote detection [39]. Visual assessment of stained hair roots to detect *STS* has also been used. Southern blot hybridization of leukocyte DNA provides an accurate measure of the anticipated 50% *STS* gene dosage in carriers, but is applicable only to the 90% of XLRI families with complete gene deletion [40]. FISH analysis, a technically less demanding diagnostic technique, is currently the method of choice for carrier detection in XLRI families where a gene deletion is the underlying defect [27]. In the remaining 10% of carriers without gene deletions, PCR and direct DNA sequencing is necessary. Somatic and germinal mosaicism for the *STS* gene deletion in a carrier has been reported [41].

Treatment. The same principles apply to treatment of XLRI as have been outlined for ichthyosis vulgaris. Most patients achieve an acceptable level of control of their scaling and dryness with daily emollient application, and may improve sufficiently in the increased humidity of temperate summers to forgo any therapy. Keratolytic and urea-containing preparations are generally less irritating than in ichthyosis vulgaris. In severe XLRI, short or intermittent courses of oral retinoid therapy may be considered. A topical receptor-selective retinoid, tazarotene, showed promising results in a small number of patients [42]. Topical application of cholesterol reversed the effect of cholesterol sulphate in hairless mice [10], and a 10% cholesterol cream improved scaling in 18 of 20 patients after 3–5 weeks [43]. Abnormalities of genital or secondary sexual development should be investigated by an endocrinologist and appropriate treatment planned. Short stature warrants early investigation, including a radiological check of long-bone epiphyses. Neurological and developmental assessments will detect those patients with neurological damage or Kallmann's syndrome and help identify special educational needs.

Multiple sulphatase deficiency (MIM 272200)

This is an exceedingly rare, autosomal recessive disorder caused by deficiency of two or more of the nine lysosomal and microsomal sulphatase enzymes, usually including aryl sulphatases A, B and C. This leads, in infancy, to a combination of features of mucopolysaccharidosis type 2 (aryl sulphatase B deficiency), metachromatic leukodystrophy (aryl sulphatase A deficiency) and XLRI [1]. Multiple sulphatase deficiency is due to mutations in *SUMF1* (sulphatase-modifying-factor 1 gene), which encodes lysosomal C-α-formylglycine generating enzyme (FGE) [2]. FGE produces peptides which are necessary for sulphatase activity.

Developmental delay and failure to thrive occur from early infancy with features of Hurler's syndrome (coarse facies, stunted growth, hepatomegaly and skeletal defects) becoming evident in the first year of life. A positive urine spot test for glycosaminoglycans (GAGs) suggests a lysosomal storage disorder. A mild ichthyosis and progressive neurological degeneration evolve in the second or third year but the phenotype varies according to the degree of reduction of each enzyme [3,4]. The neurological disease is often fatal in childhood.

Multiple sulphatase deficiency is confirmed by enzyme assays on fibroblasts, fresh leukocytes or serum, and fibroblast iduronate sulphatase activity is reduced. Urinary sulphatides and GAGs (heparan and dermatan sulphate) are elevated. Prenatal diagnosis by enzyme assay of amniocytes is possible. Mutational analysis on chorionic villus biopsy should allow early prenatal diagnosis.

Collodion baby

This accurate, if outdated, term is used to describe the transient appearance at birth and in the neonatal period of a baby who, in general, subsequently develops congenital ichthyosiform erythroderma [1]. It was reported sporadically in the 19th century [2], and familial, self-healing cases and localized forms have been noted [3,4]. There are no reliable figures on incidence and it may be overlooked or misdiagnosed in some cases. Collodion is a syrupy solution of pyroxylin (nitrocellulose) in ether and alcohol which has medicinal and commercial uses.

Aetiology and pathogenesis. The collodion membrane is thought to develop during the third trimester, although the author has seen a 24-week gestation female neonate with a typical collodion membrane (self-healing). At birth the defective stratum corneum barrier, associated with the collodion membrane, moves from an aquatic to a dry environment, and the membrane desiccates and peels off. The association between fetal periderm, which evolves in the second month of gestation and dissolves with the onset of epidermal differentiation in the sixth month, and the neonatal collodion membrane, is unknown. Periderm does not express profilaggrin nor contain keratohyalin granules, which are present in the collodion membrane. In fetal skin biopsies of lamellar ichthyosis and harlequin ichthyosis, the periderm was normal in appearance [5].

The collodion membrane shares the same aethiopathogenesis as the subsequent ichthyosiform erythroderma, which evolves in the majority of collodion babies. Functional mutations in transglutaminase 1, *ALOX* genes, *ABCA12*, *ichthyin*, *ABHD5* and other genes involved in epidermal lipid and protein homeostasis have been identified in ichthyosiform erythrodermas preceded by collodion baby presentation. Self-healing collodion baby is caused by compound heterozygous transglutaminase 1 mutations which *in utero* render the enzyme inactive in its *cis* form. In the extrauterine environment the enzyme isomerizes back to its partially active *trans* form, allowing a normal phenotype [6]. The rare type 2 variant of the lysosomal (sphingolipid) storage disorder, Gaucher disease is due to β-glucocerebroside mutations. It presents with collodion membrane and evolves to ichthyosis. Ultrastructural

abnormalities in lamellar body and membrane formation and defects in ceramide production underlie the epidermal dysfunction [7]. Transglutaminase deficiency, keratin-associated-protein defects (e.g. loricrin mutations) and other lipid metabolic disorders also cause collodion membrane and ichthyosis by disrupting epidermal differentiation and function.

Histopathology. Light microscopy of skin in the early neonatal phase of a collodion membrane shows a compact hyperkeratosis with a thick eosinophilic periodic acid–Schiff stain (PAS)-positive stratum corneum. However, the epidermis is attenuated because of a reduced granular layer. The mid- and lower epidermis and the dermis are usually unremarkable.

Electron microscopy features in the early neonatal phase vary. In one case, cells of the upper two-thirds of the stratum corneum were convoluted and irregular in shape, with prominent nuclear debris and dense intracytoplasmic granules. Lamellar bodies were numerous in the intercellular spaces and desmosomes were well preserved [8]. Repeat skin biopsy at 16 months showed that, in spite of apparent 'self-healing', the ultrastructural changes persisted. However, in a further two cases, the ultrastructural features on the 15th day of life were predictive of the outcome, with a self-healing case showing relatively normal epidermal ultrastructure, while an infant who developed erythrodermic ichthyosis showed continuing dysplastic changes [9].

Clinical features and prognosis. Premature delivery is more common but not usually a significant problem. At birth, the typical collodion baby presents a striking and characteristic clinical picture with a generalized glistening, taut, yellowish film stretched over the skin (Figs 19.5a, 19.6a & 19.9a). It resembles a Clingfilm wrap or sausage skin, although it may variously be described as 'plastic skin', 'parchment-like' or 'as if dipped in hot wax'. Normal skin markings are obliterated, the eyelids and sometimes the lips are tethered and everted (ectropion and eclabion), the pinnae may be flattened and the nostrils obstructed (Figs 19.5b & 19.9a). Sausage-shaped swelling of digits may result from acral extension of the membrane and, rarely, constricting bands encircle the limbs or digits. General examination is usually normal and movement is minimally restricted.

The collodion membrane desiccates and cracks around flexures during the first days of life (Fig. 19.5c), and is usually completely shed within the first few weeks of life. It may be incomplete or localized in some infants; it may peel away only to partially reform, this pattern being repeated over a period of up to 12 weeks. In most cases, shedding reveals an erythrodermic ichthyosis (Fig. 19.5d).

Previously common and potentially lethal complications of a collodion membrane, especially when associated with erythroderma, were renal failure and neurological sequelae of hypernatraemic dehydration [10], hypothermia and bacterial sepsis. Affected infants require intensive nursing care in humidified incubators to control body temperature, prevent infection and combat electrolyte upset and dehydration. Increased absorption of topical agents through the skin may lead to systemic toxicity, and topical steroids should be avoided. Improved neonatal care has resulted in a reduction in neonatal mortality from 33% in the 1970s to less than 11% in one review [11], and in uncomplicated cases, mortality is now negligible [12].

Sequelae and genetics. In 60–80% of these infants, the features of non-bullous ichthyosiform erythroderma or lamellar ichthyosis become apparent as the collodion membrane is shed [11,12]. The severity of the subsequent ichthyosis cannot be predicted from the duration or complications of the collodion membrane. The rare autosomal dominant form of lamellar ichthyosis also presented with collodion membrane [13]. A minority of patients with lamellar ichthyosis or non-bullous ichthyosiform erythroderma appear not to have a collodion membrane at birth.

Certain ichthyosiform syndromes, including trichothiodystrophy (IBIDS), neutral lipid storage disease, Sjögren–Larsson syndrome, Conradi–Hünermann disease and CHIME syndrome [14], and the non-syndromic autosomal dominant loricrin keratoderma [15] may present with collodion membrane. Up to 20% of collodion babies subsequently have normal or near-normal skin (Fig. 19.6), so-called self-healing collodion baby or 'lamellar ichthyosis of the newborn' [16]. This autosomal recessive condition has been attributed to compound heterozygous transglutaminase 1 mutations which *in utero* render the enzyme inactive in its *cis* form, while post partum it isomerizes back to its partially active *trans* form [6]. Mutation of the *ALOX12B* and *ALOXE3* genes underlie most of the Scandanavian cases of 'self-improving collodion ichthyosis' [17]. An acral self-healing collodion baby phenotype has also been reported [18].

Collodion membrane presentation has also been reported in anhidrotic ectodermal dysplasia [19], Gaucher disease type 2 [20,21] and Neu–Laxova syndrome [22]. An adult with isolated palmoplantar keratoderma who was a collodion baby, was observed by the author and a similar case was included in a review of 10 collodion babies in the Thai literature [23]. A further case of evolution of collodion baby to palmoplantar keratoderma also had anogenital leukokeratosis [24].

Differential diagnosis. A collodion baby is generally easily distinguished from the more severe harlequin fetus or harlequin ichthyosis presentation, but occasional cases with intermediate features have been recorded. These cases have been referred to as 'chrysalis babies'. Restrictive dermopathy, or the 'stiff baby syndrome', produces a generalized taut, thick, tethered and unyielding skin at birth, which does not desiccate in the neonatal period. Its persistence causes respiratory failure and early neonatal death. Collodion-like presentations have been described in Gaucher type 2 and Neu–Laxova syndromes [20–22]. Infective causes of desquamation such as staphylococcal scalded skin should be included.

Management. Skin biopsy is not usually performed at this stage, but hair analysis, blood film microscopy and hearing tests should be arranged. Collodion babies should be nursed in the neonatal intensive care unit (NICU) in a humidified incubator. Cleansing with warm water and sterile aqueous cream or antiseptics daily, and barrier nursing, reduces the risk of infection (which is associated with skin barrier dysfunction, emollient use and high humidity). An emollient, such as sterile white soft paraffin in single-dose containers, is usually applied 4-hourly to keep the membrane

pliable and reduce transepidermal water loss. Analgesics may be required before handling. Intravenous lines should be avoided and regular skin swabs carried out. Signs of skin or systemic sepsis (including *Candida* and *Pseudomonas*) require investigation and prompt treatment, but prophylactic antibiotics are unnecessary. Poor sucking and weight loss may necessitate nasogastric tube feeding, and a higher than normal fluid and calorie requirement can be anticipated. The risk of exposure keratitis due to ectropion can be reduced by the regular use of lubricating drops and ointments, and antibiotic if necessary. Early ophthalmological advice should be sought. Nasal obstruction can be improved by gentle probing, and constricting bands on the limbs should be divided if causing acral pressure effects. Systemic retinoids have been used in severe cases. Every effort must be made to allow the parents to nurse and bond with their baby and their involvement from the beginning will enhance their confidence in managing at home.

The need for continuing intensive care, once the membrane is shed, depends on the baby's condition, but most can be discharged within the first 4 weeks with a skin care plan (including ample emollient supplies) and home nursing support. Accurate information on the condition, its management and prognosis should be made available to family and carers and contact with a patient support group is often appreciated. The details and outcome of an individual case, along with appropriate investigations, are important for genetic counselling of the family, which should be arranged soon after discharge.

Non-bullous ichthyosiform erythroderma (MIM 242100)

Non-bullous ichthyosiform erythroderma (NBIE) is a rare and usually severe autosomal recessive inflammatory ichthyosis. There are little data on incidence, but an English population study suggestion of 1 in 300 000 is likely to be an underestimate [1]. It occurs in all races, more so when consanguineous marriage is common. NBIE is probably more common than lamellar ichthyosis, but they were regarded as a single disorder (congenital ichthyosiform erythroderma, CIE) until the 1980s, when clinical, histological and biochemical features helped to differentiate them. However, there are intermediate phenotypes and a lack of disease specificity of the gene mutations that have been found in each disorder points to genotype-phenotype variability [2,3]. NBIE is sometimes referred to as erythrodermic lamellar ichthyosis.

Aetiology and pathogenesis. NBIE is characterized by epidermal hyperplasia with increased mitoses and expression of hyperproliferative keratins K6/K16/K17. *In vitro* studies of NBIE keratinocytes showed hyperkeratosis, and more marked parakeratosis, than control keratinocytes [4]. No consistent changes in epidermal lipids in NBIE have been found, including the alkanes, a saturated hydrocarbon group [5]. Variations in the stratum corneum enzymes, β-glucosidase and butyrase, highlighted differences between the autosomal recessive ichthyoses [6].

Abnormal intracellular cytoplasmic accumulation of keratinocyte transglutaminase 1 (TGase1) was reported in a subset of patients with NBIE [7]. Whereas TGase1 activity in some patients with lamellar ichthyosis was entirely absent, partial deficiency was found in the NBIE patients [8]. Further reports of *TGM1* gene mutations in NBIE followed [9,10] and 38 of 80 patients with NBIE/lamellar ichthyosis (LI) spectrum, who were included in a Swedish national survey of congenital ichthyosis, also proved to have *TGM* mutations [3]. In fact, the same *TGM1* mutation can give rise to either the NBIE or LI phenotype [8,10]. Transglutaminases are Ca^{++} dependent enzymes involved in the assembly of the cornified cell envelope, which is just beneath the corneocyte cell membrane. TGase1 specifically binds ceramide lipids to envelope proteins, such as involucrin. The *TGM1* gene has 15 exons and is sited at chromosome 14q11.2. Several different mutations have been identified and TGase1 deficiency correlates with certain ultrastructural features, even corneocyte collapse seen on light microscopy of epidermal scales [11].

Mutations in two lipoxygenase enzymes, lipoxygenase-3 (ALOXE3) and 12-lipoxygenase (ALOX12B) were identified in six Mediterranean families affected by NBIE, known to be linked to chromosome 17p13.1 [12]. One deletion and six novel missense mutations in the *ALOX12B* gene were found in six of 11 families in France [13]. These two lipoxygenases are mainly expressed in epithelial cells including suprabasal keratinocytes, and are involved in the maintenance of the cutaneous permeability barrier and possibly in terminal differentiation. Lipoxygenases are involved in essential fatty acid, phospholipids and triglyceride metabolism, and deficiency affects lamellar body-derived lipid lamellae and membranes responsible for the epidermal permeability barrier [14]. A mouse model with an *ALOX12B* mutation provides a laboratory model for epidermal barrier function [15].

Mutations in ichthyin, a transmembrane receptor in the 12-lipoxygenase pathway, were found in several families with NBIE in different countries [16]. They all had palmoplantar keratoderma and some were not collodion babies. Three patients with typical NBIE phenotype had missense mutations in *ABCA12* (an epidermal lipid transporter protein), which usually lead to harlequin ichthyosis [17,18]. Two had multiple skin malignancy (squamous carcinoma, melanoma and cutaneous lymphoma), not usually seen in NBIE [17].

Histopathology. Light microscopy of skin sections reveals compact hyperkeratosis and moderate increase in stratum corneum thickness. There is variable mild parakeratosis, acanthosis, a normal or prominent granular layer, increased mitoses and an accentuated broad rete ridge pattern. A mild upper dermal lymphocytic infiltrate and prominent dermal blood vessels may be present. Lipid vacuoles in the stratum corneum were noted in a family with autosomal dominant NBIE, and sweat glands were normal [3].

PAS staining of frozen sections showed positivity in cell membranes of the stratum corneum and granular layer and in the basement membrane, which is absent in normal skin and in other ichthyoses, with the possible exception of Netherton's syndrome [19]. Kinetic studies, using labelled thymidine, confirmed an increased epidermal turnover rate in NBIE, similar to that seen in psoriasis, and in contrast to the relatively normal epidermal kinetics of lamellar ichthyosis [20]. This was unaffected by retinoid therapy [21].

Electron microscopy reveals abnormal lamellar bodies, which are retained in the corneal layer. In the so-called autosomal dominant variant (see below), reduced keratohyalin and tonofilaments, normal lamellar bodies and lipid vacuolation in the stratum corneum were noted [3]. Ultrastructural features more typical of harlequin ichthyosis have been found in several patients with severe NBIE [22]. Classification of autosomal recessive congenital ichthyosis into four subtypes, based on ultrastructural findings, shows some correlation to clinical and genetic subtypes of the NBIE/LI spectrum [23–25]. Type I correlates to NBIE, type II and III to LI and type IV to a mild NBIE variant.

Clinical features. NBIE, in approximately 90% of cases, presents at birth with a collodion baby appearance (Fig. 19.5). The rest are erythrodermic from birth, and some are premature. After shed-

(a)

(b)

Fig. 19.7 Non-bullous ichthyosiform erythroderma: (a) in a 4-year-old-boy; and (b) same child.

ding of the collodion membrane, generalized scaly erythroderma is apparent and persistent (Fig. 19.7). Erythroderma may lessen while scaling increases in early childhood, but there is considerable heterogeneity and even intrafamilial variation. Congenital ichthyosiform erythroderma should be regarded as a clinical spectrum with NBIE at one end and lamellar ichthyosis at the other, with many patients in the centre ground.

Typically, scaling affects all areas including the scalp, ears, face, flexures, palms and soles. The scale of NBIE is white or grey, thin, superficial and semi-adherent. It appears feathery on the face, arms and trunk but may become lamellar or plate-like on the lower legs. Scaling may be cyclical, with build-up and shedding over periods of 2–4 weeks and, rarely, clinically normal skin may evolve on limited sites. Palmoplantar hyperkeratosis/keratoderma occurs in up to 70% of patients, and can cause recurrent painful fissures, digital contractures and sclerodactyly. Scalp involvement may lead to tinea amiantacea and patchy cicatricial alopecia, especially on the temporal scalp.

Ectropion improves during infancy, but persists into adult life in 30% or so and, if untreated, may lead to exposure keratitis and even blindness [26]. Loss of eyebrows and lashes in severe cases accentuates the ocular problem. Hypoplasia of the nasal and aural cartilages may result from compression and scarring, increasing the cosmetic burden.

A mild nail dystrophy consisting of ridging, subungual hyperkeratosis or hypoplasia occurs in up to 50% of patients, but hair, teeth and mucosal surfaces are normal. Nail growth and skin healing are accelerated. In most patients, sweating is absent or markedly reduced in childhood, and care is needed to avoid hyperpyrexia during intercurrent illness, leisure pursuits or in hot climates. Sweat gland function improves in adolescence, and in patients treated with retinoids. Hypohidrosis is therefore thought to be a result of sweat duct obstruction by the hyperkeratotic stratum corneum. Pruritus is not uncommon in NBIE and coexistent atopic eczema can be difficult to diagnose. Cutaneous bacterial and viral infections are rare, but patchy or widespread fungal infection of skin and nails is a common complication (Fig. 19.5d) [27,28]. Mildly affected patients may present with an intertrigo-like pattern, mild palmar hyperkeratosis and subtle facial tightness.

Many severely affected children are of short stature, with a delayed growth spurt in adolescence. They are at increased risk of rickets due to vitamin D deficiency [29]. NBIE may limit a child's ability to take part in sports, but swimming and less vigorous activities should be encouraged. Psychological problems often arise at school because of insensitive comments and reactions of others. However, in general, children with NBIE seem to cope well with their disability, and many achieve academically, on a par with their peers.

Congenital reticular ichthyosiform erythroderma. Three cases of a variant of NBIE were described [30]. In childhood they developed enlarging areas of normal skin on a background of ichthyosiform erythroderma (with hypertrichosis), which accounts for the alternative names, 'ichthyosis en confetti' and 'ichthyosis variegata' [31]. An orange-tinted palmoplantar keratoderma occurred. Specific ultrastructural changes were reported, including perinuclear vacuolation and binuclear cells, and autosomal dominant inheritance was suspected.

Ichthyosis prematurity syndrome (MIM 608649) (IPS; congenital ichthyosis with fine/focal scaling, CIFS). A mild NBIE variant, typified by premature (with polyhydramnios) delivery of a red neonate with striking areas of caseous hyperkeratosis has been reported, especially in Scandinavian populations and encountered once by the author [32]. Neonatal respiratory distress and blood

eosinophilia have been noted in some cases. Fine follicular scaling may persist though most resolve. Electron microscopic features, categorized as type IV, are helpful in diagnosis [21]. A mutation in the fatty acid transport protein 4 gene, which results in reduced incorporation of very long chain fatty acids into cellular lipids, has been reported [33].

KLICK syndrome (keratosis linearis, ichthyosis congenita, keratoderma). The characteristic feature of this rare but mild CIE is linear or striate keratoses in flexural areas [34].

Loricrin keratoderma with ichthyosis (MIM 604117). This is a variant of Vohwinkel's syndrome (constrictive palmoplantar keratoderma) but with a collodion baby presentation and normal hearing. A mild generalized erythrodermic ichthyosis and progressive keratoderma with pseudoainhum ensues [35]. The sixth affected family included two Japanese siblings and their father [36]. Skin biopsy shows characteristic ultrastructural features and loricrin mutations have been identified [37]. Vohwinkel's syndrome is associated with deafness and is due to connexin 26 mutations.

Diagnosis. Classic NBIE presents a characteristic clinical picture enabling differentiation from lamellar ichthyosis. Other causes of congenital erythroderma and collodion membrane presentation need to be considered in the neonatal period. Collodion presentation of loricrin keratoderma is mentioned above. Congenital infections including candidiasis, congenital psoriasis, Netherton's syndrome, immunodeficiency disorders, trichothiodystrophy (IBIDS) and neutral lipid storage disease may mimic the cutaneous signs of NBIE in the neonate. There have been sporadic cases of coexistent congenital ichthyosiform erythroderma and psoriasis [38,39].

Genetics. Classical NBIE is an autosomal recessive condition and therefore more likely to occur in societies where consanguineous marriage is common. In a personal series of 25 patients with NBIE, there were five sibling pairs and also seven patients, including three Caucasians, with consanguineous parents. The risk of further affected children for the parents of the proband is 25% for each child. Affected individuals should not have affected children (unless their partner is a heterozygote carrier of the same allele), and their offspring have a 50% risk of carrier status.

A non-consanguineous Swedish kindred, with typical features of NBIE in a mother and her two daughters, was thought to have an autosomal dominant variant [40]. However, it transpired that the father and presumably the mother's parents were heterozygous for the disease allele, an example of genetic pseudodominance [32]. The incidence of heterozygosity was estimated at 1.8–3.2 per 1000 population.

Prenatal diagnosis may be attempted on fetal skin biopsy using ultrasound guidance at 19–22 weeks (amniocyte pellets have also been used) to detect premature or abnormal keratinization or abnormal ultrastructural inclusions [41,42], but it is far from satisfactory for two reasons [43,44]. First, phenotypic heterogeneity can exist between members of the same family, so that the severity of the proband may not reflect that of the affected fetus. Secondly, normal interfollicular keratinization is established only at 24 weeks' gestation and shows a regional pattern of evolution. To avoid errors, multiple skin biopsies from different sites including the scalp are recommended. The identification of a specific genetic mutation in the proband will allow first trimester DNA-based prenatal diagnosis on chorionic villus samples taken at 10–12 weeks' gestation.

Treatment. The principles of emollient and keratolytic treatments for patients with NBIE are much the same as those outlined for treatment of ichthyosis vulgaris. Because of the inflammatory nature of the condition, the potential for irritation with topical treatment is high, and keratolytics and topical retinoids are rarely used. Topical steroids are ineffective and readily absorbed, and they may even cause systemic steroid toxicity, particularly in infants. Topical and/or systemic antifungal therapy is indicated when tinea infection has been confirmed. Hypohidrosis with the attendant risk of hyperpyrexia may be aggravated by the occlusive action of ointments. Prevention of sunburn and sunstroke in children is important.

Systemic retinoids are effective in many disorders of keratinization, and have been shown to be helpful in reducing scaling, pruritus and erythema in most patients with severe congenital ichthyosis, including NBIE [45]. For many patients, this may allow a more active role in daily activities, such as schooling, sport and socializing. The recommended starting dose of acitretin is 0.5–0.75 mg/kg/day, tending to higher doses in younger children. A response is apparent within 2–3 weeks, and the maintenance dose is titrated down to the lowest effective level between 0.1 and 0.5 mg/kg/day. Effective doses tend to be lower than in the treatment of other disorders of keratinization. Because of potential toxicity and the chronicity of the disease, intermittent therapy is preferred (e.g. 3 months on, 3 months off). Patients with ectropion or corneal damage may not be able to tolerate the side effects of retinoids. Peeling of palmar skin may induce an unpleasant hypersensitivity and increased skin fragility delays healing (see Fig. 19.8b). Rare cases of skeletal toxicity have been reported with retinoid therapy [46], but long-term use of etretinate in 42 children, 14 with NBIE, did not cause significant skeletal abnormalities [47]. Pretreatment baseline selective skeletal survey was recommended for all patients, with follow-up studies restricted to those with pretreatment lesions or who develop musculoskeletal symptoms. Long-term retinoid therapy in two siblings with NBIE, 21 years uninterrupted treatment in one and 20 years in the other, did not cause any obvious cardiovascular or skeletal toxicity [48]. Older children and adults must be (repeatedly) advised of the teratogenicity of retinoids and, where appropriate, contraceptive measures undertaken. The period of mandatory contraception is less with isotretinoin than with acitretin but it is less effective.

A small, open trial of 4 weeks' treatment with oral ciclosporin in congenital ichthyosis (three cases with NBIE and two with lamellar ichthyosis) showed no benefit [49]. Topical tacrolimus ointment 0.1% was associated with dramatic improvement in one case but increased absorption led to potentially toxic blood levels with daily application [50]. Evening primrose oil orally has been helpful in occasional cases.

Patients and families may benefit from contact with other affected people and patient support groups exist in several countries. Advice to carers and teachers, careers advice and ongoing support assists children and young adults in coping with the educational, occupational and social problems resulting from their chronic skin disease.

Lamellar ichthyosis (MIM 242300, 601277, 146750)

Of the two major autosomal recessive ichthyoses, lamellar ichthyosis (LI) is probably less common than NBIE, with an incidence of less than 1 in 300 000. It has a worldwide distribution. In its severe form it is easily recognized, but phenotypic heterogeneity exists and it may be confused with other ichthyoses. It is likely that the so-called 'alligator boy' reported by Fox in 1884 suffered from LI [1].

The term 'lamellar ichthyosis' (Latin *lamella*, plate) was, in the early 20th century, used for any congenital ichthyosis excluding harlequin fetus and, until the 1960s, it also referred to the collodion baby phenotype. In the European literature, the prefixes erythrodermic or non-erythrodermic LI correspond to NBIE and LI [2]. Evidence for clinical, histological and biochemical heterogeneity in autosomal recessive ichthyosis helped distinguish between NBIE and LI [3,4] and specific genetic mutations have been found in a proportion of LI patients. An autosomal dominant pattern of inheritance of LI has also been described [5].

Aetiology and pathogenesis. The salient histological features point to a disorder of cornification or terminal epidermal differentiation. Reduced skin barrier function was evident in studies of transepidermal water loss, and paralleled stratum corneum lipid defects [6]. Scale lipid analysis in severe LI showed a mild but significant rise in sphingolipids (ceramides) and free sterols, a pattern similar to that of normal palmoplantar skin [3].

Cornification involves the construction of the cornified envelope from intracellular protein precursors including loricrin and involucrin. These are cross-linked to lipid ceramides in the granular layer by the action of transglutaminase 1 (TGase1; see above). Defects in this pathway were first detected on immunohistochemistry and reported in 1993 [7]. There was increased expression of abnormally distributed loricrin and involucrin in keratinocyte cytoplasm, and diminished cytoplasmic TGase1 staining in three patients with autosomal recessive LI [7]. Several reports of transglutaminase 1 gene (*TGM1*) mutations followed [8–10] and *TGM1* mutations were found in 38 of 80 patients with NBIE/LI spectrum in a Swedish national survey of congenital ichthyosis [11]. Many had complete loss of TGase1 activity but a compound heterozygous *TGM1* mutation was associated with mild LI [12]. TGase1 deficiency correlates with certain ultrastructural features, but also corneocyte collapse seen on light microscopy of epidermal scales, and this cytology screen can be used to identify patients likely to have *TGM1* mutations [13]. Patients with CIE, but without *TGM1* mutations, may have increased expression of TGase1.

Some patients with LI experience partial resolution of scaling which clears from the face and limbs. This is called bathing suit

Fig. 19.8 Lamellar ichthyosis, severe (a) in a 10-year-old girl, before and (b) on retinoid therapy.

(a) (b)

ichthyosis and is due to temperature-sensitive TGase1, which was demonstrated to have reduced activity with a rise in temperature from 25° to 37°C [14,15]. Classical LI (designated type II) with palmoplantar keratoderma can also result from missense mutations in the *ABCA12* gene (which codes for a keratinocyte lipid transporter), the same gene implicated in Harlequin ichthyosis (HI) and occasional cases of NBIE [16]. Mutations in the ichthyin gene have been reported in NBIE but are also implicated in mild LI (designated type III) [17]. Mutations in a P450 gene have been reported in 12 Mediterranean families with mild LI who were not collodion babies [18].

Histopathology. Light microscopy of the skin in LI shows striking, compact ortho-hyperkeratosis with variable mild focal parakeratosis, and a stratum corneum thickness at least twice that of NBIE. The granular layer appears normal or increased, the lower epidermis is normal, and overall epidermal thickness is slightly increased. There may be mild papillomatosis, extension and blunting of rete ridges, and dilatation of dermal capillaries reminiscent of psoriasis.

Kinetic studies surprisingly revealed a near-normal transit time, in contrast to the hyperproliferative epidermis of NBIE and psoriasis, and LI is therefore classified as a retention ichthyosis [4].

Electron microscopy features in LI are variable. Niemi *et al.* reported prominent cholesterol clefts or crystals in the stratum corneum, lipid droplets in corneocytes and a thin or absent cornified envelope in nine Finnish patients with clinical features of LI [19]. These ultrastructural signs led to the subclassification of ichthyosis congenita type II and correlated closely with TGase1 deficiency. Other changes including abnormal membrane structures and vesicles within lamellar bodies were noted in patients with a reticulated form of LI, also called ichthyosis congenita type III [20].

Clinical features. At birth, most affected infants present as collodion babies, and after shedding the membrane, show a less intense erythroderma than infants with NBIE—an important and persistent distinguishing feature. Scaling occurs within the first month of life and may affect the whole skin surface, or localize to the scalp, abdomen and lower legs.

The scale in LI is typically large, dark brown or grey and firmly adherent (Figs 19.8 & 19.9). In severely affected individuals, the thick, rigid scale is intermittently shed or splits, causing erythematous patches and deep, painful fissures, especially around flexures and on the digits, palms and soles. Limitation of joint movement, flexion contractures and digital sclerodactyly may result. Additional features in severely affected patients are palmoplantar keratoderma, scarring alopecia, persistent ectropion, and congenital hypoplasia of aural and nasal cartilages. Erythema is mild in LI, pruritus rarely occurs, but sweating is severely impaired. The nails may be small but the hair shaft, teeth and mucous membranes are not affected. Growth is delayed in severe LI and both nutritional and vitamin D deficiency rickets have been reported in children [21,22]. Intellectual ability is normal, unless there have

(c)

Fig. 19.9 *Continued*

been serious perinatal complications. Extracutaneous manifestations have not been reported. Severe LI does not improve with age, and psychological problems resulting from the cosmetic effects, discomfort and limited mobility can lead to isolation, depression and poor school performance.

In mild LI (Fig. 19.10), the typical plate-like scale may only occur on the lower legs, upper arms, and rarely the forehead and trunk [12,20]. These patients usually have fine grey scales on the flexures and neck and mild erythema. They have focal hypohidrosis, hyperlinear palms and soles, and tend to improve in summer months. Cyclical shedding or peeling may occur.

Autosomal dominant lamellar ichthyosis (MIM 146750). Traupe outlined the clinical, ultrastructural and biochemical features of an ichthyosis that clinically resembled LI, but that showed an autosomal dominant transmission in four members, two male and two female, through three generations of a German family [23]. These patients had non-erythrodermic, lamellar-type, generalized scaling from birth, palmoplantar hyperkeratosis and lichenification of the dorsa of the hands and feet and major flexures. They did not have a collodion membrane at birth, and pruritus was a problem in one child. The light microscopy features were similar to those of classical LI. The electron microscopy findings in two of them differed from those of autosomal recessive LI, and included normal tonofilaments and keratohyaline granules, a prominent transforming zone at the granular–corneal junction and sparse corneocyte lipid inclusions.

Since then, reports of a similar disorder in separate families (French and Swedish) have appeared, although in these cases, a collodion baby phenotype and subsequent mild erythroderma were notable features [24,25]. Of the 32 collodion babies reviewed by Larregue [24], 10% were said to have developed autosomal dominant LI, but the disease phenotype is not clearly defined. Lipid analysis of plantar scale from two patients with autosomal

(c)

Fig. 19.10 Lamellar ichthyosis, (a) and (b) mild in a child, shown with his brother, and (c) an adult.

dominant LI revealed a different profile to that of classical LI [26].

Bathing suit ichthyosis. A rare variant of LI, which is characterized by scaling confined to the warmer areas of skin, has been reported [27]. It presents with collodion membrane and is due to TGase1 temperature sensitivity, resulting from an autosomal recessive, missense transglutaminase mutation (p.R315L) [14,15].

Diagnosis. Differential diagnosis of LI includes XLRI and ichthyosiform erythrodermas with collodion presentation. It is now accepted that there is considerable clinical and genetic heterogeneity in CIE, ranging from NBIE at one end to classical LI at the other, with intermediate 'mild' phenotypes which lack the erythroderma or lamellar scaling of the more typical forms. Ichthyosiform syndromes, such as Sjögren–Larsson syndrome and trichothiodystrophy, may be mistaken for LI but the associated neurological problems serve to distinguish them.

Light microscopy alone does not help to distinguish between the phenotypic variants of CIE and the disease spectrum includes many different ultrastructural patterns. The TGase1 deficient subtype is detected by electron microscopy (intercorneosomal, electron-lucent rod shaped vacuoles) and phase contrast light microscopy changes of scale scrapings. TGase1 deficiency can be confirmed on TGase1 immunoassay of cryostat sections of a skin biopsy [9,13]. Mutational analysis of the *TGM1* gene, to identify known or novel mutations, is performed on PCR-amplified and sequenced leucocyte DNA, from a blood sample.

Genetics. Genetic studies of families with severe LI revealed genetic linkage, compatible with recessive inheritance, to the region on chromosome 14q11 containing the transglutaminase 1 gene, *TGM1*. This was followed by the identification of several homozygous or compound heterozygote mutations in the *TGM1*, associated with reduced or absent transglutaminase activity [9–13,28]. A minority of patients with LI show partial resolution of scaling which clears from the face and limbs. This is called bathing suit ichthyosis and is due to a temperature-sensitive TGase1 [14,15]. There is biological heterogeneity; 13 of 23 families with a clinically similar phenotype had no evidence of linkage to the *TGM1* gene locus [29]. Linkage of classical LI to chromosome 2q33–35 revealed missense mutations in the *ABCA12* gene (also responsible for harlequin ichthyosis) [16], while other genes related to a mild LI phenotype include ichthyin on chromosome

5q33 [17] and a cytochrome P450 gene on chromosome 19p12–q12 [18]. There is close genotype–phenotype correlation in those families with linkage to these three sites. An autosomal dominant keratoderma with ichthyosiform erythroderma in a kindred reported by Camisa *et al.* [30] is a result of a loricrin mutation [31] (Vohwinkel's syndrome variant).

Classical LI is an autosomal recessive disorder, and the same principles apply in the counselling of families as outlined for NBIE. Because of the rare occurrence of autosomal dominant LI, examination of any relatives with skin disease is indicated, and in non-consanguineous families with an affected parent and child the possibility of dominant or pseudodominant transmission should be borne in mind.

Treatment. Mild LI can be controlled with regular emollients and keratolytics as outlined for the treatment of ichthyosis vulgaris. Topical calcipotriol has been efficacious in LI [21,32] and beneficial effects of a 10% urea lotion and topical *N*-acetylcysteine have been reported [33,34]. A trial of oral retinoid therapy is indicated in severe LI (Fig. 19.8). Of six patients with typical severe LI, five had a marked improvement, while the sixth had a moderate response with reduction of scaling, pruritus and skin tenderness [35]. The main side effects were cheilitis, epistaxis and hair loss in one. In three of these patients, low-dose therapy was effective. The management of systemic retinoid therapy is detailed in the section on the treatment of NBIE, p. 19.19. A topical receptor-selective retinoid, tazarotene 0.05% gel, has also produced good results [36].

Harlequin ichthyosis (MIM 242500)

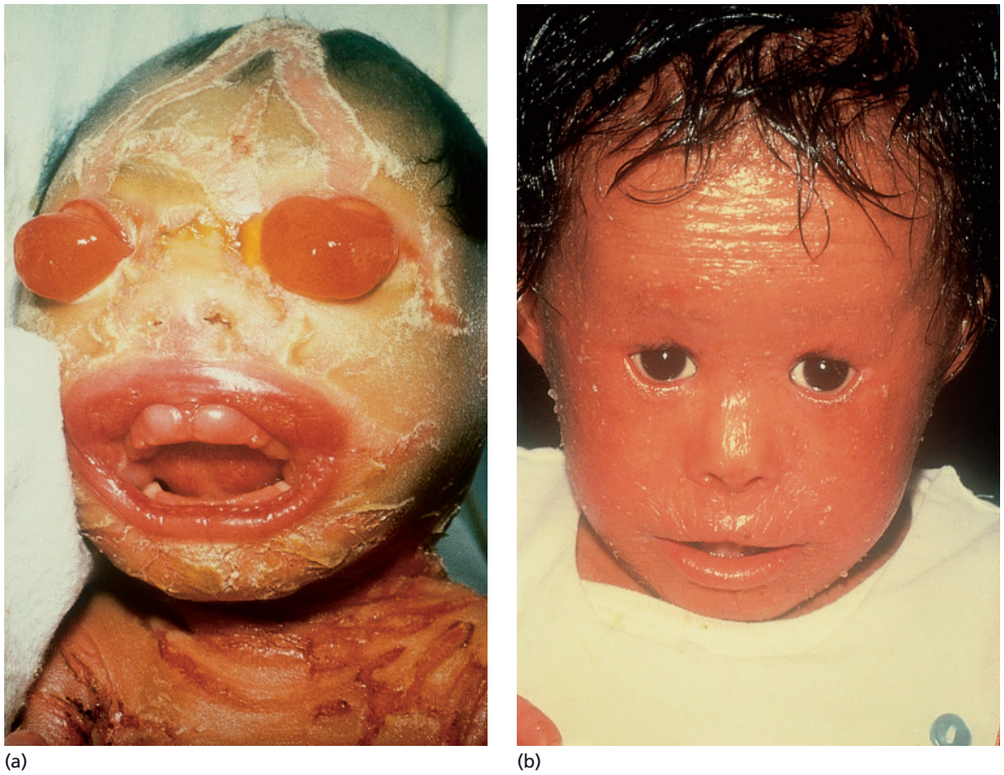
Harlequin ichthyosis (HI) describes a severe erythrodermic ichthyosis that causes a distinctive and alarming appearance at birth. The skin patterning and associated high mortality prompted the label of 'harlequin fetus' but, as survival is possible, the term HI is more appropriate. This was one of the first genodermatoses to be recorded. An affected baby, who survived for 2 days, was described by Oliver Hart, a Charleston pastor, in his diary of 1750, published in 1896 [1]. HI is presumed to be a very rare occurrence (estimated five cases in the UK annually) but, as there is no national genodermatoses register, this may be an underestimate. HI was

invariably associated with stillbirth or early neonatal death until Lawlor's report of a survivor in 1985 [2,3]. Several survivors have been reported since, with the majority eventuating in a severe erythrodermic ichthyosis [4–9]. Most cases are sporadic with autosomal recessive inheritance, but some kindred have had several affected children [2,8–10].

Aetiology and pathogenesis. Defects in keratin expression and epidermal lipid deposition were reported in the 1970s [11,12]. HI cultured keratinocytes show excessive cornification and failure of desquamation. A study of 10 HI cases revealed defective lamellar bodies and intercellular lipid lamellae in all, but variable keratin and filaggrin expression suggested genetic heterogeneity [13,14]. Three subtypes were identified based on keratin and profilaggrin staining; filaggrin was absent in all types [14]. In types 1 and 2 HI, abnormal expression of protein phosphatase 2Ac was found [15]. Reduced calpain 1, a calcium-dependent neutral protease, was also reported in HI epidermis but not in other epidermal disorders [16]. Calpain 1 plays an important role in epidermal differentiation, as a regulator of signal transduction and of profilaggrin, transglutaminase and cytoplasmic protease activity.

In 2003, missense mutations in the epidermal lipid transporter gene for ABCA12, were reported in several patients with lamellar ichthyosis [17]. Two separate research groups identified deletions of the *ABCA12* gene in several families with HI [18,19]. ABCA proteins bind ATP and actively transport lipids across cell membranes against a concentration gradient. ABCA12 is responsible for the formation of the lamellar granules/bodies which contain Golgi-body derived polar lipids, lipid-processing enzymes, proteases and their inhibitors. It is therefore pivotal in the development of epidermal barrier function (which is dependent on lamellar body-derived intercellular lipid lamellae) and desquamation. Akiyama's group further demonstrated localization of ABCA12 staining to lamellar granules in normal epidermis, abnormal lipid secretion in cultured HI keratinocytes and recovery of lamellar body function after corrective *ABCA12* gene transfer into cultured patient keratinocytes [19]. The *ABCA12* gene is large and encoded by 53 exons. Different *ABCA12* mutations have been reported in patients with HI, and a minority of those with NBIE and LI. The closely related ABCA3 protein is responsible for the production of alveolar surfactant and between them, ABCA3 and ABCA12 were essential in the evolutionary progression from aquatic to terrestrial life.

Histopathology. Skin biopsy shows marked, compact orthohyperkeratosis extending down into dilated hair follicles and pilosebaceous units. Parakeratosis is marked in type 3 HI and may occur in types 1 and 2 [13]. Usually, no other specific changes are noted on light microscopy, and the basal and spinous layers appear relatively normal. In some cases, vacuoles are seen in the stratum corneum and the granular layer is reduced in thickness. Rarely, papillomatosis and a dermal inflammatory infiltrate are present. Pilosebaceous and sweat glands are preserved and non-keratinizing mucous membranes are normal.



Electron microscopy of 10 cases, including one fetal skin biopsy, revealed multiple vacuoles, lipid droplets and cellular remnants in corneocytes in all cases [13]. Keratohyaline granules were abnormal in types 2 and 3. Lamellar bodies in spinous and granular layer cells are either absent or abnormal, and the intercellular lipid lamellae at the granular–corneal junction are absent or poorly formed [20]. Immunohistochemical staining of the cytoplasmic vesicles seen in granular layer cells suggested that they were abnormal lamellar granules. In fetal biopsies, large abnormal mitochondria in keratinocytes were noted at 16 weeks' gestation, prior to keratinization [21]. Adnexal keratin plugging at 18–20 weeks preceded interfollicular changes, and a thickened cornified envelope was also evident.

A skin biopsy from a 2-year-old survivor showed histological and ultrastructural features similar to those of severe NBIE with more pronounced lamellar body defects [10].

Clinical features. The affected infant, usually premature, sometimes stillborn, is encased in a rigid, taut, yellow-brown, adherent thick skin, a hyperkeratotic 'coat of armour', covering the whole body surface. Deep fissures occur prenatally over the scalp and soon after birth, the inflexible 'cast' splits at sites of stress, producing further red fissures and a skin pattern resembling a harlequin's costume. The head may appear microcephalic, and facial features are distorted because of severe ectropion, conjunctival oedema, which obscures the eyes, and eclabium (everted lips) (Fig. 19.11a and Fig. 19.12a). The scalp feels boggy, and the nose and external ears are tethered and appear rudimentary. Oedematous hands and feet may either be encased in hard mitten-like casts, or covered with a mucoid membrane, but the digits are well formed underneath. Additional congenital defects have been found in some cases.

Movement is restricted, and respiratory insufficiency results from limited chest expansion and sometimes coexistent skeletal deformity. Absence of effective sucking causes feeding difficulties which may lead to hypoglycaemia, dehydration and renal failure. Temperature instability and infection commonly supervene, and may lead to rapid demise. However, several survivors have been reported in recent years [2–10]. In these cases, intensive nursing and medical care prolonged survival until the plate-like scale was shed over several weeks (Fig. 19.12b,c). Early retinoid therapy was instituted in some cases and in all but one a severe ichthyosis resembling NBIE was the eventual outcome. One survivor was reported to be well grown and of normal intelligence and had discontinued retinoid therapy [4]. Another, now in her early twenties, has severe ichthyosiform erythroderma, short stature and mild limb contractures following osteomalacia but had attended mainstream school (Fig. 19.11b) (F. Lawlor, personal communication, 2007) [2,3]. Vitamin D deficiency leading to rickets is a high-risk complication [22].

Genetics and prenatal diagnosis. HI is an autosomal recessive disorder. The relatively uniform HI phenotype is now known to result from loss-of-function mutations in the *ABCA12* gene, which codes for a membrane-based lipid transporter protein responsible for the formation and function of the lamellar granules. One group, using homozygosity mapping, identified the *ABCA12* containing region of chromosome 2q35 and found large intragenic and frameshift mutations in 11 of 12 HI patients [18]. The 12th patient was later shown to have a heterozygous intragenic dele-

(a) (b)

Fig. 19.11 Harlequin ichthyosis: (a) neonate, (b) aged 18 months.

tion in exon 8 of the *ABCA12* gene [23]. A second group found five different compound heterozygous or homozygous *ABCA12* mutations, which caused truncation or deletion of the highly conserved regions of the ABCA12 protein [19]. In a further report of 14 HI patients, all had *ABCA12* mutations but in three only one affected allele could be identified [23]. Therefore affected families possess a range of different *ABCA12* mutations resulting in variable protein truncation, but within families disease expression is consistent. Certain mutations which affect functionally less critical *ABCA12* sites cause milder HI phenotypes. The mutation dataset suggests ethnic-specific founder mutations in the *ABCA12* gene [24]. The most common mutation in HI patients of Pakistani and Indian origin (occurring in 80% of this group) is 7322delC in exon 49 of *ABCA12* [23]. Homozygous mutations suggest parental consanguinity. Awareness of founder mutations will facilitate screening and prenatal diagnosis by targeting specific mutations known to occur more often in ethnic groups.

Detailed genetic counselling is required for affected families, and prenatal diagnostic testing should be offered in any future pregnancies. Previously, this depended on identifying premature keratinization at 20 plus weeks' gestation [25] or ultrastructural abnormalities from 18 weeks in fetal skin biopsy [26]. Amniocentesis at 17 weeks revealed intracellular lipid vesicles in shed keratinocytes [27] and ultrasound detection of amniotic fluid debris was noted [28]. The identification of a specific *ABCA12* mutation in an affected family opens the way to early DNA-based prenatal diagnosis on chorionic villus biopsy [19] or amniocytes, as in the case of a successful prenatal diagnosis of an affected fetus at 17 weeks' gestation [29]. Preimplantation genetic testing is also now possible [24].

HI has been reported in one non-identical twin [30] and in two twin pairs [10,31].

Differential diagnosis. The distinctive clinical features of HI are unlikely to be confused with the less severe presentation of the collodion baby, but some neonates have an intermediate phenotype, which has been termed 'chrysalis baby'. The multiple, different *ABCA12* mutations (and their occasional absence) help to consolidate genotype–phenotype correlation. The early neonatal appearance of HI may resemble that of restrictive dermopathy, but in the latter the tight, thick skin persists and skeletal and facial abnormalities are evident. A variant of infantile systemic hyalinosis and the 'stiff skin syndrome' (congenital fascial dystrophy) also present with tight skin. The Neu–Laxova syndrome has some similarities in its neonatal presentation [32] and Gaucher type 2 lysosomal disease may also present with a restrictive collodion membrane [33].

Treatment. Up to the 1980s, the outcome was uniformly bleak with death resulting in the first days or weeks of life. Since then there have been several long-term survivors, most with severe ichthyosiform erythroderma. The potential for survival of HI babies presents families and carers with the dilemma of providing intensive neonatal care while accepting the outcome of severe, lifelong ichthyosis. The family should be informed of the implications of the condition, encouraged to consider all options and

Fig. 19.12 Harlequin ichthyosis: (a) neonate, (b) aged 6 weeks, on retinoid therapy and (c) 6 months.

supported in the part they wish to play. Staff unfamiliar with the startling and distressing deformity also need to be enlightened about the features, evolution and practical problems associated with HI. If survival seems possible and intensive care is available, a care plan should be drawn up within the first day of life and support provided for staff in their difficult role. The facilities of a neonatal intensive care unit are required to cope with the predictable problems of hypothermia, feeding and respiratory difficulties, and dehydration, with possible electrolyte and renal complications and sepsis.

Regular (3–4 hourly) paraffin-based emollient, such as emulsifying ointment or 50/50 paraffin mix, and skin cleansing with antiseptic washing lotion are required from day 1 onwards. Nursing in a humidified incubator or on a heated cot help maintain body temperature. Early feeding problems (which improve with lessening of eclabium) can be overcome with nasogastric tube feeding but aspiration is a potential risk. A higher fluid requirement can be expected and needs are monitored by daily weighing and renal function assessment (though blood testing is challenging). The apparent benefit of early retinoid therapy is difficult to assess and not all survivors have received it [8]. Early introduction of acitretin probably accelerates shedding of hyperkeratotic plates within the first few weeks without influencing the eventual outcome (Figs 19.11 & 19.12). Whether or not to continue retinoid therapy depends on the severity of the ichthyosis, the degree of improvement in disability and the risk–benefit assessment. An oil-based liquid form of acitretin can be formulated and administered via a nasogastric tube. It should be stored in the dark and treated as a teratogenic agent. HI survivors are at risk of osteopenia, vitamin D deficiency and short stature, in addition to chronic ectropion (with possible exposure keratitis) and constrictive deformities of ears, hands and feet. Later, staged plastic surgery may improve the cosmetic burden. Some HI survivors follow a daily routine of vigorous exfoliation.

The demonstration that ABCA12 deficiency could be corrected by gene transfer in cultured keratinocytes offers the hope that corrective therapy (by administration of ABCA12-like peptides or *ABCA12* gene delivery pre- or postnatally) may eventually be possible [19].

Bullous ichthyosiform erythroderma (MIM 113800)

Bullous ichthyosiform erythroderma (BIE) is a rare autosomal dominant disorder of keratinization that, in its early phase, is associated with blistering. It was first described by Brocq in 1902 [1]. The incidence is thought to be approximately 1 in 100 000 births, although it is likely that some mild cases go unrecognized. The characteristic histological features of BIE, hyperkeratosis with lysis and tonofilament clumping in granular layer keratinocytes, are termed 'epidermolytic hyperkeratosis' and in some countries this term is also used to define the clinical picture. To date, all investigated cases of BIE have been shown to result from mutations in particular keratin genes, with good correlation of phenotype and genotype as skin lesions occur in sites where the affected keratin is expressed.

Aetiology and pathogenesis. The aggregation of tonofilaments in suprabasal keratinocytes in BIE is suggestive of an underlying genetic defect of keratin synthesis or degradation, involving keratins K1 and/or K10, as they are distributed only in the suprabasal compartment in normal epidermis [2]. Immunoelectron microscopy, using highly specific keratin monoclonal antibodies, showed selective involvement of K1/K10 in the aggregated tonofilaments suprabasally, while the non-aggregated filaments seen in basal cells consisted of K5 and K14 [3]. These data pointed to a primary genetic defect in K1 or K10. Increased filaggrin reactivity was also evident on immunohistochemistry and protein blotting, but was preceded by keratin filament aggregation, suggesting that the aggregation was independent of the action of profilaggrin. Affected fetuses have been shown to develop suprabasal tonofilament clumps at a stage of skin development where keratohyalin granules are not yet expressed, implying that filaggrin changes are secondary [4]. There are also alterations in the staining pattern and electron density of cornified envelope proteins, thought to be secondary to the keratin defects [5]. Loricrin staining was prematurely expressed and associated with keratin aggregates. Trichohyalin reactivity, not normally found in epidermis, was found in granular cells. However, the abnormal barrier function in epidermolytic hyperkeratosis has been attributed to defective lamellar body lipid secretion rather than problems in the corneocytes [6].

Genetic linkage studies confirmed autosomal dominant inheritance, and revealed linkage to either of the keratin gene clusters on chromosomes 12q and 17q [7–9]. Transgenic mice carrying mutant K10 developed skin abnormalities similar to BIE [10] and transgenic mice expressing a severely truncated K10 protein displayed a BIE-like phenotype in heterozygotes and a more severe phenotype in homozygotes [11]. Several groups have described heterozygous mutations in the highly conserved regions of K1 (47 different mutations) and K10, predominantly involving point mutations resulting in amino acid substitutions within the specialized sequences of the ends of the rod domains ([12–19], see also Human Intermediate Filament Mutation Database, http://www.interfil.org). These conserved regions are critical for filament integrity and assembly, and the mutations disrupt higher filament assembly in a dominant-negative fashion, leading to collapse of the network and filament aggregation around the nucleus. Most mutations occur within the conserved sequence motif at the beginning of the helical rod domain, with a particular arginine codon in K10 being most vulnerable, the 'hotspot arginine' [14,16]. Specific mutations involving different amino acid substitution within the 2B rod domain of K1 have been associated with the rare annular migratory variant of BIE [20].

Identification of the gene abnormality in a parent can permit prenatal diagnosis by direct gene sequencing from a chorionic villus sample earlier than by prenatal skin biopsy [16]. In a genetic study of 21 American families, the presence or absence of palmoplantar keratoderma (PPK) was used to subset the patients [21]. Of the six families with PPK, four had K1 mutations whereas eight of the 15 families without PPK had K10 mutations.

Histopathology. Skin biopsy shows marked epidermal acanthosis and hyperkeratosis. In the cells of the prominent and degenerate granular layer, and in the upper spinous layers, there are multiple perinuclear vacuoles and large clumped keratohyaline granules. Inter- and intracellular spaces form as a result of suprabasal cytolysis or cell rupture (epidermolysis), and a split with oedema in the granular layer marks the site of a blister (Fig. 19.13). These features together describe 'epidermolytic hyperkeratosis' (EHK). In mild forms of the disease, these changes may be subtle. The basal keratinoyctes are normal and there is a mild upper dermal lymphocytic infiltrate. The epidermis is hyperproliferative and the number of basal keratinocyte mitoses approaches that of psoriatic erythroderma [22].

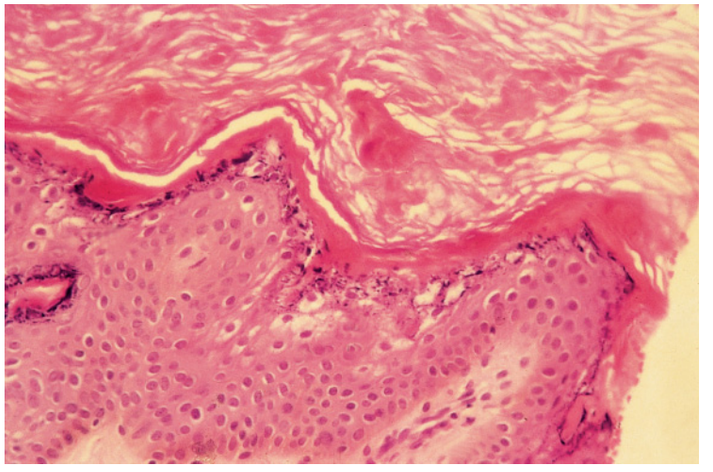

Fig. 19.13 Bullous ichthyosiform erythroderma; histological features of epidermolytic hyperkeratosis.

Electron microscopy reveals clumped keratin tonofilaments dispersed around the keratinocyte nucleus. Desmosomes are disrupted to a variable degree, and clefts between keratinocytes are associated with oedema and acantholysis. The ultrastructural tonofilament changes precede the vacuolation in spinous and granular cell layers [2,23]. There is no defect in the cornified envelope but intercellular lipid bilayers may be abnormal [6]. EHK is not unique to BIE but is seen in ichthyosis bullosa of Siemens, some cases of ichthyosis hystrix, Vorner's palmoplantar keratoderma, a subgroup of epidermal naevi, and as an incidental finding in a variety of unrelated lesions such as solitary acanthoma, dermatofibroma, melanocytic, actinic and inflammatory lesions, in the walls of epidermal cysts and even occasionally in normal oral mucosa [24,25].

Clinical features. BIE typically presents with fragile skin (epidermolysis), which gives way to progressive hyperkeratosis. A mild, generalized erythroderma is present at birth. Flaccid blisters, peeling and superficial erosions at sites of minor trauma or friction are apparent within the first few hours of life (Fig. 19.14). Frequent misdiagnoses at this stage include staphylococcal scalded skin syndrome and epidermolysis bullosa. However, the baby is generally apyrexic and stable, and focal hyperkeratosis may hint at the diagnosis. In the past, many of these infants developed severe infection, dehydration and malnutrition leading to a considerable mortality, but with intensive neonatal care their prognosis has greatly improved. The superficial erosions heal rapidly without

Fig. 19.14 Bullous ichthyosiform erythroderma, neonate.

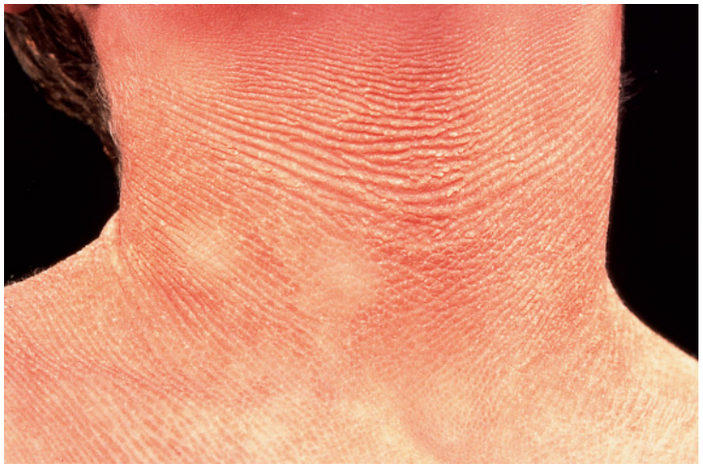

Fig. 19.15 Bullous ichthyosiform erythroderma, neck.

scarring, and easy blistering ceases in the first few months of life. Localized blistering at sites of trauma (the nappy/diaper area, thighs, knees) or infection continues through childhood. Erythroderma fades while the characteristic grey, waxy scale evolves.

Increasing hyperkeratosis is obvious from early childhood and is most prominent around the anterior neck, flexures, abdominal wall, infragluteal folds and scalp (Figs 19.15 & 19.16). Yellow–brown, waxy, ridged or corrugated scale builds up in skin creases, sometimes forming spiny (hystrix) outgrowths. Cobblestone-like keratoses occur at other sites such as the dorsal hands and feet, and over the trunk. Keratotic plaques may coat bony prominences, scalp and areolae, and chunks are easily dislodged, leaving tender erosions where scale slowly accumulates again. Skin colonization by *Staphylococcus*, brevibacterium and possibly yeasts produces a distinctive and embarrassing body odour. Repeated skin infections, causing blisters, pustules or cellulitis, especially in macerated flexural areas, are a troublesome complication in some children. The central face is mildly affected but scalp involvement can be severe and cause patchy alopecia. Spontaneous blistering virtually disappears by adolescence and only a mild erythema persists. Some mildly affected individuals have transient blistering in infancy with focal hyperkeratosis thereafter.

Palmoplantar hyperkeratosis develops in approximately 60% of patients with BIE and may result in recurrent painful fissures, contractures, sclerodactyly and foot deformity with impaired function. It does not relate to disease severity but is usually associated with keratin 1 mutations [21,26]. Nail dystrophy is rare, although curvature may result. Severely affected children may be of short stature, although many catch up in adolescence. Rickets due to vitamin D deficiency has been reported [27].

Evolution of BIE is variable, but in common with other autosomal dominant skin disorders it tends to improve with age. BIE sufferers may have significant physical and psychological morbidity. Visible scaling, skin fragility, keratoderma and odour can lead to social isolation and occupational problems. Mild learning difficulties in some patients may be related to perinatal complications.

Annular epidermolytic ichthyosis (MM 607602). This unusual variant of BIE, characterized by recurring, migrating, truncal annular and polycyclic plaques in association with more typical flexural lesions has been reported under a variety of titles (including annular epidermolytic hyperkeratosis and cyclic ichthyosis with epidermolytic hyperkeratosis) [28]. Histological features of EHK and keratin K10 or K1 mutations (including a 2B domain keratin 1mutation), similar to those of BIE, have been identified [20,28,29].

Naevoid BIE. There have been several reports of individuals with an asymmetrical linear, focal or naevoid lesion (including epidermal naevus with EHK, comedo and systematized naevi) showing histological features of EHK, who have had a child with generalized BIE [30–32]. The limited or naevoid disease expression in the parent (sometimes overlooked), distributed in Blaschko's lines, is suggestive of a post-conceptional somatic mutation of keratin K1 or K10. This produces phenotypic and, in some cases, gonadal mosaicism which in turn may lead to an affected child with generalized disease [31]. K10 gene mutations have been reported in lesional, but not normal skin or peripheral blood, of patients with naevoid BIE [33,34]. A keratin 1 mutation has recently been reported [35]. A palmoplantar epidermal naevus with EHK was found to be due to a keratin 16, V1 domain mutation [36].

Differential diagnosis. In the neonatal period, other blistering and exfoliative disorders such as epidermolysis bullosa, cutaneous mastocytosis, zinc deficiency, staphylococcal scalded skin syndrome, herpetic infection and incontinentia pigmenti must be excluded by clinical, histopathological and microbiological assessment. In older patients, ichthyosis hystrix, ichthyosis bullosa of Siemens and non-epidermolytic epidermal naevi may resemble BIE or its variants.

Genetics. At least half of cases of BIE have no family history of the disease and are presumed to have a new, spontaneous keratin 1 or 10 gene mutation. However, both parents of an affected child should be carefully examined for focal keratotic lesions suggestive of somatic and gonadal mosaicism (naevoid BIE, see above). In the

Fig. 19.16 Bullous ichthyosiform erythroderma: (a) arms, (b) legs and (c) palms.

absence of suspicious parental lesions, further siblings should not be at risk, but an affected parent will transmit the condition in an autosomal dominant fashion to their offspring, who will have generalized disease. The occurrence of inter- and intrafamilial variation in disease severity further complicates genetic assessment. A mildly affected parent may have a severely affected child, either because they have improved with age or because they have a mosaic expression. The reverse can also happen with an attenuated form of familial BIE appearing in the next generation, or variation in severity among affected offspring. It is postulated that a benign simultaneous polymorphism in keratin or keratin-associated protein genes has a modifying effect on the phenotypic expression of the disease in these families [15]. It is also evident that the same keratin 1 mutation has resulted in differing phenotypes/severity of lesions. A number of cases of autosomal recessive BIE, caused by *KRT10* mutations, have been reported [37].

Prenatal diagnosis, based on identification of the characteristic ultrastructural changes on fetal skin biopsy, has traditionally been performed at around 20 weeks' gestation, with ultrasound-guided fetoscopy [38]. Tonofilament clumping is the earliest

morphological abnormality, occurring during the second trimester, and precedes the formation of keratohyalin granules and stratum corneum [39]. First trimester prenatal diagnosis is based on DNA screening by direct gene sequencing to identify specific K1 and K10 gene mutations in chorionic villus samples (following informative direct gene sequencing of the index case) [16,40].

Treatment. Emollients are of limited value in BIE as the scale is often waxy and macerated. Keratolytic preparations (salicylic acid, α-hydroxy acid or propylene glycol compounds) reduce hyperkeratosis on exposed sites but their irritancy limits patients' tolerance. Patients are best placed to decide which, if any, they wish to use and their needs will change over time. Regular use of antiseptic washes and cleansing lotions may improve skin colonization and body odour and reduce the risk of bacterial and fungal infection. Systemic antibiotics are indicated for widespread cutaneous or soft tissue infections; regular sensitivity testing of *Staphylococcus aureus* isolates informs treatment. Long-term antibiotics are rarely justified. Topical calcipotriol produces a slight reduction in scaling at the cost of skin irritation [41]. Retinoid therapy is beneficial in some patients, but significant reduction in scaling is often associated with unacceptable skin fragility, blistering and tenderness [26,42] (for details of acitretin dosage and surveillance, see treatment of NBIE, p. 19.19). It has been noted that patients with K10 mutations (who usually do not have palmoplantar keratoderma) respond better to retinoid therapy than those with K1 defects [26]. UVB phototherapy has proved useful in a few adolescent and adult patients.

Ichthyosis bullosa of Siemens (MIM 146800)

A mild variant of BIE affecting a large Dutch kindred was described by Siemens, a Dutch dermatologist, in 1937 [1]. The concept was revived by Traupe who confirmed autosomal dominant inheritance [2] and the phenotype was described in detail in additional Dutch kindreds [3]. Ichthyosis bullosa of Siemens (IBS) is probably less common than BIE, but some milder cases may escape detection.

Aetiology and pathogenesis. In addition to keratins K1 and K10, suprabasal keratinocytes in the upper stratum spinosum and stratum granulosum express a further type II keratin, K2e (now K2), a protein of molecular weight 65.8 kDa encoded by a 2.6 kb mRNA species [4,5]. It is an accessory, unpaired keratin, expressed in skin (K2e) and hard palate (K2p), coded for by the *KRT2* gene which has nine exons and 7634 bp. As epidermolytic hyperkeratosis in IBS correlates with expression of K2e, it was recognized as a likely target gene [6]. Linkage analysis of two affected Dutch families showed linkage with the type II gene cluster on chromosome 12 [7]. Direct sequencing of PCR products of keratin K2e showed a point mutation in the highly conserved helix termination motif in a five-generation kindred and a sporadic UK case [8]. The same mutation was found in two unrelated Dutch families, including the descendants of Siemens' original kindred [9]. Up to 30 missense *KRT2* rod domain mutations have been reported in IBS patients, all except one in the helix initiation or termination motifs [10–15]. A common mutation, E487K (E493K in some reports) at codon 487 in exon 7 of *KRT2* is detected in a majority of IBS cases, including sporadic cases (Intermediate Filament Mutation Database, http://www.interfil.org), indicating a mutation hotspot [8–10,13,14]. This causes a G to A change in nucleotide 1477, leading to a substitution of a glutamic acid codon with a lysine, that is a protein sequence change of E to K. The exception is E178K, a glutamic acid to lysine substitution at codon 178 in exon 1 of the H1 domain of K2e [16].

Histopathology and pathogenesis. On histological examination, features of EHK are confined to the prominent granular layer and the upper spinous layer. Basal and lower spinous layer keratinocytes appear normal. Sites of 'mauserung' (moulting) reveal intracorneal blistering with orthohyperkeratosis above and below the split. Electron microscopy shows granular cell oedema with disrupted keratin filament network and clumped tonofilaments [2].

Clinical features. IBS is phenotypically milder than BIE and typically lacks erythroderma. The characteristic features are mild neonatal disease, or delayed onset in the first year of life, with episodes of superficial blistering persisting through childhood and sometimes into adult life. These occur predominantly on the flexures, shins and abdomen, and quickly rupture to produce annular peeling. There is variable, grey, rippled hyperkeratosis on the limbs, dorsal hands and lower trunk and buttocks, with flexural accentuation and mild hypertrichosis in some (Fig. 19.17). Circumscribed, patchy scaling occurs elsewhere, and focal desquamation or moulting of scale, which Siemens called 'mauserung', is seen at hyperkeratotic flexures and acral sites, especially the dorsal hands and feet (Fig. 19.17). Palmoplantar blistering, associated with hyperhidrosis, occurs in some patients and is more severe in summer, but PPK and skin odour are absent. Children with IBS are also prone to bacterial infection and sudden widespread erythema and peeling due to staphylococcal infection has been observed.

A similar ichthyosis, also caused by K2e mutations, has been reported under the title of ichthyosis exfoliativa [17,18]. This and IBS are now regarded as a single entity [7]. An autosomal recessive form of exfoliative ichthyosis (without epidermolytic hyperkeratosis) in an inbred Bedouin family has been documented [19].

Diagnosis. This condition may be mistaken for other autosomal dominant ichthyoses, ichthyosis vulgaris, the dominant variant of lamellar ichthyosis and mild BIE. In certain phases, epidermolysis bullosa simplex, peeling skin syndrome, infected atopic eczema or staphylococcal scalded skin syndrome may be suspected.

Molecular diagnosis can be performed using whole blood to sequence genomic DNA. Prenatal diagnosis is theoretically possible.

Treatment. Emollients and mild keratolytic preparations suffice in most, and often appear to induce an impressive remission. A beneficial effect from 12% lotion of ammonium lactate has been reported in IBS [20]. Avoidance of friction and measures to reduce hyperhidrosis are indicated. Appropriate antibiotics should be used to treat skin infection or episodic blistering. Some patients responded well to low-dose retinoid therapy [21].

Ichthyosis hystrix (MIM 146590)

The subgroup, ichthyosis hystrix (IH), encompasses a number of rare conditions, characterized by spiny hyperkeratotic scale similar to that of BIE. IH differs from BIE in that blistering does not occur, erythroderma is mild or absent and localized or naevoid forms are more common. In addition, IH has specific histological and ultrastructural features.

History and nomenclature. The first documented kindred with IH was the Lambert family of Suffolk, which between 1731 and 1851 had 11 affected members in four generations [1]. The first, Edward Lambert, attended the Royal Society of Medicine in 1731 and some of his affected descendants, known as the 'porcupine men', appeared in circuses as 'a new species of man'. A review in the 1950s showed that, contrary to reports, females were also affected and the ichthyosis was autosomal dominant [2]. Their skin, normal at birth, developed dark warty scaling after 7 weeks of age. There was no blistering, and the face, palms and soles were spared. The severity of the ichthyosis varied among family members and lessened in later generations.

Similar cases of ichthyosis were reported during the 19th century, and in 1954 Ollendorff-Curth and Macklin described two teenage brothers who had congenital verrucous scale on the scalp, neck and limbs, palmoplantar keratoderma and keratoses on the lips, ears, nipples and buttocks [3,4]. Skin histology showed acanthosis, hyperkeratosis and swollen hydropic granular layer keratinocytes. Affected relatives spanning five generations had a variable phenotype and it was regarded as an autosomal dominant condition.

Other variants include an isolated case reported by Bafverstedt with striking hystrix scaling on the face [5] and IH gravior of

Rheydt (two patients with ichthyosiform erythroderma, palmoplantar keratoderma and deafness) now known as HID (hystrix ichthyosis and deafness) syndrome [6,7]. HID syndrome is allelic with KID syndrome and caused by the same connexin 26 mutation [8]. Zeligman proposed that, on histological grounds, many cases of IH were variant BIE [9]. A single case of a biphasic ichthyosis (typical IH followed by centrifugal scaly lesions in middle age) was described [10]. IH shows considerable phenotypic heterogeneity [11].

Aetiology and pathogenesis. Features suggestive of abnormal keratin expression in spinous layer keratinocytes, from affected and unaffected skin, were reported [12]. However, other groups found normal epidermal keratin labelling and absence of linkage to the keratin gene clusters [13]. The ultrastructural features are suggestive of a disorganized keratin intermediate filament network [14] while epidermal proliferation rates are normal. In 2001, a novel keratin mutation affecting the carboxy-terminal of the non-helical variable tail domain (V2 domain) of keratin 1 was found in an African American family with severe mutilating palmoplantar keratoderma diagnosed as IH of Curth–Macklin (IHCM) [15]. They had a distinctive cytoskeletal abnormality (unlike that of BIE), with failure of intermediate filament bundling, retraction of the cytoskeleton from the nucleus and failure to translocate loricrin to the desmosomal plaques at the cell periphery. Interestingly, a British Caucasian family with an almost identical frame-shift mutation in K1 had a striate keratoderma of the palms and focal keratoderma of the soles, a phenotype much milder than and quite distinct from that seen in the IHCM [16]. Desmosomal structures were normal in IHCM but altered in striate palmoplantar keratoderma. This feature along with changes in other type II keratins and local mechanical factors may explain the phenotypic disparity [17]. A further, new heterozygous mutation in the V2 region of keratin 1 (in addition to a K1 polymorphism common in African Americans) in a familial IHCM case confirms the influence of changes in the tail domain of keratin molecules [18].

Histopathology. Light microscopy shows orthohyperkeratosis, patchy parakeratosis, acanthosis and papillomatosis. Scattered vacuolated and binucleate keratinocytes in the upper epidermis are characteristic. The granular layer is reduced and contains rounded and some vacuolated cells. Electron microscopic studies of Curth–Macklin type IH highlighted a characteristic thick, continuous perinuclear keratin tonofilament shell (in contrast to the clumped intermediate filaments in EHK) in the upper spinous and granular layers, resulting in three distinct cytoplasmic compartments [12,14,19,20]. That inside the tonofilament shell contained ribosomes, mitochondria and deformed lamellar bodies, while the band outside had normal tonofilament structure terminating on desmosomes. Conspicuous perinuclear vacuoles (some of which contained lipid material) were present in 30%, and double nuclei in 10% of spinous and granular keratinocytes. Similar changes were seen in clinically uninvolved skin, and persisted with retinoid therapy [20]. An unusual histological finding in eight affected members in one family was the presence of cornoid lamellae [21].

(a)

(b)

Fig. 19.18 Ichthyosis hystrix: (a) adult male; and (b) naevoid acral lesions in Blaschko's lines in a child.

Clinical features. Patients may present at birth with a generalized or naevoid, scaly, erythema without blistering or skin fragility. However, delayed onset in infancy or childhood has been noted. Symmetrical hystrix ('porcupine spine') scaling, of dull brown or grey colour, accumulates during childhood and affects extensor aspects of the limbs (Fig. 19.18a), truncal areas, to a variable degree, and flexures, but to a lesser extent than in BIE. Mild scaling may occur at other sites including the scalp. Palmoplantar keratoderma (PPK), diffuse or striate, affects most patients and may extend to the dorsal hands. Severe PPK leads to fissures, contractures, nail dystrophy and functional impairment. Scaling stabilizes or improves slightly in adulthood. Naevoid lesions follow

the lines of Blaschko (Fig. 19.18b) and are accentuated by sun-induced tanning of unaffected skin. There is little seasonal variation, and disturbance of sweating is rare.

IH of Rheydt was reported in two unrelated sporadic cases [6,7]. Generalized scaling, more pronounced on the face and limbs, developed from birth and was associated with profound deafness and palmoplantar keratoderma. This is now known as HID syndrome.

The development of multiple keratoses and squamous cell cutaneous carcinoma in two patients may have been linked to prior carcinogenic treatments, but a cancer proneness related to IH cannot be excluded [22,23].

Genetics. Where a positive family history is evident, IH has been inherited as an autosomal dominant trait [2,4,12]. There is considerable inter- and intrafamilial variation, and the occurrence of naevoid forms also complicates genetic counselling.

Treatment. Non-greasy emollients are used by some patients, while others prefer keratolytic preparations such as salicylic acid, propylene glycol or urea-containing compounds to reduce hystrix scaling and keratoderma [18]. Their use is not influenced by the fragility or malodour that occurs in patients with BIE. Topical calcipotriol or retinoid may be helpful. Systemic retinoid therapy, intermittent or continuous, is beneficial in some [18,20] but not in others [21] (for details of acitretin dosage and surveillance, see treatment section of NBIE, p. 19.19).

Netherton's syndrome (MIM 256500)

Netherton's syndrome (NS) is the most common of the multisystem ichthyosiform syndromes. It comprises an inflammatory, scaly dermatosis (primarily episodic peeling) with a variable erythroderma, hair shaft defects and atopic features. It is an autosomal recessive condition with a worldwide distribution, and an incidence similar to NBIE, in the order of 1 in 200 000. Diagnosis is often delayed and missed diagnosis, combined with previously high neonatal mortality, have contributed to an underestimate of its incidence.

Netherton's original patient, reported in 1958, was a young girl with a generalized, scaly, erythematous 'dermatitis', paroxysmal pruritus and a hair shaft defect, now known as trichorrhexis invaginata (TI) [1]. Later reports noted the association of TI with migratory double-edged scaly lesions termed ichthyosis linearis circumflexa (ILC) [2]. ILC had been described by Comel in 1949, but there was no comment on the patient's hair [3]. TI is a pathognomonic finding in NS, while the skin manifestations are variable and fluctuate.

Aetiology and pathogenesis. Although various mutations in the serine protease inhibitor Kazal type 5 (*SPINK5*) gene have been identified in NS patients [4–6], the pathogenetic mechanisms are not fully elucidated. Clinicopathological features suggest an intermittent disruption of epidermal and hair shaft maturation and keratinization. Electron microscopy shows premature lamellar body secretion and abnormal lipid processing in the intercellular space, which accounts for the severe impairment of the stratum corneum permeability barrier in NS [7]. This leads to an increase in epidermal DNA synthesis and turnover, further disrupting lipid metabolism. In the hair follicle, the TI lesion coincides with a bulge of external root sheath cells, which invaginate the hair shaft at the level of the keratogenous zone [8]. Failure to convert sulphydryl groups to disulphide bonds in the cortical cells of the hair at this level may contribute to the focal softening [9]. The intermittent nature of the hair shaft defect and the migratory skin lesions are, as yet, unexplained. Retinoid therapy induces deterioration in most patients with NS, and a parallel exists in a

transgenic mouse model with negative retinoic acid receptors, which develops erythroderma and poor skin barrier function. Impaired transcription of retinoic acid receptor genes in NS has been suggested [10].

Certain features of NS are reminiscent of atopic eczema and the skin permeability barrier is disrupted in both. Histological changes in NS include spongiosis and exocytosis as seen in atopic eczema, but immunohistochemical markers differed [11]. Raised total and specific IgE levels are characteristic of both [12,13]. Other immune function tests have usually shown only minor and inconsistent abnormalities. The *SPINK5* gene is located adjacent to a cytokine gene cluster and research efforts are also focusing on the genetic mechanisms of atopy and IgE responses [14].

The *SPINK5* gene is composed of 33 exons spanning over 61 kb on the distal long arm of chromosome 5q32 [4]. It encodes a serine protease inhibitor proprotein called LEKTI (lympho-epithelial Kazal-type inhibitor), which is thought to be necessary for epidermal cell growth and differentiation. LEKTI has 15 different protease inhibitory domains and each *SPINK5* mutation results in truncated LEKTI of different lengths, which correlate with the severity of the clinical features. *SPINK5* transcripts are expressed in the upper stratum spinosum, the stratum granulosum and in hair follicle and sebaceous gland epithelium. The peptides derived from LEKTI proteolysis exert an inhibitory effect, *in vitro*, on epidermal serine proteases, such as trypsin, chymotrypsin, plasmin, subtilisin, cathepsin, elastase, mast cell tryptase and kallikreins [4], which control corneocyte desquamation and help to maintain the epidermal permeability barrier [15]. Elevated epidermal trypsin-like proteolytic activity in NS is associated with reduced desmoglein 1 and desmocollin 1 cadherin activity and premature corneodesmosome degradation, which helps to explain the inflammation and barrier disruption [16]. In NS patients with severe erythroderma, the trypsin levels were higher than in those with a mild phenotype. Phenotypic variation may also relate to the activity of other protease inhibitors and variations in transglutaminase and related protein expression. Specific protease inhibitors may prove useful in the treatment of NS [17].

Histopathology. The histological features vary with the type and phase of the lesion sampled. Hyperkeratosis is mild in contrast to other ichthyoses, but parakeratosis and a reduced or absent granular layer occur at the spreading border of a lesion. Eosinophilic material may collect within the corneal and granular layers in ILC lesions. An intracorneal split at the site of degenerative parakeratotic corneocytes was noted by Comel [3] and others. Psoriasiform epidermal hyperplasia, papillomatosis and a mixed perivascular inflammatory infiltrate occur in older ILC lesions and in the more diffuse, scaly erythroderma. Acute erythroderma in NS is accompanied by pronounced inflammatory changes with spongiosis, exocytosis, intraepidermal microabscesses and upper epidermal eosinophilic necrolysis, which may lead to a subcorneal split. Features of a non-specific dermatitis may be reported.

Ultrastructural studies in NS have identified inclusion bodies (possibly lysosomes) containing finely granular material in suprabasal keratinocytes, reduced numbers of tonofilament–keratohyalin structures and desmosomes and abnormal lamellar bodies [7,10]. Intercellular lipid lamellae in the stratum corneum were disorganized and even absent in places. Lesions of ILC and erythroderma may show similar epidermal changes of retarded keratinization and eosinophilic granular material between and within cells [10].

Fig. 19.19 Trichorrhexis invaginata.

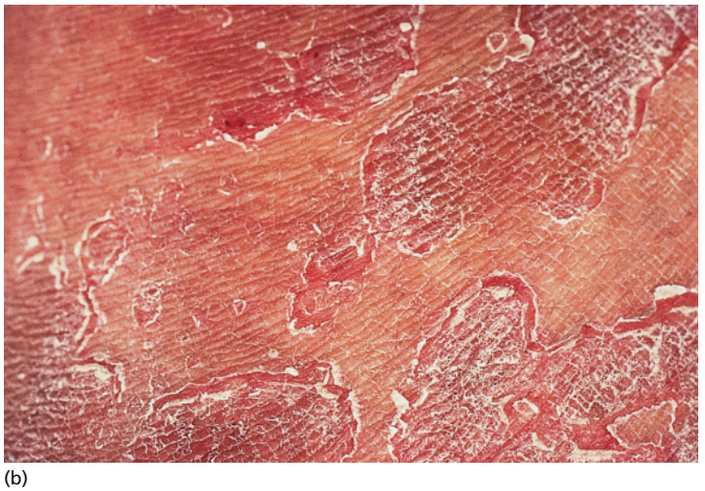
Microscopy of the scalp and eyebrow hair in NS shows, in a variable proportion of intact hairs, the 'bamboo' nodal dilatation consisting of a bulbous distal hair end invaginating a concave dilated proximal hair terminal (Fig. 19.19). The proportion of scalp hair affected varies from 5 to 50%, and the only clue to its presence may be ragged cupped proximal hair ends, where the fragile node has fractured, so-called 'golf tee hairs' [18]. Hair sampling may have to be repeated several times, and clipped hairs, especially eyebrows, may be the most informative. Pili torti and trichorrhexis nodosa also occur. Scalp biopsies have shown early nodal deformity occurring at the keratogenous zone within the hair follicle and variable perifollicular inflammatory changes [8–10].

Clinical features. Generalized (congenital) erythroderma of variable intensity is usually evident at or shortly after birth, and desquamation and scaling quickly develop (Fig. 19.20). In a French study of 51 patients with neonatal and infantile erythroderma, nine (18%) were eventually diagnosed as NS [19]. A minority of neonates is mildly affected. Collodion membrane is not a feature, and the infant is usually born at term with average birth weight. Common complications in the neonatal period and infancy, resulting from epidermal barrier disruption, are temperature instability, skin and systemic infection including fungal sepsis and hypernatraemic dehydration. Hypernatraemia in infancy is more common in NS than in other congenital erythrodermas and can lead to renal failure and neurological complications [20,21]. Severely affected infants often suffer from marked failure to thrive in the first year or so, and may have mild diarrhoea. This occurs even with dietary supplementation and, although malabsorption is a recognized though rare complication of other types of erythroderma ('dermopathic enteropathy'), it is more pronounced in NS. Jejunal villous atrophy was found in one of three NS infants who had biopsies (non-gluten sensitive and resolving spontaneously at 10 months old) [13] and in three of five patients in another report [22]. In fact, most of these infants begin to put on weight in their second year, although they generally remain below the 25th centile for height and weight. The defective barrier function of NS skin predisposes infants, in particular, to systemic toxicity from topically-applied

(a) (b)

Fig. 19.20 Netherton's syndrome, erythrodermic neonates with (a) severe failure to thrive and (b) sparse, spiky 'Mohican' hair; she required gastrostomy feeding for 8 years.

agents, including steroids and iodine-containing cleansers which caused hypothyroidism in one reported case [23]. The erythroderma tends to improve also, but can recur unpredictably. Infant mortality in NS was, in the past, significant and often attributed to 'Leiner's syndrome' or other congenital erythroderma. Complications in the first few months increase the risk of developmental and neurological problems.



During childhood, approximately half of NS patients develop lesions of ILC on the trunk and limbs, but they may still be at risk of acute erythroderma. A typical ILC lesion is an erythematous, exfoliating or scaly, annular or polycyclic, patch with an incomplete advancing double edge of peeling scale (Fig. 19.21). ILC is episodic, with migrating lesions, often in a cephalocaudal pattern, lasting several days. Lesions without the double-edged scaly margin are commonly seen. While many patients have recurrent ILC every few months, some have infrequent lesions. In severe NS, a fluctuating erythroderma persists, which may be triggered by intercurrent illness, and rarely pustular lesions are superimposed. Between acute attacks, the skin may look surprisingly normal. In a literature review of 43 cases, ILC was recorded in 30, while ichthyosiform erythroderma was predominant in 13 [12]. Many patients are distressed by prominent facial, particularly perioral, erythema and peeling. Palmoplantar peeling and mild keratoderma are noted in severely affected patients while peeling at the margins of the palms and soles is common. Pruritus or burning irritation may be troublesome, and also reminiscent of atopic eczema is flexural lichenification. Impaired sweating can lead to hyperpyrexia. Bacterial and yeast colonization of the skin and human papilloma virus (HPV) viral warts (in older patients) are common in NS. Chronic blepharitis and ectropion can cause a keratitis. Short stature is common in severe NS. Vitamin D deficiency may occur in any chronic erythrodermic condition. A rare, late complication is dilated cardiomyopathy [24].

A modest improvement with age is noted in most patients, but those with chronic erythroderma may develop persistent, painful flexural oedema, maceration and papillomatosis of the axillae, groin, vulva and lower legs [12,13]. This is a premalignant lesion with pseudoepitheliomatous histology; carcinoma of the vulva has been reported in a 63-year-old woman [25]. There are several reports of squamous cell skin cancer in adults with NS [26–30]. In one of these patients, multiple skin cancers (including basal cell carcinoma) occurred on photoexposed sites over 21 years of follow-up [28]. He had a history of widespread, chronic viral warts and oncogenic HPV types were isolated from skin lesions. The other patient, an outdoor worker, developed eight skin cancers, the first on the scalp at age 27. A 29-year-old female patient with two squamous carcinomas on the hand and arm, had a history of multiple infections throughout her life [29]. A 28-year-old female patient had plane warts on the face and arms (from which oncogenic HPV16 was isolated) and papillomatous groin tumours which yielded HPV 51 and 52 subtypes [31].

Hair defects. A pathognomic feature of NS is the hair shaft defect known as trichorrhexis invaginata (TI) or ball and socket defect (Fig. 19.19). TI is detected on light or scanning microscopy and may be picked up on dermatoscopy [32]. It is often missed in infancy, as scalp hair growth is sparse and attributed to erythroderma. In childhood, scalp, eyebrow, eyelash and body hair

(a)

(b)

Fig. 19.21 Ichthyosis linearis circumflexa: (a) in a 12-year-old boy; (b) a young girl. See also Fig. 19.20a.

remains sparse, slow growing, lustreless and brittle (due to fractures at trichorrhexis nodes). Scalp hair growth improves with age, but in many remains unruly or spiky, and some patients opt to wear a wig. A few older patients have clinically normal, but microscopically defective hair. Brittle hair produces a peppered appearance, especially on the limbs. Rarely, a nail dystrophy, ranging from thickening to pterygium, is seen.

Atopic features. Many patients with NS have a personal or family history of atopic asthma or hay fever. The pruritus, flexural accentuation, periods of remission and raised IgE are suggestive of atopic eczema; however, the skin lesions are not clinically eczematous, histological features are not consistent and they do not respond to appropriate eczema therapy. Recurrent urticaria and facial angioedema, triggered by certain foods, are common complications, although the incidence varies [12,13]. The most common food allergens are nuts and fish, and it can manifest in childhood or even in infancy.

Diagnosis. The diagnosis of NS was suspected prenatally in one case because of ultrasound detection of amniotic fluid debris [33]. The triad of congenital erythroderma, poor hair growth and failure to thrive in infancy, or the detection of ILC suggests the diagnosis. In milder cases without a family history, diagnosis is delayed until the specific hair shaft defect of TI is detected. Atopic features in childhood are associated with positive skin prick tests, eosinophilia and high specific serum IgE tests to common airborne and food allergens. Total IgE levels peak, often at very high values, in early childhood and then may fall towards the normal range [5,12,13]. Mild IgG subclass deficiencies have been noted. Lymphocyte subpopulations were normal, though evidence of T- or B-cell activation, altered cytokine profile and reduced natural killer cell numbers have been found in a few [13,34]. Impaired lymphocyte mitogen responses were reported in one case [26]. Transient aminoaciduria and neutrophil function defects were identified in one patient [12]. C1 esterase inhibitor levels were normal in eight patients studied, and complement C3 or C4 were raised in three of them [13]. Skin and hair microscopy are discussed above. Immunohistochemical stains for epidermal and hair root LEKTI antigen reveals absent LEKTI protein (and fragments) in severely affected patients and reduced positivity in those with a milder phenotype [35].

In infancy, the differential diagnoses include erythrodermic atopic or seborrhoeic eczema, staphylococcal or candidal infection, non-bullous ichthyosiform erythroderma (NBIE), psoriasis, hyper-IgE syndrome, immunodeficiency states, zinc or biotin deficiency, cystic fibrosis and protein metabolic disorders. In older children and adults, NBIE is the usual misdiagnosis, but atopic eczema, familial peeling skin syndrome, pemphigus foliaceus and erythrokeratoderma variabilis have been considered.

Genetics. NS is an autosomal recessive disorder with several reports of affected siblings and a proportion of patients coming from consanguineous families. There is significant phenotypic variation and clinical manifestations may also vary between siblings. Several *SPINK5* mutations have been identified in NS [4–6,15,16,35–37]. Close genotype–phenotype correlation has been reported by three groups [5,15,37] but not by another [6]. Komatsu's group used recombinant techniques to show that the length of residual LEKTI, which determines the number of active protease inhibitory domains, correlated with the severity of skin disease (including palmoplantar peeling), risk of skin infections and growth retardation (but not with atopic features, pruritus or hair defects) [37]. Growth retardation may, in part, be due to proteolytic destruction of growth hormone by the overactive proteases (*SPINK5* is expressed in the pituitary) [37].

Molecular diagnosis, using primers to sequence all coding exons and intronic regions of the *SPINK5* gene, is available for patient and heterozygote identification [6]. Homozygous frameshift and splicing *SPINK5* mutations were associated with more severe disease than downstream nonsense mutations which allow for longer LEKTI and more inhibitory domains, resulting in milder ILC-type lesions [5]. Prenatal diagnosis has been carried out by mutational analysis of *SPINK5* gene on a chorionic villus sample

in one case [5] and amniotic fluid in another [36], successfully predicting an unaffected fetus in both.

Treatment. In the neonatal period, intensive medical, nursing and nutritional care will be required to manage erythroderma and its complications and, specifically, to prevent hypernatraemic dehydration and failure to thrive. Frequent paraffin-based ointments, such as 50/50 white soft and liquid paraffin, provide a partial skin barrier, which reduces insensible water loss that contributes to hypernatraemia. Regular skin and eye swabs and stool culture will guide decisions on antimicrobial therapy; staphylococcal, Gram-negative and candidal isolates are common. Supplementary nasogastric tube feeding is often required and a gastrostomy is occasionally necessary. Topical steroids are ineffective, and should be avoided as the erythroderma and high surface area at this age quickly lead to systemic steroid toxicity.

The day-to-day treatment of older patients with NS is similar to that of other ichthyosiform erythrodermas. Regular emollients are helpful, and patients tend towards greasy paraffin-based products. Excessive use in one patient led to a granulomatous lymphadenopathy [38]. Ammonium lactate lotion 12% has been recommended [39]. Keratolytics, such as salicyclic and lactic acids, are poorly tolerated, but intermittent mild topical steroid therapy may help to lessen facial erythema and antifungal compounds improve intertrigo. Tar shampoos are useful in reducing scalp scaling. Topical or systemic antibiotics may be required for skin and respiratory infections. Antipruritics are only partially effective. Significant improvement in the cutaneous features was reported with both topical tacrolimus (0.1% and 0.03%) and pimecrolimus 1% [39,40]. However, blood levels of tacrolimus in patients treated with standard formulations showed that there was significant percutaneous absorption which could cause toxicity [41,42]. Even very dilute 0.005% tacrolimus gave raised blood levels, though below the toxic range [43]. Tachyphylaxis was noted at all concentrations and short-term treatment with topical immunomodulators was advocated. Pimecrolimus 1%, applied to 99% of the skin surface, did not produce detectable blood levels in one patient [41].

A notable feature of NS is the deterioration induced by systemic retinoid therapy (in standard doses), which is usually beneficial in other erythrodermic ichthyoses [9,12,13,28]. Retinoids are known to aggravate atopic eczema. Some patients with ILC do benefit from low-dose therapy [44]. Psoralen with ultraviolet A (PUVA) therapy has produced variable results [26,45]. UVA1 at medium doses was helpful in one adult patient [46] and balneophototherapy cleared ILC [47]. Methotrexate and ciclosporin A were ineffective [28,48]. Dermabrasion and subsequent excision of papillomatosis lesions on the lower leg, with split-skin grafting, was performed in an adult patient [13]. Grenz ray therapy has been used in the past, and laser ablation of hypertrophic areas has been suggested. A trial of topical protease inhibitors in NS patients was suggested in 2002 [15] but topical α_1-antitrypsin did not improve five treated patients [17].

Sjögren–Larsson syndrome (MIM 270200)

Sjögren–Larsson syndrome (SLS) is a rare autosomal recessive condition comprising a congenital ichthyotic hyperkeratosis, spastic diplegia and mild to moderate mental retardation. In addition, a characteristic retinopathy has been noted. Although this syndrome may have been described some years before, Sjögren and Larsson, Swedish psychiatrists, published a detailed monograph in 1957 of the syndrome that bears their name. They reported a clinical and epidemiological study of 28 institutionalized patients from 13 families, many of them consanguineous, in an area of north-west Sweden where there is a relatively high incidence [1]. Common ancestry for most of these was traced back to the 17th century, and a founder mutation introduced to the area in the 13th century has been proposed [2]. Over 200 cases worldwide have been reported, and it occurs in all races. The incidence in Sweden has been estimated at 1 in 100 000 rising to 1 in 10 000 in the northwest region of Vasterbotten [2]. In the UK, the estimated incidence of 1 in 300 000 may be an underestimate [3].

Aetiology and pathogenesis. A defect in essential fatty acid metabolism in plasma phospholipids, involving δ6-desaturase deficiency, was reported in the 1980s [4,5]. Rizzo's group demonstrated elevated plasma hexadecanol (C16) and octadecanol (C18) long-chain fatty alcohols, due to a deficiency of microsomal fatty alcohol:NAD oxidoreductase (FAO) in leukocytes and cultured skin fibroblasts [6,7]. The fatty aldehyde dehydrogenase component (FALDH) of FAO, a two-part enzyme, is predominantly affected. Reduced enzyme levels in the absence of clinical signs were found in obligate carriers [7,8]. FAO activity combines an alcohol dehydrogenase, converting fatty alcohols to fatty aldehydes, and microsomal FALDH, oxidizing medium- and long-chain fatty aldehydes to fatty acids. FALDH is also involved in the metabolism of leukotriene B_4. The histochemical demonstration of absent alcohol–hexanol dehydrogenase in the epidermis (Fig. 19.22) and jejunal mucosa in SLS, but not in other ichthyoses, provided further evidence of the importance of abnormal fatty

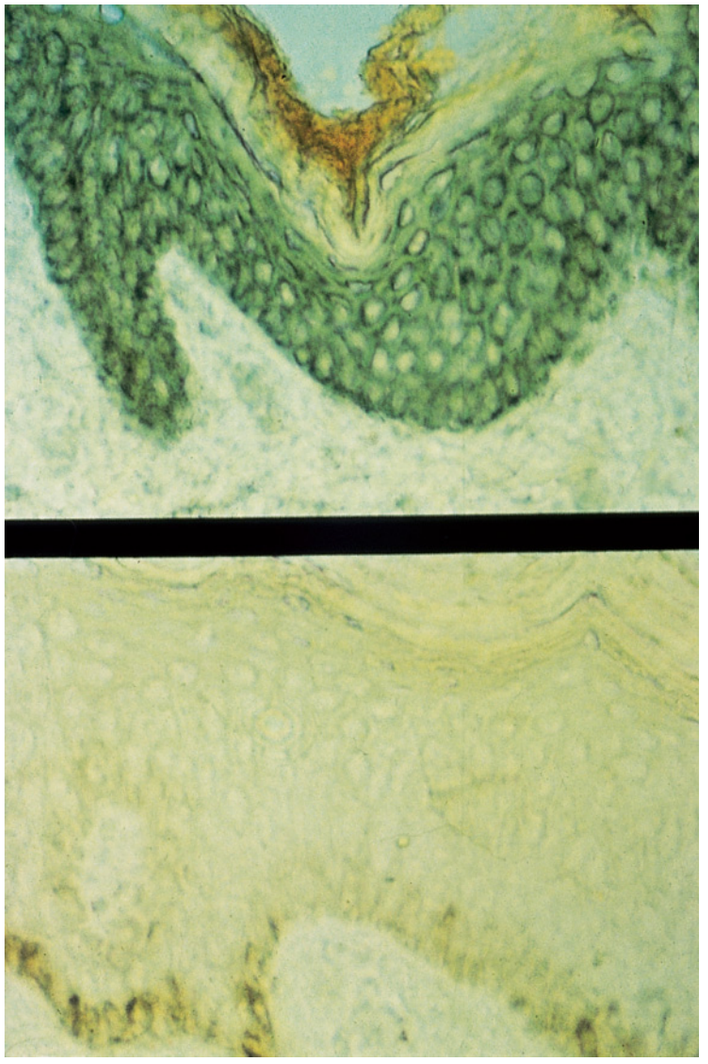

Fig. 19.22 Sjögren–Larsson syndrome, negative staining for alcohol dehydrogenase in skin, lower panel. (Courtesy of Dr B. Lake, Institute of Child Health, London, UK.)

(a) (b) (c)

Fig. 19.23 (a), (b) and (c). Sjögren–Larsson syndrome: a 3-year-old girl with spastic diplegia.

alcohol metabolism in SLS [8]. Skin changes in SLS (abnormal barrier function and inflammation) are due to disturbed epidermal lipid metabolism and overexpression of leukotriene B_4 in fibroblasts and keratinocytes [9,10]. The neurological defects result from abnormal lipid development in myelin, specifically in the glycerol ether pathway, a side arm of the fatty alcohol cycle, in sphingolipids and plasmalogens [11].

The 31-kb FALDH gene (*ALDH3A2*) is located on chromosome 17p11.2, close to the neurofibromatosis-1 gene [12]. Several different mutations have been reported [11–14]. FALDH is a 485 amino acid membrane-bound protein with a hydrophobic carboxy-terminus, which is necessary for microsomal membrane anchoring.

Histopathology. Skin sections show orthohyperkeratosis, acanthosis and papillomatosis. The granular cell layer is normal or increased, and there may be mild upper dermal inflammatory change. Kinetic studies in one patient indicated a hyperproliferative epidermis [15]. Ultrastructurally, atypical membranous structures have been reported in spinous and granular layer cells, associated with numerous, large lamellar bodies some of which were irregular or disc-shaped. A proportion contained granular material in addition to lipid lamellae [16]. Membranous inclusions persisted into the corneal layer and the intercellular spaces were widened. Increased numbers of mitochondria were present in the basal epidermal cells.

Clinical features. Preterm birth is common and has been attributed to abnormal leukotriene B_4 inactivation [9]. Collodion baby presentation has been reported [17,18], but usually the skin is dry and mildly erythematous at birth, and scaling develops within the first 3 months of life. Thereafter, a mild erythroderma persists and a variable degree of scaling evolves, consisting of diffuse peeling on the trunk and more pigmented, lamellar-type ichthyosis on the lower limbs. Scaling tends to follow a cyclical pattern of accumulation and shedding, and predominantly affects the limbs and face (Fig. 19.23). A velvety orange or brown lichenification, often with verrucous hyperkeratosis, is most obvious in and around the flexures, neck and mid-abdomen (Fig. 19.23b). This characteristic feature may even be noted during the first year of life, and is helpful in diagnosis. Lichenification slowly progresses and is embarrassing to older children, in whom it may also restrict the mobility of already hypertonic limbs. Severe and persistent pruritus is a notable feature of SLS; scratch marks and dermographism are often seen on the trunk but skin infections are rare.

Neuro-ocular features. Variable neurological dysfunction is obvious in early infancy, with delayed motor milestones and evolution of upper motor neurone signs (a non-progressive, spastic paraparesis) in the legs and rarely the arms also [13,19]. With early physiotherapy, most patients learn to walk unaided or with crutches in childhood. Increased muscle tone leads to altered posture and movement which predispose to contractures (ankles, knees, hips), kyphoscoliosis, dislocated hips and short stature. Development of speech is delayed and seizures are a rare complication. Mild to moderate learning disability is the rule and all 17 patients in a Dutch study attended special schools [19]. However, there is phenotypic variation among families [13,20] and even between affected siblings [21]. They are notable for their cheerful, friendly disposition. Although many SLS patients were institutionalized in the past, most can achieve a degree of independence if appropriate education, training, physiotherapy and rehabilitation are available to them. The neurological features are non-progressive but contractures due to spasticity may adversely affect gait and mobility in older children. Patchy leukodystrophy and myelination defects have been reported on CT and MR scanning and in post-mortem studies in SLS [13,22].

Ocular signs were reported in 1980, and consist of glistening dots on the fovea and parafovea of the retina, which develop during childhood [23]. They are detected in up to 80% of patients and may fade with advancing age. They may be caused by deposition of lipofuscin pigment granules in the specialized retinal epithelium [24] and can be detected subclinically by optical tomography [25]. Visual acuity is normal or mildly impaired but some patients are photophobic.

Diagnosis. The cutaneous and retinal features are characteristic and quite unlike those of other ichthyosiform syndromes. Biochemical assay of cultured fibroblasts from a skin biopsy or of leukocytes to identify reduced FAO activity, in particular FALDH, confirms the diagnosis. Histochemical analysis of hexanol dehydrogenase in skin is also diagnostic. Assays of plasma C16 and C18 fatty alcohols and urinary leukotriene B_4 metabolites have been used as screening tests and to assess the effect of dietary interventions. Mutational analysis of *ALDH3A2* provides genetic confirmation of SLS, identification of carrier status and the opportunity to do prenatal diagnosis.

The main differential diagnoses are congenital ichthyosiform erythrodermas with neurological signs and neurocutaneous disorders such as neutral lipid storage disease, multiple sulphatase deficiency, hystrix-like ichthyosis and deafness (HID) syndrome. A neuroichthyotic condition resembling SLS but with absent laboratory markers was described in one patient [26].

Genetics. Although rare outside northern Sweden, SLS is a severe autosomal recessive disorder and fully penetrant [2]. Many families seek prenatal diagnosis in subsequent pregnancies, and relations of affected consanguineous families may also request an assessment of their risk. Although FAO is reduced in most obligate carriers, this assay does not allow accurate identification of carrier status. In contrast, the fibroblast FALDH component of FAO was significantly reduced in 10 of 11 heterozygotes [27], and combination of the two enzyme assays was deemed useful in carrier detection. Prenatal diagnosis by fetal skin biopsy was successful in detecting premature keratinization at 20–22 weeks [28]. Accurate first and early second trimester diagnosis based on FALDH and FAO deficiency in cultured chorionic villus cells and amniocytes has been reported [29,30].

SLS is caused by mutations in *ALDH3A2* which catalyses the oxidation of fatty aldehydes to fatty acids. More than 70 different mutations, including amino acid substitutions, deletions (25%), insertions, splicing errors and point missense mutations (38%) have been reported [11–14]. Many of these are unique to individual families but common mutations, as in north-west Sweden, reflect a founder effect and high levels of consanguinity. Successful prenatal diagnosis using PCR-based mutational analysis of the *ALDH3A2* gene confirmed homozygous mutation in the affected fetus [31].

Treatment. The abnormal fatty acid profile in plasma phospholipids in three SLS patients prompted treatment with a 6-month course of essential fatty acid supplements, but there was minimal improvement in the skin or neurologic features [5]. A report of beneficial effects of a diet rich in medium-chain triglycerides on the skin manifestations in SLS [32] has been followed by further small trials with mixed results. Reduction of total fatty intake (to 30% of total calorie intake) with essential fatty acid supplements resulted in significant improvement in the skin and neurological features (and in plasma fatty alcohol levels) in two infants after some months but was less effective in older children [18,33]. This approach failed in another study [34].

Regular emollient and keratolytic therapy may help but does not alleviate the pruritus. Topical calcipotriol ointment for 3 months in two patients produced improvement [35]. Retinoid (etretinate, acitretin) therapy has proven effective in relieving scaling and disabling lichenification in several patients [18,36]. Retinoids are less successful in controlling itching and tolerance may develop after some months; intermittent therapy may be a preferred option. Intensive physiotherapy and skills learning in early childhood clearly improve motor and social development in SLS, and orthopaedic treatment of skeletal deformities of the legs is beneficial in some cases [37]. The discovery of a role for leukotrienes in SLS led to a 3-month trial of a 5-lipoxygenase inhibitor, zileuton, in five patients [9,38,39]. There was a reduction in pruritus and improved well-being associated with a reduced urinary leukotriene B_4 excretion but no change in neuropsychological performance [39]. A single report of reduced pruritus with montelukast therapy, also a leukotriene antagonist, is encouraging [40]. Bezafibrate, a lipid lowering agent, was shown to induce FALDH levels in fibroblasts from SLS patients with some residual enzyme activity and milder phenotype but clinical studies have not been reported [41].

New therapies using viral vectors to restore FALDH activity or to correct the genetic defect are being developed in the laboratory [11,42].

Refsum's disease (MIM 266500)

Refsum's disease (RD) is a very rare autosomal recessive neurocutaneous disorder, caused by defective fatty acid metabolism. Sigvald Refsum, a Norwegian neurologist, first defined it as a clinical entity in 1946, in a monograph titled *Heredopathia atactica polyneuritiformis* [1]. Clinical manifestations, primarily neuropathy, ataxia, deteriorating vision and hearing and a mild ichthyosis, develop insidiously in early adult life.

Aetiology and pathogenesis. In the early 1960s, accumulation of a storage product identified as a branched-chain 20-carbon fatty acid in plasma and tissues of patients with RD was reported [2]. Some years later, impaired oxidation of phytanic acid, a long-chain, 20-carbon branched fatty acid (3,7,11,15-tetramethylhexadecanoic acid), in cultured skin fibroblasts, was demonstrated in 11 patients with RD [3]. Asymptomatic heterozygote carriers possessed 50% phytanic acid oxidase levels, pointing to autosomal recessive inheritance.

Phytanic acid is derived from plant chlorophyll and, to a lesser extent, animal sources (phytol) in the diet, and cannot be synthesized by human tissues. In health, it is barely detected in serum (1 mg/100 mL or <30 μMol/L) but in RD it accounts for 5–30% of serum lipids, and levels rise to over 60 mg/100 mL or >200 μMol/L. In lipid-rich tissues and body fluids, it replaces other fatty acids and binds to sterols, thus interfering with membrane structure and function. Storage of phytanic acid results in lipid vacuoles in the basal epidermis. Phytanic acid is a unique branched fatty acid

(it has a methyl group at the 3 carbon position) whose breakdown requires α-oxidation by phytanoyl-CoA hydroxylase, a peroxisomal enzyme, which removes a carbon to produce pristanic acid [4]. Phytanoyl-CoA hydroxylase function depends on accessing the peroxisome via the PTS2 (peroxisome-targeting signal type 2) receptor, encoded by the *PEX7* gene [5]. The genes for both the enzyme and receptor have been cloned and their products localized to peroxisomes [6]. Mutations in the phytanoyl-CoA hydroxylase gene (*PAHX or PHYH* located on chromosome 10p13), are responsible for 90% of cases of RD while the remainder are deficient in the PTS2 receptor, encoded by *PEX7*.

Histopathology. Light microscopy changes are similar to those of ichthyosis vulgaris (acanthosis and hyperkeratosis) but with hypergranulosis. An important feature is the presence of lipid droplets in the basal and suprabasal layers of the epidermis (also seen in neutral lipid storage disease). Their significance may only be appreciated with special lipid stains. Kinetic studies in one patient with advanced disease showed a hyperproliferative pattern [7]. Electron microscopy reveals non-membrane bound vacuoles and enlarged, distorted mitochondria [8].

Clinical features. Age of onset of symptoms ranges from infancy to over 50 years. Due to the insidious and variable development of clinical symptoms, diagnosis is often delayed until late childhood or early adult life [9,10]. Progressive retinitis pigmentosa initially causes night blindness and, later, failing vision and constricted visual fields; cataracts may also develop. Electroretinography reveals reduced rod and cone response in subclinical cases. Neurological features develop in adolescence or the early twenties, and progress slowly over a period of months or years. Anosmia occurs in the majority in the early stages and impaired taste may be noted [11]. Sensorineural deafness with tinnitus develops in more than 50%. A mixed sensorimotor polyneuropathy (type IV) with hypertrophied peripheral nerves and an elevated cerebrospinal fluid (CSF) protein are characteristic findings. Progressive weakness, foot drop and loss of balance due to cerebellar ataxia cause increasing disability. In the early stages, the neurological symptoms and signs of RD may fluctuate, and patients may be labelled as clumsy and neurotic. Delayed diagnosis may result in severe neurological impairment, wasting and depression, and a high mortality has occurred in the past. Some patients develop a cardiomyopathy with serious conduction defects [12]. Skeletal defects have been noted in 35%, usually shortening of the fourth metacarpals and metatarsals.

Ichthyosis occurs in 25% of RD patients and either coincides with or postdates the onset of neurological signs. It resembles ichthyosis vulgaris with a fine white scaling, most noticeable over the lower trunk but also affecting the limbs. In late untreated cases, lamellar scaling develops.

Variability in the clinical features between family members reflects different dietary phytanic acid content. Accelerated or acute RD may develop secondary to sudden weight loss and fasting which mobilize stored fatty acids. Hypokalaemia is reported in acute RD [13].

Infantile Refsum's disease (MIM 260510). This is an autosomal recessive peroxisomal disorder with several enzyme abnormalities including phytanic acid oxidase deficiency. It manifests in early infancy with neurodegenerative disease and signs similar to those seen in adult RD, but ichthyosis is an unusual feature.

Genetics. Diagnosis of a new case of RD should prompt family screening for presymptomatic cases [14]. Heterozygote carriers may have marginally elevated phytanic acid levels and intermediate values for phytanic acid oxidase but biochemical testing is unreliable. Prenatal testing can be performed on cultured amniocytes, obtained by amniocentesis at 15–18 weeks' gestation, to assay phytanic acid oxidase activity. Molecular DNA-based diagnosis may be carried out on amniocytes or a chorionic villus sample taken at 10–12 weeks, but the possibility of early diagnosis and effective dietary therapy may reduce the demand for this approach [15]. It has been suggested that all families with retinitis pigmentosa should be screened for RD [14].

Treatment. Exclusion of sources of chlorophyll in the diet is mandatory in the treatment of RD. The major dietary exclusions are green vegetables (phytanic acid) and animal fat (phytol), and the aim of dietary treatment is to reduce daily intake from the usual level of 50 mg/day to less than 5 mg/day [16]. Rapid weight loss should be avoided, as it mobilizes tissue phytanic acid, which can lead to acute clinical manifestations [13,17]. A high carbohydrate intake ensures adequate calories and, when instituted in the early stages of the disease, blood levels of phytanic acid fall rapidly, followed by clearance of the ichthyosis and, to a variable extent, reversal of recent neurological signs. Retention of vision and hearing is less certain but has been reported [18]. Lifelong strict adherence to the diet is necessary, and recurrence of scaling is an obvious marker of rising phytanic acid levels. Plasmapheresis has been used to reduce phytanic acid levels rapidly in acutely ill patients at diagnosis and as a maintenance therapy once or twice monthly when diet alone is insufficient [17,19–21]. Lipapheresis or cascade filtration which saves albumin and IgG has also been reported in the treatment of RD [22].

IBIDS/PIBIDS syndrome (MIM 601675)

Synonyms
- Tay's syndrome
- Trichothiodystrophy E, F, A

This rare and heterogeneous genodermatosis belongs to a group of disorders that has in common a hair defect termed trichothiodystrophy (TTD) or sulphur-deficient, brittle hair. The trichothiodystrophies are classified into subtypes A–H, three of which (IBIDS, PIBIDS, TTD-A) feature skin lesions. They are grouped within the ectodermal dysplasias. The acronym (P)IBIDS describes *p*hotosensitivity, *i*chthyosis, *b*rittle hair, *i*mpaired intelligence, *d*ecreased fertility and short *s*tature. In 1968, a sibling pair with brittle hair, intellectual impairment, short stature and trichorrhexis nodosa was reported [1]. Reduction of sulphur-containing amino acids in the hair (Greek *thio*, sulphur) was a central feature of the disorder [1,2]. In 1971, Tay reported three Chinese siblings (of consanguineous parents) who also had a generalized ichthyosiform erythroderma and progeric facies [3]. Decreased fertility (in an affected Amish kindred) was added to the list of features of the syndrome [4]. Other rare genetic disorders such as the Marinesco–Sjögren syndrome are variants (BIDS), and misreporting of IBIDS cases has occurred [5]. Photosensitivity was added to the clinical spectrum in 1980 [6] and the acronyms coined soon after [7,8]. IBIDS (TTD type E) and PIBIDS (TTD type F) are autosomal recessive syndromes and occur worldwide. A review of the DNA-repair diagnostic testing services in Western Europe revealed an incidence of 1.2 per million for native and immigrant populations [9]. UV-induced DNA repair defects have been demonstrated in subgroups of patients and several different mutations described [10].

Aetiology and pathogenesis. Reduced levels (approximately 50% of normal) of hair sulphur and sulphur-containing amino acids, cysteine, methionine and proline, are the hallmark of trichothiodystrophy syndromes but circulating amino acid levels are normal. The cornified envelope of stratum corneum cells is cysteine-rich, and sulphur-rich amino acids form hair-specific matrix proteins that cross-link keratin fibres in the hair shaft. The specific reduction in cysteine-rich matrix proteins in the hair indicates a defect in terminal keratinocyte differentiation and this also contributes to the nail dystrophy and ichthyosis.

UV-induced DNA damage is normally corrected by nucleotide excision repair (NER). NER assays on cultured fibroblasts from patients with typical IBIDS revealed three patterns: one with a normal UV response (for which no gene mutation has been identified); one showing a xeroderma pigmentosum (XP) complementation group D response pattern; and a third with reduced clearance of 6–4 photoproducts, reduced DNA repair synthesis and normal cell survival [11,12]. Fibroblasts and lymphocytes from IBIDS patients without and with photosensitivity (PIBIDS) revealed markedly reduced levels of duplicative and unscheduled DNA synthesis on UV exposure [10,13–15]. The response pattern of transcription-coupled repair defects was similar to that seen in XP group D and some cases of Cockayne's syndrome (a neurodevelopmental disorder) [16]. In contrast to classical XP (with more critical mutations), PIBIDS and XP group D patients rarely develop skin malignancies. The DNA repair helicase gene *ERCC2/XPD*, located on chromosome 19q13.2–13.3, corrected the photosensitivity of both (P)IBIDS (the transcriptional function) and XP group D (the repair role of *ERCC2*) and different mutations within *ERCC2*, specific to each disorder (PIBIDS, XPD and Cockayne syndrome) were identified [15,16]. The causative mutations in PIBIDS patients are found in DNA/RNA helicase at the C-terminus while in XPD patients they occur in a highly conserved domain [10]. *XPD* mutations account for 95% of PIBIDS. Mutations in *ERCC3/XPB* helicase (chromosome 2q21) were found in a small number of PIBIDS cases [17]. The *ERCC2* and *ERCC3* gene products are subunits of the DNA repair and RNA transcription superfactor known as TFIIH. A third, rare subgroup of PIBIDS known as TTD-A [18] has been attributed to mutations in a newly recognized subunit of the TFIIH complex [19]. This helps to explain the DNA repair defect, which complemented all XP types, noted in a TTD-A patient who developed photosensitivity [7,18]. Mutations in TFIIH or other transcription factors which affect basal transcription function rather than repair function may explain the absence of photosensitivity in IBIDS patients [20]. DNA repair-deficient transgenic and knock-out mouse models have been produced, including one that mimics PIBIDS [21]. Correction of the DNA repair defect *in vitro* using recombinant adenovirus transfection of wild type *XPD* has been reported [22].

The growth defects, brittle hair and nails and neurological abnormalities of IBIDS/PIBIDS are not related to NER defects, and

may be caused by defective gene transcription of RNA and cellular proteins due to altered function of TFIIH [10,16]. The differences in the incidence of UV-related cancers between IBIDS/PIBIDS and XPD (low risk) and classical XP (high risk) are thought to be due to additional defects in XP, including UV-induced apoptosis, catalase activity and natural killer cell function [16,20,23].

Histopathology. In most cases, skin biopsy has shown changes similar to those of ichthyosiform erythroderma, with hyperkeratosis, focal parakeratosis, acanthosis and a normal or reduced granular layer. Ultrastructural features include perinuclear vacuoles and abnormal tonofilaments. Hair microscopy shows wavy hair shafts with pili torti, trichorrhexis nodosa, trichoschisis (clean transverse fractures) and distal 'brush breaks'. Polarizing light reveals characteristic alternating zig-zag light and dark bands, which give rise to the term 'tiger tail' hair. This defect may also occur in inherited amino acid and zinc deficiencies, as a complication of malnutrition and occasionally in healthy children [24]. Amino acid analysis of hair will identify true trichothiodystrophy [24]. Scanning electron microscopy highlights flattening and irregular ridging of and grooves in the shaft. The cuticle cells are degenerate or missing, leading to weathering and fragile hair.

Clinical features. IBIDS typically presents with a collodion membrane or congenital erythroderma in a low-birth-weight, premature infant. Ichthyosis develops during childhood but skin manifestations vary widely from generalized fine scaling to an erythrodermic hypohidrotic ichthyosis. Additional features in some patients are eczema, palmoplantar hyperkeratosis, pulp atrophy, digital flexion contractures, fragile small nails and hypoplastic aural cartilage [7]. An elfin-like and aged (progeric) face, resulting from fat atrophy, prominent ears and chin recession, is typical (Fig. 19.24).

Scalp and eyebrow hair is fragile, sparse, short and unruly, but its growth may improve with age. Mild to moderate intellectual impairment is the rule, and hypogonadism leads to delayed puberty and infertility in most adult patients. Moderate to severe growth failure is usual and skeletal defects including osteosclerosis have been reported [25,26]. Cataracts, otosclerosis, dental anomalies, cardiac defects and neurological signs (microcephaly, spasticity, cerebellar dysfunction, seizures, nerve deafness, autism) also occur [6,26,27]. Abnormal myelination due to reduced oligodendrocyte-specific structural proteins may account for the wide range of neurodevelopmental problems [20,27]. An increased incidence of asthma has been noted and bronchiectasis developed in one patient, although no immune defect was found [7]. A temperature-dependent deterioration in hair, skin and neurological features has been recorded in several patients at the time of febrile illnesses and attributed to an increased instability in the TFIIH transcription complex which fails to deliver cysteine-rich amino acids during terminal differentiation [28–30]. Early death from sepsis or cachexia may occur and recurrent infections with chronic neutropenia and monocytosis have been reported [10,31]. A friendly disposition is characteristic.

Photosensitivity and photophobia occur in 50% or more of IBIDS patients. Severe photosensitivity was noted in a review of 15 patients with features of IBIDS [10]. In this group, neurological disease and cataracts were more common and hypogonadism less common than expected. Although an increased risk of malignancy is not regarded as a feature of IBIDS or PIBIDS, two cases of cutaneous squamous cell cancer have been reported [32,33].

Fig. 19.24 IBIDS/trichothiodystrophy, in an 18-year-old male. (Courtesy of Professor J.I. Harper, Great Ormond Street Hospital for Children, London, UK.)

Diagnosis. Light and scanning electron microscopy of hair, and cross polarization microscopy are the first step but hair amino acid analysis by ion exchange chromatography is essential in confirming trichothiodystrophy. Skin biopsy shows non-specific features. Phototesting and DNA repair studies may be indicated but immune studies and growth hormone assay are generally normal. The main differential diagnoses are Netherton's syndrome, Sjögren–Larsson syndrome, non-bullous ichthyosiform erythroderma, Cockayne and other progeric syndromes, other ectodermal dysplasias and XPD-TTD variant (which has normal cysteine levels).

Genetics. The clinical heterogeneity of IBIDS and PIBIDS appears to result from the variety of DNA repair gene mutations within the critical functional areas of the transcription complex TFIIH. The majority are caused by mutations of the *ERCC2/XPD* gene (chromosome 19q13.2–13.3) which codes for a helicase subunit of TFIIH [15,17]. A minority are due to mutations in the *ERCC3/XPB* gene (chromosome 2q21) and the rare variant, TTD-A, is caused by mutations in the tenth subunit of the TFIIH complex which affects overall TFIIH function [19].

IBIDS and its variants are autosomal recessive disorders. Successful prenatal diagnosis has been reported in two families by identifying defective UV-induced DNA repair in amniocytes taken at 21 weeks' gestation and trophoblasts (chorionic villus biopsy)

at 9 weeks' gestation, as well as on fetal hair analysis [29,34–36]. Prenatal DNA studies are relevant only to the 70% or so of families with DNA repair defects.

Treatment. Emollients are helpful in improving skin comfort and suppleness. The influence of retinoid therapy and keratolytics on the ichthyosis has been disappointing. However, retinoid therapy was used in an effort to reduce the incidence of further skin cancers in a single patient [32]. Strict sun avoidance, protective measures and sunscreens are necessary for photosensitive patients. Advice on avoidance of physical hair treatments is helpful in reducing further hair damage and loss. Growth hormone treatment failed in one patient, and the effect of sex hormone therapy in hypogonadal patients is unknown. Physiotherapy, splinting and surgical release may reduce the severity of digital contractures [33].

Conradi–Hünermann–Happle syndrome (MIM 302960)

Synonyms

- Happle's syndrome
- X-linked dominant chondrodysplasia punctata type II/ichthyosis/cataract syndrome
- X-linked dominant ichthyosis

Conradi–Hünermann–Happle syndrome (CHHS) is a distinctive skin disorder occurring in a mosaic pattern in females, often associated with skeletal and ocular defects. It is usually lethal *in utero*

in affected males. It is considerably rarer than congenital ichthyosiform erythrodermas. The characteristic features were described by Happle in 1979, and, though originally labelled Conradi–Hünermann syndrome (CHS) or X-linked dominant ichthyosis (XLDI), it is now referred to as Happle's syndrome or Conradi–Hünermann–Happle syndrome [1]. It is one of the variants of chondrodysplasia punctata (variant CDPX2), a group of genetic disorders that have in common a congenital punctate epiphyseal and skeletal calcification which affects growth. CDP was first described by Conradi in 1914. There are three other subgroups of CDP: an autosomal recessive rhizomelic type 1; an autosomal dominant form without cutaneous disease, now referred to as Conradi–Hünermann syndrome [2]; and an X-linked recessive variant. CDP also occurs in Down's syndrome, Smith–Lemli–Opitz syndrome, CHILD syndrome and as an acquired defect in congenital hypothyroidism, and fetal warfarin or phenytoin toxicity.

Aetiology and pathogenesis. A deficiency of a peroxisomal enzyme, dihydroxyacetone phosphate acyltransferase (DHAPAT), was identified in cultured fibroblasts from patients with both rhizomelic chondrodysplasia punctata and CHHS [3,4]. DHAPAT is responsible for synthesis of plasmalagen phospholipids and glycolipids. An animal model, the 'bare patches mouse', has an X-linked dominant disorder with a phenotype and peroxisomal defect similar to that of Happle/XLDI syndrome [5]. Accumulation of 8(9)-cholesterol and 8-dehydrocholesterol in tissue samples from seven CHHS/XLDI patients suggested a defect in C8–C7 isomerization, which is catalysed by sterol-Δ8-isomerase, an emopamil-binding membrane protein (EBP) [6]. Functional mutations of the candidate gene, located at Xp11.22–p11.23, were confirmed in these patients and several *EBP* mutations have since been identified [7]. There is poor genotype–phenotype correlation and lyonization of X-linked genes at this site may influence the severity of the clinical phenotype as well as causing functional mosaicism. Similar mutations have been found in the X-linked dominant 'tattered mouse' [8], whereas the 'bare patches mouse' and the CHILD syndrome are due to a mutation of the gene coding 3β-hydroxysteroid dehydrogenase, which maps to Xq28 [9]. Ichthyosis in CHHS may, in part, result from impaired cholesterol biosynthesis and toxic effects of precursors which affect epidermal lamellar body structure and function. Abnormalities of sterol metabolism have also been implicated in other genetic skeletal dysplasias, possibly by interfering with gene transcription (via the hedgehog signalling pathways), growth patterns and steroid hormone metabolism [10]. The Indian hedgehog protein is necessary for vertebrate skeletal development and mutations cause chondrocyte degeneration which affects epiphyseal growth plates, and leads to ectopic calcification. Ectopic epiphyseal, and epidermal, calcification are recognized features of X-linked dominant ichthyosis. Rhizomelic CDP is caused by three different peroxisomal enzyme mutations, including two involved in phospholipid biosynthesis [11].

Histopathology. Neonatal skin biopsy revealed marked orthohyperkeratosis and prominent keratotic follicular plugs containing dystrophic calcification [12]. Biopsy of ichthyotic skin in the child and adult shows changes similar to those of ichthyosis vulgaris, but without the typical ultrastructural features. There is orthohyperkeratosis with a reduced granular layer, mild acanthosis and a light perivascular inflammatory infiltrate in the upper dermis in childhood. Older lesions show prominent perifollicular atrophy. Epidermal calcification, needle-like inclusions in granular keratinocytes and reduced numbers of Langerhans' cells, some of which are degenerate, have been reported [13]. Electron microscopy reveals persistent desmosomal structures in the stratum corneum layer. Abnormal degenerate mitochondria and vacuolated lamellar bodies were seen, and the dilated intercellular spaces contained disordered lipid lamellae and debris [3].

Fig. 19.25 CHHS/X-linked dominant ichthyosis in a 2-year-old girl. (Courtesy of Dr D.J. Atherton, Great Ormond Street Hospital for Children, London, UK.)

Clinical features. Affected babies are typically female, premature and born with either a partial collodion membrane or generalized ichthyosiform erythroderma. Within the first year, generalized linear and swirling patterns of erythroderma and scaling, following the lines of Blaschko, are established (Fig. 19.25). Intervening areas of skin are unaffected. Palmoplantar hyperkeratosis and nail dystrophy may occur. Recurrent infections, especially in the flexures, can be troublesome, and scalp and eyebrow hair growth is sparse and lustreless. The ichthyosis improves in early childhood and the residual signs are often so subtle in adult life that an affected mother may be missed. Signs to be sought in older children and adults include swirls of fine scale, linear pigmentary change, patchy atrophy, follicular atrophoderma mainly on the limbs and dorsal hands, and a striate cicatricial alopecia, all in a Blaschkoid pattern. An adult patient

had persistent ichthyosis and also developed psoriasis in Blaschko's lines [14].

Other variable features include rounded or asymmetrical facies with frontal bossing and hypertelorism, a broad flat nasal bridge, congenital asymmetric cataracts in 60% of patients (mosaic lens involvement), short stature, asymmetrical or, rarely, symmetrical shortening of limbs [15], kyphoscoliosis, supernumerary digits and other skeletal defects. Stippled calcification (asymmetric) of long-bone epiphyses, vertebrae, pelvis, carpus and tarsus, and cartilage, including trachea, is a characteristic but not universal radiological finding in the neonatal period, and usually resolves by adulthood. Patients have normal or mildly impaired intellectual development and neural hearing loss has been reported [14,15]. Renal, cardiac, intestinal and neurological anomalies have also been reported but occasional patients have minimal clinical signs [16,17].

Genetics and diagnosis. The mosaic phenotype of CHHS/XLDI reflects the effects of the two populations of keratinocytes that result from the X chromosome alleles, one normal, the other mutated (functional mosaicism). This X chromosome mutation is compatible with survival in female embryos, because of the Lyon effect of random X inactivation allowing expression of either allele in a given somatic cell. CHHS shows variable penetrance in females and is generally lethal in male embryos. A history of miscarriage and a predominance of female offspring have been noted in affected kindred. However, male patients with cutaneous and skeletal features have been reported, and at least one had the Kleinfelter karyotype [18–20]. The spontaneous improvement with age may reflect progressive elimination of mutant cells by adjacent normal cells, which have a growth advantage. However, clinical severity may worsen in successive generations, so-called anticipation [16,17]. Mutations in the emopamil-binding protein gene, *EBP* which contains five exons, are responsible for CHHS. Up to 50 novel and recurrent disease-causing mutations in the *EBP* gene, mostly in exons 2 and 4, have been reported, including missense, nonsense, deletions, frameshift, splice-site and intronic [6–8,11,16,17,20–22].

Autosomal recessive rhizomelic CDP can cause cataracts but rarely affects skin. An X-linked recessive variant may represent XLRI with contiguous gene defects. Genetic counselling must include assessment of all members of the extended family, looking for dysmorphism, residual skin signs, subclinical cataracts and a history of radiological abnormalities or pregnancy loss. Fetal warfarin or hydantoin toxicity, congenital rubella or varicella and other X-linked dominant genodermatoses (such as Goltz syndrome) can mimic CHHS/XLDI.

The diagnosis is usually clinically suspected in the first weeks of life. Skin biopsy is helpful at this stage [12] and abnormal plasma sterol profile (raised 8(9)-cholesterol and 8-dehydrocholesterol ratio to cholesterol) confirms the metabolic defect [5,6,8,17,21]. Mutational analysis of the *EBP* gene on peripheral blood lymphocytes is available in selected centres.

Prenatal testing, assaying DHAPAT, was successfully used in one family. Sterol assay can be done on amniotic fluid. Ultrasound scans in the second trimester may detect skeletal and other defects. First trimester mutational analysis of the *EBP* gene on chorionic villus biopsy is now widely available [23]. The variability of disease expression and improvement with age make treatment decisions based on prenatal diagnosis difficult.

Treatment. Emollients are helpful in controlling ichthyosis and antimicrobial therapy may be needed for skin infections in infancy. Some adult patients with scarring alopecia may opt to use a wig. Clofibrate, a peroxisome inducer, did not help one patient [24]. The effect of retinoids is unknown and the need for treatment diminishes with age. Continued orthopaedic surveillance and appropriate procedures may be indicated for skeletal anomalies. Cataracts do not usually affect vision. Growth hormone has been tried in one patient [17].

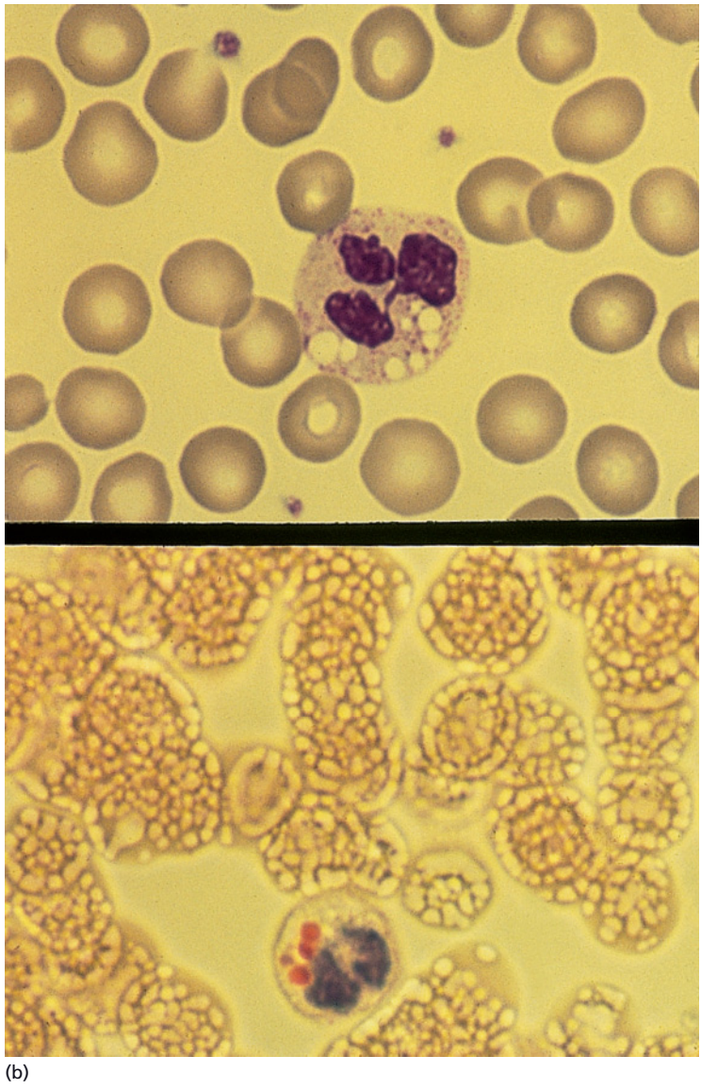
Neutral lipid storage disease with ichthyosis (MIM 275630)

Synonym
- Chanarin–Dorfman syndrome

The association of an autosomal recessive congenital ichthyosis and leukocyte lipid vacuolation affecting two sisters was first described in 1966 [1]. Dorfman reported four cases including a follow-up of the two sisters and recognized that this was a specific multisystem lipoidosis [2]. Chanarin, describing a similar case, referred to it as neutral lipid (triglyceride) storage disease (NLSD) [3]. The triglyceride deposition in white blood cells and several organs results in a combination of skin, hepatic, muscle and ocular abnormalities. There are more than 50 reported cases of NLSD, mainly in people of peri-Mediterranean (especially Turkey) or Arabic descent, many from consanguineous families [4,5]. Some families suffer from myopathy but not ichthyosis and the designations NLSDI and NLSDM are used accordingly.

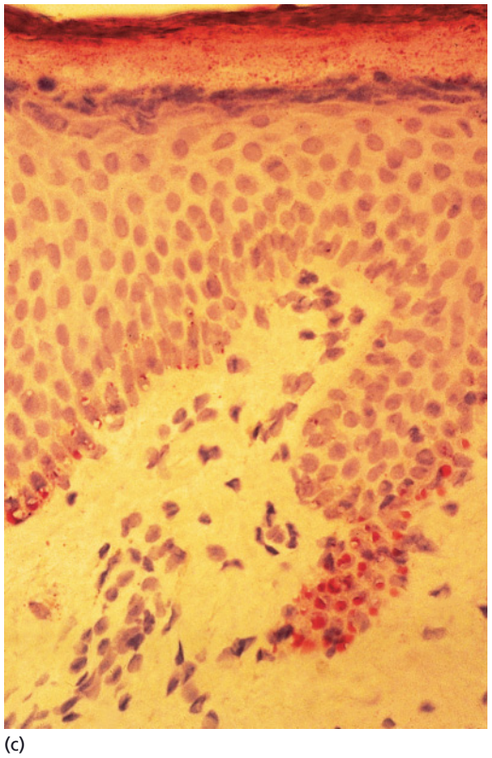
Aetiology and pathogenesis. Cytoplasmic lipid droplets are found in leukocytes, bone marrow, skin, muscle and liver in NLSD. Serum lipid analysis is normal but scale lipids show raised triglyceride content [6]. Histochemical studies on cultured fibroblasts and keratinocytes confirmed that the stored lipid was neutral lipid triacylglycerol or triglyceride [3]. Increased fibroblast triglyceride synthesis with a complete failure of endogenous triglyceride breakdown was demonstrated [6,7]. Exogenous triglyceride metabolism was normal and dietary lipid restriction was unhelpful. A defect in recycling of mono- or diacylglycerols from triglycerides to phospholipids or in long-chain fatty acid oxidation was suspected [8].

Linkage in several families with NLSD to a locus (the *NCIE2* locus) at chromosome 3p21 led to the identification of mutations in the *CGI-58* gene in 13 patients [9]. *CGI-58* (now known as *ABHD5*) is a seven-exon gene which encodes a large family of proteins, many of them enzymes, with a characteristic α/β-hydrolase fold. *ABHD5* is widely expressed in tissues such as skin, muscle, liver and brain, but also lymphocytes [10] and localizes to the surface of cytoplasmic lipid droplets [11]. Families with NLSDM (NLSD with myopathy, without ichthyosis) have mutations in *PNPLA2*, which encodes adipose triglyceride lipase necessary for lipolysis of cellular fat stores [12]. Adipose triglyceride lipase requires the *ABHD5* gene product as a cofactor and it may be that *ABHD5* additionally regulates epidermal function and influences arachidonic acid-mediated inflammation. Basal epidermal and stratum corneum barrier dysfunction are linked to abnormal phase separation of the stored lipid [13].



Histopathology. A notable feature of NLSD (seen to a lesser extent in heterozygote carriers) is the presence of lipid droplets, visible on light microscopy, in circulating polymorphs (neutrophils, eosinophils and basophils) and monocytes but not in lymphocytes, red cells or platelets (Fig. 19.26b). The vacuoles are oil red O and Sudan black positive and this feature is termed 'Jordan's anomaly'. Electron microscopy shows non-membrane-bound cytoplasmic lipid droplets. Biopsies of muscle, liver and skin and cultured fibroblasts also reveal numerous cellular lipid droplets. Skin biopsy shows acanthosis and hyperkeratosis, and closely packed lipid droplets of varying size are seen in basal (Fig. 19.26c), granular and adnexal (sweat gland and duct) keratinocytes and in dermal fibroblasts, smooth muscle cells and endothelium. Lipid vacuoles are seen in the epidermis, but not in other tissues, in Refsum's disease. Ultrastructurally, vacuoles may be seen in upper epidermal layers and arrector pili muscles [7]. Epidermal lamellar bodies and intercellular lipid lamellae are disrupted by globular electron lucent inclusions [14]. Lipid vacuoles are present in muscle fibres and marrow. Liver biopsy reveals hepatocyte fatty vacuolation, lobular fibrosis in late-stage disease and normal Kupffer cells.

Clinical features. NLSD is a multisystem disorder but clinical features are variable [4–6,9]. Affected newborns are either collodion babies or erythrodermic. The pattern of skin disease thereafter resembles mild to moderate NBIE with fine white scale on an erythematous background and lamellar scaling on the trunk (Fig. 19.26a) and legs. Scaling may diminish in warm weather and with advancing age. Pruritus is often troublesome and hypohidrosis may occur. Mild ectropion, flexural and neck lichenification and palmoplantar hyperkeratosis are common. Nail dystrophy and scalp alopecia have rarely been reported. Adult twins with late-onset clinical features of NLSD presented with an oily ichthyosis but had negative mutational analysis [15].



Muscle involvement ranges from an asymptomatic or subclinical myopathy with elevated muscle enzymes in most patients, to marked proximal myopathy in a few late cases. Hepatomegaly, abnormal liver enzymes and fatty infiltration of the liver are common, even in childhood. Cirrhosis may evolve rapidly and in childhood. Liver biopsy is more sensitive than biochemical markers in detecting the degree of involvement. Splenomegaly and malabsorption, resulting from intestinal mucosal lipid deposition, are occasional features. Cataracts of the nuclear type (subcapsular) may be detected from infancy in over 50% of cases but rarely affect vision, though nystagmus may occur. Short stature, retinal disease, nerve deafness, ataxia, microcephaly, spasticity, neuropathy and developmental delay have been reported, but most patients are intellectually normal. Fatal renal complications occurred in an infant with NLSD [16]. Prognosis depends on the pattern and degree of organ involvement.

(a)

(b)

(c)

Fig. 19.26 Neutral lipid storage disease in an infant. (a) In an 18-month-old boy. (b) Lipid vacuoles (lower panel, oil red-O positive) in neutrophils; and (c) in basal keratinocytes.

Diagnosis. The diagnosis is confirmed by direct microscopy of a peripheral blood smear, which shows lipid droplets in approximately 25% of granulocytes (Jordan's anomaly) [1,16]. Careful inspection of a fresh blood film may also be used to detect carriers and should be a routine investigation in all patients with congenital ichthyosis [17]. Moderate elevation of muscle and hepatic enzymes is usual but raised urinary creatine with normal serum muscle enzymes has been noted [5]. Liver biopsy changes are noted above. Muscle biopsy reveals lipid droplets in muscle fibres and EMG/MR signs of myopathy are detected.

Gaucher disease type 2, muscle carnitine deficiency, Wolman's disease, other storage disorders and multiple sulphatase or carboxylase deficiency should be excluded, as they share some of the features of NLSD. Lipid vacuoles are seen in the epidermis, but not in the blood smear, in Refsum's disease. Skin lesions may mimic erythrokeratoderma variabilis [18].

Genetics. The majority of NLSD patients comes from countries bordering the Mediterranean and most are of Arab descent. Many patients have consanguineous parentage reflecting autosomal

recessive inheritance. Asymptomatic heterozygote carriers may be identified by detection of lipid vacuoles in myeloid leukocytes, especially eosinophils on a fresh blood film [19]. This screening test should be offered to members of the extended family. Several different mutations in *ABHD5 (CGI-58)* have been reported [9,10,11,20] and mutational analysis can be performed on peripheral blood lymphocytes, even though lipid storage is not seen in lymphocytes [10]. However, 20% of patients with the classical phenotype have no identifiable *ABHD5* mutations [15,16]. Prenatal diagnosis using fetal blood microscopy, or skin biopsy at 20 weeks' gestation, is possible and identification of the *ABHD5* mutation in an affected family should allow first trimester diagnosis by chorionic villus sampling and mutational analysis.

Treatment. Emollients are helpful and retinoid therapy, either low-dose continuous or intermittent courses, improves the cutaneous features. Dietary manipulation to reduce intake of long-chain fatty acids and increase medium-chain fatty acids has been reported to benefit two patients, but one was also receiving retinoid therapy [5,21]. In another case, dietary treatment was ineffective [7].

KID syndrome (MIM 148210) and HID syndrome (MIM 602540)

The condition now known as KID syndrome (*k*eratitis, *i*chthyosis, *d*eafness) was first reported in 1915 as a generalized congenital keratoderma with ocular, aural and mucosal involvement [1]. The acronym KID was coined in 1981 to highlight the main features of the syndrome, which is included in the broad category of ectodermal dysplasias [2]. However, the skin disease combines features of a hystrix-like ichthyosis and an erythrokeratoderma, and keratitis is not present in all cases. Many cases have apparently been sporadic but autosomal dominant inheritance is increasingly reported. It has a worldwide distribution and more than 100 cases have been recorded in the literature. A change in terminology has been suggested but not agreed [3]. HID syndrome describes *h*ystrix-like *i*chthyosis and *d*eafness. It was originally reported in two patients from Germany [4] but is now regarded as an allelic variant of KID.

Aetiology. Mutations in gap junction proteins, namely connexins, have been reported in various epidermal diseases including hidrotic ectodermal dysplasia (connexin 30), erythrokeratoderma variabilis with and without deafness (connexin 31 and 30.3), Vohwinkel's syndrome (connexin 26), Charcot–Marie–Tooth (connexin 32) and non-syndromic hearing loss (connexin 26 and 31). Connexins are universal membrane proteins that form inter- and intracellular channels for ion and molecule transfer, which is the basis of all cellular communications. Mutant connexin expression leads to abnormal cellular and calcium homeostasis and, in some cases, immune responses which cause cell dysfunction, lysis and death. They were considered likely candidate genes for KID and HID and in 2002, two groups reported three different missense mutations of the connexin 26 gene (*GJB2*) in 10 patients [5,6]. KID and HID shared the same connexin 26 mutation [7]. Recurrent and novel *GJB2* mutations have been recorded in 40 patients since [8–11], including the common pAsp50Asn mutation in 12 of 14 patients in one report [11].

Histopathology. Skin biopsy shows marked orthohyperkeratosis and acanthosis, focal parakeratosis and papillomatosis. Fungal and bacterial elements are frequently present within the keratin, and perinuclear vacuolation with keratohyaline clumping are minor features. Proliferating keratoses should be examined for signs of pseudoepitheliomatous hyperplasia and malignancy. There is a mild upper dermal inflammatory infiltrate with plasma cells, and atrophic or plugged hair follicles with scattered folliculitis and foreign body reaction reflect the widespread alopecia.

Fig. 19.27 KID syndrome in an 8-year-old boy. (Courtesy of Dr D.J. Atherton, Great Ormond Street Hospital for Children, London, UK.)

Immunohistochemistry for connexins expression in skin is informative.

Ultrastructural study has shown irregular clumped tonofilaments in lower epidermal layers with perinuclear distribution in the granular layer (similar to changes noted in ichthyosis hystrix) and indented keratinocyte nuclei [12]. Intercellular membrane-bound granules have been noted.

Clinical features. Many affected neonates have generalized erythema and some also have diffuse scaling and a leathery skin. The typical skin changes gradually develop during infancy with linear and spiny hyperkeratosis around the flexures, elbows and knees, and hystrix-like scaling on the limbs [12]. Scattered follicular hyperkeratoses appear on the trunk. Typical features are the evolution of symmetrical, well-demarcated hyperkeratotic and warty plaques on the scalp, ears, face (Fig. 19.27) and occasionally the trunk and limbs. Some patients develop thick perioral rugae, and an aged or leonine facies [13,14]. Keratotic, hyperplastic and inflammatory nodules may develop on the scalp, face, trunk and lower legs, and *in situ* and invasive squamous cell carcinoma arising within these dysplastic lesions have been reported in several KID patients in adult life (Fig. 19.28) [5,11,15–17]. A 37-year-old man died of metastatic squamous carcinoma of the skin; his daughter also has KID syndrome [16]. Squamous cell carcinoma of the tongue has occurred in three young patients [11,18,19] and a 28-year-old had a fatal malignant fibrous histiocytoma [20]. Multiple hair follicle tumours (including malignant progression to tricholemmal tumours) occurred in an adult with KID syndrome [21] and two further adult patients developed metastatic, malignant pilar tumours [22].

Fig. 19.28 KID syndrome: adult with squamous cell carcinoma on the arm. (Courtesy of Dr D.J. Atherton, Great Ormond Street Hospital for Children, London, UK.)

Most patients have extensive scarring alopecia of the scalp and loss of eyebrows, lashes and body hair resulting from follicular hyperkeratosis and atrophy. A reticulate PPK resembling grained leather is a characteristic feature, and progressive nail dystrophy and shedding may occur. Acneiform eruptions and cysts on the upper trunk are common, and chronic deep abscesses and discharging sinuses (follicular occlusion triad) are a distressing late complication in some [22]. Chronic cutaneous, granulomatous fungal and candidal infections may develop and contribute to the alopecia, nail dystrophy and body odour. Scabies was diagnosed in a father and daughter pair [16]. Death in infancy from overwhelming infection (viral, bacterial and mycotic) has been reported in at least four patients with KID syndrome [23–25]. No specific immune defect has been identified. Premature caries, oral leukoplakia, short stature, breast hypoplasia and cryptorchidism are occasional complications.

Congenital, severe sensorineural deafness is evident during infancy in most patients. Conductive hearing loss has also been reported [26,27]. In typical KID syndrome, progressive corneal vascularization occurs in early childhood, often after a febrile illness, and leads to photophobia and blindness by adolescence in 75% of patients [11,28]. Delayed onset of keratitis has been reported [27,28]. A progressive peripheral neuropathy has occurred in several adults with KID [13]. Intellect is unaffected and it is no surprise that the combined disabilities of deafness, blindness and disfigurement impose severe limitations and hardship on the individual.

The cutaneous features of the HID syndrome vary from a diffuse hyperkeratosis with pruritus to a generalized hystrix hyperkeratosis with mild PPK. Multiple squamous cell skin cancers occurred in an adult patient [7]. The deafness runs a similar course to that of KID syndrome and mild punctate keratitis has been noted in some patients (evidence that HID and KID are allelic disorders).

Diagnosis. KID/HID syndromes are clinical diagnoses, supported by audiological and ophthalmological evidence of neurosensory deafness and vascularizing keratitis in early childhood. In spite of

the occurrence of chronic skin infections in most and fatal sepsis in a subgroup of patients, consistent immune defects are not found. The differential diagnosis includes congenital erythrokeratoderma with deafness, ichthyosis hystrix and unusual ectodermal dysplasias. Typical HID syndrome must be differentiated from Sjögren–Larsson syndrome.

Genetics. Most reported cases of KID/HID syndrome have been sporadic, but autosomal dominant inheritance was evident in several families with KID [3,6,11,16,26,29] and one with HID syndrome [7]. A report of two affected sisters with consanguineous ancestors pointed to autosomal recessive transmission [30] but this sibship and half-sibs affected with KID could also be explained by gonadal mosaicism [31]. Germinal mosaicism was also suspected, but could not be verified, in the case of two adult sisters with unaffected parents; one of them also had an affected child [11]. Dizygotic twins with KID syndrome (who died in infancy) each had a heterozygous *GJB2* mutation which again was not detected in their parents [25].

The commonest *GJB2* mutation found in KID syndrome, p.Asp50Asn, occurs in 80% of patients and accounts for most of the familial cases [11,26]. These patients may have less severe skin disease but develop skin cancers [11]. A rare mutation, p.Ser17Phe, causes more extensive skin lesions and infections and one patient died from tongue cancer [11]. A different mutation, p.Gly45Glu, was found in four patients who died in infancy [10,24,25]. First trimester prenatal molecular diagnosis on a chorionic villus sample should be possible where the connexin mutation in the index case in a family has been defined.

Treatment. Early and frequent audiological and ophthalmological assessment of patients with KID and HID syndromes is necessary to enable appropriate treatments such as hearing aids, cochlear implants and speech therapy to be instituted [32]. The ocular lesions are treated topically with lubricants, tears, antibiotics, steroids and ciclosporin drops as indicated. Surgical procedures and corneal transplant for advanced keratitis have usually failed [27,29,33]. Keratolytics, urea and emollients have a limited role. Antiseptic baths and cleansers, intermittent antibiotic and antiviral therapy and prolonged systemic antifungal agents [34] all play an important part in controlling skin infections and odour, and regular bacteriology screening of the skin should guide the choice of antimicrobial treatment. Cleansing, débridement, dressings, excision and grafting of hyperplastic lesions may be needed and may reduce the potential for malignant transformation. Mohs microsurgery is appropriate for invasive malignancies. Systemic retinoids have been tried in several patients with variable success [12,16,29,35]. The potential of acitretin to reduce the skin cancer risk provides further justification for its use. Isotretinoin aggravated the keratitis in one patient [36] and caused headaches in another [12]. PUVA phototherapy was unhelpful in an adult patient [12].

CHILD syndrome (MIM 308050)

This very rare disorder was reported in 1963, 1968 (in siblings) and 1974 [1–3]. The acronym CHILD, coined by Happle, describes the characteristic *c*ongenital *h*emidysplasia with (lateralizing) *i*chthyosiform erythroderma (or naevus) and unilateral *l*imb *d*efects, mainly skeletal hypoplasia [4]. The skin lesion more often resembles a unilateral inflammatory epidermal naevus, rather than an ichthyosis. Happle suggested that it was a unique inherited naevus determined by an X-linked dominant mutation, as the female : male ratio in the then 20 reported cases was 19 : 1 (indicating lethality in male embryos) and skin involvement may occur in Blaschko's lines [5]. Two male patients are known of, including a 2-year-old Egyptian boy, who had a normal karyotype [6]. Over 40 cases have been reported since the 1960s.

Aetiology. Keratin expression studies indicate a hyperproliferative epidermis [7]. Abnormal differentiation markers in lesional skin normalized in culture whereas abnormal intercellular structures and communication did not [8]. Defective fibroblast activity, increased prostaglandin E_2 synthesis in lesional skin [9] and defective peroxisomal structure and function in lesional skin were reported [10] and similarities to X-linked dominant ichthyosis (Conradi–Hünermann–Happle syndrome) noted. Indeed, abnormal 3β-hydroxysteroid-Δ8,Δ7-isomerase activity was found in one case [11] but the phenotype of each condition is so distinctive that they should not be confused. Reduced NAD(P)H steroid dehydrogenase (NSDHL) due to point mutations in the *NSDHL* gene on chromosome Xq28, has been identified as the cause of CHILD syndrome [12]. *NSDHL* encodes a novel 3β-hydroxysteroid dehydrogenase and the animal model, the 'bare patches' mouse, carries a similar mutation [13]. This enzyme is involved in cholesterol biosynthesis and is the precursor of 3β-hydroxysteroid-Δ8,Δ7-isomerase, which is mutated in Conradi–Hünermann–Happle syndrome. An unusual case of CHILD syndrome with virtually symmetrical lesions was also found to have this mutation [14]. X-linked dominant genodermatoses usually show a pattern of lesions in Blaschko's lines due to the Lyon effect of random X-chromosome inactivation but the lateralizing form of the lesions in CHILD syndrome suggests that the *NSDHL* gene influences the development of body symmetry in the early embryo [12]. The combined effect of random X-inactivation and migration of a clone of organizer stem cells which controls an area of skin and visceral development may explain the unique lateralization of the CHILD naevus and syndrome [15].

Histopathology. Light and electron microscopy of lesional skin in CHILD syndrome shows characteristic features. The epidermis is acanthotic with areas of hyper- and parakeratosis. Neutrophilic collections in the stratum corneum and a dermal lymphocytic inflammatory reaction are suggestive of psoriasis. Hair follicles are plugged, and foamy macrophages may be seen in distended dermal papillae. Foam cells were also seen in a gastric mucosal biopsy in one patient [4]. These changes are similar to those described as verruciform xanthoma [5,16]. Ultrastructural features include lipid vacuoles in granular layer keratinocytes, keratin filament defects, disrupted mitochondria, patchy disruption of lamellar bodies, vacuolated intercellular lamellae and lamellated structures with cytoplasmic lipid-containing vacuoles in fibroblasts and macrophages [7,10,17].

Clinical features. The skin lesions are usually noted in the first days of life as an inflamed, hyperkeratotic, crusted or verrucous plaque covering a large area or most of one side of the body, with sharp demarcation at the edge and midline. Surface scale may have a waxy, yellow appearance. Linear bands of normal skin on the affected side and of ichthyotic scaly red skin on the 'normal' side may occur, and suggest a mosaic somatic mutation [4,7]. The flexures on the affected side are preferentially, and often persistently, involved (ptychotropism), and the head is usually spared. The skin lesions may progress in the first year of life and then improve with time. One patient with almost symmetric but typical skin lesions has been reported [14] and a report of a patient with left-sided skin involvement implies that most are affected on the right side of the body [18]. Unilateral alopecia and nail dystrophy may occur. Various other defects, some of which may prove lethal, include mainly ipsilateral congenital heart and pulmonary disease, spina bifida, brainstem, intestinal and renal defects [3–5,18]. Cataracts do not occur. The most common skeletal defect is ipsilateral limb hypoplasia (phocomelia or amelia) but truncal skeletal hypoplasia and body asymmetry is also characteristic. Occasional patients have minimal or no skeletal defects. Calcific stippling of epiphyses, as seen in chondrodysplasia punctata syndromes including Conradi–Hünermann–Happle syndrome, may be detected on X-rays in affected infants. A sibling of an affected patient had bilateral limited skin disease in the absence of extracutaneous features [19]. Bilateral symmetrical lesions were reported in one patient with a novel *NSDHL* mutation [14]. The lesions, when localized, may be mistaken for an epidermal naevus or inflammatory linear verrucous epidermal naevus (ILVEN), lichen striatus or linear psoriasis. Extracutaneous features may suggest the epidermal naevus syndrome.

Genetics. The theory of X-linked dominant inheritance is convincing and explains the apparent lethality in male embryos [5]. Male patients with CHILD syndrome may have Kleinfelter's syndrome or have suffered a post-zygotic somatic mutation in an X chromosome, which could be passed to a daughter if it were also

in germinal tissue [6]. The predominantly unilateral and mosaic distribution is attributed to the Lyon effect of random X chromosome inactivation and a presumed role for the *NSDHL* gene in determining body symmetry in early embryonic development. Four different nonsense and missense *NSDHL* mutations were found in six patients including a mother–daughter pair [12]. Affected siblings were recorded [2]. An early teratogenic insult and syndromes associated with limb reduction defects must be included in the differential diagnosis.

Treatment. Emollients, urea compounds and keratolytics are helpful. Retinoid therapy and methotrexate have improved the skin lesions in individual patients [5,17]. Surgical excision of skin lesions with grafting with a good result was reported in one patient in Happle's original report [4] but dermabrasion was unsuccessful in another [6]. Orthopaedic procedures may improve limb function [6].

Ichthyosis follicularis with alopecia and photophobia (MIM 308205)

Isolated follicular ichthyosis is an ill-defined and controversial entity and may overlap with keratosis pilaris and coexistent ichthyosis vulgaris. On the other hand, the syndrome of *i*chthyosis *f*ollicularis with *a*lopecia and *p*hotophobia (IFAP) is a well-recognized but very rare ectodermal disorder, which was first reported by MacLeod in 1909 [1]. Up to 30 cases have been recorded, the majority in males.

Histopathology. Skin biopsy shows follicular plugging and orthohyperkeratosis with a normal granular layer (which is thickened at the infundibulum), effaced rete ridges and thin dermis. Absence of sebaceous glands, atrophy of hair follicles with perifollicular lymphocytic infiltrates and reduced numbers of sweat glands are characteristic findings [1,2]. No specific ultrastructural features have been noted, although disrupted intercellular connections and reduction in the number and size of desmosomes has been reported [3,4]. Histology of the cornea showed avascular scarring and amyloid deposition [5]. Electron microscopy of the adult cornea revealed desmosome, tonofilament and anchoring fibril anomalies, a thickened basement membrane and absent Bowman's capsule [3,5]. These changes reflect a disturbance in epithelial cell adhesion.

Clinical features. The phenotype is variable, but patients have a striking facial similarity. One presented at birth with a collodion membrane [2]. All have generalized, non-inflammatory follicular keratoses, persistent non-cicatricial scalp, eyebrow, eyelash and body alopecia, and severe photophobia from birth. Alopecia may not develop until childhood [1]. The keratotic papules are most pronounced on the knees, elbows and fingers, and follicular, spiny (filiform) projections develop over extensor surfaces. Generalized xerosis and cheilitis, lamellar scaling, psoriasis-like lesions, skin infections and pruritus are common, and the keratoses may improve in time. Pregnancy-related vulvitis occurred in one patient and her affected daughter developed psoriasiform plaques in early childhood [3]. Teeth, nails and sweating are generally normal, although one infant had natal teeth [6], and nail dystrophy does occur [2,3]. Palmoplantar erythema was present in one case [2]. Severe photophobia, progressive reduction in visual acuity, nystagmus and head tilt are caused by punctate keratitis, which leads to corneal erosions and vascularization. Bilateral cataracts were noted in a 3-year-old girl with IFAP syndrome [4] and retinal vascular tortuosity was regarded as a marker of the heterozygous state in a female carrier of the IFAP mutation [7]. Occasional features include atopy [1,2,6], recurrent chest infections, inguinal hernia, growth and psychomotor retardation [7], hypotonia and seizures [5,8]. Hearing is normal.

The mothers and sister of an affected boy both had linear follicular keratoses with scalp and body alopecia reflecting random X-chromosome inactivation producing a mosaic phenotype, the Lyon effect [9].

Diagnosis. IFAP must be distinguished from the keratosis pilaris variants, keratosis follicularis spinulosa decalvans (KFSD) and

keratosis pilaris rubra atrophicans facei, which are associated with inflammatory scarring alopecia of the scalp and eyebrows. Ocular disease is prominent in KFSD, the KID syndrome and IFAP, but palmoplantar hyperkeratosis is not a feature of IFAP. Skin histology helps to exclude other congenital ichthyoses, such as ichthyosis vulgaris. An autosomal recessive congenital atrichia with papular lesions has been reported [10]. Hereditary mucoepithelial dystrophy/dysplasia shares certain clinical traits with IFAP, but the striking mucosal changes do not occur in IFAP [11]. A syndrome comprising alopecia, contractures, dwarfism, prominent skeletal abnormalities, ectrodactyly, facial dysmorphism and mental retardation (ACD syndrome MIM 203550) has been described in up to seven patients and in one, ichthyosis and photophobia indicated crossover between the two syndromes [12].

Genetics. X-linked recessive inheritance was proposed in the original family with three affected male siblings [1] and in the case of a severely affected boy who reportedly had two affected maternal male relatives [8]. Mosaic features in the mother and sister of a boy with IFAP also points to X-linked transmission [9]. A maternal uncle had died in infancy with the same condition. However, several girls with typical lesions and generalized skin involvement have been reported [4,13,14]; as one had an affected father, autosomal dominant transmission was suggested in that family [13]. This pattern was evident in an affected Japanese mother and daughter [3].

Treatment. Keratolytics, urea preparations and emollients are used. Topical calcipotriol may improve psoriasiform lesions. Oral retinoid therapy produced a partial response (improvement in the ichthyosis and corneal erosions) in two cases [2,15], while topical retinoid proved too irritant [2]. Early and regular ophthalmological assessment is necessary.

Neu–Laxova syndrome (MIM 256520)

A rare and striking ichthyosiform disorder which proves lethal in the neonate was first reported by Neu in 1971 [1] and Laxova in 1972 [2]. They each described three siblings with microcephaly and multiple congenital defects. There have been 60 or more cases reported since [3,4]. It is regarded as a neuroectodermal dysplasia with a variable phenotype.

Clinical features. Affected neonates are usually premature and often stillborn. They are severely growth retarded and microcephalic with a characteristic facial dysmorphism and sloping forehead. A thick, parchment-like membrane covers the baby at birth and restricts movement and breathing. It fissures and sheds within days or weeks, revealing erythematous and ichthyotic skin. Generalized oedema, desquamation and erosions are the predominant findings in some neonates [5]. Flexion deformities of the limbs are common and the hands and feet are swollen. Digital, ocular (proptosis, ectropion), cardiac and genitourinary defects have been recorded [3]. X-rays reveal osteoporosis and brain scans confirm microcephaly with other CNS defects. There are ongoing feeding and respiratory problems requiring intensive neonatal care [6]. All reported cases of Neu–Laxova syndrome have died within weeks from sepsis or respiratory failure; the oldest survivor lived for 134 days [5].

Diagnosis. Second trimester prenatal diagnosis depends on detecting ultrasound and X-ray signs of growth retardation, head and skeletal defects, fetal oedema and, in some pregnancies, polyhydramnios [3,7–9]. Skin biopsy shows epidermal and dermal atrophy and absence of sebaceous glands [5].

Although the neonatal presentation of Neu–Laxova syndrome is distinctive, other conditions to be considered include collodion baby, harlequin ichthyosis, restrictive dermopathy, COFS (cerebro-oculo-facio-skeletal) syndrome and Smith–Lemli–Opitz syndrome [4].

Genetics. Males and females are equally affected and 28% in one review had consanguineous parents, suggesting autosomal recessive inheritance [3]. Many cases come from Turkey and Egypt and several families with multiple affected siblings are recorded [1–4,10]. No chromosomal abnormality has been detected and the cause is unknown.

CHIME syndrome (MIM 280000)

In 1983, Zunich and Kaye [1] reported a child with migratory ichthyosiform erythroderma, retinal colobomas, neurological disease, fine sparse hair and dental abnormalities—the acronym CHIME derives from *c*oloboma, *h*eart disease, *i*chthyosis, *m*ental retardation and *e*ar defects. Further cases have been described [2–4] and occurrence in a sibling pair suggests autosomal recessive inheritance. Generalized pruritus, erythema and scaling develop within the first month, and figurate, red, scaly and itchy patches migrate on the head and body from early childhood. Palms and soles are thickened; the scalp hair is fine, sparse and hypopigmented. Cranial defects, alopecia, hypertelorism, a broad nasal bridge, wide mouth, full lips and wide-spaced teeth combine in a characteristic facial appearance. Neurological features include hearing loss, seizures, severe developmental delay and outbursts of violent behaviour. A 4-year-old with CHIME syndrome and renal anomalies developed leukaemia [5]. CHIME syndrome is regarded as a cancer-prone genodermatosis. Degenerative changes in the myelin sheaths of cutaneous nerves were detected ultrastructurally. Impaired epidermal maturation was associated with a distinctive perinuclear oedema and nuclear pyknosis in upper granular keratinocytes [4]. A similar syndrome of generalized ichthyosis, mental retardation, hypotonia and craniofacial anomalies occurred in a Turkish boy of consanguineous parents [6]. Abnormal myelination also occurred in a patient with ichthyosis associated with congenital sensory neuropathy [7].

Sporadic genetic syndromes with ichthyosis

There are several reports of individuals or small groups with congenital ichthyosis occurring in association with extracutaneous defects that do not fit within the classification of recognized inherited ichthyoses. These are discussed under headings indicating the main non-cutaneous features but some may belong to more than one category.

Ichthyosis associated with neurological and ocular disorders

The rare type 2 variant of the lysosomal storage disorder, Gaucher's disease, is a progressive, multisystem condition with neurologic complications which prove fatal. It presents with collodion membrane and evolves to ichthyosis which may be subclinical [1]. Ultrastructural abnormalities in lamellar body and membrane formation and defects in ceramide production underlie the epidermal dysfunction and are due to glucocerebroside mutations [2,3].

Generalized ichthyosis with mental retardation and spasticity was noted in a patient in whom Sjögren–Larsson syndrome was excluded [4], and a similar syndrome in identical twins was also associated with cortical atrophy, epilepsy and a hearing defect [5]. An inbred Swedish family was reported in which there were two siblings and an aunt and uncle with ichthyosis, mental retardation, alopecia, eclabiun and ectropion [6]. Ichthyosis was noted in a patient with Dubowitz syndrome, which causes microcephaly and growth retardation [7], and in a boy with microcephaly and lentigines, diagnosed as LEOPARD syndrome [8].

A syndrome comprising *a*lopecia, *c*ontractures, *d*warfism, prominent skeletal abnormalities, ectrodactyly, facial dysmorphism and mental retardation, has been described in up to seven patients (ACD mental retardation syndrome, MIM 203550). One patient had follicular ichthyosis and photophobia suggesting a crossover between ACD and IFAP syndromes [9].

Retinitis pigmentosa associated with congenital ichthyosis and other defects was reported in two women [10], and another adult female patient had ocular albinism, Noonan's syndrome and ichthyosiform erythroderma (with collodion baby presentation) [11].

An infant with ichthyosis and deafness may have had KID syndrome but he died of malnutrition brought about by Hirschsprung's disease [12]. A patient with ichthyosis, deafness and mental retardation had, in addition, dental and skeletal defects and developed thyroid cancer [13]. A family with a variable syndrome of unspecified deafness, microphthalmos and ichthyosis is recorded [14]. A syndrome of cerebral dysgenesis, neuropathy, deafness, ichthyosis and keratoderma (CEDNIK syndrome, MIM 609528) was reported in two consanguineous Arab families in Israel and attributed in the *SNAP29* gene mutation [15]. A child with a complex neurodevelopmental disorder has ichthyosis affecting the legs, dorsal feet and hands (Fig. 19.29). The known 'neuroichthyoses' have been excluded.

Fig. 19.29 Congenital ichthyosis in a teenage girl with a complex neurodevelopmental syndrome.

Ichthyosis associated with renal disease

Passwell reported three siblings of consanguineous parents who had ichthyosiform erythroderma with atrophic and pigmentary changes and blisters over the dorsal hands and feet. They had a generalized aminoaciduria, hypergammaglobulinaemia, dental defects, dwarfism, neurological problems and mental retardation [16,17]. Skin biopsy revealed vacuolation in basal keratinocytes, reminiscent of neutral lipid storage disease, and collagen disruption. Hair microscopy was normal, excluding a trichothiodystrophy syndrome.

Congenital ichthyosis has also occurred with renal parenchymal disease, growth and mental retardation and hypogonadism in three siblings of another family [18]. A possibly autosomal dominant syndrome of renal disease, prolinuria, nerve deafness and a poorly-defined ichthyosis affected a third family [19]. Fanconi's syndrome with jaundice occurred in association with congenital ichthyosis [20].

Ichthyosis and skeletal defects

The ICE syndrome, reported in five subjects in four generations of one family, consisted of *i*chthyosis vulgaris, fullness of the *c*heeks and thinning of the *e*yebrows [21]. Other dysmorphic features occurred, and skeletal abnormalities included kyphoscoliosis. Accessory ribs, cortical thickening, arthrogryposis and osteopetrosis have been recorded in individual patients with ichthyosis [13,22–24].

Ichthyosis with immune defects

Patients with ichthyosiform erythroderma associated with defective chemotaxis have been described [25]. Abnormal T cells, hypogammaglobulinaemia, neurological defects, eczema and fungal infection were reported in an infant boy who died at 9 months (cf. Ommen's syndrome) [26]. Three patients with congenital ichthyosiform erythroderma and IgM or IgG deficiencies had recurrent respiratory infections [27].

Ichthyosis and cancer

Apart from the increased incidence of skin and oral cancer in KID and Netherton's syndromes, skin malignancy as a complication of genetic ichthyosis is rare. Two patients with an ill-defined reticular ichthyosis, micropinnae, universal alopecia and ectropion (MAUIE syndrome) developed squamous cell carcinomas in early adult life [28,29]. A 32-year-old man with an autosomal recessive ichthyosisform erythroderma had eight skin cancers, mainly squamous cell carcinomas on the bald scalp [28]. Two adult Japanese patients with congenital ichthyosiform erythroderma due to *ABCA12* mutations developed multiple skin malignancies, including melanoma, squamous cell carcinoma and lymphoma in one [30]. The predisposition to testicular cancer in XLRI is likely to be related to the endocrine dysfunction in that disorder. Non-cutaneous malignancies, including thyroid cancer [13], medulloblastoma [31] and leukaemia [32,33], have been reported in patients with congenital ichthyoses.

Miscellaneous

Ichthyosiform erythroderma from early infancy has been reported in 50% or more of patients with Shwachman's syndrome (MIM 260400). The main features are exocrine pancreatic insufficiency, growth retardation, bone marrow failure and increased risk of leukaemia [33,34]. Granular droplets in keratinocytes and defective lamellar bodies were seen ultrastructurally [34] and it is caused by mutations in the *SBDS* gene on chromosome 7q11 [33]. Migratory ichthyosis and pruritus associated with type 2 diabetes mellitus and acanthosis nigricans occurred in a large

consanguineous family [35]. A sibship with an autosomal recessive ichthyosis, developmental delay, deafness and cirrhosis was reported in 1971 but this syndrome (Desmons' syndrome) was, in later reports, included in the spectrum of KID syndrome [36]. Single cases of ichthyosis, hepatomegaly and cerebellar degeneration [37] and a syndrome of erythrodermic ichthyosis associated with palmoplantar keratoderma, hypogonadism and hepatosplenomegaly have been reported [38]. Dilated cardiomyopathy was reported in association with congenital ichthyosiform erythroderma in an infant (possibly related to malnutrition) and also in an 8-year-old with Netherton's syndrome [39]. Two related inbred Moroccan families with diffuse non-erythrodermic ichthyosis, scarring alopecia, sclerosing cholangitis and eosinophil vacuolation showed linkage to chromosome 3q27–q28 [40]. The NISCH (*n*eonatal *i*chthyosis, *s*clerosing *ch*olangitis) syndrome (MIM 607626) is now known to be due to mutations in claudin 1, a tight junction protein [41]. The autosomal dominant Stormorken's syndrome (MIM 185070), affecting four generations of a family, included ichthyosis, abnormal platelet function, asplenism, migraine, fatigue and dyslexia [42]. It may, however, be an ichthyosis vulgaris variant. Ichthyosis is apparent in some patients with ectodermal dysplasias [43,44]. Two reports of ichthyosis vulgaris-like scaling associated with follicular atrophoderma with pitted scars on the hands and face, hypotrichosis, hypohidrosis (in a sibship of five with consanguineous parents) plus woolly hair in a sixth case (MIM 602400) have been published [45,46]. Three of eight children of first cousin parents had ichthyosis, brittle hair (pili torti), photophobia and dental defects (MIM 610765). A mutation of matriptase, a transmembrane serine protease was identified [47].

Acquired ichthyoses

Acquired or late-onset ichthyosis is a rare and significant occurrence, as it is generally associated with underlying pathology such as malignancy. It presents with features similar to ichthyosis vulgaris and must be distinguished from xerosis, eczema, ichthyosis vulgaris and Refsum's disease in which scaling develops in early adult life. The scaling is not associated with inflammation and ranges from pityriasiform to lamellar. It is more obvious on the extensor aspects of the limbs and poorly responsive to topical therapy.

Ichthyosis associated with malignancy

The most common ichthyosis-associated malignancy is Hodgkin's disease, and the skin changes may occur simultaneously, postdate or rarely precede the diagnosis [1–3]. The fine scaling affects the trunk and limbs, usually spares the flexures and histologically resembles ichthyosis vulgaris with orthohyperkeratosis and reduced or absent granular layer. It clears with effective anticancer treatment and can be an early marker of subsequent recurrence. It may be associated with pruritus, an independent symptom of lymphoma. Reduced dermal lipogenesis, measured by radiolabelled carbon uptake, paralleled the severity of the ichthyosis and contrasted with results in ichthyosis vulgaris in one study [3]. Increased expression of transforming growth factor-α or epidermal growth factor receptors mediated by the tumour may cause hyperproliferative paraneoplastic cutaneous conditions, including ichthyosis [2].

Acquired ichthyosis has also been reported in association with non-Hodgkin's lymphoma [3–5], cutaneous T-cell lymphoma (Fig. 19.30) [6–9], lymphomatoid papulosis [10], multiple myeloma [11],

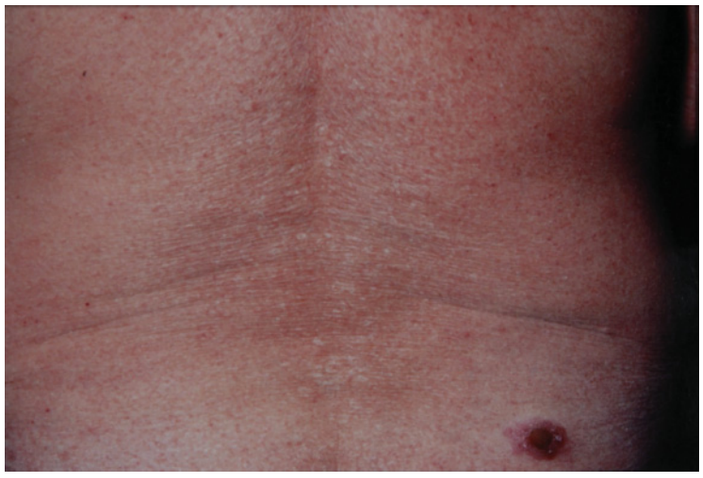

Fig. 19.30 Acquired ichthyosis in a man with cutaneous T-cell lymphoma.

carcinoma of breast, lung, cervix [12] and liver [13], leiomyosarcoma [14], rhabdomyosarcoma [15] and Kaposi's sarcoma [16]. It occurs in patients with acquired immune deficiency syndrome (AIDS), with or without demonstrable malignancy [17,18].

Ichthyosis and non-malignant disease

Ichthyosis may occur with chronic metabolic derangement such as malnutrition [4,7], malabsorption (including coeliac disease and Crohn's disease) [6], essential fatty deficiency [19], and Shwachman syndrome (pancreatic insufficiency) [20]. In these conditions, there is a disturbance of lipid and possibly vitamin absorption; because epidermal structure and integrity are dependent on complex lipid interactions, disordered epidermal maturation and desquamation with permeability barrier dysfunction ensue. Various conditions which apparently cause acquired ichthyosis may do so by virtue of associated malnutrition. Ichthyosis may be a presenting feature of inborn errors of metabolism, such as methylmalonic acidaemia [21], holocarboxylase and biotinidase deficiencies [22]. It may complicate renal failure with or without secondary hyperparathyroidism [6,7,23], primary hyperparathyroidism [24], hypopituitarism [4], hypothyroidism [6] and diabetes, where it affects the shins [25,26]. Ichthyosis may rarely occur with connective tissue diseases such as systemic lupus erythematosus [27], dermatomyositis without associated malignancy [28] and systemic sclerosis/lupus overlap [29]. It has been noted in patients with the granulomatous disorders, sarcoidosis (Fig. 19.31) [30] and leprosy [31], in HIV infection [7,17,18] and HTLV-1-associated myelopathy [32]. Acquired ichthyosis was the presenting sign of myelodysplasia [33], followed on bone marrow transplant [34], occurred with graft-versus-host disease [35] and in association with Haber syndrome [6,36] and eosinophilic fasciitis [37]. A single case of ichthyosiform erythroderma with alopecia and lichenoid features, starting at 10 years old and proving fatal at 28 years old, was reported [38]. No underlying cause was identified.

Drug-induced ichthyosis

The cholesterol-lowering drugs, triparanol and nicotinic acid, induced ichthyosis in a proportion of patients [39,40]. Triparanol

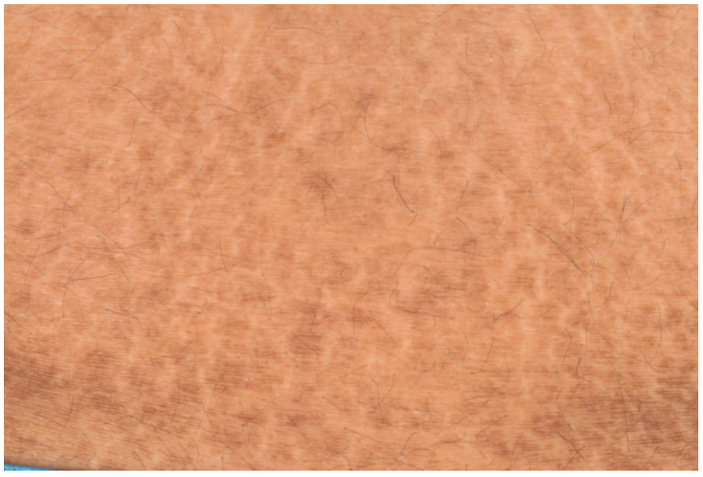

Fig. 19.31 Acquired ichthyosis in an adult Asian man with multisystem sarcoidosis.

also caused poliosis and alopecia. Normal desquamation depends on the conversion of cholesterol sulphate (which maintains the structure of intercellular lipid lamellae in the subcorneal layers) to cholesterol, by cholesterol sulphatase, located on keratinocyte cell membranes. This enzyme is unaffected by hypocholesterolaemic agents but cholesterol constitutes 25% of stratum corneum lipid. Keratinocytes lack low-density lipoprotein receptors, which may explain why so few treated patients show this complication. HMG CoA (hydroxymethylglutaryl coenzyme A) reductase inhibitors are also a rare cause of ichthyosis [41]. Ichthyosis and variable effects on hair have been attributed to certain butyrophenones [40], the phenothiazine dixyrazine [40], maprotiline [42], cimetidine (an antiandrogen) [43], allopurinol, hydroxyurea [44] and clofazamine [45].

Pityriasis rotunda

Definition. Pityriasis rotunda describes a rare, persistent, sharply defined, circular patch of ichthyosiform scaling with no inflammatory changes. This name is preferred to pityriasis circinata, reported by Toyama in 1906, and to acquired pseudo-ichthyosis [1].

Aetiology. Pityriasis rotunda is relatively common in the Far East, especially Japan, where it accounts for some 0.2% of dermatological cases [1]. It has been reported also in South African Bantus [2], in an Egyptian [3] and in Afro-Caribbeans living in London [4]. It has been described in Caucasians [5] and in two cohorts from Sardinia [6,7]. Its true incidence and geographical distribution are unknown. It is possible that genetic factors are involved and familial occurrence has been observed [6–10]. A familial association with ichthyosis vulgaris has also been noted [1,7,10]. Systemic illnesses, particularly tuberculosis and malnutrition, coexisted in up to 50% of South African patients [1,2,11]. It may rarely be an acquired cutaneous marker of malignancy [12–14]. Pityriasis rotunda was observed in 16% of 63 South African black patients with hepatocellular carcinoma and nearly 5% of those with tuberculosis in one report [15]. However, cases reported from Sardinia had no associated systemic disorders and pityriasis rotunda tended to occur at a younger age [6,7].

Pathology. The histological changes are unimpressive and resemble those of ichthyosis vulgaris, with orthohyperkeratosis and reduced granular layer. There may be pigmentary incontinence and mild perivascular lymphocytic infiltrate. Electron microscopy in one case revealed epidermal lipid vacuoles and other changes [8].

Clinical features. Typical lesions of pityriasis rotunda are circular, sharply defined patches of dry skin with ichthyosiform scaling, usually 2–3 cm in diameter but sometimes much larger, up to 14 cm (Fig. 19.32). Lesions number between four and 200. They rarely itch, slowly enlarge and coalesce and may be hypo- or hyperpigmented. Onset in childhood may have a better prognosis, with remission in later childhood in almost 50% [6,7]. Lesions are commonly situated on the buttocks, thighs, abdomen, back or upper arms, and may be solitary or multiple. They most often develop between the ages of 20 and 45 years (2 and 76 years are the reported extremes) and may remain unchanged throughout life.

Diagnosis. The age of onset, distribution, strikingly circular outline and absence of pruritus and inflammatory change should suggest the diagnosis. Investigations for an underlying cause may be indicated. In prelymphomatous eruptions, the lesions show atrophy and telangiectasia. Dermatophytosis and pityriasis versicolor can be excluded on negative mycology (microscopy and culture).

Fig. 19.32 Pityriasis rotunda.

Treatment. Emollients, urea compounds and topical keratolytics may help, but topical steroid and antifungal agents do not. Where an underlying cause is found, appropriate therapy should clear the lesions.

Fig. 19.33 Keratolysis exfoliativa of palms.

Peeling skin syndromes (MIM 270300, 609796)

Periodic or continuous peeling of the superficial layers of the skin resulting from damage to or disruption of the stratum corneum has widely differing aetiologies. Histologically, there is cleavage within the stratum corneum (above the stratum granulosum) and some alteration in histochemical staining. Individual cases and families with either acral peeling or generalized skin peeling (deciduous skin, familial continual skin peeling or shedding) have been reported. In Oudsthoorn disease (erythrokeratolysis hiemalis), the peeling is more pronounced and is associated with erythema.

Acral peeling skin syndromes

Acquired peeling of the palms. The most common peeling skin disorder is *keratolysis exfoliativa.* This affects the palms in young adults, usually in the summer months. It may be related to sweating. Lesions appear as tiny white rings or 'air bubbles', which soon rupture and peel off ('ringed keratolysis') (Fig. 19.33). Attempts to identify a specific fungal or bacterial agent proved negative [1]. Emollients are usually prescribed but are not very effective.

Some patients have non-seasonal, episodic, acral/palmar peeling which may be preceded by a few days by intense itching of the palms. Histologically, there is minimal spongiosis and it may represent a *forme fruste* of hand eczema. The use of degreasing chemicals can produce similar damage to the stratum corneum by affecting intercorneocyte adhesion.

Acral peeling. A congenital, and in one case familial, predominantly acral peeling has been reported in four patients [2–4]. It causes lifelong episodic, painless, non-inflammatory peeling of the dorsal and volar aspects of the hands and feet, especially after immersion in water, which is more severe in summertime. Occasional cases have recurrent painful acral blisters followed by peeling. Electron microscopy showed abnormal lipid lamellae, moth-eaten keratohyaline granules and defective keratin filament aggregation which allowed a mid stratum corneum split. An adult with delayed onset, well-defined palmar erythema and peeling extending to the periungal area was reported as localized peeling skin syndrome [5]. A transglutaminase 5 mutation has been identified in acral peeling skin syndrome [6] but excluded as a cause of generalized skin peeling in four kindred.

Familial peeling skin syndromes

Variously reported as keratolysis exfoliativa congenita in 1921 [1] or deciduous skin in 1938 [2], the label 'familial continual skin peeling' was suggested in 1969 in a case report of four affected siblings [3]. Two further kindreds and a number of individual cases were reported and the title peeling skin syndrome (PSS) was preferred [4–8]. The peeling was generalized and variations in the salient features among reported cases led to the identification of type A non-inflammatory [2–4,6] and type B inflammatory PSS [5,7,9,10]. Several affected patients were from consanguineous families [3–5] and the occurrence of affected siblings suggested autosomal recessive inheritance. Eleven paediatric cases were seen over a 20-year period in Saudi Arabia, all from Bedouin tribes [11]. Familial occurrence was documented in eight and consanguinity in six cases. Estimation of the frequency of PSS is difficult; it occurs worldwide.

Aetiology. A defect in profilaggrin or a site-specific keratin with resultant abnormal keratin filament aggregation was suggested. Evidence for a desmosomal abnormality and altered vitamin A metabolism has been put forward in one atypical case [12]. Reduced tryptophan with aminoaciduria was reported in at least one case [5]. Some patients with Netherton's syndrome have widespread peeling, which leads some to conclude that deficient protease inhibitor activity in skin may cause PSS type B. This theory was disproven, while the close phenotypic overlap between the two conditions was acknowledged [13,14]. On the other hand, increased levels of kallikrein trypsin-like serine proteases in the stratum corneum (which mediate desquamation) and serum of patients with PSS type B, mimic the increased serine protease activity in the skin of patients with Netherton's syndrome due to *LEKTI* (protease-inhibitor)/*SPINK* mutations [14]. Therefore, upregulated epidermal protease activity, which disrupts intercellular adhesion molecules, is the final common pathway responsible for increased stratum corneum desquamation in both conditions but occurs due to different pathogenetic mechanisms. Both disorders share a disrupted epidermal barrier function and a risk of increased absorption of topical therapy [14].

Histopathology. Mild hyperkeratosis with loose irregular stratification at follicular orifices and a normal granular layer thickness are common findings [4], although psoriasiform acanthosis was noted in two reports [5,9]. Kinetic studies suggested a hyperproliferative disorder [3], but this has been disputed [6]. The split exists at the corneal–granular interface and ultrastructurally inter and intracellular disruption occurs above the lower two layers of stratum corneum, within the stratum lucidum and with intracellular cleavage in the granular cell layer as well [9]. Corneal intercellular lamellae are irregular and fragmented, keratohyalin granules are abnormal and desmosomes may be normal, reduced [4] or disrupted [12]. Lamellar bodies are aggregated in the upper granular layer, but other cytoplasmic structures are normal. A patient with adult-onset disease was found to have intracellular keratinocyte cleavage with globular lipid deposits between corneal cells at all levels [6]. Immunofluorescence studies were normal in three cases [5,15,16].

Clinical features. Generalized superficial peeling starts at birth or in early childhood and is then persistent or periodic in most affected people. Collodion membrane and blisters do not occur in this condition, although vesicles and congenital erythroderma were noted in separate cases [8,14]. Peeling is not preceded by fever or erythema, and can be produced by rubbing intact skin, especially if pre-soaked in water. Exfoliating flakes and peeling sheets of stratum corneum spread across the trunk, limbs and occasionally face, leaving mildly erythematous intact skin. Pruritus is a problem for some patients and patchy hyperpigmentation has been noted. The palms and soles are either spared or mildly thickened without peeling, and hair, nails and teeth are usually normal. However, one atypical patient had severe palmoplantar subcorneal blistering, ichthyosis and keratotic cheilitis (PSS type C) [12]. Two patients had easily plucked hair [5,15], others noted fast-growing hair and nails [7], one shed nails [17], several showed stunted growth [5,14,16,18] and one of these, a woman of 26, had hypogonadism and anosmia [5]. Developmental delay was noted in one case [16]. Some cases are more severely affected in the summer [2,8,15], but generally there is only slight seasonal variation. Shedding occurred in a cephalocaudal pattern for a week once a year in an Indian boy [17]. A Pakistani infant had continuous peeling limited to the face, with two other family members also affected [19].

Diagnosis. Electron microscopy of skin is helpful. Many patients have elevated IgE [5,7,13,14,16,18]. Several unrelated skin disorders eventuate in skin shedding, but differentiation from peeling skin syndrome is generally not a problem. Ichthyosis bullosa of Siemens (autosomal dominant) produces transient blisters and erosions on a background of flexural hyperkeratosis and typical histopathology. An autosomal recessive form of exfoliative ichthyosis (without epidermolytic hyperkeratosis) in an inbred Bedouin family has been documented [20]. It shares some of the clinical features of familial peeling skin syndrome type A. In epidermolysis bullosa simplex superficialis and the Weber–Cockayne variant, subcorneal or basal layer blisters occur with friction but there is no continual peeling. The histology is characteristic and these are autosomal dominant skin fragility disorders [21]. Peeling lesions without double-edged scale occur in Netherton's syndrome and some patients with PSS have stunted growth and atopic features [13,14,18]. However, the absence of typical hair shaft defects and normal LEKTI staining in skin exclude Netherton's syndrome. Acquired keratolysis may complicate tinea (the original definition of keratolysis exfoliativa, an id reaction mainly affecting the palms), staphylococcal or streptococcal infection, atopic eczema and pemphigus foliaceus (where epidermolysis occurs in the superficial layer of the stratum spinosum). It is a common side effect of retinoid therapy and occasionally of azathioprine.

Treatment. Minimizing immersion in water is recommended. Absorbing powders or aluminium antiperspirants may help, especially in the acral variant, by reducing sweating and friction. Keratolytic and urea creams speed up shedding and topical calcipotriol has been reported effective [18]. Topical and oral steroids, emollients and tar, oral retinoids [7,16], methotrexate [8] and UVB phototherapy [5] are among those agents tried without success. Increased absorption of topical agents has been reported [14].

Oudtshoorn disease (MIM 148370)

Synonyms
- Keratolytic winter erythema
- Erythrokeratolysis hiemalis

This rare epidermal disorder, characterized by recurrent skin peeling, palmoplantar erythema and seasonal variation, was originally described as erythrokeratolysis hiemalis in 1977. It has been observed in at least 35 white or mixed-race related South African families of European descent originating from the Oudtshoorn district of Cape Provence [1,2]. The incidence in this population is 1 in 7000. Cases have since been identified in several other countries, and a familial link to the Oudtshoorn cluster is evident in most. It is an autosomal dominant disorder with variable penetrance and linkage to chromosome 8p22–p23 has been reported in five South African and one German kindred [3]. The genetic mutation may have arisen in a French immigrant in the late 1700s. Over 400 descendants are affected. A Norwegian family with four affected members did not show linkage to chromosome 8p22–p23, suggesting genetic heterogeneity [4].

Histopathology. Biopsy of the advancing edge of a lesion shows focal cellular oedema, necrobiosis of the Malpighian layer and absence of the overlying granular layer, through which the Malpighian layer is ejected. It forms a parakeratotic wedge, which becomes sandwiched within the hyperkeratotic stratum corneum and is shed [2]. Hyperproliferative features were evident in the basal layer—so-called basaliosis [2]. Skin histology in the Norwegian family was non-specific [4].

Clinical features. Symmetrical keratolysis of the hands and feet may begin at any age from infancy to early adult life but it is not usually present at birth (Fig. 19.34a). Cyclical centrifugal peeling (sometimes preceded by erythema multiforme-like papules) at several sites on the palms and soles is a constant feature, and may spread to the dorsal hands and feet, and the interdigital spaces. Episodes may be preceded by itch and hyperhidrosis and associated with pustulation. Palmoplantar erythema develops, and is followed by the evolution of painless, superficial opaque dry blebs, which peel or can be pulled away, leaving a red base with intact markings. A second wave may begin at the centre of a lesion, resulting in gyrate and polycyclic annular erythema, which eventually resolves. Cycles repeat every few weeks and the palms and soles appear normal between attacks. Similar rosette lesions may arise on the lower legs, knees and rarely thighs (Fig. 19.34b), upper arms and shoulders. Truncal lesions were reported in one patient [2]. The father of an affected toddler was unaffected but paternal aunts and other family members had similar palmoplantar eruptions and her paternal great-great grandmother came from Oudtshoorn [5].

A frequent precipitant is cold dry weather and, although in South Africa it is most active in winter months, it may be perennial in temperate climates. Other triggers include febrile illness, surgery, stress and menstruation, and it improves in pregnancy and with age.

Diagnosis. The differential diagnosis includes familial peeling skin syndromes, pustular bacterids, annular erythema, erythema multiforme, Hailey–Hailey disease, erythrokeratoderma en cocardes and variabilis, and Weber–Cockayne epidermolysis bullosa simplex. A similar phenotype affecting the palms, more active in summertime, was reported in two siblings (British) who also had atypical, autosomal recessive erythropoietic protoporphyria [6].

Treatment. There is no effective treatment, and topical keratolytics, retinoids and steroids may aggravate the condition. Urea and tar compounds, antiperspirants and oral retinoids have been tried.

Erythrokeratoderma

Erythrokeratoderma (sometimes erythrokeratodermia) is the association of localized hyperkeratotic plaques with overlapping or distinct areas of circumscribed erythema. Many associations and possible syndromes are reported. There is clinical overlap with KID and transgredient keratoderma syndromes. Identification of underlying genetic defects in gap junction proteins in many cases of erythrokeratoderma variabilis (EKV) (Table 19.1) has led to re-evaluation of their classification [1–3], but the status of clinical variants remains uncertain.

Erythrokeratoderma variabilis (MIM 133200)

Synonym
- Mendes da Costa's syndrome

Mendes da Costa described a mother and daughter with relatively fixed hyperkeratotic plaques and erythematous areas with geographical margins that changed by the hour [4].

Aetiology. Inheritance of EKV is usually autosomal dominant, although recessive pedigrees are reported [3,5–7]. The disease locus is at chromosome 1p34–p35.1, near the rhesus cluster [8], where several genes encode members of the connexin family of gap junction proteins [9]. Dominant negative mutations in gap junction beta3 (*GJB3*), encoding connexin 31 (Cx31), or beta4 (*GJB4*), encoding connexin 30.3 (Cx30.3), are found in many pedigrees of erythrokeratoderma variabilis [7,10–13]; homozygous missense mutations in *GJB3* also cause recessive disease [5,7]. Other mutations in *GJB3* cause autosomal dominant or recessive deafness, in isolation or with peripheral neuropathy [14–16]. EKV associated with erythema gyratum repens [17,18] appears to be specific to mutations in *GJB4* [19,20], but other mutations in this gene cause typical EKV. In some pedigrees of EKV mutations have not been identified in either *GJB3* or *GJB4* [10,21]. Connexins are synthesized in the endoplasmic reticulum and transported to the cell surface via the Golgi apparatus [22,23]. The fact that Cx31 and Cx30.3 both cause EKV may reflect their co-expression to form heteromeric connexons. In an *in vitro* model, co-expression enhances gap junction formation [24]. Trafficking to the cell membrane of Cx31 mutants which cause EKV is defective [22]. In contrast to mutations causing deafness or neuropathy, some EKV mutations increase death amongst cultured cells [22,25], but cell death is not a major feature of EKV lesions [25]. In a transgenic murine model of EKV, mutant Cx31 resulted in hyperproliferation in tail skin but also accelerated wound healing [26].

Pathology. Histology is non-specific: orthohyperkeratosis or parakeratosis, with acanthosis and papillomatosis. Immunohistochemistry shows aberrant staining for basal cytokeratins in the stratum corneum, improved by etretinate [27]. There is an increase of suprabasal staining for involucrin [28]. Connexin 31 is expressed in an abnormal perinuclear distribution, rather than at the cell membrane [22]. Reduced numbers of keratinosomes within the stratum granulosum, restored by isotretinoin, and clumped tonofilaments have been reported [29]; the latter were not confirmed in other cases [30,31].

Clinical features [3,31–35]. Onset is usually in infancy. The manifestations vary within a family and within the individual. There are two types of lesion. Relatively fixed, well-demarcated keratotic and erythematous plaques, often bizarrely shaped, show a predilection for extensor surfaces, lateral trunk and buttocks. They extend and regress in area, thickness and degree of erythema. Secondly, transient erythematous polycyclic or comma-shaped macular lesions occur at any site (Fig. 19.35). These may be triggered by trauma, irritation or temperature change, and evolve in shape over hours. They last days or weeks, fading *in situ* or migrating slowly, leaving a residual fine scale. Improvement may be seen after extended sun exposure. In some cases the erythema is annular or 'en cocarde' (Degos' syndrome) [36,37]; others may show erythema gyratum repens [17,18]. Migratory erythematous plaques resembling EKV are also seen in annular or polycyclic forms of

Fig. 19.35 Erythrokeratoderma variabilis: migrating polycyclic erythematous lesions.

bullous ichthyosiform erythroderma (BIE), due to mutations in keratin 1 or 10 genes (Table 19.1). Palmoplantar involvement in EKV may take the form of mild scaling or peeling [33], but transgredient keratoderma resembling Greither's syndrome is recorded [38]. The condition persists throughout life, but may improve at puberty or worsen during pregnancy or with oral contraceptives [39].

Treatment. Acitretin is now the treatment of choice [40]. Isotretinoin may also be helpful [29]. Successful use of bath PUVA has been reported [41]. Non-sedating antihistamines have been reported to benefit pruritic erythematous lesions [42].

Progressive symmetrical erythrokeratoderma (MIM 602036)

Synonym
- Gottron's syndrome

In progressive symmetrical erythrokeratoderma (PSEK) [1–3], fixed plaques of hyperkeratotic erythema, which gradually extend during childhood, resemble those of EKV, but migratory erythema is not seen. In some pedigrees autosomal dominant inheritance is reported [3,4] but cases are often sporadic. PSEK is probably heterogeneous, and it's existence as an entity has been questioned [5]

since in practice it may be hard to distinguish the static symmetrical lesions of PSEK from the plaques and migratory geographic lesions of EKV.

Aetiology. Connexin or other mutations have not been demonstrated in undisputed cases of PSEK. In an atypical Japanese pedigree, lesions resembling PSEK were associated with honeycomb keratoderma, and an insertional mutation in loricrin of the type found in loricrin keratoderma with ichthyosis was identified [6]. In a Chinese pedigree with an autosomal dominant disorder diagnosed as PSEK, but involving predominantly hands and feet, a locus was identified at 21q11.2–21.2 [4]. In an apparent autosomal recessive case, *GJB3, GJB4* and loricrin mutations were excluded [7].

Pathology [8,9]. The epidermis is acanthotic with a preserved granular layer. The stratum corneum is hyperkeratotic with a basket-weave pattern and foci of parakeratosis. The variable presence of perinuclear vacuolation of keratinocytes further suggests heterogeneity. Ultrastructurally, the granular cells contain swollen mitochondria, and corneocytes show lipid-like vacuoles, both of which are reduced by etretinate therapy. Labelling studies show increased epidermopoiesis with shortening of the interphase [10].

Clinical features [3,11]. The skin is usually normal at birth. Large, geographical but symmetrical fine scaly plaques with an orange–red erythema appear in infancy (Fig. 19.36). There is little pruritus. The shoulder girdle, cheeks and buttocks are most often affected with limited plaques on the ankles and wrists. Keratoderma may be present. Hair and nails are usually normal, but one case showed thickened nails [12]. The plaques extend during childhood but become fixed or occasionally remit. Erythroderma present at birth [13], and onset delayed to 17 years [14], have been recorded. A family with mal de Meleda keratoderma first presenting with inguinal lesions was originally diagnosed as PSEK [15].

Fig. 19.36 Symmetrical progressive erythrokeratoderma: sharply demarcated 'geographical' orange–red plaques. (Courtesy of Dr A.G. Smith, North Staffordshire Hospital, Stoke-on-Trent, UK.)

Treatment. Limited data suggest that etretinate and acitretin are effective [14,16] although etretinate was reported in one patient to cause generalization of the erythema [13]. PUVA treatment has been reported [17].

Other syndromes featuring erythrokeratoderma

Erythrokeratoderma with sensorineural deafness [1] may be a form of KID syndrome (see above), now known to be due to mutations in connexin 26 [2,3]. Schnyder's syndrome (asymmetrical erythrokeratoderma with deafness, peripheral neuropathy, muscle

atrophy and mental retardation, and occasionally keratitis) [4–6] and overlapping syndromes may be pathogenetically related. Affected members of three Québécois pedigrees with a recessive disorder of this type were homozygous for a common haplotype at 7q22 but mutations were not found in the gene encoding connexin 31.3 at this locus [7]. In a five-generation Canadian pedigree, erythrokeratoderma appearing in infancy and clearing in later life was associated with late-onset ataxia and neuropathy (Giroux–Barbeau syndrome, MIM 133190) [8]; the defect maps to the connexin gene cluster at 1p34–p35 [9]. A reticulate erythrokeratoderma reported by Itin *et al*. was not due to *GJB3* or *GJB4* mutation [10]. A sporadic case of a boy with atypical erythrokeratoderma involved mainly the periorificial regions but he also had acral involvement and pachyonychia [11]. Vakilzadeh and Rose [12] described a boy with slowly migrating orange–brown plaques over the buttocks and legs from the age of 1 year, without large zones of erythema and without fixed plaques, so distinct from EKV and PSEK. Faninger [13] reported a case of localized hyperkeratosis resembling symmetrical interdigital keratoderma, but with marked underlying erythema.

Folliculocentric keratotic disorders

Keratosis pilaris (MIM 604093)

Keratosis pilaris [1,2] is characterized by keratinous plugs in follicular orifices with varying degrees of perifollicular erythema. Mild forms, appearing in childhood and reaching a peak incidence in adolescence, can be regarded as physiological. Mevorah *et al.* [3] recorded its presence in 44% of 155 normal people, but few were markedly affected. Prevalences of 2.7–4% are recorded in schoolchildren from various countries [4–6]. It is often seen in ichthyosis vulgaris [3]. It was present in 72% of 54 atopic black children with eczema [7], but in a group of white children only 37% of patients with keratosis pilaris had a personal history of atopy [8], and it is a poor discriminator of atopic eczema [9].

Aetiology. Follicular hyperkeratosis is a feature of several inherited disorders (see below) but keratosis pilaris may occur in isolation. Familial keratosis pilaris is seen in ichthyosis vulgaris due to loss of function mutations in filaggrin (*FLG*) [10]. Another locus is suggested by the occurrence of more severe forms with translocations and deletions of chromosome 18p [11–13]. An X-linked dominant form in women has been suggested [14].

Pathology. The follicular orifice is distended by a horny plug which may contain one or more twisted hairs. There may be mild inflammatory changes in the dermis. Lectin staining did not demonstrate abnormal keratinization [15].

Clinical features [9] (Fig. 19.37). Small grey–white plugs of keratin obstruct the mouths of the follicles, entrapping the hair. Extensor surfaces of the upper arms (92%), thighs (59%) and buttocks (30%) are most commonly involved. Occasional cases are generalized; sharply demarcated generalized but unilateral keratosis pilaris has been reported [16]. Uneven involvement of a given area is usual, with some follicles completely spared while adjacent ones are grossly plugged. Individual follicles show a long strand of keratin glinting when examined in side light (antenna sign).

Fig. 19.37 Keratosis pilaris on the extensor aspect of the upper arm.

Perifollicular erythema is often present, and may be psychologically distressing for the patient [17]. The age at onset was in the first decade in 51%, the second decade in 35% and the third decade in 12%. Improvement in the summer months was noticed in 49% [9]. Improvement with age is common, occurring at a mean age of 16 years [9]. The term keratosis rubra pilaris is used when erythema is marked, especially on the cheeks and eyebrows [18]. The erythematous component without plugging is also seen. Severely affected follicles may show a tiny pustule.

Associations. Keratosis pilaris is commoner in obesity and insulin-dependent diabetes [19]. Keratosis pilaris is seen in association with ichthyosis vulgaris including that associated with atopic eczema, rather than atopic eczema *per se* [3]. Keratosis pilaris (or 'follicular ichthyosis') also occurs with Noonan's and cardiofacial-cutaneous syndromes [20–23], renal insufficiency [24], prolidase deficiency [25], Down's syndrome [26] and various mental deficiencies, in which it overlaps with trichostasis spinulosa [27,28], and in Fairbanks' [29] and Olmsted's [30] syndromes. A syndrome with hypotrichosis and leukonychia is recognized [31,32]. Follicular hyperkeratoses occur in monilethrix, pachyonychia congenita and ectodermal dysplasias [33–40]. Follicular hyperkeratosis may be seen during systemic steroid [41] or lithium therapy [42] and with lichenoid disorders such as the Graham-Little syndrome.

Keratosis pilaris with atrophy [43–52]. Keratosis pilaris is sometimes succeeded by atrophy. The nosology is debated [43,44] as only keratosis follicularis spinulosa decalvans can be distinguished genetically at present. *Ulerythema ophryogenes* or *keratosis rubra pilaris faciei atrophicans* shows prominent facial erythema with involvement of the eyebrows and scalp and prominent atrophy, with simple keratosis pilaris on extensor surfaces, and may occur in Noonan's syndrome [22] or with woolly hair alone [40]. The late stage of a previously active case shows fine follicular atrophy. The isolated condition is thought to be inherited as an autosomal dominant [44]. *Atrophoderma vermiculatum* is rare, and affects the cheeks and preauricular regions with a combination of keratotic papules giving way to an atrophic worm-eaten appearance, and may be recessively inherited [44,51,52].

Erythromelanosis follicularis faciei et colli (Fig. 19.38). This is a triad of well-demarcated erythema, hyperpigmentation and follicular plugging on the cheeks [41,53], spreading onto the neck anterior to the angle of the mandible. The majority of cases are in Asian or Middle Eastern men [54–57], but women can be affected [58]. The disorder is probably a variant of keratosis pilaris in pigmented skin, since keratosis pilaris on the arms frequently coexists; overlap with ulerythema ophryogenes is also reported [59]. Juhlin and Alkemade [60] reported a woman with centrifacial erythrosis pigmentosa peribuccalis which moved onto the cheeks, and argued that these entities are also the same. Unilateral cases occur [61,62]. Reported dermal calcium deposition [63] has not been confirmed as a specific histological feature [54].

Follicular ichthyosis. The capacity of this term to describe an entity distinct from keratosis pilaris is doubtful. IFAP is discussed above. A report of follicular hyperkeratosis distinguished from keratosis pilaris may be Noonan's syndrome [64].

Fig. 19.38 Erythromelanosis follicularis faciei in a young Asian man.

Treatment. Simple emollients are rarely effective in keratosis pilaris. One recommended routine is based on initial control of the inflammatory component with a topical steroid, followed by 2% salicylic acid in 20% urea cream and an abrasive sponge [16]. Systemic retinoids are ineffective, and calcipotriol was not effective in nine patients [65], but benefit from topical tazarotene has been claimed [66].

Keratosis follicularis spinulosa decalvans (MIM 308800)

Keratosis follicularis spinulosa decalvans (KFSD) [1,2] is an X-linked recessive disorder mapped to a locus at Xp21.13–p22.2 [3,4]; there may also be an autosomal form [3,5,6]. A child with a complex phenotype including KFSD had a duplication of Xp21.1–

Fig. 19.39 Keratosis follicularis spinulosa decalvans showing atrophy and loss of scalp hair.

p22.12 which included the spermidine/spermine N(1)-acetyltransferase (*SSAT*) gene [7]. It was suggested that because mice overexpressing SSAT develop hair loss [8], mutations resulting in overexpression of this gene might be responsible for KFSD. Keratotic follicular papules develop on the scalp in the first few years of life [9–13] followed by progressive scarring alopecia resembling folliculitis decalvans with variable degrees of inflammatory change (Fig. 19.39). Erythema and plugging of eyebrow follicles, follicular hyperkeratosis and prominent cuticles are seen. Ocular signs include blepharitis, ectropion, corneal dystrophy and photophobia. Variable focal plantar keratoderma may be present [14]. Female heterozygotes may exhibit a mild phenotype [11,13]. The cutaneous and ocular features overlap with ichthyosis follicularis and photophobia in which palmoplantar involvement is absent [15,16]. Other reported associations include Noonan's syndrome [17], deafness [18], cutis laxa, big pinnae and clinodactyly [19], and aminoaciduria high in aspartic acid [20]. Treatment is generally unsatisfactory. *Staphylococcus aureus* is occasionally found in the inflamed lesions but antibiotic therapy does not help. Retinoids, either topically or systemically, produce little improvement [21] but were helpful in one report [12].

Other folliculocentric disorders

Lichen spinulosus (syn. keratosis spinulosa). Typical grouped lesions appear predominantly in childhood as crops of minute follicular papules, each with a projecting keratinous spine [1,2] and without erythema, chiefly about the neck, buttocks, trochanteric regions, abdomen, thighs, popliteal spaces and extensor aspects of the arms (Fig. 19.40). The face, hands and feet are usually spared. The isolated disorder is rare, but similar appearances may arise in lichen planus, seborrhoeic dermatitis and reactions to dermatophytes, syphilis and tuberculosis. Friedman [2] studied 35 cases and concluded that it was probably a reaction pattern to several pathogenic processes. Many older reported cases show follicular atrophy and loss of scalp hair, and might be ulerythema ophryogenes. One case was associated with Crohn's disease [3] and another was considered to be a reaction to omeprazole [4]. In human immunodeficiency virus (HIV) associated follicular syndrome, lesions termed 'PRP-like' or 'lichen spinulosus-like' appear to be more filiform and florid [5].

Phrynoderma. This condition, rare in developed countries, is a distinctive form of follicular keratosis associated with nutritional deficiency first reported among prisoners in Beijing province [6]. Horny plugs with perifollicular papules are seen on the elbows, knees, neck and posterior axillary fold. The lesions are 2–3 mm in

Fig. 19.40 Lichen spinulosus: even flesh-coloured grouped keratotic papules.

diameter and easily distinguished from keratosis pilaris. Adjacent skin may be pigmented and scaly. Hypovitaminosis A, although implicated, is not always present, and complex nutritional problems may be involved [7].

Keratosis follicularis squamosa (Dohi). This is an acquired disorder of follicular hyperkeratosis with a surrounding scale 'like lotus leaves on the water', well-recognized in Japan, but apparently unusual elsewhere [8]. The condition responds to antibiotics or tacalcitol [9].

Disseminate and recurrent infundibulofolliculitis. This striking eruption of unknown cause has been reported almost exclusively in young black male adults [10,11]. Recent reports are few. Profuse, monomorphic, tiny follicular papules with a variable degree of follicular plugging occur mainly over the trunk and back. There is no erythema. The epithelium of the upper follicle is oedematous and in parts spongiotic, and is surrounded by a predominantly lymphocytic infiltrate. Immunofluorescence was negative [11]. Both recurrent and chronic cases have been described. It has been suggested that it is a reaction pattern of atopic eczema in black people. The condition may respond to oral vitamin A [12], isotretinoin [12,13] or photochemotherapy [14].

Familial dyskeratotic comedones [15–18]. This is an autosomal dominant condition characterized by scattered comedo-like lesions. The lesions appear around puberty, showing a predilection for the trunk, arms, legs, face and the shaft of the penis. The glans, and palms and soles are spared. The comedones can be picked out without producing bleeding. The lesions reform over a few weeks, and the condition gradually worsens with time. The lesions usually lack any inflammatory signs, but around puberty approximately 50% may show concomitant acne. Histologically, there is a lamellar keratin plug with patchy parakeratosis; there may be acantholysis and scattered but not universal evidence of dyskeratosis. A naevus comedonicus is usually unilateral and the lesions are more closely packed [19]. Retinoid therapy has proved unrewarding.

Pityriasis rubra pilaris

Pityriasis rubra pilaris (PRP) is a group of rare disorders that have in common circumscribed follicular keratoses, branny scale and an orange-red erythema, and palmoplantar keratoderma [1–5]. Incidence was approximately 1 in 5000 among patients presenting to a specialist dermatology centre. Of several classifications [6–8] that of Griffiths [6] has been most widely used. There is a bimodal age of onset [9,10]. Juvenile and adult forms of PRP, particularly atypical forms, may be unrelated disorders although transition between types is recognized.

Aetiology. The causes are unknown. Rarely, the disorder is familial (MIM 173200) [11,12], but remitting congenital PRP in two daughters of a chronically affected mother may indicate transplacental transmission rather than inheritance [13]. An infective aetiology is suggested, especially in the juvenile form [14–18], and a

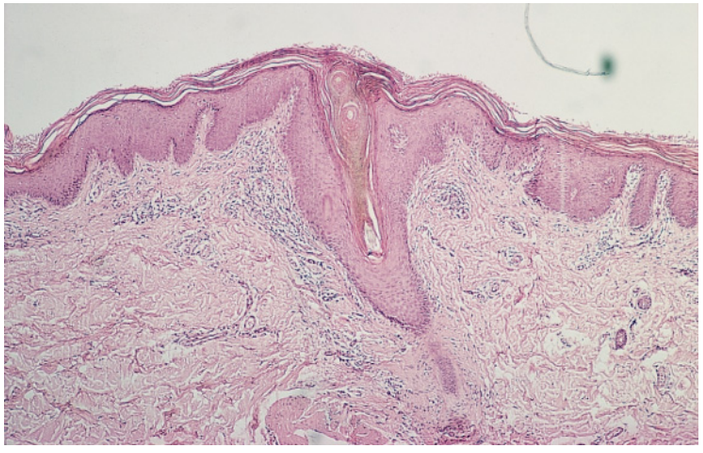

Fig. 19.41 Histopathology of pityriasis rubra pilaris: follicular plugging, acanthosis with exaggerated follicular shoulders, spotty parakeratosis and mild upper dermal inflammatory infiltrate.

Table 19.3 Some differences between pityriasis rubra pilaris and psoriasis.

	Pityriasis rubra pilaris	Psoriasis
Age at onset	Bimodal	Second decade
Scalp scaling	Furfuraceous	Adherent
Keratoderma	Constant	Less common
'Islands' of pale skin	Constant	Less common
Nail changes	No salmon patches	Present
Nail growth rate	Moderate increase	Marked increase
Epidermal kinetics	Moderate increase	Marked increase
Munro microabscesses	Absent	Common
Response to UVB	Poor	Good
Response to corticosteroids	Poor	Positive
Response to methotrexate	Variable	Good
Seronegative arthropathy	Rare	Common

PRP-like eruption is seen in patients with HIV [19]. Human leukocyte antigen (HLA) phenotype frequencies in 31 Finnish PRP patients did not differ significantly from those in a control population [17]. Epidermal thymidine labelling is increased [20–22] from an average normal 3% to 27%, and nail growth is accelerated (although less so than in psoriasis).

Pathology [23,24]. The histology of classical adult PRP is distinctive, but varies with the stage of the process, and may differ from site to site. Affected follicles are filled with dense horny plugs and there are foci of parakeratosis in the perifollicular shoulder and interfollicular epidermis (Fig. 19.41). At other sites, basket-weave hyperkeratosis overlies a prominent granular layer and there is little parakeratosis, but there may also be attenuation of granular and horny layers. Dermal capillaries are dilated, but not tortuous, and there is a lymphohistiocytic dermal infiltrate. Unlike psoriasis, the acanthotic epidermis is not thinned above the dermal papillae, and there is no neutrophil infiltration. In discriminating PRP from psoriasis, follicular plugging and an increased granular layer in PRP may be valuable signs [24], but focal acantholysis also occurs. In one study there was increased staining of keratinocytes for β-D-galactose [25]. Expression of keratins K6/K16, a marker of epidermal proliferation, was present in affected epidermis in familial cases [12]. Circumscribed juvenile PRP shows dense lamellated hyperkeratosis with a normal or increased granular layer and little acanthosis. There is little capillary dilatation, and a sparse histiocytic dermal infiltrate. The pattern of keratin components seen by protein gel electrophoresis indicated a rapid epidermal turnover, as in normal skin, following adhesive-tape stripping of the stratum corneum, which contrasts markedly with that found in psoriasis [26]. Ultrastructural changes of uncertain significance have been reported [14,27].

Clinical features. In view of the clinical and histological heterogeneity, confident diagnosis of PRP necessitates strict criteria, and in the early or late stages of disease distinctive findings may be lacking. Repeated observation and multiple biopsies may be necessary. Psoriasis, notably follicular psoriasis in children [28], may present difficulties, but these are resolved by the clinical course or histology of psoriasis. Some differences between psoriasis and PRP are indicated in Table 19.3. Atypical forms of PRP must be regarded as provisional diagnostic categories.

Type I: Adult onset, classical. The most common and recognizable form, classical adult PRP, affects the sexes equally with highest incidence between 40 and 60 years of age. The eruption usually starts without obvious precipitating factors as an erythematous, slightly scaly macule on the head, neck or upper trunk. Further macules appear within a few weeks, then a profusion of erythematous perifollicular papules with a central keratotic acuminate plug. Follicular lesions appear singly at first, and then coalesce to form groups of two, three or more (Fig. 19.42). Irritation is initially absent, but may be pronounced as the disease spreads. Interfollicular erythema appears, and the follicular lesions are gradually submerged in sheets of erythema with a slight orange colour, which typically spreads from head to feet [6]. The face becomes uniformly erythematous and mild ectropion may follow. Prolonged erythema may give rise to peripheral oedema, and in the elderly precipitate high-output cardiac failure. The scalp shows diffuse bran-like scaling. The palms and soles become hyperkeratotic and yellow (PRP 'sandal'; Fig. 19.43). Erythroderma frequently develops within 2–3 months. In most cases, sharply demarcated islands of unaffected skin 1 cm in diameter remain as a helpful diagnostic sign (island of sparing). Islands of deeper erythema are also sometimes seen. The nails are thickened and discoloured distally, showing splinter haemorrhages, but unlike psoriasis there is no dystrophy of the nail plate and pitting is minimal [29] (Fig. 19.44). Spontaneous resolution occurs in 60–80% of patients in 1–3 years, but the condition may persist indefinitely [9,10]. The eruption resembles seborrhoeic dermatitis as it resolves. Relapses are rare [30].

Type II: Adult-onset, atypical. This uncommon variety affects some 5% of patients. Follicular hyperkeratosis is prominent in some areas, while more lamellar scaling may be seen elsewhere, especially on the legs. Many patients show areas of eczematous

(a)

(b)

Fig. 19.42 Pityriasis rubra pilaris type I: (a) cephalocaudal spread of follicular papules; and (b) follicular papules beginning to coalesce.

Fig. 19.43 Pityriasis rubra pilaris (PRP) type I: the PRP 'sandal'.

Fig. 19.44 Pityriasis rubra pilaris type I: thickening of the nails, subungual hyperkeratosis and splinter haemorrhages.

change. The orderly caudal progression seen in type I does not occur and there is less tendency for the disease to become erythrodermic.

Type III: Juvenile-onset, classical [31] (Fig. 19.45). The onset is between the ages of 5 and 18 [31]. It resembles type I PRP, but may rapidly follow acute infection [15–18], and spontaneous clearing is usual within 1–2 years [7,31]. Evolution from type III to type IV and *vice versa* may occur [31,32]. A case of childhood PRP recurring 15 years later in adulthood is recorded [33]. The atypical varieties described below are less exanthematic and have a poorer prognosis.

Type IV: Juvenile-onset, circumscribed. This usually occurs below the age of 12 years [31]. Well-demarcated plaques of follicular plugging with variable degrees of erythema appear on the knees and elbows (Fig. 19.46). A few scattered scaly erythematous macules are often found on the trunk or in the scalp. Some cases also show marked keratoderma. The histological changes are more reminiscent of psoriasis, but lack neutrophil microabscesses, and evolution to psoriasis is not reported. *Keratosis circumscripta*—prominent follicular papules on the knees, elbows, nape of the neck, and posterior axillary folds—reported in African patients may be the same disorder [34–36]. Circumscribed juvenile PRP must also be differentiated from the erythrokeratodermas. The prognosis is uncertain but some cases clear in the late teens.

Type V: Juvenile-onset, atypical. Familial PRP is often of this type, which overlaps clinically with ichthyoses and erythrokeratoderma [12]. Patients show erythema and hyperkeratosis at birth or in the first few years of life. Follicular plugging and erythema suggest a diagnosis of PRP, but keratoderma is common and several patients have shown a scleroderma-like change of the digits. The disorder is chronic, but in two girls with congenital type V PRP born to a mother with type 1 disease appeared self-limiting [13].

Fig. 19.45 Pityriasis rubra pilaris type III: orange-red erythema with cephalocaudal spread.

Fig. 19.46 Pityriasis rubra pilaris type IV (circumscribed juvenile PRP) showing well-demarcated plaques of follicular plugging.

PRP and immunodeficiency. A PRP-like eruption associated with HIV infection and responding to antiretroviral therapy is recognized [37,38]. Some cases resemble classical PRP, but others show a filiform pattern of keratoses on the face and upper trunk and often have marked acne conglobata [39–41]. The term *type VI PRP* has been proposed [40] but HIV-associated follicular syndrome seems preferable. Hypogammaglobulinaemia [42] has been reported in an isolated case.

Investigation. There are no diagnostic laboratory tests for PRP. Plasma vitamin A and carotenoid levels are normal [43] and reduced serum retinol-binding protein has been disputed [44,45]. Elevated cellular retinol-binding protein (CRBP) and cellular retinoic acid-binding protein (CRABP) levels similar to those found in plaques of psoriasis are reported [46]. Elevation of parathyroid hormone level [47] was not confirmed in five patients (W.A.D. Griffiths, unpublished data). Takematsu *et al.* [48,49] reported a normal level of leukotriene B_4 (LTB_4) and low levels of anaphylotoxins in scale extracts from PRP, within the range found for normal and non-inflamed skin, and differing from psoriatic scale. Shvili *et al.* [50] reported activated suppressor T cells and impairment of helper T-cell function.

Associated disorders. Many associations of uncertain significance have been reported. PRP has been associated with leukaemia [51], Sézary syndrome [52], or other malignancy [53,54]. Conversely, Sézary syndrome and chronic T-cell lymphomas can mimic PRP [55,56]. PRP-like eruptions may also be seen with arthropathies [57–60] and in 'Wong type' dermatomyositis [61,62]. A patient with type I PRP had lichen planus, alopecia universalis, vitiligo and chronic viral hepatitis C [63]. Another developed Kaposi's varicelliform eruption from herpes simplex virus [64]. Photosensitivity and worsening with UVB and UVA have been noted [65,66]. Other reported associations have been reviewed [3].

Treatment. Intensive topical and supportive treatment is needed for the erythrodermic state. Rest and emollient applications reduce exfoliation, and help to restore the skin barrier. Topical and systemic corticosteroids are ineffective. Topical vitamin D analogues are reported to be beneficial [67]. Oral retinoids are widely used [68–74], but no systematic trials have been conducted, and results are unpredictable, with some patients showing dramatic clearing while others appear to be resistant. In children, isotretinoin produced the best response [31]. In the erythrodermic phase, acitretin or isotretinoin are used [73,74]. Methotrexate has been effective as an alternative or adjunct to oral retinoids [69,73,74], but may be less efficacious in PRP than in psoriasis [3,31]. Success [75–78] and failure [69,79] with ciclosporin are reported. Single reports have claimed effectiveness for fumaric acid esters in atypical juvenile PRP [80], intravenous immunoglobulin in adult type II PRP [81], and thyroid replacement therapy in a patient with hypothyroidism [82]. Biological agents such as infliximab, etanercept and efalizumab, sometimes with acetretin, were thought to be effective in some but not all cases [83–91]. Phototherapy may also exacerbate the condition, but narrow-band UVB, UVA1, PUVA, bath PUVA and extracorporeal photopheresis have all been reported as beneficial [73,92–95]. Phototherapy may be combined with acitretin

[96,97], and capsaicin was used to relieve phototherapy pruritus [98]. Antiretroviral therapy, of value in the PRP-like eruption of HIV disease [99], did not help three non-HIV cases [100].

Darier's disease and related disorders

Darier's disease (MIM 124200)

Synonyms
- Keratosis follicularis
- Darier–White disease

Darier's disease, described independently by White and Darier in 1889, is an autosomal dominant condition characterized by a persistent eruption of hyperkeratotic papules, histological examination of which shows suprabasal acantholysis with a distinctive overlying dyskeratosis [1,2]. Expressivity is variable but penetrance complete in adults [3]. Sporadic cases are common. It has a worldwide distribution. Reported prevalence varies from 1 in 100 000 in Denmark [4] to 1 in 30–35 000 in Northern England and Scotland [3,5].

Aetiology. Darier's disease is due to mutations in the *ATP2A2* gene at chromosome 12q24.1, which encodes the sarco/endoplasmic reticulum calcium ATPase type 2 (SERCA2) [6–10]. SERCA2 is a member of a family of ion pumps which maintain high calcium concentration in the endoplasmic reticulum [11–13]. It has two main isoforms; SERCA2a is expressed in cardiac and smooth muscle, whereas SERCA2b is more widely expressed, including in epidermis. A less common third isoform, SERCA2c, has been identified [14]. Many mutations have now been identified. Darier's disease is caused by both nonsense and insertion/deletion mutations likely to produce haploinsufficiency, and hence

reduction in SERCA2b function [6–9,15,16], although some missense mutations may interfere with the normal SERCA2 [15]. The relationship of these defects to clinical and histological features is yet to be fully elucidated. One hypothesis proposes a failure in compensatory mechanisms when the endoplasmic reticulum is stressed [14], and consequent reduced calcium concentrations mean that the folding of secreted or membrane proteins is disrupted. Darier's disease keratinocytes exhibit reduced trafficking of desmosomal proteins to the cell membrane, underlying the failure of adhesion [17]. An impaired stress response may also predispose to apoptosis, which could explain the dyskeratotic cells [18]. There is evidence of reduced expression of Bcl-2 and related antiapoptotic proteins in lesional skin [19,20]. Localization to skin and late-onset of Darier's disease may be explained by an age-related critical dependence on SERCA pumps in the epidermis. Alternatively it may be due to lack of redundancy in calcium pumps; the SERCA3 isoform is co-expressed with SERCA2b in many tissues, but not epidermis [21]. The focal nature of the lesions is intriguing, and recent evidence suggests that defects in SERCA2 may encourage the accumulation of mutations [22,23].

Pathology. In the earliest papular lesions, lacunae appear above the basal layer [1,2], and extend irregularly throughout the Malpighian layer. Small groups of cells around the lacunae become separated from their neighbours, enlarge and present a darkly staining nucleus surrounded by clear cytoplasm and a glistening ring simulating a membrane. These 'corps ronds' show premature partial keratinization (dyskeratosis); they give rise to the grains, small cells with shrunken cytoplasm, seen in the upper layers of the epidermis. This dyskeratosis may or may not be a form of apoptosis [18,24]. Lesions are not exclusively follicular [25], as acantholysis and dyskeratosis appear to occur preferentially around sweat ducts and mucous and salivary glands as frequently as around follicular openings. With the electron microscope, the lacunae can be seen to result from changes in the tonofilaments, which become separated from the desmosomes [26]. Immunocytochemical studies confirm that desmomosal proteins of affected cells are not localized to the membranes but diffusely distributed in the cytoplasm [27–29] and their intra- and extracellular domains are dissociated [30].

Focal acantholytic dyskeratosis also occurs in other conditions, such as solitary dyskeratoma, and transient and persistent acantholytic dermatoses. Hailey–Hailey disease (chronic familial benign pemphigus) may overlap clinically and histologically, although there is more suprabasal clefting and acantholysis and grains and corps ronds are less evident in Hailey–Hailey disease.

Clinical features [1,3]. The distinctive lesion of Darier's disease is a firm, rough papule, which is skin coloured, yellow–brown or brown. Seborrhoeic areas of the trunk (Fig. 19.47) and face, particularly the scalp margins, temples, ears and scalp, are most often involved. Many lesions are subtle; the occurrence of multiple minute acanthomas is easily overlooked. Flat and freckle-like lesions may appear as pale macules (guttate leukoderma) in pigmented skin [31,32], and while thought to be rare, are probably under-recognized in paler skins. Limb involvement usually consists of scattered papules but confluent lesions on lower legs and arms may be a problem [33]. Coalescent papules form irregular warty fissured plaques or papillomatous masses, which may become vegetating and malodorous [1] especially in the flexures, notably the anogenital region, the groins and the natal cleft. On the scalp, the heavy crusting simulates seborrhoea, but has a characteristic spiny feel to palpation. Loss of hair is exceptional. The external auditory meatus may be blocked by keratotic debris [34]. On the dorsa of the hands and feet, discrete papules are clinically indistinguishable from acrokeratosis verruciformis of Hopf [35,36]. These may be the earliest manifestations of the disease [3] (Fig. 19.48). In Darier's disease, characteristic nail changes include red or white longitudinal bands of varying width, often ending in a pathognomic notch at the free margin of the nail (Fig. 19.49). The nails are often brittle. Palms and soles show minute pits or, in older subjects, punctate or filiform keratoses [37] (Fig. 19.50). In severe cases, palmoplantar hyperkeratosis may occur. Lesions of the mucous membranes are uncommon, but white umbilicate or cobblestone papules on the palate resembling nicotinic stomatitis may be seen [38,39]. Lesions of the tongue, buccal mucosa, epiglottis, pharyngeal wall, vulva, oesophagus or rectum may occur, as may gingival hypertrophy [39–43]. Confluent buccal lesions may simulate leukoplakia. Vaginal involvement may result in abnormal cervical cytology [44,45].

Fig. 19.47 Darier's disease: profuse keratotic papules in the seborrhoeic region of the back.

The majority of patients first become aware of lesions in the second decade [1], although minor lesions or nail or palmar changes may be detected earlier [3]. Spontaneous remissions do occur, but the disease usually runs a chronic relapsing course, without affecting general health. The rash is typically exacerbated

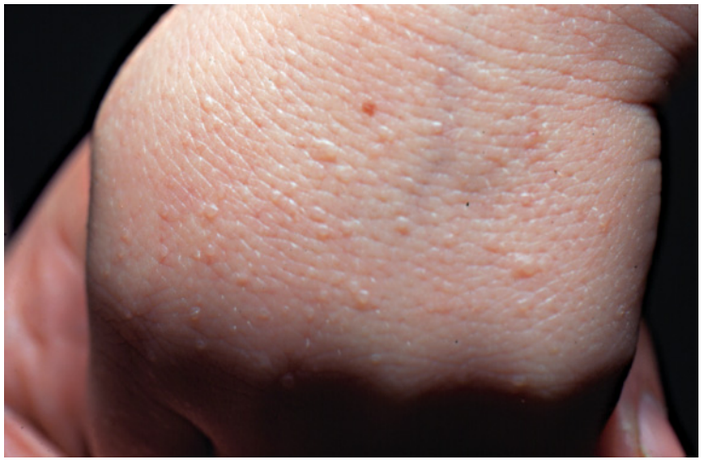

Fig. 19.48 Acrokeratosis verruciformis is a sometimes subtle feature of Darier's disease.

Fig. 19.49 The typical nail dystrophy of Darier's disease.

by heat and light, especially sunburn, and lesions can be experimentally induced by UVB exposure [46]. Lithium therapy precipitates and exacerbates the rash. Exacerbations have also been reported following steroids in naevoid disease [47].

Clinical variants. Most patients have the classical seborrhoeic distribution of papules, but there is considerable variation in severity, from isolated nail or palmar changes to universal and grossly disfiguring involvement. A minority of patients have predominantly vesicobullous [48], flexural or erosive disease or hyperkeratotic lesions, particularly of the distal limbs [33]. The most malodorous cases occur in these patients. Some patients present with multiple comedones or nodulocystic acne with deep pitted scars, and typical histology of Darier's disease may be found in these lesions [49]. Haemorrhagic macules occasionally seen on the hands and feet (Fig. 19.51) represent a true genetic variant, as they occur consistently within families [50], and may be due to specific mutations [8,51]. Atypical or unusually severe Darier's disease is usually due to missense mutations rather than haploinsufficiency [7,8], consistent with evidence of the complex molecular effects of missense mutations [15,16] *in vitro*.

(a)

(b)

Fig. 19.50 (a) Palm prints show focal interruption of dermatoglyphics; (b) palmar pits and keratoses in Darier's disease.

Acantholytic dyskeratotic epidermal naevi following the lines of Blaschko are commonly of late onset and display photoaggravation, suggesting they are naevoid forms of Darier's disease [47,52,53]. *ATP2A2* mutations have been identified in some such naevi [54,55], a finding which implies the potential for transmission of the disorder if the gonads are affected by somatic mosaicism. Somatic mosaicism may also explain cases with linear exacerbation—or amelioration—of generalized disease [56].

Associated features. Despite the wide expression of SERCA2, the phenotype of Darier's disease is largely confined to the skin. Patients do have an increased susceptibility to herpes simplex [40]. Kaposi's varicelliform eruption (Fig. 19.52) is common [57,58], and poxvirus infection is reported [59]. There may also be an increased incidence of chronic pyogenic infection [60]. There is conflicting evidence regarding a defect in cell-mediated immunity [61–64]. Salivary duct narrowing can cause recurrent salivary gland swell-

Fig. 19.51 Haemorrhage into palmoplantar lesions of Darier's disease is found with specific *ATP2A2* mutations. (Ruiz-Perez V.L. *et al. Hum Mol Genet* 1999; **8**: 1621–30, by permission of Oxford University Press.)

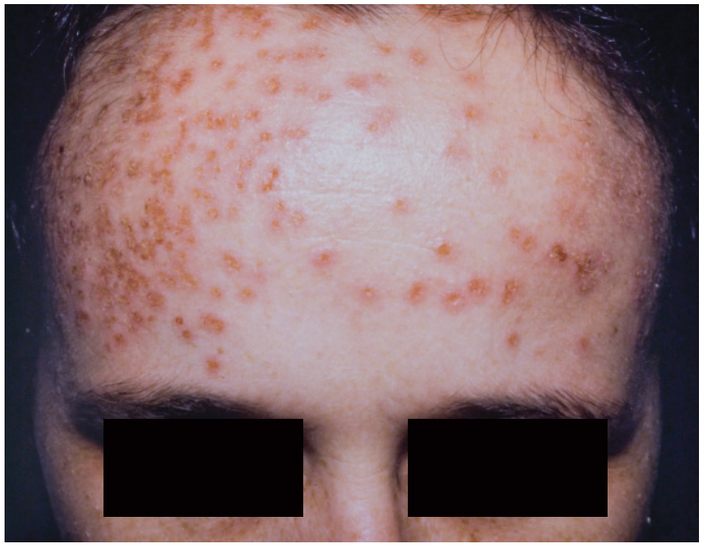

Fig. 19.52 Disseminated herpes simplex virus infection in a patient with Darier's disease.

Table 19.4 Focal and follicular keratoses.

	Age of onset	Distribution	Morphology	Associated features
Keratosis pilaris				
Physiological	Childhood or adolescence	Extensor limbs	Horny follicular plugs	None or erythrocyanosis
Ichthyotic	Early childhood	Extensor limbs	Horny follicular plugs	Ichthyosis—autosomal dominant type
Keratosis pilaris atrophicans (including atrophoderma vermiculatum)	Childhood	Eyebrows, cheeks	Erythema, follicular plugs, alopecia	Miliary cysts
Keratosis pilaris spinulosa decalvans	Childhood	Face, scalp, trunk	Follicular plugs, scarring alopecia	
Phrynoderma	Any age; usually childhood	Elbows, thighs, buttocks	Horny follicular plugs	Skin dry, pigmented
Pityriasis rubra pilaris	Childhood or middle life	Especially dorsa of fingers, knees, elbows; may be widespread	Fine, red papules with central horny plug	Plaques of erythema and scaling; palmoplantar keratoderma
Darier's disease	Usually above 10 years	Seborrhoeic areas	Yellow-brown, greasy papules	Nail and palmoplantar lesions
Kyrle's disease	50–70 years	Mainly arms and legs	Large irregular horny plugs	

ing, and subclinical narrowing may be common [39,65,66]. Most patients are of normal intellect, but clinical experience suggests that mild degrees of learning difficulty are common. There are numerous reports of cases of Darier's disease with a range of neuropsychiatric disorders, including a high prevalence of epilepsy [1,4]. Families in whom Darier's disease is associated with bipolar disorder may be explained by cosegregation of closely linked loci [67–70]. Transgenic mice haploinsufficient for SERCA2 display impaired cardiac contractility [71] and an increased incidence of gastro-oesophageal and other squamous cancers [72,73]. However, SERCA2 haploinsufficiency in human hearts appears to be compensated by other mechanisms, and there is no evidence of a general cardiac dysfunction in Darier's disease [74,75]. Although individual reports document cases of squamous carcinoma of skin, nailbed, mouth, oesophagus and vagina, an increase in the overall incidence of skin or mucosal cancer has not been documented.

Differential diagnosis. In mild forms, acne and seborrhoeic dermatitis may be confused, unless the warty papules are carefully sought. Confluent lesions resemble discoid eczema and may respond to treatment for this. Flexural Darier's disease may overlap clinically and histologically with benign familial pemphigus (Hailey–Hailey disease) but patients with intertriginous Darier's disease have changes typical of Darier's disease elsewhere, and the age of onset is usually earlier. In Dowling Degos disease or acanthosis nigricans, lesions are flexural and pigmented. In confluent reticulate papillomatosis (see below) the lesions are flat and largely confined to the upper trunk. Other follicular keratoses are listed in Table 19.4. The harshness on palpation distinguishes

the disorder from many visually similar disorders such as the reticular erythematous mucinosis syndrome and prurigo pigmentosa [76].

Treatment [77]. Many patients with mild disease require no treatment other than emollients, simple hygiene and advice to avoid sunburn. Topical tretinoin and isotretinoin, adapalene and tazarotene have been reported as effective [78–81]. In practice, irritancy limits the value of most topical preparations and extra emollients are needed. Antiseptics may help with infected plaques, which may respond to topical steroid/antibiotic combinations. For those with more severe disease, oral retinoids are usually effective; both acitretin and isotretinoin are used [82,83]. Severe inflammatory exacerbations of Darier's disease occur in some patients, and may respond to ciclosporin [84,85]; the use of biological agents has not been reported. Dermabrasion [86] or laser treatment [87–89] may prove useful, usually in limited areas. Benefit from photodynamic therapy [90], and with topical 5-fluorouracil in two patients has been reported [91,92].

Transient and persistent acantholytic dermatosis

Synonyms
- Grover's disease
- Papular acantholytic dermatosis

These papular acantholytic dermatoses mainly affect the trunk in middle-aged or elderly people, and typically present as an eruption of pruritic papules or papulovesicles with focal acantholysis with or without dyskeratosis on histology [1–5]. Distinction between transient and persistent forms of disease may be artificial [2,4].

Aetiology. The cause is unknown. Heat and sweating are predisposing factors [6,7] and it is suggested that the disorder results from leakage from blocked acrosyringeal ducts. Scheinfeld *et al.* [8] found an increased incidence in winter in non-hospitalized

subjects, and suggested that winter xerosis was contributory. The condition has been regarded by some as a minimal expression of Darier's disease [9] but mutations in the *ATP2A2* gene were not found in four patients [10].

Pathology. Many conditions show histology of focal acantholytic dyskeratosis [11]. In transient acantholytic dermatosis, the histology mimics Darier's disease, pemphigus and Hailey–Hailey disease, and there is also a spongiotic form in which acantholytic cells are contained within spongiotic foci in the epidermis [2,5,12]. Acantholysis is confined to the acrosyringium in a subset of cases [13,14]. Darier-type [2] or pemphigus-type histology [6] appears to predominate in the more persistent type of lesion. Dermal eosinophilia and degranulation is sometimes seen [12]. Immunofluorescence studies are negative [15]. Electron-microscopic studies have shown intra-desmosomal separation, diminution in the number of desmosomes and perinuclear aggregation of tonofilaments [16]. Cells with the electron-microscopic features of corps ronds have also been seen [17]. In a study of the focal acantholytic dermatoses, Hashimoto *et al.* [18] reported that the attachment plaque proteins dissolved and diffused into the acantholytic cells. Internalized desmosomal structures were seldom found in acantholytic cells of non-immune diseases.

Clinical features. Transient acantholytic dermatosis presents as an acute eruption of pruritic, discrete, greyish pink papules or papulovesicles. Lesions most commonly occur on the trunk, and mostly affect middle-aged or elderly men, especially those with a fair skin. The initial lesion may be mistaken for a solar keratosis. The disease may occur on a background of pre-existing skin disease [19]. It is common in hospitalized patients [20]. The rash is usually transient, lasting from 2 weeks to several months. Exposure to sun [1,2], ionizing radiation [21] and 2-chlorodeoxyadenosine [22] and the epidermal growth factor receptor antagonist cetuximab [23] have been noted as precipitating factors. An association with internal malignancy has led to the suggestion that it may be paraneoplastic, but many other medical conditions are associated [5].

The prognosis is variable, and the disease may run a chronic relapsing course. Most patients with persistent disease are men with significant solar damage.

Differential diagnosis. Darier's disease and Hailey–Hailey disease are distinguished by the late onset of scattered truncal lesions without a tendency to confluence, and the absence of family history. Pemphigus is clinically distinct and is also excluded by negative immunofluorescence, although coexistence with pemphigus foliaceus has been recorded [24]. Other conditions in which focal acantholysis can occur include actinic keratoses or pityriasis rubra pilaris [25], and these may need to be differentiated.

Treatment. In mild cases symptomatic treatment of pruritus and topically applied steroids may be all that is required. Success with calcipotriol is recorded [26]. In more troublesome cases, etretinate [2,27], isotretinoin [28], systemic steroids [6], PUVA [29] and UVA1 [30] have been successfully used. A recent report notes clearance during treatment of follicular lymphoma with rituximab [31].

Acrokeratosis verruciformis

Acrokeratosis verruciformis of Hopf [1] is characterized by multiple flesh coloured or lightly pigmented papules on the dorsa of the hands and feet and other sites. Its existence as an independent entity has been debated [2–4].

Aetiology. The lesions are typical of acral lesions in Darier's disease, but may occur as an isolated autosomal dominant trait. Causative mutations in *ATP2A2*, the gene implicated in Darier's disease, have been found in a pedigree of acrokeratosis verruciformis [5], but this was not confirmed in three other pedigrees [6] in one of which linkage to the *ATP2A2* locus was excluded. The occurrence of these lesions with other associations (see below) suggests that there could be multiple causes.

Pathology. Hyperkeratosis, acanthosis and a prominent granular layer may be accompanied by papillomatosis and discrete pointed epidermal upgrowths said to resemble church spires. It has been claimed that the absence of subprabasal clefts distinguish this entity from Darier's disease [2], but in practice lesions from the latter do not show always show clefting [4].

Clinical features. Flat or convex, skin-coloured, warty papules are present on the dorsa of the hands and feet, on the knees and elbows, and on the forearms [7]. Small groups or isolated papules may develop in other sites. Friction of the lesions may cause blister formation. The eruption affects both sexes and is usually present at birth or appears in early childhood; however, the onset may be delayed until the fifth decade [8]. Transformation to squamous cell carcinoma has been reported [2,9]. Nail or palmar lesions may suggest the diagnosis of Darier's disease, even in the absence of the rash [5,6]. Lesions consistent with AKV have also been recorded in association with Hailey–Hailey disease [10], naevoid basal cell carcinoma syndrome [11], multiple keratoacanthomas [12], congenital poikiloderma [13], and steatocystoma multiplex and hypertrophic lichen planus [14]. The condition resembles extensive plane warts but in more severe cases epidermodysplasia verruciformis can be differentiated by histopathology and virological studies.

Treatment. Systemic treatment of isolated acrokeratoses is not usually justified. Oral retinoid treatment has variable results [15,16].

Other focal disorders

Perforating keratotic disorders [1]

The nature and number of perforating (epidermal elimination) disorders is uncertain. They present as keratotic papules, but as epidermal involvement may be secondary to dermal disease they are probably not true disorders of keratinization. A case has been made for unifying some or all disorders because, with the exception of elastosis perforans serpiginosa, all have been reported in association with diabetes mellitus or renal failure [2]. The unifying term 'acquired perforating dermatosis' has been proposed.

Acquired perforating dermatosis. Kyrle's case was a young diabetic female in whom keratotic nodules appeared around the axillae and later became generalized [3], and Kyrle's disease (hyperkeratosis follicularis et parafollicularis in cutem penetrans) is probably synonymous with acquired perforating dermatosis [4–6]. Keratinous 1-cm nodules are seen mainly on the limbs (Fig. 19.53).

Trauma from scratching is thought to initiate the lesions. It is most often seen with diabetes or before, during or after dialysis for renal failure [7]. Eleven per cent of 72 British patients on renal dialysis developed a perforating dermatosis [8]. Many individual reports of association with malignancy, infection or inflammatory conditions have been published, but often also with renal failure or diabetes [9]. A patient who developed a perforating folliculitis with each of two anti-TNF agents, improving on withdrawal, has been reported [10]. Familial occurrence, with ocular involvement, is reported (MIM 149500) [11,12]. Histology of acquired perforating dermatoses [9] may show follicular and non-follicular lesions

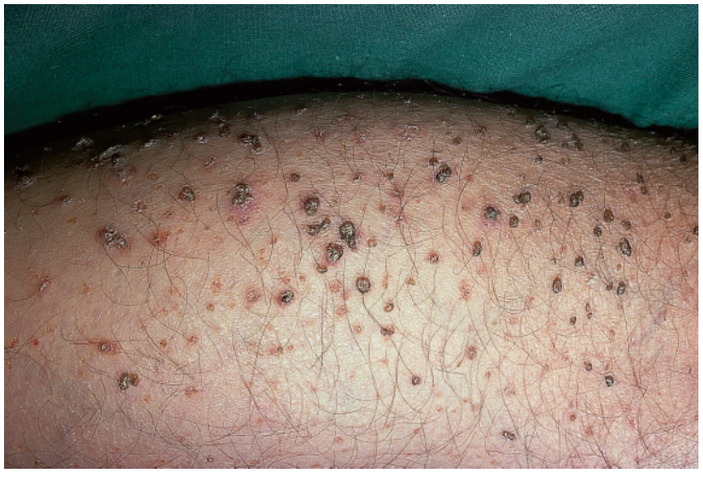

Fig. 19.53 Kyrle's disease/acquired perforating dermatosis: large keratinous plugs on the thigh.

with broad or narrow ulcer craters, and evidence of perforation of both collagen and elastic fibres [13]. Degenerate collagen, elastic tissue and keratin are seen mixed with an unidentified clear material, which has been regarded by some as an accumulation of a metabolite [2]. Changes diagnosed as perforating folliculitis, reactive perforating collagenosis or Kyrle's disease may all be found [9,13] and may depend on the age of the lesions, or sampling. In most cases of acquired perforating dermatosis, lesions could be cleared by treatment with potent topical or intralesional steroids. Success with conventional or narrow-band UVB phototherapy [14–16] has also been recorded. Topical tretinoin may reduce the lesions. Other agents reported to be effective include allopurinol [17] and doxycycline [18].

Necrotizing infundibular crystalline folliculitis. Lucke *et al.* [19] reported two cases of a disorder characterized by transepidermal elimination of negatively birefringent needle-shaped crystals similar to monosodium urate. Kossard *et al.* [20] reported a similar case and suggested that the disorder was due to initiation of crystal formation around microorganisms from follicular lipids at critical concentrations.

Elastosis perforans serpiginosa (see Chapter 45). This presents as grouped arcuate or serpiginous keratotic papules and is associated with Down's syndrome, disorders of connective tissue and penicillamine treatment. Histologically, amorphous masses that bind elastic tissue stains can be seen traversing the epidermis.

Reactive perforating collagenosis (see Chapter 45). This affects children, with the formation of 2 to 5-mm papules, usually on the limbs. Lesions in all stages of eruption and resolution are present at one time [21].

Flegel's disease (hyperkeratosis lenticularis perstans)

This is inherited as an autosomal dominant condition (MIM 144150). Lesions differ markedly from Kyrle's disease [1]. In the third or fourth decade, 2–3 mm keratotic papules with discrete irregular margins ('cornflake sign', Rowland–Payne) appear over the calves and extensor surfaces of the ankles (Fig. 19.54). Lesions may spread to the arms and the concha of the ears. The keratotic scale separates from many lesions, leaving a non-exudative red base. Irritation may be severe. Histologically, there is hyperkeratosis, sometimes with foci of parakeratosis. The underlying epidermis alternates between atrophy and acanthosis, and there is a dermal infiltrate of mononuclear cells [1,2]. Despite the strong genetic component in the disorder, no reports identifying a candidate gene have appeared to date. The profusion of lesions and poor response to cryotherapy, topical and systemic retinoids, and to 5-fluorouracil make management difficult.

Porokeratoses

Porokeratoses are characterized by marginate scaling lesions, histologically showing a column of parakeratotic keratinocytes (the coronoid lamella). Various forms are recognized, but terminology and classification are debated [1,2]. Some forms appear to be premalignant [3].

Aetiology. In Chinese pedigrees of disseminated superficial (actinic) porokeratosis (DSAP) loci at chromosomes 12q (MIM 175900) [4], 15q (MIM 607728) [5], and 18p [6] have been reported. Loss of heterozygosity at 12q and sequence variations in genes at this locus are reported, but the significance of these findings is uncertain [7–11]. The centrifugal progress of individual lesions is thought to reflect the migration of a clone of abnormal cells [12]. There is keratinocyte dysplasia and Otsuka *et al.* [13,14] have reported aneuploidy and chromosomal abnormalities in lesional keratinocytes. The tumour suppressor protein p53 is overexpressed in the coronoid lamella [15–18], but D'Errico *et al.* [18] found no evidence of p53 mutations or radiation hypersensitivity in DSAP-derived keratinocytes and fibroblasts. Cytogenetic anomalies in fibroblasts, particularly chromosome 3, are also recorded [19]. An association with immunosuppression [1] suggests impaired immunity is permissive, perhaps by reduced immune surveillance of dysplasia, but the possibility of an infective aetiology [20] remains. Esser *et al.* [21] found evidence of HPV types 66 and x14 respectively in two patients with porokeratosis of Mibelli.

Fig. 19.55 Disseminated superficial actinic porokeratoses: annular keratotic lesions with a raised margin.

Pathology [22]. Lesions may or may not involve the eccrine sweat duct. The characteristic histopathology is seen in the edge of the lesion. The stratum corneum is hyperkeratotic, and at the raised border a column of poorly staining parakeratotic stratum corneum cells, the cornoid lamella, is seen running through the surrounding normal-staining cells. The underlying keratinocytes are oedematous with spongiosis, shrunken nuclei and a moderate dermal lymphocytic infiltrate under the lamella [22]; a lichenoid reaction pattern, and the presence of amyloid material may be detected [23]. The central area of a lesion is usually atrophic, but may occasionally show gross hyperkeratosis [24]. Cornoid lamellae may also be found in other conditions, such as viral warts, some ichthyoses and naevoid hyperkeratoses.

Clinical features

Disseminated forms. Clinical distinction between the various forms of disseminated porokeratosis may not be justified [25]. *Disseminated superficial actinic porokeratosis* (DSAP) is the most common presentation, with very many lesions of up to 10 mm predominantly in sun-exposed sites in middle-aged individuals, especially those with sun-sensitive skin (Fig. 19.55). They are easily mistaken for actinic keratoses, with which they may coexist. Lesions were not induced by artificial light exposure [26], but have been provoked by photochemotherapy [27]. No evidence that skin cancer arises in the porokeratotic lesions was found in a study of 29 patients [28]. *Disseminated superficial porokeratoses of immunosuppression* are recognized after renal, hepatic, cardiac and bone marrow transplantation, and in AIDS [1]. The distribution is similar to DSAP, but a history of sun exposure is less likely [29]. *Disseminated superficial porokeratosis of childhood* may be inherited as an autosomal dominant condition, but sporadic cases are seen. Widely disseminated, flat lesions usually begin in childhood, the majority between the ages of 5 and 10 years, but may be present at birth or may first appear at puberty or later. Palmoplantar lesions may be associated (porokeratosis palmaris et plantaris dis-

Fig. 19.56 Porokeratosis of Mibelli.

seminata) [30]. Widespread lesions appeared first at the age of 1 month in a male infant with craniosynostosis and other congenital abnormalities [31].

Porokeratosis of Mibelli [32,33]. The eponym Mibelli is sometimes used generically for porokeratoses, but usually refers only to the form with single or scanty and larger lesions. These develop as annular dry plaques (Fig. 19.56) surrounded by a raised, fine keratotic wall and sometimes also a furrow. Lesions are most common on the limbs and by centrifugal spread may achieve several centimetres in diameter. The centre is usually atrophic but may be hyperkeratotic [34]. The face, genitalia, oral mucosa and cornea may also be affected. The condition may be familial, inherited as an autosomal dominant with onset in childhood (MIM 175800), or sporadic and of later onset.

Giant porokeratoses (up to 20 cm in diameter with a surrounding wall of 1 cm). These are very rare [34], and are most often found on the foot. Large lesions are said to have the highest malignant potential [3,35,36].

Palmoplantar porokeratosis (of Mantoux). Parakeratotic hyperkeratosis histologically reminiscent of the cornoid lamella occurs in some punctate keratodermas, but the absence of marginate lesions distinguishes from true porokeratosis [37]. Nonetheless, annular lesions of palms and soles with a cornoid lamella are recognized [30,38].

Linear porokeratosis [36,39,40]. Linear porokeratoses showing typical cornoid lamellae and following the lines of Blaschko usually appear in childhood. These lesions probably result from a predisposition to porokeratosis in an abnormal clone of epidermal precursors. Malignant degeneration and metastasis has been reported in this variety [37,41]. Linear accentuation of disseminated actinic porokeratosis is reported [42–44].

Treatment. Treatment of disseminated superficial porokeratoses is usually unnecessary, but cryotherapy, carbon dioxide and pulsed dye laser therapy, and photodynamic treatment have all been used [45–47]. Keratolytics offer little relief. Topical tacalcitol [48], 5-fluorouracil ointment [49,50], imiquimod cream [51] and oral etretinate [52] have been effective. Diclofenac gel was disappointing [53].

Minute and filiform keratoses

A number of entities have been described using names including filiform keratoses, minute aggregate keratosis, and multiple minute digitate hyperkeratosis [1–4] (Fig. 19.57). Ramselaar and Toonstra propose an inclusive approach to classification [5], under the name multiple minute digitate hyperkeratosis. Filiform or spiny palmoplantar keratoses are also recognized [6,7].

Fig. 19.57 Digitate hyperkeratosis. (Courtesy of Dr F.A. Ive, Dryburn Hospital, Durham, UK.)

Cases may be sporadic [3] or familial with probable autosomal dominant inheritance [2,8,9], early or late onset, transient or persistent, follicular or non-follicular. Reported associations include drugs, malignancy, especially haematological, and X-irradiation [4,5,9–13]. One case associated with carcinoma of the larynx cleared following surgery [14]. Filiform keratoses occur with a PRP-like eruption and acne conglobata in association with HIV infection [15]. Histologically, there are focal areas of compact orthohyperkeratosis with few dermal changes and keratohyalin granules thought to be smaller than normal are reported [16]. Parakeratosis may be present [17] but the use of the term porokeratosis is probably misleading [5,6].

Miscellaneous circumscribed keratotic disorders

Waxy keratoses of childhood. Three children in two families were reported with a disorder consisting of generalized discrete domed keratotic papules, which were flesh-coloured or yellowish [1]; two young patients reported earlier with 'disseminated hypopigmented keratoses', appear to be identical [2]. The disorder has been reported in a linear form [3] and as linear exacerbation in generalized disease [4], further supporting the notion that this is a genodermatosis. Histological findings were marked orthokeratotic hyperkeratosis, tenting of the epidermis and mild acanthosis. Differential diagnosis includes the leukodermic macules in Darier's disease in dark skin [5].

Facial Afro-Caribbean childhood eruption. A monomorphic, mildly hyperkeratotic, papular facial eruption in black children was reported by Marten *et al.* [6] in 1976. Further cases in children were termed granulomatous perioral dermatitis [7]. Williams *et al.* [8] suggested the name and acronym FACE. The eruption shows a predilection for the perioral and periorbital regions and nose. The condition is of unknown cause, and does not appear to be a rebound phenomenon from the use of topical steroids. A relationship to sarcoid was suggested in one case [9]. Histology shows peri-follicular inflammation with foci of granuloma formation. It does not respond to topical steroids, but resolution within a year without scarring was usual.

Florid cutaneous papillomatosis [10,11]. This term was used to describe the appearance of multiple acuminate keratotic papules in association with an underlying gastric adenocarcinoma. The first patient also had acanthosis nigricans and eruptive seborrhoeic warts (Léser–Trelat sign). Worret's case also had acquired hypertrichosis lanuginosa from metastatic bronchial carcinoma.

Hyperkeratosis of the nipple [12]. Marked hypertrophy of the nipple and areola was noted in association with a T-cell lymphoma, which resolved following chemotherapy.

Knuckle pads [13,14]. These are classified with the fibromatoses (see Chapter 45). Nevertheless, it appears that the dry, rather fleshy lesions occurring over the knuckles and interphalangeal joints differ from the acanthotic grossly hyperkeratotic lesions seen in association with some keratodermas. In Morginson's series of 30 patients [13], seven showed hyperkeratosis, keratodermas and fissuring of varying degree involving the palms and soles. Confusion sometimes occurs with pachydermodactyly (see Chapter 45). Knuckle pads may be seen in keratodermas such as the Papillon–Léfèvre syndrome, epidermolytic keratoderma resulting from keratin 9 mutation [15] and Bart–Pumphrey syndrome [16].

Palmoplantar keratodermas

Classification of palmoplantar keratodermas

Palmoplantar keratodermas (PPKs) are a diverse group of hereditary and acquired disorders defined by excessive epidermal thickening of palms and soles. Many keratoderma syndromes are restricted to palms and soles but marked palmoplantar hyperkeratosis may also be seen in generalized disorders of keratinization such as ichthyosis vulgaris, epidermolysis bullosa or EHK, in ectodermal dysplasias, dysmorphic syndromes or metabolic disorders, and in inflammatory disease, notably psoriasis, eczema and lichen planus. This section deals mainly with conditions in which keratoderma is the primary or presenting feature, or a major clinical problem. Many such cases are genetic in origin. The molecular basis has been elucidated in the majority of well-defined syndromes (Table 19.5), but clinically homogeneous entities may have distinct molecular pathogenesis, and different mutations in one gene can give rise to distinct syndromes. Consequently, although a number of classifications of keratodermas have been published [1–7], none unite satisfactorily clinical presentation, pathology and

Table 19.5 Principal hereditary palmoplantar keratodermas (fuller descriptions and references are given in the text).

Type	Eponym(s)	Inheritance (presumed)	Gene or locus	Onset (years)	Transgredient/ cicatrizing	Comments/special features
Keratodermas and ectodermal dysplasias						
Diffuse group						
Epidermolytic keratoderma	Vörner	AD	Keratin 9	0–3	N	Most common but histology needed to confirm
Diffuse non-epidermolytic keratoderma*	Thost–Unna	AD	some 12q11–q13 Keratin 1	2–5 or later	N	Likely to be heterogeneous
Loricrin keratoderma	Camisa; variant Vohwinkel	AD	Loricrin	2–5	Y	Mild ichthyosis; honeycomb pattern keratoderma
Autosomal dominant transgredient keratoderma*	Greither; Sybert	AD	some 1p; Keratin 1	3–8	Y	Likely to be heterogeneous
Keratoderma with scleroatrophy	Huriez	AD	4q23		Y	Squamous carcinomas
Mal de Meleda		AR	*SLURP-1*	0–3	Y	Dermatophyte infection common
Autosomal recessive transgredient keratoderma*	Gamborg–Neilsen	AR	—	8–10	Y	Likely to be heterogeneous
Palmoplantar and periorificial keratoderma	Olmsted	?AR	—	0–1	Y	Periorificial and flexural erythema and hyperkeratosis
Focal or areate group						
Focal/areate/nummular keratoderma	Wachters	AD	—			Includes painful hereditary callosities Likely to be heterogeneous
Focal keratoderma with oral leukokeratosis		AD	Keratin 16	3–5	N	Oral leukokeratosis
Pachyonychia congenita type 1	Jadassohn–Lewadowsky	AD	Keratins 6a, 16	3–5	N	Oral lesions, follicular keratoses
Pachyonychia congenita type 2	Jackson–Lawler	AD	Keratins 6b, 17	3–5	N	Natal teeth, multiple cyst, follicular keratoses
Striate keratoderma	Brunauer–Fuhs–Siemens	AD	Desmoplakin Desmoglein Keratin 1		N	
Hidrotic ectodermal dysplasia	Clouston	AD	Connexin 30		Y	Nail and hair dystrophy
Keratodermas with extracutaneous features						
Keratoderma with oesophageal carcinoma	Howel–Evans	AD	17q23		N	Focal PPK with oral lesions
Striate keratoderma, woolly hair and arrhythmogenic cardiomyopathy	Naxos disease	AR	Plakoglobin		N	
Striate keratoderma, woolly hair and dilated cardiomyopathy	Carvajal	AR	Desmoplakin		N	
Cicatrizing keratoderma with hearing loss	Vohwinkel	AD	Connexin 26	5–10	Y	Papular lesions becoming confluent, starfish keratoses. Mild hearing impairment
Keratoderma with prelingual deafness		AD	Connexin 26	0–5	Y	Mild diffuse PPK but profound deafness
Mitochondrial hearing loss with keratoderma		Matrilineal	*A7445G*		N	Variable mild focal PPK
Keratoderma with neuropathy*		Varies	(SNAP29)		N	Peripheral neuropathy; spastic paralysis
Keratoderma with periodontitis	Papillon–Léfèvre	AR	Cathepsin G		N	Severe periodontal and other pyogenic infections

Table 19.5 *Continued*

Type	Eponym(s)	Inheritance (presumed)	Gene or locus	Onset (years)	Transgredient/ cicatrizing	Comments/special features
Keratoderma with eyelid cysts	Schöpf–Schulz–Passarge	AR	—		N	Diffuse keratoderma, hypotrichosis, nail fragility, loss of deciduous teeth, adnexal tumours
Oculocutaneous tyrosinaemia	Richner–Hanhart	AR	Tyrosine aminotransferase		N	Corneal ulcers, painful keratoses, progressive mental impairment
Punctate group						
Punctate keratoderma*	Brauer–Buschke–Fischer	AD	8q24; 15q22	10–40	N	Possible association with malignancy in some families
Punctate keratoderma of palmar creases		AD	—	10–40	N	Palmar creases, sometimes marginal lesions
Marginal papular keratoderma	Costa/Dowd	AD	—	Childhood	N	Marginal crateriform papules with or without elastorrhexis
Papuloverrucous keratoderma	Touraine; Jakac–Wolf	AR	—	2–6	N	Follicular keratoses; dysplastic teeth

* These are pragmatic clinical groupings likely to encompass a variety of genetically distinct syndromes.
AD, autosomal dominant; AR, autosomal recessive.

molecular pathogenesis. Inherited keratodermas described in this chapter are outlined in Table 19.5, but many isolated reports of unusual or unique associations are necessarily excluded.

Keratodermas are often grouped by clinical pattern as diffuse, focal (areate), striate or punctate, but there are no absolute boundaries between these groupings. The presentation of a single disease may vary with site, age, gender or occupation. Plantar skin tends to be more severely or diffusely affected than palmar skin. In assessing an isolated case of keratoderma, it may be unwise to limit the differential diagnosis on the basis of distribution. However, the following definitions may offer some guidance. In *diffuse keratodermas*, the whole of the palmar or plantar epidermis, usually including the centripalmar skin and the instep, is abnormally but uniformly thickened. In *focal (or areate or nummular) keratoderma*, the areas of palmoplantar skin under most pressure are disproportionately thickened, for example at either end of the metatarsal arch, sides or tips of the toes, or margins of the heel. Focal lesions may be painful. *Striate keratoderma* overlaps clinically with focal keratoderma, but the lesions are conspicuously longitudinal, particularly on the fingers, where keratoderma overlies flexor tendons. *Punctate (papular or disseminated) keratoderma* consists of multiple scattered discrete round lesions, not bearing a consistent relationship to pressure points.

Transgredient keratoderma extends beyond palmoplantar skin, contiguously or as callosities on pressure points on the fingers or knuckles, or elsewhere. Confluent hyperkeratosis may extend round whole digits. *Cicatrizing keratodermas* (the term 'cicatrizing' is suggested in preference to the more emotive 'mutilating') are those in which constricting bands appear around digits, usually distal to proximal interphalangeal joints. Such constrictions ('pseudo-ainhum') are found in many severe transgredient keratodermas, and are not diagnostic of any one syndrome. *Hyperhidrosis* is also a commonly used descriptor, as many keratodermas, particularly on the feet, are spongy and malodorous. There may be a real increase in sweat excretion, but water retention by abnormally keratotic and porous stratum corneum also contributes to maceration and microbial overgrowth.

Diffuse keratodermas

Epidermolytic palmoplantar keratoderma (EPPK) (MIM 144200)

Synonym
- Vörner's keratoderma

Vörner described diffuse palmoplantar keratoderma with autosomal dominant inheritance, clinically indistinguishable from that

described by Thost and Unna but with histological features of EHK in affected palms and soles [1]. Thost's original family in fact had epidermolytic histology; indeed Vörner's is probably the most common form of diffuse keratoderma [2,3]. A prevalence of 4.4 per 100 000 was found in Northern Ireland [4].

Aetiology. Epidermolysis with tonofilament clumping suggested an intermediate filament defect, and the type I epithelial keratin 9 (K9), preferentially expressed in palmoplantar skin, was a strong candidate [5,6]. Linkage to the type I keratin gene cluster on chromosome 17 and many causative mutations in highly conserved regions of K9 have been demonstrated, including in Vörner's original pedigree [7–11]. Most mutations are in the helix initiation peptide, but a 3-bp insertion in the helix termination motif has also been identified [12]. Cases with transgredient lesions may be localized forms of epidermolytic hyperkeratosis due to mutation in keratin 1 (see Greither's syndrome, below). However, keratin 1 is a candidate even in localized EPPK [13]. EPPK resembling Vörner PPK but with unusual 'tonotubular' filaments on electron microscopy [14] is due to mutation in the 1B rod domain of keratin 1 [15]. In a pedigree with subconfluent diffuse keratoderma and only mild epidermolysis, a splice-site mutation causing insertion of 18 amino acids into the 2b domain of keratin 1 was identified [16]. Disruption of intermediate filament integrity consequent on these mutations is predicted to reduce the resilience of the cytoskeleton to minor external trauma, leading to blistering and hyperkeratosis. Possible autosomal recessive inheritance was reported in two children born to consanguineous parents [17].

Pathology. Histologically, Vörner's PPK shows epidermolytic change in suprabasal keratinocytes. Round or ovoid eosinophilic inclusions may be detected [18], with large tonofilament aggregates visible on electron microscopy. The morphological appearance of keratin filament bundles in palmoplantar epidermis is different from other epidermis, with thicker bundles in a distinct orientation, so care must be undertaken in the assessment of filament aggregation [8]. There are secondary changes in the expression of markers of cornified envelope formation [19].

Clinical features [1,20]. Diffuse keratoderma develops in infancy. In adults, there is confluent keratoderma, sparing dorsal surfaces, with a sharp demarcation and erythematous edge (Fig. 19.58). Blistering is not a major feature, but a history of blisters or fissuring of the palms may hint at reduced structural strength. Hair, teeth and nails are normal, but knuckle pads and nail changes were found in Vörner's original families [1], many of whom have K9 mutations. Families with associated cancer [21–22] are exceptional and probably coincidental.

Treatment. Response to oral retinoids is good, but excessive peeling may be a problem [23]. Topical calcipotriol has reportedly been helpful [24].

Non-epidermolytic palmoplantar keratoderma

Synonym
- Thost–Unna keratoderma

Thost and Unna separately described keratoderma characterized by even, thick, yellow hyperkeratosis over the whole palm and sole [1,2]. The eponym refers specifically to non-epidermolytic keratoderma, although the original Thost family is now known to have epidermolytic keratoderma [3]. It is inherited as an autosomal dominant disorder but may be genetically heterogeneous.

Aetiology. Studies of a family from Bothnia in northern Sweden and three English pedigrees showed linkage centromeric to the type 2 keratin gene cluster on chromosome 12 [4–6], but the cluster itself was excluded. In another family with diffuse PPK, a mutation occurred in a highly conserved lysine residue in the V1 domain of keratin 1 [7]. This residue is thought to be important in cross-linking in the cornified envelope formation [8].

Pathology. The histological changes are non-specific: orthokeratotic hyperkeratosis, hypergranulosis or normogranulosis and moderate acanthosis [2]. There is usually a mild perivascular infiltrate. A biopsy serves mainly to exclude epidermolytic keratoderma. Although vesiculation secondary to dermatophyte infection may be a confounding factor, the large Bothnian pedigree of diffuse PPK showed no evidence of true epidermolysis in 91 biopsies [9].

Clinical features [10,11]. The condition may present in the first few months of life and is usually obvious by the age of 4 years. It rarely appears in the third decade. An even, very thick, yellow hyperkeratosis occurs over the whole of the foot, starting on the heel and anterior arch, spreading later to the palms (Fig. 19.59). There is a sharp cut-off at the wrist, and no tendency to spread to the extensor surfaces. The margins show a livid red border, which can be seen also to underlie the hyperkeratosis. Hyperhidrosis is usual, and dermatophyte infections and pitted keratolysis are frequent. The nails are usually normal, but may be thickened without evidence of dystrophy. Hair and teeth are normal.

Treatment. Keratolytic therapy, such as 6% salicylic acid in white soft paraffin, or a gel of 6% salicylic acid in 70% propylene glycol may be used. Occlusion with polythene for a few nights enhanced the efficacy of these preparations. Benzoic acid compound ointment is mildly keratolytic, and is useful in reducing fungal and bacterial overgrowth. Topical retinoids have little effect. Acitretin may be effective for patients with marked functional impairment, but response is unpredictable and in some patients the loss of the thick keratin leaves the foot markedly hypersensitive. Response to erythromycin has been described in the Bothnian type [12].

Fig. 19.60 Loricrin keratoderma.

Transgredient keratodermas

Loricrin keratoderma (MIM 604117)

Synonyms
- Variant Vohwinkel's syndrome
- Mutilating keratoderma with ichthyosis
- Camisa's syndrome

In two related pedigrees, Camisa and Rossana delineated a diffuse transgredient honeycomb keratoderma with annular constrictions around digits, accompanied by a mild ichthyosis (Fig. 19.60) [1–3]. In true Vohwinkel's syndrome, there is impaired hearing but no generalized ichthyosis [4].

Aetiology. The disorder is caused by mutations in the gene encoding loricrin, a glycine-rich cornified envelope protein [3–7]. Several different single nucleotide insertions have been identified in this gene, but all shift the reading frame and lead to expression of an abnormal protein with a foreign, arginine-rich C-terminal peptide containing nuclear recognition signals [4]. The mutant protein is transported to the nucleus, where it can be identified from the upper spinous layer upwards, and is thought to interfere with regulation of cornification [8]. Direct or indirect consequences of causative mutations include an alteration on the cornified envelope scaffold, and defective barrier function [9]. Transgenic mice in whom loricrin has been knocked out are largely asymptomatic [10], but mice expressing a pathogenic loricrin mutation showed generalized scaling, thickened footpads and a constricting band causing autoamputation of the tail [11,12]. In one Japanese father and son, an insertion mutation in loricrin analogous to these producing keratoderma in other human pedigrees gave a phenotype resembling progressive symmetrical erythrokeratoderma [13].

Pathology. In addition to hyperkeratosis, nuclei may be retained in the stratum corneum [1]. Immunoelectron microscopy shows the presence of loricrin in these nuclei [3,4]. Camisa noted elevated serum levels of the lysosomal enzyme β-glucuronidase [2].

Clinical features [1–6]. The combination of honeycomb keratoderma with mild ichthyosis is typical [7]. Generalized desquamation may be noted at birth, and collodion babies are reported [6,7]. However, the ichthyosis is generally mild and may pass unnoticed. A rugose keratoderma develops during childhood, gradually extending to the confluent 'honeycomb' pattern. The edges of the keratoderma are diffuse (in contrast to true Vohwinkel's syndrome) and cicatricial bands (pseudo-ainhum) may develop around digits. Knuckle pads and warty keratoses have been reported, but are not a prominent feature. There are no consistent extracutaneous features.

Treatment. The successful use of isotretinoin has been reported [1] and acitretin also promotes desquamation.

Autosomal dominant transgredient keratoderma

Transgredient autosomal dominant keratodermas are distinguished by involvement of the extensor surfaces of hands, knees and elbows, including overlying the Achilles tendon.

Greither's syndrome (palmoplantar keratoderma transgrediens et progrediens). Greither described a syndrome with gradual onset

and a tendency to improve in the fifth decade [1], but cases reported under this eponym are likely to be genetically heterogeneous [2]. There is clinical overlap with erythrokeratoderma [3]. One pedigree mapped to chromosome 1p [4], but this was not confirmed in another family [5]. The changes on light microscopy are non-specific [6] but Beylot-Barry *et al.* [7] found tonofilament aggregates, numerous desmosomes and abnormal cell–cell junctions on electron microscopy. Two unrelated British pedigrees had an identical keratin 1 mutation, N188S [8], and represent a localized form of epidermolytic hyperkeratosis.

Clinical features. Onset of Greither's syndrome is at 8–10 years old, and it may improve with age. There is diffuse but transgredient hyperkeratosis with patchy lesions of knees and elbows. Erythema at the margins and hyperhidrosis may be present. Some patients experience Raynaud-like vasomotor disturbances.

Sybert's keratoderma. A more severe transgredient keratoderma reported by Sybert *et al.* [9] resembled mal de Meleda but had dominant inheritance. Onset was earlier than in Greither's syndrome. Glove and stocking hyperkeratosis, including autoamputation of toes, extended also to the elbows, knees, posterior aspects of the forearms, shins, groins and natal cleft. Histologically, excessive accumulation of lipid-laden cells was seen in stratum corneum. Electron microscopy showed keratohyalin granules that were abnormal in distribution and structure. Abnormal filaggrin staining suggested that the association of filaggrin and keratin filaments in the stratum corneum was disturbed. Isotretinoin was used with benefit.

Other transgredient keratodermas. Magro *et al.* [10] reported several cases with a milder phenotype clinically resembling that of Sybert, but characterized ultrastructurally by perinuclear accumulations of ribosomes and abnormal keratohyaline granules. In one case, a father and child were affected. The histological features were felt to resemble ichthyosis hystrix (IH) of the Curth–Macklin type. Sprecher *et al.* [11] described an African American family with a more severe, dominant disorder of keratinization diagnosed as Curth–Macklin IH. The main feature was a gross palmoplantar hyperkeratosis, with cobbled papular hyperkeratoses mainly over extensor surfaces. Ultrastructural studies showed retraction of the cytoskeleton to the nucleus and failure of loricrin transport to the cell membrane. They identified a causative frameshift mutation in the V2 domain of Keratin 1 [11]. Linkage to keratin gene clusters was excluded in another family with IH Curth–Macklin [12].

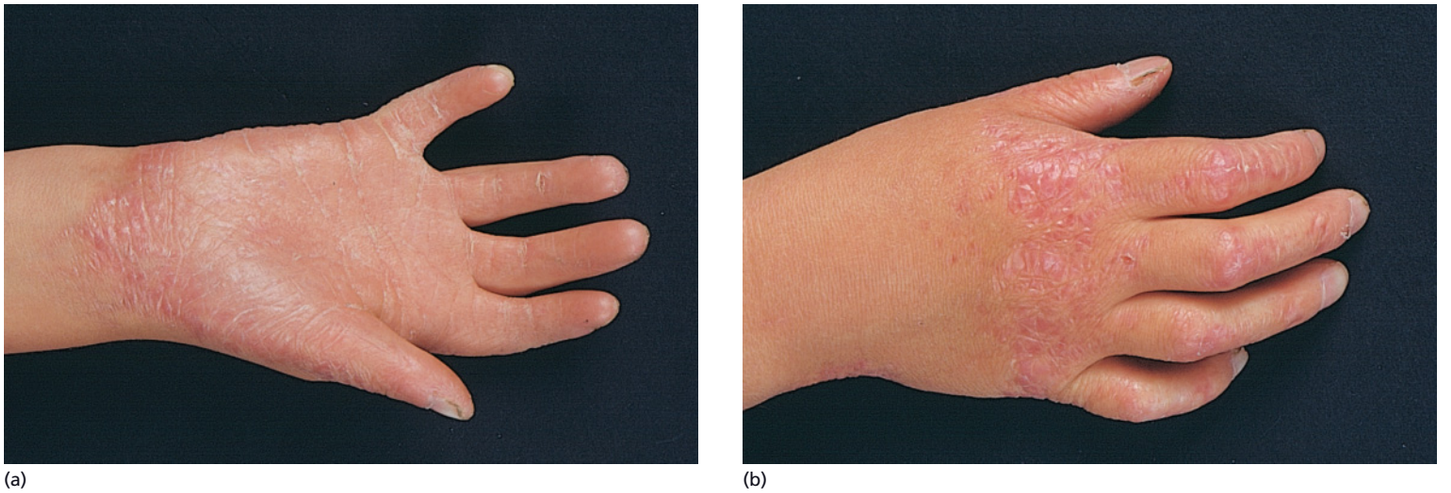
Keratoderma with scleroatrophy (MIM 181600)



Synonym
- Huriez syndrome

This rare autosomal dominant transgredient keratoderma, first reported in three Franco-Belgian families, is characterized by scleroatrophy of the fingers and a high frequency of squamous carcinomas in affected skin [1–4]. The causative gene maps to chromosome 4q23, but has not been identified [5]. Excision repair of UV damage to lymphocytes was normal [6].

Pathology [6]. Acanthosis with an accentuated granular layer and orthohyperkeratosis were seen in thickened skin. On electron microscopy, dense bundles of tonofilaments were seen in all epidermal layers. The granular layer showed large, coarse, clumped keratohyalin. In the scleroatrophic area, similar changes were seen, with the addition of thinning of the elastic fibres, which on electron microscopy had irregular borders and looked non-homogeneous. There is a reduction in Langerhans' cells in affected palmar epidermis [3,7].

Clinical features [1–4,6,7]. Palms are more often affected than the soles, the keratoderma lacks an underlying erythema, and dermatoglyphics are often absent (Fig. 19.61a). Atrophic parchment-like skin over the dorsal surface of the hands, associated with diffuse keratoderma, is present from birth (Fig. 19.61b). Dense hyperkeratosis gives a pseudosclerodermatous appearance with nail atrophy. Nail changes include hypercurvature, longitudinal ridging, onychorrhexis and koilonychia. Squamous cell carcinomas of the affected skin developed in six cases, and internal malignancy was the cause of death in six out of 33 deaths in the original report. One of the original families was re-examined and reported in 1995 [6]. Only two of the 23 deaths in the family resulted from internal malignancy.

Other scleroatrophic keratodermas. Pujol *et al.* [8] and Vahlquist *et al.* [9] reported cases of sclerosing keratoderma associated with ichthyosis, and bizarre striate keratoses of the flexures. Inheritance

(a) (b)

Fig. 19.61 Huriez syndrome: (a) keratoderma; and (b) atrophy skin over dorsa of hand and sclerodactyly. (Courtesy of Dr M. van Steensel, Department of Dermatology, University of Maastricht, the Netherlands.)

appears to be autosomal recessive. A scleroatrophic keratoderma has been reported in association with sex reversal in a 46,XX subject with a male phenotype [10].

Mal de Meleda (MIM 248300)

Synonyms
- Keratoderma palmoplantaris transgrediens
- Acroerythrokeratoderma

Mal de Meleda is a rare autosomal recessive transgredient keratoderma named after the Croatian island of Meleda (Mljet) where it was first identified [1,2], but it has been reported widely in the Mediterranean littoral. Maritime dissemination is inferred.

Aetiology. Mal de Meleda is caused by homozygous mutation in the *ARS* (component B) gene, encoding SLURP-1 (secreted Ly-6/uPAR related protein 1) [3–6]. Almost all cases occur in consanguineous pedigrees and families from Croatia (including Meleda), Algeria and Tunisia share very few ancestral haplotypes [3,6,7], indicating founder mutations. SLURP-1 is a member of a superfamily of secreted and receptor proteins implicated in transmembrane signal transduction, cell activation and cell adhesion, which has homologues to reptilian and amphibian toxins. The gene is expressed late in epidermal differentiation, in the granular layer, and particularly in association with the acrosyringium [8]. SLURP-1 modulates the effects of acetylcholine on the keratinocyte α7 nicotinic ACh receptor [9], and regulates keratinocyte differentiation and apoptosis [10].

Pathology. There is a greatly thickened corneal layer, increased stratum lucidum, with marked acanthosis, pseudospongiosis, and a prominent perivascular lymphohistiocytic infiltrate. Sweat glands are enlarged. Electron microscopy showed a less abrupt than normal transition from stratum granulosum to stratum corneum [11].

Clinical features [2,12–14]. Onset is in early childhood, and the development of hyperkeratosis is preceded by erythema. Patches of waxy ivory–yellow hyperkeratosis (Fig. 19.62) extend across the whole palms and soles, and on to the dorsal surfaces of hands and feet. Similar lesions of knees and elbows may develop. The erythematous component often persists in central palms and soles, with hyperhidrotic maceration and malodour. Fungal superinfection is common and should be excluded [13]. Circumferential hyperkeratosis of fingers may lead to sclerodactyly and digital constrictions; nail changes include hypercurvature, thickening and koilonychia [13–14]. Angular cheilitis is common. Melanoma arising within affected skin has been reported (reviewed in [15]). There is clinical overlap with Olmsted's syndrome, keratosis lichenoides chronica striata and progressive symmetrical erythro-

Fig. 19.62 Mal de Meleda.

keratoderma [3,12]. Heterozygous female carriers may have a mild clinical phenotype [16].

Treatment. Oral retinoids are effective but the hyperkeratosis may respond better than the erythema [17–21].

Other autosomal recessive transgredient keratodermas. Other pedigrees of autosomal recessive transgredient PPKs, such as the mutilating keratoderma with knuckle pads identified by Gamborg-Nielsen [22,23], and the transgredient PPK in Japan first reported by Nakajima [24]. Some such cases may prove to be related to mal de Meleda, but multiple disease entities are likely and linkage to the *SLURP-1* locus, or mutations of the ARS coding sequence, have not been found in pedigrees with this phenotype [24–27]. In Japanese siblings with a severe recessive transgredient keratoderma Akiyama *et al.* [28] excluded linkage to the epidermal differentiation complex.

Congenital palmoplantar and perioral keratoderma

Synonym
- Olmsted's syndrome

This rare and severe cicatrizing transgredient keratoderma associated with periorificial lesions [1–5] has been reviewed [6,7]. Most cases are sporadic, but there is occasional familial occurrence. Pathogenesis is unknown, but there is cytochemical evidence of hyperproliferation of the epidermis [8,9]. Onset is in the first year of life, with symmetrical, sharply defined palmar and plantar keratoderma surrounded by erythema, and flexion deformities, constriction or spontaneous amputation of the digits (Fig. 19.63a). Other abnormalities include periorificial erythema and warty hyperkeratosis (Fig. 19.63b) and linear keratoses on the flexor forearms [3,4]. Alopecia, nail and tooth anomalies and joint laxity

(a) (b)

Fig. 19.63 Olmsted's syndrome: (a) gross keratoderma with striate features; and (b) periorificial hyperkeratosis. (Courtesy of Professor R.K. Winkelmann, Mayo Clinic, Scottsdale, AZ, USA.)

and corneal dystrophy have been reported [10], and squamous carcinoma is reported. The condition can be confused with acrodermatitis enteropathica, hidrotic ectodermal dysplasia of the Clouston type, mal de Meleda and Vohwinkel's keratoderma. Etretinate has been used in several cases with variable effect [11,12]. Topical tretinoin slightly improved the keratosis but proved irritant in one case [13].

Focal keratodermas

Synonyms
- Wachters' keratoderma
- Palmoplantar keratoderma varians

Focal, areate or nummular, and linear or striate keratodermas have been distinguished. The occurrence of both areate and striate forms within a family led Wachters [1] to suggest a single entity, keratoderma varians. Although focal and striate may coexist (Fig. 19.64), several distinct disorders can now be discriminated clinically and genetically. The pattern and severity depends on both the underlying defect and environmental factors, such as the stresses on the tissue. Blisters may be a feature [2]. Striate forms are particularly but not uniquely associated with desmosomal defects (see below). Focal keratoderma may also be associated with other cutaneous or ectodermal disorders, including Dowling–Meara epidermolysis bullosa simplex, or with disease in other systems. Focal keratoderma with oesophageal carcinoma (Howel-Evans' syndrome) and keratodermas with deafness are described separately.

Painful hereditary callosities [2–5]. Plantar callosities of sufficient size are inevitably painful, and the term is probably non-specific. Painful callosities are a feature of conditions corresponding to keratoderma nummularis of Brunauer and Fuhs and keratoderma areata of Siemens, but also pachyonychia congenita and type II oculocutaneous tyrosinaemia (Richner–Hanhart syndrome); reported cases with blisters and tonofilament clumping [2] are likely be an epidermolytic disorder.

Focal keratoderma with oral leukokeratosis (MIM 600962)

Focal non-epidermolytic keratoderma, inherited as an autosomal dominant trait, may be associated with white plaques on the sides of the tongue and buccal mucosa. This syndrome is clinically and genetically a mild variant of pachyonychia congenita; subtle associated nail changes include splinter haemorrhages and a widening of the onychocorneal band, and causative mutations in the helix initiation motif region of keratin 16 have been identified [1]. Kolde *et al*. reported a family with focal epidermolytic PPK and gingival keratoses not mapping to keratin or TOC loci [2]. An isolated patient with leukoplakia and florid oral papillomatosis, and keratoderma without nail changes has been recorded [3]. Oral lesions without nail changes are also seen in Howel-Evans' syndrome [4].

Pachyonychia congenita

Synonyms
- Jadassohn–Lewandowsky syndrome
- Jackson–Lawler syndrome

Pachyonychia congenita (PC) is characterized by subungual hyperkeratosis of the distal nails and focal palmoplantar hyperkeratosis. A large number of associations have been reported [1], but only the simplest clinical classification into PC-1 (Jadassohn–Lewandowsky) and PC-2 (Jackson–Lawler) syndromes is borne out genetically [2].

Aetiology. Autosomal dominant inheritance is usual, but a recessive form is reported [3]. Tonofilament aggregates seen on electron microscopy suggest an intermediate filament disorder [4,5]. The distribution of lesions in PC-1 corresponds to the expression patterns of keratins K6a and K16, and a wide variety of causative mutations have been found in these genes [5–10]. By contrast, K17 is constitutively expressed in the pilosebaceous unit and basal appendage keratinocytes, with lesser basal expression in palmoplantar skin and a number of other minor epithelial populations, but not in mucosae [11–13]. Point mutations in the K17 gene and occasionally in K6b isoform of keratin 6 have been found in many families with PC-2 [2,9,10,13]. Identical mutations may also present as isolated steatocystoma multiplex with or without mild nail changes [14]. The prominent nail involvement of pachyonychia

reflects the expression of these keratins in the ventral nail [15,16].

Pathology. Palmoplantar epidermis shows gross hyperkeratosis with alternating ortho- and parakeratosis. Acanthosis is present with patchy hypergranulosis, in which large and misformed keratohyalin granules are present, but there is no gross epidermolysis [4]. In PC-2, the cysts may be keratinous epidermoid cysts, eruptive vellus hair cysts or true steatocysts. Different histologies may be seen within a family, an individual, or even a single cyst.

Clinical features [1,17–19]. A comprehensive analysis of clinical features is given by Leachman [19]. Hyperkeratosis of the nail bed appears in the first year or two of life, followed by focal thickening of palms and soles. Late onset PC has been termed pachyonychia congenita tarda [20,21]. Frictional blisters may occur on the feet, especially in hot weather in childhood. In adults, focal hyperkeratosis may produce marked pain on walking. Severity varies, even within families. The mildest nail changes are similar to those seen in focal keratoderma with oral leukokeratosis, with which PC-1 is allelic.

PC-1 (Jadassohn–Lewandowsky type; MIM 167200). Thick yellow keratoses are found on sites of pressure (Fig. 19.65a), associated with wedge-like thickening of distal finger- and toenails (Fig. 19.65b), keratosis pilaris and follicular keratoses on the knees and elbows. Patchy white thickened areas are seen on the tongue and oral mucosa (oral leukokeratosis). Severe oral lesions resemble candidiasis [22]. Laryngeal involvement may produce hoarseness and in infancy even fatal respiratory obstruction [23]. Squamous carcinoma has been reported in a persistently ulcerated area [17].

PC-2 (Jackson–Lawler type; MIM 167210). Findings are similar to PC-1 but palmoplantar keratoses are possibly less severe. Despite the absence of mucosal lesions, hoarseness is a feature. This variant was first described by Murray, who noted a history of teeth present at birth in many cases [24]; in this family, adult dentition is also affected [25]. Unruly hair and milia may be seen in infancy, and adults have protuberant eyebrows. Multiple epidermal cysts appearing after puberty include both epidermoid and steatocysts. Axillary cysts may mimic hidradenitis suppurativa [26]; extensive and infected vulval, scrotal or scalp cysts also cause significant disability for some patients. Within families, some patients may have only nail changes and some only cysts.

Other clinical variants. Feinstein *et al.* [1] reviewed the many reported associations, although many are coincidental. Thickening of the nails may occur in a variety of ectodermal dystrophies and some suggested PC variants may merit further genetic study. Involvement of the nails alone has been reported [27,28]. Heterozygous missense mutations in the connexin 30 gene, normally associated with Clouston's syndrome (see below), have been identified in a number of families with pachyonychia-like nail changes and no other phenotype [29]. Schafer [30] reported corneal leukokeratosis; Buckley and Cassuto [31] and Tidman *et al.* [32] flexural pigmentation and amyloid.

(a)

(b)

Fig. 19.65 Pachyonychia congenita: (a) keratoderma on weight-bearing areas; and (b) typical wedge-shaped nail.

Treatment [33]. Emollients and keratolytics may help keratoderma in milder cases, and attention to footwear may reduce blistering and callosities. Mechanical reduction of hyperkeratosis and of nails produces symptomatic benefit. Acitretin 25–35 mg/day make the keratin more flexible and less pronounced without complete clearing [34,35], but treatment is often unsatisfactory due to increased tenderness [4]. Retinoids produce a degree of flattening of the nails if given for prolonged periods. Treatment of hyperhidrosis may reduce blistering [36] and the use of botulinum toxin under regional analgesia provided pain relief for several months in three patients with PC [37]. The use of small interfering RNAs (siRNA) to regulate keratin expression is being explored [38].

Striate keratoderma (MIM 148700)

Synonym
- Brunauer–Fuhs–Siemens

Striate keratoderma in isolation, usually inherited as an autosomal dominant trait, can be caused by defects in at least three different genes [1].

Aetiology. Autosomal dominant striate keratoderma was mapped to the desmosomal cadherin cluster on 18q12.1 [2]. Mutations causing haploinsufficiency have been identified in the desmoglein 1 gene (*Dsg1*) [3,4]. In another pedigree Armstrong *et al.* [5] had found linkage to 6p21 and identified a heterozygous nonsense mutation in the desmoplakin (*Dp*) gene. Other nonsense mutations in desmoplakin also produce the phenotype, again due to haploinsufficiency [6]. Compound heterozygosity for nonsense and missense mutations in desmoplakin were found in two patients with keratoderma, skin fragility and woolly hair [7]. Other mutations in desmoplakin cause recessive and dominant cardiomyopathy with or without keratoderma (see p. 19.107). The majority of mutations in striate keratoderma are in *Dsg1* or *Dp1* [1], but two pedigrees had frameshift mutations in the V2 tail domain of keratin 1 which may be important in cross-linking to cornified envelope proteins [8].

Pathology. Electron microscopy of involved skin in patients with keratoderma associated with Dp mutations showed abnormal bunching of keratin filaments and reduction in the peripheral keratin network, with loss of connections with desmosomes [5]. Wan and colleagues [9] found differences between lesions of *Dsg1*- and *Dp*-associated PPKs. Desmosome number was reduced in both but desmosome size was reduced only in the former, and reduced expression of other plaque components and keratins K5, K14 and K10 was more marked. Perinuclear aggregation of keratin filaments was more marked in *Dp*-associated disease [9].

Clinical features. As the name implies, there is a linear pattern of skin thickening on the palms and flexor aspects of the fingers (Fig. 19.64b). However, lesions on the soles may be more areate or

confluent, and striate lesions can be seen in affected members of pedigrees in which other patterns of keratoderma predominate. The presence of other features, especially woolly hair, should be specifically sought, and the possibility of cardiac disease considered.

Hidrotic ectodermal dysplasia (MIM 129500) [1]

Synonym
- Clouston's syndrome

This autosomal dominant ectodermal dysplasia, characterized by dystrophic nails and sparse hair, and caused by mutations in the gap junction beta-6 gene encoding connexin 30 [2–4], is described in Chapter 15. It is mentioned here because a papillomatous and fissured transgredient keratoderma is a significant feature, and the presentation may resemble pachyonychia congenita [2].

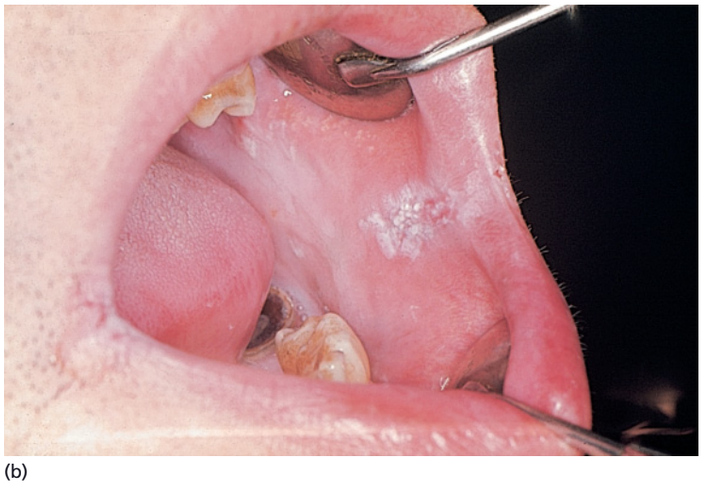
Keratodermas with extracutaneous features

Extracutaneous features in cases of hereditary keratoderma are often reported. Unusual associations with well-recognized syndromes may be coincidental, and in isolated cases it is rarely possible to establish their significance. Readily recognizable or clinically important syndromes are described below.

Keratoderma with oesophageal carcinoma (MIM 148700)

Synonyms
- Howel-Evans' syndrome
- Tylosis with oesophageal cancer



Howel-Evans described two families of autosomal dominant keratoderma associated with later development of oesophageal cancer [1]. The term tylosis, originally synonymous with (diffuse) keratoderma, is now particularly associated with this syndrome, and to avoid unnecessary anxiety is probably better avoided for other keratodermas. Clinical reappraisal has shown that TOC (tylosis with oesophageal cancer) should be considered a focal PPK, as the lesions predominantly affect pressure points of the sole (Fig. 19.66a), and less so the palm [2,3]. There is variable oral leukokeratosis (Fig. 19.66b) and follicular prominence, but the disorder can be distinguished from PC type 1 by the absence of even mild nail changes [3]. Thirty-seven per cent of the original affected family members developed oesophageal cancer 30–40 years later. A further, extensive German American family has been reported, also with an increased (38-fold) risk of oesophageal cancer [3]. The disorder maps to a 42.5-kB segment of chromosome 17q23 [3–7]. The region is commonly deleted in oesophageal carcinomas [8], implying a tumour suppressor gene. Only three genes are present in the minimal region, amongst which both alleles of the cytoglobin gene were downregulated in oesophageal biopsies from the disorder by an undetermined mechanism [9,10].

Keratoderma, woolly hair and cardiac disease

The occurrence of congenital heart disease in patients with keratoderma has been reviewed [1]. The possibility of cardiomyopathy or conduction disorders should be particularly considered in patients with keratoderma and woolly hair. Defects in proteins of the desmosomal plaque are common to the two clearly identified genetic syndromes.

Naxos disease (MIM 601214). An autosomal recessive syndrome of arrhythmogenic right ventricular cardiomyopathy, keratoderma and woolly hair was reported in seven pedigrees from the Greek island of Naxos [2,3]. These families have been found to share a 2-bp deletion causing premature termination in the gene encoding plakoglobin [4], a cell junction protein found in association with desmosomes in the epidermis and in striated and cardiac muscle. Homozygous but not heterozygous individuals show an increased incidence of arrhythmias, cardiac failure or sudden death [5]. A similar autosomal dominant syndrome has been reported [6]. The association may be genetically heterogeneous [7].

Keratoderma, woolly hair and dilated cardiomyopathy (Carvajal syndrome; MIM 605676). Three Equadorian pedigrees displayed recessive inheritance of a striate keratoderma and woolly hair associated with dilated left ventricular cardiomyopathy developing in teenage years. Histology of keratoderma showed wide intercellular spaces, clustering of desmosomes and a collapsed intermediate filament network [8]. Affected cases were all homozygous for a deletion mutation producing a premature stop codon in the tail of the desmoplakin gene [9].

Dominant mutations in desmoplakin have also been reported, causing woolly hair, striate PPK and biventricular cardiomyopathy [10] or arrhythmogenic right ventricular cardiomyopathy without cutaneous phenotype [11]. Skin fragility and woolly hair resulting from compound heterozygosity for nonsense and missense mutations in desmoplakin are also reported [12]. Compound heterozygosity causing loss of the tail domain of desmoplakin presented as lethal acantholytic epidermolysis bullosa [13].

Keratoderma and hearing impairment (MIM 148350)

The association of disordered keratinization with impaired hearing is most commonly caused by defects in genes encoding members of the connexin family of gap junction proteins [1], but mitochondrial defects may also be responsible [2].

Keratoderma and prelingual deafness. Premature termination codons in connexin 26 are the single most common cause of non-syndromic autosomal recessive deafness [1,3–5]. Connexin 26 is expressed in the cochlea where it may permit the recycling of potassium to endolymph [5]. In skin, connexin 26 is found in palmoplantar epidermis and sweat glands, and is up-regulated in conditions such as psoriasis [6,7], but patients homozygous for mutations preventing any expression of connexin 26 have no discernible cutaneous phenotype. However, in several pedigrees with diffuse or transgredient autosomal dominant keratoderma and varying degrees of prelingual deafness, missense mutations in connexin 26 have been found [8–12]. Other mutations in connexin 26 cause cicatrizing keratoderma with impaired hearing (Vohwinkel's syndrome; see below), keratoderma with knuckle pads (Bart–Pumphrey syndrome; see below) and KID syndrome [13,14]. Mutations that cause skin disease may exert a transdominant effect, disrupting gap junction communication by interfering with the function of other epidermal connexins [10].

Cicatrizing keratoderma with hearing impairment (MIM 124500)

Synonyms
- Keratoma hereditarum mutilans
- Vohwinkel's syndrome

Vohwinkel [1] and Wigley [2] independently reported honeycomb-like keratoderma associated with stellate keratoses on the knuckles and the formation of circumferential bands around digits ('pseudo-ainhum'). Vohwinkel's family also had moderate sensorineural deafness [3], and subsequent cases have confirmed autosomal dominant inheritance [4–7].

Aetiology. In three unrelated English, Spanish and Italian pedigrees with true Vohwinkel's syndrome, Maestrini *et al.* [8] found the same mutation, D66H, in the gap junction beta-2 gene encoding connexin 26. This mutation was also found in another English family [9]. Other mutations in the same gene cause KID syndrome or keratoderma with prelingual deafness (see above). The probable mechanism, transdominant inhibition of gap junction function, can be reproduced *in vitro* [10], but expression of mutant Cx26 in transgenic mice resulted in cytoplasmic accumulation of Cx26 and Cx30, with reduced expression at intercellular junctions [11]. The reason for the less profound deafness but more severe cutaneous phenotype with this specific mutation is not understood.

Clinical features [1–8,12]. PPK begins in childhood as shiny or translucent papular hyperkeratosis, gradually becoming confluent on hands and feet. Striate lesions may be seen in some individuals. Warty papules on the knuckles and other extensor sites coalesce into the pathognomonic 'starfish' keratoses (Fig. 19.67a). The edge of the keratoderma at the wrists and Achilles tendon consists of spiky digitate hyperkeratotic projections onto normal skin, sometimes showing koebnerization. This contrasts with the diffuse edge seen in loricrin keratoderma [12]. Multiple keratoses on digits produce circumferential hyperkeratosis, which predisposes to the formation of cicatricial bands (Fig. 19.67b) and autoamputation. The little finger and fifth toe are most commonly affected. A high-tone sensorineural hearing loss [6] is probably present from birth, but is relatively subtle and may escape detection in childhood unless specifically sought. It does not appear to be progressive. A reported association with craniofacial anomalies [13] proved coincidental [8].

Treatment. Vohwinkel's syndrome has been successfully treated by etretinate [7] and the cicatricial bands released surgically [14].

Bart–Pumphrey syndrome (MIM 149200). This is an autosomal dominant condition associating knuckle pads (similar to the focal keratoses of Vohwinkel's syndrome), keratoderma, leukonychia

(a) (b)

Fig. 19.67 Cicatrizing keratoderma with deafness: (a) 'starfish' lesions; and (b) pseudo-ainhum.

and mixed sensorineural and conductive deafness [15] due to specific mutations in connexin 26 [16,17].

Keratoderma with hearing impairment caused by mitochondrial mutation (MIM 590080)

In a Scottish family, Reid *et al.* [1] reported familial progressive post-lingual deafness caused by specific mutation in mitochondrial DNA, encoding both a serine transfer RNA and the first subunit of cytochrome oxidase [2]. The same point mutation (A7445G) was identified in a New Zealand family who also had keratoderma, and in a previously reported Japanese pedigree of keratoderma and deafness [3,4]. The original Scottish family also has a variable plantar keratoderma (Fig. 19.68). Further pedigrees of this association have been reported [2,5–6].

Keratoderma with neuropathy

Various reports associate neuropathy or spastic paralysis with keratoderma. These include striate keratoderma with spastic paraplegia, pes cavus and mental retardation in four brothers [1]; autosomal dominant punctate keratoderma and spastic paralysis [2]; autosomal dominant focal keratoderma with nail dystrophy and motor and sensory neuropathy [3]; and Charcot–Marie–Tooth disease [4]. Atypical erythrokeratoderma with deafness has also been associated with peripheral neuropathy [5]. Connexin genes seem good candidates for causative mutations [6]. In two families with a complex recessive disorder including cerebral dysgenesis and neuropathy as well as ichthyosis and keratoderma, Sprecher *et al.* identified deletions in *SNAP29*, encoding a protein involved in membrane fusion [7].

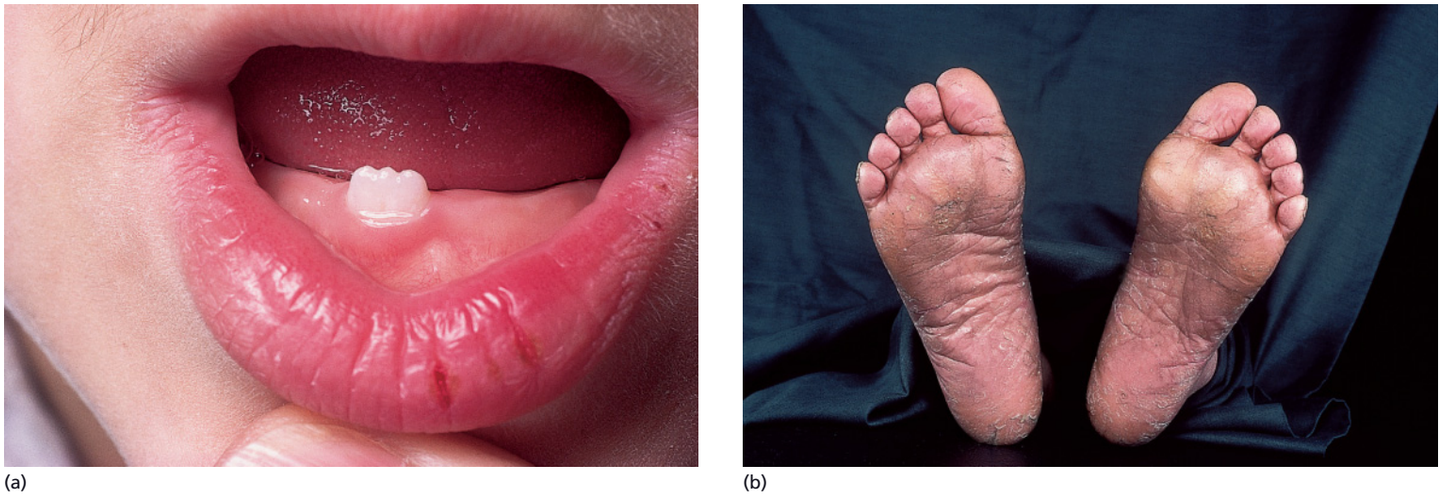
Keratoderma with periodontitis (MIM 245000)

Synonym
- Papillon–Léfèvre syndrome

In this syndrome, redness and thickening of the palms and soles is associated with periodontosis and frequent pyogenic skin infections. The prevalence has been estimated as 1–4 in 1 million [1].

Aetiology. Neutrophil phagocytosis and reactivity to T- and B-cell mitogens are impaired [2–4]. Inheritance is recessive, and the condition is caused by homozygous mutations in the gene encoding the lysosomal protease cathepsin C [5]. This finding explains the predisposition to pyogenic infection, but the mechanism of keratoderma is not established.

Pathology. Histopathological changes are non-specific, but show hyperkeratosis with irregular parakeratosis and a moderate perivascular infiltrate [6]. Electron microscopic findings include lipid-like vacuoles in the corneocytes and granulocytes, reduction in tonofilaments and irregular keratohyalin granules. These changes improve during retinoid therapy [7].



Clinical features [8,9]. Periodontosis resulting in severe gingivitis (Fig. 19.69a) in children leads to the loss of deciduous teeth by the age of 4–5 years unless treated; permanent teeth may be lost in the same fashion. Transgredient palmoplantar keratoderma, preceded by erythema, appears in the first year of life (Fig. 19.69b), and spreads to dorsal surfaces and up the Achilles tendon. Psoriasiform plaques on the knees and elbows may be present, but in a survey of 47 patients cutaneous involvement was not related to the severity of periodontal disease and did not correlate with age [9]. Virulent Gram-negative organisms invade the alveolar socket, usually including *Actinobacillus actinomycetemcomitans* [10–12]. Frequent pyogenic infections of the skin and internal organs occur. Associated hyperhidrosis causes an unpleasant odour [13]. The hair is usually normal but may be sparse [14]. Dural calcification, especially in the attachment of the tentorium and choroid, has been noted in some cases. Malignant melanoma has been reported as a complication [15].

Haim–Munk syndrome (MIM 245010). This variant syndrome combines the features of Papillon–Léfèvre syndrome with onychogryphosis, arachnodactyly and acro-osteolysis [16,17]. The syndrome is allelic with Papillon–Léfèvre syndrome, and all reported cases may be members of a single family of Cochin Jews [18]. Van Steensel *et al.* [19] reported a mother and daughter with a syndrome resembling Haim–Munk syndrome, but with hypotrichosis and an unusual linear and reticulate keratoderma, apparently not caused by mutations in cathepsin C.

Treatment. Etretinate [14,20,21], isotretinoin [22] and acitretin [7] have all been successful in improving the keratoderma, in combination with antibiotics and dental care lessening the gingival inflammation and saving the teeth [23,24].

Schöpf–Schulz–Passarge syndrome (MIM 224750)

Synonyms
- Keratoderma with eyelid cysts
- Hypodontia and hypotrichosis

In this rare autosomal recessive syndrome, diffuse palmoplantar keratoderma is associated with hypotrichosis, nail fragility and early loss of deciduous teeth [1,2]. Hydrocystomas of the eyelids but also follicular and other adnexal tumours occur in older patients [3–5].

Oculocutaneous tyrosinaemia (MIM 276600) [1–5]

Synonyms
- Tyrosinaemia type II
- Tyrosine transaminase deficiency
- Richner–Hanhart syndrome

Tyrosine aminotransferase deficiency causes palmoplantar keratoderma, dendritic corneal ulcers and progressive mental impairment.

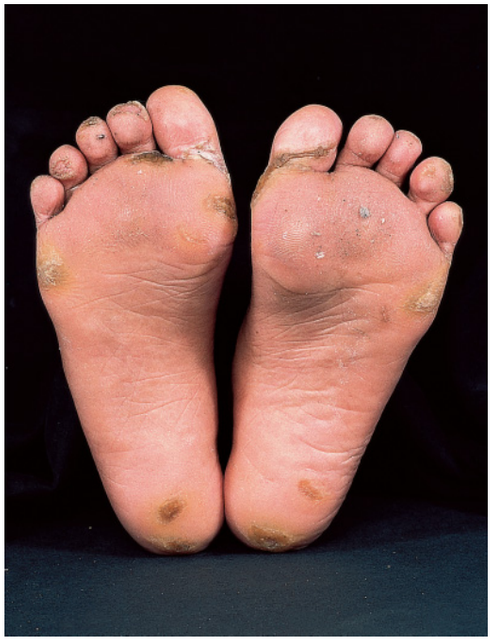

Fig. 19.70 Oculocutaneous tyrosinaemia (Richner–Hanhart syndrome). Callosity-like hyperkeratoses.

Aetiology. This autosomal recessive condition is caused by homozygous defects of the tyrosine aminotransferase gene at 16q21.1–q22.3 [6]. Deficiency of the enzyme leads to increased levels of serum tyrosine and aminoaciduria [6–8].

Pathology. Biopsy shows acanthosis with hyperkeratosis and hypergranulosis. At ultrastructural level, the keratinocytes contain clumped tonofilaments with adherent globoid keratohyalin granules resembling 'dew drops on a blade of grass' [9].

Clinical features (Fig. 19.70). In the first year of life, photophobia and corneal ulcers occur, and the diagnosis may be made by slit-lamp examination showing tyrosine crystals in ocular lesions [10]. Corneal lesions may be misdiagnosed as herpes simplex keratitis [11]. A year or two later, erythematous areas appear on the pressure-bearing areas of the soles, followed by painful circumscribed hyperkeratoses, making the child walk on the toes. In incomplete forms keratoderma may be the presenting feature [12] although conversely keratoderma may be delayed until the second decade [13]. The keratoses vary from gross keratoderma to dry lamellar patches. Bullous lesions and hyperhidrosis are sometimes seen. Unless correctly treated, behavioural problems arise within a few years and progressively worsen, ending in inanition or death. Chitayat *et al.* [14] reported two siblings with tyrosinaemia, only one of whom showed signs of the Richner–Hanhart syndrome.

Treatment. Early institution of a diet low in phenylalanine and tyrosine causes prompt resolution of the ocular and cutaneous symptoms and prevents the development of mental disorder [4,8,15–17].

Punctate and porokeratotic keratodermas (MIM 148600)

Synonym

- Brauer–Buschke–Fischer keratoderma

Punctate keratodermas differ from focal ones in showing a random distribution of small rounded papular lesions, but clinical differentiation is not always possible. The various terms used for morphological patterns of punctate keratoderma—keratoma dissipatum; keratoderma punctata, papulosa; disseminated clavus; papulotranslucent acrokeratoderma—probably do not justify distinction [1]. Excepting pedigrees with parakeratotic histology, the delineation of entities is uncertain.

Punctate keratoderma [1–4]. This autosomal dominant condition has a much later onset than other hereditary keratodermas, with lesions appearing in the second or third decades or later. Loci at 15q22–15q22.31 [5,6] and 8q24.13–8q24.21 [7] are reported. Occasional reports of punctate PPK with macular pigmentation [8,9]

suggest a mechanistic relationship with chronic arsenicism. Pinpoint, hard keratotic papules, initially translucent but later opaque and warty, appear on the palms and soles (Fig. 19.71). In many families, small and large lesions coexist, including broader focal plantar callosities. Lesions are more florid in manual workers. There is no hyperhidrosis. In most cases, punctate lesions are orthokeratotic on histology. Multiple associations of punctate keratoderma have been described, including association with diverse Lynch type II malignancies [10–12]. Topical retinoids and calcipotriol have only a slight effect on softening the keratoses but may be tried. Results with systemic retinoids are better but variable. Etretinate 0.5–1 mg/kg/day produced good results in three patients, moderate in four and no effect in two patients [13]; acitretin was rapidly effective in another case [14]. Intravenous infusion of 5-fluorouracil produced sustained benefit in a father and son with punctate PPK [15].

The terms punctate PPK type II (MIM 175860) or porokeratosis of Mantoux have been used for cases with parakeratotic histology, but the parakeratosis is columnar rather than lamellar and the suggestion of a relationship to porokeratosis [16] is probably misleading. It has been reported that these lesions fluoresce under Wood's light [17]. Some pedigrees show crateriform lesions or keratoses that can be picked out; histology of these lesions shows parakeratosis [10,16]. A linear distribution of punctate lesions is seen in porokeratotic eccrine ostial and dermal duct naevus (see Chapter 18).

Punctate keratoses of the palmar creases [18–20] is characterized by hard warty lesions of the finger and palmar creases (Fig. 19.72a), often with a clavus-like lesion at the medial border of the distal palmar crease. The absence of marginal lesions distinguishes this entity from marginal papular acrokeratodermas. It is inherited as an autosomal dominant trait and has been reported mainly in patients of African origin. Lesions may coexist with punctate or nummular keratoderma (Fig. 19.72b) [21].

Filiform keratodermas

Synonym
- Music box spine keratoderma

Fine keratotic lesions that project a millimetre or so from the palmoplantar surface are variously described as filiform, spiked, spiculate, spiny, minute digitate, minute aggregate and music box spine keratodermas (Fig. 19.73). Like disseminated filiform keratoses, large morphological differences within this group probably reflect distinct aetiologies. Lesions may be inherited as an autosomal dominant trait, when they appear in the second or third decade [1]. They may be sporadic, and may involve other parts of the skin or palms and soles alone. Histology may show compact orthohyperkeratosis or parakeratosis resembling porokeratosis [2]. Attempts have been made to provide a unifying clinical classification based on histological features and distribution [3–5]. Tosti *et al.* [6] found dyskeratotic foci in the nail matrix. Hashimoto *et al.* [7] demonstrated the presence of hair-type keratin immunostaining in the lesions, suggesting that spiny keratoderma may represent ectopic hair formation. Reported associations include polycystic kidneys and liver [8], Darier's disease [3,9], epidermodysplasia verruciformis [10], renal failure [11], tuberculosis [12], hyperlipidaemia [13] and malignancy [5,14–16]. Profuse filiform keratoses are also associated with multiple myeloma and with HIV-associated PRP.

Fig. 19.73 Filiform keratoderma. Present since age 20 on palms and soles. Son and daughter also affected.

Treatment. Keratolytics are usually prescribed but are rarely successful. Etretinate gave variable slight improvement [10] or good results [6]. Topical 5-fluorouracil ointment cleared the lesions temporarily in one patient [2] but failed in another [8].

Marginal papular keratodermas [1,2]

Costa [3,4] reported 13 cases with cornified and umbilicated papules distributed along the borders of the hands and feet (Fig. 19.74). He noted fragmentation and rarefaction of elastic fibres in the dermis, and introduced the term acrokeratoelastoidosis. Fiallo *et al.* [5] argued that the primary defect is in the elastic tissue. However, Dowd *et al.* [6] reported 15 cases, several familial, with

Fig. 19.74 Marginal papular keratoderma: crateriform punctate keratoses at the margin of the sole (Wallace's line).

Fig. 19.75 Aquagenic syringeal acrokeratoderma showing whitish maceration of palmar skin following immersion. (Courtesy of Dr G. Kavanagh, Royal Infirmary of Edinburgh.)

similar oval or polygonal crateriform papules along the borders of the hands and feet in whom there was no solar damage or elastorrhexis. To distinguish this entity, it was termed focal acral hyperkeratosis. However, eight of Costa's 13 patients [3] appear identical. One patient illustrated by Dowd *et al.* [6] also had marked punctate keratoses of the palmar creases. Many patients with these disorders are of Afro-Caribbean origin, but a Filipino patient with focal acral hyperkeratosis and hearing loss has been reported [7].

Rongioletti *et al.* [1] suggest unifying the marginal papular keratodermas with a pragmatic division into the hereditary type with elastorrhexis (acrokeratoelastoidosis), or without it (focal acral hyperkeratosis), and an acquired type, degenerative collagenous plaques [8–11]. The latter are firm plaques, sometimes concave, forming a linear band principally around the web of the thumb and index finger at the margin of the volar and dorsal surfaces. There is marked clinical and histological evidence of solar damage. Pathogenesis and a possible relationship with knuckle pads is discussed by Abulafia and Vignale [11].

Mosaic acral keratosis. Jacyk and Smith [12] reported African patients with widespread polygonal papular lesions over the ankles and shins under the title mosaic acral keratosis. It is not a marginal keratoderma [13] but is included here for convenience, as Costa's case 13 [3] had similar features.

Miscellaneous keratoderma syndromes

Aquagenic syringeal acrokeratoderma. Several patients are reported in whom a subtle keratoderma is revealed by sweating or immersion (Fig. 19.75) [1–4]. Patients typically bring a vessel in order to immerse the hand in water and demonstrate the signs [3]. The painful, whitish papular lesions are associated with dilated acrosyringeal ostia; Kabashima *et al.* found altered expression of the water channel protein, aquaporin 5 [5]. Botulinum toxin has been successfully used to treat this condition [6].

Acro-osteolysis with keratoderma (Bureau–Barrière syndrome) [7,8]. Marked diffuse keratoderma is associated with osteolysis in the forefoot area, polyneuropathy of the lower legs and painless ulcers of the feet. Finger clubbing is a feature of this syndrome [9–11].

Papillomatoverrucous palmoplantar keratoderma. The association of a florid warty keratoderma, dysplastic teeth and follicular keratoses was reported by Jacak and Wolf in four siblings in one family, with a possible autosomal recessive mode of inheritance [12]. Baran and Juhlin [13] reported a similar case, which responded to etretinate.

Symmetrical interdigital keratoderma. This is a sporadic condition of the hands, in which thickening of the interdigital spaces occurs from the second decade. The absence of occupational or

other factors and the poor response to corticosteroids or keratolytics were said to be features supporting the diagnosis [14,15].

Circumscribed hypokeratosis of the palms and soles [16,17]. This occurs in middle aged women and is characterized by solitary atrophic lesions with reduced stratum corneum and granular cell layer, and intraepidermal vacuolation [18]. It may respond to topical calcipotriol [19], cryotherapy [20], or photodynamic therapy [21].

Keratoderma and cancer

Cancers may arise in keratodermatous skin. Squamous and verrucous carcinomas are common in Huriez syndrome [1]. Isolated cases are reported in mutilating keratoderma [2], porokeratosis [3] and Clouston's syndrome [4] or with non-syndromic focal or diffuse PPKs [5,6]. Melanoma of affected skin is reported in various keratodermas [7–12]. Nakajima *et al.* suggest that it may be more common in Japanese keratoderma patients because of the increased incidence of acral melanoma in this population [13]. Predisposition to internal cancer may be part of a keratoderma syndrome, of which the Howel-Evans' syndrome (see p. 19.106) is best known. A reported association between epidermolytic keratoderma caused by keratin 9 mutation and breast and ovarian cancer [14–16] is not a general feature of this syndrome. Familial punctate keratoderma has been reported with a variety of malignancies [17–20].

Acquired keratoderma may be paraneoplastic. In addition to 'tripe palms' (see p. 19.120), and Bazex's acrokeratosis paraneoplastica (see Chapter 62), reports include acquired diffuse PPK with cancer of the bronchus [21,22], and filiform PPK with cancer of the breast, colon and kidney [23–25].

Carcinogens, of which the best documented example is arsenic, may produce both keratoderma and internal malignancy [26,27]. One survey showed that palmar keratoses occur four to five times more frequently in patients with cancer than in controls [28]. An increased incidence of keratoses in patients with lung or bladder cancer has been debated [29–31]. Smoking [29] and papillomavirus infection [30] are suggested culprits. Keratoses associated with cancer are histologically distinct from arsenical keratoses [32].

Agents used in cancer treatment commonly cause palmoplantar erythema (the hand–foot syndrome) and may cause keratoderma [32–35].

Other acquired keratodermas

Callosities or more extensive thickening of plantar epidermis is a common concomitant of obesity [1], and symptomatic plantar hyperkeratosis is common with increasing age or orthopaedic problems.

Keratodermas caused by other dermatoses. Palmar or plantar lesions occur in a wide range of dermatoses [2]. In psoriasis, both diffuse gross and centripalmar hyperkeratosis are seen. A scalloped margin (*Festonné*), Caro–Senear lesions (depressed plaques) on the sides of the fingers and involvement of the knuckles may suggest the diagnosis. The lesions of Reiter's disease are compact, heaped up and resemble the heads of nails (keratoderma blenorrhagica). The even yellow hyperkeratosis of PRP is associated with an acute follicular eruption in adults and by lesions on the knees and elbows in children. Extensive hyperkeratotic eczema may be difficult to distinguish on clinical and histological grounds from keratoderma but marked itching may indicate eczema. Trichophytosis, especially resulting from *Trichophyton rubrum*, may be unilateral and lacking in inflammatory signs. Keratoderma may be seen in crusted scabies (Fig. 19.76). The tendency of secondary syphilis lesions to involve the palms is well known, and hyperkeratotic late syphilides may be warty or focal [3]. In late yaws, keratoderma may induce a peculiar crab-like gait in those affected. In immunocompromised patients, viral warts may be confluent on the palms or soles. Lupus erythematosus may show dry and atrophic [4], hypertrophic (Fig. 19.77) [5] or ulcerative [6] palmar lesions. Antidesmocollin 3 antibodies were found in a patient with an immunobullous disorder and acquired diffuse PPK [7]. In lichen planus, warty lesions may be mistaken for viral warts, and it and lichen nitidus may mimic punctate keratoderma [8]. Keratoderma may be seen as a result of hypersensitivity to drugs such as iodine. Keratoderma may result from tegafur, glucan, lithium and halogenated weed-killers, and dioxin intoxication [9–13]. Arsenical induced irregular warty keratoses, or more even glassy lesions, are still occasionally seen [14].

Fig. 19.76 Norwegian scabies causing keratoderma. (Courtesy of Dr N. Walker, Oxford Radcliffe Hospital, Oxford, UK.)

Keratoderma climactericum (Haxthausen's disease) [15,16]. The specificity of this syndrome described in women over the age of 45 is uncertain, as many patients are obese. Pressure areas of the heel and the forefoot are involved first (Fig. 19.78). Erythema and heavy hyperkeratosis with fissuring make walking painful. The condition slowly extends to become confluent. Later, the central palms may be affected. Symptoms may be worse in winter. Deschamps *et al.* [16] excluded endocrine dysfunction, contact dermatitis and fungal infection, and found normal serum vitamin A levels. However, Wachtel [17] described three young women in whom an identical condition arising following bilateral oophorectomy was reversed by oestrogen replacement. Laurent *et al.* [18]

Fig. 19.78 Keratoderma climactericum.

implicated keratinization of the acrosyringium by the finding of composite keratohyaline granules in the granular cells of the interductal granular cells, believed to serve as a marker for acrosyringeal differentiation [19]. Low-dose etretinate produces improvement in several weeks. In this age group, hypertension, cardiovascular disease or lipid abnormalities may prove contraindications. In one report, topical 0.05% oestradiol in a water-in-oil base was successful where keratolytics and emollients had failed [20].

Myxoedema. Palmoplantar hyperkeratosis with myxoedema, improving with treatment, has been reported on several occasions [21,22].

Lymphoedema and other circulatory disorders. In chronic lymphoedema, the skin overlying the lymphoedematous area first becomes diffusely thickened, and then develops a velvety papillomatous surface, which is ultimately covered by large irregular warty projections (lymphostatic verrucosis; mossy foot) [23–25]. The condition may simulate chromoblastomycosis. Lymphoedematous keratoderma occurs most characteristically in filariasis, but may develop in chronic lymphoedema of any origin. Histologically, there is hyperkeratosis, acanthosis and papillomatosis. The dermis is oedematous with dilated lymphatics, conspicuous new-vessel formation, some sclerosis and a variable infiltrate of inflammatory cells. Both the hyperkeratotic component and the lymphoedema improved in three cases given etretinate 0.6 mg/kg/day [23]. Keratoderma is also reported in association with acrocyanosis and livedo reticularis [26].

Acanthosis nigricans [1–3]

Skin affected by acanthosis nigricans (AN) is hyperpigmented, with papillomatous hyperkeratosis giving a velvety texture. Neck and flexures are most severely affected. Palms may be involved by papillomatous hypertrophy ('tripe palms').

Aetiology. Acanthosis nigricans has a variety of causes whose likely common mechanism is stimulation of tyrosine kinase growth factor receptor signalling pathways in epidermis [4]. In insulin resistance syndromes, high levels of circulating insulin directly or indirectly activate the insulin-like growth factor 1 receptor (IGF1R) [5,6]. IGF1R is a transmembrane protein related to the insulin receptor, present in many tissues including keratinocytes and some ovarian compartments. Specific activating mutations of fibroblast growth factor receptors (FGFRs), also tyrosine kinase receptors, are associated with acanthosis nigricans in Beare–Stevenson syndrome (FGFR2), Crouzon's syndrome with acanthosis nigricans (FGFR3), and thanatophoric dwarfism (FGFR3) [7]. Verrucous epidermal naevi may resemble AN [8] and somatic mosaicism for specific FGFR3 mutations is common in these; acquired mutations of the same type also occur in seborrhoeic keratoses [9,10]. Transgenic mice bearing activating mutations of FGFR3 also display cutaneous papillomatosis [11]. In malignant acanthosis nigricans, tumour-derived growth factors, in particular transforming growth factor-α, acting through the epidermal growth factor receptor (EGFR) are presumed [12–15], although anti-insulin receptor antibodies have also been implicated [16]. Transient AN has been reported in a woman receiving recombinant keratinocyte growth factor [17].

Pathology. Hyperkeratosis and irregular spiky papillomatosis alternating with areas of attenuation are seen [3,18].

Fig. 19.79 Benign acanthosis nigricans: velvety thickening with skin tags.

Clinical features [1,3,18]. The essential clinical features are common to all forms of the disease, but vary in distribution and degree. In congenital forms, skin lesions may be present at birth, but usually develop during childhood or puberty. The earliest changes in affected sites are grey–brown or black pigmentation and dryness and roughness of the skin, which is palpably thickened and covered by small papillomatous elevations, giving it a velvety texture (Fig. 19.79). As the thickening increases, the skin lines are further accentuated and the surface becomes mammillated or rugose, and larger warty excrescences develop. The sites most commonly involved are the axillae, the back and sides of the neck, the anogenital region and the groins, but the other flexures, the submammary region, the umbilicus and, in some cases, almost the entire skin may be affected. Distal extremities are usually spared. Involvement of the mucous membranes is uncommon, but oral mucous membrane may show delicate velvety furrows [19]. Hyperpigmented plaques over elbows, knuckles, knees, and dorsal feet, but sparing the flexures, in dark-skinned individuals has been suggested as an acral variant of AN; a role for elevated leptin levels has been mooted [20,21].

Inherited forms of acanthosis nigricans. Acanthosis nigricans has been reported in many genetic syndromes [1]. Acanthosis nigricans in isolation may be inherited as a Mendelian dominant trait (MIM 100600) [22,23] and may be due to FGFR3 mutation [24]. Activating mutations of FGFR3 are also found in the dysmorphic syndromes with AN, as noted above. Other known causes include insulin resistance due to insulin receptor defects (type A insulin resistance) such as Leprechaunism, Rabson–Mendenhall syndrome, lipodystrophies and other causes of hyperinsulinaemia [4]. Lelis syndrome is the association of widespread AN with hypotrichosis, hypohidrosis, loss of dentition and other ectodermal features [25].

Benign acquired acanthosis nigricans. The term 'pseudo'-acanthosis nigricans is obsolete, as this condition differs only in degree from other forms. As a complication of obesity, it is seen most often in adults [26,27], but also occurs in childhood [27], and with

increasing obesity in prosperous countries is likely to become commoner. Small patches of pigmentation and velvety thickening, often with multiple skin tags, are present in body folds especially axillae (Fig. 19.79), groins and natal cleft. Stuart [28] examined 1412 unselected American high school children and found acanthosis nigricans in 7%, which correlated well with severe obesity. In a study of native Americans, subjects affected by acanthosis nigricans had two-fold higher fasting insulin levels than weight-matched controls [27]. With weight reduction, the skin changes may slowly regress, although the pigmentation often persists.

HAIR-AN syndrome. The triad of *h*yper*a*ndrogenism, *i*nsulin *r*esistance and *a*canthosis *n*igricans in women is known as the HAIR-AN syndrome [2,6], and may be seen with insulin resistance of various causes. Chronic hyperinsulinism is thought to induce ovarian hyperandrogenism [6], and *in vitro* ovarian tissue from hyperinsulinaemic diabetic women responds to supraphysiological insulin concentrations by enhanced steroidogenesis [29]. The finding of pubic hair before the age of 8 years (premature adrenarche) with acanthosis nigricans was associated with insulin resistance [30].

Autoimmune acanthosis nigricans. Acanthosis nigricans disorder may occur in autoimmune disease, including SLE, due to antibodies to the insulin receptor [2,31], so called type B insulin resistance. Fareau *et al.* [32] report a case of a woman whose acanthosis nigricans remitted, together with refractory hyperglycaemia and insulin receptor antibody titre, following cyclophosphamide chemotherapy.

Drug-induced acanthosis nigricans. Reported causes include nicotinic acid [33,34], fusidic acid [35], stilboestrol in young males [36], triazinate, a folic acid antagonist [37], and antiretroviral agents [38,39].

Malignancy-associated acanthosis nigricans. This is comparatively rare, and lesions are more severe and extensive. Pigmentation is conspicuous and is not confined to hyperkeratotic areas. The nails may be brittle or ridged, and the hair may be shed. Irritation is common. The mucous membranes and mucocutaneous junctions are involved in at least 50% of the cases, and warty papillomatous thickening around the lips and eyes may be a presenting symptom (Fig. 19.80). It may be accompanied by eruptive keratoses (Leser–Trélat). The sexes are equally affected. There is usually an underlying adenocarcinoma, especially of stomach, but other tumours are sometimes found, including those of oesophagus, rectum, bronchus, urinary tract, ovary, bile-duct and thyroid [1]. Acanthosis nigricans occasionally precedes other symptoms by some years. The clinical signs may regress following removal of the tumour, but relapses are common. Rendon *et al.* [40] provide a practical algorithm for investigating these patients. Malignant acanthosis nigricans is very rare in childhood—rapidly progressing lesions and mucous membrane involvement are useful warning signs. Malignant acanthosis nigricans may have to be differentiated from tumour-associated hypertrophic osteoarthropathy simulating pachydermoperiostosis.

Fig. 19.80 Malignant acanthosis nigricans: warty thickening of the oral margins in a patient with carcinoma of the breast.

Tripe palms. Velvety, rugose thickening of the palms, resembling tripe (the villous lining of ruminant stomach), is almost always associated with internal malignancy [41,42]. Acquired diffuse keratoderma may also occur with malignancy, but this and familial keratoderma associated with malignancy (as in Howel-Evans' syndrome) is compact and not rugose. Elevated serum epidermal growth factor was described in a patient with tripe palms and carcinoma of the bronchus [43]. Tripe palms with malignancy may occur alone (25%) or associated with acanthosis nigricans [44].

Treatment. Treatment is of the underlying cause, or is otherwise symptomatic and of little help. Removal of the tumour in the malignant form may allow partial improvement. A case of hereditary benign acanthosis nigricans improved dramatically with etretinate [45]. Rosenbach [46] reported successful use of the alexandrite laser.

Confluent and reticulate papillomatosis [1–3]

Synonym
- Gougerot–Carteaud syndrome

This syndrome of mild truncal hyperkeratosis is included here in view of the suggestion that it is a keratinizing disorder, but there is strong evidence of an infective component in its aetiology.

Aetiology. Most cases are sporadic, although occasional familial cases could suggest an abnormal response to microbial products [4]. *Pityrosporum orbiculare* has been implicated [5], but fungal elements are found in only a minority of cases and antiyeast therapy is unreliable. Response to several antibiotics supports a bacterial contribution [2,3,6]. Natarajan *et al.* [7] isolated a novel Actinomycete, for which they propose the name *Dietzia papillomatosis* [8], but this finding is yet to be reproduced [9].

Pathology. Histologically, hyperkeratosis and papillomatosis are present without acanthosis; increased transitional cells on electron microscopy [10] and increased keratin 16 and Ki67 expression [11] indicate hyperproliferation. Amyloid has been reported [12].

Clinical features [1–3]. The condition is commonly seen in teenagers and young adults, beginning around puberty. Both sexes were equally affected among 39 cases attending the Mayo clinic [2]. Flat, dry papules up to 5 mm in diameter commonly appear on the neck, upper chest, between the breasts or in the interscapular area and the axillae. Neighbouring papules become confluent in the centre of the affected areas, but only partially so at their periphery to form an irregular network (Fig. 19.81).

The lesions gradually extend. They cause few symptoms and little disfigurement. The age of onset and the distribution of lesions differentiate the condition from acanthosis nigricans, although coexistence in childhood has been noted [13]. Darier's disease and reticulate pigmentary disorders [14] must also be considered.

Fig. 19.81 Confluent and reticulate papillomatosis: red–brown reticulate papules with a fine scale in the central area of the chest. (Courtesy of Professor R.J. Hay, St John's Institute of Dermatology, London, UK.)

Treatment. A variety of antibiotics have been found to be effective [15]; minocycline has been most used [2] but azithromycin is also recommended [3]. The response to antifungal agents is variable, even if yeasts are demonstrated [16,17]. Systemic or topical retinoids, or topical vitamin D analogues may also be effective [18–20].

Definition. A common, chronic, disfiguring, inflammatory and proliferative condition of the skin, in which both genetic and environmental influences have a critical role. The most characteristic lesions consist of red, scaly, sharply demarcated, indurated plaques, present particularly over extensor surfaces and scalp. The disease is enormously variable in duration, periodicity of flares and extent. Morphological variants are common.

Epidemiological aspects

Incidence and prevalence

Accurate figures concerning epidemiology and morbidity of psoriasis are difficult to obtain given that diagnostic criteria have never been validated, different methodologies have been employed and patient ascertainment techniques have varied. Nevertheless, it is clear that psoriasis is a very common disease. Most robust prevalence data come from Northern Europe and Scandinavia where studies of Caucasians indicate population prevalence between 1.5% and 3% (Table 20.1) [1–9], although prevalence as high as 4.8% has been reported [10]. There are, however, considerable racial variations with most other populations having a lower prevalence of disease. In China, psoriasis is estimated to affect 0.3% of the population [7], while the disease is very rare or non-existent in Inuits [11], Latin American Indians [9] or Samoans [8]. It appears to be more common in East than West Africa. Climate also appears to affect psoriasis prevalence, with higher rates recorded in single countries at greater latitudes from the Equator [12].

The incidence of the disease, that is the number of new cases occurring in a given population in a defined time, has been estimated to be 60 individuals per 100 000 per year [13]. This study also provided support for seasonal variation, with 68% of cases first diagnosed in winter and spring months. A recent US study has suggested that the annual incidence of psoriasis has doubled in the 30 years between 1970 and 2000 [14], although whether this reflects a true change in incidence or changes in diagnosis patterns is unclear.

All figures quoted above relate primarily to psoriasis vulgaris (chronic plaque psoriasis). Estimates of disease variants are much less robust. They probably account for approximately 10% of all cases.

Age of onset

Considerable variation exists between studies in age of onset, perhaps in part reflecting the lack of strict criteria used. Lomholt [1] reported average age of onset as 12 years in his study in the Faroe Islands. In a large US survey [5], the average age of onset was 28 years, while in the largest study reported in China, average age of onset was 36 years [7]. It has been reported that 35% of cases have disease onset before age 20 years and 58% before age 30 [8]. In a UK study [4] of a defined population, mean age of onset was 33 years with the mode in the second decade; 75% had disease onset before the age of 46 years.

These studies, however, hide the fact that it appears that psoriasis has a bimodal distribution of age of onset. In a German study, two peaks were identified: the larger, early peak between 16 and 22 years and the later one at 57–60 years [15]. Several other studies,

Table 20.1 Worldwide studies on prevalence of psoriasis.

Place and reference	Sample size	Percentage with psoriasis
Faeroes [1]	10984	2.84
Sweden [2]	159200	2.3
UK [3]	2180	1.56
UK [4]	5395	1.48
USA [5]	20749	1.4
USA [6]	7514	1.4
China [7]	670000	0.3
Samoa [8]	12569	0
South America [9]	25000	0

including from the UK [16], broadly support this observation. Those individuals with early onset appear, in general, to have more severe disease and are much more likely to have an affected first-degree relative with psoriasis (see below) [1,5,17].

Sex effects

Males and females are equally affected by psoriasis vulgaris. Many studies indicate that age of onset is younger in females. Thus, one German study demonstrated a peak age of onset of 22 years in males and 16 years in females in early-onset disease [15]. However, results of studies are highly dependent on sampling techniques used and are variable in their results. There is no evidence that the disease is phenotypically different between the sexes.

Aetiology and pathogenesis

Genetic epidemiology

There is overwhelming evidence that psoriasis has an important genetic component. Lomholt's classic epidemiological study of psoriasis in the Faroe Islands (1963), in which he examined more than 10000 inhabitants [1], made the key observation that the incidence of psoriasis was much greater amongst first- and second-degree relatives of sufferers than unaffected control subjects.

A further large-scale study performed in Sweden supported these data showing the prevalence of psoriasis to be 7.8% in first-degree relatives compared with a prevalence of 3.14% in matched controls, and 1.97% in the overall population [2]. Based on population data, several investigators have calculated the risk for a child to develop psoriasis. In a German study, the risk was 14% if one parent was affected, 41% if both parents affected, and 6% if one sibling affected, compared to 2% when no parent or sibling was affected [3]. Henseler and Christophers [4] demonstrated that the bimodal peak in disease onset (see above) could be taken as evidence for the existence of two pathogenetically distinct forms of the disease, similar to the model for diabetes mellitus. Thus, type 1 is hereditary, strongly HLA associated (particularly HLA-Cw6), early onset and more likely to be severe. Type II is sporadic, HLA unrelated, of late onset and usually mild. A study in Iceland has confirmed much of these data [5]. Others, however, have suggested that the true situation is more complex [6], and certainly there are many individuals in extended family pedigrees with late-onset disease.

Support for these population studies comes from analysis of various family pedigrees in which psoriasis appears throughout multiple generations [7]. While some authors have argued that the data are most consistent with an autosomal dominant pattern of inheritance with reduced penetrance and others that the best fit is a double recessive model, most regard the data as consistent with a polygenic or multifactorial pattern (see below). Interestingly, the development and severity of psoriasis may be influenced by the sex of the contributing parent. Thus several studies have noted evidence for a preferential paternal effect, while one Scottish study further showed earlier age of onset when the disease was inherited from the father, consistent with 'genetic anticipation' [8].

Perhaps the most robust data supporting a genetic basis to psoriasis come from studies examining concordance for the disease in twins. Examination of individuals from the Danish Twin Registry has shown concordance for psoriasis in 64% of monozygotic (identical) twins compared to 15% for dizygotic twins, corresponding to an estimated heritability of 91% [9]. Very similar figures (73% and 20% respectively) were found in the retrospective study of Farber *et al*. [10], although in an Australian study lower concord-

ance rates were observed; 35% in monozygotic twins compared to 12% in dizygotic twins [11]. Of interest when monozygotic twins are concordant for psoriasis the age of onset, distribution of the disease and severity are very similar suggesting that genetic factors play a role in these parameters. However, it is self-evident from the data that concordance rates do not reach 100%, even when older twins are examined, indicating that the environment plays a key role in disease expression. Based on the variable extent and pattern in which it is inherited through families, it is suggested that psoriasis represents a spectrum of genetic diseases. At one end are the rare families in which changes in a single gene may be sufficient to cause the disease. At the opposite end of the spectrum is the more common form in which an obvious family history may be lacking. In these individuals, it is likely that changes in multiple genes, interacting both with each other and the environment are required for disease expression [12].

All the above studies have concentrated upon chronic plaque psoriasis, the most common variant. Little is known of the epidemiology of other forms. Guttate psoriasis (see below) is almost invariably HLA associated [13,14] and thought to be closely linked pathogenetically to type 1 plaque psoriasis.

Environmental risk factors

Present evidence indicates that interactions between genes and the environment are important in disease causation. Many environmental factors have been linked to psoriasis, and have been implicated in, for example, initiation of the disease process and exacerbation of pre-existing disease. However, conclusive evidence is so far lacking.

Trauma

Psoriasis at the site of an injury is well known (Koebner phenomenon; see below). A wide range of injurious local stimuli, including physical, chemical, electrical, surgical, infective and inflammatory insults, has been recognized to elicit psoriatic lesions [1].

Infection

Acute guttate psoriasis is strongly associated with preceding or concurrent streptococcal infection, particularly of the throat [2]. There is evidence that streptococcal infection may be important in chronic plaque psoriasis [3], and that treatment with rifampicin and penicillin may lead to clearance of skin lesions. Further, acute episodes of guttate psoriasis are much more common in individuals with a family history of plaque psoriasis [4] and one-third of cases of guttate psoriasis progress to the chronic plaque form [5]. As mentioned earlier, guttate and chronic plaque psoriasis share strong HLA associations, particularly with HLA-Cw6. HIV infection has also been associated with psoriasis (see below).

Drugs

There are many drugs reported to be responsible for the onset or exacerbation of psoriasis [6]. Chief amongst these are lithium salts, antimalarials, beta-adrenergic blocking agents, non-steroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors and the withdrawal of corticosteroids. Their risk, however, has never been formally assessed in controlled epidemiological studies. The adverse effect of beta-blockers is based on early experiences with practolol [7], although data implicating those in current usage are lacking. Likewise, the risk of withdrawal of systemic or potent topical corticosteroids requires careful re-evaluation.

Anecdotal personal experience of the authors and questioning of colleagues have suggested that beta-blockers and NSAIDs have little, if any, adverse effects on psoriasis but that the effect of lithium salts or antimalarials may be severe. Patients with unstable psoriasis should receive appropriate advice before travelling to countries where antimalarial prophylaxis is required.

Sunlight

Although sunlight is generally beneficial, in a small minority of patients, psoriasis may be provoked by strong sunlight (Fig. 20.1) and cause summer exacerbations in exposed skin. In a questionnaire study of 2000 patients in Sweden, the prevalence of photosensitivity in psoriasis was estimated at 5.5% [8,9]. Approximately 40% of these patients gave a history of polymorphic light eruption (PLE) with psoriasis appearing as a secondary phenomenon with PLE lesions. Recent work has indicated that severely photosensitive psoriasis is predominantly female, distinct from PLE, and strongly associated with HLA-Cw6, family history and very early age of onset [10]. Photochemotherapy (PUVA) can be helpful in these patients.

Metabolic factors

The early onset of psoriasis in women, with a peak around puberty, changes during pregnancy and provocation of psoriasis by high-dose oestrogen therapy potentially indicates a role for hormonal

Fig. 20.1 Psoriasis exacerbated by sun exposure. (Courtesy of St John's Institute of Dermatology, London, UK.)

factors in the disease. A questionnaire study has provided data from 65 females who had one or more pregnancies after the diagnosis was made. Psoriasis remained unaltered in approximately 40% of pregnancies, improved in 40% and worsened in 14% [11]. In contrast, in the 3-month postpartum period, 30% remain unchanged, 10% improved and 50% deteriorated. Thus, if psoriasis changes in pregnancy, it is more likely to improve than worsen, while in the postpartum period it is more likely to deteriorate. These results have been broadly supported in other studies [12]. Although rare, generalized pustular psoriasis precipitated by pregnancy has repeatedly been reported [13].

Hypocalcaemia, for example following accidental parathyroidectomy, has been reported to occur in severe forms of psoriasis, particularly generalized pustular psoriasis [14,15] and may be a predictor of poor outcome.

Importantly, it has also been reported that psoriasis *per se* may have an adverse effect on pregnancy outcomes with one study showing increased recurrent abortions, hypertension and need for caesarean delivery [16].

Psychogenic factors

Considerable clinical evidence exists for the role of stress in onset and exacerbation of psoriasis. Seville [17] reported consistent links between major stressful life events and disease manifestation. In a UK study, over 60% of a sample of psoriasis patients believed stress was a principal factor in the cause of their psoriasis [18]. Gupta *et al.* [19] reported that several psychocutaneous characteristics, including increased exacerbations and worse disease, correlated with stress reactivity. Not all studies have supported these observations and prospective epidemiological studies, using appropriate psychometric instruments, are required to answer these important issues.

It is without doubt, however, that psoriasis has a detrimental effect on the psychosocial quality of life of patients and that stress management programmes significantly shorten the time to clearance with standard therapies [20]. Furthermore, psoriasis in patients who are categorized as being high or pathological worriers is less likely to clear with photochemotherapy (PUVA) than in those patients with low worry [21].

Without doubt, the emotional and physical disability that psoriasis may cause is underestimated. One study showed the impact of psoriasis on physical and mental components of the health related quality of life index is very similar to that of many other major diseases, including heart disease and arthritis [22].

Alcohol and smoking

It has long been suspected that both cigarettes and alcohol have a detrimental effect on psoriasis. While recent large epidemiological studies are not conclusive, support for an association is observed [23]. When controlled for confounding variables, studies suggest that alcohol may exacerbate pre-existing disease but does not appear to induce psoriasis [24]. This effect seems greater in men than in women. Heavy drinkers tend to have more extensive and inflamed disease [25,26]. Increased alcohol consumption is a recognized stress response. Excess drinking is undoubtedly also a consequence of the disease and leads to treatment resistance and reduced therapeutic compliance. Abstinence has been reported to induce remission [27].

In the Rochester incidence study [28], female patients at first diagnosis smoked more than a random sample of the population, in contrast to male patients who were comparable. These data were confirmed by Naldi *et al.* [29] in a case–control study. In women who smoked more than 15 cigarettes per day, the odds ratio for association with psoriasis was 3.9 (men = 1.4). Most striking is the link between smoking and pustular forms of psoriasis, particularly palmoplantar pustulosis, a disease most frequently observed in females (see later). Individuals smoking more than 15 cigarettes per day had an odds ratio of 10.5 for association with palmoplantar pustulosis.

HIV and acquired immune deficiency syndrome

The association between severe psoriasis, psoriatic arthropathy and human immunodeficiency virus (HIV) infection is well recognized [30–33]. In a study of 13 HIV-positive psoriasis patients followed over 2.5 years, psoriasis was found to flare severely or to appear *de novo* in explosive form as features of HIV infection developed. The prognosis of acquired immune deficiency syndrome (AIDS) in patients with psoriasis also appeared poor, nine out of 13 patients having died during the course of the above 2.5-year study [30]. The mechanism of worsening of psoriasis in these circumstances is unclear. Furthermore, the knowledge that psoriasis may be aggravated by AIDS, a disease in which the helper T cell is the major target, and the evidence that psoriasis may be greatly improved by ciclosporin, which inhibits helper T-cell function, create a paradox that remains to be fully explained.

The cardinal features of lesional psoriatic skin are: (i) epidermal hyperproliferation with loss of differentiation; (ii) dilatation and proliferation of dermal blood vessels; and (iii) accumulation of inflammatory cells, particularly neutrophils and T lymphocytes. A vast array of growth factors, cytokines, inflammatory mediators and other biological markers have been shown to be altered in lesional psoriatic skin [1]. Significant progress has been made in understanding the basic pathogenetic mechanism which increasingly underscore the role of interplay between epidermal aberration and innate and acquired immunity (see below) [2,3].

Pathogenetic mechanisms

Epidermal proliferation

A variety of techniques have demonstrated that the increased keratinocyte proliferation observed in psoriasis is a consequence of an increase in the proliferating cell compartment in the basal and supra basal levels of the epidermis, and not due to shortened cell cycle time. The number of cycling cells is increased approximately sevenfold [4]. These changes are not specific for psoriasis as, for example, increased numbers of proliferating keratinocytes are also seen in wound healing and atopic dermatitis. Multiple growth factors, which experimentally have been shown to modulate keratinocyte proliferation, are present in lesional skin [5]. In particular, transforming growth factor-α (TGF-α) appears to be an important autocrine mediator of these events [6].

Vascular changes

Vertical dermal capillary loops in lesional skin are dilated, elongated and twisted. Image analysis quantification of immunostained microvessels has demonstrated a fourfold increase in endothelium of superficial but not deep microvasculature, indicating that these changes are confined to the upper plexus [7]. Autoradiographical and immunohistochemical studies have demonstrated proliferating endothelial cells in pustular and plaque forms of psoriasis, with a proliferation index of approximately 3% [7], indicating that vascular growth, or angiogenesis, is an important component of this process.

Using various *in vivo* models of angiogenesis, it has been demonstrated that epidermal keratinocytes are the primary source of angiogenic activity [8]. These cells produce an array of soluble mediators with angiogenic activity including vascular endothelial growth factor (VEGF). It is over-expressed in psoriatic epidermis as are its receptors on lesional psoriatic microvasculature [9]. Transgenic mice, which over-express VEGF in basal epidermis, have an expanded superficial dermal vasculature similar to that observed in psoriasis [10]. Interestingly, it has been shown in an animal model that cutaneous inflammation can be prevented by an inhibitor of VEGF pathways [11]. Some patients with erythrodermic or severe plaque psoriasis have evidence of systemic capillary leak such as proteinuria. In such patients, circulating VEGF is detectable and correlates with proteinuria [12]. While most studies suggest a primary role for the immune system in psoriasis pathogenesis (see below), it has been argued that vascular change precedes the immune response [13] and some evidence suggests a genetic link [14].

Table 20.2 Replicated genetic loci.

Gene/locus	Chromosomal location	Odds ratio	Putative function	Other disease association	Reference
PSORS1	6p	6.4	–	None	[26]
					[20]
PSORS2	17q	–	–	None	[27]
IL12B	5q	1.4	T-cell differentiation	Crohn's	[28]
					[29]
IL23A	12	1.34	T-cell differentiation	None	[30]
IL23R	1p	2.0	T-cell differentiation	Crohn's	[31]
				Ankylosing spondylitis	[29]
TNIP1	5	1.59	TNF-α pathway	None	[30]
LCE	1q	1.4	Stratum corneum	None	[32]
					[33]
ZNF313	20q	1.25	Ubiquitin pathway	None	[34]
PTPN22	18p	1.3	T-cell development	Type I DM	[35]
				JIA	[36]
				SLE	
				RA	
				Autoimmune thyroid disease	
CDKAL1	6p	1.26	Unknown	Crohn's + Type II DM	[31]

DM, diabetes mellitus; JIA, juvenile idiopathic arthritis; SLE, systemic lupus erythematosus; RA, rheumatoid arthritis.

In addition to vascular growth, dermal capillaries contribute to the inflammatory process actively through surface expression of molecules involved in leukocyte homing, induced by inflammatory mediators such as histamine, neuropeptides, interleukin-1 (IL-1) and tumour necrosis factor-alpha (TNF-α). Importantly, E-selectin is induced and intercellular adhesion molecule-1 (ICAM-1) up-regulated on dermal vessels in lesional tissue, thus providing a mechanism for skin homing T lymphocytes to accumulate within lesional dermis and epidermis [2,15].

Molecular genetics

Classical, genome-wide linkage analysis has identified at least nine chromosomal loci with statistically significant evidence for linkage to psoriasis (nomenclature *PSORS1–9*) [16]. Of particular interest are *PSORS2*, a replicated locus on chromosome 17q, at which a polymorphism causing loss of binding to the RUNX1 transcription factor has been identified associated with psoriasis with low relative risk [17]; *PSORS4* [18], which is located within the epidermal differentiation complex on chromosome 1q and *PSORS8* [19], which overlaps with the Crohn's disease locus on chromosome 16q. The latter is of note because psoriasis and Crohn's disease are observed together more frequently than expected by chance (see below), although several studies have failed to find association of psoriasis with the *CARD15/NOD2* mutation linked to Crohn's disease.

However, by far the major psoriasis genetic determinant is *PSORS1*, which probably accounts for 35–50% of the heritability of the disease [20], and has been replicated in virtually all linkage studies [21]. *PSORS1* is located within the major histocompatibility complex (MHC) on chromosome 6p, spanning an approximate 300-kb segment within the class I region telomeric of HLA-B. The region contains fewer than 10 genes, of which three have been the major focus of attention for investigators, based on the strong association of polymorphic coding sequence variants with psoriasis vulgaris. HLA-C (associated variant = HLA-Cw6) encodes a class I MHC protein. *CCHCR1* (variant *WWCC*) encodes the coiled-coil x-helical rod protein 1, a ubiquitously expressed protein that is over-expressed in psoriatic epidermis [22]. *CDSN* (variant = allele 5) encodes corneodesmosin, a protein which is uniquely expressed in the granular and cornified layers of the epidermis and which is upregulated specifically in psoriasis [23]. Absolute identification of the causative gene at this locus has been hampered by the extensive linkage disequilibrium observed within the MHC.

Investigations have clearly shown that the phenotypic variants of psoriasis are genetically heterogeneous at least at the level of *PSORS1*. Thus guttate psoriasis is strongly *PSORS1* associated [24], whereas palmoplantar pustulosis and late-onset (>50 years of age) psoriasis vulgaris are not associated [25].

The availability of large, well-characterized cohorts of psoriasis patients together with advances in high-throughput genotyping at the genomic level have combined to permit disease case–control association studies producing robust replicated data on associated genes. Several genome-wide association (GWA) scans have now been reported which provide evidence for a multitude of genes involved in disease causation. These include genes involved in immune responses and epidermal function as well as those of (at present) unknown function (Table 20.2) [26–36]. Although the relative risk of associated polymorphisms in these genes is low, the importance of these genetic observations is that they highlight key biological pathways involved in psoriasis pathogenesis and point to potential therapeutic targets. Thus, these studies provide genetic support for the role of Th17 T cells in disease pathogenesis (see below) and provide a scientific rationale for the use of antibodies to p40 in disease management (see below) [37,38].

Immunology and inflammation

There is considerable evidence that T lymphocytes play an important role in development of plaques of psoriasis. This includes: (i) early influx of T cells into expanding lesions [39,40]; (ii) strong association with the MHC, particularly HLA-Cw6 [41]; (iii) ablative (albeit temporary) effect of anti-T-cell therapy [42]; (iv) increased antigen presentation in psoriatic plaques [43]; (v) anecdotal evidence of development of psoriasis after syngeneic bone marrow transplant [44]; and (vi) change in phenotype to lesional psoriatic skin in non-lesional psoriatic skin transplanted on to severe combined immunodeficient mice and injected with autologous T cells [45]. Those T cells involved in psoriasis pathogenesis express markers of memory, activation and skin homing (CLA) [46].

However, it is increasingly clear that the innate immune system, which provides an early response against harm to the host, is dysregulated in psoriasis [47]. Further, in psoriatic stratum corneum, there is an abundance of antimicrobial peptides such as defensins and cathelicidins, which have the capacity to activate innate immunity.

Innate immune mechanisms in turn lead to antigen driven T-cell expansion and activation. The key question remains as to the nature of the antigen involved. To date this is unresolved but evidence of an antigen-specific response includes: (i) limited clonality of infiltrating T cells; (ii) persistence of T-cell clones in plaques over several years; and (iii) identical T-cell clones in tonsils and skin of patients with *Streptococcus*-associated psoriasis [48].

Historically, evidence has suggested a primary role for Th1-type response in disease pathogenesis. However, it has recently been established that a more recently described subset of T cell, thought to play a key role in autoimmunity, termed Th17, is the primary pathogenic subset. Evidence includes genetic association (see above), with IL-23 being a key cytokine in generation of Th17 cells, abundance of IL-23 in psoriatic tissue [49] and induction of a psoriatic phenotype by IL-23 in animal models [50]. Other cytokines downstream of IL-23 in Th17 pathways, including IL-17 and IL-22, have similar functional effects.

Based on the above information, a pathogenic model has been suggested in which aberrations in the stratum corneum trigger activation of innate immune mechanisms, which in turn lead to recruitment and activation of Th17 cells, which provide effector cytokines leading to epidermal hyperproliferation and a pro-inflammatory state [3]. Such mechanisms provide a scientific rationale for the use of biological therapies (see Chapter 74).

Koebner and reverse Koebner phenomena [1]

Psoriasis is one of several conditions in which various types of trauma may elicit the disease in previously uninvolved skin [2] (Koebner reaction; Fig. 20.2). The Koebner reaction usually occurs 7–14 days after injury [3], and the reported incidence has varied between 38 and 76% of patients with psoriasis [4]. In a given patient, an all-or-none phenomenon occurs at multiple sites of injury, that is if psoriasis occurs at one site of injury it does so at all sites of injury [5,6]. Clearing of existing psoriasis following injury has been observed and termed the reverse Koebner reaction [5]. This reaction also obeys an all-or-none rule, and the Koebner and reverse Koebner reactions are mutually exclusive [5]. Using a standardized injury, one study found that 25% of patients gave a Koebner reaction and 67% a reverse Koebner reaction [5].

The Koebner reaction is often thought to be more frequent in actively spreading, severe psoriasis. Although this may be true, it has yet to be established by prospective studies [1]. The reaction does, however, appear to be a marker for a subgroup of patients

with a tendency to early onset and early relapse after various forms of therapy [7].

Histopathology

Early changes

Vasodilatation, papillary oedema and leukocyte infiltrates appear to precede epidermal changes in early developing lesions [1]. Compact hyperkeratosis, disappearance of the granular layer and slight epidermal hyperplasia follow. Mitotic figures in keratinocytes, and leukocytic infiltration in spongiotic foci, are seen in the lower half of the epidermis. Scattered mounds of parakeratosis, set in a still predominantly orthokeratotic stratum corneum, appear, with or without neutrophils. In the Malpighian layer, neutrophils may accumulate to form the characteristic spongiform pustules of Kogoj [2] (Fig. 20.3). Epidermal hyperplasia with rete ridges of even length and prominently dilated, tortuous papillary capillaries associated with mixed mononuclear and neutrophil infiltrates are seen [1,3].

Changes in fully developed plaques

There is parakeratosis associated with focal orthokeratosis and Munro microabscess formation (Fig. 20.4), near absence of the granular layer, spongiform pustules in the Malpighian layer [2], hyperplasia with elongation of rete ridges and suprapapillary epidermal thinning (Fig. 20.5). The rete ridges are often clubbed, branched or fused at their bases, with mononuclear leukocyte infiltrates in the lower half of the epidermis. Dilated, tortuous papillary blood vessels almost touch the undersurface of the thinning suprapapillary epidermis and are surrounded by a mixed mononuclear and neutrophil infiltrate, as well as extravasated erythrocytes. Invasion of the epidermis with leukocytes takes place particularly in the suprapapillary region [1,3,4].

Clinical features

Modes of onset

The first manifestation of psoriasis may occur at any age. The common ages of onset, and the tendency for females to develop psoriasis earlier than males, are described above. Its duration may

vary from a few weeks to a whole lifetime. The course is unpredictable and the variations numerous. Certain patterns are, however, more common than others.

The patterns of onset in childhood, including congenital psoriasis, are discussed below [1]. Acute guttate attacks characteristically occur in this age group. Nail changes may herald the development of psoriasis elsewhere, or remain localized for several years. Most forms of psoriasis present before the fourth decade.

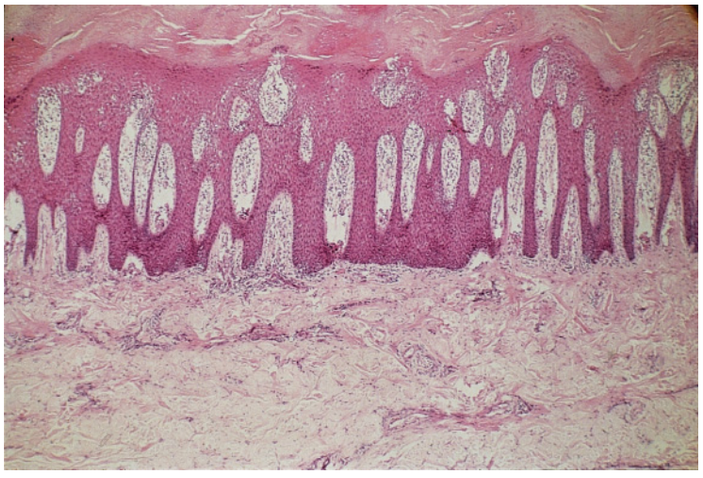

Fig. 20.5 Psoriasis: irregular epidermal hyperplasia with suprapapillary thinning. H&E, × 50. (Courtesy of St John's Institute of Dermatology, London, UK.)

Post-traumatic psoriasis is not uncommon in young, athletic men, who develop psoriasis initially at the site of injury, and later elsewhere. Minor lacerations of the legs during shaving are believed to precipitate psoriasis in some women. Flexural varieties make their appearance either alone or following a pre-existing intertrigo from other causes. Flexural lesions become increasingly common in obese, middle-aged subjects. Psoriasis entirely limited to the groins, perineal and perianal regions may develop insidiously and often remains undiagnosed for several years.

In old age, psoriasis may appear unexpectedly for the first time, either spontaneously or following a pre-existing skin disease. Onset at the age of 108 years has been reported [2].

Morphology of common chronic stable plaque psoriasis (psoriasis vulgaris) [1–3]

The appearance of a typical lesion is characteristic (Fig. 20.6). The diagnostic features may not all be present at the same time or in every case, and are sometimes obscured or evanescent.

The colour, a full rich red (often referred to as 'salmon pink'; Fig. 20.7), has a particular depth of hue not normally seen in eczema, seborrhoeic dermatitis or lichen simplex. This quality of colour is of special diagnostic value in lesions on the palms, soles and scalp. On the legs, a bluish tint is often present, but this differs from the violaceous hue of lichen planus. In the fair-skinned indi-

Fig. 20.8 Psoriasis: in the darker-skinned individual, the characteristic red colour is lost, although silvery scaling is readily seen. (Courtesy of St John's Institute of Dermatology, London, UK.)

vidual, the colour is less rich and almost magenta pink. In dark-skinned races, the quality of the colour is lost (Fig. 20.8).

The amount of scaling is variable. It may, as in rupioid forms, be waxy yellow or orange–brown. A similar colour occurs in nails ('oil drop sign'), but most psoriatic lesions are surmounted by the very characteristic silvery white scaling, which varies considerably in thickness (Fig. 20.8). The successive removal of psoriatic scales usually reveals an underlying smooth, glossy red membrane with small bleeding points where the thin suprapapillary

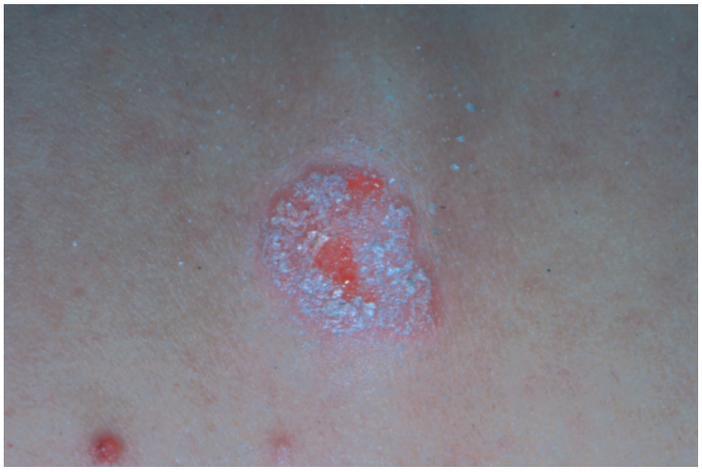

Fig. 20.9 Auspitz's sign: removal of the thinned suprapillary epidermis, by gentle scraping, reveals vascular bleeding points.

epithelium is torn off (Auspitz's sign) (Fig. 20.9). When scaling is not evident, it may often be induced by light scratching, a useful sign in diagnostically uncertain lesions.

Psoriatic lesions exhibit a considerable degree of uniformity, modified little by site except on the palms and soles. The colour remains consistent, although the scaling varies in degree.

The lesions are well defined, with a sharply delineated edge. When they merge, annular and gyrate figures may be produced. This definition is of special diagnostic value on the scalp and penis, when other evidence of psoriasis is absent, and in the flexures.

The epidermal thickening characteristic of the psoriatic process causes the lesions to be raised from the adjoining skin, and easily palpable. When the hyperkeratosis is removed by thorough washing or treatment, this character may sometimes be lost temporarily.

Discs and plaques of varying sizes are often found on the trunk and limbs. They vary in diameter from one to several centimetres and are oval or irregular in shape. There may be any number of lesions or only a single one and, when multiple, may be symmetrically distributed. Large plaques form by their coalescence and are commonly seen on the legs and sacral region. When plaques occur across the line of joint movement, fissuring may occur.

The psoriatic plaque may be encircled by a clear peripheral zone, the halo or ring of Woronoff (Fig. 20.10) [4]. The variety of morphologies of chronic plaque psoriasis has led some authors to attempt a reclassification according to phenotype and to speculate that 'psoriasis' may in fact be several distinct diseases [3,5].

Clinical variants

Guttate psoriasis

This describes the shower of small lesions, appearing more or less generally over the body, particularly in children and young adults, and after acute streptococcal infections (Fig. 20.11). In the early stages, there may be little scaling. The lesions are from 2 or 3 mm to 1 cm in diameter, round or slightly oval. They are scattered more or less evenly over the body, particularly on the trunk and

Fig. 20.10 Woronoff's ring: vasoconstriction around active plaques of psoriasis.

Fig. 20.11 Guttate psoriasis. (Courtesy of St John's Institute of Dermatology, London, UK.)

proximal part of the limbs, rarely on the soles but not infrequently on the face, ears and scalp. The lesions on the face are often sparse, difficult to see and disappear quickly. Although guttate lesions are normally profuse, there are occasionally no more than half a dozen present on the body, and in the early stages the colour is not specific. The diagnosis is made chiefly on the nature of the scaling, the general distribution and evidence for preceding infection. In one series, only 1.9% of all affected psoriatics showed this form [2].

Rupioid, elephantine and ostraceous psoriasis

These terms describe plaques associated with gross hyperkeratosis. Rupioid psoriasis refers to limpet-like cone-shaped lesions.

Fig. 20.12 Elephantine psoriasis: large plaques with gross hyperkeratosis. (Courtesy of St John's Institute of Dermatology, London, UK.)

The term elephantine psoriasis might be used to describe unusual but very persistent, thickly scaling, large plaques that sometimes occur on the back, limbs, hips or elsewhere (Fig. 20.12). Ostraceous psoriasis, an infrequently used term, refers to a ring-like hyperkeratotic lesion with a concave surface, resembling an oyster shell.

'Unstable' psoriasis

This term, which has no aetiological connotation, may be usefully employed to describe phases of the disease in which activity is marked and the course and immediate outcome unpredictable; for example, in stages when a previously stable and chronic form is exacerbated by inappropriate management and threatens to become erythrodermic or pustular, or when localized pustular or ill-defined erythematous lesions appear spontaneously for the first time. Patients may develop such unstable phases repeatedly, settling back again into the classical forms of the disease. Withdrawal of intensive systemic or topical corticosteroid therapy, hypocalcaemia, acute infection, overtreatment with tar, dithranol or UV irradiation, and perhaps severe emotional upset, may precipitate this condition.

Pustular psoriasis

Erythrodermic psoriasis [1–3]

Two forms exist [4]. In the first form, chronic lesions may evolve gradually into an exfoliative phase, and can be regarded as extensive plaque psoriasis involving all, or almost all, the cutaneous surface (Fig. 20.13). There are usually some areas of uninvolved

Fig. 20.13 Extensive chronic plaque psoriasis with coalescence of lesions and the potential to evolve into an erythrodermic form. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 20.14 Acute unstable erythrodermic psoriasis. (Courtesy of St John's Institute of Dermatology, London, UK.)

skin. The psoriatic characteristics are retained, mild treatment is well-tolerated and the prognosis is good.

The second form is part of the spectrum of 'unstable' psoriasis (Fig. 20.14) [5]. It may occur at any time, either presenting suddenly and unexpectedly, or be ushered in by a period of increasing intolerance to local applications, UV therapy and of loss of control over the disease. It is more frequent in arthropathic psoriasis [6]. Generalized pustular psoriasis may revert to an erythrodermic state. It can be precipitated by infections, hypocalcaemia, antimalarials, tar [7] and classically by withdrawal of corticosteroids [8]. The characteristics of the disease are often lost, the whole skin is involved, the patient may be febrile and ill, the course is often prolonged, relapses are frequent and there is an appreciable mortality. In contrast to the stable form, itching is often severe.

Metabolic complications of erythroderma [2]

Persistent, universal inflammation of the skin may have important consequences for thermoregulation, haemodynamics, intestinal absorption, protein, water and other metabolism.

Under normal environmental conditions, radiant and convective heat loss from the body surface is increased, occasionally leading to dangerous hypothermia [9]. An increase in metabolic activity provides compensatory increases in body heat production, but at the expense of tissue catabolism and muscle wasting if prolonged. At the same time, the psoriatic or erythrodermic skin is hypohidrotic or anhidrotic [9], because of intraepidermal occlusion of the sweat duct [10]. Hyperthermia is a hazard in very high (e.g. tropical) ambient temperatures.

Skin blood flow, blood volume and cardiac output may all be increased, and if these changes persist, they may lead to failure of a cardiovascular system already compromised by hypertension, myocardial or valvular heart disease, or anaemia (particularly in old people). A healthy cardiovascular system will tolerate the increased metabolic demand for years. Malabsorption (dermatogenic enteropathy) may occur, reverting as the psoriasis remits, but earlier reports of structural small bowel changes have not been confirmed [11].

The principal loss in the profuse scaling of exfoliative psoriasis is of protein (keratin) but some iron is also lost. In fulminating psoriasis, further protein loss may be attributable to enteropathy, as well as leakage from the circulation into the skin [12]. Eventually, hypoalbuminaemia may contribute to the oedema caused by the skin inflammation itself, or cardiac failure. Mild anaemia is prone to develop, because of a combination of iron loss and possibly impaired absorption and utilization of iron. Serum and red cell folate and serum B_{12} may also be low.

The barrier efficiency of the skin in psoriatic erythroderma is impaired, the chief effect being increased transepidermal water loss. The urine output tends to drop and, if water intake is inadequate for any reason, dehydration results.

Modification by site

Scalp

Often, very thick plaques develop, especially at the occiput. The whole scalp may be diffusely involved, or multiple discrete plaques of varying size may be seen [1]. A morphological entity consisting of plaques of asbestos-like scaling, firmly adherent to the scalp and associated hair, has been termed pityriasis (tinea) amiantacea [2] (Fig. 20.15). It is most common in children and young adults, and is best regarded as a non-specific reaction pattern, which may be seen in other scaling scalp conditions. It may be an early manifestation occurring before the other stigmata of psoriasis. Hair loss, sometimes cicatricial, is seen in pityriasis amiantacea. Otherwise, common scalp psoriasis is not a frequent cause of alopecia, although it may occur [3]. Psoriatic erythroderma is associated with severe hair loss, as is vigorous local treatment. Hair-shaft abnormalities have been described on electron microscopy [3], but the rate of hair growth is normal [4].

Penis (Fig. 20.16)

A solitary patch on the glans of the uncircumcised male lacks scales, but its colour and well-defined edge are usually distinctive. Where confirmatory signs elsewhere are absent, a diagnostic biopsy may be necessary, as it may resemble erythroplasia or Zoon's plasma cell balanitis (see Chapter 71).

Fig. 20.16 Psoriasis: circumcised penis. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 20.17 Psoriasis: vulval region. (Courtesy of St John's Institute of Dermatology, London, UK.)

Flexural (inverse) psoriasis

Psoriasis involving the groins, vulva (Fig. 20.17), axillae, submammary folds, gluteal cleft and other body folds is more common in older adults than children. The frequency with which the genital area alone is involved appears to be low, but this area is not uncommonly involved together with other areas [5].

Scaling is greatly reduced or absent, and an assured diagnosis may therefore be difficult. Flexural psoriasis may occur as a primary disorder or as a Koebner phenomenon on top of infective or seborrhoeic intertriginous dermatoses. Failure to respond to antibacterial or antifungal preparations should arouse suspicion.

Fig. 20.18 Psoriasis of soles. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 20.19 Psoriasis of palms and fingers with sharply demarcated edge on forearms. (Courtesy of St John's Institute of Dermatology, London, UK.)

Although the lesions are themselves anhidrotic [6], the effect of hyperhidrosis of the surrounding skin, maceration and friction alter the appearance of the psoriasis, which retains its characteristic colour. The surface has a glazed hue and fissuring at the depth of the fold is common, especially in the gluteal cleft. The edges of the lesions are usually well-defined, unless secondary infection or medicament dermatitis, both quite common events, have occurred. Psoriasis of the retroauricular fold or the external auditory meatus may be particularly difficult to distinguish from infective or seborrhoeic dermatitis.

Hands and feet [7]

On the palms and soles (Fig. 20.18), psoriasis may present as typical scaly patches on which a fine silvery scale can be evoked by scratching; as less well-defined plaques resembling lichen simplex or hyperkeratotic eczema; or as a pustulosis. Mixed forms occasionally occur. It may often be difficult to distinguish the psoriasis from eczema, with which it may sometimes alternate. A sharply defined edge at the wrist or forearm (Fig. 20.19) and absence of vesiculation are helpful. On the dorsal surface, the knuckles frequently show a dull red thickening of the skin. Elsewhere on the hands and feet, psoriasis retains its typical character. There may be a relationship to trauma or occupational irritants.

Nail involvement [8,9]

This is seen in association with all types of psoriasis of the skin, and is frequently present with psoriatic arthropathy [10,11]. Figures for its incidence vary considerably. Minor degrees of involvement (e.g. pitting) are difficult to define and may occur in apparently normal subjects. If looked for carefully, nail changes are present in 25–50% of all cases [12]. There is no sex predilection, but patients over 40 years of age are affected twice as often as those under 20 years. Nail disease is more likely to be severe if psoriasis is early onset and familial [13].

Fig. 20.20 Fingernail pitting in psoriasis. (Courtesy of St John's Institute of Dermatology, London, UK.)

Although pitting (Fig. 20.20) is the most frequent change seen, discoloration, subungual hyperkeratosis (Fig. 20.21) and onycholysis are common, and splinter haemorrhages occur. Longitudinal biopsy of the nail bed and matrix has clarified understanding of these changes [14,15]. Pits, ridges and grooves are a result of

Fig. 20.21 Subungual hyperkeratosis in psoriasis. (Courtesy of St John's Institute of Dermatology, London, UK.)

psoriasis of the nail matrix, whereas onycholysis, subungual hyperkeratosis and splinter haemorrhages are attributable to disease of the nail bed or hyponychium [16]. Circular areas of discoloration of the nail bed and hyponychium may resemble an 'oil drop' below the nail. Histologically, these are areas of psoriatic change in the hyponychium [14]. *Candida* species frequently contaminate the psoriatic nail and bed, but dermatophytes are rare. In one series, 19 of 105 patients with candidal paronychia were found to have psoriasis [17].

Psoriasis in children [1–4]

Psoriasis is quite common in children; in approximately one-third of patients psoriasis begins in the first two decades of life [5]. Congenital psoriasis is very rare [6]. Guttate psoriasis is discussed below. Apart from the common forms, several other patterns of psoriasis occur in childhood. Interdigital tinea is uncommon in children and a toe cleft intertrigo may be psoriatic. Other flexural forms also occur (Fig. 20.17). The disease may mimic chronic blepharitis or perleche, usually unilaterally, with a small plaque of psoriasis on one eyelid extending to the lid margin, or on the cheek at the angle of the mouth. Psoriasis involving the face appears more common in children than adults [7]. In an Australian study of 1261 children with psoriasis, 26% had a psoriatic rash in the napkin area and facial involvement occurred in 38% [8]. The disease often first appears in the scalp [4], where it may present as pityriasis amiantacea (Fig. 20.15). An indolent pustular acrodermatitis, sometimes of only one digit, usually eventually proves to be psoriatic. More extensive, chronic lesions of the hands and feet may occur with persistent dryness, hyperkeratosis and fissuring. Pitting of the fingernails may be the only manifestation for months or even years. Follicular psoriasis occurs on the extensor prominences of elbows and knees. A child with apparently true psoriasis in a unilateral linear distribution has been reported [9].

All the more serious forms of the disease occur in childhood but are rare. Erythrodermic psoriasis [10] may be intractable for years and may or may not become pustular. Generalized pustular psoriasis is well documented in childhood [11,12]. Arthropathic psoriasis is rare but has been reported.

Atypical forms [1,2]

In a disease as common and variable as psoriasis, atypical forms are frequent. Many unusual localizations have been recorded,

including digital and interdigital forms. Verrucous lesions particularly affect the legs. A follicular form, especially in children, may be confused with pityriasis rubra pilaris but this form seems to be more common in the elderly [3,4]. A lichenoid variety has been reported to involve the flexures or the extremities in a 'glove and stocking' distribution [5].

Linear and zonal lesions

Linear psoriasis may occur in the presence of other typical lesions, as part of the Koebner phenomenon. Zonal lesions may represent a Koebner reaction at a site of herpes zoster. True linear psoriasis in the absence of lesions elsewhere is extremely unusual. It may be confused with inflammatory linear verrucous epidermal naevus (ILVEN) or may occur as a Koebner response on verrucous epidermal naevi of the non-inflammatory type [5]. True psoriasis arranged in linear bands unilaterally has also been described [6].

'Seborrhoeic psoriasis'

There is no reason why a genetically constituted psoriatic should not develop seborrhoeic dermatitis. Lesions involving the scalp, eyebrows and the region of the ears are often of this type, having features of both diseases or changing during the course of observation. Difficulties also occur in the flexures as in the 'napkin psoriasis' of infants [7] and in obese, middle-aged or elderly patients.

Mucosal lesions

True mucosal involvement by psoriasis appears to be rare, but has been associated with cutaneous involvement by pustular, erythrodermic and plaque forms [8–12]. Various lesions have been described, including grey, yellowish, white or translucent plaques or annular forms, diffuse areas of erythema and the geographic tongue [8,10,12]. The association of both psoriasis and geographic tongue (benign migratory glossitis) with HLA-Cw6 provides further evidence that the two disorders are related [13].

Ocular lesions

Blepharitis, conjunctivitis, keratitis, xerosis, symblepharon and trichiasis have been recorded. Chronic uveitis has been found, particularly in patients with psoriatic arthritis [14]. Uveitis was also reported in patients with generalized pustular psoriasis or psoriatic arthritis, who were receiving treatment with methotrexate. It was unclear whether methotrexate contributed to the ocular lesions [15].

Disease associations

Studies have reported association between psoriasis and many other diseases, both cutaneous and systemic. Psoriatic arthritis, a seronegative arthritis, is a frequent and classical association and will be discussed elsewhere. Crohn's disease is also more frequently observed [1], an observation that has led to considerable advances in our understanding of genetic mechanisms particularly with respect to key T-cell differentiation pathways. Skin diseases associated with psoriasis include acquired bullous disorders most notably, bullous pemphigoid [2], and vitiligo [3] with psoriasis sometimes reported to be confined to vitiliginous areas.

Intriguingly, Henseler and Christophers [4] reported, in a series of 40 000 patients seen in a dermatology clinic in North Germany, the under-representation of several cutaneous disorders including infections (bacterial, fungal, viral) and atopic dermatitis. Proper community-based epidemiological investigations are required to confirm these findings.

Patients with psoriasis are at an increased risk of developing malignancy, particularly non-melanoma skin cancer and lymphoproliferative cancers. The risk is greatest for those with severe disease and probably reflects those treated with systemic agents and phototherapy [5]. A recent study of 67 761 patients on the UK general practice research database confirms this observation, particularly with respect to lymphohaematopoietic and solid tumours, and provides evidence that risk remains after controlling for systemic therapy [6], although the excess risk is low.

Psoriasis has been reported rarely to occur more frequently in certain metabolic disorders. These include gout [7], although whether it is a true association requires formal epidemiological study. It has been suggested that gout may be precipitated by systemic antipsoriatic therapy [8]. Hypocalcaemia has been reported in association with severe and pustular forms of psoriasis, including certain syndromes [9] and following thyroidectomy [10].

Chronic, recurrent, multifocal osteomyelitis is an unusual, sterile, inflammatory entity of unknown cause characterized by pain and swelling in affected bones. Association with pustular and non-pustular forms of psoriasis has been reported [11,12]. Closely related to this entity is the SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, osteitis) most frequently described in the radiological and rheumatological literature [13].

An association of psoriasis and cardiovascular disease (CVD) has long been recognized. CVD risk is highest in those with more severe disease, with standarized mortality rates reaching 2.6 [14], particularly in younger patients. Much of this risk is due to coexistence of known CVD risk factors, including type II diabetes mellitus, dyslipidaemia, hypertension and obesity [15,16], increasingly referred together as the 'metabolic syndrome'. However, emerging evidence suggests that the risk may in part remain even after controlling for known risk factors [17]. Taken together, these studies indicate that treating patients with moderate or severe psoriasis requires attention to these important general medical issues.

Complications

These are uncommon.

Infection

Secondary infection of psoriatic lesions is rarely a problem except during topical steroid therapy under occlusive dressings, when folliculitis and furunculosis are a hazard. However, staphylococci are carried by 50% of psoriatics, especially on the lesions [1]. This relative 'resistance' of psoriatic skin to infection despite the carriage of staphylococci is probably in part caused by the presence of endogenous antimicrobial peptides—cathelicidins and β-defensins—in the skin of patients with psoriasis [2]. Furthermore, psoriasis is associated with increased β-defensin genomic copy number [3]. Carriage of staphylococci may prove to be a problem if a surgical procedure is to be carried out through a psoriatic plaque. Because of exfoliation, these patients may disseminate infections in hospital wards. A series of postoperative deaths resulting from sepsis was caused by an anaesthetist with psoriasis carrying *Staphylococcus aureus* [4]. Rarely, flexural psoriasis may become clinically infected, especially if fissuring occurs (e.g. in the natal cleft).

Itching

This is very variable in psoriasis, ranging from complete absence to severe pruritus in a minority of patients. It is more common in unstable forms. One study from Poland reported that 80% of patients complain of itching [5]. Pustular and erythrodermic patterns are more usually accompanied by sensations of burning or tightness. Often, the degree of itching reflects the emotional state of the patient and, if severe, may be a symptom of anxiety or depression.

Arthritis

See below.

Alcoholism

Heavy drinking was found significantly more commonly in male patients with severe psoriasis than in other groups with the disease, and could be a symptom of stress caused by severe skin disease [6,7]. The prevalence of psoriasis in patients with alcoholic liver disease (15%) is significantly higher than in the normal population [8].

Nephritis and renal failure

The role of streptococcal infection, especially in the throat, in provoking acute guttate psoriasis is discussed above. It is exceptionally rare for post-streptococcal guttate psoriasis to be associated with glomerulonephritis. One such case has been reported [9], as well as a case of concomitant onset of diffuse psoriasis and mesangiocapillary glomerulonephritis [10]. Renal failure brought about by acute tubular necrosis may rarely result from the oligaemia after loss of albumin into and from the skin in acute pustular psoriasis [11].

Hepatic failure

Severe abnormalities of liver function may occur in erythrodermic or pustular psoriasis, and are likely to be related to drugs, alcohol intake and oligaemia [6,7,12,13].

Apical pulmonary fibrosis

This has been established as a non-articular complication of ankylosing spondylitis, and has been reported in association with a case of psoriatic spondylitis [14]. Two further patients with chronic plaque psoriasis, one with peripheral arthropathy and one free of joint disease, have been reported with apical pulmonary fibrosis typical of that found in association with ankylosing spondylitis. Extensive investigations and follow-up observation showed no evidence of other disease [15].

Amyloidosis

Amyloidosis of the secondary type is a rare sequel of arthropathic, generalized pustular and severe non-pustular psoriasis [16–19]. It is an additional cause of renal failure in association with psoriasis, and may follow an aggressive, fatal course [18].

Biomarkers

There is no constantly present laboratory abnormality in uncomplicated psoriasis. Erythrocyte sedimentation rate (ESR) and C-reactive protein are unaffected or inconsistently elevated. Modest hyperuricaemia may be found and has been attributed to enhanced epidermopoiesis. The occasional finding of low folate levels can be similarly explained [1]. The laboratory abnormalities associated with erythrodermic psoriasis and arthropathic psoriasis are described in the relevant sections. Immunoglobulins are generally normal, but selective IgA deficiency [2] and monoclonal IgG gammopathy [3] are documented in association with psoriasis.

Studies have reported elevation in many serum immunological markers, including soluble IL-2 receptor, soluble ICAM-1, IL-6 and TNF-α [4,5], consistent with psoriasis being a systemic immunological disease. Indeed more recent studies have further expanded the range of upregulated markers to include those relating to angiogenesis [6] and others derived from adipose cells [7], thus linking obesity and inflammation. However, the presence of these markers is inconsistent both in absolute terms and in their response to therapy, indicating that at present they have no clinical role. Identification of valid biomarkers of disease severity, type and response to therapy would represent a major advance.

Differential diagnosis

The characteristics already defined are usually sufficient to enable the diagnosis to be made, but doubt may arise in atypical cases, in particular sites, and when psoriasis is complicated by or alternates with other diseases. In seborrhoeic dermatitis, the lesions are lighter in colour, less well-defined and covered with a dull or branny scale. Eczema at times develops a psoriasiform appearance, especially on the legs. Hyperkeratotic eczema of the palms is a common cause of misdiagnosis. Colour, scratch-evoked scaling and well-defined margins are suggestive of psoriasis, and nail changes may be diagnostic. Lichen planus should give rise to difficulty only when the two diseases alternate or coexist, especially when present as hypertrophic lesions on the legs, as penile lesions and on the palms. The violaceous colour, glistening surface and presence of oral changes are usually decisive. Lichen simplex can resemble psoriasis closely, particularly on the scalp and near the elbow. The intensified skin markings, rather ill-defined edge and the marked itching are characteristic, and the point of the elbow tends to be avoided. Pityriasis lichenoides chronica can closely resemble guttate psoriasis, but the lesions are usually less evenly scattered, have a brownish red or orange–brown colour and are capped by an opaque soft 'mica-like' scale. Candidiasis shows a glistening deep red colour suggestive of psoriasis, particularly in the flexures, but scaling tends to be confined to the edge, and small satellite pustules and papules are usually evident outside the main area. Tinea cruris has a well-defined, often polycyclic edge, but *Trichophyton rubrum* infections, especially of the palm, cause difficulty. If corticosteroids have been applied, scaling may be absent and the diagnosis must be made by microscopy and culture.

Less common causes of confusion are pityriasis rubra pilaris and secondary syphilis. The resemblance to pityriasis rubra pilaris

may be close, especially in the erythrodermic phase. The colour is generally less distinct, and dark red follicular lesions are apparent, and the acquired palmar and plantar keratoderma has a yellow–orange tinge. The psoriasiform lesions of syphilis may cause difficulty to the inexperienced; condylomas, mucosal lesions and other signs of the disease are usually found, if sought. Porokeratosis of Mibelli on the palms and soles, patches of Bowen's and Paget's disease and penile erythroplasia may resemble psoriasis, but the lesions are usually solitary except in chronic arsenical poisoning. A biopsy may be necessary. The rare recurrent circinate erythematous type of psoriasis of Bloch and Lapiere may pose considerable diagnostic difficulties. It is to be distinguished from erythema annulare centrifugum, and from the annular migratory necrolytic erythema associated with carcinoma of the pancreas [1], and sometimes with subcorneal pustular dermatosis. The distribution, course and histology will usually be sufficiently decisive to distinguish these. Psoriasiform drug eruptions must be distinguished from psoriasis.

Parakeratosis pustulosa is an eczematoid eruption seen in young children and commonly mistaken for psoriasis, atopic dermatitis or tinea. It affects the skin around one or more fingernails or toenails, causing subungual hyperkeratosis and thickening of the free edges of the nail. Scaling is more marked than pustulation, the course is often protracted and recurrences are the rule, whatever the treatment. A large series has been reported [2]. Histology shows hyper- and parakeratosis, acanthosis, papillomatosis and a marked infiltrate around dilated capillary loops [3].

Course and prognosis [1–5]

This remains as unpredictable as it was 150 years ago. 'Psoriasis is at all times and under all forms a very troublesome and, often, an intractable disease, but it is rarely dangerous to life' [6]. 'It is impossible to say, in any particular case, how long the disease will last, whether a relapse will occur, or for what period of time the patient will remain free from psoriasis' [7]. Guttate attacks carry a better prognosis than those of a slower and more diffuse onset, and have longer remissions after treatment [3]. Few studies have assessed the long-term prognosis for first episodes of guttate psoriasis. In one study, only five (33%) of 15 patients followed up 10 years after an initial episode of guttate psoriasis had developed chronic plaque disease [8]. At the other extreme, erythrodermic and pustular forms carry an appreciable mortality and arthropathic forms a considerable morbidity. Early onset and a family history of the disease appear to worsen the prognosis [2].

Among environmental factors, sunlight and hot weather are favourable [1,2,4]; pregnancy had no effect in approximately half of patients [2,4], but improvement was more common than worsening. The influence of stress or 'worry' is more difficult to determine. Patients' beliefs on the importance of stress are probably dependent on cultural and linguistic differences. Sixty per cent of patients studied in Manchester, UK, believed that stress was an important trigger of their psoriasis [9]. In one series [10], 50% reported worsening with 'worry', in others 33–42% reported worsening [1,4]. Common experience suggests that stress is of considerable importance in some patients, but may be too easily accepted as a general cause of variations in this disease.

Complete remissions of psoriasis over 1–54 years were reported by 39% of patients in a large series [4], often without treatment. An even higher figure applied to Japan [11], but lower figures are also quoted [12].

In one follow-up study of 'napkin psoriasis', two out of 67 had developed true psoriasis in 5.4 years [13]; four developed seborrhoeic dermatitis. In another study [14], 123 infants were reviewed 5–13 years later. Of 71 who had shown psoriasiform napkin eruptions, 12 had developed psoriasis; of 40 who had a predominantly seborrhoeic pattern of flare, none had shown later signs of psoriasis but 15 (37%) had atopic eczema. Most of the psoriatic cases occurred within the first 3 months of life.

Relapse

Relapse is the rule, however completely the lesions are treated and by whatever method. Only three of 260 patients in one series [2] were clear for 5 years or more and most of the rest for only 6 months. In another series [15], only three out of 95 were clear for 5 years or more and 11.5% relapsed rapidly. A 7-year follow-up of 142 patients [3] indicated that intensive outpatient treatment gave longer remissions than those treated at home, or the presumably more severe cases admitted to hospital. Guttate lesions had the best prognosis.

There is little doubt that even severe cases can be maintained in prolonged remission by the use of systemic therapies, including the biologics (Chapter 74).

Management

Every patient with psoriasis presents an individual problem. Treatment depends upon age, sex, occupation, personality, general health, intelligence and resources, as well as the type, extent, duration and natural history of the disease. Extensive psoriasis may be ignored by the phlegmatic, yet trivial lesions on exposed areas can be ruinous for the sales executive or artiste. With this in mind, an assessment tool for psoriasis severity has been developed—the Salford Psoriasis Index—which takes into account physical extent of disease, psychosocial difficulty and previous therapy as a means of measuring difficulty in treatment [1]. Reassurance and emotional support are invaluable, stressing the non-contagious and benign nature of psoriasis, the possibility of spontaneous remission, and the availability of a wide range of therapeutic weapons for all psoriatic seasons. Fears for the future of children need to be allayed. The physician must take a long-term view. Treatment must always be appropriate to its severity and importance in that individual. It should never be more unpleasant, intolerable or dangerous than the disease itself. Its details must be commensurate with the patient's intelligence, physical capacity, time and socioeconomic circumstances.

General and non-specific measures

Attention to the patient's general, physical and psychological health is always worthwhile. Mild anaemia, minor but untreated arthritis, an anxiety state or depression, especially in the elderly patient, may all critically lower the patient's tolerance of his or her disability. Physical extent of psoriasis and psychosocial disability produced by the disease do not correlate [2]. Rest, mild sedation, removal from a troublesome environment, a holiday or a short stay in hospital may all help to turn the therapeutic tide. The importance of talking to patients, trying to allay their concerns, coupled with advice on how to handle negative beliefs about their disease cannot be overestimated. A study of cognitive–behavioural therapy (CBT) as an adjunct to pharmaceutical therapies in patients with psoriasis showed a significantly greater reduction in psoriasis severity in the CBT group as compared to pharmaceutical therapy alone, both at the end of 6 weeks' intervention and 6 months later [3]. Indeed, high worry appears to have a significant detrimental effect on response to PUVA therapy and is the best predictor of outcome [4]. Harmless placebos may give comfort and should not be despised.

Diet is unimportant. Diets rich in zinc [5] and turkey meat [6] or low in tryptophan [7], protein [8] or calories [9] do not influence the disease. Spa treatment, involving rest and relaxation in an area where high sunlight exposure is possible, such as the Israeli Dead Sea coast, can undoubtedly induce remissions [10].

General approach

Most stable plaque psoriasis should first be approached with outpatient topical therapy, which disrupts the patient's routine as little as possible. Written guidelines on the management of psoriasis in primary care are effective and help to ensure appropriate referral to secondary care [11].Tar preparations and vitamin D analogues are appropriate, but corticosteroids can be used for localized psoriasis. If necessary, dithranol can be introduced later but is more difficult to handle. If sunlight or UVB phototherapy are available, light can be added at this stage or earlier. Special routines may be necessary for the scalp. If the psoriasis is severe and extensive and the above initial measures have failed, more intensive tar or dithranol therapy should be considered, in a day-care unit or a hospital if such facilities exist, with or without UV phototherapy. The indications for phototherapy, photochemotherapy, systemic therapies and biologics are discussed in Chapters 74 and 78. Intralesional corticosteroid injections, PUVA therapy, retinoids, cytotoxic drugs and ciclosporin are discussed in the appropriate sections below but, in general, the more hazardous measures should be restricted to those patients whose psoriasis is physically, socially, economically or emotionally disabling, and in whom conventional and conscientious topical therapy has failed. Each of the available modalities is discussed in detail below.

Local therapy

Tar [1,2]

Coal tar is a complex mixture of thousands of substances produced by primary condensation during the carbonization of coal [3]. Some 400 known substances comprise 55% of tar by weight [2,3]. Standardization is impossible and, because great variation in biological activity of various samples of tar has been demonstrated [4], therapeutic results achieved in different centres may not be comparable.

Tar has been used in topical therapy for more than a century. It is assumed to have an antimitotic effect but this is not proven [5]. Its use in psoriasis was popularized by Goeckerman [6] and, for more than half a century since, his regimen of daily application of 2–5% crude coal tar, combined with a tar bath and UV light, has been a mainstay of in-patient treatment [7]. In skilled hands, substantial clearing of stable discoid psoriasis can be achieved in 3–6 weeks in 80% of patients [7]. Many modifications of Goeckerman's regimen have been advocated, utilizing alcoholic extracts of tar (e.g. coal-tar solution) in cream or ointment bases, tar gels [8], etc., which are 'cleaner' and easier to handle, but it seems that the cruder the tar extract, the more effective it is [2]. Concentrations of coal-tar solution up to 10% can be incorporated in various vehicles for outpatient therapy, and many commercial creams, lotions, ointments, gels and shampoos containing tar extracts are available throughout the world.

Controversies surrounding the roles of tar and UV light have not yet been fully resolved [2]. Tar alone is certainly active in psoriasis [9], as is UVB alone [10]. Coal tar seems to sensitize the skin to UVA but not to UVB [11] and phototoxicity is of photodynamic type [12,13]. Nevertheless, UVB is more valuable than UVA in conjunction with tar [14] and probably UVB erythema thresholds prevent UVA exposure sufficient to cause photosensitization in the Goeckerman regimen [15].

Despite a huge literature, it is remarkably difficult to quantify success rates with tar regimens in terms of percentage of patients cleared, the number of days of treatment needed to achieve clearance or the length of remission [2,7]. Only one placebo-controlled trial of coal tar was found in a recent systematic review [16]. This short 4-week trial showed that 5% liquor carbonis detergens was more effective than emollient vehicle [17]. Exorex®, a new formulation of 1% coal tar in esterified fatty acids, was no more effective than crude coal tar in a head-to-head comparative study [18]. Recent attempts at short-contact crude coal-tar treatment have shown that daily 1-h applications of 30% crude coal tar in yellow soft paraffin are effective in improving psoriasis, but less so than daily 23-h treatment with 5% crude coal tar in yellow soft paraffin. It was concluded that the former has no place in in-patient management, but that it may have a limited role in certain outpatients [19]. A combination of 5% crude coal tar and dithranol was found to be as effective as dithranol alone when used in short contact treatment of psoriasis, but was recommended in preference to the latter, as less irritancy was encountered [20]. Others have found that tar and dithranol combination regimens do not enhance the clearance rate of psoriasis and that they offer little benefit over dithranol alone [21,22].

The safety of tar has been regarded as one of its great virtues. In spite of the evidence that increased levels of 1-hydroxypyrene, polycyclic aromatic hydrocarbons and mutagenic activity (as determined by the Ames plate assay) may be detected in the urine of patients following 3 days of therapeutic exposure to coal tar [23], systemic toxicity is unknown. Primary irritation is uncommon except in unstable psoriasis, and on the face, genitalia and in the flexures. Allergic contact dermatitis does occur, but is rare. Folliculitis is the most common side effect. Notwithstanding the undoubted carcinogenicity of coal tar in the skin of experimental animals [24] and human workers chronically exposed to tar, long experience dictates that the risk from therapeutic tar products is small [1,24]. There are certainly case reports of various scattered skin tumours developing in patients treated previously with tar [25–27], but some of these patients had been exposed to other known carcinogens. Reports of carcinoma at the site of local coal-tar treatment are few but significant [28–31]. It may, therefore, be wise to avoid prolonged application of coal tar to the anogenital area, including the scrotum, sites that have been involved in at least two case reports. In spite of negative results in several other series [32–34], a case–control study has shown that there was a significantly greater risk of skin cancer in psoriatic patients treated with high-exposure coal tar and UV light therapy, than in matched patients treated with smaller dosage therapy [35]. This association was confirmed by further epidemiological studies in which patients receiving multiple Goeckerman regimens were compared with age- and sex-matched controls [34]. Another study involved 719 psoriatic patients in the west of Scotland, all of whom had received intermittent topical coal-tar therapy over a 10-year period, but no cytotoxic drugs, ionizing radiation or prescribed UV radiation. No increase in malignancy of skin, bladder or any other organ was found in the psoriasis patients over that in the general population [35]. The increased incidence of malignancy [36,37] may, therefore, depend on exposure to high-dose UVB. It would therefore appear prudent to place patients who have received repeated intensive Goeckerman regimens under careful surveillance. The benefits of repeated Goeckerman regimens in patients with difficult psoriasis may, however, outweigh the risk of skin malignancy, which should be easy to detect and treat.

Other contraindications to tar therapy do exist. Erythrodermic or generalized pustular psoriasis will infrequently tolerate even the weakest tars. Pre-existing folliculitis or severe acne are also possible contraindications.

Dithranol (anthralin) [1,2]

The value of chrysarobin, a tree-bark extract, in psoriasis was discovered accidentally [3] a century ago. A synthetic derivative, dithranol (1,8-dihydroxy-9-anthrone), was introduced by Unna in 1916 [4] but is unstable. The role of salicylic acid in stabilizing dithranol formulations was also an accidental discovery, and led to the development of the Ingram regimen [5], which has played a central part in psoriasis management since, especially in Europe. After a tar bath in which scales and the previous applications are removed, suberythema UVB is given, and the lesions then precisely covered with dithranol paste. The initial concentration is 0.05 or 0.1%, increasing cautiously up to 4% according to response, and aiming to avoid irritation of the normal or psoriatic skin [5–7].

Fig. 20.22 Psoriasis partially treated with dithranol, showing brownish staining. (Courtesy of St John's Institute of Dermatology, London, UK.)

The paste is kept in position with tubular gauze or stockingette. After 18–22 h, the cycle is repeated and can be on an in-patient or day-care basis. In skilled hands, most patients with discoid psoriasis can be cleared in 3 weeks, leaving deep brown staining (Fig. 20.22) of the treated skin, which soon disappears after treatment is stopped. Dithranol paste is not suitable for the head and neck, flexures or genitalia, where it is liable to spread and is too irritant; it is highly irritant if accidentally introduced into the eyes. It also stains bed linen and clothing irreversibly.

In the early 1980s, disenchantment with the side effects of cytotoxic and PUVA therapy stimulated a resurgence of interest in dithranol [2], its chemistry and pharmacology [8–10], pharmacokinetics and percutaneous absorption [11,12], and mode of action [2,13,14]. Attempts were made to modify its formulation [15] to allow easier application and removal, and relatively stable cream formulations introduced that are effective, although less so than the classical paste [16–18]. Low-strength formulations may also be active yet less irritating and staining [19–21]. Kinetic studies showing penetration of the full epidermis in 100 min or less [11,22] encouraged the notion that 'short-contact' therapy may be effective and less irritant, while being easier and more convenient for the patient. Dithranol application periods as short as 10 min/day [22–27] have been effective. One study has even shown that immediate removal of dithranol is as effective as removal at 20 min [28]. Another study showed that a 2-h short-contact regimen using dithranol in Lassar's paste was as effective as a standard 24-h Ingram regimen, but that both of these were more effective than 10–20 min contact periods using dithranol in soft paraffin base. Higher concentrations (up to 12%) applied twice daily for 30 min were surprisingly well-tolerated, but provided no advantage over 2% dithranol in Lassar's paste applied for 2 h once daily. The latter schedule was therefore recommended as optimal for home use in well-motivated patients [29]. A randomized controlled trial from the UK [30] showed that dithranol in Lassar's paste applied once daily as per the Ingram regimen was as effective as twice daily applications in clearing psoriasis in in-patients, although nursing time was longer for the twice daily group. A comparative study of short-contact dithranol versus in-patient treatment or UVB

phototherapy reported that short-contact dithranol was the most cost-effective option [31].

Combination of short-contact dithranol with broad-band UVB appears to have little advantage over short-contact dithranol alone [27,32] or broad-band UVB alone [33,34]. However, dithranol or calcitriol in combination with narrow-band UVB (311 nm) were equally effective [35] and short-contact dithranol had a cumulative UVB sparing effect when used in combination with 311 nm narrow-band UVB [36].

Attempts to address the two main side effects of dithranol usage—local staining and irritation—have led to the development of combination therapy and new formulations of dithranol.

Dithranol in 0.0125% clobetasol propionate (quarter-strength Dermovate) ointment was reported to produce more rapid clearing than dithranol in Lassar's paste. The relapse period was similar in the two groups, although folliculitis was an important side effect in the steroid group [37]. In contrast, a combination of dithranol and fluocinonide in Lassar's paste, although causing more rapid initial clearing and reducing irritancy, did not reduce total clearance time when compared with dithranol in Lassar's paste alone. In this study, the steroid combination was also associated with a more rapid relapse rate [38]. Swinkels *et al.* [39] combined short-contact dithranol with clobetasol-17 propionate, each used once daily, and found that this accelerated the improvement of psoriasis produced by dithranol alone. Micanol is a microcrystalline formulation of 1% dithranol that releases the active medication at skin surface temperature [40]. This formulation reduces staining of fabrics significantly, but skin staining can still occur. A novel aqueous gel-based liposome entrapped formulation of dithranol appears, in an open study at least, to produce no irritation and minimal staining [41].

Notwithstanding these developments, any form of dithranol therapy requires careful control and explanation if the patient is not to become quickly disenchanted. The drug has the great virtue of lacking systemic toxicity, although if very high concentrations become general, continued vigilance will be necessary. Allergic contact dermatitis is extremely rare but has been documented [42]. Overall, the relative impracticality of dithranol therapy as compared to topical vitamin D analogues indicates that use of this effective and safe therapy is in decline, particularly for outpatient use.

Topical corticosteroids

Topically applied corticosteroids are of established value in psoriasis [1,2]; in the USA, they are still the mainstay of topical therapy [3]. In appropriate concentrations, they are still the treatment of choice on the face and neck, flexures and genitalia, however topical calcineurin inhibitors are becoming widely used at these sites. Diluted topical steroids are also used in unstable, erythrodermic and generalized pustular psoriasis, in preference to tar or dithranol, although bland emollients may be more suitable. On the scalp and other parts of the body, they can be tried if tar has failed and dithranol is inappropriate or unsuccessful. Corticosteroids have the merits of ease of application and removal, lack of irritancy and the absence of staining of skin or linen. The hazards of therapy are now well known, and enhancement by polythene occlusion will magnify and hasten side effects. Topical steroids under occlusion do have a limited place in the management of recalcitrant psoriasis of the scalp, hands, feet and other areas. Superior results have been claimed with topical steroids occluded by a hydrocolloid dressing as opposed to plastic film [4]. Apart from the cutaneous adverse effects, plasma cortisol levels are easily suppressed by the most potent preparations or high doses [5,6]. As little as 7 g/day of 0.05% clobetasol propionate or 0.05% betamethasone dipropionate was sufficient to suppress morning plasma cortisol levels in 20% of patients [7]. These unwanted effects, and evidence of tolerance [8] induced by intensive therapy, have stimulated use of less frequent applications [2,3,5,9,10]. Thus, once daily applications of 0.1% halcinonide cream were as effective as thrice daily applications [2], and 0.05% clobetasol propionate used on alternate days, or even less frequently, induced and maintained remissions for up to 5 months [9]. A novel regimen of topical high-potency corticosteroid—betamethasone dipropionate—is to apply the agent three times over a 24-h period each week [10]. This so-called 'weekend therapy' was shown to maintain improvement in psoriasis in up to 60% of patients so treated. Another regimen [3] using fluticasone propionate ointment once daily for two consecutive days per week maintained control of psoriasis for up to 10 weeks.

Newer formulations of corticosteroids, particularly foams, are easier to apply than traditional creams or ointments and can be used for scalp, truncal or limb psoriasis [11]. There is evidence that intensive treatment of discoid psoriasis with the most potent preparations can induce generalized pustular psoriasis [12–14]. With less potent or diluted preparations, the volume can be increased *pro rata*. Potent preparations are likely to be needed on the scalp and knuckles particularly; conversely, the flexures and inner thighs need much weaker products, if striae formation is to be avoided. Hydrocortisone (except as the butyrate ester) [15] is too weak to be of value, except perhaps in combination with tar for facial lesions.

Intralesional corticosteroid therapy

Triamcinolone hexacetonide (5 mg/mL) or triamcinolone acetonide (10 mg/mL) can be infiltrated intradermally into localized psoriatic lesions by needle injection. This is a valuable technique in troublesome, small, resistant lesions on the backs of hands, especially the knuckles, intensely pruritic small plaques or lichenoid lesions. The effect is long-lasting and repetition of the injection may be unnecessary for several months. In treatment of psoriasis of fingernails, the nail fold can be injected, but results are disappointing and the procedure may be painful.

Topical calcineurin inhibitors

The topical calcineurin inhibitors tacrolimus and pimecrolimus were initially developed for the treatment of atopic dermatitis in childhood. Both preparations have been shown to be effective for psoriasis affecting the face, neck, flexures and genitalia [1–3]. Their advantage is that unlike topical corticosteroids they are selective, unlikely to be absorbed systemically and do not produce skin atrophy making them suitable for long-term use.

Vitamin D analogues

The naturally occurring, active metabolite of vitamin D_3, 1,25-dihydroxyvitamin D_3 (calcitriol) [1], and three synthetic analogues, calcipotriol [2–4], 1,24-dihydroxyvitamin D_3 (tacalcitol) [5,6] and 1,25-dihydroxyvitamin D_3 (maxacalcitol) [7], have all been shown to be effective when applied topically in psoriasis. The mechanism of action of these agents is via vitamin D receptor-mediated effects on the proliferation and differentiation of epidermal keratinocytes [1,8] and on the immunological features of psoriasis, including shifting the Th1 cytokine profile of plaques towards a Th2 cytokine profile [9]. The introduction of topical vitamin D analogues into clinical practice in the early 1990s [10] undoubtedly transformed first-line management of psoriasis. Topical formulations of calcipotriol and other vitamin D analogues are probably the most widely prescribed active topical therapy for plaque psoriasis. Systematic reviews [11,12] of calcipotriol therapy for psoriasis attest to its equivalence or superiority to other available topical therapies apart from potent topical corticosteroids [11]. The most widely prescribed analogue in current use, calcipotriol (50 μg/g) ointment, has been reported to be at least as effective as 0.1% betamethasone valerate ointment [13,14] and more effective than short-contact dithranol therapy [15] in plaque psoriasis. Calcipotriol (50 μg/g) ointment has also been shown to be effective and safe in children when administered in amounts up to 45 g/week/m^2 [16]. Side effects of calcipotriol include local irritation, which may affect up to 20% of patients, and can be particularly troublesome on the face, leading to the need for withdrawal of treatment [14–16]. Vitamin D and its analogues all have the potential to affect systemic calcium homeostasis with hypercalciuria and hypercalcaemia [17]. Calcipotriol (50 μg/g) ointment was found to cause no significant changes in serum total adjusted calcium when used in amounts up to 100 g/week [18,19] or 50 g/week/m^2 [18] in adults, and up to 45 g/week/m^2 in children [16]. However, subsequent work showed significant rises in 24-h urinary calcium levels with calcipotriol ointment 100 g/week [19]. Significant rises in both serum and urinary calcium levels were also seen with high doses of calcipotriol ointment of up to 300 g/week [20,21]. It would therefore be prudent to restrict the amount of calcipotriol (50 μg/g) ointment used per week to less than 100 g or 50 g/m^2, and to monitor serum and urinary calcium levels carefully should these doses be exceeded.

New vehicles for calcipotriol have been introduced and calcipotriol cream appears to be slightly less effective than the ointment formulation [22] but cosmetically more appealing. Combining calcipotriol monotherapy applied in the morning with a super-potent topical corticosteroid such as halobetasol ointment applied in the evening for 2 weeks was superior to either drug used twice daily [23]. Based on this observation, a stable ointment formulation of calcipotriol 50 μg/g and betamethasone dipropionate 0.5 mg/g has been investigated and licensed for therapy. Used twice daily, this combination shows superior efficacy to either calcipotriol or betamethasone alone [24] with better clearance and faster onset of action. Once daily application of the combination appears no less effective than twice daily applications [25]. Whether withdrawal of the combination following treatment leads to an increase in rebound or pustular relapse remains to be ascertained.

Long-term treatment of chronic plaque psoriasis with calcitriol (3 μg/g) ointment confirmed previous shorter-term studies indicating the efficacy of this natural vitamin D_3 metabolite [1]. The relative efficacy of this agent compared with topical calcipotriol, corticosteroids or dithranol is currently unclear, although the relapse rate following withdrawal of calcitriol ointment appeared lower than that after topical corticosteroid therapy [1]. No statistically significant changes in serum or urinary calcium levels were found, even in patients using large quantities of the ointment to treat up to 35% of the body surface area for 3 months [26]. Transient local skin irritation, occasionally necessitating withdrawal of treatment, may occur, but calcitriol 3 μg/g ointment is better tolerated than calcipotriol ointment for treatment of face and flexures [27].

Tacalcitol 4 μg/g ointment applied once daily is effective for the treatment of chronic plaque psoriasis [6]. A systematic review [12] indicated that it was probably inferior in efficacy to calcipotriol 50 μg/g ointment. A long-term 18-month study in 197 patients using tacalcitol once daily demonstrated efficacy and safety with no evidence of effect on calcium homeostasis [28], although 5.9% of patients discontinued therapy because of skin irritation. Maxacalcitol 25 μg/g ointment applied once daily for 8 weeks is an effective treatment for chronic plaque psoriasis and may be more effective than once daily application of calcipotriol 50 μg/g ointment [7].

Calcipotriol and tacalcitol have been combined with other therapies. Calcipotriol ointment enhances the efficacy of PUVA and UVB phototherapy [29,30]. As UVA partly inactivates calcipotriol [31] and UVB is absorbed by calcipotriol [32], it is recommended that calcipotriol is not applied until after phototherapy sessions. Tacalcitol ointment when combined with PUVA is UVA-sparing [33] and calcitriol is UVB-sparing in combination [34]. Calcipotriol 50 μg/g ointment used in combination with methotrexate enables lower cumulative doses of methotrexate to be used [35].

Vitamin A analogues

Retinoids, with their pleiotropic effects on cellular proliferation and differentiation, would appear to be an ideal topical preparation for psoriasis. Early studies were performed with topical all-*trans*-retinoic acid (tretinoin). Efficacy was reported but local irritation was a major problem [1,2]. The development of retinoic acid receptor (RAR) selective retinoids facilitated a revisitation of the role of topical retinoids. Tazarotene is a synthetic retinoid, whose main metabolite, tazarotenic acid, binds to RARs β and γ [3]. Tazarotene in a 0.05 or 0.1% gel applied once daily for 3 months is significantly more effective than vehicle in the treatment of chronic plaque psoriasis [4,5]. The main drawback of tazarotene is local irritation at the site of application, so much so that various strategies have been devised using once daily application of a potent topical corticosteroid, such as mometasone furoate or clobetasol propionate to alleviate this problem [6,7]. More recently, a cream formulation (0.05 and 0.1%) of tazarotene has been developed. A study [8] involving 1303 patients treated once daily with tazarotene cream reported significant reduction in clinical severity of psoriasis—the 0.1% formulation was more effective but less well-tolerated. Tazarotene is probably best reserved for thick, recalcitrant plaques of psoriasis.

Occlusive dressings alone

Improvement or clearing of psoriasis lesions has been described following prolonged occlusion with various tape products, including sticking plasters, although different tapes varied markedly in their effectiveness [1,2]. These findings have been confirmed in a prospective bilateral comparison study in which prolonged application of an adhesive hydrocolloid occlusive dressing was found to be superior to twice daily applications of a potent topical corticosteroid, and as effective as erythemogenic UVB treatment. Side effects included hyperpigmentation, pain on removal of dressings resulting from hair traction and, in a minority, a Koebner response or offensive odour [3]. Further evidence came from a 3-week study when occlusion alone was as effective as the potent topical corticosteroid—fluocinonide ointment [4]. Mechanism of action may relate to normalization of the permeability barrier [5]. This treatment appears to have potential in the management of limited psoriasis.

Treatment of the scalp

Psoriasis of the scalp can be intractable and resistant to therapy. Tar-containing shampoos should be the first approach, carried out daily if necessary. Tar lotions or gels may be added, rubbed in at night and shampooed out the following morning. A coconut oil-based tar and salicylic acid pomade applied at bedtime, sometimes occluded overnight with a polythene shower cap, and shampooed off in the morning, is commonly used in the UK [1]. Cream formulations of dithranol can be useful, but care should be taken to avoid irritation of the ears and eyes. Dithranol may also cause unacceptable staining of fair hair. Calcipotriol scalp application may also be of value [1,2].

If these measures fail, corticosteroid scalp lotions, gels or foams should be tried, but even the most potent (e.g. clobetasol propionate 0.05% alcoholic solution) is ineffective if painted on the surface of thick plaques of psoriasis. In these circumstances, the scalp should be copiously drenched overnight (or throughout 24 h if possible) with the coconut oil-based tar and salicylic acid pomade or similar preparation, which is shampooed out once or even twice a day. Two or three days of such treatment generally brings about marked improvement. A clobetasol propionate-containing shampoo is an innovative approach and has been shown to be more effective than the traditional tar shampoo [3]. A recent development is a combination gel containing betamethasone dipropionate and calcipotriol; this is more effective than calcipotriol scalp solution [4].

UV phototherapy

UVB

Goeckerman [1] first thoroughly documented the ability of crude coal-tar applications followed by exposure to UV radiation to clear psoriasis. Much later, it became clear that broad-band (290–320 nm) UV radiation (BBUVB) alone, if given in mildly erythemogenic dosage, was capable of clearing psoriasis [2–5] and can be as effective as PUVA [6]. In addition, continued maintenance BBUVB therapy after initial clearance with BBUVB significantly increased the duration of disease control, even though maintenance treatment was given at modest frequency (an average of six treatments per month) [7].

UVB therapy three times weekly is sufficient [2], and twice daily treatment is of no extra value over once daily treatment [8]. The benefit of additional tar therapy is accepted [8,9], but doubt has been cast on the value of adding topical steroid therapy [10,11] or short-contact dithranol to a UV regimen. The known carcinogenicity of BBUVB limits enthusiasm for phototherapy. While some studies have not shown an increased skin cancer risk in UVB-treated psoriasis patients [12–14], one study suggested that high levels of exposure to BBUVB are associated with an approximately fourfold increase in the risk of genital tumours in men [15]. Protection of the genital area from BBUVB exposure would therefore be prudent in these patients.

Philips TL-01 fluorescent lamps emit a narrow-band UVB (NBUVB) at 311 nm. Irradiation with this source has been found to be superior to conventional BBUVB in psoriasis, producing longer remissions, a lower incidence of burning and possibly a lower risk of UV carcinogenesis [16–22]. The effectiveness of NBUVB appears to be similar to that of PUVA, but it is more convenient and also probably less carcinogenic [20,21]. The use of higher intensity (100 W) TL-01 lamps has confirmed the superiority of narrow-band over conventional broad-band therapy, and has allowed shorter, more convenient exposure times [23]. In a randomized controlled trial, 100 patients with psoriasis were allocated to either twice weekly PUVA or NBUVB. Clearance of psoriasis occurred in a significantly greater proportion of patients on PUVA (84%) than with NBUVB (63%) and with significantly fewer treatments (16.7 versus 25.3, respectively) [24]. However, another trial of NBUVB three times weekly was of equivalent efficacy to PUVA and is more effective than bath PUVA [25,26]. Several studies have examined the optimal number of NBUVB treatment sessions per week. Twice-weekly treatment produced equivalent

improvement in psoriasis to four times weekly, but with only 16 as compared to 32 exposures [27]. Three times weekly appears to be the optimum regimen for efficacy in that two NBUVB sessions weekly took 50% longer to clear psoriasis compared to three times weekly (88 versus 58 days, respectively) [28]. An interesting development is home NBUVB treatment based on patient training—all patients who took part in the study preferred home- over hospital-based treatment [29]. Application of dithranol also provided a substantial additional benefit [23]. The combination of NBUVB with etretinate decreased the number of treatments and the UV exposure required for clearing, but was associated with a more rapid relapse than seen in NBUVB monotherapy [29,30]. NBUVB radiation is emerging as the UV therapy of choice in psoriasis, although its long-term safety remains to be confirmed by objective clinical studies. Unlike BBUVB, TL-01 therapy has been reported to cause asymptomatic or painful blistering at the sites of psoriatic lesions towards the middle of a treatment course. This side effect appears to be very unusual, and usually resolves with continued narrow-band treatment, although this may need to be briefly interrupted or restricted [31].

A retrospective study of 1488 psoriasis patients treated for 4 weeks at the Dead Sea Clinic from 1983 to 1986 by sun exposure and bathing in mineral-rich sea has been carried out. Nearly three-quarters improved by 90% or more, results consistent with those of a prior prospective study of 110 patients. The treatment is said to be cost-effective and pleasant, the combined costs of travel, accommodation and nominal medical fees usually being less than that of in-patient treatment for the clearing of psoriasis [32].

In general, UVB therapy is valuable for plaque psoriasis and may be especially valuable in guttate and 'seborrhoeic' patterns. It is usually of little value in psoriatic erythroderma and generalized pustular psoriasis, and may aggravate these forms of the disease.

Psoralen photochemotherapy

History. Experience with coal-tar and UV therapy of psoriasis, and psoralen photochemotherapy of vitiligo, led to the suggestion that psoriasis might benefit from the same approach [1]. The first report of successful treatment of psoriasis was ignored [2] but a decade later the effectiveness of topical psoralens followed by long-wave UV radiation (UVA) in resolving plaque psoriasis was confirmed [3,4]. Within 2 years, the first report of successful use of oral 8-methoxypsoralen (8-MOP) and UVA [5] led to intense interest and the coining of the terms 'photochemotherapy' and

'PUVA' [2,6–9]. Multiple studies soon confirmed the efficacy of oral [10–18] and topical [12,19–21] PUVA therapy in various patterns of psoriasis. In the USA, Food and Drug Administration approval of PUVA therapy for severe psoriasis was granted in May 1982. In the UK, official approval is still withheld, and no psoralen preparation has a product licence. Nevertheless, PUVA is widely used in the UK. With the introduction of narrow-band UVB phototherapy and the risk-averse practice of medicine prevalent in the USA, there is a significant reduction in the number of patients receiving PUVA per annum. The National Ambulatory Medical Care Survey revealed an 85% reduction in PUVA use from 1993 to 1998 [22].

Methodology. The methodology for using PUVA is described in detail in Chapter 29 and for the most part is the same as is used for the treatment of psoriasis. Dosage of 8-MOP is arbitrary, as is the time interval before irradiation. Different pharmaceutical preparations of 8-MOP differ markedly in bioavailability [23,24], and there are patient variations in the rate and extent of absorption [25]. In addition, there is no simple correlation between achieved plasma levels and therapeutic response [26], although patients responding unsatisfactorily are more likely to have deviant blood levels [27,28]. Liquid formulations of 8-MOP have been reported to produce higher, earlier peak levels of drug in the plasma and more reproducible plasma concentrations [29,30].

Dietary influences may be important [31], absorption being delayed and reduced by a fat-rich meal. Other photoactive drugs should be avoided. Standard oral dosage using 8-MOP tablets is 0.6 mg/kg [9], given 2 h before irradiation. High-intensity fluorescent UVA tubes are used, and initial UVA dosage is based on skin type. Some clinicians start with somewhat smaller doses. Treatment is given two to four times weekly. UVA dosage is increased by increments of 0.5–1.5 J/cm^2 according to response. Persistent tenderness or erythema of uninvolved skin may call for temporary reduction of UVA dosage, or cessation of treatment for a few days. Once substantial clearance has been achieved, the frequency of treatment can be reduced, so that maintenance treatment (usually the last UVA dose in the clearance phase) is given once every 1–4 weeks. Alternatively, the treatment may be stopped in many cases if the psoriasis remains clear. In either case, clearance schedules may have to be resumed to control relapses. A cost-effective modified UVA dosage schedule leading to an increased clearance rate and reduced cumulative UVA dose, and therefore possibly a lower incidence of long-term cutaneous side effects, has been proposed [32]. In this study, initial and incremental UVA doses were maximized to near erythemogenic levels by weekly testing for the minimal phototoxic dose, by using an automated skin testing UVA irradiation unit. However, the value of repeated minimum UVA phototoxicity dose testing in reducing the cumulative dose of UVA and improving the clearance rate has been questioned [33].

Patient selection [6,23]. In many departments, only vertical UVA irradiation units are available as they occupy less floor space than horizontal units, and they save time, as the entire skin is irradiated simultaneously. Some elderly or infirm patients may encounter difficulty standing in a vertical unit for a prolonged period. A history of previous summer exacerbation of psoriasis involving exposed areas is not necessarily a contraindication; some such patients do well with cautious PUVA treatment [34]. Previous exposure to inorganic arsenic or radiotherapy or a history of cutaneous malignancy are relative contraindications. The treatment should not be given in pregnancy nor to children under 18 years, except in the most compelling circumstances. Because the long-term carcinogenic hazard is uncertain, PUVA should only be considered as a primary treatment in those patients over 55 years of age where psoriasis covers at least 20% of the body surface, and who cannot be controlled by conventional topical therapy. In patients under 55 years or with less widespread psoriasis, other considerations may justify therapy according to individual circumstances. PUVA is of no value for psoriasis in areas where UVA access is impossible, such as the scalp (except in the bald) or certain body flexures.

Results. Therapeutic results have been uniformly good to excellent in psoriasis vulgaris. Clearance rates of up to 90% have been reported [11,13,16–18], substantial clearance being achieved by 15–25 treatments to a total of 100–200 J/cm^2. Less spectacular success rates have probably reflected selection of severe resistant cases [10,15,35] or use of lower 8-MOP or UVA doses [12,36]. The use of four treatments weekly in a European cooperative trial achieved complete clearing in 65%, and substantial improvement in another 29% in approximately 3200 patients, with a mean of 20 exposures in 5–6 weeks, a mean UVA clearance dose of 7 J/cm^2 and a cumulative UVA dose to clearance of about 100 J [18]. Although success was comparable in large US cooperative studies [13,16] in which three treatments weekly were given, higher clearance UVA doses (13–14 J/cm^2), higher cumulative doses (up to 200 J) and 10–12 weeks were needed. The European regimen of four treatments weekly possibly achieved its antipsoriatic action before increasing pigmentation necessitated higher UVA doses.

PUVA is also of value in generalized pustular psoriasis, erythrodermic psoriasis, palmoplantar pustulosis and nail psoriasis [37], but success rates are much lower in these atypical patterns of disease. The value of maintenance therapy is disputed, being thought to be of value by some authors [13,38–40] but not by others [18]. A useful compromise is to give maintenance treatment for 2 months. If the psoriasis remains clear, PUVA is stopped. Low-dose PUVA maintenance is possible after clearance has been achieved by some other modality (e.g. dithranol) [41].

Combined therapy. The simultaneous use of etretinate or acitretin and PUVA is discussed below. Dithranol and PUVA have been used together [37] and sequentially [41]. In extremely severe erythrodermic or generalized pustular psoriasis, a cytotoxic drug may be given concurrently. Methotrexate in combination with PUVA is effective; however, there is an inevitable increased risk of skin cancer [42,43]. Topical corticosteroids may be used concurrently, especially on areas inaccessible to UVA. However, it is unresolved whether this combination results in shorter remission times [44,45]. Calcipotriol combined with PUVA is more effective than PUVA alone and results in less UVA exposure [46]. Although rarely used, PUVA and UVB used together has been reported

effective in patients unresponsive to either PUVA or UVB alone [47].

The carcinogenic hazard. It is undisputed that solar UV radiation is a major aetiological factor in squamous and basal cell carcinoma and malignant melanoma in humans. Tumours have been induced in the skin of hairless albino mice by PUVA exposure using both 8-MOP and 5-MOP [1]. An early report suggested that PUVA therapy accelerated the development of skin tumours in patients with xeroderma pigmentosum [2], and it appeared to have an obvious promoter effect in a patient previously exposed to X-irradiation, arsenic and several cytotoxic drugs, who developed 25 basal or squamous cell carcinomas, the first within 21 months of onset of PUVA therapy [3].

There is now substantial literature dealing with the incidence of skin tumours in groups of PUVA-treated patients and this is dealt with in detail in Chapter 29. Although certain studies have failed to show a clear relationship between PUVA and tumour development [4–6], long-term follow-up of a large US cohort has provided conclusive evidence for the carcinogenicity of PUVA [7].

The carcinogenic risk of PUVA is compounded by subsequent systemic immunosuppressive therapies particularly ciclosporin which significantly enhances the risk of developing squamous cell carcinomas (SCC) [8].

PUVA using other psoralens

There has been interest in 5-MOP as a substitute for the standard 8-MOP in PUVA therapy. The two forms have been compared [1], and it has been reported that 0.6 mg/kg 5-MOP is as effective as the same dose of 8-MOP [2]. Higher doses of 1.2 mg/kg were more effective, but produced more erythema [2]. The main advantage of 5-MOP lies in better gastrointestinal tolerance, nausea occurring only rarely [1,2]. It has also been shown that therapeutic doses of 5-MOP are associated with a lower incidence of phototoxic reactions than 8-MOP [3]. It may therefore be preferable to 8-MOP in PUVA therapy, particularly in light-sensitive patients and subjects with 8-MOP intolerance. There is no evidence that 5-MOP is less photocarcinogenic than 8-MOP [4].

Trimethylpsoralen has been used to good effect in PUVA baths (see below). Use of 3-carbethoxypsoralen has been advocated because it is non-carcinogenic in mice [5].

PUVA therapy with topically applied psoralens

A desire to avoid some of the side effects of oral treatment, especially in patients with localized forms of psoriasis, reactivated interest in the use of 8-MOP topically. A lotion or emulsion containing 0.1–1% 8-MOP has been used, and the time interval before UV irradiation seems to be relatively unimportant, periods as short as 5 min giving results as good as those with a delay of up to 2 h [1]. If extensive areas of skin are treated with topical 8-MOP in an oil-in-water emulsion, blood levels comparable to those achieved during oral therapy are found [2], so that the usual precautions to protect the eyes must be taken and little advantage is incurred. Local treatment can be given two to five times weekly, the dose of UVA being slowly increased according to response.

Trimethylpsoralen (TMP) has also been used topically to the whole body in a bath, combined with UVA, initially mainly in Finland and Sweden [3–5]. TMP is used at a concentration of 0.33 mg/L [6]. Comparisons of TMP baths with oral 8-MOP PUVA have shown that the response and relapse rates are similar. Nausea and headache occurred in the group using systemic treatment but not in the bath group, but short-term, local cutaneous side effects, such as pruritus, were more common in the bath group [7,8]. Benefits have also been claimed for a combination of TMP bath PUVA with oral etretinate [9] and acitretin [10]. One report has suggested that TMP bath PUVA carries a lower risk for skin cancer than oral 8-MOP PUVA, possibly because the doses of UVA are 15–20 times lower with bath PUVA [11]. However, the data are preliminary and may be confounded by the fact that there were fewer high-dose PUVA patients among the bath group, that maintenance treatment was not given and that the face (an important site of SCC in the oral PUVA group) was not treated in the bath PUVA patients. It is prudent to conclude that, as yet, there is insufficient evidence that bath PUVA is safer. While no excess risk of skin cancer has been reported with bath PUVA, both keratoses and lentigines are common [12].

Bath PUVA with 8-MOP, at a concentration of 2.6–3.7 mg/L, has been successful [8,13]. A comparison of 8-MOP bath PUVA and oral PUVA found no difference in efficacy between the two, but bath delivery required 50% less UVA [13]. Although plasma levels of psoralen have been reported as either undetectable or very low after bath PUVA, a relationship between plasma 8-MOP levels and severity of psoriasis has been found, raising the possibility of adverse systemic reactions in patients with extensive disease [14]. The practice of not using UVA-screening spectacles following bath PUVA [13] may therefore need to be reassessed in such patients. Bath temperature should remain constant from treatment to treatment, 37°C seems optimal with a bath time of 15 min—followed immediately by UVA; local head and foot treatment may require up to 40 min before UVA. Guidelines issued by the British Photodermatology Group provide protocols for delivery of bath PUVA [6].

Psoriasis of the fingernails has been successfully treated with topical 1% 8-MOP solution and UVA two to three times weekly [15].

Systemic therapy

For practical purposes, the alternatives are corticosteroids, methotrexate, retinoids, ciclosporin and the new biologic therapies. Photochemotherapy is discussed above.

Methotrexate

The beneficial effect of aminopterin on psoriasis was first observed in 1951 [1]. Safe regimens were soon developed [2], and aminopterin was replaced by its more stable analogue, methotrexate, which may be given orally, intramuscularly, subcutaneously or intravenously. In cancer patients, absorption of an oral dose was found to be complete [3], but variable degrees of malabsorption are found in psoriatics even with small doses, 32–98% of the oral dose being absorbed, and the degree of absorption correlating well with D-xylose absorption [4]. Excretion is largely (95%) by the kidney, but there is extensive enterohepatic cycling [5,6]. The drug is 50–70% bound to plasma albumin [3,7]. Methotrexate inhibits DNA synthesis by competitive inhibition of dihydrofolate reductase [8], and may thus exert an antimitotic action on the epidermis. Recently, *in vitro* studies showed that methotrexate was 10–100 times more effective at inhibiting the proliferation of lymphoid cell lines than cultured keratinocytes, suggesting that lymphoid cells may be a more important cellular target than epithelial cells in psoriasis [9]. In regimens for psoriasis, methotrexate also inhibits polymorphonuclear leukocyte chemotaxis [10]. These actions may explain its clinical effects.

Controlled trials have suggested that topical methotrexate is ineffective in psoriasis [11,12] in spite of evidence for local absorption [13]. In contrast, significant improvement was subsequently noted following the use of a topical methotrexate gel containing the penetration enhancer, laurocapram. It was therefore suggested that topical methotrexate may be effective in psoriasis if adequate percutaneous absorption is provided for a sufficient period [14].

Oral therapy is given once weekly, occasionally fortnightly. Daily regimens are dangerous and have been abandoned. For a 70 kg adult, an initial test dose of 5–10 mg is given to avoid early toxicity. Maintenance doses should be achieved by gradual increases of 2.5–5 mg/week, and usually range between 7.5 and 30 mg/week. Methotrexate may be given as a single weekly oral dose, or divided into three parts given 12 h apart over 24 h [15]. Parenteral therapy is equally safe, similar doses being given intramuscularly, subcutaneously or intravenously every 7–14 days. The subcutaneous route is becoming popular with the advent of this form of administration as the norm for patients on biologic therapies. In the elderly, the effective dosage of methotrexate is below the above range, and toxicity may be more readily encountered with higher dosage, probably owing to reduced renal clearance. Patients over 80 years of age have been adequately treated with as little methotrexate as 2.5 mg/week [16].

Before treatment, renal, hepatic and marrow function must be shown to be normal. If renal function is impaired, a reduced dosage of methotrexate may be given with extreme care and regular monitoring. Routine liver-function tests should be supplemented by a liver biopsy, which may be delayed for 2–4 months until it is established that methotrexate is effective and tolerated, and that long-term treatment will be carried out. Many centres are now starting to use an assay of serum levels of the aminopropeptide of type III procollagen (PIIINP) as an alternative to liver biopsy (see below) [17,18]. Anaemia, thrombocytopenia and leukopenia are contraindications to therapy, as are active infection, peptic ulceration, ulcerative colitis past or present, alcoholism, immunodeficiency, pregnancy, lactation and an unreliable patient [15].

Initial dosage should always be cautious (at the lower end of the therapeutic range). Note should always be taken of concurrent therapy with drugs that may displace methotrexate from plasma albumin, such as aspirin, NSAIDs and sulphonamides, including co-trimoxazole [19], as has been reviewed [15]. In addition to the drugs reviewed, furosemide (frusemide) has induced severe toxicity in one patient [20] and a profound fatal leukopenia in another (D.H. Jones, personal communication), probably by interfering with tubular secretion of the drug. Diuretic therapy should be avoided if possible, and used only with great caution if cardiac failure threatens. Special caution is needed if corticosteroids are being given orally, because the toxic effects of the two drugs on the intestinal tract and defence against infection may be additive [21].

Clinical response is usually evident in 7–14 days, but maximal response may take 4–8 weeks. Generalized pustular psoriasis (if acute) may respond within 48 h. As soon as acceptable control is achieved it may be possible to lower the dosage or to extend the interval between doses. It is prudent to accept less than 100% control; quite small doses (e.g. 7.5–10 mg or less weekly) may afford adequate control, especially in the elderly patient. Subsequent minor fluctuation in activity can be treated by other means. In the treatment of erythrodermic or pustular psoriasis where gross oedema, especially of the legs, is common, the temptation to use diuretics, especially furosemide (frusemide) [20] should be

resisted. As the psoriatic inflammation is controlled, a spontaneous diuresis will follow.

Laboratory control of treatment is essential. Initially, the haemoglobin, leukocyte and platelet counts should be shown to be within normal limits; weekly, but later less frequent counts, say monthly or even less often, are adequate. Maximal myelosuppression occurs 7–10 days after an oral dose. The liver enzymes give the simplest guide to hepatic function, and serum albumin, liver-function tests and blood urea or creatinine levels should be checked every 3–4 months during maintenance therapy, although the value of liver enzyme measurements in predicting significant hepatotoxicity is controversial [22]. Liver biopsy should usually be undertaken not less frequently than after every 1.5 g of cumulative methotrexate dosage [15,22]. However, the need for repeated follow-up liver biopsies in carefully selected and monitored patients who have no other risk factors for hepatotoxicity has been questioned, especially in view of the morbidity and cost associated with liver biopsy, and the low yield of pathological findings leading to discontinuation of methotrexate [23].

Numerous toxic effects of methotrexate therapy are recognized. In one long-term study, 73% of patients had side effects, most frequently abnormal liver-function tests, nausea and upper gastrointestinal symptoms [24]. Oral regimens commonly provoke transient anorexia, nausea and dyspeptic pain. Many patients feel slightly unwell for 24 h or so after each dose. Bursting headaches, lasting a day or so, may follow large parenteral doses. Burning sensations in the psoriatic plaques, lasting several days, are not uncommon after full doses, and herald rapid resolution of lesions. Toxic effects on the marrow include leukopenia, thrombocytopenia and, rarely, folate-deficient megaloblastic anaemia. Folic acid given regularly during treatment with methotrexate can prevent nausea and reduce the chances of bone marrow suppression. A UK audit [25] of folic acid prescribing during methotrexate therapy indicated the preferred regimen to be 5 mg/day every day including the day of methotrexate dosing. Modest thrombocytopenia ($100–125 \times 10^9$/L) and low to normal white cell counts ($3.5–4.5 \times 10^9$/L) do not necessarily preclude safe long-term treatment if the counts remain stable.

It is now established beyond all doubt that methotrexate is hepatotoxic, causing fibrosis and cirrhosis, the incidence of which has varied in different series [15,26,27]. One report described cirrhosis and liver failure leading to liver transplantation in three patients receiving largely unsupervised methotrexate treatment for psoriasis, although no information was given about other potential aetiological factors [28]. In general, the incidence of cirrhosis is low with total dosage of less than 1.5 g. Higher incidences of fibrosis and cirrhosis have been reported by Danish authors in patients receiving higher cumulative dosage or longer exposure, findings that have conflicted with the data of others [15]. These higher incidences in Denmark may possibly be explained by a higher average age and previous intake of hepatotoxins, such as arsenic, vitamin A and alcohol [29].

Pre-existing liver disease adds to the risk from the drug, and both functional and structural abnormalities have been demonstrated frequently in severe psoriatics being assessed prior to methotrexate therapy. In one series, premethotrexate liver biopsies showed that steatosis, periportal inflammation and focal necrosis were all found with a statistically significant higher grading among psoriatic patients than controls [26]. Other risk factors include impaired renal function, diabetes, obesity and increasing age [11,15,29–31]. The presence of chronic hepatitis B or C infection is also likely to be a risk, and should be excluded prior to methotrexate therapy.

The clinical course of cirrhosis induced by methotrexate may, however, not be aggressive, some patients being able to continue on the drug without worsening of liver biopsy findings [27,32]. Generally, it is an indolent, slowly developing process that will be detected by serial liver biopsies, when the hazards of stopping and continuing therapy can be weighed against each other. Fatty change and mild inflammatory infiltrate can be ignored, as can the mildest stage of fibrosis if the need for methotrexate is compelling. Progressively more severe damage in serial biopsies demands withdrawal of the drug, as do the findings of advanced fibrosis or cirrhosis, but the serial biopsies may show apparent reversibility or fluctuation of changes [23]. At present, liver biopsy remains the gold standard for the exclusion of significant hepatotoxicity, as indicated in the guidelines of Roenigk *et al.* [15]. However, there is now compelling evidence that 3-monthly monitoring of serum levels of PIIINP may permit dispensing with liver biopsy altogether in approximately 70% of patients. Careful work by researchers in Manchester, UK, and Aarhus, Denmark, [17,18,33] has established that serum levels of PIIINP accurately reflect liver pathology. If serum levels of PIIINP remain within the normal range liver histology is normal; there are occasions when high serum levels of PIIINP occur with a normal liver biopsy—in such circumstances patients can continue on methotrexate but hepatotoxicity is monitored by regular (1.5 g cumulative dosage of methotrexate) liver biopsy.

Another focus of anxiety has concerned the possible hazard of the development of malignant disease. Metastasizing SCC of the skin has been described in a patient on long-term methotrexate [34]. Furthermore, long-term follow-up of a large cohort of patients on PUVA, and other treatments for psoriasis, has suggested a relative risk of 2:1 for SCC of the skin in those who have had high-dose methotrexate exposure (a probable cumulative dosage of more than 3 g over 4 years or more) versus low or no exposure. This risk was independent of PUVA therapy [35]. Careful examination of the skin at intervals would therefore be prudent in any patient on high cumulative dosage of methotrexate.

Anagen alopecia, cutaneous erosions, ulceration and bleeding are rare with weekly dose regimens [36]. Other uncommon side effects include epidermal necrolysis [36], candidiasis [36], folliculitis, ataxia [37], keratoconjunctivitis [38], depression and other psychotic symptoms [21], reactivation of tuberculosis [39] and other pulmonary illnesses [40]. Gastrointestinal bleeding has been reported. Fatal complications of therapy [21] have included rapidly progressive renal failure [41] and septicaemia, as well as the consequences of irreversible marrow or hepatic failure. Death has followed a single intravenous injection in a patient with severe renal failure. The majority of the published deaths are attributable to absolute or relative overdosage [21]. Renal damage is not a recognized hazard of conventional antipsoriatic dosage [41]. Oligospermia is an important hazard in men [42] and may persist long after the drug is withdrawn. Methotrexate osteopathy is a

little-recognized complication of long-term low-dose treatment, affected patients presenting with the triad of severe pain localized to the distal tibia, osteoporosis and compression fractures of the distal tibia. The condition is readily confused with psoriatic arthropathy and, as the only treatment is said to be withdrawal of methotrexate, it is important that it should be recognized [43].

Despite these dangers, methotrexate has a secure place in the treatment of severe psoriasis that is physically or socially disabling, and which is resistant to conventional topical therapy and photochemotherapy. It is particularly valuable in the chronic erythrodermic and generalized pustular forms, where it may be life-saving, and for weaning such patients off systemic steroids. It is useful in intractable non-pustular forms of psoriasis of the hands and feet. Nevertheless, it has long-term hazards and it should never be used as an easy substitute for topical therapy. It should rarely be used in the first half of life, but this is sometimes inevitable, and the use of methotrexate (0.2–0.4 mg/kg/week) in children with severe psoriasis has been reported [44]. It is abortifacient and teratogenic in early pregnancy [45] and fertile patients should take contraceptive precautions. Conception should not be allowed within 3 months of stopping treatment, but is probably safe after that time [46].

In the event of accidental overdosage or unexpected acute toxicity, folinic acid should be given intramuscularly in full dosage (10 mg/m^2) and repeated every 6 h orally or parenterally as tolerated by the patient [15]. After the first dose, subsequent administration of folinic acid should ideally be governed by the serum methotrexate level [15]. Its effectiveness in counteracting the haematological toxicity of methotrexate diminishes with increasing delay.

Methotrexate has been combined successfully with various other therapies such as UVB phototherapy [47–49], PUVA [50] and etretinate [51], in the hope of reducing dosage and therefore toxicity of each modality, while maintaining efficacy. Methotrexate and acitretin should only be used with caution because of the risk of hepatitis. Combining methotrexate with ciclosporin [52] appears to be effective in patients (particularly those with psoriatic arthritis) in whom either drug as monotherapy is poorly tolerated and/or ineffective. This combination approach is analogous to that practised by rheumatologists. Reactivation of UV-induced erythema by methotrexate [47–49] ('erythema recall') may be a problem. Colchicine and methotrexate together have been used in generalized pustular psoriasis [53], and methotrexate can be used to maintain clearance induced by PUVA or a dithranol regimen [54]. However, in view of a report of possible cancer induction, care should be exercised in using PUVA and methotrexate concomitantly [55].

Head-to-head trial of methotrexate compared to ciclosporin revealed that efficacy is similar in the short term [56] but a controlled trial against the TNF-α antagonist adalimumab over 16 weeks demonstrated inferiority of effect [57].

Developments in the understanding of methotrexate pharmacology and the identification of single nucleotide polymorphisms in the enzymes responsible for methotrexate action indicate that pharmacogenetics may have an important role to play in predicting efficacy and side effects of the drug for management of psoriasis [58,59].

Hydroxycarbamide

Hydroxycarbamide (hydroxyurea) is an antimetabolite that has been used principally for the treatment of malignant disease, particularly chronic myeloid leukaemia. The active drug, which is converted *in vivo* from its parent, blocks the conversion of ribonucleotides to deoxyribonucleotides by interfering with the enzyme ribonucleoside diphosphate reductase, thereby inhibiting DNA synthesis in proliferating cells [1,2]. Hydroxyurea was first recommended for psoriasis by Yarbro in 1969 [3,4]. It is quickly and well absorbed and excreted by the kidney. Bone marrow suppression is a common side effect of treatment with hydroxyurea, leukopenia is seen in most treated patients. Profound anaemia and thrombocytopenia occur less frequently, although a fall in haemoglobin to 110 g/dL is common [5–8]. Macrocytosis is almost universal. Irreversible bone marrow failure and death have not been reported. Because it is teratogenic, hydroxyurea must be avoided during pregnancy. Compared with methotrexate, it has the virtue of being a less frequent cause of anorexia, nausea and hepatotoxicity. In the three largest case series of patients with psoriasis treated with hydroxyurea [1,9,10], the reported satisfactory response rates have ranged from 45 to 80%. Clinical response is slow, and may become evident only over several weeks [4]. A therapeutic trial should therefore last at least 2 months. It is only modestly effective in palmoplantar pustulosis [11], and is less effective than methotrexate overall. That it may be a valuable reserve drug for patients needing systemic treatment and who are resistant to methotrexate or develop side effects, has been confirmed by a report of its use in 85 patients [1]. Hydroxyurea may be effective when other systemic drugs have failed, but is a less potent antipsoriatic agent. Its use has been advocated in combination with methotrexate [12], ciclosporin [13] and acitretin [14].

Regimens should rarely exceed 0.5 g three times daily, and sometimes 0.5 g once or twice daily long-term suffices for therapy [1,2]. A cutaneous vasculitis resulting from the drug has been reported [9,15]. Other recently recorded side effects include diffuse hyperpigmentation, actinic psoriasis, alopecia and psychological effects [1].

Retinoids

Vitamin A has long been recognized to have profound effects on epithelial differentiation, and the toxicity of hypervitaminosis A is well known. Deficiency causes cutaneous hyperkeratosis and squamous metaplasia of mucous membranes. This knowledge stimulated development of synthetic derivatives, and the term 'retinoid' has been applied to a family of natural and synthetic analogues of vitamin A [1,2].

Etretinate [3–6]

This analogue was first reported in 1975 by Ott and Bollag [7] to have antipsoriatic efficacy, and many subsequent reports have confirmed this [8–13]. In a dosage of 1 mg/kg/day, resolution of psoriasis vulgaris [9,10], pustular [10,14] and erythrodermic psoriasis [14] has been demonstrated. Etretinate is little used for the treatment of psoriasis nowadays as it has been superseded in many countries by acitretin, which has a shorter half-life.

Isotretinoin (13-cis-retinoic acid)

Isotretinoin was reported to improve generalized pustular psoriasis, but additional therapy was required to produce satisfactory control during maintenance treatment. Isotretinoin was also found to be less effective than etretinate in the treatment of chronic plaque psoriasis [1]. However, it may have a place in the management of psoriasis in fertile females who urgently need treatment, in view of its short half-life [2], and has been advocated in combination with PUVA in this patient group [3].

Acitretin

This is the main active metabolite of etretinate. Being a free acid as opposed to an ester as in the case of etretinate, acitretin has the great advantage of decreased lipophilicity. It is therefore not sequestered in the adipose tissue, and has an elimination half-life of approximately 50 h compared to more than 80 days for etretinate [4,5]. Several clinical trials showed that the clinical efficacy and side effects of acitretin are similar to those of etretinate [6–11]. The greatly reduced half-life of acitretin compared with etretinate suggested that it would have clinical advantages over the latter, especially for women of child-bearing potential. Accordingly, marketing of etretinate ceased in the UK in 1993 and acitretin took its place. However, in an unpredictable number of patients, reversed metabolism of acitretin to etretinate has been found to occur [12]. It has therefore been essential for women on acitretin to avoid pregnancy during and for 2 years after the course, as in the case of etretinate. A further comparative study [13] confirmed the equal efficacy of etretinate and acitretin in psoriasis, but in this study etretinate was better tolerated both objectively and subjectively, and to an extent that was statistically significant. Limited recent experience also indicates that the occasional patient previously controlled on etretinate may not do well on acitretin but benefits from transfer back to etretinate once again [14]. Thus, the great advantages initially perceived for acitretin have not been realized in practice. If reversed metabolism to etretinate only occurs in 50% of subjects, albeit unpredictably [12], and the levels of etretinate thus obtained are low, this may confer a theoretically lower risk of fetal abnormalities in women becoming pregnant inadvertently before expiry of the 2-year period. The use of acitretin in fertile women therefore has a theoretical advantage, but it seems to have no major advantages over etretinate in other patients. In combination with PUVA, acitretin has been shown to be therapeutically superior to PUVA with placebo. Acitretin in a regimen of 50 mg/day for 2 weeks followed by up to 10 weeks of 25 mg/day combined with PUVA significantly reduced the number of PUVA treatments required for clearance and the cumulative dosage of UVA (by 40%) [15]. These results were confirmed by Tanew *et al.* [16], in that acitretin at 1 mg/kg/day in addition to PUVA reduced the total UVA dosage and time to clearance. Similarly, acitretin enhances the efficacy of broad-band UVB in that the number of subjects who improve or clear with the combination therapy is significantly greater than with UVB alone: 60%

versus 24% in one study [17] and 74 and 35%, respectively, in another [18]. Acitretin may also reduce the photo-ageing effects of phototherapy and act as a chemopreventive against the development of cutaneous malignancy. This benefit has not been proven, but extrapolates from the known effects of retinoids on photo-aged skin and as chemopreventive agents in kidney transplant recipients [19,20]. Acitretin can be combined with UVB or PUVA [21].

The side-effect profile of acitretin is generally similar to that of etretinate [5–10,22–24] and is detailed in Chapter 74. Side-effects are usually inevitable, but are often a nuisance rather than a real danger.

Although apparently 1.5% of patients on acitretin may develop a toxic hepatitis, there is no histological evidence of hepatotoxicity on liver biopsy [25]. The starting daily dosage in adults is usually 25 mg, the optimum being about 50 mg (0.66 mg/kg/day) depending on therapeutic response and side effects.

To summarize, despite the high incidence of nuisance side effects, acitretin has been a valuable addition to the antipsoriatic weaponry, especially in generalized pustular psoriasis. The drug should not be used in children except in compelling circumstances nor in young women unless essential. Active liver disease and pre-existing hyperlipidaemia are contraindications to treatment.

Ciclosporin

The antilymphocytic effects of ciclosporin, a cyclic undecapeptide derived from the fungus *Tolypocladium inflatum* Gams, were first described in 1976 [1]. The ability of ciclosporin to clear the skin lesions of psoriasis was first noted in four patients in 1979, as an incidental finding during a trial of this drug in inflammatory arthritis [2].

This information appears to have been somewhat disregarded until 1984, when the dramatic therapeutic effect of ciclosporin was again noted in a single patient with otherwise unresponsive psoriasis [3]. Subsequently, several case reports appeared [4–10], followed by unequivocal evidence for therapeutic efficacy in the form of double-blind placebo-controlled trials with both high [11] and lower [12,13] dosage. The mechanism of action of ciclosporin in psoriasis is not entirely certain, but is likely to be related to its inhibitory effects on T-cell activation [14], a possibility that has substantially affected attitudes towards pathogenic mechanisms in psoriasis.

Ciclosporin is highly lipophilic, but is active orally and metabolized in the liver by the cytochrome P-450 system. A series of consensus conferences on its use in psoriasis have been held and the proceedings published [15–17]. Briefly, a twice daily oral regimen is recommended. The side effects associated with ciclosporin (see below) demand that it should be given only to patients with sufficiently severe disease, in whom less toxic forms of treatment have been unsuccessful. Such treatment should include conventional topical therapy, if possible carried out in an inpatient department or day-treatment centre on at least one occasion, UVB, PUVA and possibly a retinoid. However, the prolonged use of high-dose PUVA may predispose certain patients to skin malignancy, and constitute a relative contraindication to ciclosporin. The choice between ciclosporin and methotrexate is not straightforward, the latter being thoroughly tried, relatively safe in the right hands and much cheaper, but currently requiring repeated invasive investigation in the form of liver biopsies. There has, to

date, been no published head-to-head comparison of the two drugs in the treatment of psoriasis. Ciclosporin should not be given to unreliable patients or if regular monitoring for side effects is not possible. Other major exclusion criteria include renal dysfunction, uncontrolled hypertension, past or present malignancy, history of epilepsy, acute infections, other immunosuppressive therapy, concomitant therapy with nephrotoxins, previous serious side effects from ciclosporin and known hypersensitivity. Minor exclusion criteria include abnormal liver function, previous therapy that may predispose to skin malignancy, malabsorption, drug or alcohol abuse, and concomitant treatment with drugs that affect the metabolism of ciclosporin. NSAIDs are often used by patients with psoriatic arthropathy, and may enhance the nephrotoxicity of ciclosporin (see below). Other drugs interacting with ciclosporin are described in a consensus report [17] and elsewhere [14], and include anticonvulsants which induce hepatic cytochrome P-450 and thus enhance metabolism of ciclosporin, which may never reach therapeutic blood levels [18].

An initial daily oral regimen of 2.5 mg/kg equally divided in two doses has been recommended. Improvement may be seen within days, but if this does not occur within 2 weeks, the dosage may be increased gradually to a maximum of 5 mg/kg/day [14,17]. Maintenance dosage should be reduced to the minimum that allows adequate control and, as for methotrexate, the aim should not be to achieve complete clearance. Withdrawal of ciclosporin in patients with severe psoriasis is usually associated with relapse within weeks but, with few exceptions [19], has not been associated with the severe rebound phenomenon seen following withdrawal of systemic steroids. In patients with moderately severe chronic psoriasis, the relapse rate (41% at 6 months) following cessation of ciclosporin therapy (5 mg/kg/day) was no greater than that seen with dithranol or PUVA [20]. A systematic review of therapies for severe psoriasis [21] concluded that 'ciclosporin is a well-tested treatment for severe psoriasis and in the short term is probably more effective than other forms of systemic therapy'. Ideally, ciclosporin should be used for short courses of 3–4 months' maximum duration [22,23]. Only in exceptional circumstances should ciclosporin be used as continuous therapy for periods exceeding 6 months. The accepted modern regimen (intermittent short courses of ciclosporin) is effective for at least 2 years—most patients require less than four courses of treatment over this time with good control of the disease and no significant side effects [23]. A Japanese study that compared intermittent with continuous ciclosporin for psoriasis showed that an intermittent regimen was probably safer [24].

The most important side effects associated with ciclosporin are dose-related hypertension and nephrotoxicity. The blood pressure may rise sharply within weeks of starting treatment, and plasma creatinine levels may increase or glomerular filtration rates decrease within the same period [14]. Immunosuppression associated with the long-term use of ciclosporin may increase the risk of cutaneous malignancy, especially in patients who have previously had high-dose UV irradiation, PUVA, Goeckerman regimens or arsenic. SCCs of the skin have been reported in patients receiving ciclosporin for psoriasis [14]. A prospective 5-year survey of 1252 European patients with psoriasis who had on average received ciclosporin for 1.9 years [25] found that ciclosporin produced a sixfold increase in risk for developing non-melanoma skin cancer (mainly SCC). The risk was compounded by contributions from PUVA and other immunosuppressants such as methotrexate. There was no increase in non-cutaneous malignancies. Lymphoproliferative disorders are an important risk of high-dose immunosuppressive treatment in transplant recipients, although these diseases were not more common in transplant recipients receiving ciclosporin than in those not receiving it [14]. Eight malignant lymphomas developed in more than 6000 patients receiving ciclosporin for autoimmune disorders, although a causal relationship was not proved [14]. Overall, there is no clear association between ciclosporin treatment and a risk of other internal malignancies, although cases have been reported [26,27] and vigilance is essential. The finding of cervical intraepithelial neoplasia associated with possible human papillomavirus infection underlines the need for cervical smears in female patients on ciclosporin, perhaps every 6 months [14,27]. Human papillomavirus-associated penile carcinoma has also been reported [28]. Other side effects include elevated serum potassium and uric acid levels, decreased serum magnesium, mild normochromic normocytic anaemia, gum hyperplasia, hypertrichosis, acral paraesthesia or hyperaesthesia, tremor, altered liver-function tests and gastrointestinal intolerance [14]. Gum hyperplasia is associated with poor dental hygiene and regular dental check-ups are recommended. The hyperplasia may respond to treatment with azithromycin [29].

Regular monitoring is therefore essential during ciclosporin therapy, and has been reviewed [14,17]. Further details can be found in Chapter 74. There is no evidence that monitoring of serum trough levels of ciclosporin is indicated during treatment of psoriasis unless there is doubt about compliance and/or absorption of the drug [30].

Systemic glucocorticosteroids [1]

The glucocorticosteroids (steroids) have shown themselves to be double-edged weapons. The fluorinated forms such as triamcinolone and betamethasone have more effect on psoriasis than prednisolone [2,3]. When triamcinolone, 12–20 mg/day, is given for the first time, clearance of the psoriasis is rapid but the disease usually eventually 'breaks through', necessitating progressive increases in dosage and incidence of side effects [4]. If withdrawal is attempted, the psoriasis tends to relapse often promptly [4] and may 'rebound'. 'Rebound' may take the form of widespread, small-patterned, eruptive psoriasis, often involving the face and backs of hands. Erythrodermic or generalized pustular phases may be precipitated [1,5]. Systemic steroids should not be used in the routine care of psoriasis. They do have a role in the management of persistent, otherwise uncontrollable erythroderma that is causing metabolic complications and in fulminating generalized pustular psoriasis of the von Zumbusch type [6] if other drugs are contraindicated or ineffective. Associated psoriatic arthropathy is not an indication *per se*, but steroids may occasionally be needed, and in high dosage (prednisolone 40 mg/day initially), to control hyperacute polyarthritis that is threatening severe irreversible joint damage. Patients with psoriasis who have concomitant psoriatic arthritis controlled with low-dose steroids often have active labile skin disease that is difficult to control [7].

Psoriasis may remain labile and treatment resistant for many months after the withdrawal of systemic corticosteroids [8].

6-Thioguanine

6-Thioguanine is closely related to 6-mercaptopurine. The observations of one group [9] led to studies confirming that thioguanine appears to be effective in psoriasis [10]. Further experience in 81 patients was reported [11]. This drug may prove to be a useful alternative when other forms of treatment have failed. In 21 patients with severe psoriasis that had failed to respond to other systemic therapies, 14 of 18 had greater than 90% improvement in psoriasis [12]. Treatment was for an average of 15 months and regimens ranged from 20 mg twice weekly to 120 mg/day. Bone marrow toxicity is common, and is usually inevitable if an effect on psoriasis is to be seen. Increased liver enzymes are also seen and veno-occlusive disease of the liver may be a consequence of therapy [13], but preliminary evidence suggests that 6-thioguanine does not induce hepatic fibrosis [11]. Clearance of psoriasis correlates with depletion of T cells in the skin [14].

Fumaric acid esters (fumarates)

For more than 20 years fumarates have been used extensively in northern Europe, particularly German-speaking countries, for the treatment of moderate to severe psoriasis [15,16]. The commercially available preparation of fumarates, Fumaderm, comprises a mixture of dimethylfumarate and the calcium, magnesium and zinc salts of monoethylfumaric acid. After ingestion, dimethylfumarate is hydrolysed to monomethylfumarate—the main active metabolite. Clinical trials [17–19] attest to the efficacy of fumarates. The drug is introduced gradually, starting at 30 mg/day, building up over several weeks to a maximum dosage of 240 mg three times daily. It is estimated that if they tolerate the drug then approximately 57% of patients will achieve a 70% reduction in severity of psoriasis. Two-thirds of treated patients develop gastrointestinal symptoms such as dyspepsia and diarrhoea; one-third of patients develop flushing. In most patients these side effects settle down over time. Lymphocyte counts fall in nearly all treated patients, sometimes by 50% [17,19–21]. Renal function and liver function should be monitored but impairment is unusual. The mechanism of action of fumarates appears to be mediated at least in part by an ability to inhibit nuclear binding of nuclear factor kappa B and promoting the secretion of Th2 cytokines such as IL-10, which are beneficial in psoriasis [22,23].

Biological therapies

Biological therapies (biologics) directed at selected targets integral to the pathogenesis of psoriasis are the logical progression of the biotechnological revolution as applied to a more detailed knowledge of the roles of T cells, their differentiation pathways and pro-inflammatory cytokines in psoriasis. Several of these therapies are now in widespread clinical use for moderate and severe psoriasis [1]. In general these treatments are highly effective, including in patients in whom standard systemics are either ineffective or contraindicated. However, the recent withdrawal of one agent, efalizumab, on safety grounds, coupled with their high cost illustrates the need for careful patient selection.

Biological agents. The introduction of biological therapies into the management of moderate and severe psoriasis has made a dramatic impact on practice and on patient outcomes, for example in one of the author's practice, admission rates have dropped by 90%. These drugs are extensively reviewed in Chapter 74 so comments below refer specifically to use in psoriasis.

The British Association of Dermatologists has recently prepared guidelines [2] for their usage incorporating all licensed biologics up to mid-2009. In keeping with the licensed indications for each of these drugs, their use should be restricted to: (i) patients with severe disease defined by a psoriasis area severity index (PASI) score of 10 or more (or a body surface area (BSA) of 10% or greater where PASI is not applicable) and dermatology life quality index (DLQI) of greater than 10; and (ii) who have failed to respond to, or who have a contraindication to, or who are intolerant to other systemic therapies such as ciclosporin and methotrexate.

Importantly, there are some key exceptions. Firstly, some patients will have disease affecting high impact sites such as face, hands and feet that will cause considerable psychological or functional morbidity. Secondly, given the beneficial effect of these drugs on psoriatic arthritis, patients with both skin and joint involvement should be considered earlier for intervention with a biological therapy, particularly the TNF-α antagonists. Thirdly, there is increasing evidence that forms of psoriasis other than plaque type respond to biological agents and the patient with resistant disease should be considered.

When using these agents it is essential that appropriate safety screening and monitoring measures are implemented as discussed elsewhere and information provided to national registries where appropriate. Further, validated measures of treatment outcome such as PASI and DLQI should be recorded at appropriate intervals to provide evidence of effectiveness and justification for continuation of therapy. These include values at baseline and at 10–16 weeks, depending upon the intervention.

At present, there are five biological agents licensed for the treatment of psoriasis vulgaris. They are: (i) etanercept, a fully human soluble p75 TNF-α receptor fusion protein; (ii) infliximab, a chimeric human-immune antibody to TNF-α; (iii) adalimumab, a fully human recombinant antibody to TNF-α; (iv) ustekinumab, a fully human recombinant antibody to the p40 component of IL-12/IL-23: and (v) alefacept, a fusion protein of lymphocyte function associated antigen-3 and IgG that inhibits T-cell activation—this is not licensed in the UK. Infliximab is administered by intravenous infusion while the others are administered by subcutaneous injection.

The lack of head-to-head studies coupled with a paucity of data concerning these drugs in various clinical scenarios makes recommendations concerning their individual use difficult. Thus, the choice of which of the three TNF-α antagonists to use first should be based on clinical need and requires a careful assessment of risks and benefits of each agent in the context of the individual patient [2]. For stable disease, particularly if not too severe (e.g. PASI >10 but <20), etanercept or adalimumab are often first options. For patients requiring rapid disease control, adalimumab or infliximab may be considered first choice due to early onset of action. For patients with unstable or generalized pustular psoriasis, limited evidence indicates that infliximab is effective and may be considered first choice amongst the biologics. Equally, it appears to be the most active agent for severe nail disease [3] including acropustulosis of Hallopeau.

For patients who do not respond to a TNF-α antagonist (either primary or secondary failure), a second TNF-α antagonist may be considered.

The role and place of ustekinumab in the management of psoriasis is complicated by the lack of patient years' exposure and long-term safety data limited to 1 year (at time of writing). The British guidelines suggest it should therefore be reserved for use as a second-line biological agent [2].

Miscellaneous therapies

Sulfasalazine

Sulfasalazine (sulphasalazine) is an anti-inflammatory agent, 5-{[*p*-(2-pyridylsulfamoyl)phenyl]azo}salicylic acid, commonly used in the treatment of inflammatory bowel disease. One open study and one randomized controlled trial provide evidence that sulfasalazine for 8 weeks at 3–4 g/day can produce marked improvement in about one-third of patients [1,2]. Approximately 25% of patients find the side effects of headache, nausea and vomiting disabling. Oligospermia, pruritus and haemolytic anaemia may occur. Sulfasalazine is a useful alternative systemic therapy for psoriasis.

Azathioprine

This is a synthetic purine analogue synthesized by attaching 6-mercaptopurine to an imidazole ring—*in vivo* it is converted to its active metabolite 6-mercaptopurine by hepatic xanthine oxidase. Several uncontrolled or case studies [3–5] describe efficacy in psoriasis but, in the absence of data from controlled trials, it is best to conclude that there is no good evidence that azathioprine is an effective treatment for psoriasis. The most important side effect is bone marrow suppression.

Mycophenolate mofetil

Following ingestion, mycophenolate mofetil (MMF) is hydrolysed to its active metabolite—mycophenolic acid. Mycophenolic acid inhibits inosine monophosphate dehydrogenase, a key enzyme in *de novo* purine synthesis—this results in blockade of T- and B-cell proliferation. Dosage is 1–2 g/day increased to a maximum of 4 g/day. MMF is only moderately effective as monotherapy for psoriasis [6–8], but its place in the therapy of severe psoriasis is probably in combination with ciclosporin as a ciclosporin-sparing agent [9,10], used at an average dosage of 1–2 g/day. Side-effects include gastrointestinal symptoms and bone marrow suppression.

Tacrolimus and pimecrolimus

Despite the undoubted efficacy of ciclosporin in the treatment of psoriasis, its long-term use is limited by nephrotoxicity and hypertension. In an effort to find drugs that have a similar mechanism of action, namely blockade of calcineurin phosphatase and consequent inhibition of T-cell activation, a number of drugs structurally dissimilar to ciclosporin, but with a similar mechanism of action, have been investigated.

Tacrolimus and pimecrolimus, both of which are derived from species of the soil fungus *Streptomyces*, have been trialled for the treatment of severe psoriasis. Oral tacrolimus at a dosage of 0.05–0.15 mg/kg/day can significantly improve severe psoriasis in the short term (10 weeks) [11,12]. Side effects include paraesthesia, headache and minor elevations in serum creatinine and blood pressure. Tacrolimus is rarely used for the treatment of psoriasis, but is a useful alternative.

Oral pimecrolimus showed highly promising results in severe psoriasis in a placebo-controlled, 12-week trial but has not been developed further for this indication [13]. Side effects were minimal, with no effect on either blood pressure or serum creatinine. A novel calcineurin inhibitor, ASA247, has recently proven safe and effective for plaque psoriasis in a 24-week study [14].

Cytokines

Plaques of psoriasis contain a predominance of Th1 cytokines such as IL-2, IL-12 and IFN-γ. Systemic administration of Th2 cytokines such as IL-4 or IL-10 appears to neutralize the Th1 bias and improve psoriasis. IL-10 was the first Th2 cytokine to be used for treatment of psoriasis. Phase II trials show that subcutaneous injections of recombinant IL-10 given either daily or three times weekly produce a mean reduction in psoriasis severity of 50% [15,16]. This response is associated with a Th2 cytokine shift and, when used as maintenance therapy, length of remission correlates with T-cell production of IL-4 [17]. Systemic administration of IL-4, in an open study, has demonstrated very significant reduction in clinical severity of psoriasis [18].

Protein kinase C inhibitor

The orally administered novel protein kinase C inhibitor, AEB071, demonstrated efficacy in moderate-severe plaque psoriasis in an early phase 2-week study. It was well tolerated and its mechanism of action is believed to reside in inhibition of T-cell activation [19].

Zidovudine (azidothymidine, AZT)

The skin lesions of patients with therapy-resistant AIDS-associated psoriasis have been reported to clear with oral zidovudine [20,21]. This drug may be the treatment of choice for retinoid-resistant AIDS-associated psoriasis, as therapies such as methotrexate, ciclosporin and PUVA may be contraindicated.

Somatostatin

Following uncontrolled reports of the efficacy of somatostatin in psoriasis, a double-blind placebo-controlled study of intravenous somatostatin suggested benefit in recalcitrant psoriasis [22].

Liarozole

Liarozole, a member of the imidazole family and an inhibitor of retinoic acid 4-hydroxylase, belongs to a new class of drugs, the retinoic acid metabolism blockers. It delivers a retinoid-like effect

by increasing endogenous levels of naturally occurring all-*trans*-retinoic acid and other retinoids upstream of retinoic acid 4-hydroxylase. The advantage of liarozole over acitretin is that the raised levels of retinoic acid return to normal within a few days of cessation of therapy. Trials [23,24] indicate that liarozole is effective for chronic plaque psoriasis. Side effects are 'retinoid' in nature (teratogenicity, hyperlipidaemia and mucocutaneous symptoms).

Gluten-free diet

Studies, primarily from Sweden [25,26], have established that approximately 16% of patients with psoriasis have IgA and IgG antibodies to gliadin. In a further study [27], 33 psoriasis patients with IgA antibodies to gliadin (15 of whom had evidence of a lymphocytic infiltrate in the duodenal epithelium) were placed on a gluten-free diet for 3 months. All 33 patients had significant improvement in psoriasis severity while on the diet. These fascinating results indicate that in a very few patients a gluten-free diet may be worth trying if antigliadin antibodies are present.

Photodynamic therapy

Photodynamic therapy has been investigated for the treatment of small plaques of psoriasis. Using 5-aminolaevulinic acid as the topical photosensitizer has produced improvement in the treated plaques, but use is limited by local pain at the site of treatment [28,29]. Further work is required to ascertain the value of photodynamic therapy for treatment of psoriasis—if larger plaques could be treated in a relatively painless manner then this would be an advance.

Lasers

Recalcitrant plaques of psoriasis have been treated with lasers. Local destruction of psoriatic epidermis using carbon dioxide laser resurfacing gave mixed results [30,31]; further investigation is required. Pulsed dye laser (585 nm) therapy appears to be more effective than the carbon dioxide laser; indeed some plaques treated with pulsed dye laser remain in remission for a year or more [32,33].

Excimer laser-generated 308-nm UVB radiation is the laser source most likely to be used for routine management of psoriasis. The UVB source is handheld and delivers high-intensity UVB selectively directed to plaques, thereby sparing uninvolved skin. Controlled trials show it to be safe and effective for localized plaques, and it requires fewer treatments than conventional phototherapy [34,35].

Dialysis and related therapies [1,2]

The clearing of incidental psoriasis during haemodialysis for uraemia was reported in 1976 [3]. Others then recorded similar experiences with both haemodialysis and peritoneal dialysis [4–6]. It soon became clear that dialysis could favourably influence psoriasis in patients with normal renal function [1,6–9] and that peritoneal dialysis is more effective than haemodialysis [1,9,10], possibly because substances of higher molecular weight can be removed in larger quantities [2].

Success rates with dialysis have been variable. Although some patients clear completely, others do not improve, and successfully treated patients may relapse quickly afterwards [4,8]. Not all have achieved success [11] and, confusingly, there are several reports of psoriasis worsening or appearing *de novo* during chronic haemodialysis for renal disease [12–14].

Plasmapheresis and leukapheresis were ineffective, findings that led to the suggestion that there is no pathogenic circulating factor or leukocyte abnormality in psoriasis [15,16].

Pustular forms of psoriasis

Neutrophilic accumulation in the epidermis is a characteristic histological feature of all types and patterns of psoriasis, but in clinical practice the term 'pustular psoriasis' is reserved for those forms of the disease in which macroscopic pustules appear.

It is convenient to separate two main types of pustular psoriasis: localized and generalized. In the localized forms, the disease is confined to the hands and feet and tends to be chronic. There is a rapidly developing and widely held opinion that palmoplantar pustulosis is a disease distinct from psoriasis and as such should not be included in a chapter on psoriasis save as a comorbidity. In the generalized forms, the whole body may be involved and the course is subacute, acute or even fulminating and life-threatening.

A convenient classification is as follows.

1 Localized pustular psoriasis:
  (a) palmoplantar pustulosis
  (b) acrodermatitis continua
2 Generalized pustular psoriasis:
  (a) acute
  (b) of pregnancy
  (c) infantile and juvenile
  (d) circinate
  (e) localized (not hands and feet).

Localized pustular psoriasis

Palmoplantar pustulosis

Synonyms
- Chronic palmoplantar pustular psoriasis
- Pustulosis palmaris et plantaris
- Persistent palmoplantar pustulosis

Definition. A common condition in which erythematous and scaly plaques studded with sterile pustules persist on the palms or soles. The disease is chronic, very resistant to treatment and probably a separate disease to psoriasis.

Pathogenesis. The relationship of palmoplantar pustulosis (PPP) to psoriasis vulgaris is controversial [1,2]. Sometimes the presence of typical psoriasis elsewhere, or a personal or strong family history of psoriasis, or the future development of psoriasis vulgaris, establishes the relationship. However, typical PPP often occurs in the absence of such evidence [1–3]. This, and the absence of immunogenetic associations characteristic of psoriasis (see below) in such patients, indicate that PPP may represent a separate and distinct entity. Furthermore, PPP is more common in females, unlike psoriasis vulgaris there is no seasonal variation, and it tends to start at a later age [2].

HLA antigens. Three potential candidate genes for psoriasis susceptibility reside within *PSORS1* locus on chromosome 6, HLA-Cw6, *HCR WWCC* and the *CD5N5*. A recent immunogenetic study demonstrated categorically that PPP is not associated with any of

the three candidate genes—indicating that it is a distinct disorder [4]. Combining the results of these and other studies, it may be concluded that there is no predominant HLA locus associated with PPP [2].

Provocative factors. PPP usually starts without obvious provocation. Septic foci have been blamed [1,5,6] but their removal may not cure the eruption. The disease has appeared for the first time after several months of treatment with lithium [7]. Japanese otolaryngologists remain interested in the tonsils as a site of relevant focal infection [8]. Smoking has also been reported as a possible provoking factor [9]. With the advent of TNF-antagonist biologic therapies for rheumatoid arthritis and psoriasis has come a series of reports of *de novo* occurrence of PPP or exacerbation of the condition [10–11]. An immunohistochemical study of biopsies of palmar skin revealed an altered staining pattern for nicotinic acetylcholine receptors in PPP—the authors suggested that an abnormal response to nicotine in patients with PPP resulted in inflammation [12].

Clinical features [1–3]. PPP is a disease of adults and is rare in children. It usually starts in the fifth or sixth decade, although sometimes earlier. In most series, there has been a preponderance of women [4]. The disease presents with one or more well-defined plaques. On the hands, the thenar eminence is the most common site. Less commonly, the hypothenar eminence or the central palm or the distal palm are involved. On the feet, the instep, the medial or lateral border of the foot at the level of the instep, or the sides or back of the heel are involved. Less frequently, the distal sole or the whole sole is implicated. Digital lesions are uncommon. A striking symmetry of the lesions on the hands or feet is common, but sometimes a solitary lesion persists for weeks or months before others appear.

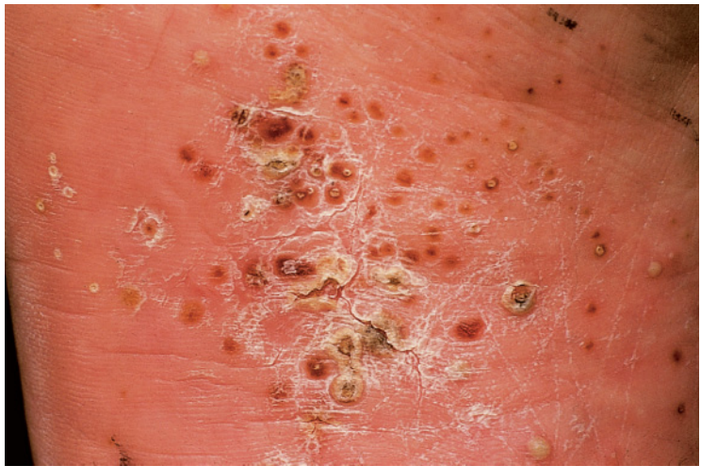

Fig. 20.23 Palmoplantar pustulosis. Note pustules in different stages of evolution. (Courtesy of St John's Institute of Dermatology, London, UK.)

The affected area is dusky red and often scaly. Removal of scale (e.g. by treatment) leaves a glazed dull-red surface. Within this plaque, numerous pustules are present, usually 2–5 mm in diameter. Fresh pustules are yellow; older ones are yellow-brown or dark brown as the pustule dries. Eventually, the desiccated pustule is exfoliated. Normally, pustules in all stages of evolution are seen (Fig. 20.23). Itching is variable; more often the patient complains of 'burning' discomfort in the lesions.

Associations. A significant incidence of hyper- and hypothyroidism and the presence of thyroid antibodies has been found in association with PPP [5–7]. A greater tendency to develop diabetes was found in a Japanese study [8]. Various arthropathies are also associated [9], including chronic recurrent multifocal osteomyelitis [10,11], sternoclavicular involvement [12,13], pustular arthro-osteitis, axial and peripheral arthritis [9,14]. The association of some of these conditions with PPP may represent part of the spectrum of SAPHO syndrome [15]. More than 90% of patients with PPP are current or previous smokers [5,16]. Some patients have anti-gliadin antibodies [5].

Differential diagnosis. Tinea and eczema are the most common alternatives. Tinea is usually asymmetrical or unilateral. The toe clefts may be involved. Acute vesiculopustular tinea is more common in hot weather. Microscopy and culture confirm the diagnosis. Secondary infection of eczema may be pustular but is more painful, and Gram stains and culture of pustule contents will establish the diagnosis. Chronic allergic contact dermatitis caused by rubber in footwear should not cause difficulties. Typically, the insteps are spared. The chronic acropustulosis seen in black infants does not occur in adults, and affects the digits and dorsal aspects of the extremities as well as the palms and soles [17,18].

Prognosis. The usual course is prolonged. Sometimes spontaneous remission does occur but is more often temporary than

Fig. 20.24 Acute palmoplantar pustulosis. (Courtesy of St John's Institute of Dermatology, London, UK.)

permanent. Slow spread or extension may be refractory to all treatment.

Pustular bacterid

This term was first used [19] to describe an acute monomorphic eruption of sterile pustules occurring on the hands and feet (Fig. 20.24). Whether it is a distinct entity or merely an acute variant of PPP is unclear. The term 'bacterid' implies that the eruption is provoked by a remote bacterial infection.

Acrodermatitis continua

Synonyms
- Acropustulosis
- Pustular acrodermatitis
- Acrodermatitis perstans
- Dermatitis repens
- Acrodermatitis continua of hallopeau

Definition. A chronic, sterile, pustular eruption affecting initially the tips of fingers or toes that tends slowly to extend locally but which, in adults, may evolve into generalized pustular psoriasis.

Clinical features. Whereas PPP is a disease of middle life, acrodermatitis may be seen in children. It is rare in young adults and, unlike PPP, not infrequently begins in old age. It is more common in females.

The first lesion starts on a finger or thumb more often than on a toe. Onset is often related by the patient to minor trauma, or infection at the tip of the digit. The skin over the distal phalanx becomes red and scaly, and pustules develop. The nail folds and nail bed may be involved, leading to nail dystrophy. The proximal edge of the lesion is bordered by a fringe of undermined epidermis, irregular, often sodden and sometimes preceded by a line of vesiculopustules. Removal of scale or desiccation of pustules may leave a brighter red, glazed, very sore and painful digit. Slow proximal extension is the rule but this may be spread over years. Eventually, other digits may be involved. The nail plate may be completely destroyed (Fig. 20.25). Bony changes can occur with osteolysis of the tuft of the distal phalanx [1]. The free end of the digit may become wasted and tapered, mimicking scleroderma. In such digits, the circulation may be secondarily affected so that discomfort is greatest in cold weather.

Acrodermatitis continua may evolve into generalized pustular psoriasis, especially in the elderly [2]. The tongue may become involved with fissuring or the annulus migrans of pustular psoriasis [3].

Differential diagnosis. In the earliest stage, staphylococcal infection, pulp infection, herpetic whitlow, tinea or contact dermatitis may be suspected. Candidiasis is only likely to be a problem in

Fig. 20.25 Acrodermatitis continua with destruction of nail plate. (Courtesy of St John's Institute of Dermatology, London, UK.)

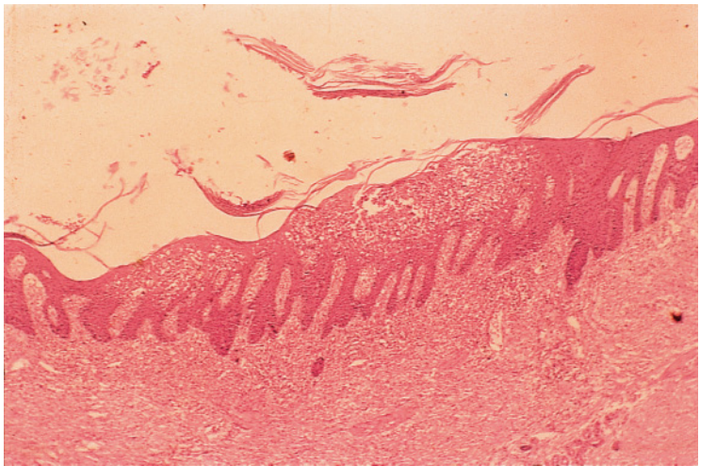

Fig. 20.26 Pustular psoriasis: intraepidermal pustule packed with neutrophils. (Courtesy of St John's Institute of Dermatology, London, UK.)

the immunocompromised. Parakeratosis pustulosa [4] should be considered in children.

4 Hjorth N, Thomsen K. Parakeratosis pustulosa. *Br J Dermatol* 1967; **79**: 527–32.

Histopathology. The changes are essentially psoriatic, but the central feature is a fully developed, large pustule within the epidermis, unilocular and full of neutrophils (Fig. 20.26). Spongiform pustules may be found in the wall of the larger unilocular pustule. There is some overlying parakeratosis. The acrosyringium is involved in the inflammation, and there are at times large numbers of eosinophils and mast cells present [1].

Management. Effective therapy is elusive and treatment is often as disappointing for the physician as for the patient. In view of the finding that PPP is an immunogenetically distinct disease from psoriasis vulgaris [2], it is perhaps unsurprising that using traditional therapies for the treatment of PPP is not ideal. The choice of treatment is influenced by its side effect profile. It is usual to start with topical therapy but topical treatments alone tend to be ineffective for PPP [3]. Superpotent topical corticosteroids may be beneficial in the short term. Hydrocolloid gel occlusion can enhance efficacy of moderate potency steroid cream, which is applied every third day up to a maximum of 4 weeks [4,5]. Atrophy, particularly of the skin around the medial longitudinal arch, is a significant risk. There are no published controlled trials to support efficacy of coal tar or dithranol [3]. Tar-impregnated occlusive bandages may be helpful for acrodermatitis continua. Neither calcipotriol nor tazarotene have been formally evaluated for the treatment of PPP. Studies of topical psoralens in either soak, paint or gel form have failed to demonstrate superiority over placebo [6]. Open studies, particularly for 8-MOP soaks, indicate efficacy; in one study the majority of patients achieved remission [7].

Systemic therapies offer the best opportunity for remission. Oral retinoids either alone or in combination with oral PUVA are the best of the second-line therapies [8–11]. Acitretin produces objective improvement in PPP [10]. Liarozole—an imidazole derivative that blocks metabolism of all-*trans*-retinoic acid and thus boosts endogenous levels of retinoids—may be effective, as shown in a small, placebo-controlled study [12]. Oral PUVA is effective [9,13] and the response is enhanced by combination with retinoid (Re–PUVA) [13–15]. Various other forms of oral therapy have been used. Placebo-controlled trials of clomocycline 170 mg three times daily [16] or tetracycline 250 mg twice daily [17] have demonstrated efficacy in PPP. Ciclosporin at the low dosage of 2.5 mg/kg/day significantly improved PPP in most patients [18]—this placebo-controlled trial confirmed observations made in earlier open trials [19,20]. Dosage as low as 1 mg/kg/day may be effective [21]. Biologic, TNF antagonists are more likely to exacerbate than improve PPP [22]. Methotrexate is occasionally beneficial, but an open study refutes this claim [23]. Anecdotal evidence exists for dapsone [24] and clofazimine [25], and grenz ray therapy may be a useful adjunct [26]. Oral corticosteroids should be used with extreme caution; triamcinolone in a dosage of 6 mg/day or less initially and 2–4 mg as maintenance may be effective.

Oral tetracycline and topical betamethasone valerate [27], and a combination of oral propylthiouracil and methotrexate [28], have been advocated for treatment of acrodermatitis continua, as has low-dose ciclosporin [29]. Narrow-band UVB and 8-MOP [30] and the TNF antatagonists [31,32] have all been reported as beneficial for acrodermatitis continua.

Remission of pustulosis in three obese patients after jejunoileal shunt operations leading to marked weight reduction awaits confirmation [33].

Generalized pustular psoriasis

Definition. Generalized pustular psoriasis (GPP) is an uncommon variant of psoriasis in which an acute, subacute or occasionally chronic eruption has sterile pustulosis as its central feature.

Relationship to psoriasis vulgaris. GPP is an extreme form of psoriasis in which all the main pathological features of the disease are accentuated. Its relationship to psoriasis vulgaris is clear, because patients may have phases of ordinary psoriasis before or after the GPP [1]. Family data are similar to those found in psoriasis vulgaris [2,3]. In addition, methotrexate, etretinate, PUVA and ciclosporin A are effective in both psoriasis vulgaris and GPP.

Provocative factors. Provocation is most obvious in the acute forms. Von Zumbusch's original patient [4] was provoked by irritating topical therapy. Coal tar [5] and dithranol [2] may provoke pustulation if injudiciously continued when the psoriasis is intolerant. Other documented factors have been infection [2,6], pregnancy (see below) and hypocalcaemia associated with hypoparathyroidism [7–9]. Drugs implicated have included salicylates [10], iodide [11], lithium [12], phenylbutazone and oxyphenbutazone [13] and progesterone [14], terbinafine [15–17] and amfebutamone (bupropion) prescribed to assist with cessation of smoking [18]. The most important drug provocation is by corticosteroids. There is substantial evidence that withdrawal of systemic steroid therapy can precipitate GPP [1,2]. Intensive topical therapy with strong corticosteroids under occlusion has also been implicated [2,19,20]. Withdrawal of ciclosporin therapy has also been documented to induce GPP [21,22]. Chronic, previously stable acrodermatitis continua has been converted to GPP by high-dose oral prednisolone followed by sudden withdrawal [23].

HLA antigens. There is a strong positive correlation of GPP with HLA-B27 [1,2]. The association of GPP with polyarthritis [1,2] may partly explain this finding. A Japanese study has reported an association between HLA CW1 and HLADQβ*0303 and GPP [3].

Histopathology [2,4]. In acute GPP, there is intense inflammation. The earliest infiltrate is lymphocytic. Intense papillary and epidermal oedema cause spongiosis. The arrival of masses of neutrophils leads to spongiform pustule formation (Kogoj) and abscesses that quickly become macroscopic. There is acanthosis with elongation of rete ridges [2]. The stratum corneum soon becomes parakeratotic and the subcorneal pustule is shed as epidermal turnover is accelerated. Essentially, the same features are seen in subacute as in chronic patterns but in a less intense form.

Acute generalized pustular psoriasis (von Zumbusch)

Clinical features [1–3]. Two main groups have been distinguished [1]. In the first, typical psoriasis of early onset develops into pustular psoriasis after some years, often after provocation by steroid withdrawal or other extraneous factors. In the second, the onset of psoriasis is later in life and usually atypical, acral [4] or flexural [2,4] in distribution. A rapid and apparently spontaneous progression to the generalized pustular form follows.

The eruption may be ushered in by a sensation of burning. The skin becomes dry and tender. These warning signs—not always present—are followed by an abrupt onset of high fever and severe malaise. Pre-existing lesions become fiery and develop pinpoint pustules (Fig. 20.27). Sheets of erythema and pustulation spread to involve previously unaffected skin, the flexures and genital regions being particularly involved. Any configuration or variety of pustular exanthems may occur—isolated pustules, lakes of pus, circinate lesions, plaques of erythema with pustular collarettes or a generalized erythroderma. Waves of pustulation may succeed each other, subsiding into exfoliation of the dried pustules.

Fig. 20.27 Acute generalized pustular psoriasis. (Courtesy of St John's Dermatology Centre, London, UK.)

The nails become thickened or separated by subungual lakes of pus. The buccal mucosa and tongue may be involved, the lesions on the latter being clinically and histologically indistinguishable from 'geographic' tongue [1,5,6]. Persistent fissured tongue has also been associated with GPP and geographic tongue [7]. If the patient does not die of exhaustion, toxicity or infection, a remission may occur within days or weeks, the psoriasis returning to its normal state, or erythroderma develops. Relapses are common.

Complications. In the absence of effective treatment, death can occur in the acute stage. Hypoalbuminaemia may be profound, perhaps because of a sudden loss of plasma protein into the tissues [8]. In one patient, albumin half-life was shortened to 4 days (normal 11–12 days) [8]. Hypocalcaemia may be a consequence of the hypoalbuminaemia [1,9]. The consequent oligaemia can cause acute and fatal renal tubular necrosis [10]. There may be evidence of liver damage or even jaundice, perhaps caused by a combination of oligaemia, general toxicity and drugs [10,11]. Cholestatic jaundice of uncertain pathogenesis, closely related to acute episodes of GPP, has been described [12]. Deep-vein thrombosis in a leg can cause fatal pulmonary embolism. Staphylococcal infection may complicate GPP, usually because of hospital ward cross-infection. *Staphylococcus aureus* may be grown from pustules and rarely from blood cultures. However, claims that most GPP is caused by staphylococcal bacteraemia [13] were not substantiated [14].

Inflammatory polyarthritis is common. In one large series, one-third of patients were eventually affected [1]. Malabsorption may be a feature of the acute episode [9,15] and may further contribute to hypocalcaemia [9]. The absorption of therapeutic drugs may be impaired. Amyloidosis is a rare complication [16,17]. The obstetric complications of GPP in pregnancy are discussed below.

If GPP lasts more than a few days, gross hair loss may follow from all areas of the body. Occasionally, a telogen effluvium follows 2–3 months after the height of the illness.

Laboratory findings. There may be an absolute lymphopenia at the onset of GPP [18]. A polymorphonuclear leukocytosis quickly follows [1,18]. Plasma albumin, zinc [19] and calcium may be abnormally low. The ESR is usually raised. Malabsorption partially explains these findings. Hyperlactataemia is probably secondary to hyperproliferation [20].

Generalized pustular psoriasis of pregnancy [1–4]

Synonym
- Impetigo herpetiformis

Definition. A rare eruption, occurring especially in pregnancy, with the features of generalized pustular psoriasis, but with a tendency to be symmetrical and grouped, and often starting in the flexures. Constitutional disturbance may be severe.

Pathogenesis. The worsening of pustular psoriasis just before menstruation is well recognized [5,6] and challenge with progesterone [7] or clomifene (clomiphene) [5] has produced pustular exacerbations in such patients. The syndrome was first described by Hebra [8] and an endocrine cause is suspected. The claims that impetigo herpetiformis stands as an entity separate from GPP have been restated [3,9].

Clinical features. The disease is rare; by 1982 less than 200 cases were documented [2]. Onset is usually in the last trimester of pregnancy, but may be earlier, and has been recorded in the first month of pregnancy [6] and in the first day of the puerperium [10]. The disease tends to persist until the child is born, and occasionally long afterwards [6]. There is one report of familial disease [11]. Essentially, the features are of a GPP, usually of flexural onset and with a marked tendency to symmetry, and sometimes grouping of areas of pustulation. Constitutional disturbance is characteristically severe with fever, and death may occur, attributable to cardiac or renal failure. Delirium, diarrhoea, vomiting and tetany have been described. The eruption usually starts in the inguinogenital region and other flexures, with minute pustules arising on an acutely inflamed area of skin. These extend centrifugally, drying in the centre, or form plaques in which eroded greenish yellow pustules become fetid, crusted or vegetating. Condyloma-

like lesions may form in the flexures [12]. The eruptions may become widespread. As individual areas heal, they leave a reddish brown pigmentation. The tongue, buccal mucosa and even the oesophagus may be involved, with circinate or erosive lesions following short-lived pustules.

The more severe and long-standing the disease, the greater are the risks of placental insufficiency leading to stillbirth, neonatal death or fetal abnormalities [3,9,13].

Prognosis. Characteristically, the disease recurs in subsequent pregnancies [2,14]. Recurrence has been described in up to nine pregnancies, and on subsequent use of oral contraceptives [2,3]. In one case, the disease continued unabated despite termination of the pregnancy [6].

Laboratory findings. Hypocalcaemia has often been reported [1,6]. Lowered levels of serum vitamin D have been found, probably attributable to its malabsorption [2].

Treatment. This is discussed with that of other forms of GPP (see below). In one case, where termination failed to halt the disease, a mestranol–ethynodiol combination orally was effective when other measures had failed [6].

Infantile and juvenile pustular psoriasis

All forms of pustular psoriasis are rare in childhood. Five cases were seen in one series of 479 children with psoriasis [1], and one case of GPP in another series of 112 [2]. In a series of 104 cases of GPP in patients of all ages, there were only five children [3]. Although GPP can begin at any age in childhood, in over 25% of certain series onset has been in the first year [4,5]. The disease may begin in the first few weeks of life and two cases of congenital GPP have been described [5].

Fig. 20.28 Juvenile pustular psoriasis. (Courtesy of St John's Institute of Dermatology, London, UK.)

In contrast to psoriasis vulgaris in childhood [6] and GPP in adults [3], a male preponderance is seen in GPP of childhood (about 3:2) [4,5]. Infantile cases are usually benign. Systemic symptoms are often absent and spontaneous remissions occur [4,5]. In at least one-third of infantile cases, a history of an eruption diagnosed as seborrhoeic dermatitis [7], napkin dermatitis or sudden-onset napkin psoriasis [8] is obtained [4,9]. More severe forms with fever and toxicity do occur, necessitating active treatment. Rarely, pustulosis has supervened on a congenital erythroderma [4,10].

The majority of children are aged 2–10 years at onset. The disease may be of Zumbusch pattern, but annular and circinate forms are the most common [4,9,11]. Onset of Zumbusch-type psoriasis may be abrupt with toxicity, and an erythrodermic background can become generalized rapidly (Fig. 20.28). Attacks often settle within a few days, but repeated waves of inflammation may follow [4]. Systemic steroid therapy carries the hazard of disseminated infections with varicella and other viruses [9]. In older children, the disease resembles that in the adult and may be of any of the recognized patterns.

The prognosis may be variable [3] but has been generally good in two series [9,12]. Treatment is discussed below.

Circinate, annular and linear pustular psoriasis

Annular and other patterned lesions may be seen in acute GPP, but are more characteristic of the subacute or chronic forms of widespread pustular psoriasis [1,2]. Lesions begin as discrete areas of erythema, which become raised and oedematous. Slow centrifugal spread may mimic erythema annulare centrifugum [3,4]. Pustules appear peripherally on the crest of the advancing edge, become desiccated and leave a trailing fringe of scale as the lesion slowly advances.

Some authors have separated a related pattern, well described by Lapière as recurrent circinate erythematous psoriasis [5,6]. It was originally described in 1907 as 'recurrent circinate erythema'. It may occur alone (in the complete absence at any stage of recognizable psoriasis) or as a phase in what is clearly generalized pustular psoriasis.

Linear forms of pustular psoriasis are occasionally observed within the context of more generalized pustulosis [7,8].

Localized forms of GPP

These must be distinguished from PPP or acropustulosis. The term 'psoriasis with pustules' is perhaps more appropriate. One or more plaques of psoriasis vulgaris may develop pustules (e.g. after excessively irritant topical therapy).

Differential diagnosis. Subcorneal pustular dermatosis of Sneddon and Wilkinson remains a controversial entity [1,2]. Acute generalized exanthematous pustulosis (AGEP) is perhaps the most important differential, occurring as an acute, spontaneously healing reaction to drugs, usually antibiotics [3]. It is probable that some cases previously reported as drug-induced GPP (see above) may in fact have been AGEP. In infantile acropustulosis, the process does not become generalized and is not associated with constitutional disturbance [4,5]. The distinction between GPP and pustular lesions in Reiter's disease is probably academic. Acute pemphigus foliaceus can mimic subacute GPP, but histological and immunofluorescence testing will distinguish the two. The wasting, glossitis and anaemia associated with the migratory necrolytic eruption of glucagonoma should allow easy differentiation. Occasionally, the bowel bypass syndrome [6,7], Sweet's syndrome [8] and Behçet's syndrome will cause difficulty. Staphyloderma, rampant impetigo or candidiasis in the immunosuppressed or pustular drug eruption (e.g. caused by halides) should be remembered.

Management [1]. The treatment of acute GPP requires admission to hospital, removal of possible provocative factors, general support measures and topical and usually systemic drug therapy.

Withdrawal of provocative factors. Tar or dithranol can be withdrawn abruptly, but massive overdosage with potent topical corticosteroids requires more care. The application of serially diluted topical steroids over several days may be the safest course, and is preferable to substitution of oral or parenteral corticosteroid, however temporary. Infection, where present, should be treated rigorously with the appropriate antibiotic, usually erythromycin or flucloxacillin. Rarely, when GPP in pregnancy is threatening maternal life, termination or early delivery may be indicated.

General measures. If there is no immediate metabolic threat in acute GPP, and generally in subacute forms, initial treatment

should be conservative [2]. This is particularly so in infancy and childhood [3]. Bed rest in hospital, mild sedation, bland local applications with fluid and protein replacement may promote spontaneous reversion to a quieter erythrodermic psoriasis or even psoriasis vulgaris [2]. This approach is particularly apt if a provocative factor has been at play [2]. However, such a course has to be weighed against the risk of repeated waves of pustulation that may exhaust the patient, and the hypostatic and thrombotic hazards of prolonged bed rest, particularly in the elderly patient. Excessive heat loss must be prevented by maintaining an adequate ambient temperature, avoiding cool draughts of air. A low-reading thermometer is essential. Fluid intake should be increased so that the daily urine volume remains adequate.

Topical therapy. Often, completely bland creams or lotions are best. Weak corticosteroid creams may be helpful in subacute forms. Tar [4] and dithranol are contraindicated.

Systemic therapy. Most cases of GPP require systemic therapy. Retinoids are probably the treatment of choice. A recent survey of 385 Japanese patients with GPP [5] reported that acitretin was effective in more than 80% of cases. Response to high doses of acitretin (1 mg/kg/day) may be rapid [6] and lower doses of 0.5–0.75 mg/kg/day may be sufficient to maintain control [7]. Disease control can sometimes be achieved with intermittent therapy [8]. Combination of etretinate with PUVA is beneficial [9].

PUVA therapy is effective in acute and subacute GPP [9–12]. Very ill patients may have to be treated in the horizontal position. Small doses of UVA should be given initially three or four times weekly; the dose of UVA is slowly increased.

Methotrexate is probably as effective as acitretin but no comparative studies are available [2]. In fulminating GPP, small (7.5–10.0 mg) intravenous doses, repeated every 5–7 days may be safest. The intramuscular route can be used, but the intravenous or intramuscular dosage should rarely exceed 0.3 mg/kg/week. Oral therapy is less predictable, because of variable absorption. Sudden unexpected toxicity from repeated methotrexate doses may follow, because of improved absorption of the drug as the GPP subsides. Orally, dosage of 0.2–0.4 mg/kg/week should suffice, starting at the lower end of the range. If the patient is very ill, renal function may have to be monitored daily if methotrexate overdosage is to be avoided. Methotrexate has been used with success in children with GPP [13].

Control of GPP has been achieved with very high dosage of ciclosporin alone (9–12 mg/kg/day), but toxicity prevented prolonged treatment at these dose levels. With lower dosage, the addition of topical steroids allowed adequate control [14]. However, ciclosporin (5–7 mg/kg/day) failed to alleviate GPP in a renal transplant recipient during periods of prednisolone withdrawal [15]. In contrast, a case of GPP was reported to respond rapidly to ciclosporin 7.5 mg/kg/day, and was successfully maintained in remission at 3.5 mg/kg/day [16]. Three patients, including two children, were successfully treated with low-dose (1–2 mg/kg/day) ciclosporin; the lesions cleared within 4 weeks of starting therapy [17].

Razoxane has been effective in acute GPP [18] but is rarely used now. Hydroxyurea is less effective [19]. Colchicine has been used either alone [20,21] or in combination [22] with methotrexate. 6-Thioguanine has also been used successfully [23].

In the subacute and chronic forms of GPP, the use of dapsone (50–200 mg/day) [24–26] can be considered, and may be particularly valuable in atypical variants and children [2,27]. Oral or parenteral corticosteroid should be used only when urgent control of metabolic complications is needed [2]. The short-term effects of prednisolone (30–40 mg/day) are excellent [2,28], but serious relapses are liable to occur as the dosage is reduced unless another form of therapy (e.g. methotrexate or acitretin) is given simultaneously [2].

Biologic agents have been used occasionally and to excellent effect. It appears that these therapies are perhaps well-suited to rapid control of GPP. The TNF-antagonists, and basiliximab, an antibody directed at the IL-2 receptor, have all been reported to rapidly control acute GPP [29–32]. It is likely that TNF-antagonists will become the treatment of choice in cases of fulminant disease, however there are cases of paradoxical exacerbation of PPP by these agents [33].

Acitretin, methotrexate and PUVA cannot be used in GPP of pregnancy unless termination has become inevitable. Fulminating disease in pregnancy is best treated with prednisolone, the drug that carries the least hazard for the fetus, but ciclosporin has been used safely for treatment of impetigo herpetiformis [34]. Methotrexate, retinoids, PUVA or combination therapy may be needed after delivery to allow weaning off the steroid or ciclosporin [35].

Prognosis. There is a paucity of data on the long-term prognosis of GPP. Von Zumbusch's patient [1] survived many acute episodes over a number of years, and perhaps had the good fortune to live before potent (and dangerous) remedies were available. Ryan and Baker [2,3] reported on the prognosis in 155 patients with all types of GPP. Thirty-four of 106 patients followed up had died, and 26 of these deaths were attributable to the disease or its treatment. GPP developing from acropustulosis (acrodermatitis continua) had the worst prognosis, seven out of 11 patients having died and a further one remaining severely disabled. To some extent, this particularly poor outlook reflected the age at onset of these patients, who were predominantly elderly. However, death was a direct result of GPP in all of these cases, resulting from cardiac failure or respiratory infection during uncontrolled pustular psoriasis. In general, patients with preceding ordinary psoriasis had a better prognosis than those with atypical prepustular psoriasis [2,3].

The better prognosis of GPP of pregnancy reflects the abrupt removal of the main provocative factor by childbirth or, *in extremis*, termination of the pregnancy [4,5]. GPP of childhood also carries a more benign prognosis [6], providing oral corticosteroids and methotrexate can be avoided [7]. Khan *et al.* [7] stressed the hazard of fatal virus infections in corticosteroid-treated children and advocated bland topical therapy, if necessary in hospital, for up to 3 months in anticipation of spontaneous remission. In their patients, where oral corticosteroids were avoided, growth and development progressed unimpaired despite GPP [7].

Psoriatic arthritis

Definition. An inflammatory arthritis associated with psoriasis of the skin and/or nails, with usually a negative serological test for rheumatoid factor and the absence of rheumatoid nodules [1].

Epidemiology. Like psoriasis of the skin, good population studies remain to be performed and thus estimation of population prevalence is difficult and highly variable, depending on the study. Historically, arthritis prevalence amongst psoriasis patients has been estimated at 2.6–7% [2,3]. However, more recent, large questionnaire-based studies have indicated that the real prevalence may be much higher. Thus, a Scandinavian study revealed arthritis in 30% [4] of psoriatics and in the USA, 23% (http://www.psoriasis.org). In general, it appears that there is no direct relationship between the extent and severity of psoriasis and of psoriatic arthritis [5,6]. Further, nail disease is more frequent in cases with arthritis. A review of population-based studies estimated the population prevalence of psoriatic arthritis at 0.02–0.1% [7]. There appears to be a stronger association with generalized pustular psoriasis [8] or erythrodermic psoriasis [9] and arthritis.

The age of onset for psoriatic arthritis is, in general, later than for the skin disease, with peak age of onset being the fourth decade. Biodi-Oriente *et al.* [10] reported psoriasis predating arthritis in 68% of cases occurring at the same time in 11%, and following it in 21%. There is a rare but well-recognized juvenile-onset form of psoriatic arthritis [11], with age of onset between

9 and 12 years. Psoriatic arthritis appears more common in individuals with type 1 early-onset psoriasis vulgaris.

In contrast to rheumatoid arthritis, where females predominate 3:1, in psoriatic arthritis the sexes appear equally affected.

Aetiology and pathogenesis.

Genetics. Familial clustering of psoriatic arthritis has been reported [2] although much less frequently than for cutaneous psoriasis. There is no evidence that psoriatic arthritis follows Mendelian patterns of inheritance. A large number of HLA association studies have been performed [3]. In general, results concur with studies of cutaneous disease, with HLA Cw6, B13, B17 and DR3 occurring most frequently. A specific association with psoriatic arthritis, not seen in the cutaneous form, is HLA-B27, seen particularly in spondyloarthritis (see below). Genome scans have recently been reported with evidence for a susceptibility locus on chromosome 16q [4]. CARD15, a molecule involved in macrophage–monocyte cell signalling, has been implicated as a candidate gene, at least in some patients [5]. This molecule has also been implicated in Crohn's disease but not in cutaneous psoriasis.

Environmental factors. Studies of families in which psoriatic arthritis aggregates suggest an important environmental component to disease pathogenesis [6]. Increased immunoreactivity to streptococcal antigens has been reported in sera of patients [7], but establishing a pathogenic link has proved elusive and appears much more tenuous than for the skin disease. An increased prevalence of psoriatic arthritis has been reported in HIV [8] and hepatitis C infection [9], and antibodies to enterobacterial antigens are also recorded [10].

Trauma as a precipitating event has also been noted. Interestingly, trauma appears to be more important in psoriatic compared to rheumatoid and other inflammatory forms of arthritis [11]. Neuropeptides and the nervous system have been implicated in these events [12].

Pathogenetic mechanisms. As for cutaneous psoriasis, T cells probably have a key role in arthritis pathogenesis. Those implicated possess activation and memory surface markers but, unlike skin, do not express the skin homing molecule CLA [13]. Thus, when skin and joint manifestations coexist, different populations of T cells mediate disease at different sites. Intra-articular clonal expansion of CD8-expressing T cells have been observed, but putative antigens remain elusive. As observed in the skin, the morphology of blood vessels in psoriatic arthritis is altered with the presence of dilated tortuous vessels and evidence of angiogenesis [14]. Interestingly, these features are different from that seen in rheumatoid arthritis.

Clinical features.

In one series of 180 patients, the mode of onset was studied, and skin lesions were found to precede arthritis in 65%, arthritis antedated skin lesions in 19%, and in 16% skin and joint involvement occurred almost simultaneously. The peak age of onset of arthritis in this series was 40–60 years [1].

Clinical subgroups. Psoriatic arthritis is not accompanied by rheumatoid-type nodules. The Moll and Wright classification includes five clinical groups, which often overlap [2,3].

1 Predominantly peripheral mono- or asymmetrical oligoarthritis is the most common form, and often overlooked. An appearance

Fig. 20.29 Psoriatic arthritis, showing peripheral oligoarthropathy with sausage-like digital swelling. (Courtesy of St John's Institute of Dermatology, London, UK.)

similar to low-grade gout, as well as sausage-like swelling of one or more digits (dactylitis) resulting from terminal and proximal interphalangeal joint involvement and flexor sheath synovitis are recognized (Fig. 20.29). Enthesitis—inflammation at the site of tendon insertion into the bone—is common.

2 Predominantly distal interphalangeal arthritis, the well-recognized classical form, but less common than previously emphasized.

3 Predominantly symmetrical, rheumatoid-like, rheumatoid factor-negative polyarthritis, usually less severe than rheumatoid arthritis.

4 'Arthritis mutilans', a relatively uncommon, severely deforming arthritis involving fingers and toes predominantly. Gross osteolysis may cause digital foreshortening and ankylosis (Figs 20.30–20.32).

5 Predominantly axial arthritis: psoriatic spondylitis and/or sacroiliitis, with or without variable peripheral arthropathy. Spinal involvement may be clinically silent, but radiological examination suggests that it may affect about one-third of all cases of psoriatic arthritis. Clinically, this form may involve: (i) both spine and sacroiliac joints, as in idiopathic ankylosing spondylitis; (ii) sacroiliac joints alone; and (iii) spine alone. It may be less disabling than the idiopathic form [3,4].

Several more recent clinical studies have indicated a need to reclassify psoriatic arthritis. In two studies, each involving 100 patients, three subgroups were proposed, any of which may include the classical features of psoriatic arthritis, such as distal interphalangeal joint involvement, dactylitis or spondylitis [5,6].

Fig. 20.30 Arthritis mutilans showing gross digital foreshortening. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 20.31 Arthritis mutilans: osteolysis and bony ankylosis. (Courtesy of Royal London Hospital, London, UK.)

1 Asymmetrical arthritis usually, but not always, involving a small number of joints with few erosions, infrequent deformity and good preservation of function

2 Symmetrical polyarthritis, frequently erosive, deforming and functionally disabling, but distinguished from rheumatoid arthritis by association with distal interphalangeal joint involvement, spondylitis and negative rheumatoid factor (titre less than 1:80)

Fig. 20.32 Arthritis mutilans: gross osteolysis of metatarsal heads and phalanges. Note pencil-in-cup changes at metatarsophalangeal joints. (Courtesy of Royal London Hospital, London, UK.)

3 Predominant spondylitis, similar to ankylosing spondylitis, possibly accompanied by peripheral arthritis but behaving independently of it [6].

Cervical spinal involvement. This is well recognized [7,8] and may be primarily ankylosing in nature or inflammatory and rheumatoid-like [9]. Both forms may be associated with cord or nerve-root compression related to intervertebral subluxation and/or fusion, and neurological deterioration may require surgical stabilization [8,10–13].

Temporomandibular joint involvement. This may manifest as local pain, often aggravated by eating [14,15] and may progress to ankylosis requiring surgical management [16]. Orthopan-tomographical examination showed that 31% of patients with psoriatic arthritis had radiographical changes in the condyle of the temporomandibular joint, as compared with 13% of controls [17]. Computed tomography may reveal changes not visible on conventional radiography [18].

Sternal joint involvement. This is becoming increasingly recognized but is unusual as an initial manifestation [19,20].

Nail involvement. Psoriasis of the nails occurs in about three-quarters of psoriatic patients with arthritis, but only in about one-third of those with skin lesions alone [1,21,22]. The distal and mutilating forms of arthritis are particularly associated with severe nail dystrophy, and the distal joints and nails affected are often but not necessarily correlated in the same digits [22]. All types of nail involvement may occur [23].

Extra-articular features. These occur less frequently than in rheumatoid arthritis. Subcutaneous nodules are not seen, and tendon sheath effusions are uncommon. In contrast, inflammatory eye lesions are common, conjunctivitis being reported to occur in 20%, uveitis in 10%, and episcleritis and keratoconjunctivitis sicca in about 2 and 3%, respectively [24]. Cardiac involvement similar to that seen in ankylosing spondylitis has been reported [25].

Laboratory findings. The most important serological feature is the negative test for rheumatoid factor, particularly in patients with distal and mutilating arthritis. In patients with psoriatic arthritis of the rheumatoid type, about one-quarter had a positive test or a test that fluctuated between positive and negative [1]. Some of these patients probably represent the coincidental association of psoriasis and rheumatoid arthritis, but a weakly or intermittently positive rheumatoid factor occurs in approximately

5% of the normal population [2] and should not necessarily lead to the diagnosis of rheumatoid arthritis. Other reported laboratory abnormalities, such as anaemia, raised ESR and C-reactive protein, transient leukocytosis, and raised immunoglobulin levels, most consistently IgA, have been reviewed [3,4]. It has been concluded that none of these is sufficiently specific to contribute to diagnosis, management or prognostic evaluation [4]. The conflicting reports of the association between hyperuricaemia and psoriasis are outlined above. Antinuclear antibodies have been reported as both positive and negative [3], but in an American study of 1285 patients they were found to have little predictive value [5].

Histopathology. The histopathologies of psoriatic and rheumatoid arthritis appear to be similar, except that characteristic rheumatoid granulomas have not been found and there may be more fibrosis [6,7] and vascular changes [8] in the psoriatics. In spite of these possible differences, synovial biopsy usually has no place in the routine clinical management of psoriatic arthritis [4].

Radiological changes [1–3]. The changes may be indistinguishable from those of rheumatoid arthritis: local demineralization, narrowing of joint spaces, articular erosion of varying degree and soft-tissue swellings. Atypical features include destructive changes in the terminal interphalangeal joints, a tendency to hypertrophic changes and absence of generalized demineralization.

In the distal type of psoriatic arthropathy, early changes may consist only of minimal 'fluffiness' and osteoporosis of the distal phalanx, but gross destruction eventually occurs. Four characteristic signs of psoriatic arthropathy, seen in one controlled series [1], were:

1 A destructive distal interphalangeal arthropathy—bony ankylosis of the interphalangeal joints
2 Destruction of the interphalangeal joints with abnormally wide joint spaces and sharply demarcated adjacent bony surfaces
3 Destruction of the interphalangeal joint of the great toe with bony proliferation of the distal phalanx
4 Resorption of tufts of the distal phalanges of hands and feet (uncommon).

In arthritis mutilans, the joint changes are widespread. The 'opera-glass hand', in which the fingers can be pulled in and out, results from gross destruction and absorption of the bones. The heads of metacarpals and metatarsals may completely disappear, leaving a tapered bone looking like a sharpened pencil. Such gross osteolysis may be followed by bony fusion (Figs 20.31 & 20.32).

Intermittent hydrarthrosis may occur. Sacroiliac changes similar to those of ankylosing spondylitis are common [4–6]. Syndesmophytes and calcification of the interspinous ligaments are also seen [6]. Cervical changes including apophyseal sclerosis or joint narrowing, and calcification of the anterior ligament, are common [7], and there is a tendency to posterior fusion of the cervical vertebrae [3]. Paravertebral ossification of the lumbar and thoracic regions may occur more laterally in psoriasis than in spondylitis [8].

Magnetic resonance imaging has enhanced the ability to identify early changes of psoriatic arthritis and to visualize enthesitis [9,10].

Differential diagnosis. This has been reviewed in detail elsewhere [1]. One of the subgroups of psoriatic arthritis may be clinically indistinguishable from rheumatoid arthritis. As a weakly or intermittently positive rheumatoid factor occurs in 5% of the normal population [2], this should not necessarily lead to the diagnosis of rheumatoid arthritis. Gout may be simulated, especially if the onset is acute and monoarticular, or if widespread psoriasis is associated with hyperuricaemia. Ankylosing spondylitis may be similar, but the onset tends to be later, peripheral involvement is more common, and the arthritis does not necessarily begin in the spine. The acute Heberden's node of osteoarthritis may cause confusion, and distinction from Reiter's disease may be difficult or impossible.

Treatment. Treatment follows the general lines of management of inflammatory polyarthritis, and is best supervised by a rheumatologist. Assessment of efficacy of therapies for psoriatic arthritis is hindered by inexact definition of the condition, the variable clinical presentation and lack of validated outcome measures. The treatment of psoriatic arthritis has been recently reviewed [1].

Symptomatic treatment. Mild arthritis can usually be controlled with NSAIDs. There is concern that NSAIDs may exacerbate the

skin lesions of psoriasis [2,3], although a randomized controlled trial showed no worsening of psoriasis in patients treated with the NSAID nimesulide [4]. Cyclo-oxygenase-2 (COX-2) selective inhibitors are effective but, as with traditional NSAIDs, caution should be exercised in the elderly and those with impaired renal function.

Systemic glucocorticosteroids are not recommended for the long-term treatment of psoriatic arthritis not only because of the well-recognized side effects but also because chronic glucocorticosteroid use can make psoriasis more labile and withdrawal can on occasion lead to a rebound pustular flare [2,5]. Intra-articular injections of glucocorticosteroid are used to treat monoarthritis [6].

Disease-modifying antirheumatic drugs (DMARDs). Ascertaining effectiveness of DMARDs in the management of psoriatic arthritis is complex [1]. The clinical subgroups respond differently, for instance axal involvement associated with HLA-B27 has a relatively poor response to treatment [7]. The most commonly used DMARDs for psoriatic arthritis are methotrexate, ciclosporin and sulfasalazine although there are few randomized controlled trials.

Methotrexate is the most widely used of the DMARDs for psoriatic arthritis—particularly as it is effective for the skin lesions, and is amenable to combination with other DMARDs to enhance efficacy. Only two randomized controlled trials provide evidence [8,9], one [8] used parenteral injections of high-dose methotrexate (1–3 mg/kg)—a dose probably too toxic. A second study [9] showed that methotrexate 7.5–15 mg/week was superior to placebo only in physician assessment of arthritis. Thus, the data imply that methotrexate is beneficial for synovitis but there is no evidence of benefit for axial disease.

Ciclosporin is probably less effective than methotrexate for the treatment of psoriatic arthritis but evidence is mainly accrued from open studies. In an 18-week open study [10], ciclosporin 4.8 mg/kg/day benefited psoriatic arthritis but the effect was less marked than for the skin lesions. In a trial comparing methotrexate to ciclosporin [11], ciclosporin 3–5 mg/kg/day produced significant improvement in clinical and serological measures of severity of psoriatic arthritis. An Italian study [12] found that ciclosporin was more effective than either sulfasalazine or placebo in reducing a variety of clinical measures of severity. Long-term use of ciclosporin may control progression of radiological damage in peripheral joints [13].

Sulfasalazine has been subject to more open trials and randomized controlled trials than either methotrexate or ciclosporin for the treatment of psoriatic arthritis. Despite encouraging results from open studies and one short (8-week) study [14], this promise has not been substantiated by most randomized controlled trials [1,15,16]. Overall, the evidence suggests that sulfasalazine has a small beneficial effect on peripheral synovitis, particularly pain [17], but whether efficacy is enhanced by increasing the daily dosage above 3 g is unclear [1,18]. Axial disease is not benefited [1].

Gold salts (oral auranofin) and intramuscular sodium thiomalate are used to treat psoriatic arthritis [19,20]—on the evidence sodium thiomalate appears to be the better of the two, but less effective than methotrexate [21,22]. Occasional exacerbation of the skin lesions of psoriasis by gold salts can occur [23].

A variety of other DMARDs have been investigated and advocated for the treatment of psoriatic arthritis, none of which has been subject to good randomized controlled trials. Leflunomide (a pyrimidine synthesis inhibitor effective for rheumatoid arthritis) appeared to have some benefit in psoriatic arthritis in both the short term (3 months) and long term (2 years) in a longitudinal study of eight patients [24].

A limited randomized controlled trial of azathioprine versus placebo showed benefit [25].

Biological therapies. The most significant advance in the management of psoriatic arthritis has been the introduction of the TNF-antagonist biologics therapies. Not only are TNF-antagonists capable of producing significant improvement in joint disease, there is good evidence that they can prevent joint destruction. These data hold firm for infliximab, adalimumab, etanercept and golimumab [26–29]. The T-cell antagonist alefacept is modestly effective [31]. The anti-IL12/IL23p40 ustekinumab is also effective for psoriatic arthritis but whether this is comparable to the TNF-antagonists remains to be determined [31].

Surgery. The place of surgery has been reviewed [32,33]. In spite of past reluctance to perform elective surgical procedures in view of perceived risks of infection, a review of 41 orthopaedic operative procedures and 54 other surgical procedures in patients with psoriasis and arthritis revealed a low prevalence of wound sepsis and other complications. It was therefore suggested that elective surgery should not be withheld from these patients [32]. Such procedures might include joint prosthesis and cervical spine stabilization, and the use of digital distraction lengthening and bone grafting for severe arthritis mutilans has also been described [33].

Prognosis. A 10-year follow-up study suggested that psoriatic arthritis produced less pain and disability than rheumatoid disease [34]. Excluding the arthritis mutilans group, in this study 30% lost no time off work, only 3% had more than a total of 1 year off work in 10 years, and many patients showed little or no radiological deterioration. Thus, it is usually perceived that psoriatic arthritis may be a mild disease, and that the descriptions of mutilating digital disease and occasional severe spondylitis may give a false impression of the usual prognosis in these patients. However, in a Canadian study of 220 patients with psoriatic arthritis, deforming erosive arthropathy was found in 40% of cases. The concept that psoriatic arthritis is often a benign arthropathy was therefore challenged [35]. Indicators of poor prognosis include younger age at onset, extensive skin involvement, polyarticular synovitis, HIV infection, high ESR at presentation, large numbers of effusions and association with HLA B27, B39 and DLW3 [1,36].

Introduction and classification

Pruritus (itching), the predominant symptom of skin disease and an important symptom of systemic disease, is now, after years of comparative neglect, the subject of active investigation. Itch can be defined subjectively as a poorly localized, non-adapting, usually unpleasant sensation which elicits an immediate desire to scratch. Itch has recently been classified by Twycross *et al*. [1] as *pruritoceptive* (cutaneous, e.g. scabies, urticaria), *neuropathic* (due to lesions of afferent pathways of the nervous system, e.g. peripheral neuritis, nerve entrapment, brain tumours), *neurogenic* (due to centrally acting mediators which do not damage the central nervous system, e.g. morphine, opioid peptides of cholestasis) and *psychogenic*, including delusional parasitosis.

Itch and pain can readily be dissociated since the former elicits the scratch reflex, but the latter causes withdrawal and since morphine relieves pain but aggravates itch. Although they broadly share similar overall molecular mechanisms and neurophysiological pathways, new evidence indicates the existence of separate dedicated neurones for itch in both the peripheral and central pathways [2,3].

When itching is caused by a low-intensity mechanical stimulation moving across the skin involving weak activation of mechanoreceptors, the itch sensation is immediate, often provokes uncontrollable laughter, persists for no longer than the stimulus and is interpreted as a 'tickle' [4]. Chronic itch is multidimensional, the sensation being variably modified by emotional and cognitive components. In dry skin and skin of some atopics, mechanical stimulation may trigger a more persistent itching sensation (alloknesis) [5]. Prurigo is a term frequently incorrectly used to describe chronic itching of any cause. As originally defined by Hebra [6], prurigo denotes papules induced by scratching. On this basis, prurigo would include 'scratch prurigo', a rarely used synonym for symptomatic dermographism and, at the other end of the spectrum, chronic inflammatory and pigmented papules due to long-continued or repeated scratching (prurigo nodularis of Hyde) [7].

When itching is a symptom of skin disease it is generally independent of external stimulation. The quality of itch varies greatly, ranging from burning, through pricking, to sensations of insects crawling over the skin. The psychophysiological basis of these differences remains unclear. Teleologically, itching, with resultant scratching, is of possible biological value in combating parasitic infestation. Although often publicly perceived as a trivial—even humorous—disability or even, with its associated scratching, as a pleasurable personal indulgence, it is more often socially disabling and a cause of serious impairment of quality of life.

Epidemiology

We all itch from time to time, but the prevalence of chronic pruritus is unknown. One study in a UK urban community indicated a prevalence of 20% [8] but the prevalence in a Norwegian city setting is reported as about 8% [9]. In one recent retrospective study of patients with chronic pruritus [10], 35.6% of patients with

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

generalized pruritus had an underlying systemic disease and in 7.6% the cause was unknown. The remainder had skin disease-associated pruritus.

Measurement

Results from animal models of pruritus need to be interpreted with caution. Hind limb scratching in response to intradermal injection of a pruritogen has been widely used [11], but whether the scratching is in response to pain or itch is unclear [12]. Methods used in humans include visual analogue scales (VAS) and recording of scratch movements [13] using limb movement meters. The 'Symtrack' computerized continuous itch-rating system, which is based on the VAS, or a variant of it, is the most widely used [14]. However, results obtained with a new method for quantifying scratching, in which a piezoelectrical device is attached to the middle fingernail, have been impressive [15].

Pathophysiology

Significant progress has recently been made in elucidating the neurophysiological pathways for itch. Although specialized nerve endings have been identified for a wide range of stimuli [16], no specific receptor structure has been identified for itch. It is generally agreed that itch (and pain) are received by unspecialized free nerve endings [17], identified immunohistochemically by protein gene product (PGP) 9.5 or by neurone-specific enolase [18] and located close to the dermal–epidermal junction. Itch nerve endings are unmyelinated, confined to the skin and cornea, and are members of the polymodal nociceptor class. That itching is alleviated by cooling and menthol but aggravated by warmth is a common experience now explained by the close association of temperature-sensitive transient receptor potential (TRP) ion channels [19] with afferent itch transmitting nociceptor neurone terminals. Interestingly, other members of this same class of receptors (TRPV1; vanilloid receptors) are activated and desensitized by capsaicin (the active principle of chilli), now widely used topically to alleviate localized pruritus [20]. Keratinocytes also express TRPV1 and these receptors are greatly up-regulated in prurigo nodularis [21]. The co-localization of cannabinoid receptors (CB1) with TRPV1 in sensory neurones and the ability of endocannabinoids to activate TRPV1 [22] raises the possibility of functional interactions between cannabinoids and TRP channels in the modulation of itch.

Apart from TRPV1 ion channels, keratinocytes also express voltage-gated ATP channels, adenosine receptors, cannabinoid receptors, opioid receptors and PAR-2 (proteinase activated receptors-2) [23]. They also express several itch-modulating mediators, prompting the provocative notion that the epidermis itself may constitute the hitherto elusive 'itch receptor'.

Itch-transmitting, polymodal, unmyelinated C fibres enter the dorsal horn of the grey matter of the spinal cord, synapse there with secondary neurones, which cross over to the contralateral spinothalamic tract and ascend to the thalamus. There, tertiary neurones relay itch to the level of conscious perception in the cerebral cortex.

There is now convincing evidence that dedicated itch-transmitting neurones exist in both peripheral and central afferent pathways [2,3]. Microneurographic technology using ultra-fine glass electrodes, which can be inserted into individual afferent nociceptor neurones, has enabled electrical recordings to be made from individual polymodal C fibres in peripheral cutaneous nerve fascicles. Stimulation of these neurones using histamine iontophoresis to cause itching has resulted in identification of a small (less than 5% of the total) subset of slowly conducting C fibres distinct from, and with a larger receptor field than, mechanosensitive polymodal neurones. However, it is unlikely that these mechanoinsensitive neurones represent the only afferents involved in itch transmission. Itch due to electrical stimulation seems to involve a different subset of afferent neurones stimulation, which causes itch but no axon reflex flare [24]. Using the microneurography technique, dedicated histamine-sensitive secondary transmission neurones have also been demonstrated in the lateral spinothalamic tract of the cat [3]. It is evident that specialized itch-specific afferent pathways project this sensation from the skin to the thalamus.

Recent studies, using functional positron-emission tomography and functional magnetic resonance imaging to record activation of cortical responses to itching and associated scratching, suggest the involvement of the anterior cingulate and insular cortex in the recognition of itch sensation at conscious levels [25–27], whilst the premotor cortical areas participate in intention to scratch.

The relief obtained by scratching an itch is centrally mediated. Pain induced by noxious heat or scratching diminishes itch by a central, probably gated, mechanism [28,29]. The effect of scratching is short lived but a more prolonged relief may be obtained by cutaneous electric field stimulation, which can be used therapeutically [30]. There is also evidence that itch may be modulated by descending pathways originating in the periacqueductal grey [25]. Ascending and descending pathways are represented in a simplified form in Fig. 21.1.

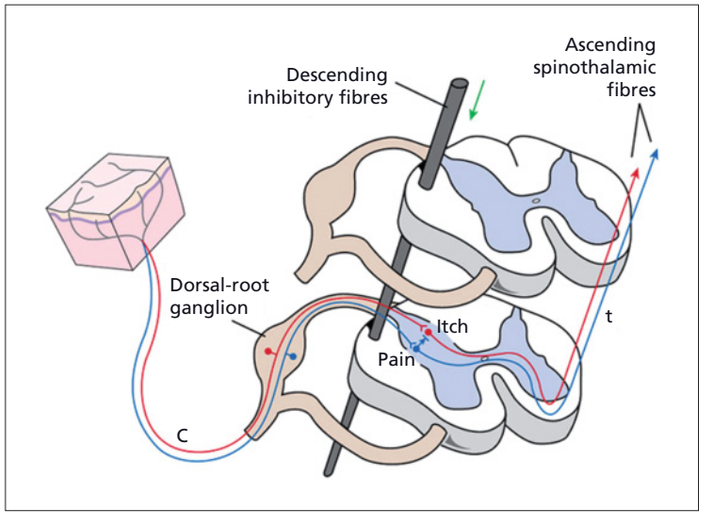

Fig. 21.1 Ascending and descending pathways modulating itch. C, unmyelinated slow-conducting C fibres; t, transmission neurone. (Reproduced with permission from Elsevier Science Ltd, *Lancet* 2003; **361**: 690–4.)

Central itch

Psychoneurophysiological aspects of itching are complex and poorly understood. They have led to the important concept of 'central itch', that is itching which is perceived as occurring in the skin but which actually originates in the central nervous system due to dysfunctional processing of sensory information in the central pathways. Melzack and Wall [28] proposed the involvement of large, fast-conducting, myelinated sensory fibres in modulation of the discharge of the unmyelinated itch- or pain-transmitting fibres via the substantia gelatinosa ('gate' control of pain). According to this proposal, itch is due to a combination of peripheral excitation and central disinhibition. Scratching, by activating inhibitory fast-conducting myelinated fibres, closes the 'gate' by activation of suppressor neurones of the substantia gelatinosa and reduces the itch. Alloknesis (slight mechanical stimulation of skin causing intense itching) characteristically occurs in some patients with atopic eczema. It is thought to be due to excitation of central itch-transmission neurones due to reduced gating [5,28]. Chronic pruritus may also cause 'sensitization' of central itch pathways so that scratching can enhance itching rather than allaying it [31].

Opioid peptides have important peripheral actions, but also have an even more crucial central role. Morphine, administered spinally or epidurally, as well as alleviating pain, frequently causes intense itching [32–34], especially of the face, without visible inflammatory changes, and this symptom is rapidly relieved by intravenous naloxone or other opioid peptide μ-receptor antagonists [33–35]. Thus, the presence of opioid peptides and their μ-specific receptors, which modulate function of calcium channels specifically on unmyelinated C fibres in the central nervous system [36], provides a central itch- and pain-regulatory mechanism which is capable of therapeutic manipulation. Although μ-opioid receptor ligation causes central pruritus, κ-opioids are antipruritic so that central pruritus may result from an imbalance of the two systems [37].

Peripheral mediators of itching in skin diseases

Itch can be evoked or augmented by a variety of mediators (Table 21.1). That peripheral pharmacological mediators play a key role in the production of itching in inflammatory skin disease, originally proposed by Lewis as his 'H-substances' [38], is supported by several lines of evidence. These include the ability of a wide range of naturally occurring pharmacological agents, including histamine and proteases, to reproduce the sensation of itch on injection into skin, the ability of antagonists of these agents to reduce itching and the regular experimental recovery of mediators known to be capable of causing or enhancing itching from inflamed pruritic skin. However, it must be appreciated that not all forms of itching involve release of peripheral mediators. Low-grade mechanical and electrical stimuli and the 'dry itch' of senescent skin may not involve peripheral mediators, although in these cases pruritus is likely to be peripheral rather than central. Nevertheless, it is a reasonable assumption that peripheral mediators cause itching in the majority of inflammatory dermatoses.

Table 21.1 Important mediators and receptors for itch.

Mediator	Receptor(s) involved in itch	Function in itch
Histamine	H_1; possibly H_4	Pruritus of urticaria, controversial role in atopic eczema
Acetyl choline	Muscarinic acetyl choline receptors	Possibly in itch of atopic dermatitis
Substance P	Neurokinin (NK)	Prime mast cells for release of histamine and other mediators
Calcitonin gene-related peptide (CGRP)	CGRP receptors	Sensitization of itch-receptive neurone terminals
Opioid peptides	μ-opioid (κ-opioid receptors are anti-itch)	Cause central itch, especially in cholestasis
Proteases	Proteinase-activated receptor-2 (PAR-2)	Evokes itch by neurogenic mechanism involving release of substance P
Neurotrophins	Trk a, b, c; NT3, NT4	Neurotrophin levels elevated in atopic eczema, sensitizes itch-receptive neurones
Prostaglandin E	PGE receptors	Sensitize itch receptors to pruritogenic action of histamine
Cytokines	Receptor mediated?	Indirect via other mediators?

Histamine and its receptors

Histamine causes severe itching if injected or iontophoresed into skin, or if it is applied to superficially abraded skin, although it produces pain if injected more deeply into skin. At present, four subclasses of histamine receptors are recognized. The recently described histamine H_3 subclass behave as autoreceptors, regulating release and biosynthesis of histamine in brain slices and certain other tissues, but they have yet to be positively identified in skin [39]. Both H_1 and H_2 receptors have been characterized in human skin using specific H_1- and H_2-receptor agonists and antagonists, and these studies have consistently implicated histamine H_1 but not H_2 receptors in histamine-induced itching [40]. Thus, there is no theoretical basis for the use of H_2 antagonists (cimetidine, ranitidine) in the suppression of itching caused by histamine. In the mouse, ligation of H_4 receptors induces intense scratching [41] but whether these receptors are important in human skin is unclear.

Cutaneous responses to histamine may not be due solely to the direct actions of histamine. Recent work on the kinetics of the inflammatory responses of skin to histamine raises the possibility that some of these may be mediated indirectly by hitherto unrecognized substances whose release or formation is evoked by histamine [42]. The majority of histamine released in skin as a consequence of injury originates from the dermal mast cells. Evoked release of histamine and other mast-cell mediators is a consequence of an energy-dependent signal-transduction process. That alternative sources of histamine-evoked itching may exist in skin cannot be ruled out. A recent immunohistochemical study in

rat skin [43] has clearly demonstrated immunoreactive histaminergic nerves, although this phenomenon has yet to be reported in human skin.

Histamine has been recovered directly from involved skin in a number of inflammatory dermatoses. In cold urticaria, release of histamine into the venous blood effluent from the cold-challenged limb consistently reflects the onset, development and regression of itching and other local changes occurring following cold exposure. Suppression of evoked histamine release by oral doxantrazole treatment also suppressed itching, but not wealing, in patients with cold urticaria [44]. Histamine has also been recovered from affected skin in ultraviolet-induced inflammation [45] and atopic eczema [46]. Further evidence of the involvement of histamine in inflammatory dermatoses derives from the well-known symptomatic relief obtained in some of these by systemic H_1 antihistamine treatment, although the sedative effect of the traditional H_1 antihistamines has been claimed to be at least as important as the antihistaminic action in atopic eczema [47].

Acetyl choline

Acetyl choline behaves as a pruritic in atopic eczema via muscarinic receptors, although it does not cause pruritus in healthy subjects [48]. This may explain the pruritus commonly experienced by atopic eczema patients when they sweat.

Substance P

In view of their location in unmyelinated afferent nerve fibres in skin, neuropeptides are candidate mediators of itching in inflammatory dermatoses. Substance P, an 11-amino-acid neuropeptide, causes redness, wealing and itching [49,50], mainly via NK1 receptors. Immunoreactive substance P is present in normal skin and in increased amounts in inflamed, itchy skin [51]. Of special interest is the fact that—unlike anti-IgE, compound 48/80 and other mast-cell degranulators—substance P selectively and rapidly releases histamine but little or no prostaglandin D_2 or other cutaneous mast cell products from human, isolated, cutaneous mast cells *in vitro* [52]. It seems likely that this neuropeptide has a priming function on histamine release evoked by other mast cell activators, including specific antigen–IgE interaction [53]. Recent work has shed further light on links between dermal mast cells and afferent C neurones (Fig. 21.2). It is now recognized that substance-P-expressing neurones are in close and functional proximity to mast cells in the skin [54]. Tryptase released by activated mast cells acts on PAR-2 (proteinase activated receptor-2) located on C neurone terminals [55]. This results in release of vasoactive peptides, including substance P. As already indicated, substance P can activate mast cells, thus closing the loop. Topical capsaicin application, which is known to deplete substance P from sensory nerve endings, abolishes pain and itch [56]. Substance P is co-localized with other neuropeptides, including calcitonin gene-related peptide (CGRP) and vasoactive intestinal peptide (VIP), in cutaneous human sensory nerve endings, but the involvement of CGRP and VIP in itch has not been fully explored. Substance P is synthesized in the dorsal root ganglion of nociceptor C fibres and transmitted peripherally in granules.

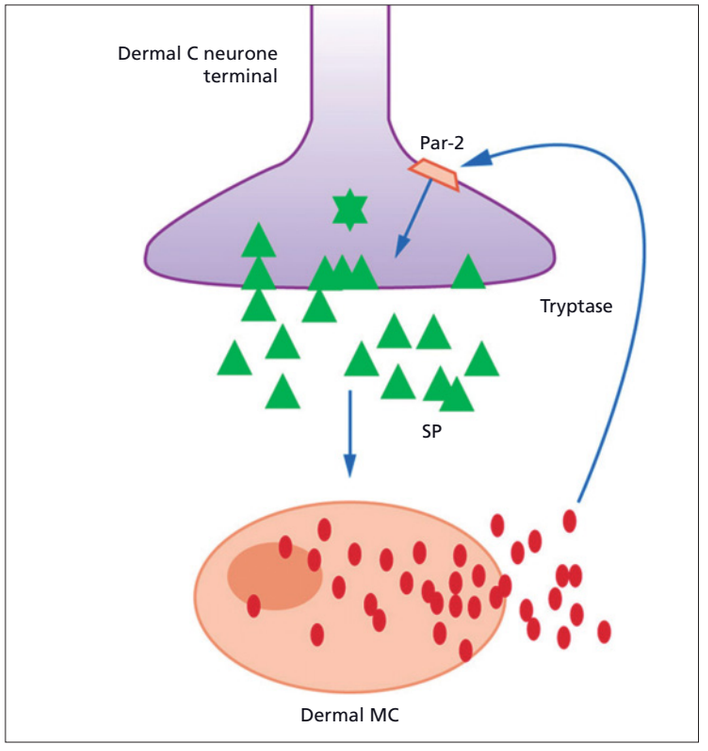

Fig. 21.2 Functional links between C neurone terminals and dermal mast cells: role of proteinase-activated receptor-2 (PAR-2). SP, substance P; MC, mast cell.

Calcitonin gene-related peptide (CGRP)

This 37 amino acid peptide is the most highly expressed neuropeptide in human skin and is probably the principle mediator of capsaicin erythema [57]. Like substance P, CGRP appears to act as a modulator of itch rather than as a pruritogen. It also up-regulates secretion of pro-inflammatory cytokines including TNF-α, IL-1 and IL-8 and it is found in abundant amounts in involved skin of prurigo nodularis [58].

Opioid peptides

Opioid peptides are classified into three groups: endorphins, enkephalins and dynorphins. The opioid receptors also consist of three classes: μ, δ and κ. The pruritic action of opioids is antagonized by naloxone and therefore belongs to the μ category. However, ligation of the κ-receptor has an antipruritic action. Opioid peptides are believed to cause pruritus by a central rather than a peripheral action [59]. Although opioid peptides degranulate mast cells *in vitro*, insufficient concentrations are present in skin for this to be a relevant action *in vivo* [60].

Proteases

The use of the fine spicules of *Mucuna pruriens* (cowage) as probes enabled Shelley and Arthur [61] to carry out simple pathophysiological studies of itching in human volunteers, which led them to propose the involvement of peptide products of proteases as mediators of itching. The protease of cowage (mucunain) proved to be more active than histamine on a molar basis in inducing itching. However, no potent itch-producing peptide released by

protease activity *in situ* has yet been recovered from human skin.

As mentioned above [55], dermal mast cell-derived tryptase acts on the PAR-2 receptors localized on cutaneous nociceptor afferent neurones, leading to release of substance P and other neuropeptides.

The protease kallikrein is pruritogenic in human skin [62], but bradykinin produced by the action of kallikrein has little or no pruritic activity, although it causes pain [62]. In the rat, bradykinin type 2 receptor antagonists and kallikrein inhibitors suppressed experimentally evoked itch suggesting a role for kallikrein in this model [63]. Other proteases besides kallikrein cause itching, including chymotrypsin [64].

Cytokines

Cytokines are low-molecular-weight proteins produced by almost all eukaryotic cells, and they act on specific cell-surface receptors. They include the interleukins, chemokines, interferons and colony-stimulating factors. The first to be studied, interleukin-1 (IL-1), although powerfully pro-inflammatory in human skin [65], does not cause itching. Few others have been systematically studied from this standpoint. However, human recombinant interleukin-2 (IL-2) given intravenously to cancer patients for therapeutic reasons was noted regularly to cause intense itching, associated with redness and a blood eosinophilia [66]. Human recombinant IL-2 injected intradermally caused intense itching in skin of atopic and non-atopic human volunteers alike [67]. Since activated T lymphocytes, an important source of IL-2, are a feature of the dermal infiltrate of atopic dermatitis, a role for IL-2 in the characteristic itching of this disorder has been proposed. That ciclosporin, a potent inhibitor of IL-2 production by T lymphocytes, causes relief of itching in atopic dermatitis lends further support to a proposed role for IL-2 in the itching of atopic dermatitis [68].

There has been considerable recent interest in the role of interleukin-31 (IL-31) in the itch of atopic eczema. Over-expression of IL-31, produced by T-helper lymphocyte type 2 (TH2) cells, in a transgenic mouse caused intense scratching behaviour and eczematous changes [69]. Subsequently, new evidence has emerged that IL-31 is involved in the pruritus of atopic dermatitis in man [70]. Targeting IL-31 may be a promising approach to improved drug treatment of atopic eczema.

Prostaglandins and other eicosanoids

Increased cutaneous levels of arachidonate metabolites are found in a wide range of inflammatory skin diseases, including physical urticarias, ultraviolet inflammation, psoriasis and eczema [71]. The lipoxygenase metabolites most frequently identified in these conditions—leukotrienes B_4, C_4, D_4 and E_4, and 12- and 15-hydroxyeicosatetraenoic acid—cause little or no pruritus, despite being potent pro-inflammatory agents in human skin. Prostaglandin E also shows little or no pruritic activity in human skin, even when applied in a wide range of doses. However, it has the striking property of potentiating itching due to other mediators in concentrations which, by themselves, have no visible pro-inflammatory activity [72]. Similar results were subsequently reported by others who have also shown potentiation by prostaglandin E_2 of itch due to other substances [73], and a study in which the H_1 antihistamine clemastine failed to antagonize the prostaglandin E enhancement of itching [74] suggests that this prostaglandin enhances itching due to other mediators. Increased skin concentrations of E prostaglandins have been reported in eczema and ultraviolet B inflammation, both of which are associated with pruritus [45]. Although aspirin, a prostaglandin synthetase inhibitor, has little or no effect as an antipruritic when administered orally [75], topical application effectively reduces pruritus in patients with localized itch [76]. Non-steroid anti-inflammatory drugs have also been demonstrated to reduce pruritus associated with morphine-induced spinal analgesia [77]. Recent work in mice suggests that the eicosanoid thromboxane A2 may cause itching via neural TP receptors in skin [78].

Neurotrophins

Nerve growth factor (NGF) and neurotrophin-4 induce nerve terminal proliferation, increased expression of neuropeptides and sensitization, associated with enhanced responsiveness to neuropeptides. Serum levels of NGF are increased in atopic dermatitis patients causing increased secretion of tryptase by mast cells [79]. Furthermore, neurotrophin-4 serum levels, probably derived from keratinocytes, are elevated in atopic dermatitis [80]. Thus neurotrophins seem likely to be involved in the pathophysiology of atopic dermatitis.

Scratching

Scratching is a reflex functioning at a spinal level, although modified greatly by higher centres. Scratching relieves itching for several minutes after scratching has ceased. Since the sensation of itching is reinforced by facilitating circuits in the relay synapses of the spinal cord, the prolonged scratch-induced relief could be due to temporary suppression of these circuits [28]. Stimulation of fast-conducting myelinated afferents inhibits these circuits via pre- and postsynaptic mechanisms. These afferents could be activated by vibration, transepidermal electrical nerve stimulation (used therapeutically to allay itching) [30], or more simply by scratching. Alternatively, scratching could simply damage sensory nerve endings, repair occupying several minutes. Why some itches evoke scratching and excoriation (as in scabies) whereas others prompt rubbing (as in lichen planus) is unknown. Scratching has been ingeniously utilized as an indirect, objective method of quantifying itch and as such has been utilized in the evaluation of treatment of itching [13,14].

Itching in non-inflamed skin

The molecular and physiological basis of pruritus associated with clinically normal skin in the absence of underlying systemic disease is in most instances uncertain, although clues are beginning to emerge. The problem of itch in ostensibly healthy skin is likely to become more pressing, with the increasing emergence of pruritus in senescent but visibly normal skin as a challenging therapeutic problem. Initially, careful examination of the skin must be made to exclude visible signs of skin disease. Patients

with symptomatic dermographism who have the will to forbear scratching may have a normal-looking skin at the time of examination. It is also conceivable that localized or widespread itching without physical signs may be a manifestation of mild urticaria ('weal-less urticaria'). In such cases, levels of histamine and other mediators could be subthreshold with regard to vascular, but not sensory, effects. This phenomenon is recognized in aquagenic pruritus, contact urticaria, dermographic pruritus and cholinergic urticaria [81–84].

A detailed history is of paramount importance, including the quality, distribution and periodicity of itching. Itching, likened by the patient to insects crawling over the skin, is often psychoneurotic in origin. Itch that is migratory in timing and distribution may be secondary to internal malignancy. Most patients with itching are especially uncomfortable in bed, probably because of warmth and little to distract their attention. Localized, fixed itching may be due to organic neurological disease—for example, in nerve entrapment or segmental neurofibromatosis [85].

Itching in systemic disease

Except for the itch of atopic dermatitis, the subject of recent intense research, pruritus associated with primary skin disease (pruritoceptive pruritus) is discussed in the chapters dealing with each of the diseases and will not be considered further here. This section deals with itch in skin devoid of primary skin disease, and occurring in response to systemic or internal disease (neurogenic pruritus), any signs in the skin being secondary to scratching or rubbing. The more important conditions are listed in Table 21.2.

Chronic renal disease

Persistent itching is a major cause of impairment of quality of life in patients with chronic renal failure [1]. It is becoming less prevalent due to more efficient dialysis techniques, but still occurs in around 20% of patients [2]. It is rarely a feature in children, or in patients with acute renal failure [3] but the reasons for this are unknown. It is more common in patients receiving haemodialysis than in patients on continuous ambulatory peritoneal dialysis (CAPD) [4]. The clinical features have been comprehensively described [1]. Although the skin of some patients may appear dry, frequently it is essentially normal in appearance. Itching may be persistent, extensive and intractable, but in other patients it may

Table 21.2 Itch in response to systemic/internal disease (neurogenic itch).

Adverse drug reaction
Pruritus due to morphine and related drugs

be transitory and localized [1,3]. Secondary skin changes due to scratching and rubbing are very common. These include pigmentation, prurigo nodules and eczematization, often secondarily infected. Histologically, the clinically normal skin may show attenuation of sweat and sebaceous glands, and increased population densities of cutaneous mast cells have been described [5]. However, no correlation between mast cell population densities and pruritus has been established. There may be a microangiopathy [6]. Abnormal sprouting of neurone-specific enolase-positive unmyelinated nerve fibres in skin of uraemic patients has also been reported [7]. Other suggested factors in the pathogenesis include raised serum parathyroid hormone levels due to secondary hyperparathyroidism [8], and it is of interest that parathyroid hormone is known to cause increased populations of tissue mast cells [9].

However, although parathyroidectomy has relieved pruritus in some patients [10], no convincing correlation between parathormone levels and pruritus has been demonstrated in renal failure patients [8]. Renal pruritus has been proposed to be related to aluminium overload during haemodialysis [11] treatable by administration of desferrioxamine mesylate, but this has not been confirmed. Pharmacological mediators have been proposed to be responsible for renal pruritus. Histamine is an improbable candidate, since treatment by antihistamines is ineffective. Skin biopsies from patients with chronic renal failure show increased numbers of intraepidermal $CD1^+$ T cells, raising the possibility that T-cell-derived cytokines could be implicated in pruritus [12,13]. Interestingly, uraemic pruritus in haemodialysis patients has been associated with elevated proportions of Th1 lymphocytes and elevated C reactive protein and interleukin-6 serum levels compared with levels in non-pruritic haemodialysis patients termed 'microinflammation' [14]. However, the topical calcineurin inhibitor tacrolimus 0.1% proved ineffective in a double-blind, randomized placebo-controlled study in haemodialysis-related pruritus [15].

Opioid peptides have also recently been implicated, elevated plasma met-enkephalin levels having been reported in haemodialysis patients [16], although a correlation has yet to be established [17]. A recent report claims that pruritus of renal failure responds to a κ-opioid agonist [18], suggesting a role for opioid peptides although this needs to be confirmed. The pathophysiology of uraemic itching has been usefully reviewed by Murphy and Carmichael [19].

Important general therapeutic measures include emollients for xerosis. Secondary eczematization and its accompanying secondary infection should be treated vigorously. Dialysis itself has little beneficial effect on uraemic pruritus, although its frequency and severity has lessened since the advent of dialysis membranes with better biocompatibility. The only curative and reliably effective treatment for renal pruritus is renal transplantation. Parathyroidectomy may be followed by remission of pruritus in patients with secondary hyperparathyroidism [10]. Phototherapy with ultraviolet B (UVB) is frequently effective and may act systemically as well as locally (Table 21.3). Its value has been supported by a recent meta-analysis [20]. That ultraviolet therapy depletes the vitamin A content of the skin has been proposed as a mode of action [21]. Only UVB phototherapy and activated charcoal have an established track record for this indication [22,23].

Table 21.3 Treatments for pruritus of chronic renal failure.

Treatment	Level of preference	Level of effectiveness
Broad-band UVB phototherapy	1	high
Activated charcoal	1	high
Gabapentin	2	medium
Erythropoietin	2	medium
Naltrexone	2	medium
Antihistamine	3	low
Corticosteroids (topical, systemic)	3	low

1 = high; 2 = moderate; 3 = low.

A double-blind placebo-controlled crossover trial in 25 patients indicated that gabapentin is effective in treatment of pruritus of renal failure [24]. Other treatments, including heparin, mexiletine, ion-exchange resin and intravenous lidocaine (lignocaine) have been advocated, but are of uncertain effectiveness and usually impractical to use. A 1996 report of a placebo-controlled trial of an orally administered opioid antagonist, naltrexone, attracted much attention, but the apparent effectiveness of this treatment remains to be independently confirmed [25]. The possible value of a κ-opioid agonist for this indication has been alluded to above, but these compounds are as yet unavailable. Antihistamines and topical steroids are generally unhelpful in uraemic itching, but emollients may provide relief in those with a dry skin.

Since itching may be restricted to certain areas, topical capsaicin 0.025% has been reported to be effective in localized uraemic pruritus [26]. In the longer term, only expansion of the renal transplant programme is likely to bring sustained relief to these greatly distressed patients.

Cholestasis

Pruritus may be generalized or localized, for example to the hands and feet, and can be an early symptom of hepatobiliary disease. It is associated with rubbing rather than scratching so secondary excoriation, eczematization and infection are less common than in renal pruritus. It is a frequent and distressing symptom of cholestasis, and its molecular basis is still debated. Hepatitis C is an important cause of intense cholestatic pruritus, occurring in 15% of infected patients [1]. That it should be considered as part of the routine work-up of patients with pruritus is questionable since a case-controlled study failed to show a higher frequency of hepatitis C infection in patients with pruritus compared with the general population [2].

Cholestatic pruritus is associated with elevated plasma levels of bile salts [3], but evidence of a direct correlation has been lacking. Measurements of skin-tissue levels of bile salts and their relationship to serum levels, and to intensity of itching, gave inconclusive results and the bile-salt levels did not differ from corresponding values in control subjects [4]. Bile salts applied to blister bases in human skin, although causing pruritus, do so at minimal effective concentrations far exceeding those achieved in cholestatic jaundice [5]. Analysis of individual bile acids in skin and serum, including quantitatively minor components of the bile-acid family, also failed to show a quantitative relationship with pruritus [4]. Lack of demonstrable quantitative relationships has not, however, discouraged a number of investigators from exploring methods for lowering serum and skin bile-salt levels in the management of itching due to cholestasis. For example, plasma perfusion through charcoal-coated glass beads was associated with a marked improvement in cholestatic pruritus, although a relationship between clinical response and fall in bile-salt level was not demonstrated. Similar results have been achieved with ion-exchange resins, including cholestyramine [6,7], and with a newer bile acid sequestrant, colesevalem hydrochloride [8]. These reports raise the possibility that observed clinical improvements may be a consequence of removal of pruritogenic factors other than bile salts following such procedures.

Table 21.4 Treatments for hepatobiliary pruritus.

Treatment	Level of preference	Level of effectiveness
Cholestyramine*	1	high
Opioid antagonists	1	high
Rifampicin	2	high
Ursodeoxycholic acid	3	low
UVB phototherapy	3	low
Antihistamines	3	low

* Ineffective in total biliary obstruction.
1 = high; 2 = moderate; 3 = low.

Treatments for pruritus of cholestasis are summarized in Table 21.4. In a randomized cross-over trial comparing cholestyramine, terfenadine (a low-sedation H_1 antihistamine now withdrawn by the manufacturer owing to cardiac side effects) and chlorpheniramine with placebo in pruritus due to obstructive liver disease, only terfenadine and cholestyramine showed evidence of significant suppression of pruritus, but cholestyramine was associated with a high incidence of side effects [6]. Other methods advocated for the relief of itching of cholestasis include rifampicin [9,10], extracorporeal albumin dialysis [11] and phototherapy [7]. Rifampicin is effective, but is associated with hepatotoxicity [12]. Ursodeoxycholic acid has proved disappointing in a recent meta-analysis [13]. Effective treatments of hepatobiliary pruritus have been reviewed [14].

Earlier work highlighted the importance of dysregulation of central opioid peptides in patients with cholestatic pruritus [15]. The evidence can be summarized as follows. Plasma levels of opioid peptides are elevated in human [15] and rat [16] cholestasis. Furthermore, plasma from patients suffering from pruritus of cholestasis induces facial scratching, reversed by naloxone, when injected into the medullary dorsal horn of the monkey [17]. Most importantly, carefully controlled trials established the effectiveness of parenteral and oral opioid antagonists in the treatment of cholestatic pruritus [18,19]. Thus, the conclusion that opioid antagonists are of value in treatment of the pruritus of cholestasis is based upon evidence of increased opioidergic tone in chronic cholestasis patients, and the impressive response to naloxone or naltrexone (specific opioid μ-receptor antagonists). This response can be associated with opioid withdrawal symptoms [20].

Apart from biliary disease, cholestatic pruritus may also occur in pregnancy [21] and premenstrually [22]. However, the role of opioid peptides in these contexts has yet to be established.

Iron deficiency

Iron deficiency has been implicated as a cause of intractable pruritus in the absence of visible skin disease, or even in the absence of anaemia [1]. Of special interest is a report by Salem *et al*. [2] of pruritus and severe iron deficiency in polycythaemia vera. In these patients, correction of iron deficiency apparently correlated with improvement in pruritus. A study of iatrogenic venesection-induced iron deficiency over a 60-month period revealed no instance of pruritus in 21 patients [3]; however, iron deficiency is a factor in pruritus of polycythaemia in some patients [4].

Polycythaemia vera

Pruritus is a common symptom in polycythaemic patients [1]. As many as 50% of untreated patients with polycythaemia develop a severe, prickly and distressing discomfort within minutes of water contact, lasting 15–60 min [2]. As it frequently occurs after the patient emerges from bathing, it is often referred to as 'bath itch'. No visible changes are present in the skin, and the symptom may be associated with elevated serum and urinary histamine levels [2]. Platelet aggregation has been suggested as a possible mechanism and source of pruritogenic factors, including histamine [3]. Water-induced itching may precede development of polycythaemia vera by several years [4]. Bathing by regional sponging may mitigate the itch. Successful treatment of the underlying polycythaemia may not relieve the itching and although correction of venesection-induced iron deficiency may give relief, it may be at the expense of exacerbating the polycythaemia [5]. Antihistamines are generally ineffective. Psoralen ultraviolet A (PUVA) photochemotherapy, with 8-methoxypsoralen and UVA, has been successful in some patients [6]. Success has been claimed for narrow-band UVB phototherapy [7]. One report cites the use of long-term treatment with interferon-α 2b for severe pruritus of polycythaemia vera [8]. Another advocates use of serotonin reuptake inhibitors such as paroxetine [9]. Some patients may respond to aspirin [3].

Intense, widespread pruritus is also a major feature of the Sézary syndrome (T-cell leukaemia) and occurs in cutaneous mastocytosis (urticaria pigmentosa) if the skin is rubbed to provoke a weal (Darier's sign). In mycosis fungoides, pruritus may be the presenting symptom without skin signs ('invisible mycosis fungoides') [10].

Endocrine disease

Thyrotoxicosis

Intractable itching, associated with a warm, moist skin, is a recognized accompaniment of thyrotoxicosis and may be the presenting symptom [1]. The cause is uncertain. Localized pruritus may result from mucocutaneous candidiasis. Cutaneous vasodilatation, a regular feature of the disease, leads to increased skin surface temperature, which lowers the itch threshold [2]. Myxoedema may also cause troublesome itching, but in this case the cause is usually excessive drying of the skin, which feels cool, and which responds to application of moisturizing creams.

Diabetes mellitus

Contrary to popular wisdom, generalized pruritus is not a manifestation of diabetic mellitus, the erroneous belief having originated from a 1927 report of a 3% prevalence in 500 patients [3], which coincides with the expected frequency in the general population. A more recent study [4] reported generalized pruritus in eight of 300 diabetic patients, which was not more common than in non-diabetic patients. However, intractable anogenital itching may occur due to mucocutaneous candidiasis. Localized pruritus of the scalp is also a recognized manifestation of diabetes and is usually resistant to antipruritic measures [5].

Malignancy

The problem of pruritus as a manifestation of malignant diseases has been the subject of numerous publications reviewed by Lober [6] and Paul *et al.* [7]. Paul *et al*. followed up 125 patients with generalized pruritus for 6 years [7]. Of these, 66% still had pruritus at the end of the study. Although four proved to have a malignant condition at the onset of the study, only four others developed malignancy during the follow-up period. This is no different from the expected frequency in the general population. However, pruritus, often induced by contact with water, is a recognized presenting symptom of polycythaemia vera [8]. Pruritus is intense in Sézary syndrome, but the skin is inflamed in this malignancy. The practical issue of the extent to which patients with generalized pruritus in the presence of a normal skin should be investigated cannot be separated from economic considerations [9]. Pruritus may be an early B symptom of Hodgkin's disease [10].

Aquagenic pruritus

This term was first used by Shelley [1] to describe what was considered to be a variant of aquagenic urticaria. Three cases of aquagenic pruritus were subsequently reported in detail and shown to be distinct from aquagenic urticaria [2]. The condition was subsequently extensively reviewed [3,4]. Typically, contact with water at any temperature leads to an intense pricking itch in the exposed skin, without visible change in the appearance of the skin. The same symptoms may be evoked by a sudden drop in temperature of the skin. The condition is very chronic and intractable, and sufferers frequently are wrongly considered to be psychoneurotic. The condition, which closely resembles the pruritus of polycythaemia vera, responds poorly to antihistamine treatment but may respond to UVB phototherapy or PUVA [5–7]. It may be a premonitory symptom of polycythaemia vera [8]. Other underlying causes recently reported include metastatic carcinoma of the cervix [9], hypereosinophilic syndrome [10], juvenile xanthogranuloma [11] and the myelodysplastic syndrome [12]. Aquagenic pruritus may also be a manifestation of an adverse drug reaction [13].

The molecular basis of the pruritus is uncertain. Investigation of affected skin has shown elevated histamine concentrations and increased cutaneous mast cell degranulation, and the serum histamine concentration has also been shown to be raised [2]. The lack of visible evidence of histamine release can be explained by its slow rate of release, leading to skin concentrations sufficient to cause itching but below the threshold for visible vascular changes. However, histamine is unlikely to be the sole mediator, since antihistamine treatment is generally ineffective, and there is also evidence of the involvement of acetylcholine, since topical hyoscine treatment rendered skin unresponsive to water contact [2]. Further evidence for acetyl choline as a mediator derives from a report of increased acetyl cholinesterase activity localized to nerve fibres investing eccrine sweat glands in patients with aquagenic pruritus [14]. There has also been a report of increased tissue fibrinolytic activity in affected skin of patients with aquagenic pruritus [15], which could be a response to increased local concentrations of histamine or acetyl choline.

Pruritus of senescence

Persistent and widespread itching, often associated with extensive excoriation, is experienced by at least 50% of people in the seventh decade of life or beyond. Because of the gradually increasing proportion of elderly persons in the population, it is also a burgeoning problem. In women, itching may be a manifestation of the postmenopausal syndrome. Pruritus of elderly people may be a symptom of subtle skin disease such as scabies, especially in institutionalized elderly persons, a manifestation of underlying systemic disorder, including renal, hepatic or malignant disease, a skin manifestation of an adverse drug reaction or symptomatic of depression and loneliness. However, in most instances, itching is a result of excessive dryness (xerosis) of the skin. In a study of 149 elderly men and women, 39% had pruritus due to xerosis [1]. There is evidence of slow reduction of sebum production by skin in association with ageing, and its composition also alters [2,3]; however, this is not thought to be a major factor in xerosis of the elderly. Senescence in the skin is frequently associated with failure of the skin to retain water. The resulting dryness and fine cracking of the skin is associated with troublesome itching, which in most instances responds to emollient treatment. Water-induced itching in elderly people [4] is a variant of senescent pruritus, being particularly common in institutionalized elderly people who may be exposed to an overheated, dry environment, resulting in skin desiccation, and both it and the common spontaneous variety respond to emollient treatment. Analysis of senescent stratum corneum has shown a greatly reduced water content [5]. Recently dystrophic changes in afferent nerve terminals have been identified in pruritic senescent skin and may have a pathogenetic role [6,7].

It is usually most expedient to prescribe several different emollients and encourage the patient to experiment with these, since it is not possible to predict with confidence individual responses. Soft white paraffin ointment is cheap, occlusive and has been shown to accelerate recovery of barrier function in damaged skin [8]. The patient must be encouraged to apply emollients at least four times daily and, if necessary, ambient temperature and humidity should be modified. Doxepin 10–20 mg at night is useful in patients in whom there is a significant element of depression. Corticosteroids, antihistamines and cooling lotions are not indicated in itching due to xerosis.

Psychogenic pruritus

Itching, either localized or generalized, can be a skin manifestation of psychological disturbance. There are no satisfactory 'rule in, rule out' diagnostic paradigms; therefore, in practice the conclusion that local or generalized itch is psychogenic in origin is arrived at by a process of exclusion of cutaneous or systemic causes.

Perianal and, in women, vulval itching are recognized manifestations of local psychogenic pruritus and are in some cases stress related, although this cause is probably over-rated and care must be taken to rule out occult remediable causes, including threadworms (pinworms), dermatitis medicamentosa, diabetes-induced candidiasis and local inflammatory or neoplastic disease. Attacks of nocturnal pruritus, associated with a sensation of heat and accompanied by sweating, are often due to anxiety. Such episodes of pruritus were recently reported in patients awaiting transplant surgery [1]. Widespread psychogenic pruritus may result in extensive and disfiguring excoriations and even scarring to the extent of self-mutilation. Parasitophobia (delusions of parasitic infestation of the skin) is normally readily recognizable, because of the patient's description of the itch and even the presentation by the patient of particulate material considered by the sufferer to represent the supposed insects or their products. Of two recent patients of the author, one brought along a small portable microscope to aid viewing of the 'insects', and the other brought textbooks of dermatology and parasitology to the clinic to support her case! Although rarely successful, psychiatric advice should be sought, and antidepressant and anxiolytic drugs, including doxepin and hydroxyzine, should be tried. Treatment options for these patients have been well reviewed [2]. Pimozide (phenylbutylpiperidine), a phenothiazine, has been used for treatment of delusions of parasitosis [3] and paroxetine, a selective serotonin reuptake inhibitor, has also been advocated [4]. It is also self-evident that patients experiencing severe, persistent pruritus become secondarily depressed, and that this may itself lower the threshold for pruritus, thus completing a 'vicious circle' of itch, depression and more itch [5].

Postmenopausal pruritus

The commonest presentation of postmenopausal pruritus is pruritus vulvae, often a manifestation of oestrogen deficiency and associated with mucocutaneous candidiasis and diabetes. It should respond to corrective hormone therapy, combined if necessary with nystatin or other anti-*Candida* therapy.

Persistent or episodic widespread itching is occasionally associated with the postmenopausal syndrome. The itching characteristically evokes rubbing, rather than heavy excoriation, and is frequently associated with hot flushes. It is especially troublesome at night, and is usually associated with raised plasma levels of pituitary follicular and luteal stimulating hormones. These hormones are unlikely, however, to be the direct cause of the itching and associated flushing, which are probably attributable to local tissue mediators. Hormone-replacement therapy with ethinyl oestradiol is usually sufficient to control postmenopausal pruritus due to this cause [1], but since systemic oestrogen therapy can be hazardous, expert endocrinological advice should be sought.

Pruritus of atopic dermatitis

The itch of atopic dermatitis is aggravated by scratch damage, which causes enhanced inflammation (itch–scratch cycle). Itching is usually worse at night, and is aggravated by contact with wool, sweat, spicy foods and alcohol. Considerable sleep loss and incapacity ensues. No aspect of pruritus has provoked more debate than the pathophysiology of itching in atopic dermatitis and its management. The itching of atopic dermatitis is multifactorial, being due to dryness, almost invariable in atopic dermatitis sufferers, inflammation and probably to disturbed regulation of itch traffic in the central nervous system. In this context, alloknesis (itchy skin; see p. 21.5) forms a major component of the itch suffered by the atopic dermatitis patient—explaining, for example, the paroxysms of itching experienced by patients in response to sweating, sudden changes of temperature, humidity, undressing or dressing, etc. These multiple and distinct mechanisms may explain seemingly conflicting views on the nature and causation of pruritus in atopic dermatitis. Pruritus in atopic dermatitis involves pruritoceptive neurogenic, and probably psychogenic, mechanisms. Several studies, reviewed by Rajka [1], have reported an enhanced and abnormally prolonged response to application of pruritic pharmacological stimuli in unaffected skin in atopic patients. Studies of the itching response of atopic dermatitis patients to histamine iontophoresis suggest a decreased response of afferent cutaneous fibres to high doses, but an increased sensitivity to low concentrations—possibly because of increased permeability of clinically normal-looking skin of these atopic patients [2]. There is also an increased population density of sensory nerve fibres in the affected lichenified pruriginous skin [3], although this is probably non-specific. It is important to distinguish itching associated with inflammatory changes or chronic lichenification from that simply due to excessive drying of the skin in patients with atopic dermatitis. Emollients, which should always be prescribed and which in many cases may be all that is required, will be inadequate alone where inflammatory changes are responsible for the itching. Recent dermal microdialysis studies have demonstrated the involvement of mast-cell mediators other than histamine in lesional skin of atopic dermatitis patients [4]. An evidence-based review [5] of the effectiveness of H_1 antihistamines concluded that they are of little value in relieving pruritus. However, it is self-evident that most patients with itchy atopic dermatitis receive antihistamines, mainly of the sedative type, and usually find them of some value—presumably due to their central action. On the basis of a comparison of itching in atopic dermatitis patients receiving successively terfenadine (now withdrawn by the manufacturers due to adverse cardiac side effects) or astemizole (low-sedation antihistamines), trimeprazine (sedative antihistamine) and nitrazepam (non-antihistamine sedative), one study [6] concluded that sedation was a required component of successful systemic treatment of itching in atopics, and that, moreover, itching in atopic dermatitis involved a central component. However, numbers of patients were small and subsequent studies have yielded conflicting results.

Systemic antibiotics frequently bring about relief from pruritus. *Staphylococcus aureus* behaves as a superantigen leading to T-cell activation, and also activates dermal mast cells via toll-like receptors [7].

Topical steroids are frequently effective in suppressing itching in the atopic dermatitis patient. Corticosteroids are not inherently antipruritic, but suppress the inflammatory component of the dermatosis thereby alleviating the itching indirectly. They are especially effective in highly pruritic children with atopic dermatitis applied by the 'wet wrap' technique [8]. Phototherapy is widely used for the pruritus of atopic dermatitis in older children and adults, especially when it is intractable and widespread. Both broad-band and narrow-band ultraviolet B are used, the latter being deemed superior [9]. Immunosuppressives—including systemic azathioprine and ciclosporin—are highly effective in relieving the itching (and other signs and symptoms) of chronic atopic dermatitis in selected patients [10,11], probably due to an action on activated $CD4^+$ T-helper lymphocytes. The recent introduction of topical calcineurin inhibitors, tacrolimus and pimecrolimus, provides an effective new measure for amelioration of pruritus of atopic dermatitis [12,13]. These agents owe their action to down-regulation of activated T cells. Recent work [14] has highlighted the role of interleukin-31 (IL-31) in the itch of atopic dermatitis

Table 21.5 Treatments for pruritus of atopic dermatitis.

Treatment	Level of preference	Level of effectiveness
Emollients	1	high
Topical steroids	2	high
Sedative antihistamines	2	medium
Topical calcineurin inhibitors	2	high
Narrow-band UVB phototherapy	1	high
Azathioprine	3	high
Ciclosporin	3	high

1 = high; 2 = moderate; 3 = low

and this cytokine is likely to be a target for future antipruritic therapeutic intervention (see section Cytokines, above).

Opioid antagonists such as oral naltrexone may be of value in patients with intensely pruritic atopic dermatitis [15]. Aspirin given systemically is ineffective in the suppression of itching in atopic dermatitis but may be effective in a topical formulation [16]. Treatment approaches to itching in atopic dermatitis are summarized in Table 21.5.

Acquired immune deficiency syndrome

Itching is an important symptom of acquired immune deficiency syndrome (AIDS) [1]. It may be associated with underlying systemic disease (cholestasis, hepatitis B or C, renal failure, lymphoreticular malignancy) as well as numerous skin diseases including seborrhoeic dermatitis, psoriasis, scabies, candidiasis, ringworm, staphylococcal skin infections, eosinophilic folliculitis [2], lichenoid dermatitis and prurigo nodularis. In some patients, intractable itching occurs in the absence of any obvious primary skin or systemic cause apart from the HIV infection itself [3]. Patients with intense pruritus tend to have high IgE levels, a rapid decline in CD4 lymphocyte counts, hypereosinophilia and a high viral load [4]. Pruritus as a presenting feature of adverse drug reactions in HIV-positive patients must not be overlooked, and these reactions may be associated with photosensitivity. Thalidomide can be useful in the treatment of HIV-positive patients with intractable pruritus and prurigo nodularis [5]. Other treatments reported to be effective include dapsone, pentoxifylline, UVB phototherapy and PUVA [6–8].

Pruritus in pregnancy

Pruritus occurs in about 20% of pregnant women. In the majority of these the itching is localized to the anogenital area, often secondary to vulvovaginitis due to candidosis, bacterial causes or to pre-existing dermatoses such as psoriasis and endogenous eczema. However, more widespread pruritus is also frequent. Important possible causes include scabies and exacerbation of pre-existing atopic dermatitis or psoriasis. The specific dermatoses of pregnancy may also present with pruritus. The commonest is pruritic urticated papules of pregnancy (PUPP; polymorphous eruption of pregnancy), but the less common pemphigoid gestationis and cholestasis of pregnancy are also intensely pruritic; these have been reviewed [1].

No treatment for itching is absolutely safe in pregnancy, but it is a reasonable assumption that persistent, intense pruritus is itself prejudicial to healthy pregnancy. The following are deemed the least unsafe measures in the pruritic pregnant patient: (i) topical—

1–2% menthol cream or lotion; 5% urea cream (for dry skin); benzyl benzoate application (for scabies); topical steroids (low–moderate potency only); (ii) systemic—chlorpheniramine; diphenhydramine; hydroxyzine; (iii) other—UVB phototherapy.

Pruritus ani and pruritus vulvae

Pruritus ani occurs in 1–5% of the adult population, and is more common in males than females [1]. The frequency of pruritus vulvae is unknown, but it is evident that most women suffer from it at some time in their lives, most commonly postmenopausally. Anogenital pruritus in both sexes is a cause of severe distress and sleep disturbance due to persistent treatment-resistant itch–scratch–itch cycle. It may be a manifestation of skin or systemic disease. Common dermatoses involving the anogenital area include psoriasis, atopic dermatitis, lichen sclerosus, lichen planus, seborrhoeic dermatitis, scabies and allergic contact dermatitis—especially to perfumed soaps. In one study, 18 of 40 patients with pruritus ani had positive patch tests [2]. Common culprits include topical antihistamines and local anaesthetics (dermatitis medicamentosa) [3]. There are also several important local causes of anogenital pruritus including threadworms (pinworms), viral warts, haemorrhoids, lichen simplex chronicus, squamous cell carcinoma, exposure to detergents, bubble baths and urinary or faecal incontinence. In both sexes, but especially in the female, candidosis is an important cause and should always prompt screening for diabetes mellitus. In a large study of 1104 patients with pruritus vulvae, 85% were found to have vaginitis due to *Candida*, *Trichomonas* or bacterial causes [4]. Oestrogen deficiency is also an important cause in postmenopausal females. 'Stress' is often cited as a psychogenic cause but in reality is probably over-diagnosed [4]. Treatment includes avoidance of overenthusiastic use of cleansers, foam baths, perfumed soaps. Sitz baths (warm water hip baths) yield immediate relief. Ointments rather than creams, including silicone or zinc ointments, are helpful. The priority must be to remove or treat any underlying cause and a rectal and/or vaginal examination should always be performed. However, no cause may be identified or, even if identified and treated, itching may persist and in these cases topical corticosteroids are normally prescribed. However, in one comparative study of idiopathic perianal pruritus, topical methyl prednisolone cream applied for 2 weeks in 28 patients and application of a liquid cleanser in 32 patients were equally effective, with a good response in 90% of patients in each group [5]. Topical capsaicin is also effective. In one double-blind cross-over study comparing capsaicin 0.006% cream with menthol 1% cream in 44 patients with idiopathic intractable pruritus ani, capsaicin was effective in 31, menthol being invariably ineffective [6].

Important miscellaneous causes of intense itching

Hydroxyethyl starch [1]

Hydroxyethyl starch (HES) is used widely as a plasma substitute, especially on the continent of Europe. It is also used to improve the function of the microcirculation. Generalized pruritus has been reported as a well-recognized complication, occurring in 15–42% of patients [2]. It results from deposits of HES in macrophages and peripheral nerves in the skin, and may be associated with erythema [1,3]. It is poorly responsive to antihistamines, but may respond to topical capsaicin [4].

Pemphigoid nodularis

Bullous pemphigoid can present with non-specific pruritus. There have also been reports from several centres [5–7] of patients presenting with a chronic prurigo nodularis-like eruption who subsequently proved—by histological examination, direct immunofluorescence and clinical follow-up—to have bullous pemphigoid; blisters eventually developed in most cases reported. It is important to carry out a skin biopsy for histological examination and direct immunofluorescence for immunoreactants on all patients with what appears to be prurigo nodularis.

Notalgia paraesthetica

This is a fairly common cause of localized persistent pruritus. Characteristically, patients complain of persistent burning pruritus localized to the mid-scapular area, but often extending from there to a more widespread distribution, including the scalp. Apart from mild lichenification and pigmentation with or without macular amyloidosis, there is usually little to see. Reports of increased cutaneous innervation are probably correct, but may represent a non-specific change [8]. Recent reports stress the importance of nerve root entrapment (neuropathic pruritus) [8–10]. Capsaicin cream appears to be effective in some patients, and the current view is that it is a type of localized sensory neuropathy [11].

Brachioradial pruritus

This increasingly common sunlight-induced chronic pruritus is localized to the outer aspect of the elbow, and adjacent lower and upper arms [12]. The increased popularity of prolonged and frequent outdoor holidays in areas of high insolation amongst middle-aged and elderly fair-skinned people probably accounts

for its increased frequency. A typical patient of the author with this diagnosis had spent much of the year sailing and golfing in the Caribbean region. She responded to treatment with capsaicin cream [13]. However, brachioradial pruritus can be unresponsive to treatment. Gabapentin has been reported to be effective in such cases [14]. Pruritus and prurigo due to chronic sun exposure may occasionally be much more widespread and has been termed 'solar pruritus'. They are probably identical to brachioradial pruritus [15]. Bilateral cases should prompt investigation for a spinal tumour [16].

Anorexia nervosa

That generalized pruritus is one of several skin manifestations of anorexia nervosa is well recognized [17]. Itching is associated with low body weight and resolves with weight restoration. The itching is independent of underlying disease, including endocrine factors, renal or hepatic complications, or excessive washing. The skin may be excoriated and present a prurigo-like appearance. The itching could be central (neurogenic) in origin, but further evidence is awaited [18].

Clinical and laboratory investigation of generalized pruritus

Pruritus is a highly subjective symptom and careful history taking is crucial. The onset, quality, severity and timing of the itching should be established. Quantification of itch frequency is best achieved by using categoric scales (e.g. never, rarely, occasionally, frequently, always). For severity, a continuous visual analogue scale [1] is usually employed. Other more sophisticated methods for measuring itch, including scratch behaviour measurement devices, are discussed above (p. 21.2) and are primarily useful for research applications.

The location and fixed or ephemeral nature of bouts of itching should be determined, together with relationship to activities, provoking factors, medications, recreational, social and ablutional habits. It is always worth listening to the patient's own views on causation. Sufferers from aquagenic pruritus were rarely believed until the disease became recognized as an entity in the 1970s. Use of a questionnaire, for example the Eppendorf Itch Questionnaire [2], enables elicitation of standardized historical information.

To distinguish secondary eczematization due to persistent scratching from primary skin disease as a cause of pruritus is a common diagnostic challenge, especially in the elderly. In the absence of obvious causative primary skin disease or symptoms or signs indicating systemic disease, it is essential to carry out a full physical examination, including lymph node, rectal and pelvic examination. This should be followed by full blood count urine examination for sugar protein and blood, erythrocyte sedimentation rate, chest X-ray and thyroid, renal and liver-screening tests. Other routine imaging investigations and endoscopy are probably not justified in the absence of localizing symptoms or signs, although examination of the stool for occult blood is a useful and cheap investigation. The possibility that persistent, generalized pruritus in the absence of skin signs can be an adverse reaction to a systemic drug should never be overlooked.

In the absence of clinical evidence of primary skin disease, histological examination of a skin biopsy is rarely helpful and is not recommended as part of the routine work-up. All patients with generalized pruritus of unrecognized cause should be followed up regularly as long as the symptom persists.

Management of itching

Obviously, the most important step is to identify and treat the fundamental cause of the itch, whether it is primarily in the skin or of a systemic origin. At the same time, patients require symptomatic relief. At the time of writing there are no specific anti-itch medications. Pruritus is temperature dependent [1], and therefore wearing light clothes, keeping the bedroom cool, using light

Table 21.6 Topical treatments for itchy dry skin.

Medication	Mode of action	Comment
Emollients	Form water-impervious barrier, reduce transepidermal water loss	
Aqueous cream		Short lived action, needs to be applied frequently
Emulsifying ointment White soft paraffin Hydrous wool fat		More greasy and substantive
Hydrating creams	Attract and bind water within stratum corneum	
Creams containing 5–10% urea		For dry very scaly skin, can be irritant in some patients

Table 21.7 Topical antipruritic medications.

Topical antipruritic	Mode of action	Comment on usage
Calamine	Cooling as a shake-lotion	Short lived relief, use as a cream in itch associated with dry skin
Menthol	Acts on TRP temperature-sensitive neural channels	Of proven but short-lived value
Capsaicin	Depletes neuropeptides of afferent nerve terminals, acts on TRPV1 vanilloid neural channels	Proven effect in some localized recalcitrant itches (see text), but compliance poor due to burning sensation in early stages of treatment
Doxepin	Tricyclic, also potent H_1 antihistamine	Effective in allaying itch of eczematous dermatitis, but may cause drowsiness, contact allergic sensitization
Corticosteroids	Anti-inflammatory, indirectly antipruritic	Ineffective in itching of clinically normal skin
Calcineurin inhibitors	Down-regulate activated T cells in skin, indirectly antipruritic in eczematous skin	Ineffective in itching of clinically normal skin; relieve itch of atopic dermatitis
Local anaesthetics	Cause temporary loss of all skin sensation at site of application	Suitable for short-term relief only, due to risk of contact allergic sensitization

bedclothes and keeping the working environment as cool as possible are all helpful measures. A cool shower before retiring may allow sleep. Pruritus due to dry skin, especially prevalent in elderly people, will respond to emollients such as soft yellow paraffin and aqueous cream as well as creams containing 5–10% urea (Table 21.6). Water-induced itching in elderly people, which is distinguished from aquagenic pruritus by the presence of clinical evidence of dry skin, is especially responsive to treatment by moisturizing preparations.

Topical phenol and crotamiton [2], though widely used as antipruritics, are of unproven value. A carefully controlled study suggested that topical 1% menthol in 90% ethanol is of significant value in the symptomatic relief of histamine-induced pruritus [3], probably due to activation of cold-sensitive TRP channels on afferent nerve terminals. Topical H_1 antihistamines and topical corticosteroids should not be used in the absence of visible inflammatory changes in the skin. Antihistamine creams and ointments carry a significant risk of contact sensitization. The topical tricyclic compound 5% doxepin cream has been shown to be effective for treatment of itch due to eczema [4] but can cause sedation due to percutaneous absorption and occasionally causes contact sensitization. Local anaesthetic creams are occasionally justifiable for short-term relief, but carry a risk of evoking contact sensitization following prolonged use. Capsaicin, the active alkaloid principle of chilli pepper is being used topically in several localized chronic pruritic disorders. Controlled clinical trials have verified its effectiveness in post-herpetic dysaesthesia [5] and diabetic neuropathy [6]. Its effectiveness in the localized pruritus of nostalgia paraesthetica and brachioradial pruritus has already been alluded to above and has been supported by controlled trials [7,8]. Its main drawback is the burning discomfort associated with its application in the initial stages of treatment, which leads to poor compliance.

Effective antipruritic topical medications are listed in Table 21.7.

Systemic treatments of proven effectiveness for itching are few in number and usually cause some degree of sedation. H_1 antihistamines, mainly the first generation sedative compounds, are widely used for this purpose. Proof of efficacy is often hard to acquire as placebo effects in itching are substantial [9]. H_1 antihistamines are the treatment of choice for the itch of urticaria [10]. In the itch of atopic dermatitis the role of H_1 antihistamines is controversial, there being no clear evidence of effectiveness [11]. Nevertheless, first-generation H_1 antihistamines are widely prescribed to allay itching in atopic dermatitis, any effectiveness for this or other causes of pruritus being probably attributable to their sedative properties. Systemic tricyclic antidepressants such as doxepin 10–25 mg at night may be of help in some patients with intractable itching [12]. Other suggested measures of uncertain efficacy include transcutaneous nerve stimulation [13] and acupuncture [14]. Opioid μ-receptor antagonists, including naloxone, show promise in the management of otherwise intractable pruritus [15] but other than in pruritus of cholestasis, firm evidence of effectiveness is lacking. Paroxetine, a selective serotonin reuptake inhibitor, may have a place in the treatment of intractable pruritus, including the pruritus of advanced cancer according to a recent placebo-controlled double-blind trial [16]. Recently mirtazapine, a dual serotonergic and noradrenergic antidepressant, has been advocated for intractable pruritus including the itch of cutaneous T-cell lymphoma [17,18].

Gabapentin, an anticonvulsant, has also been advocated recently for treatment of pruritus of unknown origin [19]. It is also reported effective in uraemic pruritus in a controlled study [20]. Systemic treatments for pruritus are listed in Table 21.8.

Table 21.8 Systemic antipruritic medications.

Systemic antipruritic	Mode of action	Comment on usage
H_1 antihistamines	Inverse agonists at the H_1 receptor	Proven efficacy in urticaria; controversial in atopic dermatitis and other pruritic dermatoses in which efficacy may be due to sedative action of 1st generation compounds
Doxepin	Tricyclic, and potent H_1 antihistamine	Avoid in presence of cardiac disease, do not prescribe concurrently with other anti-depressants, do not withdraw abruptly
Naltrexone	μ-opioid receptor antagonist	Only of proven efficacy in pruritus of cholestasis; worth trying in other cases of intractable itch
Paroxetine	Selective serotonin reuptake inhibitor	Advocated on the basis of controlled trial data for management of intractable pruritus, especially that associated with internal malignancy; avoid in patients with heart disease
Mirtazapine	Serotonergic and noradrenergic antidepressant	Advocated anecdotally for intractable nocturnal pruritus
Gabapentin	Prevents release of neurotransmitters from pre-synaptic nerve terminals by action on voltage-dependent calcium channels	Effective in uraemic pruritus according to results of a controlled trial

Ultraviolet phototherapy for generalized pruritus

Broad-band or narrow-band ultraviolet B phototherapy (UVB) is used extensively for symptomatic treatment of generalized pruritus whether due to underlying systemic disease, primary skin disease or idiopathic [21]. It has largely superseded UVA photochemotherapy (PUVA). However, randomized controlled trial data are hard to come by. UVB has a good track record in the treatment of pruritus of renal failure and in the treatment of pruritus of polycythaemia vera (see p. 21.10). Its mode of action is unknown, however it may have a systemic rather than an exclusively local action. Other conditions reported to be responsive to UVB phototherapy include Hodgkin's disease, pruritus of HIV infection, prurigo nodularis and aquagenic pruritus.

Urticaria

Introduction

Urticaria is a common disease with many different clinical presentations. Dermatologists, allergists, accident and emergency specialists, general physicians, paediatricians and general practitioners may see a quite different selection of cases, and this may cause confusion. The literature is large, and there are several monographs that can be consulted for a detailed bibliography [1–5].

Definitions

The urticarias are characterized by short-lived swellings of the skin and mucosa due to plasma leakage. Urticaria is commonly used to describe an eruption of weals, as distinct from angio-oedema, although this does lead to confusion with classification of the physical urticarias. The term 'urticaria' is increasingly being used to describe a disease that may present with weals, angio-oedema or both [1]. Weals and angio-oedema often occur together and for practical purposes are similar processes resulting from superficial and deep swellings, respectively. However, angio-oedema that is caused by C1 esterase inhibitor deficiency shows some differences clinically and in response to treatment.

Weals (synonym 'nettle rash', hives) is the descriptive term for transient, well-demarcated, superficial erythematous or pale swellings of the dermis, which are usually very itchy and are associated with a surrounding red flare initially.

Angio-oedema (synonym angioneurotic oedema, Quincke's oedema) swellings affect the deeper dermal, subcutaneous and submucosal tissues. They are usually painful rather than itchy, poorly defined, and pale or normal in colour.

Anaphylaxis, in the strict sense, is an acute, severe, life-threatening, generalized or systemic hypersensitivity reaction. It consists of a combination of symptoms and signs, including diffuse erythema, pruritus, urticaria and angio-oedema, hypotension and difficulty in breathing. A similar clinical picture from non-allergic causes used to be called an anaphylactoid reaction but the term 'non-allergic anaphylaxis' is now preferred [2]. 'Anaphylaxis' is frequently used to describe the clinical picture whatever the cause (see Chapter 13).

Historical background

Urticaria has been recognized since the days of Hippocrates. The term dates back to the 18th century, when the stinging and burning was likened to the sting of a nettle (*Urtica dioica*). The changing opinions on the pathogenesis and management of urticaria provide a fascinating reflection of the changing fashions in medical thought [1,2].

Classification (Table 22.1)

Urticaria is a heterogeneous group of disorders that may be broadly classified by duration of disease and clinical features.

Urticaria is traditionally classified into acute and chronic, with a time division arbitrarily chosen between 6 weeks and 3 months. When urticaria is present daily or almost daily for less than 6 weeks it is called acute. If urticaria occurs continuously on most days for longer than this, it is called chronic. This applies to all patterns of urticaria, but is most relevant to the ordinary presentation of urticaria, because physical urticarias and urticarial vasculitis nearly always have a chronic course. Contact urticaria usually presents with brief episodes. Repeated episodes of continuous urticaria over a period of time are acute or chronic intermittent depending on their usual duration. This classification by disease duration is of limited value, but an exogenous cause is more likely to be found in acute urticaria than in chronic urticaria.

A classification based on clinical features and trigger factors is convenient (Table 22.1), but has inherent inconsistencies. Several types of urticaria may coexist in the same person—for example, ordinary urticaria and various forms of physical urticarias, including delayed pressure urticaria. The term 'ordinary urticaria' can be used when other patterns of urticaria have been excluded. It refers to the usual presentation of continuous urticaria with no implication about the aetiology, duration or severity of the illness. The new terminology is preferred because it is now evident that around 50% of patients previously diagnosed with chronic 'idiopathic' urticaria have an autoimmune basis for their disorder. The criteria for 'idiopathic' will vary between clinicians depending on whether or not non-specific aggravating factors (such as aspirin and food additives) are regarded as causes [1]. It is useful to separate patients who have angio-oedema *without* weals from the majority who have angio-oedema *with* weals. Some patients presenting with the former will have C1 esterase inhibitor deficiency, some will be due to angiotensin-converting enzyme inhibitors (ACEIs) or non-steroidal anti-inflammatory drugs (NSAIDs), but many will remain 'idiopathic' after full evaluation.

Table 22.1 Clinical classification of urticaria.

1 Ordinary urticaria
Acute
Episodic (acute and chronic intermittent)
Chronic (previously qualified as 'idiopathic' prior to recognition of the autoimmune subtype)
2 Physical and cholinergic urticarias
3 Urticarial vasculitis
4 Contact urticaria
5 Angio-oedema without weals
6 Other syndromes resembling urticaria or angio-oedema, or with urticaria as a component

Associations (Table 22.2)

There have been many reports of an association between chronic ordinary urticaria and autoimmune thyroid disease, which was reported initially by Leznoff [1]. There also appears to be a higher frequency of autoimmune diseases in patients with autoimmune urticaria [2]. An association between chronic urticaria and coeliac disease in children has been proposed [3]. The older literature suggests that chronic 'idiopathic' urticaria may be associated with chronic infections, especially dental, and *Candida* infections of the bowel, but in the authors' experience this occurs rarely, if at all. A meta-analysis of therapeutic trials for patients with active *Helicobacter pylori* infection and chronic urticaria showed that those who responded to eradication treatment were more likely to go into remission of urticaria than those who did not [4]. Bowel helminth infection as a cause of chronic urticaria is rare in developed countries but should be considered in countries where it is endemic. The evidence linking chronic urticaria and infections has been reviewed [5]. These authors describe a link between *H. pylori* and a positive autologous serum skin test (ASST), also known as autoreactivity. They draw attention to the relatively high frequency of upper respiratory tract viral infections (47%) with acute urticaria and conclude that the evidence base to link viral, bacterial, parasitic and fungal infection with chronic urticaria is lacking. Although there have been anecdotal reports of urticaria occurring with systemic malignancies, including lymphoma, no overall association was found in a large epidemiological study [6].

Prevalence

Urticaria is a common problem, with a point prevalence of 0.1% in one survey [1]. Estimates of the cumulative lifetime prevalence of chronic urticaria have varied from 0.05% to 23.6% in the general population, but a range of 1–5% seems more realistic [2].

2 Schäfer T, Ring J. Epidemiology of urticaria. *Monogr Allergy* 1993; **31**: 49–60.

Genetics

Hereditary angio-oedema, the autoinflammatory syndromes (now known collectively as the cryopyrin-associated autoinflammatory syndrome) and a few other rare physical urticarias are inherited as autosomal dominant traits. There is a highly significant linkage of human leukocyte antigen (HLA) DRB1*04 (DR4) and its associated allele DQB1*0302 (DR8) with histamine-releasing autoantibody-positive chronic ordinary urticaria [1]. Polymorphisms of the FcεRIα promoter [2] and leukotriene C_4 synthetase genes [3] have been associated with aspirin-sensitive urticaria and associations with other allelic variants have been reported.

Histology

The histology of urticarial weals is usually non-specific, with vascular and lymphatic dilatation, oedema and a variable perivascular cellular dermal infiltrate consisting of lymphocytes, neutrophils and eosinophils (Fig. 22.1). On electron microscopy, dermal mast cells show signs of degranulation. In one study, dermal mast cells in weals of chronic urticaria were increased by 10 times [1] compared with non-urticated skin, using conventional histochemical stains, but this increase was not confirmed in a study using tryptase and chymase as markers [2]. In the majority of weals, there is a sparse perivascular infiltrate, predominantly of helper T lymphocytes [3,4] with a TH_0 cytokine profile expressing mRNA for interleukin (IL)-4, IL-5 and interferon-γ (IFN-γ) [5]. In a minority of weals, neutrophils are a conspicuous feature, within the vessel walls or scattered in the dermis [6]. Eosinophils may play a more important role than their sparse numbers seen on light microscopy would suggest, as extracellular eosinophil major basic protein is frequently deposited in spontaneous weals [7] and they stain for activation markers [8]. The spectrum of cellular changes may depend on the age of weals and their underlying cause. Biopsies are generally performed if individual weals are persistent, and they may show features of delayed pressure urticaria or urticarial vasculitis. In delayed pressure urticaria, the infiltrate is denser, with neutrophils often present in early weals, and eosinophils extending deep into the fat in early and late weals. These cellular changes correlated with moderate up-regulation of the vascular endothelial adhesion molecules E-selectin, intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) on perivascular cells [9]. Urticaria with histological evidence of vasculitis (venulitis) is defined as urticarial vasculitis.

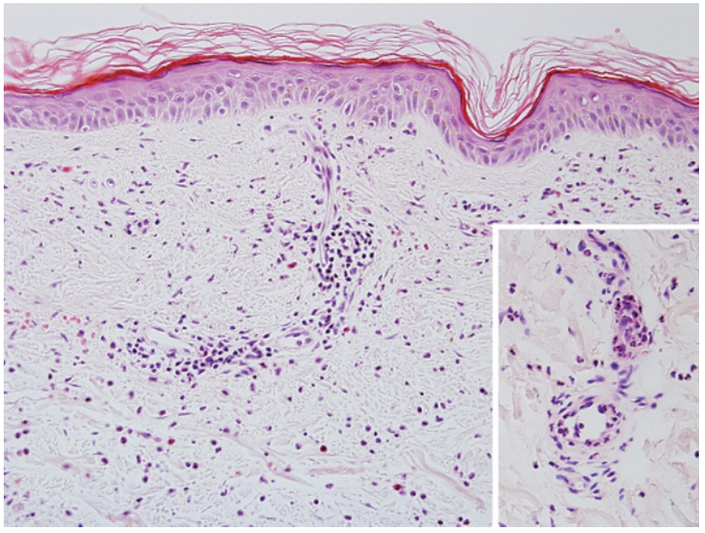

Fig. 22.1 Histology of a spontaneous weal from a patient with chronic ordinary urticaria showing dermal oedema with a moderate perivascular and interstitial mixed inflammatory infiltrate, including intravascular neutrophils (inset) but no vasculitis. Pathophysiology [1] (Table 22.3)

Mast cell mediators

Urticaria is due to a local increase in permeability of capillaries and venules. These changes are dependent on activation of cutaneous mast cells in nearly all types of urticaria except C1 esterase inhibitor deficiency and ACEI-induced angio-oedema, where kinins are primarily responsible for the increased vasopermeability, and the autoinflammatory syndromes in which interleukin (IL)-1 and -18 are activated by caspase 1. Mast cells contain a range of pro-inflammatory mediators, but predominantly histamine. Increased concentrations of histamine have been recovered in tissue fluid from lesions of chronic idiopathic urticaria [1] and from venous effluent draining the urticated areas in most physical urticarias. The clinical improvement on treatment with H_1 antihistamines underlines the role of mast cell-derived histamine as a major mediator in urticarias. Activation of H_1 receptors in the skin induces itching, flare, erythema and wealing. Activation of H_2 receptors contributes to erythema and wealing, but not itch or flare. So far, H_3 receptors—identified in the nervous system as inhibitory autoreceptors, in that their activation leads to reduced biosynthesis and release of histamine—have not been identified in human skin. H_4 receptor activation leads to scratching behaviour in mice [2] but a human equivalent has not been confirmed. Other vasoactive and chemoattractant mast cell-derived mediators, and secondary release of non-mast cell mediators from inflammatory cells, may amplify and prolong the weal. Little is known of the process of weal resolution.

Table 22.3 Pathophysiology of urticaria.

Mast cell mediated urticaria
Mediators
Histamine
Cysteinyl leukotrienes (C_4 D_4 E_4)
Prostaglandin D_2
Platelet activating factor
Cytokines
Interleukin-3, -4, -5
Granulocyte macrophage colony stimulating factor
Tumour necrosis factor-α
Releasing stimuli (*in vivo*)
Allergen cross-linking of specific IgE on FcεRI
Anti-FcεRI and anti-IgE autoantibodies
IgG1 and 3 subclasses for functionality
Complement dependence
Immune complex deposition (serum sickness and urticarial vasculitis)
Neuropeptides (*in vitro* only)
Cellular response
Basophil, eosinophil, neutrophil and lymphocytes
Non-mast cell mediated urticaria (angio-oedema without weals)
Kallikrein-kininogen-kinin-kininase system
C1 esterase inhibitor deficiency
Angiotensin converting enzyme inhibitors

Compared with normal controls, the cutaneous mast cells from chronic urticaria also release more histamine spontaneously and in response to non-specific degranulating agents such as codeine and morphine [3]. There is no evidence for decreased skin histamine metabolism in the skin of chronic urticaria subjects. However, their cutaneous vasculature is more responsive to histamine than skin of normal controls [4]. Tryptase and chymase are released in conjunction with histamine. Potentially, they could play a part in the pathogenesis of urticaria, as chymase can induce mast cell degranulation and tryptase and chymase cleave C3 to C3a and C3b. C3a can activate mast cells, and C3b can activate the alternative complement pathway. The example of hereditary angio-oedema has encouraged a search for other inhibitor deficiencies as a cause for other types of urticaria. A decrease of α_1-antitrypsin has been reported in cold urticaria [5]. Low levels have only sometimes been found in other types of urticaria, including chronic idiopathic urticaria [6]. Usually there is a poor correlation between the levels found and the clinical activity.

There is no direct evidence that prostaglandin D_2 (PGD_2) and leukotriene C_4 (LTC_4) released from cutaneous mast cells play a significant role in spontaneous urticaria but the response of some patients with aspirin-sensitive urticaria to leukotriene receptor antagonists suggests that release of cysteinyl leukotrienes may be clinically important in certain clinical situations. Whilst TNF-α upregulates vascular endothelial adhesion molecules, IL-8 stimulates neutrophil activation and accumulation, and IL-4 influences T-lymphocyte differentiation towards a Th2 phenotype, a direct role for these cytokines in urticaria has not been proven.

Mast cell activation

Mast cell activation may be non-immunological or immunological. Non-immunological mast cell activation occurs with a variety of substances including: neuropeptides, such as substance P; drugs, including opiate derivatives such as morphine and codeine, vancomycin and polymyxin; some radiocontrast media; and some foods, such as strawberries. Neuropeptides elicit histamine but not PGD_2 or LTC_4 release *in vitro*.

Immunological mast cell activation (Chapter 12) occurs as a result of linkage of two adjacent α-subunits of high-affinity IgE receptors (FcεRIα) of a mast cell. Preformed histamine, proteases and newly generated mediators, including PGD_2 and cytokines—IL-3, -4, -5, -6, -8, -13 and tumour necrosis factor-α (TNF-α)—are released from mast cells. In classic immediate allergic reactions, receptor cross-linking occurs indirectly when an allergen (such as latex, nuts, etc.) reacts with two or more allergen-specific IgE antibodies, each bound to FcεRIα. Activation also occurs by cross-linking autoantibodies directed against IgE bound to FcεRIα or against the α-subunit of FcεRI itself. Complement C3a and C5a can release histamine directly and appear to be necessary for some autoantibody-induced degranulation [7]. Basophils also express FcεRIα and release histamine, IL-4, IL-13 and LTC_4 on activation.

Neuropeptides

Some mast cells are positioned close to nerve endings. Histamine can stimulate sensory afferent nerves to release substance P. Neuropeptides appear to be responsible for the neurogenic axon flare after intradermal histamine injection [8], but there is no direct evidence for neuropeptide involvement in weal formation.

Cellular involvement

The dermal leukocyte cellular infiltrate in chronic ordinary urticaria, consisting of lymphocytes, neutrophils and eosinophils, releases a variety of cytokines with pro-inflammatory properties. Blood basophils may be involved in the pathogenesis of chronic ordinary urticaria, as their numbers are substantially reduced in the presence of histamine-releasing factors in serum [9], and they also release less histamine in response to anti-IgE stimulation [10]. They may contribute to prolongation of urticarial weals by active recruitment from the circulation [11]. The observation that the cellular infiltrates in weals of patients with chronic autoimmune and idiopathic ordinary urticaria are similar [12] suggests that the inflammatory response is determined by the event of mast cell degranulation rather than its stimulus.

In physical urticarias, there is no evidence for increased mast cell numbers. Infiltrates tend to be mild and mixed in dermographism [13]. In addition to histamine release, ill-defined eosinophil and neutrophil chemotactic factors have been demonstrated in venous effluent from cold, cholinergic and solar urticarial lesions. The mode of activation of mast cells in physical urticaria is poorly understood, but in some patients with dermographism, cholinergic, cold and solar urticaria, a transferable IgE-like factor has been identified. It has been speculated that the physical stimulus in these patients may induce a neo-antigen that could stimulate IgE production directed specifically against it. On rechallenge, this neo-antigen would react with its specific IgE bound to mast cells and activate mediator release. Increased substance P and vasoactive intestinal peptide (VIP) have been recovered from dermographic and cold urticarial lesions, while clinical lesions of cold and localized heat urticaria were diminished by prior application of topical capsaicin, a depletor of neuropeptides.

Kinins and complement

Plasma-derived kinins do not appear to have a significant role in chronic urticaria, but it is thought that production of bradykinin by the action of kallikrein on kininogen and kinin-like peptides derived from the early components of complement are important in the pathogenesis of angio-oedema associated with C1 esterase inhibitor deficiency. The angio-oedema seen with ACEI is believed to be due to inhibition of breakdown of bradykinin by ACE, also known as kininase II. Complement activation, with production of the anaphylatoxins C3a and C5a, occurs in urticarial vasculitis.

Ordinary urticaria

Clinical features

Itching erythematous macules develop into weals consisting of pale to pink, oedematous, raised areas of the skin often with a surrounding red flare. They occur anywhere on the body, including scalp, palms and soles, in variable numbers and sizes, ranging from a few millimetres to lesions covering large areas, and of varying shapes including rounded, annular, serpiginous and bizarre patterns due to confluence of adjacent lesions (Fig. 22.2). Very rarely, bullae may form when oedema is intense. Weals generally last a few hours and resolve within 24 h, passing through a macular erythematous phase, leaving the skin with a normal appearance. They are generally very itchy, especially superficial weals and particularly at night. Patients tend to rub rather than scratch, so excoriation marks are unusual, but occasionally bruising may result, which may be seen particularly on thighs. Weals may be more pronounced in the evenings or premenstrually.

There may be associated angio-oedema in 50% of patients with ordinary urticaria. These deep swellings, which may be the same colour as normal skin, occur most frequently on the face, affecting the eyelids and lips, but any other area of the body may be affected, such as ears, neck, hands, feet and genitalia. Mucosal swellings may also occur inside the oral cavity on the buccal mucosa, tongue and pharynx but laryngeal involvement is fortunately rare. Angio-oedema may be preceded by an itching or tingling sensation, but it is not always itchy and may be painful. The lesions may last for several days.

Urticaria may be preceded by vomiting [1] and be associated with systemic symptoms of malaise, loss of concentration, low mood, feeling hot and cold, headache, abdominal pain, diarrhoea,

Fig. 22.2 Different morphology of urticarial weals. (Courtesy of Addenbrooke's Hospital, Cambridge, UK (a); courtesy of St John's Institute of Dermatology, London, UK (b–d).)

arthralgia, dizziness and syncope and, in its most severe acute form, with anaphylaxis.

Urticaria in childhood

The same multiplicity of factors is found as in the adult [1], with a tendency to more cases of acute disease. Cow's-milk allergy is the commonest cause of urticaria in infants under 6 months old [2]. In infants, there may be less itching and a greater tendency for

Fig. 22.3 Acute haemorrhagic oedema of infancy or cocarde purpura of childhood. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

weals to become purpuric. A not uncommon pattern is one of bizarrely shaped weals, not seen as frequently in adults. No specific aetiology or natural history has emerged in such cases. Acute haemorrhagic oedema of infancy (purpura en cocarde) occurs in very young children and is borderline between urticaria and vasculitis (Fig. 22.3).

Aetiology of ordinary urticaria (Table 22.4)

Although some cases of acute urticaria can be ascribed to allergy, non-allergic causes or infections and around 50% of chronic urticaria may be attributed to autoimmunity, other cases will remain idiopathic after evaluation.

Acute urticaria

Most acute urticaria is ordinary and some will become chronic. Serum sickness due to injection of therapeutic animal antisera (e.g. to snake venoms) is now rare. Physical urticarias will go through an acute phase but most will last more than 6 weeks. Contact urticaria does not usually present as acute urticaria because it tends to be localized, intermittent and short-lived. The incidence in the community is not well defined. Many cases will not present to secondary care.

Idiopathic

This form of acute urticaria, in which no cause can be identified, was found in more than 50% of patients with acute urticaria presenting to a city 'walk-in' dermatology centre [1]. In the others, the most common preceding event was an upper respiratory tract infection, followed by drug ingestion, but allergy or intolerance to food was rare [1,2].

Allergic

This is commoner in the community than in dermatological practice, where it is rare. Allergic urticaria is due to interaction of an allergen with specific preformed IgE bound to the mast cell. It is commoner in people who are atopic and have elevated IgE levels. Although it is unusual to find an allergic cause for acute urticaria [1], any drug, food, foreign substance from blood transfusion, injection, implant, contactant and inhalant should be considered as a potential allergen (Table 22.5). In an IgE-mediated reaction, there will have been a previous exposure and the reaction may occur in minutes and no longer than 60 min. Patients will usually recognize this and avoid the offending substance. Acute urticarial

Table 22.4 Aetiology of ordinary urticaria.

Vaccines	Spices
Blood products	Apples
Crustaceans (lobsters, shrimp, crab)	Peaches
Fish	
Milk	

reactions from drugs are common [3] (Table 22.6), usually occurring within 36 h of drug administration although it should be noted that *urticarial* drug reactions (i.e. reactions with an urticarial component) are not synonymous with acute urticaria due to a drug. It is unusual for urticaria to develop from a drug taken continuously for months. Sometimes, it is uncertain if a drug-induced urticaria is allergic and, if it is, whether the reaction is IgE-mediated or IgG-mediated via immune complexes [4]. Antibiotics, especially penicillins and cephalosporins, are common causes. Increased risk factors include previous exposure and reaction to the drug or a chemically related drug, intermittent and multiple drug therapy, and a familial predisposition.

Acute urticarial reactions to food are believed to be common and many go unreported [5]. Urticarial reactions may not be to the basic nutrient but to other ingredients, such as seeds or spices. Reactions typically occur within minutes and no more than 30 min. Rarely, allergic reactions to food occur only if intake is followed by exercise, with neither food nor exercise alone inducing weals (food-dependent exercise-induced anaphylaxis) [6]. Substances reported to cause this include wheat, hazelnuts and shellfish.

Stinging insects are members of the order Hymenoptera, of which bees and wasps are its two major subgroups. Allergic reactions to injected sting venom are not uncommon and occasionally are fatal [7]. Development of bee-sting allergy usually requires multiple exposures, and is commonly seen in beekeepers. Development of allergy to wasp stings and the pattern of severity of reactions to any subsequent stings are unpredictable. Hypersensitivity to insect stings is unrelated to an atopic background.

Reactions to some substances may be dramatically severe and may proceed rapidly to systemic anaphylaxis [8–10]. Here, prodromal symptoms include itching or tingling of the mouth, palms, soles and genital area. Subsequent signs include widespread erythema, urticaria, lacrimation, nasal stuffiness, bronchospasm, laryngeal oedema, nausea, diarrhoea, vomiting, hypotension or cardiac arrhythmias and can rarely lead to death. This is a medical emergency, and first-line treatment is with epinephrine (adrenaline) [10] given by intramuscular injection.

Some substances more readily evoking IgE-mediated anaphylactic reactions include penicillins, sesame seeds, peanuts, latex and Hymenoptera stings. The need to label food with individual constituents is increasingly recognized. In some patients, despite all efforts, no cause for anaphylactic symptoms can be identified [11].

Table 22.6 Some substances implicated in causing non-allergic urticaria and anaphylaxis.

Drugs
Acetylsalicylic acid (aspirin)
Other non-steroidal anti-inflammatory drugs
Polymyxin
General anaesthetic agents (especially muscle relaxants and opioids)
Radiocontrast media (especially ionic)
Plasma expanders (especially dextrans)

Non-allergic

Acute urticarias from ingested substances may be non-allergic (see Table 22.6). They are then referred to as intolerance reactions. These may be due to direct histamine release from mast cells (histamine liberators) or due to other mechanisms (pseudoallergic). If they are very severe, resembling anaphylaxis, they are known as non-allergic anaphylaxis [12].

Histamine liberators

Here, mast cell histamine release is not immunological and may occur after first exposure to a substance. Examples include morphine, codeine, atracurium and antibiotics, such as polymyxin and vancomycin. Iodine-based radiocontrast dyes may cause non-allergic anaphylaxis. Exactly how radiocontrast media, low- and high-molecular dextran plasma expanders cause these reactions is not known. Complement activation is thought to play a role in serious dextran reactions.

Pseudoallergic reactions

The reaction is not substance-specific, and similar reactions may occur to unrelated compounds in the same individual. The severity of reaction is usually related to the dose of the offending substance. Common offending substances include aspirin and other non-steroidal anti-inflammatory agents. These cause the reactions by pharmacological mechanisms thought to be related to their activity in inhibiting the cyclo-oxygenase (COX-1) pathway of arachidonic acid metabolism, diverting it to the pro-inflammatory lipoxygenase pathway products LTC_4,D_4,E_4 and by reducing PGE_2, which is inhibitory for immunological mast cell degranulation [13].

Alcohol-induced urticaria is rare; the mechanism of causation is unknown, but appears not to be allergic [14]. Alcoholic beverages can aggravate urticaria non-specifically. White wines are often treated with sulphites, which have rarely been reported to cause urticaria and anaphylaxis [15,16]. Some red wines contain measurable concentrations of vasoactive amines including histamine [17] which could aggravate urticaria, but cutaneous symptoms relate poorly to histamine content [18].

Food may also contain vasoactive amines including histamine (such as cheese, fish, meat, tomatoes, pineapple and avocados) or histamine-releasing substances (such as in strawberries). Histamine generated in scombroid fish (underprocessed tuna, mackerel) by histidine decarboxylase from bacteria can cause acute urticaria, vomiting and diarrhoea, and high levels of histamine can usually be found in affected fish [19].

Infections

Urticaria may follow non-specific viral infections [1,2], Epstein–Barr [20] or acute hepatitis B viral infections, anisakiasis (infection by a fish parasite in pre-sensitized individuals) [21], streptococcal throat infections in children and, rarely, *Campylobacter jejuni* infections [22].

Inhalants

Grass pollens, mould spores, animal danders and house dust mite [1] have been implicated as triggers of acute or chronic urticaria, with or without respiratory symptoms, but this must be very rare. If pollen allergy is proven, desensitization may exceptionally be successful [2].

Chronic urticaria

Chronic urticaria of at least 6 weeks' duration may be ordinary, physical or vasculitic but the term is often considered to be synonymous with the ordinary presentation of chronic urticaria.

Idiopathic

Most patients were considered to have 'idiopathic' urticaria before autoimmunity was recognized as a cause. It is still not possible to ascribe a specific aetiology to around 50% of patients presenting with the ordinary presentation of chronic urticaria even after looking for autoreactivity with the ASST or testing for functional autoantibodies with the basophil histamine release assay. The reasons for this are not clear but may be due to relative insensitivity of the assay for low concentrations of functional autoantibodies that could, in theory, degranulate hyper-releasable mast cells in chronic urticaria but not the normal basophils of healthy donors. Clinical experience suggests that chronic urticaria is often a multifactorial disease and that its day-to-day activity is determined by exogenous aggravating factors (see below) acting in conjunction with an endogenous cause.

Autoimmune

There is increasing acceptance that histamine releasing autoantibodies define an autoimmune aetiology in an important subset of patients. Sera of approximately 60% of patients with chronic ordinary urticaria have been shown to cause a pink weal when injected intradermally into the patient's own skin (the autologous serum skin test) [1]. Approximately half of these patients' sera (30% of total chronic ordinary urticaria patients) released histamine *in vitro* from basophils and skin slices obtained from healthy people, in one series [2]. The proportion of chronic urticaria sera releasing histamine has been up to 50% in others [3]. Almost 100% of sera from chronic urticaria patients with a positive ASST were histamine releasers from a panel of basophils and mast cells from different donors [4]. This histamine releasing activity is due to functional IgG autoantibodies directed against the α-subunit of FcεRI or, less frequently, against receptor-bound IgE [5,6]. These functional autoantibodies are predominantly of IgG1 and 3 complement-fixing subclasses [7]. Complement dependence of autoantibody-induced mast cell degranulation has been shown [8]. In a few patients with a positive skin test but negative basophil histamine releasing activity, there was evidence of an unidentified non-IgG factor reacting with mast cells [9]. Autoantibodies against FcεRIα, of predominantly IgG2 and 4 subclasses (unable to fix complement), have been detected by western blot and enzyme-linked immunoassay (ELISA) in the sera of patients with other conditions, such as systemic lupus erythematosus (SLE), dermatomyositis, bullous pemphigoid and pemphigus vulgaris [7], and even in healthy subjects [10], but appear to be non-functional and therefore unlikely to be of pathogenic importance.

Immune-modulating treatment of severely affected chronic urticaria patients with a positive skin test, using plasmapheresis [11] and intravenous immunoglobulin [12], was associated with clinical remission in some. Thus, in some patients, chronic urticaria appears to be a manifestation of a specific autoimmune disorder. In the remaining 50% of patients, no histamine-releasing factor can be identified *in vitro* or *in vivo* and the reasons for this have not yet been clarified. It is possible that other non-antibody factors are involved. Histamine releasing autoantibodies have not been demonstrated in the physical or cholinergic urticarias.

Even now, the cause can rarely be identified with certainty, since there are no routinely available tests for histamine-releasing autoantibodies. The ASST is used in some centres as a non-specific screening test for histamine releasing factors in blood of patients with chronic urticaria but the results need to be interpreted with caution and should not be regarded as proof of an autoimmune aetiology.

Pseudoallergy

Although 30% of chronic urticaria patients were considered to have intolerance reactions to dietary pseudoallergens as causing or aggravating their urticaria in a quality of life study [13], it is the authors' experience that exposure to dietary and drug pseudoallergens is a rare cause of chronic urticaria. However, dietary additives and salicylates may be one of many factors that aggravate existing chronic urticaria and this should be explored in the medical history (see Aggravating factors, Table 22.7).

Infections and infestations

The incidence of bacterial infections, such as dental sepsis, sinusitis, urinary tract and gallbladder infections, in chronic urticaria varies in different series. If present, treatment of the infection usually does not improve urticaria and, overall, infections are a rare cause of chronic urticaria. *H. pylori* infection of the stomach has been associated with chronic urticaria [14] but appears uncommon in the UK. *Candida* infections, although described [15], are found extremely rarely to be a cause of urticaria. Intestinal parasites are a rare cause in developed and developing countries [16], but should be looked for if there is a blood eosinophilia or a history of recent travel to subtropical or tropical areas [17]. Rarely, protozoa or helminthic infection in the tissue may be a cause. Linear weals may follow migration of *Ancylostoma* and *Strongyloides* worms. *Toxocara canis* antibodies have been associated with chronic urticaria, but a causal relationship is not proven [18].

Aggravating factors (Table 22.7)

Even though a specific cause of urticaria may not be identified in individual patients it is often possible to identify non-specific aggravating factors in chronic urticaria, such as heat and clothing pressure in ordinary urticaria, avoidance of which can help to minimize exacerbations.

Drugs

Salicylates and other related NSAIDs, such as diclofenac, can aggravate urticaria and asthma by non-allergic mechanisms. Patients usually react with either urticaria or asthma, but not both [1]. The percentage of patients whose urticaria is exacerbated by aspirin (acetylsalicylic acid) varied from 20% to 30% in different studies [2,3]. Many medicines and proprietary preparations contain aspirin, but the small amounts of salicylates present in food are unlikely to be significant [4]. Although aspirin may exacerbate chronic urticaria, these reactions are usually not life-threatening. ACEIs can provoke angio-oedema and may, perhaps, aggravate urticaria. The relationship between penicillin and chronic urticaria is a complex one, but the amount present in dairy products seems unlikely to perpetuate chronic urticaria except in people with extreme penicillin sensitivity, or if penicillin is present in food above permitted levels [5].

Foods and food additives

Numerous foods have been blamed as a cause of urticaria [6]. However, an allergic cause was found in fewer than 3.5% of cases [1,7]. The general population blamed foods for their adverse clinical reactions, including urticaria, more often than could be reproduced on double-blind challenge [8].

There are many reports that food additives aggravate chronic urticaria, but the high incidence of 33% [9] has not been confirmed in some double-blind studies [10]. The discrepancies in incidence in different studies could arise from the differing populations and test methods used. Other variables during testing include antihistamine therapy, basic diet, hospitalization and whether testing

Colouring agents
Tartrazine (E102) 10 mg
Quinoline yellow (E104) 10 mg
Erythrosine (E127) 5 mg
Preservatives
Sorbic acid (E200) 100 mg
Sodium benzoate (E211) 1000 mg
4-hydroxybenzoic acid (E214–219) 1000 mg
Sodium metabisulphite (E223) 50 mg
Sodium nitrate (E251) 100 mg
Antioxidants
Butylhydroxyanisole (E320) 50 mg
Butylhydroxytoluene (E321) 50 mg
Flavour enhancer
Monosodium glutamate (E621) 200 mg
Aspirin 75 mg
Aspirin 300 mg*

* Not to be given if there is a history of asthma or severe aspirin reactions.

was placebo-controlled and double-blind, with confirmation of positive results on retesting [11]. The exact percentage of reactions to additives is not known, but is considered to be important in fewer than 10% of patients with chronic ordinary urticaria. The most frequently implicated food additives are tartrazine (E102) and other azo dyes, including sunset yellow (E110). Reactions to benzoate preservatives (E210–219) and antioxidants, such as butylated hydroxytoluene (E321) and butylated hydroxyanisole (E320), are reported less often. Sulphites (E223–228), monosodium glutamate (E621) and aspartate are very rare causes of urticaria, which is usually of the acute type. The sensitivity to additives gradually lessens as the urticaria resolves. Dyes and preservatives can be found in medicinal products, but usually in smaller doses than in food [12]. Oral challenge testing may be performed if desired by physician or patient but tends to be most rewarding in episodic than chronic urticaria (see St John's challenge test, Table 22.8).

Infections

Chronic urticaria is frequently exacerbated by intercurrent viral infections. This may be a non-specific effect of circulating pro-inflammatory cytokines or chemokines.

Menstrual cycle and pregnancy

Urticaria may occur in pregnancy, but it is difficult to evaluate any causal relationship. It should be distinguished from pruritic urticarial papules and plaques of pregnancy (PUPPP, synonym polymorphic eruption of pregnancy), which is the most common specific dermatosis of pregnancy and occurs during the third trimester. Urticaria may worsen premenstrually, but if urticaria occurs predominantly or only premenstrually, it has been attributed to progesterone sensitivity [1] or more rarely oestrogen sensitivity [2], usually on an autoimmune basis. A non-immune mechanism has been suggested for 'autoimmune' progesterone urticaria [3].

Implants and nickel allergy

Urticaria has been linked anecdotally with a metal pin in the femur [1], a metal dental prosthesis [2] and with dental amalgams [3], but an apparent association in these cases may have been fortuitous. A role for contact sensitization in chronic urticaria has been proposed [4]. The authors reported positive patch tests in 41% of their series. All nickel allergic patients went into remission within 8 weeks of a nickel-free diet, but these results have not yet been confirmed by other centres or subjected to a randomized controlled study.

Stress

Psychological factors appear to play a contributory role in a proportion of patients, and flare-ups of urticaria do occur at times of psychological stress [1]. Psychological factors are often wrongly

thought to contribute to angio-oedema because of the old name 'angioneurotic oedema', which implied something very different when it was first introduced. The importance of psychological factors is difficult to evaluate scientifically and can be over-emphasized. Depression and anxiety were found more frequently in chronic urticaria in two studies [2,3], but not in another [4]; however, depression may reduce the threshold for pruritus [5], and the effect of chronic urticaria on quality of life should not be underestimated [6].

Physical and cholinergic urticarias [1,2]

The physical urticarias are a distinct subgroup of urticarias in which a specific physical stimulus induces reproducible wealing. This feature is the basis of diagnosis and classification (Table 22.9). Cholinergic urticaria occurs in response to sweating caused by an increase in core temperature, so it is frequently included in the physical urticaria group, but it may also be triggered by emotional and gustatory sweating. The currently accepted challenge procedures for the diagnosis of physical urticarias are summarized in Table 22.10.

The frequency of physical urticarias in the general population is unknown, but they accounted for 19% of urticaria cases in a dermatology clinic [3], with dermographism making up 9% and cholinergic urticaria 4%. However, mixtures of various types of physical urticaria or of a physical urticaria with ordinary urticaria are common—for example, a component of delayed pressure urticaria occurs in 37% of people with ordinary chronic urticaria.

Wealing caused by physical stimuli usually occurs within minutes at the site of contact with the skin and persists for less than 30–60 min (immediate contact type—for example, dermographism and most cold urticarias). However, sometimes a generalized stimulus affecting the whole body is necessary (reflex type—for example, cooling body core temperature to induce reflex cold urticaria and a rise in core temperature to induce cholinergic urticaria). In a few forms of physical urticaria, a delay of several hours from the physical stimulus occurs before weals appear—for example, delayed dermographism, delayed pressure urticaria and the rare delayed cold urticaria.

In many forms of physical urticaria, if the stimulus is sufficiently great or the patient is very sensitive, angio-oedema and systemic reactions may occur from mediator release.

Table 22.9 A classification of physical urticarias and their prevalence.

	Prevalence
Due to mechanical force	
Dermographism	
Immediate	
Symptomatic dermographism	+
Simple dermographism	+ +
Red dermographism	+ –
Cholinergic dermographism	+
Delayed dermographism	+ –
Associated with mastocytosis (Darier's sign)	+
Delayed pressure urticaria	+ +
Vibratory angio-oedema	+ –
Due to heat	
Generalized heating	
Cholinergic urticaria	+ +
Variants	
Cholinergic pruritus	+
Persistent cholinergic erythema	+
Cholinergic dermographism	+
Exercise-induced anaphylaxis	+
Localized heating	
Heat contact urticaria	+ –
Due to cold	
Acquired	
Primary (idiopathic)	
Localized cooling	
Cold erythema	+
Immediate cold contact urticaria	+ + +
Delayed cold contact urticaria	+ –
Localized cold contact urticaria	+ –
Generalized	
Generalized reflex cold urticaria	+ –
Cold-dependent cholinergic urticaria	+ –
Secondary (to serum cryoproteins)	+
Inherited	+ –
Others	
Solar urticaria	+
Aquagenic urticaria	+

Combinations of different types are common.
+ –, rare; +, uncommon; + +, moderately common; + + +, very common.

Urticaria due to mechanical forces

Dermographism

Immediate symptomatic dermographism (factitious urticaria)

This involves the triple response which may arise from firm stroking of the skin [4]. This response consists of *local erythema* due to capillary vasodilatation, followed by *oedema* and a *surrounding flare* due to axon reflex-induced dilatation of arterioles. This reaction is normal, but in 5% of normal people this physiological response is sufficiently exaggerated to warrant the term simple dermographism. In a minority of these people, it is accompanied symptomatically by itching (symptomatic dermographism). Symptomatic dermographism may have an immunological basis.

Table 22.10 Challenge tests for the diagnosis of physical and cholinergic urticarias. All should be medically supervised.

Physical urticaria	Testing
Dermographism	Itching weals occur in minutes lasting less than 1 hour after: a. Firm stroking of the skin with a smooth blunt object (back preferable) b. A calibrated dermographometer set at 36 g/mm^2 or less
Delayed pressure urticaria	Sustained pressure is applied to the back, shoulder or thigh: a. 4.5 kg weighted rods with a 1.5 cm diameter applied for 15 min b. Dermographometer set at 100 g/mm^2 pressed against the back of the shoulder for 70 s, read after 2–6 h and next day c. Hanging a weight 15 lbs (7 kg) by a broad strap from a shoulder results in a weal, often painful, at the application site 4–6 h later, lasting from several hours up to 24 h
Cholinergic urticaria	Raising the core body temperature by 0.7–1.0°C by: a. Exercise in a hot environment until sweating b. Hot bath (42°C) for 15 min induces itching within minutes, with widespread small weals In an individual patient, either method may be more successful In exercise-induced anaphylaxis, only the exercised-induced challenge will be positive
Cold urticaria	
Idiopathic contact	Application of a melting ice cube in a thin plastic bag for up to 20 min results in an itching weal at the site within minutes of removal; if mild may take up to 10 min to develop after removal; induced weals last less than 1 h
Generalized reflex	Placing the patient (with supervision) in a cold room at 4°C for 30 min induces widespread small weals; the ice cube test is negative
Solar urticaria	Exposure to sunlight or solar simulator induces redness, itching weals at site of exposure within a few minutes lasting less than 1 h Exposure to a monochromator can determine the individual wavelengths that induce wealing
Aquagenic urticaria	a. Exposure of skin to water at body temperature in a bath for 15 min induces small itching weals on the immersed site within minutes b. Application of water soaked towels at body temperature for 30 min at sites where aquagenic urticaria occurs, e.g. back or upper chest, induces small itching weals at the site of application within minutes lasting less than 1 h (NB other physical urticarias should be excluded)
Heat contact urticaria	Wealing occurs in minutes localized to the site of application of heated objects at 39–45°C for 2–5 min lasting less than 1 h
Vibratory angio-oedema	Application of a laboratory vortex resting on the forearm or finger for 1–5 min results, within minutes, in a red swelling of the vibrated area, lasting less than 1 h

Dermographism has been successfully transferred when IgE (and occasionally IgM) in patients' sera has been injected into normal recipients [5,6]. It has been proposed that mast cells sensitized with immunoglobulins (especially IgE) react to a neoantigen induced by mechanical stimulation of the skin and release their mediators. Neuropeptides may contribute to the reaction [7].

Symptomatic dermographism can occur at any age, but the greatest incidence is in young adults. Patients complain of wealing and itching at sites of trauma, friction with clothing or scratching the skin. The itching is often disproportionately severe compared with wealing and is often most severe at night. The eliciting stimulus determines the shape of the weals (Fig. 22.4), but they are often linear from scratching or stroking (Fig. 22.5). Dermographism may be present but is not increased in chronic ordinary urticaria, nor is there any correlation with systemic disease or food allergy [7]. Dermographism is usually idiopathic, but sometimes may follow a drug reaction—for example, penicillin reaction [8] or an infestation, including scabies. Dermographism may last for months or years, or be present intermittently.

Symptomatic dermographism is most easily diagnosed by using a calibrated instrument, the dermographometer [9], which has a spring-loaded stylus, the pressure of which can be adjusted to a predetermined setting. Stroking the skin at a tip pressure of less than 36 g/mm^2 [7] induces a linear, itching weal within 10 min.

Other forms of dermographism

Rarer forms of dermographism exist, including *red dermographism*, where repeated rubbing is necessary to induce small, punctate weals [10]. *Cholinergic dermographism* is seen in some patients with cholinergic urticaria, whose dermographic response consists of an erythematous line studded with punctate weals characteristic of cholinergic weals [11]. *Delayed dermographism* is rare. After a normal fading of the triple response or an immediate dermographic response, a weal returns in the same site, but is usually tender and persists up to 48 h [12]. The mechanism is unknown, but it is closely related to pressure urticaria [13], in which a delayed dermographic response is not unusual.

Fig. 22.4 Dermographism, meaning 'skin writing'. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 22.5 Linear lesions of immediate dermographism induced by stroking back skin with a calibrated dermographometer. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 22.6 Extensive delayed pressure urticaria over the back after sitting against a hard surface. Induced delayed dermographism is also seen on the upper back. (Courtesy of St John's Institute of Dermatology, London, UK.)

The presence of wealing following friction (Darier's sign) is characteristic of the lesions of urticaria pigmentosa as a presentation of mastocytosis, in which the number of skin mast cells is increased.

Treatment of symptomatic immediate dermographism with low-sedating H_1 antihistamines is often effective, sometimes in low doses. For the more severely affected, there is probably no clinical benefit from combining H_1 with H_2 antihistamines [14]. However, some improvement may be obtained with narrow-band ultraviolet B (NB-UVB) or psoralen and ultraviolet A (PUVA) therapy [15].

It should be noted that not all forms of dermographism are urticarial. *White dermographism* (due to capillary vasoconstriction following light stroking of the skin) occurs normally and is particularly pronounced in atopic subjects. *Black dermographism* is discolouration of the skin after pressure from a metallic object.

Delayed pressure urticaria

Delayed pressure urticaria [16] in its predominant form is uncommon (2% of urticarias) but it occurs to some degree in about a third of patients with chronic ordinary urticaria, although they may be unaware of this unless directly questioned [17]. Patients with predominantly delayed pressure urticaria nearly always have a component of chronic ordinary urticaria. Wealing occurs at sites of sustained pressure applied to the skin after a delay of 30 min to 9 h, but usually 4–8 h, and lasts 12–72 h [16].

Weals occur frequently under tight clothing, on the hands after manual work, on the buttocks and lower back after sitting (Fig. 22.6) and on the feet after walking. Lesions may be itchy, but are often tender or painful, particularly on the soles and scalp. The severity is variable, but it may be accompanied by systemic symptoms of malaise, flu-like symptoms, arthralgia, myalgia and leukocytosis. The condition may be mistaken for urticarial vasculitis.

The diagnosis can usually be made by careful questioning and confirmed by testing. Objective testing is performed by using a dermographometer set at 100 g/mm^2 pressed perpendicularly on the upper back for 70 s [18], or rods with a convex end diameter of 1.5 cm weighted with 2.5 kg for 20 min or 4.5 kg for 15 min on the back or thighs [17]. A positive response is when indurated lesions are present at test sites at 6 h. Areas of delayed pressure urticaria may be refractory to further pressure-induced lesions for up to 48 h.

Delayed pressure urticaria responds poorly to H_1 antihistamines but higher than licensed doses of cetirizine (10 mg three times a day) have been used, as it also inhibits eosinophil migration. Although NSAIDs may be helpful for pressure-induced lesions, they may aggravate the ordinary component of chronic urticaria. Montelukast has been reported to help [19] but is not usually effective for the more severe patterns of the disease. Drugs that inhibit granulocyte infiltration (including colchicine, dapsone and sulphasalazine) may be helpful although supporting clinical studies are lacking. The use of very potent topical steroids under occlusion for the hands and feet may be effective [20] and wearing comfortable shoes or insoles can be useful.

The prognosis is variable. The symptoms fluctuate in severity; they may show spontaneous improvement, or last for many years.

Vibratory angio-oedema

Vibratory urticaria is a very rare form of urticaria, which was first described in its familial form [21]. Any vibratory stimulus such as jogging, vigorous towelling or using lawnmowers induces a localized, red, itchy swelling within minutes and lasting less than a few hours, but if the stimulus is severe, generalized erythema and headache may occur. Avoidance of the precipitating stimuli enables patients to lead normal lives. Occasionally, vibratory angio-oedema may occur in an acquired form [22,23].

Temperature-dependent urticaria

Heat urticaria

Cholinergic urticaria

Cholinergic urticaria is a very distinctive type in which characteristic small weals appear in association with sweating. It accounts for about 5% of urticaria, and lesser degrees are common in adolescents. Wealing occurs on stimulation of sweating, whether induced by a rise in core temperature, emotion or gustatory stimuli.

The pathogenesis is still not clear. It is thought to be related to stimulation of the cholinergic postganglionic sympathetic nerve supply to the sweat glands. Increased histamine levels have been detected in the blood of patients with cholinergic urticaria. It was originally proposed that acetyl choline can release histamine, perhaps in an indirect way, but such a mechanism is conjectural [24]. Passive transfer tests with serum of affected individuals are sometimes positive, probably due to an immunoglobulin [25]. Such an antibody may prime the mast cell for activation. An allergy to sweat itself has been proposed [26]. It has also been proposed that cholinergic urticaria should be classified into two subtypes based on intradermal skin test reactions to autologous sweat and serum [27]. Decreased levels of the protease inhibitor antichymotrypsin have been detected in the serum of some patients [28]. There is no generalized disturbance of autonomic function [29].

The disease typically occurs in adolescents of either sex and may be worse in the winter months [30]. It has been reported to occur in families [31] and often occurs in atopics. The patient complains of itching weals that appear within minutes of exertion, when hot, or after emotional disturbances or even eating spicy food. The weals characteristically are small, 1–3 mm across, with or without a well-marked flare (Fig. 22.7). Sometimes, the erythematous component is more pronounced, especially in the 'blush areas', and is confluent and studded with weals. Oblique lighting is helpful for observing the weals, especially in dark skin. The lesions persist for a few minutes to an hour or two. Ordinary urticaria not precipitated by heat may be associated with cholinergic urticaria in some patients. Although micropapular weals resembling those of cholinergic urticaria can occur in ordinary urticaria, these usually last for hours. Cholinergic angio-oedema has been recorded [32]. In persistent cholinergic erythema, multiple small erythematous macules are distributed symmetrically on trunk and limbs, increasing in number after exercise. Individual

Fig. 22.7 Close-up of small monomorphic lesions of cholinergic urticaria on the trunk. (Courtesy of Norfolk and Norwich University Hospital, UK.)

macules are short-lived, but appear at different sites over a prolonged period, giving the overall impression of a persisting rash [33]. Cholinergic itching without weals has been described [34].

In some patients with cholinergic urticaria, systemic symptoms of flushing, faintness or asthma may occur [35,36]. Exercise-induced anaphylaxis may occur as part of the cholinergic urticaria spectrum after severe exercise [37]. However, exercise-induced anaphylaxis in others does not appear to be associated with cholinergic urticaria and can not be reproduced by hot bathing. It often occurs in patients sporadically and unpredictably, and appears to be a distinct entity [38]. It is possible that some are examples of unrecognized food and exercise-induced anaphylaxis.

Rarely, a generalized eruption resembling cholinergic urticaria may be provoked by systemic chilling [39].

The diagnosis of cholinergic urticaria is best confirmed by provocation, with the appearance of typical weals after warming—for example in a hot bath at 42°C for 15 min, to raise the core temperature by 0.7 to 1°C—or exercise in a hot environment [40]. Intradermal injections of cholinergic drugs such as methacholine produce local axon reflex sweating and sometimes the appearance of satellite weals. However, this test is unreliable and not specific enough to be useful [40]. A few patients find that if they can bring on a severe attack by suitable exertion they can achieve freedom for up to 24 h afterwards, analogous to temporary desensitization.

Heat contact urticaria [41,42]

This is one of the rarest forms of physical urticaria. Localized warming of skin at temperatures varying from 38 to 50°C for 2–

5 min induces wealing at the test site lasting 1 h. Treatment with antihistamines or induction of tolerance by repeated heat exposure may be helpful [43].

Cold urticaria [44,45]

Cold urticaria encompasses a variety of syndromes in which cold induces urticaria (see Table 22.9). Idiopathic cold contact urticaria is the most common, comprising 96% of a series of cold urticaria patients [46], while others are rare. In some patients with idiopathic cold contact urticaria, the serum can passively transfer the cold urticarial response to normal recipients. This autoantibody is usually IgE-like [47], but IgM has been recorded. It is important to warn against cold-water bathing due to the risk of anaphylaxis and drowning. Treatment with low-sedation antihistamine is helpful. Induction of tolerance by repeated graduated exposures to cold can be helpful for selected patients [48,49], but it is time consuming and not always effective.

Idiopathic cold urticaria

Immediate cold contact urticaria. This is by far the commonest form, occurring at any age but most frequently in young adults. It may be preceded by non-specific upper respiratory viral infections, infectious mononucleosis or insect bites. Itching and wealing of the skin occur on cold exposure within minutes and last up to 1 h. Cold winds and cold rain are particularly effective stimuli. Sometimes, the mouth and pharynx may swell after drinking cold liquids. Systemic symptoms include flushing, palpitations, headache, wheezing and loss of consciousness, and drowning has occurred after cold-water bathing.

Dermographism and cholinergic urticaria are frequently associated with cold urticaria. The average duration of cold urticaria was 6 years in one series [46], but it may persist for many years.

Diagnosis is made by application of an ice cube in a thin plastic bag for up to 20 min onto the skin, and wealing occurs within 15 min, usually during rewarming [45] (Fig. 22.8). Sometimes a more extensive local challenge, such as immersion of a forearm in iced cold water, is necessary. A temperature testing device has recently been described (TempTest®, Berlin) which allows temperature thresholds to be established for individual patients as well as cold stimulation time as a measure of severity [50].

Delayed cold contact urticaria. This form, where wealing occurs after a delay of hours after cold contact, is very rare [51]. A familial form has been reported [52].

Localized cold contact urticaria. This is very rare [53].

Familial cold urticaria. This rare form is inherited as an autosomal-dominant trait and is now known to be caused by the same gene mutation as Muckle–Wells syndrome [54] (p. 22.24). The ice cube test is negative.

Acquired cold contact erythema. Painful erythema without wealing occurs in response to cold [55], but in other patients it may be a forme fruste of immediate cold contact urticaria.

Fig. 22.8 Wealing following an ice-pack application for 20 min. (Courtesy of St John's Institute of Dermatology, London, UK.)

Cold urticaria secondary to serum cryoproteins

This is rare and was found in only 1% of one series [46]. It is usually associated with other manifestations such as Raynaud's phenomenon, purpura or skin necrosis. Cryogobulinaemia may be idiopathic or occur in collagen vascular disease, chronic lymphatic leukaemia, myeloma and in infectious disease, including infectious mononucleosis. Cold urticaria is said to occur in only 3% of people with cryoglobulinaemia [56]. Blood samples for cryoprotein estimation must be kept warm until laboratory testing. Treatment is directed against the underlying condition. Cryofibrinogen occurred in the blood of 3.4% of a large hospital population [57], and in 3% of patients in cold urticaria [58]. Its significance in relationship to cold urticaria remains to be determined. Cold agglutinins are not usually associated with cold urticaria [59]. Cold haemolysins have not been detected.

Systemic cold urticaria

In generalized reflex cold urticaria, widespread wealing occurs in response to cooling of core body temperature, but a local ice-cube test is negative [60]. Testing is performed by placing the patient in a cold room at 4°C for 30 min in lightweight clothes. In cold-induced cholinergic urticaria, additional exercise is necessary in the cold room to induce weals.

Solar urticaria [61–63]

Weals develop at the site of exposure within minutes of visible, long- or short-wave ultraviolet radiation [63] and usually fade within 2 h, in contrast to polymorphic light eruption, in which urticated lesions appear hours later and last days. A rare delayed

Fig. 22.9 Aquagenic urticaria on the back after swimming, showing a few small papular weals surrounded by wide flares. (Courtesy of Norfolk and Norwich University Hospital, UK.)

form has been described [64]. The cause of solar urticaria is usually unknown (idiopathic) but may be secondary to porphyrias [65]. The pathogenesis is discussed in Chapter 29.

Aquagenic urticaria [66,67]

Contact with water at any temperature induces an eruption resembling cholinergic urticaria, although the weals are few in number and are surrounded by a wide flare (Fig. 22.9). Other urticarias that can also be induced by water, such as cold urticaria, cholinergic urticaria and dermographism, must be excluded. This is a different entity from aquagenic pruritus, in which there is water-induced itching but no wealing [68,69].

Urticarial vasculitis [1–3]

Some urticarias are considered to be due to a type III hypersensitivity immune reaction, with deposition of immune complexes in blood vessels and other tissues and are often associated with systemic symptoms. The archetypal reaction is serum sickness [4], which presents as an acute illness. Some acute drug allergies give rise to a serum-sickness response. Classically, serum sickness follows parenteral injections of therapeutic sera, the immune complexes consisting of antigen and IgG, usually with antigen excess (type III reaction). The immune complexes activate complement and are deposited in tissues, including skin. It was a prevalent illness in the pre-antibiotic era—when heterologous antisera were used extensively to treat diphtheria, scarlet fever and pneumococcal pneumonia—but is now uncommon. Other causes of serum sickness-like syndrome include drugs, especially penicillin, radiocontrast media, hepatitis B infections and, rarely, foods. Onset is after 1–3 weeks, or more quickly if there has been previous exposure. Urticarial lesions are persistent, lasting a few days, and are sometimes tender or painful with bruising. Systemic features include fever, arthropathy, lymphadenopathy, cough, gastrointestinal disturbances and nephritis. The illness usually lasts for 5–28 days.

Urticarial vasculitis is essentially the same condition, but is frequently chronic, although it may be intermittent. The cutaneous lesions resemble urticaria in appearance, but histologically demonstrate vasculitis (venulitis). Characteristic histological changes include endothelial swelling, extravasation of red cells and a perivenular cellular infiltrate rich in neutrophils, with leukocytoclasia and fibrinoid deposits in and around blood vessels [1] (Fig. 22.10). Occasionally, a lymphocytic or eosinophilic infiltrate may be prominent. The minimum criteria for vasculitis are evidence of vessel damage and/or leukocytoclasia.

Serum hypocomplementaemia may be present in a minority of patients. When it is, serum $C1_q$ levels are reduced and $C1_q$ precipitins, which are IgG autoantibodies against the collagen-like region of $C1_q$, are increased. These anti-$C1_q$ autoantibodies are also present in SLE, suggesting a relationship between the two conditions. However, no cause can be found in most cases of urticarial vasculitis. Only a minority are associated with infections (from hepatitis B and C, Epstein–Barr virus and *Borrelia burgdorferi*), serum sickness, collagen vascular disease (including lupus erythematosus and Sjögren's syndrome) or hypergammaglobulinaemia (including Schnitzler's syndrome, where IgM gammopathy is associated with fever, lymphadenopathy and bone pain). Drugs, such as cimetidine and diltiazem, and haematological diseases [1] are very rare causes.

Compared with lesions of ordinary urticaria, lesions of urticarial vasculitis usually persist for more than 24 h and may burn as well as itch, be tender or painful and sometimes resolve with

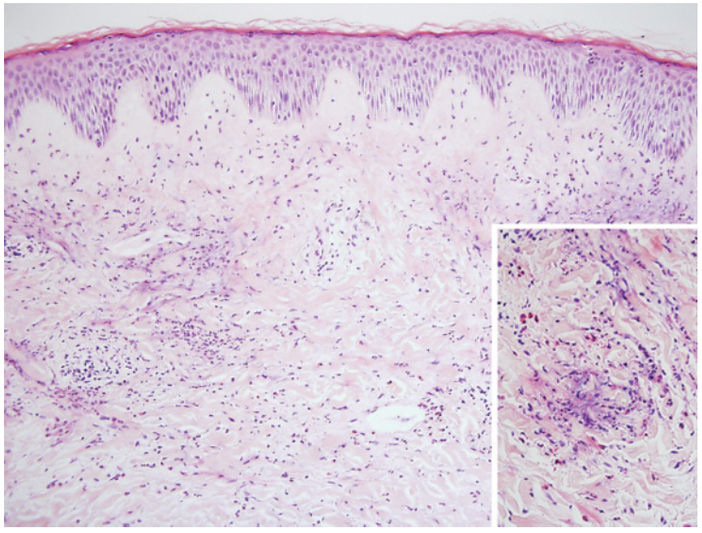

Fig. 22.10 Histology of a spontaneous lesion from a patient with urticarial vasculitis showing a heavy perivascular and interstitial inflammatory infiltrate with leukocytoclasia, eosininophils and damage to the blood vessel wall (inset).

Fig. 22.11 Lesions of urticarial vasculitis which had been present for 2 days. (Courtesy of St John's Institute of Dermatology, London, UK.)

residual bruising or staining (Fig. 22.11). Angio-oedema is present in up to 40% of cases [1]. However, it is often not possible to distinguish urticarial vasculitis from urticaria by the clinical appearance of the lesions. Systemic involvement is common; the most frequent symptom, affecting more than 50% of cases, is arthralgia, which is usually flitting and migratory, but frank arthritis is rare. Gastrointestinal involvement, with abdominal pain, nausea and vomiting, occurs in approximately 20%. A similar percentage are affected with pulmonary disease, characteristically pulmonary obstructive disease found in smokers, especially in hypocomplementaemic urticarial vasculitis (HUVS). Microscopic proteinuria and haematuria occur in 5–10% of patients, but in the absence of connective tissue disease, progression to severe renal disease is unlikely. Rarer manifestations include Raynaud's phenomenon, lymphadenopathy and splenomegaly, conjunctivitis, episcleritis, uveitis, pseudotumour cerebri, myositis, pericardial and pleural involvement.

The diagnosis is established on lesional skin biopsy. Laboratory abnormalities are common, with a raised ESR being the most frequent. Hypocomplementaemia probably occurs in fewer than 50% of cases, but often correlates with the severity of systemic involvement. Other abnormalities sometimes found include circulating immune complexes, a positive antinuclear and rheumatoid factor (usually in low titre) and presence of cryoglobulins and anti-$C1_q$.

Investigations should include a search for the occasional associated disease, and for any systemic involvement. They should include a full blood count and ESR, urinalysis, renal and liver function, serum complement and immunoglobulins, and chest radiograph. Further testing depends on other suspected clinical involvement.

Overall, the disease has a relatively benign course lasting an average of 3 years [1], although it can persist for many years.

Contact urticaria [1]

Contact urticaria is quite common, but is not usually a cause of hospital referral unless there is an occupational problem, for instance latex allergy due to glove use. The term simply means urticaria resulting from skin or mucosal contact with the provoking substance. It may be allergic or non-allergic (also called immunological and non-immunological). The range of chemical, plant, animal and food exposures causing contact urticaria is very wide [2] (Table 22.11).

Allergic

Percutaneous or mucosal penetration of an allergen to which the individual has already developed specific IgE will result in a type I hypersensitivity response involving mast cell degranulation with histamine release. This may result in an immediate, localized weal and flare resolving within 2 h, an acute episode of generalized urticaria, or even anaphylaxis if the individual is extremely hypersensitive. It is easily missed when it is responsible for exacerbations of a pre-existing eczema, for example in atopic children. Weals occur at sites of contact with the allergen, usually therefore on the hands and face. The commonest causes are foods (for example, nuts, fish, fruits) or latex. Diagnosis can be confirmed by CAP fluoroimmunassay (previously the radioallergosorbent test, RAST) if there is a history of anaphylaxis, or by skin-prick testing.

Table 22.11 Some causes of contact urticaria.

Allergic (immunological)
Cow's milk
Cod
Kiwi fruit
Peanuts
Sesame seeds
Spices
Celery
Non-allergic (non-immunological)
Balsam of Peru
Cinnamic aldehyde
Methyl salicylate
Benzoic acid
Sorbic acid
Witch hazel
Jellyfish
Nettles

Management is largely directed at avoidance of the allergen, although taking an antihistamine prophylactically reduced the number of episodes of urticaria in atopic children [3].

Oral allergy syndrome [4]

This is a form of allergic contact urticaria involving the mouth, characterized by immediate itching, swelling and burning after eating a wide range of fresh fruits, including apples, pears, cherries, plums, celery, spices and hazelnuts. Eating cooked, dried, peeled or bottled fruit often does not cause symptoms. The symptoms are due to cross-reactions between profilins (ubiquitous panallergens in plants, including grass and mugwort in north Europe) and Bet v.1 (the major allergen in silver birch pollen) and homologous proteins in plants, especially fruits. Oral allergy syndrome therefore occurs in patients with respiratory allergies to common pollens (pollinosis). Diagnosis is by skin-prick testing with the fresh fruit. CAP and skin-prick testing with commercial standardized solutions may be negative. Fortunately, the condition only rarely progresses to angio-oedema, and treatment with antihistamines is not usually necessary.

Non-allergic

This form of contact urticaria may be caused by direct injection of vasoactive chemicals by plants (e.g. nettles) or animals (e.g. caterpillars, jellyfish). A more common form, though, is from exposure to cosmetics (e.g. cinnamic aldehyde, balsam of Peru) or food additives (e.g. sorbic acid or benzoic acid). Occupational exposures include ammonium persulphate in hairdressers. The reaction may take up to 45 min to develop and is thought to be due to PGD_2 formation rather than histamine release, since it can be blocked by NSAIDs. The relevant investigation is either a prick test or patch test, read at 15–45 min rather than 48 h.

Angio-oedema (without weals) [1]

It is useful to separate angio-oedema without weals from angio-oedema with weals, as may occur in ordinary, physical and vasculitic urticarias, since the aetiology, investigation and management may be different. The same multiple aetiologies for angio-oedema and frequent lack of precise diagnosis are found as in chronic ordinary urticaria [2]. Several clinical subtypes are recognized (Table 22.12). The most common identifiable causes of angio-oedema without weals are ACEI-induced angio-oedema and C1 esterase inhibitor deficiency.

Idiopathic angio-oedema

Synonyms
- Angioneurotic oedema
- Quincke's oedema

This is a variant of urticaria in which the subcutaneous tissues, rather than the dermis, are mainly involved. The term 'angioneurotic oedema' is somewhat misleading. It was originally considered to be an abnormality of the nerve supply of the small blood vessels, without the implication of emotional disturbance that the word now suggests. Almost any part of the body may be involved, but the commonest sites are the lips (Fig. 22.12), eyelids and genitalia. The tongue and pharynx may also be affected. Individual lesions may be single or multiple and may appear with dramatic suddenness. Itching is often absent. The lesions last for a few

Table 22.12 Classification of angio-oedema without weals.

Acquired
Idiopathic
Drug-related, especially:
Angiotensin converting enzyme inhibitors
Non-steroidal anti-inflammatory drugs
Physical
Exercise-induced angio-oedema
Vibratory angio-oedema
Acquired C1 esterase inhibitor deficiency
Lymphoproliferative disease
C1 inhibitor autoantibody
Others (including systemic lupus erythematosus)
Episodic angio-oedema with eosinophilia (Gleich's syndrome)
Hereditary
Hereditary angio-oedema
C1 esterase inhibitor deficiency
Type I (reduced absolute level of C1 esterase inhibitor)
Type II (reduced functional inhibitor but normal or increased level)
Normal C1 esterase inhibitor
Type III (oestrogen-dependent)

hours, or occasionally persist for 2–3 days. Differential diagnosis includes eczema especially of the eyelids, cellulitis, lymphoedema, idiopathic oedema, idiopathic scrotal oedema and the Melkersson–Rosenthal syndrome.

The management of idiopathic angio-oedema is essentially the same as that for acute urticaria, except that mucosal lesions may occur and cause great distress. Emergency treatment of mucosal lesions is discussed along with anaphylaxis in Chapter 74. However, in contrast to hereditary angio-oedema and ACEI-induced angio-oedema, described below, life-threatening swellings are very rare. The treatment of non-histaminergic angioedema due to C1 esterase inhibitor deficiency is completely different and is discussed below.

ACEI-induced angio-oedema

ACEIs have a special ability to cause angio-oedema, nearly always without associated weals [1]. The mechanism is thought to relate to the ability of ACEIs to prolong bradykinin survival and potentiate its effects by inhibiting ACE, also known as kininase II [2]. Most cases develop within 3 weeks of commencing treatment, but can occur at any time during treatment, even years after starting. Angio-oedema affects the face and oral mucosa predominantly. Symptoms may be severe, and laryngeal involvement may be life-threatening. Intravenous antihistamines and corticosteroids have been used, sometimes repeatedly, and epinephrine injections should be given if swelling involves the airway [1], although the development of a bradykinin receptor antagonist, icatibant, is likely to be more effective and may well become the treatment of choice. Reactions are more likely to occur if the patient has had previous episodes of angio-oedema, is Afro-Caribbean, has ACEI-induced cough or has hereditary angio-oedema [3]. If such reactions do occur, it is not safe to change to one of the other ACEIs, which should be used with great care (or avoided) with angio-oedema of any cause. The angiotensin II receptor antagonists ('sartans') should also be prescribed with caution since angio-oedema has also been described in a few patients previously intolerant of ACEI, but probably by another mechanism that has been proposed to involve nitric oxide release with potentiation of the effects of bradykinin [2].

Hereditary angio-oedema [1]

This is a rare disorder, accounting for less than 5% of all cases of angio-oedema without weals. It has an estimated prevalence of 1:50 000. It is transmitted as an autosomal-dominant trait on chromosome 11. At a molecular level, several different mutations have been identified. A family history is usually, but not invariably, apparent. However, it must be remembered that a family history is not infrequent in the ordinary presentation of urticaria with angio-oedema. The clinical picture usually allows the diagnosis to be made before laboratory confirmation. Over 75% of cases present before puberty [1], but the onset may be delayed even into late adult life. There are recurrent swellings of the skin and mucous membranes throughout life, often associated with nausea, vomiting, colic and urinary symptoms. These attacks may occur regularly every few weeks, or may be less frequent. Between the attacks, the patient is well. Abdominal symptoms may occur in the absence of skin changes and cause great diagnostic difficulty. In one large series [2], 34% of patients had undergone abdominal surgery. Pharyngeal, laryngeal and even bronchial involvement, are especially significant and dominate the prognosis. The skin and mucosal lesions are often solitary and may be painful. They seldom itch. They may appear spontaneously or after trauma; dental trauma and intubation being especially hazardous. Weals do not occur, but there may be a rather distinctive reticulate erythema, perhaps with minimal oedema, which occurs prodromally [3] (Fig. 22.13) in some families. Some patients have a relatively minor disability and may improve over many years. In other families, before the advent of modern therapy, over 20% of cases used to die of respiratory obstruction before early middle age, and fatalities are still at risk of occurring.

The blood of these patients is deficient in a natural inhibitor of C1 esterase, which is made in the liver under genetic control. It seems to require the activity of both alleles to maintain normal levels. The inhibitor is present either in reduced amounts (type I) or, in 15% of affected families, in an inactive form, although it can be detected in normal amounts immunologically (type II).

A third type of hereditary angio-oedema has been proposed that is mainly restricted to women with a family history of recurrent angio-oedema, including swellings of the upper airway, but with normal levels of plasma C1 esterase inhibitor and C_4 [4]. The

Fig. 22.13 The prodromal eruption of hereditary angio-oedema. 'Chicken-wire' reticulate erythema/urticaria, non-pruritic, on the trunk of a woman aged 38 years who had had numerous episodes over many years, each one lasting many hours or even days. Many attacks, but not all, were followed within 24 h by classical attacks of hereditary angio-oedema, confirmed by history and laboratory confirmation of C1 esterase deficiency. (Courtesy of Dr A.P. Warin, Royal Devon and Exeter Hospital, UK.)

term hereditary oestrogen-dependent angio-oedema has been proposed to distinguish this entity from hereditary C1 esterase inhibitor deficiency [5]. Mutations in the Hageman factor XII have been identified in some affected families [6].

C1 esterase inhibitor is a natural inhibitor of the activated first component of complement, kallikrein and the fibrinolytic and coagulation systems. It may be that attacks are triggered by stimuli that normally activate Hageman factor and hence consume the deficient inhibitor. This C1 esterase inhibitor deficiency may be detected antigenically, but functional assays are necessary to detect type II hereditary angio-oedema. The components of complement (C_2, C_4 and CH50) are low during, after and to some extent even between attacks, or in symptomless carriers. Complement C_4 is nearly always low, and its measurement may be used as an initial screening test. There is no clear correlation between the clinical severity and laboratory abnormalities. There is a weak association with autoimmune diseases, including Sjögren's syndrome and SLE [7].

The response of hereditary angio-oedema to conventional treatment for urticaria is generally poor. Antihistamines, steroids and even epinephrine are said to be of little or no help. Not all patients need treatment. It may be considered as long-term prophylaxis, short-term prophylaxis and the emergency management of an established attack. Oestrogen therapies, such as the oral contraceptive pill, may induce or exacerbate hereditary angio-oedema [8] and should be avoided if possible.

Androgens have been used prophylactically for many years with some success, but more recently the lives of many of these patients have been revolutionized by the use of attenuated androgen/anabolic drugs such as danazol and stanozolol. They stimulate the production of the deficient inhibitor. Long-term treatment is often required and may cause androgenic problems in women and children. The usual starting doses are danazol 200–600 mg daily or stanozolol 1.0–5.0 mg daily. However, considerably smaller doses given intermittently on several days of a week may suffice. The dose is assessed on the clinical response, rather than any changes in the laboratory tests, as improvement may occur even when the C1 esterase inhibitor levels remain low. Liver function tests and blood lipids should be monitored during long-term treatment, and benign hepatic adenomas have been reported. Such therapy may also be used for short-term prophylaxis, for example 48 h before and after dental surgery, at the higher dose ranges [1]. Some, but not all, cases of the acquired variant of the disease (see below) also respond to this therapy. Epsilon amino caproic acid (not available in the UK), 12–18 g daily, or the related tranexamic acid 2.0–4.5 g daily, has been found to help some patients, but these drugs are contraindicated with thrombosis. They are less effective than danazol or stanozolol, but are useful where androgens are contraindicated, especially for short-term prophylaxis. Replacement therapy with fresh frozen plasma has been used for short-term prophylaxis and appears to work as well as purified C1 inhibitor [9], which is now widely available. It is the treatment of choice for severe attacks, especially laryngeal oedema and abdominal colic, or it can be used for short-term prophylaxis [10] prior to procedures placing the patient at risk of laryngeal swelling, including dental extraction, endoscopy or intubation. Symptoms usually subside in 30–90 min [2]. Development of a bradykinin receptor 2 antagonist, icatibant [11], a kallikrein inhibitor, DX-88 [12], and a recombinant C1 esterase inhibitor [13] offer the promise of more specific and targeted therapies for patients in the near future.

Acquired C1 esterase inhibitor deficiency angio-oedema [14–18]

An acquired deficiency of the inhibitor may also give rise to a picture very similar to the hereditary form but with later onset. This may be associated with:

1. B-cell lymphoma in which anti-idiotypic antibodies against the monoclonal antibody expressed on the surface of the abnormal cells activate complement with consumption of $C1_q$ and of its inhibitor
2. SLE [19]
3. An antibody directed against the inhibitor, but without any evidence of lymphoma

The laboratory changes are similar to those of hereditary angio-oedema, except that the C1 levels are also decreased. Danazol is helpful in some cases, but not the autoantibody type, which also fails to respond to replacement therapy but may be helped by tranexamic acid and corticosteroids. Rituximab has been reported to give long-lasting improvement in one patient [20].

Episodic angio-oedema with eosinophilia [1,2]

Recurrent episodes of angio-oedema and weals associated with pyrexia, blood eosinophilia and infiltration of the dermis with eosinophils have been described. There is no evidence of systemic involvement or progression to a cardiomyopathy. Each episode resolves with prednisolone treatment. During an attack, elevated serum levels of IL-5 have been demonstrated in some cases [3], IL-6 in others [4] and a subsequent increase in TNF-α in others with a more transient variant [5].

Other syndromes resembling urticaria or angio-oedema, or with urticaria as one component

Papular urticaria [1]

The term is misleading since lesions last for days or weeks rather than hours and should not therefore be regarded as urticaria. Injection of foreign protein by biting insects into skin of the most sensitive subjects may cause an immediate IgE-mediated reaction consisting of weals. A punctum is often visible on the weal, which may blister. This reaction sometimes evolves into a delayed hypersensitivity reaction, leading to intensely itchy, indurated papules lasting weeks or months. It is most commonly seen on the legs of children after flea and mosquito bites.

Systemic capillary leak syndrome [1–3]

Synonym
- Clarkson's syndrome

This is a rare syndrome in which there are dramatic, recurrent attacks of exudation of fluid into various organs and may involve the skin. Attacks of angio-oedema have been reported. A severe shock-like state may ensue and the eventual mortality is high. There is an IgG paraproteinaemia. The response to treatment has been poor, although patients have been helped by a combination of aminophylline and terbutaline [4]. A similar syndrome may follow therapy for metastatic cancer with IL-2 [3].

Schnitzler's syndrome [1–5]

Synonym
- Urticarial vasculitis with monoclonal gammopathy

This syndrome was first reported in 1974 [1]. There is chronic urticaria, often with rather persistent, non-itchy weals suggesting an urticarial vasculitis, which is sometimes confirmed by histology but more usually shows a neutrophilic urticaria [6]. Bone pains, with associated radiological bone changes, are present in half the cases. Malaise, fever and lymphadenopathy may occur. The characteristic finding is a monoclonal gammopathy—usually IgM, but perhaps IgG [7]. An IgG autoantibody against IL-1α was found in the sera of patients with Schnitzler's syndrome more frequently than controls [8], although the significance of this in the pathogenesis is not certain. The overall prognosis is often, but

not always, benign. Long-term follow-up is required, because evolution to Waldenström's macroglobulinaemia may occur [9]. Symptomatic treatment has included NSAIDs, thalidomide, colchicine, dapsone and IFN-α but sometimes prednisolone is required. Antihistamines are unhelpful. There have been recent encouraging reports of complete responses to anakinra and pefloxacin. A review of the response to treatments and prognosis of 94 patients in the world literature summarizes the range and success of different therapies to date [10]. The clinical behaviour of Schnitzler's syndrome and response to anakinra suggest that it may be regarded as an acquired periodic fever syndrome.

Hereditary periodic fever syndromes

Cryopyrin-associated periodic syndrome

Synonyms
- Muckle–Wells syndrome
- Familial cold urticaria
- NOMID

Urticaria is a common feature of these rare, autosomal-dominant, autoinflammatory syndromes, which are due to mutations in a common gene called *CIAS1* on chromosome 1q.44, encoding a protein with a pyrin domain [1]. They nevertheless have distinctive phenotypes. The term cryopyrin-associated periodic syndrome (CAPS) has been proposed to embrace a common pathogenesis [2].

During childhood and adolescence, patients with Muckle–Wells syndrome [3–5] suffer recurrent bouts of urticaria with chills, fever and malaise, lasting 24 h. The urticaria may start from birth and may occur daily throughout life. There may be actual weals or sometimes only macular erythema (Fig. 22.14). Conjunctival erythema may occur. Over the next two to four decades, sensory deafness appears, and in some cases progressive nephropathy due to amyloidosis. Amyloidosis is present in other parts of the body in the prereticulin pattern of deposition. C-reactive protein is persistently high and serum amyloidosis A protein levels are raised considerably.

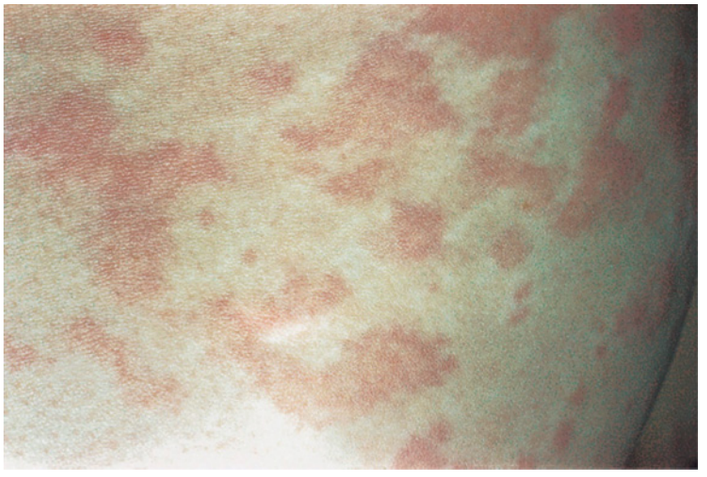

Fig. 22.14 Muckle–Wells syndrome. The characteristic, often rather faint, transient, sometimes erythematous, sometimes urticarial eruption. (Courtesy of Addenbrooke's Hospital, Cambridge, UK.)

The condition, which is inherited as an autosomal dominant trait, must be distinguished from familial Mediterranean fever, which has autosomal-recessive inheritance, and other forms of renal amyloidosis. The onset of familial cold urticaria is also noted in infancy and persists for life [6–8]. Non-itchy weals occur in response to a drop in body temperature and can persist for 48 h but may be short-lived. Fever, headache and a leukocytosis may accompany the rash. An ice-cube test is negative. Neonatal onset multisystem disease (NOMID) has a more severe phenotype than Muckle–Wells syndrome or familial cold urticaria, including arthritis, neurological and developmental impairment. All patients with CAPS treated to date have made a dramatic clinical and biochemical response to anakinra [9] and trials of a novel long-standing interleukin-1 beta antagonist are on-going.

Familial Mediterranean fever [1,2]

Familial Mediterranean fever usually has autosomal-recessive inheritance and a striking predilection for Sephardic Jews, Armenians and Arabs. The gene responsible *MEVR1* is carried on the short arm of chromosome 16. Many patients present with recurrent, self-limiting attacks of fever and a tendency to peritonitis, pleurisy and synovitis. Skin lesions include rather distinctive, erysipelas-like lesions on the lower leg, but urticarial and vasculitic lesions may occur rarely [3,4]. About one-quarter of patients develop or even present with renal amyloidosis, which is often fatal. Some symptoms are controlled by colchicine.

Hyper-IgD syndrome [1–4]

A few cases have been recognized since its first description in 1984 [1]. It has some features in common with familial Mediterranean fever and Muckle–Wells syndrome, but appears to be a distinct entity. The clinical features include periodic fever and skin lesions, among which are erythematous macules, urticaria, annular erythema and nodules. Other findings include joint pains, abdominal pain, cervical lymphadenopathy, leukocytosis and raised ESR. The special finding is a raised IgD level in the blood, although it is uncertain how this is related to the other findings. There is no tendency to amyloid deposition. The response to treatment is unsatisfactory.

TNF-receptor-associated periodic syndrome (TRAPS)

Synonym
- Familial hibernian fever [1,2]

This multisystem disorder comprises a recurrent migratory erythematous rash, fever, arthralgia, synovitis, conjunctivitis, pleurisy and amyloidosis of the kidneys and liver due to mutations in the TNF receptor I gene on chromosome 12. Levels of soluble TNF receptor are reduced in the blood during disease activity because the receptor is not shed from monocytes and neutrophils. Although the rash is typically migratory and macular rather than urticarial, oedematous plaques lasting up to 21 days may occur [2]. The condition should be considered in the differential diagnosis of the periodic fever syndromes.

Clinical history taking and diagnosis

The clinical diagnostic process is the same for all urticarias. A comprehensive history is essential for diagnosis and elucidation of any causative factors, as weals are often not present at the time of consultation. Performing an extensive panel of investigations in addition to a standardized questionnaire added little to making a final diagnosis [1]. Information should be obtained regarding the onset, duration and course of the disease. The duration of individual weals and presence of purpura are important. Weals lasting more than 24–48 h, particularly if painful or tender, suggest the possibility of urticarial vasculitis or delayed pressure urticaria, but can occur in ordinary urticaria. Purpura, although rarely seen, suggests urticarial vasculitis, but can occur in ordinary urticaria. The location, numbers and shapes of weals vary and are usually not helpful in differentiating most urticarias, except for the typical small, monomorphic, short-lasting weals of cholinergic urticaria and the linear weals of dermographism. The occurrence of angio-oedema should be noted, particularly if it has affected the oropharynx with difficulty in swallowing or breathing. Enquiry should be made for systemic symptoms sometimes associated with cutaneous lesions, including malaise, headache, abdominal pain, arthralgia, wheezing and syncope. Possible precipitating or aggravating factors—including physical factors such as heat, cold, localized pressure on the skin, friction and sunlight—should be sought directly. It is important to ask about any association with recent acute infection, drugs, non-prescription medicines and foods, although the latter are rarely a cause for chronic urticaria. A family history of atopy, autoimmunity or angio-oedema may be useful information.

Differential diagnosis

The diagnosis of urticaria is rarely a problem. Weals are distinguished by their evanescent nature and normal overlying epidermis. Papular urticaria, erythema multiforme and prebullous eruptions must be distinguished from urticaria. Acute contact dermatitis, lymphoedema and collagen vascular disease (such as dermatomyositis) may mimic angio-oedema, but these conditions last longer than 24–48 h. The part played by urticarial reactions in atopic dermatitis is discussed in Chapter 24.

Investigation of urticaria (Table 22.13)

Acute urticaria

In patients with potentially life-threatening reactions to an allergen, confirmation is by CAP fluoroimmunoassay that measures serum allergen-specific IgE to the allergen or skin-prick testing (SPT), for example for peanut sensitization. In most cases of acute urticaria in which no cause is suggested in the history, investigation rarely provides an answer. Prick testing is potentially dangerous if there is a background of anaphylaxis. Epinephrine administration for severe reactions may be less effective in patients on β-blocking drugs. The clinical relevance of the results of skin-prick and CAP tests needs careful evaluation. Routine prick testing in chronic urticaria is unhelpful [1].

Chronic urticaria

A thorough history of the rash and any associated systemic symptoms is essential. Attention should be paid to medication, especially NSAIDs. It is important to identify an associated physical urticaria, especially delayed pressure urticaria, by appropriate testing (see Physical urticarias). If weals persist and are painful, with systemic symptoms of fever or arthralgia, urticarial vasculitis should be considered, and a skin biopsy performed of a spontaneous lesion, preferably one that is 12–15 hours old. Patients frequently suspect allergy to foods, but this is rarely if ever found in adults with chronic ordinary urticaria. A food diary may be helpful, especially in episodic urticaria, but it should be remembered that the time interval may vary from a few seconds with allergy and up to 24 h with dietary pseudoallergens, and the substance may have been consumed regularly for years. If the patient suspects food additives, or if they have improved substantially on elimination of the substance or on a diet free of food additives, challenge testing can be carried out on a placebo-controlled basis. This is performed when the patient is in relative remission, and antihistamine therapy need not be stopped, although this is desirable. Daily coded test substances (see Table 22.10) are given orally in a gelatin capsule, with placebo capsules preceding different types of additives [2]. The most important test substances are tartrazine (E102), aspirin, sodium benzoate (E211) and 4-hydroxybenzoate (E214–219). The patient records any urticarial response, and if present the suspected substance and placebos should be re-administered on at least one occasion for confirmation of the results. When the provocation tests are positive, a tartrazine-free, salicylate-free or other appropriate diet can be suggested and is usually only necessary for a few months [3]. It is usually inappropriate to carry out provocation tests in patients who respond well to antihistamines. A low-pseudoallergen diet may be helpful for some patients [4], especially if antihistamines have failed or are not accepted.

Skin-prick or intradermal tests are even less helpful, and there were no relevant unsuspected positive tests in a group of urticaria patients [1]. In addition, a positive skin test is difficult to interpret, as an atopic patient with urticaria will show many irrelevant positive results, and false-negative results may also occur. Although a few patients with chronic urticaria and a positive intradermal test to *Candida albicans* were helped by an anti-*Candida*/antiyeast regimen (nystatin orally and vaginal pessaries, amphotericin lozenges and a yeast-free diet for 2–4 weeks) [5], this has not been our experience.

Other investigations are aimed at finding any associated disease, but it is uncommon for a cause of urticaria to be found in the absence of some lead from the general history. A full blood count and erythrocyte sedimentation rate (ESR) should be performed routinely. An elevated ESR suggests the possibility of an underlying systemic disease (lupus erythematosus, urticarial vasculitis, macroglobulinaemia), and an eosinophilia would prompt a search for parasitic disease. Thyroid function tests and thyroid autoantibodies may be worthwhile, as around 14% of patients with chronic ordinary urticaria may have thyroid autoimmunity [6]. Clinical experience indicates that the proportion of severe chronic urticaria patients with thyroid autoimmunity is considerably higher than this, possibly up to 40% and this may be a surrogate marker for histamine releasing autoantibodies [7]. Initial reports suggest that treatment with thyroxine to suppress thyroid activity may resolve the urticaria [8]. Further tests depend on the history. Routine biochemistry, complement levels, serum proteins and electrophoresis, serum immunoglobulins, non-organ-specific and organ-specific autoantibodies, total and specific IgE, skin tests and fastidious searching for evidence of infection are not indicated [9]. There is currently no simple clinical test for serum histamine-releasing autoantibodies, although the ASST appears to be a reasonably sensitive and specific marker for them [10]. If angio-oedema is a major component of the disease, measuring plasma C4 complement should be performed as a screening test for hereditary or acquired C1 esterase inhibitor deficiency. It is reduced and rarely, if ever, reaches normal values even between attacks of C1 esterase deficiency angio-oedema. Functional C1 esterase inhibitor is reduced in hereditary and acquired disease. A skin biopsy may be helpful if the weals persist for more than 48 h and do not respond to antihistamines. Urticarial vasculitis or delayed pressure urticaria is then suspected.

Table 22.13 Investigation of urticaria.

Acute urticaria
Usually none, except where suggested by the history
Specific IgE (CAP fluoroimmunassay or skin-prick tests)
Tests for upper respiratory viral or bacterial infection
Episodic urticaria
Pseudoallergy challenge capsules (if available)
Food additives
Non-steroidal anti-inflammatory drugs
Chronic urticaria
Physical challenge provocation tests (where suggested by the history)
Blood tests (ordinary urticaria, if unresponsive to H1-antihistamines)
FBC, ESR, thyroid antibodies, thyroid function tests
C4 complement (angio-oedema without weals and urticaria vasculitis)
Autologous serum skin test (where facilities are available)
Basophil histamine release assay (if available)
Others: as determined by the history and physical examination
Skin biopsy (12–16 h old lesions, if urticarial vasculitis suspected)
Stool examination for parasites (if infection suspected)
Testing for *Helicobacter pylori* infection (if peptic ulcer symptoms)
Testing for coeliac disease (primarily symptomatic children)
Imaging: none routinely

Natural history

Acute attacks may last a few hours or days and be of great severity. There is no way of predicting the duration of an initial attack. Chronic cases where no diagnosis is established may last for weeks, months or even years, or be intermittent with repeated episodes occurring over decades. The severity is often greatest at the onset, with subsequent waning. New lesions appear daily or at irregular intervals, and there may be periodic exacerbations, sometimes associated with intercurrent infections or NSAID intake. In general, spontaneous improvement occurs even in the absence of diagnosis or treatment. Fifty per cent of cases of those with weals alone attending a specialist clinic can be expected to clear within 6 months of onset, but 50% of those with associated angio-oedema can still be expected to have their condition 10 years later [1] (Fig. 22.15). A more recent survey of the prognosis of patients attending a tertiary referral clinic in the Netherlands confirms the poor outlook for many patients with chronic urticaria, especially those with cold urticaria [2].

Management

Explanation and non-specific measures may be helpful. Patients should minimize overheating, stress and alcohol. Aspirin and

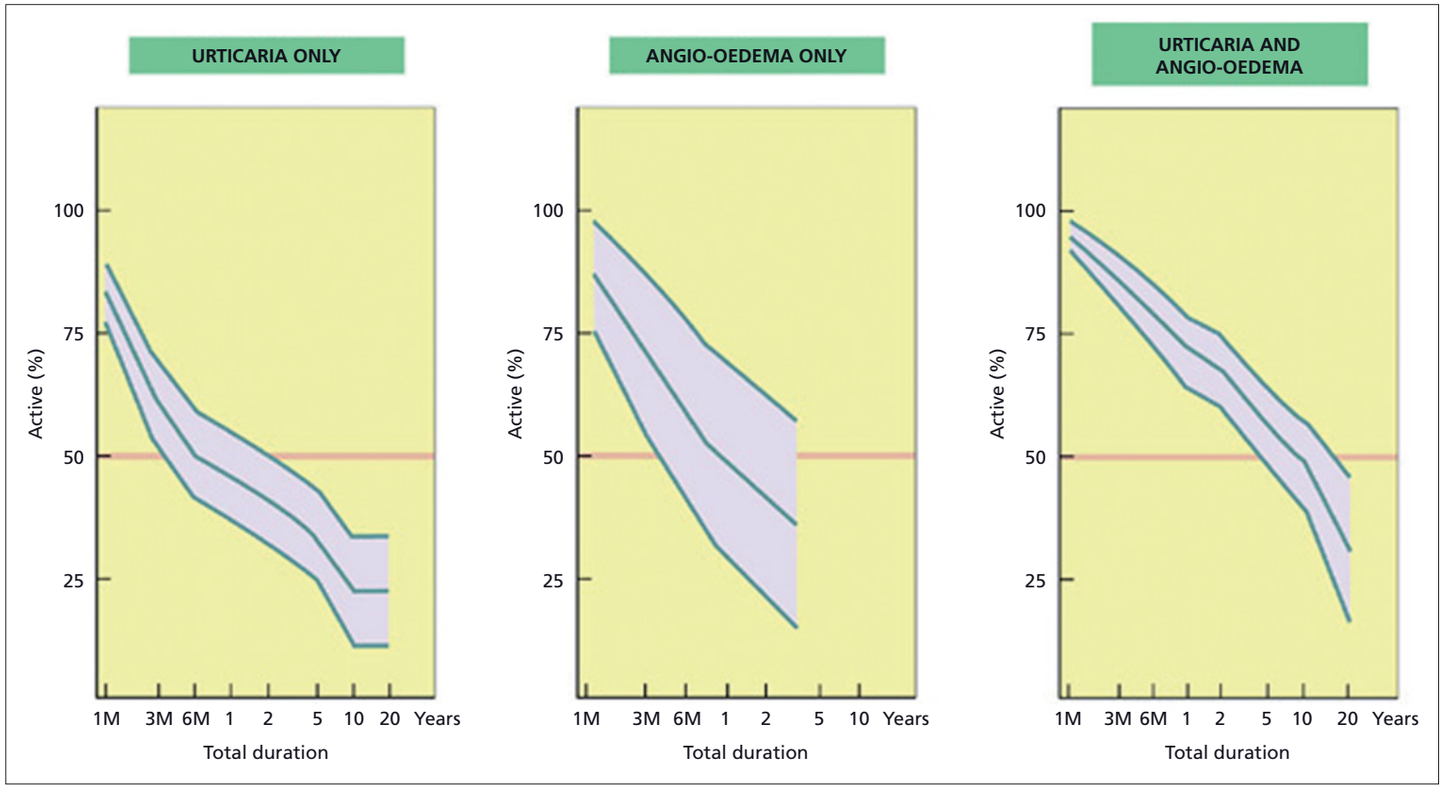

Fig. 22.15 The natural history of urticaria in 554 hospital patients. The expected percentage of patients with active urticaria, with 95% confidence limits, by the total duration of disease (log scale). M, months.

aspirin-containing compounds, other NSAIDs, and also opiates, should be avoided if possible. Paracetamol is usually a satisfactory alternative. Selective COX-2 inhibitors may be tolerated by aspirin-sensitive patients if an anti-inflammatory drug is essential. If food additives, colourings or preservatives have been proven to be a problem, diets excluding these substances may be of value to a limited number of patients. Drug therapies can be first-, second-, or third-line, the choice of treatment depending upon the response to previous measures [1] and the degree of impairment in quality of life for the patient (Fig. 22.16).

First-line therapies (antihistamines)

Histamine is the main mediator of urticaria, with H_1-receptor activation causing itch, wealing and flare, while H_2 activation plays a smaller role in weal formation. Thus, H_1 antihistamines are the first-line treatment of urticaria. Generally H_1 antihistamines are rapidly absorbed, reaching peak serum concentrations in 1–3 h.

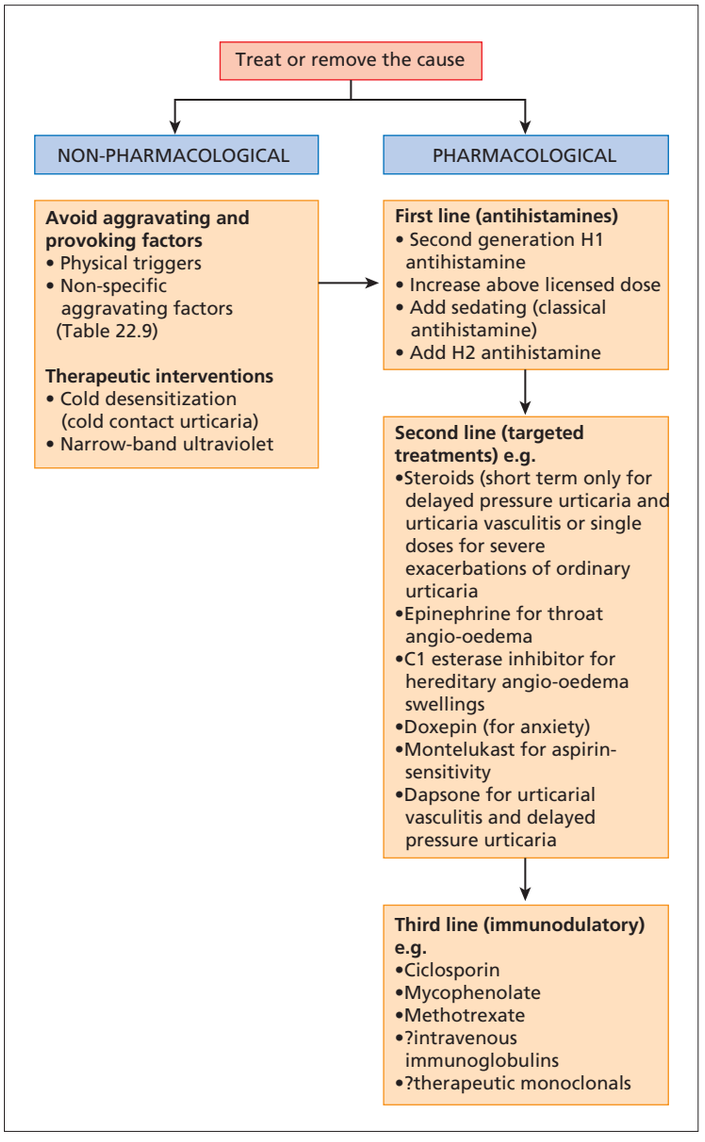

Fig. 22.16 Management of urticaria.

However, many are metabolized in the liver, and some active metabolites have a longer half-life than the parent compound and determine the activity profile of the medication. The main properties of second generation antihistamines, currently licensed in the UK, are summarized in Table 22.14.

Antihistamines for urticaria

The use of classical antihistamines is limited by their side effects, including sedation, anticholinergic properties and paradoxical excitation in children. There may be carry-over effects of sedation in the morning and patients should be warned of this. Hydroxyzine is the most potent of the classical antihistamines. Twenty five mg of hydroxyzine is equivalent to 10 mg of cetirizine.

The second generation of potent, specific, low-sedation H_1 antihistamines is now the treatment of choice [2]. Their main advantage is low sedation at doses recommended by the manufacturer and minimal anticholinergic side effects, although an occasional individual may develop sedation with any of them. They are at least as effective as hydroxyzine and generally as effective as each other. There is no clear evidence that tolerance occurs after continued use. Very rarely, antihistamines appear to make urticaria worse. This has been reported anecdotally with cetirizine but clinical experience suggests that most or all antihistamines may be implicated in those who are affected.

Acrivastine (adult dose 8 mg three times a day) has a rapid onset and duration of action and is excreted predominantly in the urine.

Cetirizine (adult dose 10 mg/day) is poorly metabolized in the liver and is excreted, predominantly in the urine, unchanged. It is also rapidly absorbed. It is more sedative than placebo in some studies and is best taken at night. Cetirizine reduces dermal eosinophil cell accumulation *in vitro* and *in vivo*. However, the clinical importance of this effect in the treatment of delayed pressure urticaria and urticarial vasculitis, where eosinophils may be an important component of the inflammatory cell infiltrate, is uncertain. There are no studies to show that its active enantiomer, levocetirizine, has an advantage in the treatment of chronic urticaria.

Fexofenadine is the metabolite of terfenadine but appears to be devoid of cardiotoxicity at clinically relevant doses and has the widest therapeutic window of the second generation antihistamines.

Loratadine (adult dose 10 mg daily) is a derivative of azatadine. Although loratadine is also metabolized in the liver by cytochrome P450 to some extent, so far no clinically proven, relevant drug interactions have been reported. It is not yet clear whether its metabolite, desloratadine, offers a clinical advantage in urticaria or any subsets of it.

Low-sedation antihistamines are used to reduce urticarial activity, with minimal side effects. Individual response is variable, but adequate dose and timing in relationship to maximal urticarial activity is important. Alternative low-sedation antihistamines can be tried, and sedating ones added at night. A combination of an H_1 antihistamine with an H_2 antagonist may be more effective than H_1 antihistamines alone in some patients. Use of ranitidine (adults 150 mg twice a day) is preferable to cimetidine, which has more antiandrogenic side effects and potential drug interactions.

Table 22.14 Properties of second generation H_1 antihistamines currently available in the UK.

Name	T_{max} (h)	T½ (h)		5 × T½ (h)	5 × T½ (days)	Principal elimination	Severe renal impairment†
		Adults	Children				
Acrivastine	1.5	1.5		7.5	<1	Renal	Avoid
Cetirizine	0.5–1	10	6	50	2	Renal	Half dose
Levocetirizine	0.9	8		40	2	Renal	Reduced dose
Loratadine	1 (2 h after food)	(8.4)*		(42)	(2)	Hepatic (CYP 3A4)	Caution
Desloratadine*	3	27		135	6	Hepatic	Caution
Fexofenadine	1–3	11–15		65	3	Biliary	Same dose
Mizolastine	1.5	13		65	3	Hepatic	Same dose

* Active metabolite is descarboethoxyloratadine (desloratadine).

† Glomerular filtration rate <10 ml/min or creatinine >700 μg/l.

T_{max} = time to maximum blood concentration after a single dose; T½ = plasma half life.

Adverse effects of antihistamines

Concerns about the potential cardiotoxity of antihistamines have receded since terfenadine and astemizole have been withdrawn from the market. Elucidation of the *HERG1* gene encoding the major K^+ cardiac repolarization channels offers a molecular understanding of the cardiotoxic properties of terfenadine and astemizole, which block the channels at clinically relevant concentrations [3] and have been withdrawn from the market. Mizolastine, which also undergoes limited conversion by hepatic CYP 3A4, is able to block HERG1 channels to some degree. Its use with drugs that prolong the Q–T interval—such as amiodarone, quinidine and neuroleptic drugs and tricyclic antidepressants—and with electrolyte disturbance should be avoided. The classical antihistamines hydroxyzine and diphenhydramine also have the ability to induce Q–T prolongation [3], emphasizing that higher than recommended doses of these antihistamines should be used only with caution.

Antihistamines in pregnancy

Antihistamines cross the placenta. There is no reliable evidence that they are teratogenic, but they should be avoided in pregnancy and particularly in the first trimester if possible. If it is not possible, then chlorphenamine appears to be the least risky to use based on its long availability and safety record. Current guidelines on urticaria support the use of cetirizine and loratadine beyond the first trimester of pregnancy if the benefits of an antihistamine are considered to outweigh any risks of administration for an individual patient [4,5].

Second-line therapies (targeted therapy)

Oral systemic corticosteroids are effective in severe urticaria when started at high doses, such as 0.5–1.0 mg prednisolone/kg/day. Although short courses are useful for acute exacerbations, prolonged use should be avoided because of the risk of side effects. Oral corticosteroids are often required for disease control in severe delayed pressure urticaria and urticarial vasculitis, but every attempt should be made to minimize the dose and duration.

The emergency treatment for histaminergic non-hereditary angio-oedema causing respiratory embarrassment from oropharyngeal–laryngeal angio-oedema is intramuscular epinephrine. It acts rapidly by vasoconstriction and stabilizing mast cells through β-adrenoceptor stimulation. For moderately severe reactions it can be inhaled for its local effect, but for severe reactions, particularly of the anaphylactic type, epinephrine must be injected intramuscularly. Treatment should be repeated if there is no improvement after 10–15 min. Patients who have had a severe reaction should be shown how to self-administer epinephrine and should keep two unexpired 'pens' available.

The choice of other second-line therapies will be influenced by the clinical situation. Perhaps the most promising new class of drugs is the leukotriene receptor antagonists, which have been shown to benefit aspirin-sensitive urticaria and may be of value in delayed pressure urticaria and autoimmune urticaria [6]. Doxepin, a tricyclic antidepressant with potent antihistaminic activity, may be useful at night in a starting dose of 10–30 mg, but as it also reacts with α-adrenergic receptors it should not be taken with monoamine oxidase inhibitors. It is especially useful for night-time itching and anxious patients but is probably not effective as an antidepressant at the dose used for urticaria. Danazol may be beneficial for patients with refractory cholinergic urticaria [7]. Thyroxine appears to reduce urticarial activity in some clinically euthyroid patients with thyroid autoimmunity [8]. Sulphasalazine [9] and dapsone [10] may be useful for delayed pressure urticaria, especially when oral corticosteroids are otherwise required for disease control although the literature on these useful agents remains surprisingly small. Tranexamic acid may suppress antihistamine-unresponsive non-hereditary angio-oedema without weals [11]. Narrow-band phototherapy may help some patients [12] especially those with symptomatic dermographism, although controlled studies are needed. Cold desensitization has been shown to be effective for well-motivated patients with cold contact urticaria [13]. There is a small literature on 'curative' antibiotic therapy for the same group [14].

Third-line therapies (immunomodulatory)

For patients with severe, unremitting urticaria not responding to conventional therapy, immunomodulatory strategies have been tested in small, uncontrolled trials. Plasmapheresis improved six out of eight such patients with autoimmune urticaria for 3–8

weeks only [15], illustrating the relevance of functional autoantibodies to disease activity. Intravenous immunoglobulin (IVIG) infusions, at 0.4 g/kg/day for 5 days (total 2 g), improved nine out of 10 patients, two of whom remained clear for 2 years [16], but subsequent clinical experience has been disappointing. Placebo-controlled studies of IVIG for urticaria are required. Ciclosporin at 2.5–3.5 mg/kg/day for 1–3 months improved or temporarily cleared the majority of patients with severe urticaria [17,18] and its efficacy has been confirmed in a randomized, placebo-controlled study at 4 mg/kg/day for 4 weeks [19]. Fewer therapeutic failures occurred with a reducing dose of ciclosporin over 4 months than over 8 weeks [20], although the optimal dose and duration of treatment has yet to be defined. Open studies of tacrolimus [21] and mycophenolate mofetil [22] suggest that they may have similar efficacy in severe chronic ordinary urticaria. There is an anecdotal literature on methotrexate [23], cyclophosphamide [24] and early reports suggest a potential benefit from omalizumab (anti-IgE) [25].

Mastocytosis

Introduction

Mastocytosis is a rare condition characterized by too many mast cells, associated with an altered immunophenotype which may express somatic mutations of the receptor for stem cell factor. It usually presents in the skin, but may affect other tissues, especially the bone marrow and gastrointestinal tract. The distinction between cutaneous mastocytosis and systemic mastocytosis (as defined by demonstrating excess mast cells outside the skin) will depend to an extent on how hard they are sought, and it is therefore of less value to the practising clinician than some classifications would suggest. The first description of mastocytosis was made by Nettleship and Tay in 1869 [1]. The term urticaria pigmentosa was used by Sangster to describe the skin lesions in 1878 [2], but it was not until 1936 that the term 'mastocytosis' was offered by Sézary to describe skin and systemic involvement occurring together [3].

There have been considerable gains in the understanding of its aetiopathogenesis and classification over the last decade, with the recognition of specific gene mutations in the proto-oncogene *KIT*, which encodes a transmembrane tyrosine kinase receptor on mast cells (KIT). The relationship between mastocytosis presenting primarily in the skin and primarily as a haematological disorder continues to be clarified. Two in-depth reviews are recommended reading [4,5].

Classification

A modification of the clinical classification embracing dermatological and haematological presentations of mastocytosis by Metcalfe [1] is shown in Table 22.15. It should be emphasized, though, that the great majority of cases presenting to dermatology clinics will be cutaneous or systemic indolent and that progression to an

Table 22.15 Clinical classification of mastocytosis.

A Cutaneous
Urticaria pigmentosa
Mastocytoma
Telangiectasia macularis eruptiva perstans (TMEP)
Diffuse cutaneous mastocytosis
B Systemic (extracutaneous mast cells in at least one organ)
I *Indolent systemic mastocytosis*
II *Mastocytosis with an associated haematological disorder (AHNMD)*
A Myeloproliferative disorders
B Myelodysplastic disorders
III *Aggressive mastocytosis*
IV *Mast cell leukaemia*

associated haematological non-mast cell disorder (AHNMD) is uncommon. Both type III (aggressive mastocytosis) and type IV (mast cell leukaemia) are rare. Classifications based on aetiopathogenesis encompassing *KIT* mutational analysis are currently of no practical value in the dermatology clinic, although it is possible that identifying subsets of disease using molecular genetics may lead to more accurate prognosis and better management in the future.

Aetiopathogenesis

That the release of mast cell mediators causes symptoms of flushing, itching and gastrointestinal disturbance in mastocytosis is not in doubt, but the reason for mast cell accumulation in tissues in the first place is not yet clear. Interest has been focused on activating mutations of *KIT* which were first found on a growth factor-independent mast cell line from a patient with mast cell leukaemia (HMC-1) and subsequently in adults with mastocytosis [1]. Several amino acid substitution mutations have been described in *KIT*, leading to autoactivation of the receptor, the commonest being D816V. However, the story is not straightforward, because activating mutations have not been found in some children with typical urticaria pigmentosa. Three of six children were found to have a novel dominant *in*activating mutation in codon 839 [2]. Furthermore, mutations in *KIT* have not been identified in familial mastocytosis or in the germ line of affected adults, indicating that they are somatic. *KIT* is also expressed on haemopoietic stem cells and melanocytes, which might be relevant to the occasional occurrence of myeloproliferative and myelodysplastic disorders in mastocytosis and the hyperpigmentation usually seen in urticaria pigmentosa lesions.

Clinical presentation

Nearly all mastocytosis with bone marrow abnormalities will show skin lesions, but few patients with skin lesions will have an associated non-mast cell haematological disease.

Prevalence

Mastocytosis is uncommon. Reliable population-based prevalence data are not available, but only two new patients were seen each year in one dermatology centre from a catchment population of 300 000 [3]. There is no sex difference or increase in atopy [4].

Genetics

Over 50 families with familial mastocytosis have been reported to date. Most of these had urticaria pigmentosa, but four cases of telangiectasia macularis eruptiva perstans (TMEP) occurred in three generations of one family, with an autosomal-dominant pattern of inheritance [5].

Cutaneous mastocytosis

Urticaria pigmentosa

This is the commonest pattern of cutaneous mastocytosis. Urticaria pigmentosa developed in the first year of life in 84% of 67 children [6]. The most common age of onset for adult urticaria pigmentosa is 20–40 years [7]. Numerous reddish-brown or pale, monomorphic maculopapules, plaques or nodules appear in a symmetrical distribution anywhere on the body except the face, head, palms and soles, with the highest concentration usually being on the trunk (Fig. 22.17) and thighs (Fig. 22.18). The edges of the lesions are not completely sharp. They urticate within a few minutes of gentle rubbing (Darier's sign) (Fig. 22.19) causing localized itch, redness and wealing, which subsides within an hour. Stroking may also produce wealing in clinically unaffected skin. Darier's sign is not always demonstrable, especially in those with

Fig. 22.17 Urticaria pigmentosa in a child, showing multiple pigmented lesions on the trunk. (Courtesy of St John's Institute of Dermatology, London, UK.)

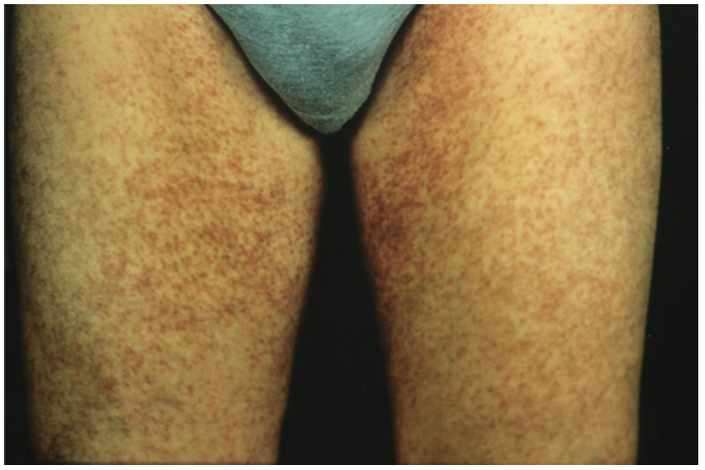

Fig. 22.18 Adult urticaria pigmentosa on the thighs, showing numerous reddish-brown lesions. (Courtesy of St John's Institute of Dermatology, London, UK.)

Fig. 22.20 Solitary mastocytoma, which urticates and blisters on rubbing. (Courtesy of St John's Institute of Dermatology, London, UK.)

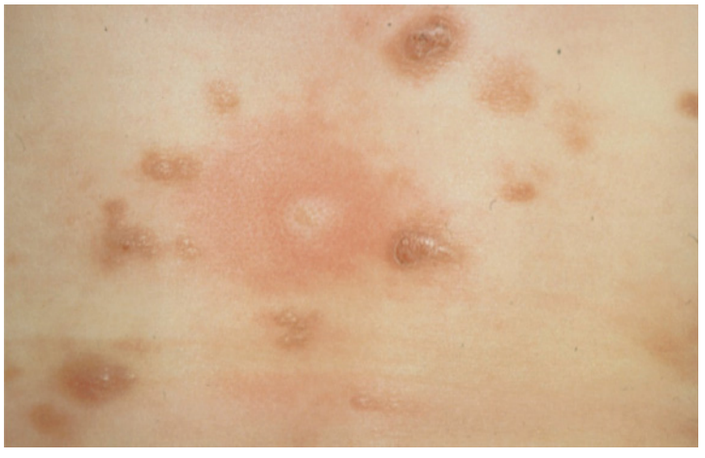

Fig. 22.19 Intense wealing and flare reaction (Darier's sign) induced by gentle rubbing of urticaria pigmentosa lesions on the back of an infant. (Courtesy of Norfolk and Norwich University Hospital, UK.)

Fig. 22.21 Telangiectasia macularis eruptiva perstans after gentle rubbing on the thigh of an adult. (Courtesy of St John's Institute of Dermatology, London, UK.)

a long history of the disorder, and is not 100% specific for mastocytosis, since it has also been described rarely in juvenile xanthogranuloma [8] and acute lymphoblastic leukaemia of neonates [9]. Lesions may blister in infancy or childhood and may be the presenting feature, but heal without scarring. Bullous mastocytosis is not a specific clinical pattern. It is most often seen with mastocytomas and diffuse cutaneous mastocytosis.

Flushing occurs in about 50% of patients, alcohol intolerance and pruritus in slightly less [10]. Other symptoms may include heat or cold intolerance, recurrent diarrhoea and headache. Wheezing is often quoted, but is extremely rare. Studies have shown that up to 60% of adult patients have bone marrow involvement [10–12], but there is no obvious relationship between finding this on biopsy and symptomatology or prognosis [10]. Clearance or fading of urticaria pigmentosa was observed in 12 of 106 adult patients with confirmed bone marrow involvement who were followed for 12–20 years, with a parallel overall improvement in the patients' well-being [13].

Mastocytoma

Cutaneous mastocytosis may present with red, pink or yellowish nodules or plaques in infancy or early childhood, measuring up to 3–4 cm in diameter (Fig. 22.20). They are usually solitary. About 15% of young children will present with localized lesions [14]. If multiple, the lesions can overlap in appearance with urticaria pigmentosa. They tend to blister if rubbed, especially in the nappy area, and occasionally attacks of flushing can be induced by rubbing a solitary mastocytoma [15]. Nearly all mastocytomas involute over the first few years of childhood.

Telangiectasia macularis eruptiva perstans

Telangiectasia may rarely be the predominant clinical feature of cutaneous mastocytosis. Patients are usually adults presenting with red, telangiectatic macules, especially on the trunk, which tend not to urticate on rubbing (Fig. 22.21). Finding excess mast cells on skin biopsy will confirm the clinical suspicion, although they may not be numerous. Historically, TMEP is a cutaneous

pattern of mastocytosis but overlaps with widespread urticaria pigmentosa (including those with systemic disease) are not uncommon and may be difficult to classify. TMEP tends to be very persistent and unresponsive to treatment.

Diffuse cutaneous mastocytosis

This is a very rare form of mastocytosis in which mast cells infiltrate the entire skin diffusely, and it usually presents in the neonatal period. The skin tends to be thickened and doughy in consistency, but may be smooth. Blistering after minor trauma or scratching is common (Fig. 22.22) and pruritus intense. Pigmentation is usually absent. Patients with this type of mastocytosis are at risk of systemic disease and severe complications including anaphylaxis and diarrhoea [16], but it may resolve spontaneously, as in other types.

Systemic mastocytosis

The WHO criteria for diagnosis of systemic mastocytosis are shown in Table 22.16. Patients must meet at least one major and one minor, or three minor criteria [17]. Not all patients with proven bone marrow involvement will be symptomatic, but in those who are, nausea, vomiting, diarrhoea, palpitations, hypotension, syncope, headache, dyspnoea, wheezing and sometimes fatigue and 'fogginess' may feature dominantly as symptoms. This is partly due to cutaneous mast cell mediator release having distant effects and partly to direct local effects of infiltration in other tissues, such as the gastrointestinal tract. Bone pain, bone cysts, premature osteoporosis, osteopetrosis or spontaneous fractures should prompt further investigation.

Fig. 22.22 Diffuse cutaneous mastocytosis in an infant, showing blistering and crusting on the face. (Courtesy of Dr C.T.C. Kennedy, Department of Dermatology, Bristol Royal Infirmary, Bristol, UK.)

Table 22.16 WHO criteria for diagnosis of systemic mastocytosis (2001).

Major
Multifocal dense aggregates of mast cells (≥15) in bone marrow or other tissues (not skin)
Minor
(a) On biopsy of bone marrow or other extracutaneous tissue ≥25% of mast cells in the infiltrate are spindle-shaped or have atypical morphology OR ≥25% of mast cells on bone marrow aspirate are immature or atypical
(b) Detection of a *KIT* point mutation at codon 816 in bone marrow, blood or other organs (not skin)
(c) Mast cells in bone marrow, blood or other extracutaneous organs that co-express CD117 with CD2 and/or CD25
(d) Total blood tryptase persistently ≥20 ng/ml (unless there is an associated clonal myeloid disorder in which case this parameter is not valid)

Diagnosis of systemic mastocytosis may be made if one major and one minor criteria OR three minor criteria are fulfilled.

As over half of adult patients investigated for urticaria pigmentosa will have bone marrow involvement and therefore, by definition, indolent systemic mastocytosis, making a distinction between them is more academic than practical. Blood tryptase and urinary methylhistamine may be useful markers for bone marrow involvement. A persistent blood tryptase of 20 ng/ml or greater is one of the WHO minor criteria for the diagnosis of systemic mastocytosis [17]. Although there is a theoretical risk of progression of systemic indolent mastocytosis to type II (associated myeloproliferative or myelodysplastic disorders) or type III disease, the literature indicates that this is unusual and that there are no markers to identify subgroups of patients at greatest risk of this. The occasional presentation of type III disease (aggressive systemic mastocytosis) or type IV disease (mast cell leukaemia) is more likely to be to a haematologist than to a dermatologist, with the patient showing changes in the peripheral blood against a background of being unwell with lymphadenopathy.

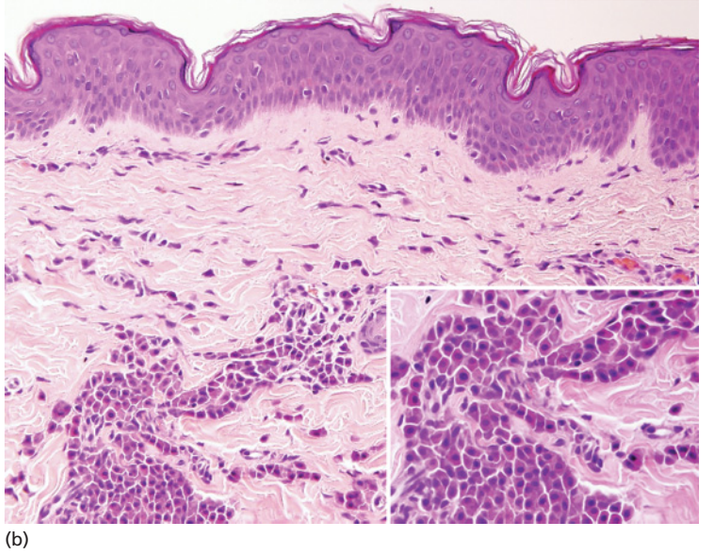
Histopathology

Skin



There are increased numbers of mast cells in the dermis of all types of mastocytosis. The epidermis is normal apart from an increase in melanin. The mast cells are usually oval or spindle-shaped and have granules that stain metachromatically with toluidine blue. They are also well demonstrated by Giemsa or chloroacetate esterase stains in formalin-fixed biopsies. Mast cell infiltrates are predominantly found around blood vessels and skin appendages in the papillary dermis (Fig. 22.23). In urticaria pigmentosa, they are increased up to 15-fold above normal [1], but may be less numerous. Careful technique when taking the skin biopsy, to minimize traumatic degranulation, is important. Injecting local anaesthetic around the lesion to be sampled and avoiding epinephrine may yield a higher number of stainable mast cells. A small increase in numbers of mast cells has been found in non-lesional skin of urticaria pigmentosa [2]. Full-thickness infiltration of skin or a band-like involvement of the upper dermis are seen in mastocytomas and diffuse cutaneous mastocytosis. By contrast, mast cells are confined to superficial capillaries and dilated venules in TMEP.

Bone marrow

Bone marrow involvement typically presents with focal aggregates of mast cells on biopsy, although infiltration may be diffuse and spindle-shaped. Mast cell infiltration of the marrow is often accompanied by increased numbers of immature neutrophils, phagocytosing macrophages, eosinophils and lymphocytes and sometimes by fibrosis [3,4].

Investigations

A skin biopsy is desirable to confirm a clinical diagnosis in most patients, although observation alone may be appropriate in very young children, especially those with a solitary mastocytoma, in whom systemic disease is very unlikely. A full blood count should be performed at presentation and at yearly intervals when systemic disease is suspected or proven to detect the onset of significant bone marrow disease. Other investigations should be guided by the clinical presentation. Routine bone marrow examination is not essential in the absence of other features, such as an anaemia, persistent leukocytosis, unexplained eosinophilia, bone pain, hepatosplenomegaly or lymphadenopathy. Blood tryptase is a useful surrogate marker for bone marrow involvement but not diagnostic of systemic disease without other features being present [1]. A basal tryptase of >20 ng/ml is considered to be a useful threshold in adults, although the significance of a raised tryptase in very young children is less certain [2]. An abdominal ultrasound scan may be helpful initially if there is a suspicion of systemic disease,

Table 22.17 Work-up of mastocytosis in adults.

Initial assessment

History: to include enquiry about allergic reactions, bowel symptoms and bone pain

Investigations:

Standard

- Skin biopsy
- FBC, blood chemistry profile and tryptase

Conditional

- IF FBC abnormal, e.g. eosinophilia, or tryptase >20 ng/ml for haematology opinion re: bone marrow and *KIT* mutational analysis on bone marrow aspirate
- IF systemic mastocytosis suspected or confirmed, bone densitometry, abdominal ultrasound or other imaging
- IF allergic disease suspected on the history, appropriate allergy assessment
- IF peptic ulceration suspected, for gastroscopy

Follow-up assessment

IF no evidence of systemic disease, discharge to primary care for annual FBC and blood chemistry

IF indolent systemic mastocytosis, at least annual review in secondary or tertiary care centres

- FBC, blood chemistry and tryptase
- 3-yearly bone densitometry
- other investigations guided by disease progression

IF AHNMD or aggressive systemic disease for follow-up in haematology or oncology clinics

and perhaps bone densitometry, especially if there is bone pain. A suggested protocol for the initial diagnostic work-up and review is summarized in Table 22.17.

Management

Most patients presenting to dermatology clinics with cutaneous or indolent systemic mastocytosis will have an excellent prognosis, particularly children, so it is important to provide reassurance about the nature and outlook of the condition. Management hinges on avoidance of trigger factors for mast cell degranulation, symptomatic relief and detection of significant systemic disease. No cures are currently available, and there are no predictors for the onset of haematological complications or occurrence of familial disease.

Avoidance measures and management of anaphylactic emergencies

The flushing and itching experienced by many patients with cutaneous mastocytosis are due to release of mast cell mediators. This can be exaggerated by physical stimuli, such as temperature extremes, towelling, massage or alcohol. Potential triggers of mast cell degranulation include known allergens, NSAIDs, opiates, Hymenoptera venoms (even in the absence of allergy), iodinated contrast media, dextrans and some muscle relaxants (Table 22.18).

Table 22.18 Potential mast cell degranulating stimuli.

Physical triggers (especially rubbing)

Alcohol

Non-steroidal anti-inflammatory drugs (including aspirin, diclofenac)

Allergens (confirmed IgE-mediated reactions, e.g. latex allergy)

Insect and snake venoms (allergic and/or toxic effects)

Radiocontrast media (especially if iodinated)

Plasma expanders (especially dextran)

Opiates (including codeine and morphine)

General anaesthetic agents

- Non-depolarizing muscle relaxants (especially benzylisoquinolinium group, e.g. atracurium, gallamine)
- Anticholinergic drugs (e.g. hyoscine)

IgE, immunoglobulin E

Patients should be advised about the possibility of an anaphylactic emergency. Consideration should be given to carrying an epinephrine pen for self-administration, especially when there is a background of allergy. Epinephrine injectors should always be carried by mastocytosis patients with a previous history of anaphylaxis. Oral antihistamines may be helpful for milder attacks not involving respiratory difficulty or hypotension. Venom immunotherapy for patients with anaphylaxis has been reported to reduce the risk of non-allergic reactions to Hymenoptera stings, when there is no evidence of specific IgE [1], but this remains to be confirmed in larger studies. Fatal cardiovascular collapse during general anaesthesia has been reported [2]. Prophylactic administration of corticosteroids (e.g. 1 mg/kg prednisolone or equivalent) and antihistamines 30 min prior to general anaesthesia [3] is not necessarily protective.

Therapies

Antihistamines

Antihistamines are the mainstay of therapy, as for urticaria. Itching and flushing can be controlled by antihistamines in many patients, but can be refractory to treatment. Taking a classical sedating antihistamine at night, with or without a non-sedating antihistamine by day, may be beneficial, although there are no controlled studies of antihistamines in mastocytosis. Doxepin may also be used for its antihistaminic properties. H_2 antihistamines and proton pump inhibitors are used for gastrointestinal symptoms, including indigestion and diarrhoea.

Mast cell stabilizing and anti-inflammatory drugs

Abdominal pain, nausea and diarrhoea also respond to sodium cromoglycate which, however, has no value for other systemic symptoms because it is not absorbed from the gut [4]. Aspirin and other NSAIDs have been reported to ameliorate prostaglandin-mediated flushing in some patients, but must be introduced with caution if there is any history of intolerance, under cover of antihistamines and with initial observation.

Photochemotherapy and phototherapy

Although oral PUVA may help itch and wealing and improve the appearance of urticaria pigmentosa [5], the benefits are only temporary, so the risks of long-term treatment need to be considered

Fig. 22.24 Considerable improvement, but not complete resolution, of urticaria pigmentosa by the age of 5 years. (Courtesy of St John's Institute of Dermatology, London, UK.)

carefully. The mechanism for improvement is not certain, but probably involves a reduction of mast cell numbers in the papillary dermis only and total histamine content in lesional skin [6], with some cosmetic improvement due to tanning. Narrow-band UVB therapy may be effective for pruritus when PUVA is not tolerated.

Corticosteroids

Use of potent or very potent topical steroids applied under polythene occlusion, or intralesional injection of individual mastocytomas, can lead to clearance of mast cells and reduction of pigmentation for at least a year [7], but steroid atrophy is an important limitation. Restriction of treatment to limited cosmetically sensitive areas, such as the forearms and lower legs, will minimize the risk of significant adrenocortical suppression. Oral corticosteroids at high doses can offer temporary symptomatic improvement for patients with aggressive systemic mastocytosis.

Others

IFN-α-2a and -2b have been reported anecdotally to ameliorate some features of systemic mastocytosis [8,9], but not the number or appearance of skin lesions. Chemotherapies do not alter the course of the mast cell disease, are given for associated haematological disorders. There has been considerable interest in the tyrosine kinase inhibitors, especially imatinib, although unfortunately this is not effective for patients with the D816V mutation. Other inhibitors with promising *in vitro* properties include PKC412 and dasatinib but clinical experience and controlled studies are lacking. Several novel therapies for the treatment of mastocytosis are under development [10].

Prognosis

Most mastocytomas resolve in childhood. Around 50% of children with urticaria pigmentosa clear by adolescence. In a review of 67 paediatric cases, five resolved over 2 years of follow-up and 20 improved but did not clear over a mean period of 6 years [11] (Fig. 22.24). The outlook for paediatric cases that do not remit is the same as for adults with indolent disease. The prognosis for this group is difficult to ascertain due to the obvious limitations of not having information on lifelong follow-up, but it does appear from the experiences of clinics with large numbers of patients under review that progression to significant haematological disorders is rare, even with proven bone marrow involvement with mastocytosis [3,12]. Spontaneous resolution of cutaneous mastocytosis was observed in about 10% of adults [13]. The main problems likely to be experienced by patients relate to the risks of anaphylaxis and peptic ulceration. Prognosis of aggressive mastocytosis will relate to the associated haematological disorder, and management will be directed primarily towards this.

Eczema

Definition. Eczema, a term derived from the Greek word έκζεμα meaning 'to boil', is a clinical and histological pattern of inflammation of the skin seen in a variety of dermatoses with widely diverse aetiologies. Clinically, eczematous dermatoses are characterized by variable intensity of itching and soreness, and, in variable degrees, a range of signs including dryness, erythema, excoriation, exudation, fissuring, hyperkeratosis, lichenification, papulation, scaling and vesiculation. Histologically, the clinical signs are reflected by a range of epidermal changes including spongiosis (epidermal oedema) with varying degrees of acanthosis and hyperkeratosis, accompanied by a lymphohistiocytic infiltrate in the dermis.

The terms 'dermatitis' and 'eczema' are generally regarded as synonymous, although some authors still use the term 'dermatitis' to include all types of cutaneous inflammation, so that all eczema is dermatitis, but not all dermatitis is eczema. Some caution is required when using the term 'dermatitis', as some patients regard it as implying an occupational cause. Unfortunately, there is still no international agreement on the use of these terms [1,2]. Ackerman has argued that, as the term eczema cannot be defined in a way that meets with universal approval, it should be dropped from dermatological parlance [1], but there seems to be a consensus that the term still serves a useful purpose for the clinician.

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

Classification. The classification of eczematous dermatoses is based on aetiology when this is understood, for example contact allergic or irritant dermatitis. When the aetiology is not so well clarified, classification is based largely on clinical features, such as the age of onset, distribution and the predominance of various signs and symptoms. For example, 'pompholyx', a term derived from the Greek word for blister, is used to define a pattern of eczema characterized by the acute eruption of blisters on the hands and feet, and 'discoid' is a descriptive term referring to eczema comprising scattered 'discs' or circular lesions on the trunk and limbs. This dual approach to classification can lead to confusion, because a clinical pattern such as pompholyx can have a range of different aetiologies, some of which are understood whereas others are not.

A useful approach to classification is the division of the various forms of eczema into exogenous and endogenous. The former are those which have a clearly recognized, exogenous trigger and the latter those which are mediated by processes originating within the body. The particular value of this dichotomy for the clinician is that it implies an approach to management. Whereas the key strategy for exogenous eczema is to remove the cause, endogenous eczema more often requires pharmacological intervention. Table 23.1 provides a list of the commonest recognized varieties of endogenous and exogenous eczematous dermatoses. All of these are defined and described in further detail in this and subsequent chapters. Some disorders in which the predominant feature is lichenification (e.g. lichen simplex) or prurigo (e.g. nodular prurigo) are also generally regarded as eczematous dermatoses. These are also described in this chapter.

Although this classification is a useful starting point, individual patients often do not fall neatly into these categories. Multiple factors may be implicated, and two or more forms of eczema may be present in the same patient simultaneously or consecutively. Although exogenous eczemas are related to clearly defined external trigger factors, inherited predisposition can also play a part. In some conditions there are both external and internal precipitating factors. Hand eczema, for example, even when primarily endogenous, is often aggravated by contact with irritants such as detergents or solvents. Discoid, atopic and asteatotic eczemas (regarded as endogenous) can be adversely affected, if not caused, by excessive dehydration of the stratum corneum by low ambient humidity.

Some forms of eczema are altered by regional variations in structure and function of the skin, and these may modify its appearance in regions such as the hands and the lower leg.

There remain cases of eczema that do not fit any of the described patterns [3]. These are not uncommon and have been termed 'unclassified eczema' [4]. These patients may have a poor prognosis, with a tendency for the disease to become chronic. It is not uncommon to see generalized, apparently endogenous, but otherwise unclassified eczema in the elderly [5].

Table 23.1 Classification of the principal forms of eczema.

Exogenous eczemas
Irritant eczema (Chapter 25)
Allergic contact eczema (Chapter 26)
Photoallergic contact eczema (Chapter 26 & 29)
Eczematous polymorphic light eruption (Chapter 29)
Infective eczema*
Dermatophytide*
Post-traumatic eczema*
Endogenous eczemas
Atopic eczema (Chapter 24)
Seborrhoeic eczema*
Asteatotic eczema*
Discoid eczema*
Eyelid eczema*
Exudative discoid and lichenoid chronic dermatosis*
Chronic superficial scaly dermatitis*
Pityriasis alba*
Hand eczema*
Venous eczema*
Juvenile plantar dermatosis*
Metabolic eczema or eczema associated with systemic disease*
Eczematous drug eruptions*

* Discussed in this chapter.

Acute versus chronic eczema. In certain types of eczema, of which a good example is atopic eczema, lesions are seen to change in morphology over time. Newly developed 'acute' lesions of eczema, seen at times when the disease is flaring, tend to be papular, oedematous, exudative (Fig. 23.1a) and, especially on the hands and feet, vesicobullous. More longstanding or 'chronic' lesions tend to have a different morphology, in which the predominant features are dryness, hyperkeratosis and 'lichenification' (Fig. 23.1b) (see below).

Other types of eczema tend to be more consistent in morphology; thus, pompholyx and acute episodes of contact allergic eczema, or phytophotodermatitis, are typified by an acute morphology. In contrast, lichen simplex and nodular prurigo tend to consistently demonstrate the features of chronic eczema.

These clinical features are reflected in a range of different histological features, as described below.

Prevalence. Eczematous dermatoses account for a large proportion of all skin disease. There have been numerous studies of the prevalence of atopic dermatitis (Chapter 24), but fewer in other types of eczema. An important survey of the prevalence of skin disease was carried out in the USA on a sample of over 20 000 people who were representative of the whole population, and who were examined meticulously for skin disease by trained observers [1]. Nearly one-third had some significant skin pathology. The prevalence of all forms of eczema was 18 per 1000, seven of whom had atopic dermatitis. Hand eczema, dyshidrotic eczema and nummular eczema each accounted for about two per 1000. In a population-based survey of public health issues in Stockholm, Sweden, a postal questionnaire was sent to 15 000 adult inhabitants. Fifteen percent of respondents reported a history of childhood eczema. The 1-year prevalence of hand eczema was 8%, skin symptoms on the face were present in 14% and allergy to nickel was reported in 15% of females [2]. Population-based studies of contact allergic dermatitis suggest 40% of subjects demonstrate at least one contact allergic reaction [3].

Consultations for eczema are a major part of the workload in primary care. A survey of records in a general practice in Leicester, England, revealed that 32% of children aged 1–4 years had been diagnosed as suffering from eczema [4]. Horn [5] recorded the details of 6819 dermatological consultations in a UK general practice of 3000–4000 patients from 1958 to 1985. Eczema patients formed the largest group (19% of the consultations; see Table 23.2 for details). In a general practice in Belfast, 8% of patients seen during an 8-week period had a dermatological condition. Eczema accounted for 25% of these, of which 63% were considered to be exogenous in origin [6].

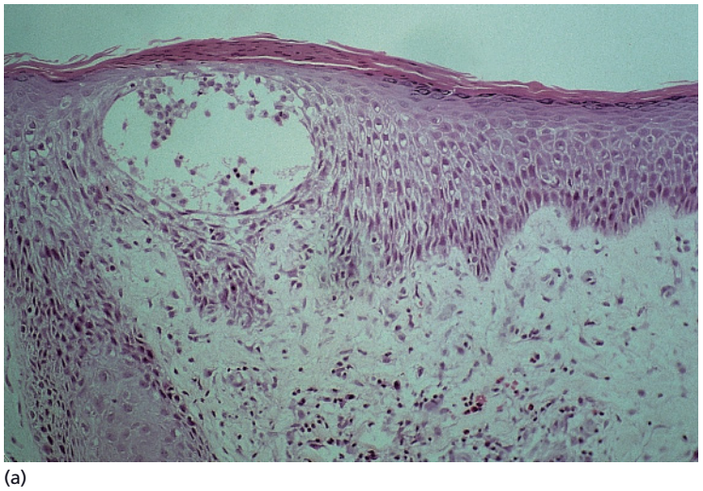
In addition, many cases are referred to hospital. These may represent 17% of all new dermatological cases [7]. A national tertiary referral centre in Singapore has described the profile of eczema referred between 1989 and 1990 [8]; 25 448 new cases were analysed. These represented 34% of new cases seen at the centre. Sixty-seven percent of eczema cases were classified as endogenous and 13.7% were contact dermatitis. Exfoliative dermatitis comprised 0.5% of all eczemas. The authors commented on the increase in the proportion of endogenous eczema seen in 1989–90 compared with that reported in 1973.

Table 23.2 Incidence of various types of eczema seen in a single general practice over 27 years in Ipswich, UK. From Horn [5].

Eczema type	Incidence (%)
Hand eczema	15
Contact dermatitis	12
Seborrhoeic	11
Discoid	7
Lichen simplex	6
Atopic	5
Gravitational	4
Other (mainly unspecified)	40

The uncertainty and variation in the nomenclature of endogenous eczema makes interpretation of statistics tentative, especially when examining changes over time. Atopic eczema is reasonably well defined, and there have been several recent studies suggesting an increased prevalence of atopic dermatitis (see Chapter 24), but prevalence of other forms of eczema may actually be decreasing [9].

Certain patterns of eczema can be seen more commonly in particular age groups. Most cases of eczema in infants and young children are atopic. In the HANES epidemiological survey in the USA [10], atopic dermatitis was by far the most common form found up to the age of 11 years; discoid and 'dyshidrotic' eczema were recorded, but were far less frequent. Perioral eczema or lick eczema around the mouth is common in children with atopic eczema (see Chapter 24), but it can also occur in non-atopic children. Hand eczema is common in atopic children, but uncommon in non-atopic children. Other specific patterns of eczematous change are almost restricted to children; for example, lichen striatus (p. 23.41), juvenile plantar dermatosis (p. 23.26), seborrhoeic dermatitis of infancy and napkin dermatitis (Chapter 17).



Pompholyx and atopic eczema are less common in elderly people, but other forms of eczema assume greater importance. Discoid eczema occurs particularly in elderly males in winter, and asteatotic eczema of the legs is also common. In elderly factory workers, irritant hand eczema can be very troublesome, although contact dermatitis becomes less common with advancing age. The subject is discussed more fully in Chapter 8.

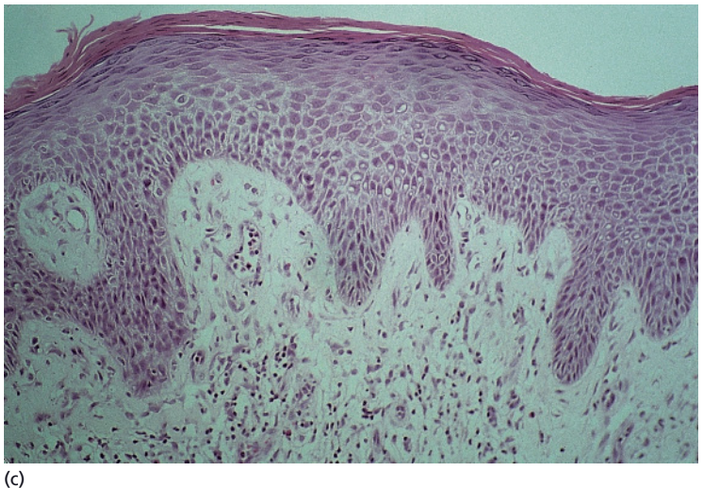
Histopathology [1–4]. The histopathological features of eczema, in common with the clinical features, are variable, and depend particularly on whether the disease is acute or chronic.



In the acute phase (Fig. 23.2a), the histological picture is dominated by spongiosis, an intercellular epidermal oedema which

(a)

(b)

(c)

Fig. 23.2 (a) Acute eczema. The epidermis shows distinct vesicle formation. The vesicle contains serum, and a moderate number of inflammatory cells. H&E, ×100. (b) Subacute eczema. There is irregular acanthosis and patchy spongiosis, with the formation of incipient microvesicles. A few lymphocytes are migrating up from the dermis into the epidermis. H&E, ×100. (c) Chronic lichenified eczema. There is compact hyperkeratosis, some patchy parakeratosis and irregular acanthosis. Mild spongiosis is seen throughout much of the epidermis, and there is a lymphocytic infiltrate in the upper dermis. H&E, ×100. (All courtesy of Dr M.J. Cook, Guildford, Surrey, UK.)

leads to stretching and eventual rupture of the intercellular attachments, with the formation of vesicles. The epidermal vesicles commonly occur in discrete foci, but on the palms and soles they tend to become large by coalescence. There is variable infiltration of the epidermis by lymphocytes. Increased epidermal mitotic activity leads to acanthosis, but if spongiosis is intense, disintegration of the suprapapillary epidermis may cause clefts to form. The intercellular oedema may be diffuse, but is commonly most intense in the mid-epidermal region. Loosening and disruption of the individual cells occur, and some intracellular vacuolation may be found, with displacement of the nucleus from the centre of the cell. Loose, shrunken epidermal cells may resemble histiocytes. Vesicles and the oedematous epidermis may be permeated by mononuclear cells, chiefly monocytes.

In the subacute stage (Fig. 23.2b), spongiosis and vesiculation diminish, and increasing acanthosis is associated with formation of a parakeratotic horny layer. This often contains layers of coagulated plasma and pyknotic nuclei of inflammatory cells.

In chronic eczema (Fig. 23.2c), hyperkeratosis gradually replaces parakeratosis. Acanthosis is more prominent than spongiosis. Inflammatory cells are less evident in the epidermis, but dermal changes become more prominent. The rete ridges become elongated and broadened. The changes are then those of lichenification.

Vascular dilatation in the dermis is marked in all stages. The papillary vessels are particularly involved, and in lichenification they may become tortuous. The infiltrate is predominantly lymphohistiocytic, although polymorphs and eosinophils may be present in very acute eczema, and eosinophils are particularly common in eczematous drug eruptions. In the presence of infection, polymorphs may invade the epidermis. In grossly lichenified eczema, prurigo and exfoliative dermatitis, the infiltrate is mixed, and may be so dense that it simulates a granuloma.

The trauma of rubbing or scratching may cause superficial erosions, haemorrhage or subepidermal fibrinoid changes. Although some degree of lichenification is always present during a prolonged attack of eczema, it is particularly prominent in atopic dermatitis. At times, extreme hyperkeratosis and papillomatosis develop.

With secondary infection, the formation of follicular or subcorneal pustules can simulate the appearance of impetigo, although typical eczematous changes are still visible at the edges of the lesion. Other modifications of the histopathological pattern are mentioned below in relation to different clinical varieties of eczema.

Although spongiosis and a dermal lymphohistiocytic infiltrate are always present at some stage in eczema, the dynamic nature of the changes and their modification by secondary events may make histological diagnosis difficult. All the changes mentioned, with the exception of the spongiotic vesicle, may also be found in burns or simple traumatic lesions of the skin.

The distinction between eczema and psoriasis can be especially difficult, particularly on the palms and soles. Seborrhoeic dermatitis (p. 23.29) is particularly difficult to distinguish from psoriasis, but the finding of Munro microabscesses is suggestive of the latter. It is generally true that cases which cause diagnostic difficulty clinically often have equivocal histological appearance.

The histological features of pityriasis rosea are those of eczema, but the clinical features, particularly the distribution, are characteristic.

Pathogenesis. There has been considerable research on the pathogenesis of some types of eczema, particularly allergic contact dermatitis, primary irritant dermatitis and atopic dermatitis (see Chapter 24). A difficulty in the research has been distinguishing non-specific common pathways from specific mechanisms. The interaction of trigger factors, keratinocytes and T lymphocytes seems particularly important in most eczema types.

Allergic contact dermatitis represents a reproducible model of eczema development [5]. The condition is an immune reaction to small molecules (haptens). On first exposure to the hapten, Langerhans' cells and dermal dendritic cells bearing the antigen migrate to the regional lymph nodes and encounter naïve T cells. Interaction with the antigen-bearing dendritic cells causes T lymphocyte differentiation into a variety of subtypes secreting different cytokine patterns (Th1 and Th2) and specialized $CD4^+$ T lymphocytes with regulatory functions to modulate allergic contact dermatitis. The T cells also acquire tissue homing antigens such as cutaneous lymphocyte-associated antigen (CLA) along with receptors permitting adhesion to skin endothelium and response to cytokines promoting specific binding to keratinocytes.

On subsequent exposure to the contact allergen, $CD8^+$ T cells display a Th1 cytokine profile that is interferon-γ (IFN-γ) predominant. The hapten in the skin may be presented to the T cells by Langerhans' cells, keratinocytes or other T cells. T-cell activation ensues, with cytokine release and upregulation of killer molecules such as perforin, granzyme-B and Fas ligand. IFN-γ promotes expression of MHC class II, the intercellular adhesion molecule ICAM 1, and increases Fas expression on the keratinocytes. In addition, IFN-γ stimulates keratinocyte production of cytokines and chemokines which attract the epidermal influx of lymphocytes. Chemokine release from infiltrating cells also modifies the reaction.

Epidermal damage and the characteristic feature of spongiosis seem to result from T-cell-mediated cytotoxicity, in particular Fas-induced keratinocyte apoptosis, which may be a final common pathway in many types of eczema [6].

Eczema may also be provoked in a non-allergic manner, as in irritant contact dermatitis. Three predominant processes occurring in irritant dermatitis are disturbed barrier function, epidermal cell change and release of inflammatory mediators and cytokines.

Certain irritants may provoke a chronic reaction in which an effect on epidermal cell turnover predominates, leading to lichenification, whereas in acute irritant reactions inflammatory mediator and cytokine release is similar to that seen in acute allergic contact dermatitis [7]. There is debate whether the cytokine profiles of the two reactions differ [7–9]. Indeed, it has been proposed that irritant reactions to haptens may be required to facilitate contact sensitization [10].

Following activation of the immune pathway by cytokine release, the accumulation of inflammatory cells progresses, leading to the morphological changes apparent histologically and clinically. In allergic contact dermatitis, the earliest changes seen by light microscopy occur some 3–6 h after the application of the allergen to the skin. Vasodilatation occurs, with extravasation of monocytes into the upper dermis [1]. After 8 h, the mononuclear cells enter the epidermis and spongiosis is seen, and by 72 h vesicles are present. The histological changes of primary irritant dermatitis are similar, but they appear to proceed more quickly, depending on the concentration of the irritant used. Both intracellular and intercellular oedema are visible throughout the epidermis at 3–6 h, and within 24 h there may be epidermal necrosis, with cellular vacuolation and nuclear pyknosis. In severe forms, the primary epidermal damage may progress to subepidermal blister formation.

Electron microscopy has shown that the earliest epidermal changes in allergic dermatitis start in the basal and Malpighian layers, where cytoplasmic vacuoles and dilated endoplasmic reticulum are seen. The keratinocytes then lose contact by breakage of their microvilli and retraction of desmosomes [11,12].

Secondary dissemination. A very characteristic feature of eczematous inflammation is its tendency to spread far from its point of origin and to become generalized [1]. This phenomenon is often termed autosensitization or, more specifically, autoeczematization [2]. Generalized spread is especially likely when the primary site of the eczema is on the legs or the feet. There is also a particular tendency for an eruption beginning on the feet to extend to the hands and vice versa. The eczema may have been present for only a few days, or for many years before dissemination occurs. The dissemination, which is often preceded by an exacerbation at the primary site, often occurs explosively. The secondary eruption may at first consist of small oedematous papules, but these soon become obviously eczematous, and grouped papulovesicles may become confluent in small plaques. Occasionally, the lesions take the form of red macules, or weals. The distribution is usually symmetrical.

The course of the secondary eruption depends largely on the progress of the primary lesion. If the primary lesion remains acutely inflamed, the eruption increases in severity and may become generalized. If the patient is rested and the local lesion allowed to settle, the secondary eruption will subside, but will often recur very readily if the local lesion relapses. In a small proportion of patients, the generalized secondary eruption evolves into erythroderma, which may become self-perpetuating.

Conditioned hyperirritability is probably closely related to dissemination of eczema. This refers to the phenomenon whereby an area of inflamed skin on one part of the body results in a generalized hyperirritability of the skin at distant sites. There is considerable evidence that eczematous patients are more vulnerable to mild primary irritants than normal people. Conditioned hyperirritability seems to be associated with any focal inflammation of the skin, and it may explain some clinical phenomena such as the tendency for patients suffering from eczema, especially acute eczema, to have a higher proportion of false positive 'irritant' reactions to patch tests. The 'angry back' syndrome, in which a strongly positive patch test response can increase the percentage of false-positive reactions on the back at the same time, is an example of this.

There may be several mechanisms underlying the dissemination of eczema and conditioned hyperirritability. Circulating activated T lymphocytes are increased in number [3,4]. In addition, peripheral blood mononuclear cells show increased proliferation in the presence of an autologous skin homogenate compared with control subjects. This suggests that an abnormal cell-mediated immune response against autologous skin antigens could be occurring [5,6]. In some cases the presence of infection may lead to a phenomenon related to infective eczema (see below). The possibility of a non-immune process such as a neurological mechanism has not been completely excluded.

Eczematous dermatoses

Some of the commonest types of eczema are discussed in separate chapters (see Table 23.1). Others are described below.

Asteatotic eczema

Synonyms
- Winter eczema
- Eczéma craquelé

Definition. Eczema developing in very dry skin, usually in the elderly.

Aetiology. Although the condition is thought to be due to a decrease in skin-surface lipid, the exact pathogenesis of the skin changes is obscure. The amino-acid content of the skin is lower in the more severe cases [1]. A decrease in the keratohyaline-derived natural moisturizers may also be important [2].

Hyposteatosis occurs in many conditions of maldevelopment, malnutrition and atrophy of the skin, but does not necessarily lead to eczema. The part played by loss of fluid from the skin has been underrated in the past. The relationship between the transpiration rate and the lipid layer has been the subject of many studies [3]. Using excised skin it was shown that removal of these lipids increased water loss by 75 times, and that this returned to normal when they were restored. The implications for treatment are obvious. At present, the relevant factors in the production of asteatotic eczema can be considered to be: a naturally 'dry' skin and a lifelong tendency to chapping; a further reduction in lipid with age, illness, malnutrition or hormonal decline; increased transpiration relative to the environmental water content; loss of integrity of the water reservoir of the horny layer; chapping and degreasing (and perhaps cell damage) by industrial or domestic cleansers or solvents; low environmental humidity and dry, cold winds increasing convection loss; and repeated minor trauma leading to inflammation and further disorganization of the surface aqueous/lipid balance. Percutaneous absorption through the degreased and damaged epidermis is increased, and contact irritants and sensitizers may further damage and irritate the skin.

A patient will often ascribe the onset to an event or change in life that is quite trivial, for example the installation of central heating or a particularly cold, dry winter [4]. In industry, years of contact with degreasing agents may be tolerated until, usually in the 50–60 age group, some small, additional hazard precipitates a disabling dermatitis.

Diuretics sometimes appear to be an important contributory factor in elderly people [5]. Asteatotic eczema may be a presenting sign of myxoedema [6]. It can also be due to zinc deficiency [7]. Cimetidine has also been reported to cause asteatotic dermatitis [8], as have topical corticosteroids [9].

Histopathology. The features are those of a mild, subacute eczema, with a varying amount of dermal infiltrate. When vesicular or nummular eczema supervenes, the changes are more marked, and are as seen in the latter disease.

Clinical features (Fig. 23.3). The condition occurs particularly on the legs, arms and hands. It tends to be more marked in the winter and in elderly people. The asteatotic skin is dry and slightly scaly. The surface of the backs of the hands is marked in a criss-cross fashion, as though the continuity and flexibility of the keratin had been disturbed. The finger pulps are dry and cracked, producing distorted prints and retaining a prolonged depression after pressure ('parchment pulps'). On the legs the pattern of superficial markings is more marked and deeper ('crazy-paving' pattern or eczéma craquelé). In some patients the fissures may become haem-

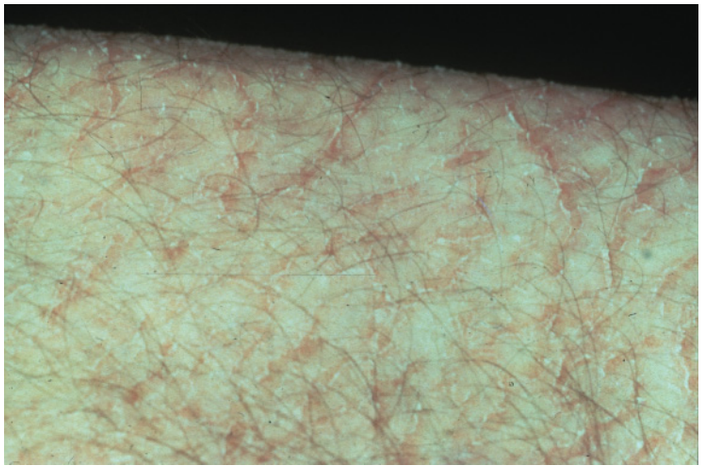

Fig. 23.3 Asteatotic eczema (eczéma craquelé, winter eczema).

orrhagic. The borders of this irregular reticulation become erythematous and slightly raised, and frank eczematous changes finally develop. Similarly, on the hands, localized areas become 'chapped' or itchy, and eventually form eczematous patches.

The condition can remain in this state for months, relapsing each winter and clearing in the summer, but eventually becoming permanent. Scratching, rubbing or contact irritants and sensitizers cause further eczematous changes or spread; or a more diffuse vesiculosquamous eruption occurs.

Nummular eczema can also occur on this background, although the relationship between the two conditions is uncertain.

Irritation in this form of eczema is often intense, and worse with changes of temperature, particularly on undressing at night.

Treatment. The patient's immediate environment may need to be adjusted. Central heating should be humidified where possible, and abrupt temperature changes should be avoided. Wool is usually poorly tolerated and possibly damaging by irritation. Baths are best restricted and should not be hot. Bath oils or oatmeal packs may be helpful, although it is important to remember that bath oils are potentially hazardous in the elderly as the bath may be made slippery. Emollients should be used after bathing or daily. Emollient creams such as those based on lanolin or paraffins are generally helpful.

Weak topical corticosteroids are often prescribed, and those contained in a urea base (Chapter 73) are very appropriate in this situation as urea encourages hydration. Among the older remedies, ichthammol is of value.

This is one of the forms of eczema in which soaps and detergent cleansers can be seen by the physician, and felt by the patient, to be deleterious. Emulsifying ointment BP, aqueous cream BP, or similar proprietary formulations should be substituted.

Chronic superficial scaly dermatitis

Synonyms

- Benign form of parapsoriasis-en-plaques
- Chronic superficial dermatitis
- Digitate dermatosis
- Persistent superficial dermatitis
- Small plaque parapsoriasis
- Xanthoerythroderma perstans of Radcliffe–Crocker

Definition. A chronic condition characterized by the presence of round or oval erythematous, slightly scaly patches on the limbs and trunk, which histologically show mild eczematous changes with little or no dermal infiltrate.

The condition is clinically benign by definition [1]. However, in some cases clonality of the lymphocytic infiltrate can be demonstrated [2], a feature suggesting that this may be regarded as an abortive form of cutaneous T-cell lymphoma [3]. Ackerman has taken this argument further and expressed the view that even an abortive T-cell lymphoma is still a T-cell lymphoma, so this condition is a clinical presentation of mycosis fungoides [4].

Nomenclature. This condition was formerly included with various potentially prelymphomatous eruptions under the general term of 'parapsoriasis' [5–7]. The term chronic superficial scaly dermatitis was introduced by Calnan and Meara [1] to distinguish a subgroup of patients who did not progress to frank lymphoma, and the features which they used to distinguish this subgroup are shown in Table 23.3. The nomenclature has been discussed in detail by Lambert and Everett [6].

Table 23.3 Features which distinguish between prelymphomatous (prereticulotic) eruption and persistent superficial scaly dermatitis.

Prelymphomatous eruption	Persistent superficial dermatitis
Bizarre or angulated shape	Regular, round or oval shape
Fine scale	Coarser scale
May be irritable	Little or no irritation
Progresses to cutaneous lymphoma	Does not become malignant
Histology	
Absence of epidermal eczema	May be eczematous changes
Dermal infiltrate	Little or no dermal infiltrate

Fig. 23.4 Chronic superficial scaly dermatitis.

Aetiology. The cause is unknown.

Histopathology. The histology is not characteristic. It usually shows the changes of a very mild eczematous eruption, consisting of patchy parakeratosis, mild spongiosis, and a slight, mainly perivascular, infiltrate in the dermis, chiefly composed of lymphocytes [7].

Clinical features. The disease occurs in all races, although it is probably rare in dark-skinned people. Its geographical distribution varies considerably; for example, it is commoner in the south than in the north of England, and appears to be uncommon in America. In most cases the onset is in middle life, and the disease persists indefinitely, with or without remission. It is much commoner in men than in women.

The disease begins insidiously with one or more erythematous, slightly scaly patches. The legs, trunk and arms are most often affected (Fig. 23.4). It seldom involves the face, palms or soles. The patches are generally round or oval, but finger-like processes are also common, especially on the trunk, giving rise to the alternative name 'digitate dermatosis'. The patches are usually about 2.5 cm across, although much larger areas occur at times, especially on the legs. The colour is pink, brown or slightly yellow. The individual patches are often slightly wrinkled and appear like cigarette paper.

Symptoms are usually minimal, but some itching may occur. The patches are more prominent in winter than in summer, and may clear temporarily with natural or artificial sunlight. They will also clear for a time with suitable topical medications, but recur in the same—or adjacent—areas when treatment is stopped. After extending for a time, in most cases they then remain static and, with minor fluctuations, persist throughout life. In a few patients the condition clears permanently.

Some cases originally diagnosed as chronic superficial scaly dermatitis later develop reticulate pigmentation or atrophy, and these cases may then need to be reclassified as prelymphomatous poikiloderma.

Differential diagnosis. The main diagnostic problems are discoid eczema, eczematides, poikiloderma in its early phase, and the early stages of the classical (Alibert) form of mycosis fungoides (Chapter 57 and Table 23.3).

The history, clinical appearance, response to treatment and histology will usually establish the diagnosis.

Treatment. Only symptomatic treatment is required to allay irritation. Mild steroid ointments are generally beneficial. Natural sunlight, broad-band UVB and PUVA can be helpful when required, but relapse often occurs soon. Narrow-band UVB may also be effective in inducing remission, which can last from a few weeks to many months [8].

Dermatophytide

Definition. A reaction, at a remote site, to a dermatophyte infection [1–3]. This diagnosis should be suspected when the presence of a dermatophyte infection has been established and no fungus can be demonstrated in the dermatophytide lesions. The diagnosis is supported further by clearing of the dermatophytide after the dermatophyte has been eradicated. A dermatophytide is thus a secondary, distant, aseptic skin lesion. The terminology implies analogy to the cutaneous tuberculides associated with tuberculosis [1], although the pathomechanisms involved may be different.

Prevalence. One study indicated that this condition is rare, as only 10 cases were confirmed in 1500 dermatophyte infections [2]. Others have suggested that dermatophytide may be more common. In one retrospective review of cases of dermatophytide, 37 cases were seen in a dermatology department in a 2-year period [4].

Clinical features. Various clinical patterns of dermatophytide can occur. Eczematous vesicles on the hands or feet are the commonest pattern. On the hands, the lesions occur symmetrically on the sides of the fingers, usually as a reaction to tinea pedis. An eczematous dermatophytide can also mimic pityriasis rosea [1].

Other dermatophytides have been described, often as single-case reports, including erysipelas-like dermatitis, erythema nodosum, erythema annulare centrifugum, urticaria and erythroderma.

A dermatophytide is probably more likely to develop with inflammatory dermatophytes, such as *Trichophyton mentagrophytes* of the zoophilic type [2].

A similar allergic reaction to a yeast infection may be termed a candidide (levuride). In this case the eczematous reaction may be localized to the hands or groin [1].

A dermatophytide can be mimicked by bacterial infection. In one study, *Staphylococcus aureus* and β-haemolytic streptococci were commonly isolated from lesions that were clinically thought to be examples of a dermatophytide [2].

Discoid eczema

Synonym

- Nummular eczema

Definition. Discoid eczema is characterized by a single, non-specific morphological feature, namely circular or oval plaques of eczema with a clearly demarcated edge. It is to be distinguished from an irregular patchy form of eczema in which the lesions do not have recognizable, clear margins. The condition is poorly defined, however, because many eczema patients have one or two circular or oval lesions and few patients with discoid eczema have only circular lesions [1,2].

Aetiology. In many cases the cause is unknown and this can then be regarded as a distinctive primary endogenous form of eczema. Some authors have found a high incidence of atopy in such patients [3], but others have not [4], and levels of IgE are often within the normal range [5]. However, lesions of similar morphology may undoubtedly occur as part of atopic eczema.

Some have stressed the role of infection [6,7]. As in other forms of eczema, heavy colonization of the lesions by staphylococci may increase their severity, even in the absence of clinical evidence of infection [6,7]. However, allergic sensitivity to staphylococci or micrococci may be responsible at least for secondary dissemination [8].

Local physical or chemical trauma plays a part in some cases, and discoid eczema sometimes develops at the site of an old injury or scar.

Specific allergy is uncommon, but may be overlooked in severe or persistent cases if patch tests are not performed [9,10].

Dry skin due to low environmental humidity is sometimes associated with discoid eczema [2,11], particularly in the elderly [12]. An association between excessive alcohol intake and discoid eczema has been reported [13].

Discoid eczema has occurred rarely as a result of sensitivity to aloe [14], depilating creams [15], mercury [16], and in patients taking methyldopa [17] or gold [18].

Emotional stress may play a role in some cases, but it is unlikely to be the primary cause.

Discoid eczema is relatively rare in children [19], except as a manifestation of atopy.

Histopathology [20,21]. There is a subacute dermatitis indistinguishable from other forms of eczema, with spongiotic vesicles and a predominantly lymphohistiocytic infiltrate. Eosinophils may also be present in the upper dermis.

Electron microscopic studies have shown that the intense intercellular oedema leads to a reduction in the number of desmosomes between the cells of the basal layer, whereas those in the stratum spinosum are mostly preserved.

Clinical features. The diagnostic lesion of discoid eczema is a coin-shaped plaque of closely set, thin-walled vesicles on an erythematous base. This arises, quite rapidly, from the confluence of tiny papules and papulovesicles. These may occur, in the phase of very acute dissemination, as individual lesions on the trunk or limbs at the same time as localized plaques are being formed. In the acute phase the lesions are dull red, very exudative or crusted and highly pruritic (Fig. 23.5). They progress towards a less

Fig. 23.5 Discoid eczema of the lower leg. (Courtesy of Dr W.A.D. Griffiths, Epsom Hospital, Surrey, UK.)

Table 23.4 Diagnosis of some discoid lesions.

Disease	Distribution	Features	Histology	Course and evolution
Prelymphomatous eruption	Flank, trunk, proximal limbs	Angular, bizarre, infiltrated, itchy	Dermal infiltrate	Persistent, may change to lymphoma
Chronic superficial dermatitis	Limbs more than trunk	Oval or round, no infiltration	Epidermal eczematous	Very chronic, benign, no fluctuations
Pityriasis alba	Face, proximal limbs	Depigmentation	Very mild eczema	Spontaneous remission after 1 or more years
Discoid (nummular) eczema	Limbs more than trunk	Oval or round, very itchy	Eczema, often intense changes	Variable, fluctuant or intermittent
Tinea corporis	Limbs or trunk	Oval or round, itchy Scraping produces scale for mycology	PAS stain shows fungus	Progresses and spreads steadily until treated

vesicular and more scaly stage, often with central clearing, and peripheral extension, causing ring-shaped or annular lesions. As they fade, they leave dry, scaly patches.

After any period between 10 days and several months, secondary lesions occur, often in a mirror-image configuration on the opposite side of the body. It is very characteristic of this disease that patches which have apparently become dormant may become active again, particularly if treatment is discontinued prematurely.

It may be convenient to recognize the following patterns:

1 Discoid eczema of the hands and forearms
2 Discoid eczema of the limbs and trunk
3 'Dry' discoid eczema.

Discoid eczema of the hands affects the dorsa of the hands or the backs or sides of individual fingers. It often develops as a single plaque, which may occur at the site of a burn or a local chemical or irritant reaction. Secondary lesions may occur on the hands, fingers or forearms, but generalized spread is uncommon. It is a not uncommon form of irritant occupational dermatitis, but may also occur in housewives or secretaries in whom the provoking factors are less clear. An atopic history appears to be more frequent in young women with discoid hand eczema than in other forms of the disease.

The more usual form of discoid eczema affects the limbs and trunk. It appears to be particularly prevalent among managerial or professional classes. It is also seen in elderly people, often with dry skin exacerbated by low humidity, central heating, car heating, etc. The initial patch usually occurs on the lower leg, and secondary lesions spread to the other leg, the arms, and often the trunk. In the course of their evolution, the lesions may become increasingly oedematous and crusted, possibly because of secondary infection. Extension then becomes rapid and, in severe cases, much of the trunk and limbs will be involved. Scattered papulovesicles may then be interspersed with large and small plaques.

All forms of discoid eczema are chronic, with partial remission during which plaques tend to clear in their centres. Most forms tend to relapse at long or short intervals, and most are worse during the colder months of the year. A review of 325 cases showed that most either cleared within a year or persisted for many years [22].

'Dry' discoid eczema is an uncommon variant, consisting of multiple, dry, scaly, round or oval discs on the arms or legs, but also with scattered microvesicles on an erythematous base on the palms and soles [23]. Itching is minimal, in contrast with other forms of discoid eczema, and the condition persists for several years, with fluctuation or remission. It is notably resistant to treatment.

Diagnosis (Table 23.4). Discoid eczema may simulate ringworm when lesions clear in the centre. If there is any doubt, scrapings should be examined for the presence of mycelia.

Exogenous contact dermatitis should be suspected if the condition is unusually severe and persistent or if patches are few, asymmetrical, or of unusual configuration. Irritants and, occasionally, sensitizers, may provoke this discoid type of response. When the history suggests this, patch tests should be performed. In one series 33% of patients were considered to have clinically relevant positive results, reacting to rubber chemicals, formaldehyde, neomycin, chrome and nickel [9]. In a series reported from India [10], positive patch tests were detected in 56% of patients, of which the commonest were to chromate, nickel, cobalt or fragrance.

In psoriasis, the lesions are dry, the scaling is more prominent, and the irritation milder. Pityriasis rosea may transiently resemble discoid eczema, but usually presents with the history of a herald patch and the characteristic oval patches with long axes parallel to the ribs (often fancifully likened to the shape of a Christmas tree). The features of exudative discoid and lichenoid chronic dermatitis and chronic superficial scaly dermatitis are discussed below.

Treatment. General considerations such as the avoidance of irritants apply, as with other forms of eczema. Bed rest and removal from a stressful environment can be helpful. Ambient conditions of low humidity should be corrected.

Emollients and topical corticosteroids, perhaps with added antibiotic or antiseptics such as clioquinol, are useful. In the early stages, a potent or very potent steroid may be needed. Traditionally, a range of coal-tar pastes or ointments were used in the less acute stages, and sometimes a combination of tar and dilute corticosteroid proved useful in long-term management.

A course of a broad-spectrum systemic antibiotic, such as oxytetracycline or erythromycin, is often helpful in severe exudative cases.

Potentially useful treatments in severe and refractory cases include topical immunosuppressants, oral steroids and immunosuppressants, PUVA and broad- or narrow-band UVB.

Eczematous drug eruptions

Eczematous drug reactions may be localized, resembling, for example, seborrhoeic or discoid eczema, or generalized. Carbamazepine is a well recognized cause of eczematous reactions, which may initially involve the flexures, resembling atopic dermatitis [1]. Eczematous eruptions, including cheiropompholyx, may follow infusion of human immunoglobulin [2]. Severe reactions can rapidly progress to erythroderma.

Drug reactions are more fully described in Chapter 75.

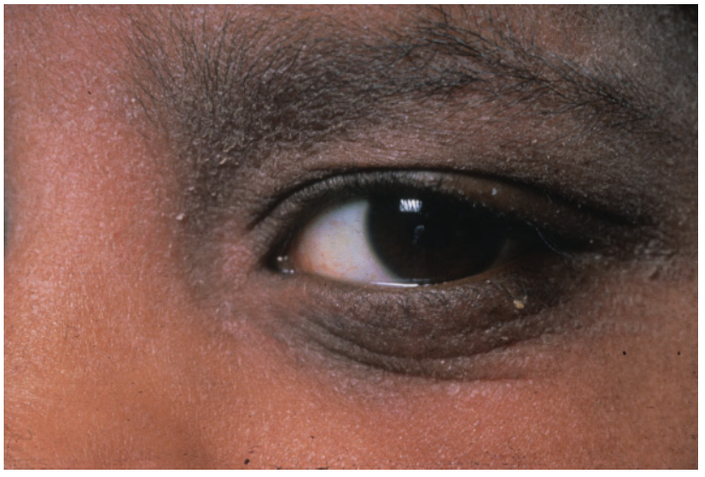

Fig. 23.6 Eyelid dermatitis (atopic, note Dennie–Morgan fold).

Eyelid eczema

Definition. Eczema affecting predominantly the eyelids.

Aetiology [1,2]. This is a common clinical presentation. Eyelid involvement is a very common feature of atopic dermatitis (Fig. 23.6) and it is therefore likely that many cases represent mild atopic dermatitis without other manifestations. Others are due to seborrhoeic dermatitis. Contact allergy to various components of eye makeup, nail varnish, fragrance, rubber [3] or ophthalmic medicaments [4] are responsible for some cases. Allergy to nickel in spectacle frames often causes eczema near the lower eyelids, originating at a site of contact with a metal frame. In some cases the cause remains obscure.

Treatment. When the condition is not amenable to removal of the cause, treatment with hydrocortisone cream is often effective. Topical immunosuppressants (tacrolimus, pimecrolimus) can also be particularly useful in this setting, and avoid the risks of inducing atrophy, rosacea or raised intraocular pressure associated with prolonged use of steroids.

Exudative discoid and lichenoid chronic dermatosis [1]

Synonym
- Sulzberger–Garbe disease

Definition. This disease has no rigid criteria, but it is a widespread, extremely pruritic eruption, characterized by discoid

Fig. 23.7 Sulzberger–Garbe disease. (Courtesy of Dr A. Warin, Royal Devon and Exeter Hospital, Exeter, UK.)

lesions with 'lichenoid' and exudative phases, which either coexist or alternate rapidly with each other. After a chronic course of months or years the condition ends in spontaneous cure. It occurs predominantly in adult male Jews, usually between the ages of 40 and 60. More than 100 cases have been reported [2], but some authors deny its existence as a distinct entity [3], and the scarcity of reports of this entity over the last two decades lends support to this contention [4,5].

Aetiology. The cause is unknown.

Histopathology. The histology is non-specific, and can mimic discoid eczema, allergic contact dermatitis or lichen simplex. There may be a characteristic swelling of the endothelial cells of the small vessels, which are surrounded by a 'cloudy' oedema. An infiltrate of mixed cells, including plasma cells and eosinophils, may form a mantle around the arterioles.

Clinical features. The eruption, which is exceedingly pruritic, comprises discoid lesions with lichenified and exudative phases, present together or alternately. The plaques are widely distributed (Fig. 23.7). In addition, there may be showers of round, urticated lesions which appear as the discoid eczematous lesions wane.

Penile and scrotal lesions are common, and are almost pathognomonic. They are also the most persistent feature. Gynaecomastia is present in some patients [2], and blood eosinophilia is frequent.

Differential diagnosis. The differential diagnosis is wide, and includes mycosis fungoides, contact dermatitis, dermatitis herpetiformis, discoid eczema and lichen planus.

Treatment. Treatment is with systemic steroids, which may have to be continued until spontaneous resolution occurs. A rapid response to azathioprine was observed in two cases [5].

Halo dermatitis

Synonyms
- Meyerson's naevus
- Meyerson phenomenon

Meyerson [1] described two patients with multiple pruritic, papulosquamous lesions surrounding melanocytic naevi (Fig. 23.8). More than 20 similar cases have since been described [2–4], mainly in young adults. Histology shows a benign naevus surrounded by a dermal lymphocytic and eosinophilic infiltrate, with overlying acanthosis, spongiosis and parakeratosis. One case developed during treatment with interferon α-2b in a patient with dysplastic naevus syndrome and Behçet's disease [5]. The condition usually resolves spontaneously within a few months, without involution of the naevus. It differs from Sutton's halo depigmentation, although the two conditions have been reported to coexist in the same patient, and in one case progression to Sutton's naevus occurred [6]. Similar changes are not infrequently seen around seborrhoeic warts [7] and other elevated skin lesions [8], and are termed the 'Meyerson phenomenon'.

Hand eczema

Hand eczema is such a common and distressing condition, and poses such difficult problems for the dermatologist, that it deserves separate consideration [1]. Up to 30% of occupational medical practice relates to hand eczema, with important issues regarding medical litigation, worker's compensation and disability. A quarter of the patients referred to a specialized contact dermatitis clinic suffered from hand dermatitis [2].

Definition. The term hand eczema implies that the dermatitis is largely confined to the hands, with only minor involvement of other areas. If the eczema is widespread and the hands appear to be involved only coincidentally, it is preferable to speak of hand involvement.

Classification. No single classification of hand eczema is completely satisfactory. As with eczematous dermatoses in general, classification is based partly on aetiology and partly on morphology. Several different morphological forms are seen clinically as fairly consistent entities, but some of these entities can have several different causes. Conversely, a single cause can sometimes produce several different morphological patterns.

Morphological variants of hand eczema are described below, and an aetiological classification is shown in Table 23.5. This may be useful to the clinician as a checklist in an individual case, although the list does not exhaust the aetiological possibilities. Other rare causes have been reported, for example venous eczema secondary to arteriovenous shunts in the forearm. There are probably other causative agents which have yet to be identified.

Most cases of hand eczema have a multifactorial aetiology. This not only makes treatment difficult, but it can cause considerable problems in medicolegal cases (e.g. occupational dermatitis in which negligence is alleged against an employer).

Atopy, a naturally dry skin, a tendency to seborrhoeic dermatitis, a superadded contact allergic or irritant dermatitis, or even the effect of rubbing or scratching may all obscure or potentiate the original cause. Even the daily, mild trauma of normal life and climatic influences may play some part [3], and litigation itself may cause an exacerbation of the condition.

The role of stress in aggravating hand eczema is difficult to evaluate, and the disease itself is very stressful [4]. Many patients give a convincing account of exacerbations at times of acute anxiety, frustration or grief.

The role of hormonal factors is also difficult to assess. Occasionally, there is a history of premenstrual exacerbation, or deterioration during pregnancy.

Table 23.5 Hand eczema: aetiological possibilities to be considered.

Exogenous
Contact irritants
Chemical (e.g. soap, detergents, solvents)
Physical (e.g. friction, minor trauma, cold dry air)
Contact allergens
Delayed hypersensitivity (type IV) (e.g. chromium, rubber)
Immediate hypersensitivity (type I) (e.g. seafood)
Ingested allergens (e.g. drugs, possibly nickel, chromium)
Infection (e.g. following bacterial infection of hand wounds)
Secondary dissemination (e.g. dermatophytide reaction to tinea pedis)
Endogenous
Idiopathic (e.g. discoid, hyperkeratotic palmar eczema)
Immunological or metabolic defect (e.g. atopic)
Psychosomatic: stress aggravates, but may not be causative
Dyshidrosis: increased sweating aggravates, but may not be causative

Fig. 23.9 Bullous eczema due to contact allergy to rubber gloves.

Exogenous causes. Contact irritants are the commonest exogenous cause of hand eczema [5], but contact allergens such as chromate, epoxy glues, rubber, etc. are also important (Chapter 26). All patterns of hand eczema are possible in contact allergy. Rubber dermatitis usually affects the dorsa of the hands (Fig. 23.9), but so can contact irritant and atopic dermatitis [6]. Certain occupations are particularly likely to provoke hand eczema. The problem of occupational eczema in hairdressers, fish industry workers, farmers, construction workers, dental and medical personnel, metal workers and caterers has provoked many studies to determine its prevalence and to develop programmes for prevention of hand dermatitis [7–9]. This topic is discussed in more detail in specialized textbooks such as that of Menné and Maibach [1].

Mention must also be made of the possibility of type 1 allergic reactions to certain proteins. In mild cases they provoke a vesicular eczema of the fingers in certain individuals, particularly those who prepare seafood. In one Scandinavian study, no less than one-third of restaurant food handlers with hand dermatitis had such a contact urticaria [10]. Greater concern has arisen in recent

Table 23.6 Morphological patterns of hand eczema.

Apron eczema

'Wear and tear' dermatitis (dry palmar eczema)
Other patterns (e.g. patchy vesiculosquamous)

years because of the increasing frequency of reactions to natural rubber latex protein found in latex gloves. The reactions range from contact urticaria to rhinitis, asthma and anaphylaxis [11]. There has been particular attention paid to hospital employees, and 7% of staff reported symptoms suggestive of latex sensitivity in a study conducted in the northwest of England [12].

Oral ingestion of allergens such as nickel, chromium or balsam of Peru has been reported to provoke or aggravate hand eczema in sensitized subjects [13–17], although the importance of this phenomenon is controversial [18].

Endogenous causes. Twin studies suggest hereditary factors play a role in the development of hand eczema [19], with the atopic diathesis as the commonest endogenous cause [20]. Hand eczema is more common in people with a previous history of atopic dermatitis elsewhere [21]. The most common site of atopic dermatitis in the adult is the hands, and in some patients the hands alone may be involved. Indeed, the atopic state may first become apparent with the development of hand eczema in an adolescent or young adult when they are exposed to school, hobby or occupational irritants. The eruption is often patchy and always very irritable. There is no specific topographic pattern, although the feet may also be involved [22,23]. Lichenification may be evident at an early stage, and pompholyx may or may not be present. The atopic diathesis may also predispose to a discoid pattern of hand eczema in young adults. Atopic hand eczema probably has the worst prognosis of all types of hand eczema [5].

A morphological classification of hand eczema is often suggested. Although most cases are of a patchy vesiculosquamous nature without any special characteristics, about one-third of cases present particular patterns that deserve recognition (Table 23.6). The various patterns are discussed below. However, there are no hard and fast divisions; the morphology frequently changes in an individual case, so that a diagnosis based on morphology may have to be revised.

Histopathology. In general, the differences between the various forms of hand eczema are clinical rather than histological, but the considerably thickened horny layer and the presence of numerous sweat glands modify the histological features of eczema on the hands.

Prevalence. Minor degrees of hand eczema are very common, and virtually everyone suffers from mild dryness and chapping at some time or another. The perception of whether these changes amount to hand dermatitis can influence the findings of epidemiological studies [24].

In most surveys, hand eczema is commoner in females, in a ratio of about two to one [5], and in adolescents with hand eczema the prevalence increases in girls as they age, whereas boys tend to improve [25]. Agrup [26] found that about 2% of people in a county in southern Sweden had active hand eczema, but only 25% of them had consulted their doctor about it in the previous year, and 25% had never sought medical advice. A study of prevalence in Sweden in 1984–8, by questionnaire of 16584 individuals, showed that 11% had suffered from hand eczema within the year, with a point prevalence of 5% [27].

In high-risk groups the figures are even higher. In Finland, 44% of 617 hospital personnel engaged in 'wet work' (nurses, cleaners, kitchen staff, etc.) had a past or present history of hand eczema, and 28% had at least two attacks [28]. This is confirmed by a study demonstrating significantly greater risk of hand dermatitis among hairdressers compared with office workers [29].

Eczema of the hands accounted for 34% of cases of eczema attending a contact dermatitis clinic in Singapore [30].

Morphological types of hand eczema

Apron eczema

This condition is a type of hand eczema which involves the proximal palmar aspect of two or more adjacent fingers and the contiguous palmar skin over the metacarpophalangeal joints, thus resembling an apron [1] (Fig. 23.10). This pattern of hand eczema can be irritant or allergic, but is often considered endogenous.

Chronic acral dermatitis

This is a distinctive syndrome affecting patients in middle age. A chronic, hyperkeratotic, papulovesicular eczema of the hands and feet, intensely pruritic, is associated with grossly elevated IgE levels in subjects with no personal or family history of atopy. The condition responds to oral corticosteroids, but the response to topical therapy is poor [2].

Fig. 23.11 Fingertip eczema resulting from allergy to plant bulbs. (Courtesy of Dr F.A. Ive, Durham, UK.)

Discoid eczema

See p. 23.9.

Fingertip eczema

This condition also presents a very characteristic pattern, involving the palmar surface of the tips of some or all the fingers. The skin is dry, cracked and sometimes breaks down into painful fissures. Usually remaining localized, it may occasionally extend along the palmar surfaces of the fingers to merge with palmar eczema (Fig. 23.11).

Two patterns may be distinguished. The first and most common involves most or all of the fingers, mainly those of the dominant hand, and particularly the thumb and forefinger. The condition is usually worse in the winter and generally improves on holiday. Patch tests are negative or not relevant; it is a cumulative irritant dermatitis in which degreasing agents combine with trauma as causative factors. The second pattern involves preferentially the thumb, forefinger and third finger of one hand. This is usually occupational (whether in factory, market garden or house). It may be either irritant (e.g. in newspaper-delivery employees) or allergic (e.g. to colophony in polish, or to tulip bulbs or stems [3,4]). The condition usually involves the dominant hand, but there may be allergy to onions, garlic [5] and other kitchen products held in the non-dominant hand when being cut. In these cases, patch testing (and 20-min contact tests) may be rewarding.

'Gut' eczema

Synonym
- Slaughterhouse eczema

Workers who eviscerate and clean pig carcasses are at risk of developing vesicular eczema which starts in the finger-webs and spreads to the sides of the fingers. This is a mild, self-limiting condition, which clears in a week or two, even if the patient remains at work, but it can recur at intervals. Workers in Danish bacon factories call this 'fat eczema', although there is little evidence that it is due to fat, and prick tests to pig fat extracts are negative [1]. The pathogenesis is unknown, but some slaughtermen have developed contact urticaria from exposure to animal blood [2].

Hyperkeratotic palmar eczema

Synonym
- Tylotic eczema

This condition is a distinct form of hand eczema which is characterized by highly irritable, scaly, fissured, hyperkeratotic patches on the palms and palmar surfaces of the fingers [1,2] (Fig. 23.12). It is a common condition, and 2–5% of all applications for permanent disability pensions in some western European countries are due to hyperkeratotic hand eczema.

The aetiology is unknown. Patch tests are usually negative, and the incidence of atopy and psoriasis is no greater than in a normal control population. The distinction from localized psoriasis of the hands can, however, be very difficult. It is most frequent in men of middle age or over, and is extremely refractory to treatment, although PUVA may be helpful [3]. Steroid ointments, crude coal tar, salicylic acid and Grenz rays may be tried. A review of 32 patients re-examined 10 years after initial presentation showed that in 29 the condition had remained more or less unchanged [1,3]. Oral retinoid tablets such as alitretinoin and etretinate may be helpful [4,5].

Patchy vesiculosquamous eczema

In a large group of cases, a mixture of irregular, patchy, vesiculosquamous lesions occur on both hands, usually asymmetrically. In contrast to the lesions of discoid hand eczema, the degree of activity and distribution of the lesions vary, appearing now at one site, now at another. Nail changes are common if the nail folds are affected.

Pompholyx

Synonyms
- Vesicular eczema of palms and soles
- Dyshidrotic eczema

Definition and nomenclature. Pompholyx is a form of eczema of the palms and soles, in which oedema fluid accumulates to form visible vesicles or bullae. Because of the thick epidermis in these sites, the blisters tend to become larger than in other body areas before they burst. When pompholyx occurs on the palms, it may be called cheiropompholyx, and when on the soles, podopompholyx. The alternative name, dyshidrotic eczema, refers to a sup-

posed connection with sweat-gland activity, as the condition is worse in hot weather. However, most authors feel that this term should be abandoned, as no causal relationship with the sweat glands or sweating has been demonstrated.

Incidence. Few figures are available, but pompholyx probably accounts for about 5–20% of all cases of hand eczema [1,2].

Aetiology. The cause remains obscure. In most cases no exogenous cause is found. Monozygotic twins have been affected simultaneously [3], suggesting that hereditary predisposition may be important, but in a study of nickel allergy in twins, only one pair out of 14 was concordant with pompholyx. In seven other pairs, pompholyx occurred only in the nickel-sensitive twin [4].

The role of the sweat glands has been disputed. Although the distribution of the lesions corresponds to that of emotionally activated palmoplantar sweating and the condition is worse in hot weather, hyperhidrosis is by no means a constant feature. Indeed, eczematous changes have been both induced and relieved by sympathectomy reducing hyperhidrosis [5,6]. A thorough examination of serial sections of pompholyx vesicles [7] showed that sweat ducts were often pushed aside by the tense vesicles or passed between them. The contents and pH of the vesicular fluid suggested that vesicles ruptured the sweat ducts rather than the reverse. In one study, biofeedback training aimed at reducing sweating produced slight improvement [8].

The role of atopy is also difficult to assess, partly because of the paucity of controlled studies [9]. In one study, a family or personal history of atopy was obtained in 54 out of 131 patients with pompholyx [10]. Lodi *et al.* [11] found personal and family atopy in 50% of their patients with pompholyx compared with 12% of control patients, but other studies have found no correlation between atopy and pompholyx [12,13]. Schwanitz [9] reviewed the evidence relating to the causes of pompholyx in some detail, and concluded that atopy is probably the most important factor and the role of dyshidrosis has been overemphasized in the past.

Primary irritants can cause pompholyx, for example in metal workers exposed to soluble oils [12].

Direct-contact allergens may sometimes evoke a palmar vesicular reaction instead of the more common dorsal pattern [14]. Responsible allergens include primin, isopropyl paraphenylenediamine, benzoisothiazolones and dichromates [15]. Perfumes, fragrances and balsam ingredients must also be considered as potential allergens [16]. Patch tests of nickel sulphate applied to the palms or fingers of nickel-sensitive subjects may produce a vesicular pompholyx-like reaction, but contact sensitivities found on patch testing may be secondary phenomena [17].

The role of ingested metals in provoking exacerbations of vesicular palmar hand eczema has been studied. Some authors [17–20] found that many nickel-sensitive patients have this pattern of hand eczema, and produced flares by giving oral nickel sulphate—although usually in doses far greater than the natural daily intake. Others have been unable to confirm this [21,22]. Chromium and cobalt allergy may also occasionally be implicated [16,23]. Oral neomycin provoked pompholyx in three of 10 neomycin-sensitive patients with leg ulcers [24].

Other haptens may give rise to pompholyx. These are difficult to detect, but a careful history, supplemented by 'feed-back' tests may occasionally pinpoint an offending allergen. Patch tests, although producing a low yield of positive results, should be performed in all cases of pompholyx.

Fungal infection elsewhere on the body, usually the feet, can provoke eczema of the palms. In the past this pompholyx *dermatophytide* [16] was diagnosed more frequently than it is now, and it has been regarded as a rare association in other studies [15,25]. Confirmation depends on disappearance of the pompholyx when the focus is treated and its relapse if fungus recurs. It is necessary, of course, to prove the presence of the fungus—coexistence of pompholyx on the hands and feet is not uncommon.

Irritant or allergic dermatitis resulting from treatment of a fungal infection of the foot may also precipitate a palmar pompholyx. Primary allergic contact dermatitis of the feet, for example from rubber shoe chemicals, may induce a sympathetic palmar eruption.

The role of *bacterial foci* cannot be dismissed. Some reported cases may have been examples of a true pustular bacteride affecting the palms or soles.

The role of *stress* is, as usual, difficult to define. In some patients, recurrences can convincingly be related to stressful episodes, but in many others there is no such correlation. It has been suggested that patients with pompholyx are unduly susceptible to stress, but it should be remembered that pompholyx itself causes stress, particularly if there are financial problems due to loss of work.

Pompholyx may rarely follow a *drug eruption*. Aspirin ingestion, oral contraceptives and cigarette smoking also increase the risk of pompholyx [13].

Histopathology. The early features have not been sufficiently well studied. Fully formed lesions show the changes of acute eczema modified by the thick, overlying epidermis. The subsequent course is that of a subsiding eczema, with hyperkeratosis and epidermal shedding.

Clinical features (Fig. 23.13). Pompholyx may occur at any age, but it is more common before the age of 40 years. Onset before 10 years is unusual. An attack of pompholyx is characterized by the sudden onset of crops of clear vesicles, which appear deeply seated and 'sago-like'. There is no erythema, but a sensation of heat and prickling of the palms may precede attacks. Vesicles may become confluent and present as large bullae, especially on the feet. Itching may be severe, preceding the eruption of vesicles. The attack subsides spontaneously, and resolution with desquamation occurs in 2–3 weeks in most cases, but recurrent attacks in this period may cause a wave-like continuation of symptoms in a minority of cases. In mild cases, only the sides of the fingers may be affected, but in a typical case the vesicles develop symmetrically on the palms and/or soles. Unilateral or asymmetrical patterns occur, but this should alert the dermatologist to look for contact causes of the eruption. In 80% of patients only the hands are involved. The hands and feet, and the feet alone each account for about 10% of patients. Secondary infection with pustule formation and lymphangitis is not uncommon, and may complicate each attack in certain patients. Rubbing and inappropriate treatment

Fig. 23.13 Pompholyx, showing confluent vesicles of the palm.

may produce secondary eczematous changes extending beyond the volar surfaces. After recurrent attacks spreading to the dorsa of the fingers, the nails may develop dystrophic changes, irregular transverse ridging and pitting, thickening and discoloration. Such changes may follow even mild attacks, and may be the patient's presenting complaint.

In cases in which no cause can be demonstrated (i.e. the majority) recurrences are usual. They may occur at intervals of 3 or 4 weeks for months or years, or at long irregular intervals. Pompholyx is more common in warm weather, and in some patients attacks occur annually each summer.

Diagnosis. There is some debate whether the term pompholyx should be reserved for typical cases in which the attacks resolve and recur. Chronic, recurrent vesiculation without periods of remission may be termed chronic vesicular dermatitis.

A circumscribed and asymmetrical area of scaling and vesiculation of the palm or sole should suggest the possibility of dermatophytosis, and scrapings should be examined for fungus. If the erythema is limited to one or two interdigital clefts, or is asymmetrical, or involves the dorsal skin to any extent, the possibility of a contact dermatitis must be considered, and excluded by a careful history and by patch testing. In pustular psoriasis of the palms and soles there are usually no clear vesicles, although this is not invariably so [26]. The pustules are sterile on culture, and leave characteristic brown marks as they resolve. Occasionally, secondary bacterial infection of pompholyx may occur, with pustule formation, but in these cases the lesions tend to be painful, with surrounding erythema, and culture of the pus yields the causative organism. A pustular bacteride secondary to bacterial infection elsewhere in the body may also lead to confusion.

Repeated attacks of pompholyx may produce hyperkeratotic lesions that mimic psoriasis vulgaris.

Pemphigoid, linear IgA disease and pemphigoid gestationis occasionally present with blisters on the palms that mimic pompholyx [27,28].

Treatment. Any obvious cause of the eruption should be eliminated, but in most cases one will have to rely on non-specific measures. In the acute phase, rest and bland applications are indicated. Involvement of the feet may require the patient to be treated in bed. The hands or feet should be soaked three or four times a day in either Burow's solution (aluminium acetate 1%) or potassium permanganate solution (diluted 1:8000). Large bullae may be aspirated using a sterile syringe. Systemic antibiotics will be required if secondary bacterial infection develops. This is most likely to be staphylococcal, and flucloxacillin is usually effective.

As the eruption subsides the soaks should be discontinued, and zinc cream or oily calamine lotion can be substituted. Topical steroids are useful in the subacute and chronic phases. In a few severe cases, a course of oral steroids may be justified.

For chronic pompholyx which has entered the hyperkeratotic phase, tar preparations such as 2–5% crude coal tar may be used, or a steroid preparation may be combined with a coal-tar solution. Low-dose methotrexate and radiation therapy have both been used with success in refractory cases [29–30].

Recurrent focal palmar peeling

Synonyms
- Desquamation en aires
- Keratolysis exfoliativa
- Ringed keratolysis of the palms

The condition is sometimes a mild form of pompholyx. During the summer months, small areas of superficial, white desquamation develop on the sides of the fingers and on the palms or on the feet (Fig. 23.14). They appear abruptly, and expand before peeling off. There is little or no irritation, and vesicles as such are not seen. The condition is probably not rare, but because it is relatively asymptomatic it often does not reach the dermatologist. Some patients subsequently develop true pompholyx.

The differential diagnosis includes the generalized peeling skin syndromes discussed in Chapter 19.

Ring eczema

This characteristic pattern particularly affects young women, rarely men. The condition usually starts soon after marriage or childbirth. An irritable patch of eczema begins under a ring—usually a broad wedding ring—and typically spreads to involve the adjacent side of the middle finger and the adjacent area of the palm. It may remain confined to these sites, but is occasionally followed by the appearance of discoid patches elsewhere; or a more diffuse vesicular eczema may develop. Despite the clearly defined demarcation of the initial eruption, these patients cannot be shown to be sensitive to gold or copper although, curiously, nickel, cobalt and even chromium sensitivity are more commonly found on patch testing than might be expected; only rarely can 'white gold' alloys be implicated. Ring dermatitis has been described as the clinical presentation of fragrance sensitization [1]. Transference of the ring to the other hand is often rapidly followed by the appearance of eczema at the new site and, once affected, patients may aver that wearing of the ring for only a few minutes, even without washing, causes irritation. This type of hand eczema is probably due primarily to concentrations of soap and detergent beneath rings (which may tighten on fingers immersed in hot water), but microtrauma, especially friction, may also play a role.

Very rarely, radioactive gold in a ring may cause radiation dermatitis which mimics this type of wedding ring eczema [2].

'Wear and tear' dermatitis

Synonyms
- Asteatotic hand eczema
- Housewives' dermatitis
- Dry palmar eczema
- Dermatitis palmaris sicca

This pattern of exogenous dermatitis affects housewives and cleaners who frequently immerse their hands in water and detergents, and is presumably due to a combination of asteatosis, exposure to mild irritants such as soaps and detergents, and mild trauma, for example from wringing out dishcloths. The skin feels dry, it becomes criss-crossed with superficial cracks associated with a damaged horny layer, and it is unable to respond with its normal pliability to hand and finger movement (Fig. 23.15). These cracks often stand out white against an erythematous background. In addition to palmar involvement there may be dryness and chapping of the skin over the dorsa of the knuckle joints. The condition may also be associated with fingertip eczema (Fig. 23.16) or with ring dermatitis.

Some patients with juvenile plantar dermatosis also have hand involvement, and some patients have the distinctive palmar dermatitis alone. This is a dry, glazed, erythematous, fissured and only mildly pruritic condition, which has been called dermatitis palmaris sicca [1]. Exudation and weeping do not occur in this condition. There seems to be little or no clear morphological distinction between this condition and 'wear and tear' dermatitis.

Fig. 23.16 Fingertip eczema in a patient with wear and tear eczema. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Reference

1 Lim KB, Tan T, Rajan VS. Dermatitis palmaris sicca—a distinctive pattern of hand dermatitis. *Clin Exp Dermatol* 1986; **11**: 553–9.

The above list by no means exhausts the possible morphological patterns of hand eczema. Some patients, for example, have dry, scaly eczema confined to a small area on the thenar or hypothenar eminence, and this is almost always endogenous. Others may have vesicular eczema confined to the edge of the hand in a very persistent form, and so on.

Differential diagnosis. The diagnosis of hand eczema is usually self-evident, but the distinction from psoriasis can be very difficult. Most experienced dermatologists have seen cases they have confidently labelled as hand eczema, which have later developed typical psoriasis in other areas [1]. In some cases even biopsy does not allow a clear distinction to be made. In most cases of psoriasis on the hands, however, the silvery nature of the scale, involvement of the knuckles, sharply demarcated 'scalloped' edges to the erythema along the borders of the hands and fingers, and the relative absence of pruritus, are helpful pointers. A family history of psoriasis and the presence of nail pits in the absence of nail-fold lesions are also suggestive.

Tinea can also be missed, especially when it is extensive and irritable (Fig. 23.17), or secondarily infected. Unilateral scaling of the palm should always suggest a possible *Trichophyton* infection, and a discoid plaque due to *T. verrucosum* is sometimes seen in farmers.

The special characteristics of palmar pustulosis are usually evident. Lichen planus (Fig. 23.18) and pityriasis rubra pilaris may resemble eczema on the hands, but usually present with typical lesions at other sites.

It must be emphasized that the whole skin should be examined in any case of hand eczema in which the diagnosis is in doubt. There may, for example, be evidence of nickel allergy or tinea pedis, or small patches of psoriasis of which the patient is unaware.

Fig. 23.17 *Trichophyton* infection of the hands, which had failed to respond to topical steroids. Note the nail involvement.

Fig. 23.18 Lichen planus mimicking hyperkeratotic hand eczema, but the margins are well demarcated, and the lesions on the left wrist are characteristic of lichen planus.

Prognosis. Unless a responsible allergen can be identified and removed, the prognosis of hand eczema is always uncertain. Some allergens, such as nickel, rubber, chemicals and fragrances, are ubiquitous, however, and complete avoidance in the home environment is difficult to achieve [2–5]. In general, eczema on the dorsa of the hands clears more readily, and is less likely to recur than palmar eczema. Acute attacks of pompholyx will usually settle down and in one-third of the cases will not recur. In another third, recurrences will take place, and in the remainder the condition will pass into a chronic, possibly hyperkeratotic stage. Those forms of hand eczema that are due in part or wholly to the effects of irritants carry a particularly poor prognosis unless these irritants can be completely removed. Interdigital dermatitis has been shown to be a potential precursor to more severe hand dermatitis in hairdressers. Recognition of this sign by the patient may allow early intervention to prevent progression of the disease [6].

A prolonged period of rest for the skin is usually necessary for complete restoration of the protective function of the stratum corneum [7]. Patients who have suffered from severe hand eczema will often remain vulnerable to mild irritants for several months after the eczema has apparently cleared.

There are few figures available for assessing the prognosis of non-occupational hand eczema. Many patients learn to 'live with' their condition, and cease to attend doctors—a poor reflection of our capabilities in this field. The prognosis is worse in patients with atopic eczema [8,9].

In one study, one-quarter of patients were symptom-free, and a further half had improved after a follow-up period of 6–22 months [10]. In a longer follow-up of 213 cases, less than one-third had entered complete remission [11]. Change of occupation did not affect the prognosis.

The behaviour of hand eczema in pregnancy is variable.

Treatment. Treatment of *acute* hand eczema is as for pompholyx (p. 23.18). For *chronic* eczema particular attention must be paid to possible causative factors, and a full occupational and social history, with details of hobbies and spare time activities, is essential. Patients must be asked exactly what their job involves, and how they protect their hands. Patch tests are advisable (Chapter 26).

The same general principles of treatment apply as for chronic eczema on other parts of the body (p. 23.38). The three most useful measures are:

1 Avoidance of irritants
2 Frequent application of emollients
3 Topical steroids.

Avoidance of irritants is particularly difficult for patients with hand eczema, as irritants are so ubiquitous. Education of the patient to the possible dangers is of paramount importance, and printed advice sheets are useful, as patients often have a poor recollection of oral instructions. Examples of suitable instruction sheets have been provided by Epstein [12].

Cleanliness is important, but too much soap and water can be harmful. A wide variety of soap substitutes are now available. Older remedies, such as a tablespoon of emulsifying ointment mixed in a cup of hot water, are often helpful. Very brief exposure to soap followed by immediate application of a topical lipid is unlikely to be harmful, and may be beneficial by removing bacteria and debris [13].

Barrier creams are usually ineffective for hand eczema of occupational origin, although new products are frequently being reported as showing some promise [14,15]. In practice they may not be applied effectively [16], and the debate continues about their actual benefit [17]. Gloves usually provide the best protection, and time should be spent discussing with the patient the details of the material, size and weight of the gloves to be used, so that they can be tailored to the individual's particular need.

Gloves with holes in them may be worse than no gloves at all, but gloves that are too thick may make it impossible to perform a particular task. It should also be remembered that some allergens, such as acrylates and epoxy resins, can penetrate vinyl or rubber gloves [18]. Rubber gloves generally give good protection for housework. In patients with rubber allergy, polyvinyl chloride household gloves should be worn instead. If sweating makes the condition worse, it may be helpful to wear cotton gloves beneath the protective gloves. Gloves should also be used for dry work, to prevent soiling and trauma, especially for gardening in cold, dry air. Thin leather is usually better than cotton for this purpose.

Emollients should be applied frequently as a thin smear rubbed gently into the skin, and several jars should be left at convenient locations near sinks, etc., so that they are readily available. The choice of emollient will vary with the patient. Some people will benefit from a greasy preparation such as emulsifying ointment, and others will prefer a more cosmetically acceptable cream such as aqueous cream, which sinks into the skin more readily, and is less likely to stain paper, etc. Numerous commercial preparations are now available. Patients should be warned that some topical preparations sold over the counter by pharmacists as antipruritics or emollients can contain irritants such as alcohol or propylene glycol, and they should use only what the dermatologist recommends.

Topical steroids are used in all but the mildest cases, but as always they should be used sparingly, and in the weakest potency that is effective. Hydrocortisone in a concentration of 1% is perfectly safe, but stronger steroids will often be required and these can cause atrophy. Even though the palms are thick, the epidermis can be rendered thin and fragile by potent topical steroids. This is not a major problem in hyperkeratotic eczema, but in these cases steroids are relatively ineffective. If bacterial infection is present, a systemic antibiotic may be needed, and the use of a combined steroid–antiseptic or antibiotic preparation may help to lessen the risk of infection and improve the response. The risk of bacterial overgrowth due to steroids, however, is probably less than one might expect. It has been shown that a potent steroid used alone can reduce or even eliminate *Staphylococcus aureus* colonization in hand eczema [19].

In difficult, unresponsive cases the use of a potent steroid under occlusion may be considered. The steroid is applied at bedtime, and polythene gloves are worn overnight, sealed at the wrist with sticky tape. This is an effective treatment, but it greatly increases the risk of atrophy and secondary bacterial infection, and should be discontinued as soon as the eczema shows satisfactory improvement.

If hand eczema does not respond to topical steroid therapy, the diagnosis should be reviewed, particularly with regard to the possibility of tinea. The patient should be quizzed again about exposure to irritants or allergens, and the possibility of sensitization to medicament bases or preservatives or even the corticosteroid itself should also be considered, with patch tests if necessary.

After improvement of the dermatitis with daily corticosteroid use, the intermittent use of a potent corticosteroid cream may safely prevent relapse [20].

Intradermal injection of triamcinolone (10 mg/ml) into recalcitrant, localized patches of hand eczema has been found helpful [12].

Topical immunosuppressants provide a further option for treating hand eczema. In a left/right comparative trial with 16 subjects, topical tacrolimus 0.1% proved similar in efficacy to mometasone furoate [21]. The response to tacrolimus was better on palms than soles.

Other measures: tar pastes are often useful for chronic unresponsive cases. Generally speaking, the messier preparations such as 5% crude coal tar tend to be more effective than the cosmetically more pleasant preparations.

Salicylic acid ointment is also sometimes helpful for hyperkeratosis and persistent scaling [22]. Various combinations of tar, steroids and salicylic acid may be tried, and Baden [23] has recommended the application of a keratolytic gel of salicylic acid and propylene glycol under occlusion for 2–4 h before the application of steroid ointments at night.

Oral psoralen phototherapy (PUVA) and UVB therapy have proved useful for several types of hand eczema, including allergic contact dermatitis, dyshidrotic eczema and hyperkeratotic palmar eczema [3,24–30]. Topical hand PUVA soaks have also been shown to be effective and safe, although patient compliance is crucial to the treatment's success [31]. A PUVA-cream approach may be more useful [32].

Radiotherapy is also effective for stubborn hand eczema. Grenz rays were widely used in the past, as these were thought to be safer than X-rays. Fairris *et al*. [33] have shown that superficial X-rays give a better result, and they advise that patients can safely receive three courses of 300 Rad (3 Gy) of superficial X-ray therapy during a lifetime.

Alitretinoin (9-cis-retinoic acid) is a retinoid which interacts with both RXR and RAR receptors. It has been shown to improve chronic hand eczema in a large placebo-controlled trial with over 1000 subjects [34]. These included patients with any morphology of hand eczema. Although patients with pompholyx improved as well as those with hyperkeratotic eczema, it remains unclear whether this drug is working as an anti-inflammatory agent or just by reducing hyperkeratosis. The side effect profile of alitretinoin is that of an RXR agonist (rexinoid). Reduction in thyroid hormone and TSH levels may occur. Cholesterol and triglyceride levels are raised. The mucocutaneous side effects associated with RAR agonists such as acitretin are much less pronounced. Acitretin and etretinate can be effective for hyperkeratotic eczema, but there is a high incidence of side effects [35]. It is probable that retinoids may work synergistically with topical therapies, as reduction of hyperkeratosis may enhance penetration. Combining retinoids with PUVA may also prove useful.

Ciclosporin has been reported to be useful in recalcitrant cases of chronic vesicular hand eczema and appears to be equivalent in efficacy to a potent topical corticosteroid, although side effects may be a concern [36,37].

Ranitidine was shown to have adjuvant benefits to topical steroid treatment of atopic hand dermatitis, without any side effects [38].

Painful fissures of the fingertips are a particular therapeutic problem. The main requirement is to keep the keratin as pliable as possible, by the use of greasy preparations, and it often helps to use polythene occlusion at night, with thin leather gloves during the day. Once formed, fissures are slow to heal, but they can some-

times be rendered painless by sealing them with a product such as compound benzoin tincture. Recurrent infection of fissured hand eczema can give rise to lymphoedema and long-term, low-dose antibiotic prophylaxis with penicillin may be required [39].

In indolent cases in which metal allergy of dietary origin is thought to be playing a part [40], the use of an oral chelating agent may be considered. Disulfiram 200 mg daily for 8 weeks produced a good result in an open study, but this treatment carries the risk of liver dysfunction [41].

Infective dermatitis

Synonym
- Microbial eczema

Definition. Infective eczema (Fig. 23.19) is eczema that is caused by microorganisms or their products, and that clears when the organisms are eradicated. This should be distinguished from infected eczema (Fig. 23.20) in which eczema due to some other cause is complicated by secondary bacterial or viral invasion of the broken skin. In practice, however, the two conditions can coexist, and the distinction can be difficult. Moreover, the bacterial flora of an eczematous lesion differs quantitatively from that of normal skin [1], and the demonstration that organisms are present does not establish that they are modifying the lesion. The distinction between colonization and infection can be very difficult, but the presence of an increased level of C-reactive protein in the blood may offer a useful clue [2].

Infective dermatitis, therefore, is a controversial entity, and some dermatologists never make this diagnosis. Nevertheless, cases are seen occasionally in which bacterial or viral invasion of

Fig. 23.19 Infective eczema in a non-atopic man. Histology of this localized rash showed eczema, and *Staphylococcus aureus* was repeatedly isolated. There was no response to topical steroid therapy, but the condition cleared rapidly with oral flucloxacillin.

Fig. 23.20 Infected dermatitis. This man had a patch of discoid eczema which became secondarily infected with *Staphylococcus aureus*.

the skin seems to occur as the primary event, and is followed by secondary eczematization which can spread for some centimetres beyond the obvious infection. The patches of eczema that occasionally develop around lesions of molluscum contagiosum provide a good example (Fig. 23.21), because the pearly papules are the initiating event, and eczema can develop in the surrounding skin some days later, even when the lesions have not been scratched or traumatized. The eczema generally clears when the

Fig. 23.21 An area of eczematization developing around lesions of molluscum contagiosum. The skin had previously appeared normal, and it returned to normal when the molluscum infection cleared. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

molluscum lesions subside. Similarly, one occasionally sees eczematous skin around infected wounds, and the eczema clears with antibiotic treatment alone.

Some experts would include seborrhoeic dermatitis as a form of infective dermatitis, on the grounds that the levels of *Malassezia* yeasts in the skin are increased, and the eczema may clear following antiyeast therapy. However, the exact role of these yeasts in the pathogenesis of seborrhoeic dermatitis is still uncertain, and some authorities do not accept seborrhoeic dermatitis as infective.

Pityriasis rosea is not usually considered to be a form of eczema, although the histology may show spongiosis (see Chapter 33).

Histopathology. The histological picture of infective eczema is in general that of subacute or chronic eczema, in which spongiosis is combined with acanthosis, hyperkeratosis and patchy parakeratosis. The dermis shows inflammatory changes, with polymorphonuclear and lymphocytic infiltration which invades the epidermis to a variable extent. In some stages, subcorneal pustulation may be conspicuous.

Pathogenesis. The mechanism by which microorganisms cause eczema is not understood. Bacterial antigens can promote a cytotoxic reaction in the skin, but such a reaction is perhaps more likely to aggravate or perpetuate than to initiate the eczematous process [3–6]. Bacterial superantigens such as staphylococcal protein A

and enterotoxin B [7] may be profound immune stimulants and may aggravate atopic dermatitis (see Chapter 24). Bacterial antigens may play this role in a variety of syndromes, including discoid eczema, and not merely in infective dermatitis. Cultured staphylococci applied topically can also provoke an eczematous delayed hypersensitivity reaction [7,8].

The possibility that bacterial antigens from systemic foci of infection may cause eczema has not been fully established. It does seem to be accepted, however, that eczematous reactions can occur as an allergic reaction to a fungal infection elsewhere in the skin (see Dermatophytide section above, p. 23.8).

Clinical features. As mentioned above, the distinction between infective and infected eczema can be difficult.

Infected eczema. Infected eczema shows erythema, exudation and crusting. The exudation may be profuse with crusting, or slight, with the accumulation of layers of somewhat greasy, moist scale, beneath which the surface is raw and red. The margin is characteristically sharply defined, and the horny layer is often split to form an encircling collarette. There may be small pustules in the advancing edge and, where a flexure is involved, it is often the site of a deep and persistent fissure.

Infective eczema. Infective eczema usually presents as an area of advancing erythema, sometimes with microvesicles. It is seen predominantly around discharging wounds or ulcers, or moist skin lesions of other types. Infective dermatitis is relatively common in patients with venous leg ulcers, but care must be taken to distinguish it from contact dermatitis due to the application of topical medicaments.

Microbial eczema of the feet is a distinctive pattern of eczema which mainly affects the interdigital spaces on the dorsum of the medial toes. Staphylococci or streptococci can be cultured, and the lesions respond to antiseptic or antibiotic therapy [9]. This condition seems to occur particularly in patients with poor standards of hygiene, and it is favoured by hyperhidrosis and heavy footwear. In children, the condition must be distinguished from juvenile plantar dermatosis.

Tinea pedis may also become eczematous due to the overgrowth of Gram-negative organisms [10]. Infective dermatitis may also complicate chronic threadworm infestation, pediculosis or scabies. It is not always clear how much of the eczematous change is due to repeated scratching, how much is due to secondary impetigo and how much, if any, is a direct response to the infestation.

Treatment. Factors predisposing to infection should be sought, and when possible eliminated. Although topical antibacterial agents are effective in mild forms of infective eczema due to bacteria, systemic antibiotics should not be withheld, especially in severe or widespread infections. In acute exudative lesions, potassium permanganate soaks are helpful for the first 2 or 3 days, in combination with a systemic antibiotic.

Infective dermatitis of children associated with human T-cell leukaemia virus 1 (HTLV-1) infection

Synonym

- Infective dermatitis of Jamaican children

Sweet, in 1966 [1], used the term infective dermatitis to describe a pattern of dermatitis observed in Jamaican children. Subsequently, Walshe documented the clinical features in 25 Jamaican children [2]. They included severe, exudative eczema with crusting involving the scalp, eyelid margins, perinasal skin, retroauricular areas, axillae and groins. There was a generalized, fine papular rash, a chronic nasal discharge and positive cultures for *Staphylococcus aureus* or β-haemolytic streptococci from nose and/or skin. The rash responded to oral antibiotic therapy, but relapsed on its cessation.

LaGrenade *et al*. [3], in 1990, found HTLV-1 infection in all of 14 children with this pattern of dermatitis. A later case report identified one of the children originally described by Sweet and Walshe who, 17 years later, had developed adult T-cell leukaemia [4]. Some of these children may also go on to develop tropical spastic paraparesis [5]. This pattern of dermatitis may be an important early marker of HTLV-1 infection [6].

Juvenile plantar dermatosis

Synonyms
- Forefoot eczema
- Peridigital dermatosis
- Dermatitis plantaris sicca
- Atopic winter feet

Definition. This condition is characterized by shiny, dry, fissured dermatitis of the plantar surface of the forefoot. It occurs mainly in children aged 3–14 years.

Nomenclature. The first record of this condition appeared in 1968, and since then it has been described under a variety of names depending on the author's beliefs concerning pathogenesis and the possible association with atopy. The name 'juvenile plantar dermatosis' has the merit of making no presumptions about cause.

Aetiology [1–6]. It seems likely that changes in fashion, and the resulting changes in the composition of children's socks and shoes, may have been responsible for the emergence of this disease. In the author's experience the condition has become much less common in the UK over the last decade, suggesting that more recent changes in the composition of footwear may have proved beneficial. Waxing and waning fashions for the use of natural materials such as cotton, wool and leather, and various synthetic materials such as nylon and plastics, which are less porous, may have been responsible, although the exact pathogenesis of the disease remains uncertain [3]. This is not the whole story, for occasional cases have occurred in children wearing open leather sandals and cotton socks. Many of the affected children are keen on dancing or sports, and this suggests that friction and enhanced sweating may be playing some part.

An association with atopy has been proposed but the evidence for this is not convincing. In a controlled study, a personal or family history of eczema or other atopic illness was not more common in cases than in controls [1].

Juvenile plantar dermatosis has been seen in identical twins [7].

Histopathology [2,8]. The histology shows a mild, non-specific eczema. Blockage of sweat ducts can sometimes be identified.

Clinical features. Only occasional cases are seen in adults or infants. There is a slight preponderance of male children. The presenting features are redness and soreness on the plantar surface of the forefoot, which assumes a shiny, 'glazed' and cracked appearance (Fig. 23.22). The condition is most severe on the ball of the foot and toe pads, and tends to spare the non-weight-bearing instep. The toe clefts are normal, and this helps to distinguish the condition from tinea pedis. The symmetry of the lesions is a striking feature. Occasionally, the disease can affect the hands, resulting in sore, shiny, fissured palms or fingertips. This is more likely in atopic subjects [9].

Fig. 23.22 Juvenile plantar dermatosis, showing the characteristic glazed appearance of the forefoot skin.

Diagnosis. This is a clinical diagnosis, although skin scrapings to exclude fungus and patch tests to exclude footwear allergy may be helpful if there is any doubt. Consultation with the manufacturer of the shoes may help to identify potential allergens.

Treatment. Most cases will clear spontaneously during childhood or adolescence, but the condition may persist into adulthood [10]. Patients are usually advised to change from non-porous footwear to 100% cotton socks, and leather shoes or sandals, although the majority report that these changes in footwear do not help significantly [1,6,10,11].

In severe cases, with cracking and exudation, bed rest may be needed. A variety of topical preparations may help, including urea preparations, Lassar's paste, white soft paraffin or tar, but no single preparation is always effective [2,12,13].

'Metabolic' eczema and eczema associated with systemic disease

Eczema associated with malabsorption

The possible interrelation of eczema and disordered intestinal absorption is not fully understood, but it seems that widespread eczema can occasionally be either the cause or the result of intestinal malabsorption [1,2].

Severe, inflammatory skin disease often seems to cause a degree of malabsorption—a condition known as dermatogenic enteropathy [1,3]. This is usually asymptomatic. The mechanism is not known, but the malabsorption improves rapidly as the skin is treated.

Many of the cases of eczema reportedly caused by malabsorption may, in reality, have been dermatitis herpetiformis as they mostly predate the establishment of modern histological and immunological criteria for this disease [4,5]. However, the response of the eczema in some cases to correction of the serum calcium suggests that there may be other mechanisms involved [6]. A case of dermatitis associated with lactose intolerance and apparently improving in response to a lactose-free diet, is also difficult to explain [7].

Wiskott–Aldrich syndrome

This syndrome is fully described in Chapter 17.

Hypogammaglobulinaemia

A form of eczema, clinically very similar to atopic eczema, has been described in boys with hypogammaglobulinaemia [1,2].

Hyper-IgE recurrent infection syndrome

Synonym
- Job's syndrome

This rare disorder is characterized by recurrent bacterial infections of the skin, nasal sinuses and respiratory tract, commencing in early childhood, in the presence of serum levels of IgE which are around 10 times normal (greater than 2000 i.u./mL). Chronic eczema, often impetiginized, is a common feature (Chapter 17).

Pyoderma, folliculitis and atopy, with defective leukocyte and lymphocyte function

Synonym
- Jung's disease

A familial immunodeficiency disease characterized by atopic dermatitis, recurrent and persistent pyoderma and folliculitis has been described in a father and son [1]. It was accompanied by abnormalities of lymphocyte function and defective leukocyte chemiluminescence responses, which were associated with defective intracellular killing of microbial organisms. The abnormalities of lymphocyte and leukocyte function and the clinical manifestations responded dramatically to treatment with the H1 antagonist chlorpheniramine, suggesting that the underlying defect in this disease may be related to defective histamine metabolism or abnormal expression of histamine receptors on lymphocytes and leukocytes.

Pellagra

Photosensitive dermatitis is a feature of pellagra, the syndrome which results from niacin and tryptophan deficiency (see Chapter 59). Hartnup disease, with massive aminoaciduria, may also be associated with a pellagra-like rash after exposure to the sun, presumably because nicotinamide synthesis from tryptophan is decreased. A similar phenomenon may occur during isoniazid therapy and as part of the carcinoid syndrome.

Phenylketonuria

Eczema occurs in 25% of untreated patients with phenylketonuria in the early years of life. It responds to dietary treatment by exclusion of phenylalanine and recurs when the treatment is stopped [1–3].

Pityriasis alba

Definition. This is a pattern of dermatitis in which hypopigmentation is the most conspicuous feature. Some erythema and scaling usually precede the development of hypopigmentation but these are often relatively mild.

Aetiology. Pityriasis alba is often a manifestation of atopic dermatitis but it is not confined to atopic individuals.

Histopathology. The histological changes are unimpressive—acanthosis and mild spongiosis, with moderate hyperkeratosis

Fig. 23.23 Pityriasis alba: the failure of the affected patches to tan may first bring them to the patient's notice. (Courtesy of Dr A. Marsden, St George's Hospital, London, UK.)

and patchy parakeratosis. There may be follicular plugging, spongiosis and sebaceous gland atrophy [1–4]. On electron microscopy, there are reduced numbers of active melanocytes and a decrease in number and size of melanosomes in affected skin [3]. Although pigment is reduced, melanocyte numbers are not, and may even be increased relative to healthy skin [5].

Clinical features [2,5–7]. Pityriasis alba occurs predominantly in children between the ages of 3 and 16 years. The sexes are equally susceptible. The individual lesion is a rounded, oval or irregular hypopigmented patch which is usually not well marginated. Lesions are often slightly erythematous and have fine scaling. Initially, the erythema may be conspicuous and there may even be minimal serous crusting. Later, the erythema subsides completely, and at the stage at which the lesions are commonly seen by a physician they show only persistent fine scaling and hypopigmentation. It is this that commonly induces the patient to seek advice. The hypopigmentation is most conspicuous in pigmented skin, and in lighter skins may become more evident after sun-tanning (Fig. 23.23).

There are usually several patches ranging from 0.5 to 2 cm in diameter, but they may be larger, especially on the trunk. In children the lesions are often confined to the face, and are most common on the cheeks and around the mouth and chin. In 20% of affected children the neck, arms and shoulders are involved as well as the face. Less commonly the face is spared and there are scattered lesions on the trunk and limbs.

The course is extremely variable. Most cases persist for some months, and some may still show hypopigmentation for a year or more after all scaling subsides. Recurrent crops of new lesions may develop at intervals. The average duration of the common facial form in childhood is a year or more.

Diagnosis. The age incidence, the fine scaling and the distribution of the lesions usually suggest the diagnosis. Conspicuous hypopigmentation may lead to a misdiagnosis of vitiligo. Naevus depigmentosus most commonly presents at birth or before 3 years of age, and most often causes single, well-marginated lesions on the trunk [8]. However, this condition may be difficult to distinguish from pityriasis alba when it occurs on the face and in cases of later onset. Discoid eczema in an atopic child is intensely pruritic, and the lesions are larger and more oedematous.

In older children and adults, the lesions on the trunk, during their early erythematous phase, may be mistaken for psoriasis but the distribution and the relatively mild scaling should exclude this diagnosis. Mycosis fungoides, although relatively rare, may present with lesions clinically resembling pityriasis alba [9]. This condition may also be difficult to distinguish histologically, so follow-up and repeat biopsy are sometimes required.

Treatment. Response to treatment is often disappointing, mainly because the pigmentation takes a long time to recover. The scaling may be reduced by a bland emollient cream, and for chronic lesions on the trunk a mild tar paste may be helpful. Mild topical corticosteroids are helpful if inflammation persists. Topical tacrolimus and pimecrolimus are effective in facial atopic eczema and seem likely to prove helpful, if required, in pityriasis alba [10].

Post-traumatic eczema [1]

It is rare for eczematous dermatoses to demonstrate the Koebner (isomorphic) phenomenon. However, this may occasionally occur, and eczema may also develop at sites of trauma in individuals who have no past history of eczematous dermatosis. Eczema can also occur in burn scars.

There have been several case reports of dermatitis occurring in the saphenous vein graft donor site for coronary artery bypass surgery [2,3]. The rash comprises reddish brown, slightly crusted and scaly patches, with occasional papulovesicles. Histology shows subacute spongiotic dermatitis. The condition responds to topical corticosteroids, but tends to relapse when the treatment is

stopped. Initially, postoperative venous stasis was suggested as the cause. Subsequently, two cases have been reported associated with sensory neuropathy in the distribution of the saphenous nerve [4]. The dermatitis was located in the same area. Otherwise, the cases were identical to those previously reported. The dermatitis and the sensory neuropathy resolved in tandem over a 2-year period.

Seborrhoeic dermatitis

Synonyms
- Pityrosporal dermatitis
- Dermatitis of the sebaceous areas

Definition. This is a chronic dermatitis which is difficult to define exactly, but it has a distinctive morphology (red, sharply marginated lesions covered with greasy-looking scales) and a distinctive distribution in areas with a rich supply of sebaceous glands, namely the scalp, face and upper trunk. In some cases the flexures are also involved, but this is not an essential diagnostic criterion.

Dandruff (visible desquamation from the scalp surface) appears to be the precursor of seborrhoeic dermatitis, and this may gradually progress through redness, irritation and increasing scaling of the scalp to true seborrhoeic dermatitis.

Incidence. The prevalence of seborrhoeic dermatitis is around 1–3% in the general population of the USA, and 3–5% in young adults, although mild degrees of dandruff are of course much commoner [1]. The figure is much higher, however, in patients with early human immunodeficiency virus (HIV) infection. Of 155 patients in the WR1A-2A stage of infection (with normal helper T-cell count and delayed hypersensitivity), 36% had seborrhoeic dermatitis [2].

Aetiology [3,4]. Yeast of the genus *Malassezia* is increased in the scaly epidermis of dandruff and seborrhoeic dermatitis [5,6]. Although it has been suggested that this is secondary to the increase in size of the habitat provided by the scaling [7], it is generally accepted that the presence of yeast of the genus *Malassezia* causes the condition [3,4,8].

The way in which *Malassezia* spp. induce inflammation and desquamation is not clear. Although patients with dandruff have high antibody titres to *Malassezia* compared with control subjects, and patients with seborrhoeic dermatitis have altered cell-mediated responses, the immunological reaction is variable [9–10]. Some of the histological features of seborrhoeic dermatitis can be reproduced by inoculating animal skin with killed yeasts [11], and the wide variety of cytokines expressed in the inflammation are similar to those seen in other yeast infections [12]. However, the principal evidence of the role of *Malassezia* spp. remains the response of the condition to treatments that reduce the yeast numbers [4].

The sebaceous glands are active at birth, but when stimulation by maternal androgen ceases they become inactive for 9–12 years. This observation has been regarded as significant in relation to the age incidence of seborrhoeic dermatitis. The condition known as seborrhoeic dermatitis of infancy (Chapter 17) is normally confined to the first months of life, but it is not established that it is the same condition as seborrhoeic dermatitis of adolescence and adult life. The latter is rare before puberty, and reaches its peak between 18 and 40 years of age; occasional cases are seen in old age. At all ages seborrhoeic dermatitis is more common in males than in females.

Although maturation of the sebaceous glands may be a permissive factor for the development of seborrhoeic dermatitis, the role of seborrhoea in the pathogenesis of the condition is debatable. Many young adults with the condition appear to have a greasy skin, but when the sebum excretion rate from forehead skin was measured in patients with classical seborrhoeic dermatitis, the rate was normal in male patients and significantly reduced in female patients [13]. On the basis of this finding, it was suggested that 'dermatitis of the sebaceous areas' might be a more accurate term than 'seborrhoeic dermatitis'. Some clinicians believe that there is an increased prevalence of seborrhoeic dermatitis among patients with acne vulgaris and rosacea, but there are no data to support this.

Seborrhoeic dermatitis may also be a complication of parkinsonism, which is associated with seborrhoea. Treatment of parkinsonism with levodopa reduced sebum excretion when seborrhoea was initially present, but had no effect on the normal sebum excretion rate [14]. Treatment of parkinsonism with levodopa can also sometimes improve seborrhoeic dermatitis in these patients [15]. Seborrhoeic dermatitis has also been reported in a patient in whom unilateral seborrhoea and seborrhoeic dermatitis developed on the face after facial nerve paralysis [16], and also in patients with paralysis of the trunk [17]. The increase in the pool of sebum in immobile skin may be important in these cases, and in parkinsonism [18].

Qualitative abnormalities in the composition of sebum have not been demonstrated. Mild abnormalities in the surface lipids [19,20] could well result from the ineffective keratinization which is often demonstrable histologically.

The heightened susceptibility of the seborrhoeic skin to bacterial infection and to physical and chemical injury results in a high incidence of contact dermatitis and skin infection. Some authors confuse exogenous dermatitis in a seborrhoeic subject with the morphologically distinctive seborrhoeic dermatitis.

Seborrhoeic dermatitis is now established as a possible marker of early HIV infection [2,21], and exacerbations may be seen with progression of the HIV infection, presumably due to the enhanced growth of yeasts secondary to immunosuppression [22]. It is also suggested that local cutaneous immunosuppression may increase the prevalence of seborrhoeic dermatitis [23].

It has also been claimed that seborrhoeic dermatitis is more common in a variety of general medical disorders, including myocardial ischaemia [24], malabsorption, epilepsy, obesity and

alcoholism, especially alcoholic pancreatitis [25]. However, the evidence is far from convincing, and poor hygiene associated with hospitalization and severe illness may play a part in some of these cases.

Seborrhoeic dermatitis involving the usual sites on the face was observed to occur in 28 of 402 patients undergoing psoralen and UVA (PUVA) therapy for psoriasis, but not in 55 patients being treated for other conditions [26]. Spongiosis was present in the three patients biopsied.

Histopathology. The histology is not diagnostic, but generally shows features of both psoriasis and chronic dermatitis. Much of the stratum corneum is often lost in the process of fixation, and most of its cells are parakeratotic. There is slight to moderate acanthosis, with slight spongiosis. Spongiosis is the major feature which distinguishes it from psoriasis. The dermis shows a mild, chronic inflammatory infiltrate.

It seems likely that the initial event is the 'squirting papilla' described by Pinkus and Mehregan [27]. Capillary dilatation in the papillae is followed by migration of inflammatory cells through the vessel walls and into the epidermis, where they incite spongiosis. This is similar to the burst of inflammation which sometimes occurs in psoriasis.

As the inflammation subsides there is an increase in production of keratinocytes. Epidermal proliferation, as measured by the mitotic and labelling indices, is increased, and desquamation is increased [28].

Ultrastructural studies show a closer resemblance to discoid eczema than to allergic or irritant contact dermatitis.

The histology of seborrhoeic dermatitis in patients with AIDS tends to show more follicular involvement, and more plasma cells. Neutrophils and nuclear dust may be present focally among the epidermal parakeratotic cells [21]. *Malassezia* yeasts are prominent in the skin of AIDS patients with seborrhoeic dermatitis compared with seborrhoeic dermatitis patients without AIDS [29].

Clinical features. Most forms of seborrhoeic dermatitis share certain distinctive characteristics. They commonly originate in hairy skin, and involve the scalp, face, presternal and interscapular regions, and the flexures. The lesions tend to be dull or yellowish red in colour and covered with greasy scales.

Morphological variants. There are several morphological variants of seborrhoeic dermatitis, which in the adult form occur in various combinations and degrees of severity (Table 23.7).

Scalp. Dandruff is usually the earliest manifestation of seborrhoeic dermatitis. At a later stage perifollicular redness and scaling gradually extend to form sharply marginated patches which may remain discrete, or coalesce to involve the greater part of the scalp and extend beyond the frontal hairline as the 'corona seborrhoeica'.

In chronic cases there may be some degree of hair loss, which is reversible when the inflammation is suppressed. It has not been established whether seborrhoeic dermatitis of the scalp accelerates the onset of male-pattern (androgenic) alopecia.

Table 23.7 Clinical patterns of seborrhoeic dermatitis.

Infantile (Chapter 17)

Face (may include blepharitis and conjunctivitis)
Trunk
Petaloid
Pityriasiform
Flexural
Eczematous plaques
Follicular
Generalized (may be erythroderma)

Fig. 23.24 This type of seborrhoeic dermatitis around the ears readily develops secondary bacterial infection.

Behind the ears there may be redness and greasy scaling, and a crusted fissure often develops in the fold (Fig. 23.24). Adherent masses of sticky scale and crusts may extend into the adjacent scalp. Both sides of the pinna, the periauricular region, and the sides of the neck may be involved. Otitis externa, irritable and intractable, may accompany seborrhoeic dermatitis in other sites, or may occur alone.

(a)

(b)

Fig. 23.25 (a) Seborrhoeic dermatitis of the forehead. (b) Severe seborrhoeic dermatitis of the face with prominent involvement of the nasolabial groove.

Face. On the face, seborrhoeic dermatitis characteristically involves the medial part of the eyebrows, the glabella and the nasolabial folds (Fig. 23.25). Areas of erythema and scaling occur, usually in association with involvement of the scalp.

Blepharitis is common. The margins of the lids are red and covered by small, white scales. Yellow crusts may form, and separate to leave small ulcers, healing to form scars, with destruction of lash follicles.

Episodic variation in intensity is common, often being precipitated by tiredness or stress. Exposure to sunlight produces a temporary exacerbation, followed by improvement as the tan develops.

Fig. 23.26 Seborrhoeic dermatitis of the presternal region. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

A superficial form of seborrhoeic dermatitis of the chin is common in men in the early stages of growing a beard, but is cured when the beard is shaved off.

Young women sometimes have paranasal erythema associated with a tendency to flushing. It is not always clear whether this is rosacea or mild seborrhoeic dermatitis, but overtreatment with strong topical corticosteroids may convert this into perioral dermatitis.

Trunk. On the trunk, several forms of seborrhoeic dermatitis occur. Commonest is the petaloid form (so-called because the lesions are petal-shaped). This is often seen in men on the front of the chest and in the interscapular region (Fig. 23.26). The initial lesion is a small, red–brown follicular papule, covered by a greasy scale. Some patients have a widespread eruption of lesions which do not progress beyond this stage. More often, extension and confluence of the follicular papules gives rise to a figured eruption, consisting of multiple circinate patches, with a fine branny scaling in their centres, and with dark-red papules with larger greasy scales at their margins.

A rarer form, involving the trunk and limbs, is the so-called pityriasiform type. This is a generalized erythematosquamous eruption, somewhat similar to, but more extensive than, pityriasis rosea. In particular it involves the neck up to the hair margin. It is not particularly pruritic, and it resolves spontaneously, although somewhat more slowly than does pityriasis rosea. In some patients the lesions may become psoriasiform.

Flexures. In the flexures, notably in the axillae (Fig. 23.27), the groins, the anogenital and submammary regions, and the umbilicus, seborrhoeic dermatitis presents as an intertrigo, with diffuse, sharply marginated erythema and greasy scaling. Crusted fissures develop in the folds, and with sweating, secondary infection and inappropriate treatment, a weeping dermatitis may extend far beyond them. The genitalia of both sexes may be involved, and the lesions show the usual range from minimal erythema and scaling to severe crusted dermatitis. In this site, and occasionally elsewhere, the chronic, thickened, dull-red, scaly patches of the psoriasiform variety of seborrhoeic dermatitis may develop.

Fig. 23.27 Seborrhoeic dermatitis of the axilla: flexural areas often become secondarily infected.

Fig. 23.28 Redness and scaling at the medial ends of the eyebrows may provide a diagnostic pointer to seborrhoeic dermatitis.

The severity and course of seborrhoeic eruptions are very variable. All show a tendency to chronicity and recurrence.

Severe and extensive forms may be complicated by eczematous reactions remote from the sites initially involved, especially by pompholyx and discoid eczema. Such eruptions are discussed separately below. The pattern and course of the disease may also be modified by contact dermatitis and provoked by medicaments, or by an infective bacterial dermatitis.

Occasionally, seborrhoeic dermatitis may become generalized, resulting in erythroderma.

Modifications in the clinical features and course may be seen when seborrhoeic dermatitis occurs in association with atopy, or with psoriasis, and in the latter case the diagnosis can be extremely difficult, because both the clinical and histological features can be equivocal. Some dermatologists use the term *sebopsoriasis* for this overlap condition.

Diagnosis (Fig. 23.28). In a classical case the diagnosis is easy, but in some cases the diagnosis can be difficult, partly because of the lack of well-defined diagnostic criteria. The diagnosis is often made too freely.

Nowadays it is very important to consider the possibility of HIV infection in any patient with severe seborrhoeic dermatitis, particularly in a patient involved in high-risk activities.

The differential diagnosis covers an enormous range of conditions. Psoriasis, when confined to the scalp, may be confused with seborrhoeic dermatitis. The lesions are often more circumscribed and usually palpably thickened in psoriasis, with a brighter pink colour and silvery scale. The rest of the body must be examined, especially the nails, and there may be a family history of psoriasis.

Lichen simplex of the nape of the neck occurs in females, and can mimic seborrhoeic dermatitis. The thickened plaques in this condition are, however, intensely irritable.

Infective dermatitis complicating pediculosis can also be confused with seborrhoeic dermatitis.

Contact allergy [30] and *Trichophyton tonsurans* infection [31] may mimic seborrhoeic dermatitis of the scalp.

Pityriasis rosea must be distinguished from the pityriasiform type of seborrhoeic dermatitis, in which the lesions are more widely distributed, and in which there is no herald patch. In the flexures, microscopic examination of scrapings from the advancing margin, and examination under Wood's light will exclude ringworm infections, candidiasis and erythrasma. Acute flexural dermatitis may also suggest the possibility of allergic sensitization to a chemical in clothing, and patch tests may be needed. Moist crusting of the face or of the midline of the chest or back occurs in pemphigus erythematosus, and in pemphigus foliaceus. Biopsy is required if these conditions are suspected. Axillary and sometimes interscapular crusting, tending to relapse in the warmer weather, occurs in benign familial pemphigus.

The brown scaly lesions of pityriasis versicolor are flatter, more extensive, and less symmetrical than the lesions of petaloid seborrhoeic dermatitis of the trunk. Microscopy of scrapings quickly establishes the diagnosis.

Follicular seborrhoeic dermatitis of the trunk must be differentiated from Darier's disease, in which the papules are brown, greasy and dome-shaped, and tend to be clustered. Biopsy is diagnostic. Lesions resembling seborrhoeic dermatitis can occur in zinc deficiency and acrodermatitis enteropathica [32].

Drug eruptions, particularly those due to methyl dopa, chlorpromazine or cimetidine may mimic seborrhoeic dermatitis.

Despite the non-specific nature of the histological appearances of seborrhoeic dermatitis, biopsy will often reliably differentiate it from many of the conditions with which it may be confused.

Treatment. It should be emphasized to the patient at the outset that, although seborrhoeic dermatitis can generally be suppressed, there is no permanent cure. The condition may require regular treatment for many years.

Dandruff is usually treated by the frequent and regular use of medicated shampoos which act against *Malassezia* yeasts, including selenium sulphide, zinc pyrithione, ketoconazole [33] and various tar shampoos; 1% terbinafine solution has also been shown to be effective [34]. Alcohol-based preparations and hair tonics should be avoided. For severe dandruff with persistent scaling or

crusting, 5% salicyclic acid ointment may be useful. If secondary bacterial infection is present or suspected, oral erythromycin or flucloxacillin may be used.

Acute forms of seborrhoeic dermatitis on the face and trunk are generally sensitive to mild steroid ointments. Hydrocortisone ointment (0.5%) is often effective, particularly if combined with sulphur (0.5%). Ketoconazole cream (2%) is possibly a more logical therapy, which has been shown to be equally effective [35–39]. In many situations, the acute inflammatory changes can be suppressed with mild topical corticosteroid creams or steroid and imidazole combination creams, which can then be changed to ketoconazole cream for long-term control.

Topical immunosuppressants (tacrolimus, pimecrolimus) are also an effective treatment [40,41], and are particularly useful for facial seborrhoeic dermatitis, when there is concern about overuse of topical steroids.

Topical metronidazole, ciclopiroxolamine and tacalcitol have also been reported to be helpful [42–44]. Frequent washing with soap and water is helpful, possibly because removal of lipid removes the substrate for the yeasts. Other topical preparations which have been shown to be effective include benzoyl peroxide [45] and 5% lithium succinate ointment [46].

For unresponsive cases, a course of UVB therapy may be helpful [47]. Oral itraconazole (100 mg daily for up to 21 days) is also effective, as is oral terbinafine [48].

Generalized seborrhoeic dermatitis usually responds to the medications listed above, but in recalcitrant cases systemic steroids may be required. Prednisolone 30 mg daily usually produces a rapid response. Isotretinoin may also be helpful [18].

Flexural seborrhoeic dermatitis is treated in the same way as intertrigo (Chapter 71).

Infantile seborrhoeic dermatitis

There is still some debate as to whether this condition occurs as a separate entity, or is merely a variant of atopic dermatitis (see Chapter 17 for discussion).

Malassezia folliculitis

Synonyms
- Seborrhoeic folliculitis
- Pityrosporal folliculitis

Definition. Folliculitis caused by *Malassezia* yeasts (e.g. *Malassezia furfur*). Although not an eczema, *Malassezia* folliculitis is included here because of its association with seborrhoeic dermatitis.

Aetiology. *Malassezia* yeasts can hydrolyse triglycerides into free fatty acids, and it has been postulated that an overgrowth of the yeast in a follicle produces folliculitis by a combination of fatty acid production and blockage of the follicular ostium by scale [1,2]. The ability of the yeasts to activate the alternative complement pathway may also be implicated in the inflammatory process.

Pathology. There is folliculitis, with a perifollicular mononuclear infiltrate, predominantly around the infundibular region of the follicle. Sparse *Malassezia* yeasts can be identified in the affected follicles, but mycelial forms are usually absent. *Malassezia* yeasts can also be identified in skin scrapings.

Clinical features [3–4]. The condition most commonly affects adult males, and is associated with a tendency to seborrhoeic dermatitis or severe dandruff. It has been reported in 12 of 42 patients with Down's syndrome [5]. The rash is dimorphic, with erythematous follicular papules and follicular pustules. Lesions occur mainly on the upper trunk and shoulders, and are usually pruritic (Fig. 23.29).

Fig. 23.29 *Malassezia* folliculitis. (Courtesy of Dr F.A. Ive, Durham, UK.)

Differential diagnosis. Acne vulgaris may be distinguished by the presence of comedones, cysts and scars, which do not occur in *Malassezia* folliculitis. Similar lesions can occur in immunocompromised individuals such as AIDS sufferers and organ transplant recipients [6]. The condition should be considered in the differential diagnosis of steroid-induced folliculitis [7]. Transmission of the condition between individuals has been suggested [8].

Treatment. Patients should be advised to avoid occlusive clothing, and broad-spectrum antibiotic therapy should be stopped whenever possible. The condition responds well to 2% ketoconazole cream [9]. However, the eruption will often relapse, and intermittent prophylactic treatment once or twice weekly may be indicated [10]. Systemic treatment with oral itraconazole may occasionally be helpful. In the Down's syndrome patients the condition improved with oral itraconazole but relapsed when the medication was stopped [5].

Venous eczema

Synonym
- Gravitational eczema

Definition. Eczema secondary to venous hypertension.

Nomenclature. This condition is also called stasis eczema or varicose eczema. It is increased venous pressure rather than stasis which seems to be the prerequisite. Although it is often associated with varicose veins these are not always present.

Pathogenesis [1–4]. The oxygen content in the femoral venous blood of the leg affected by venous hypertension is increased, and the venous blood in such limbs has a faster circulation time than normal [5,6]. These observations could be explained by the development of arteriovenous shunts in the affected areas, but the use of radioactively labelled macroaggregates or microspheres has failed to provide any evidence for such shunts.

An alternative explanation for these findings has been provided by Browse and Burnand [2], who suggested that the high ambulatory venous pressure within the calf muscle pump is transmitted to the capillary circulation in the skin and subcutaneous tissues of the calf. This distends the local capillary bed and widens the endothelial pores, thus allowing fibrinogen molecules to escape into the interstitial fluid, where they form a fibrin sheath around the capillaries. This layer of fibrin presumably forms a pericapillary barrier to the diffusion of oxygen and other nutrients which are essential for the normal vitality of the skin. The hypothesis that pericapillary fibrin impedes oxygen diffusion has been supported by a study using positron-emission tomography [7].

It has also been suggested that cutaneous inflammation in venous hypertension may result from increased sequestration of white cells in the venules, with consequent release of proteolytic enzymes and free radicals which produce tissue damage [3]. In normal subjects, white cells are sequestered in the limb when venous pressure is elevated, and in patients with venous insufficiency the effect is enhanced, with increased endothelial contact and adhesion of white cells [8]. This effect may be related to an increase in expression of adhesion molecules ICAM-1 and VCAM-1 on the vascular endothelium in affected skin [9].

Clinical features. Venous eczema is an erythematous, scaly and often exudative eruption usually seen around the ankle and lower leg (Fig. 23.30). It often occurs as a late result of deep vein thrombosis. Occasionally, similar changes occur at other sites of venous hypertension such as the pendulous skin over an obese abdomen or in association with an ateriovenous fistula in the upper limb [10]. The eczema may develop suddenly or insidiously. The patients are usually middle-aged or elderly and most often female. The increased incidence in females is presumably due to hormonal effects and the tendency for venous thrombosis to occur during pregnancy.

The eczema is often accompanied by other manifestations of venous hypertension, including dilatation or varicosity of the superficial veins, oedema, purpura, haemosiderosis, ulceration, or small patches of white, atrophic, telangiectatic scarring ('atrophie blanche'). These changes, which occur in various combinations, are discussed in more detail in Chapter 47. Leashes of dilated venules around the dorsum of the foot or the ankle are particularly common. There may be a subepidermal vascular proliferation producing purple papules around the ankle, which may resemble Kaposi's sarcoma [11]. Secondary patches of eczema may develop on the other leg, even when it is not affected by obvious venous insufficiency. Generalized secondary dissemination may occur, and occasionally this can progress to erythroderma.

Fig. 23.30 Venous (gravitational) eczema.

These changes are often modified by secondary contact dermatitis, infection and rubbing. Allergic contact dermatitis is a common complication of gravitational eczema, possibly because of the large number of antigen-presenting cells in the inflamed skin [12].

Differential diagnosis. Although most cases of eczema of the lower leg are secondary to venous hypertension, it must be remembered that many other types of eczema may affect this region, and in many cases there are multiple causative factors. In children or young adults, atopic dermatitis may manifest as lichenified patches around the ankle or behind the knees. Allergic contact dermatitis of the lower legs is usually due to topical medicaments (Fig. 23.31). Patch testing is often indicated. An infected ulcer may be complicated by infective eczema spreading from the edge of the ulcer, with response to appropriate antibiotic therapy (p. 23.23). Discoid eczema is common on the lower leg, usually on the anterior or anterolateral aspect. Asteatotic eczema commonly affects the legs of elderly patients.

Although the exact cause of eczema on the lower legs can be difficult to elucidate, other conditions can usually be readily identified. Psoriasis may present as a single, irritable plaque on the leg, but is usually more scaly and clearly marginated. Hypertrophic lichen planus of the lower leg may occasionally be mistaken for eczema if there are no characteristic lesions elsewhere. Dermatophyte infection may present as diffuse erythema and scaling and may be difficult to recognize, particularly if it has been treated with topical steroids. Profuse actinic keratoses may cause red,

Fig. 23.31 Contact eczema of the lower legs due to allergy to paste bandages.

irritable patches on the lower legs in sunny climates. In the late stage of borreliosis the leg can feel heavy, with thick cyanotic itchy skin which may mimic the changes of venous hypertension [13].

Treatment. The underlying venous hypertension should be controlled. Obese patients should be urged to lose weight. Well-fitted support stockings or firm bandages can be helpful if worn regularly and care is taken to avoid the formation of a band at the top of the leg. The legs should be elevated as effectively as possible.

Mild topical steroids may be used to relieve irritation, but the use of potent steroids should be limited to short periods of a few days as they may cause cutaneous atrophy and increase the risk of ulceration. Topical tacrolimus has been reported to be effective [14]. Bacterial infection must be treated where appropriate, but the risk of sensitization to topical antibiotics and antiseptics should be borne in mind, and systemic antibiotics may be preferable. Bacteria cultured from a swab are not necessarily playing a pathogenic role. If trauma is thought to be playing a part, and the patient cannot resist scratching, a paste bandage may be helpful.

The management of eczema

A wide range of dermatoses are encompassed by the term eczema. Specific aspects of their treatment are described under their respective headings. Some fundamental principles of management shared by all eczematous dermatoses are described here.

In order to establish the underlying diagnosis a careful history and examination is required. This will also help to identify additional aggravating factors (such as exposure to irritants) or complicating factors (such as infections or allergies to medications) which are playing a role in the pathogenesis. In order to optimize management, the dermatologist needs to be familiar with the patient's occupation, domestic circumstances and personality. It is also important to determine how the patient is affected by the disease. Which symptoms are most troublesome? How much embarrassment is experienced? Which aspects of the patient's work and social life are disrupted?

Previous treatment experience must be explored. It is necessary to assess how much time and effort a patient (or parent) is willing and able to devote to the care of their (or their child's) skin. An additional issue which must be addressed is the attitude of the patient to the risks and side effects associated with any treatment that may be required. A particularly common problem is an inappropriate level of anxiety about the use of topical corticosteroids. Only when all this information is available can the optimal treatment strategy be determined.

Diagnostic tests for eczema

Most cases of eczema can be diagnosed clinically. It can sometimes be helpful to measure the total IgE level in order to determine whether an individual is atopic, particularly when the distribution of eczema is atypical and there is no background of other atopic illness. Secondary infection can be confirmed by taking swabs for culture and sensitivity to identify any bacterial resistance, such as methicillin-resistant staphylococci. When dermatophyte infection is suspected, a potassium hydroxide preparation should be examined or scrapings sent to a laboratory for microscopy and culture. Microscopy can also be invaluable to confirm a diagnosis of scabies, which is easy to miss in a patient with pre-existing eczema. Biopsy

can occasionally be helpful in confirming the eczematous nature of the eruption, and immunofluorescence can help identify less common conditions such as dermatitis herpetiformis or, in older patients, a non-bullous presentation of bullous pemphigoid.

Patch testing in eczema [1–3]

Routine use of patch testing is not indicated for typical presentations of endogenous eczema such as atopic dermatitis, pityriasis alba and seborrhoeic eczema. This investigation is much more important in atypical or asymmetrical eruptions, and especially in dermatitis affecting the face, hands and feet [3].

In apparently endogenous eczema the threshold for patch testing should still be low. Sensitization commonly develops to topical medicaments, prescribed or self-administered, and this may exacerbate the eruption. Sometimes, topical remedies are concealed or forgotten by the patient, or the reaction they cause is partially suppressed by the concomitant use of topical corticosteroids. Sometimes, an unexpected positive test points to a 'hidden' or obscure cause, for example fragrances, preservatives, vehicles, epoxy or rubber chemicals. Such substances are commonly encountered in the environment and in topical medication.

When a strong suspicion of a contact-allergic cause for the eczema exists, it may be important to test with other potential allergens in addition to the routine battery—household plants, material extracted from footwear, phosphorus sesquisulphide, acrylates, etc. The observer must be wary of false-positive, irritant reactions, especially in an 'excited' eczematous skin [4]. For this reason it is always wise to allow the acute phase of an eczema to subside before patch testing is carried out, or to repeat any positive tests when it has done so. If a contact urticaria is thought to be occurring, the patch tests should be read 1 h after application [5].

Even if a positive patch test is judged to be relevant (i.e. the patient comes into contact with that substance), it does not necessarily follow that the exclusion of that substance from the environment of the patient will result in a cure. The allergen may be only one of several contributory factors.

Although patch tests are designed to detect allergens, many substances give an irritant reaction when tested, and it is often difficult to be sure of the relevance of such a reaction to the patient's eczema. It must also be borne in mind that many topical medicaments can produce an irritant reaction, for example alcohol-based preparations and propylene glycol. The choice of concentration of test substance and suitable vehicle are vitally important [2] (see also Chapter 26 for details of patch testing).

It is important to remember that patch testing performed in a setting of any poorly controlled eczematous dermatosis may yield false-positive results due to conditioned hyperirritability (as discussed above).

The 'atopy patch test' comprises patch testing with allergens such as pollens, animal danders and dust mite allergens, and frequently yields positive results in atopic individuals. This may be a further method of confirming the atopic status of a patient [6], but has yet to find a more useful role in routine management.

Treatment of eczema

A considerable variety of effective treatment modalities is available. These range from conservative and extremely safe approaches such as rest and the application of emollients, to 'aggressive', more hazardous treatments such as phototherapy, systemic immunosuppressants or radiotherapy. Some frequently used treatments are listed in Table 23.8. When an extrinsic cause is identified or suspected this should be removed. In all cases, exposure to irritants should be carefully avoided and the skin should be protected using emollients and appropriate dressings. Psychological support is an important aspect of management at all stages.

Acute eczema

Acute eruptions and exacerbations of eczema cause great alarm and anxiety, and the stress of the situation is usually aggravated by loss of sleep caused by intense pruritus and soreness. Patients need to be reassured that the eruption will be brought under control. Adequate rest is essential, and on occasions this is best provided in a hospital bed. An affected leg should be elevated or well supported, and affected hands should be used as little as is practicable. In extremely acute hand eczema a sling is useful.

Highly oedematous, vesicular and exudative eruptions such as pompholyx benefit from soaks in an astringent such as a 1:10 000 solution of potassium permanganate. An alternative is Burow's solution BP, which contains the astringent aluminium acetate and

is less messy than potassium permanganate. Liberal applications of aqueous cream and other bland emollients are soothing. Moderate or potent topical steroids are generally used, at least for a few days, to speed resolution of acute episodes. Topical immunomodulators such as tacrolimus and pimecrolimus seem likely to be beneficial in most forms of eczema, and especially in atopic dermatitis [1]. Tacrolimus ointment 0.1% seems to be equivalent in potency to potent topical corticosteroids such as betamethasone valerate [2] and hydrocortisone butyrate [3]. When practical, tubular bandaging can be used to help keep topical medications in place. The wet wrapping technique, in which a layer of wet tubular bandage (e.g. Tubifast®) is covered with a dry layer, can be particularly useful. Hazards include a risk of hypothermia, although, in moderation, the cooling effect is highly beneficial. Emollients and other medications can be applied under the bandaging as required. Penetration of topical corticosteroids can be significantly increased by this form of occlusion, enhancing both beneficial and adverse effects. Mild or moderate corticosteroids should be used for the face and genital areas. Potent or very potent steroids are required, at least initially, for acute pompholyx on the hands or feet.

When secondary infection is present, or staphylococcal contamination of the skin is thought to be an aggravating factor, oral antibiotics are often used. Topical preparations containing antibiotics or antiseptics in combination with steroids can also be helpful. These compound formulations should only be used when there is an indication for each constituent, in order to avoid unnecessary exposure to the risks of sensitization and emergence of bacterial resistance.

Excoriation can be reduced further by a sedative antihistamine such as hydroxyzine or trimeprazine, and additional hypnotics may be needed for a few days to ensure sleep.

Subacute eczema

If an acute eczema has failed to clear almost completely in 3–4 weeks, the perpetuating factors should be carefully sought. Has exposure to a sensitizing agent been overlooked? Has the patient become intolerant of the treatment prescribed? Has the treatment been effectively carried out?

Admission to hospital can often be helpful in these circumstances, to ensure that the aetiological factors have been fully explored and that treatment will be regularly and effectively applied. Rapid resolution usually follows admission and a period of rest. A prompt relapse on discharge may indicate photosensitivity or an allergic cause in the patient's home environment. Rapid deterioration after the arrival at the bedside of a generous bunch of flowers sometimes helps to establish the diagnosis of chrysanthemum sensitivity.

Paste bandages are of special value in occluding areas that are frequently excoriated, as in many lower leg eczemas. These must be applied skilfully to ensure that they are firm but not tight enough to cause discomfort or to restrict arterial or venous blood flow. Corticosteroids under polythene occlusion may be helpful at this stage, if only for a few days, to lessen itching. Topical immunomodulators such as tacrolimus and pimecrolimus are effective. Cleaning and bathing need not be routinely forbidden, and may be comforting, but long hot soaks and the use of soap should be discouraged. In some cases of asteatotic and discoid eczema, baths may be poorly tolerated and should be restricted. Liberal applications of emollients after bathing are helpful. Bath oils can be beneficial, but are best avoided for elderly patients as they make the bath more slippery.

Chronic eczema

In chronic eczema, oedema, vesiculation and exudation give way to a more stable picture of erythema, scaling, excoriation and lichenification. Pruritus often remains troublesome, especially in atopic dermatitis. It is important to regularly reconsider whether complications such as sensitization to medicaments or superinfection are playing a role.

Emollients should be applied frequently. Soaps and other potential irritants and sensitizers such as perfumes should be avoided. Mild, moderate or potent topical corticosteroids and topical immunomodulators [1–3] are helpful. In seborrhoeic dermatitis, and most cases of discoid eczema and atopic dermatitis, mild or moderate steroids are usually adequate. In severe atopic dermatitis and endogenous hand eczema, more potent steroids may be required. Long-term use of potent corticosteroids requires particular caution to minimize atrophy of the treated skin. For patients prone to frequent flares of eczema a strategy which may prove useful to limit steroid requirement is to induce remission with once or twice daily application of a potent topical steroid and then apply the steroid only for 2 days each week to maintain remission [4]. The use of topical immunomodulators such as tacrolimus and pimecrolimus provides a useful alternative, and these will also help in reducing cumulative exposure to steroids. This is particularly beneficial when prolonged treatment is required for eczema involving the face—a common situation in atopic dermatitis. Coal tar or shale tar (ichthammol), usually applied as creams containing tar extracts or bandages impregnated with tar paste, can be soothing and reduce pruritus. Occlusive dressings and bandages may be useful.

In the most severe cases, systemic steroids may be required. These act rapidly, improving symptoms within a day or two, but they should be discontinued as soon as possible. Alternatives to steroids include ciclosporin, which also acts rapidly [5], and azathioprine, which has a more gradual onset of action [6]. Cytotoxic immunosuppressants such as mycophenolate mofetil, methotrexate and cyclophosphamide have also occasionally been used. All these systemic modalities require careful monitoring. Various modalities of phototherapy have been successfully used in chronic eczema, especially in atopic dermatitis. These include UVB and, more recently, narrow-band UVB [7,8], PUVA [9] and UVA1 [10]. PUVA is also used for hand and foot eczema, often with topical application of 8-methoxypsoralen. However, phototherapy is potentially carcinogenic. In carefully selected cases of severe hand or foot eczema, superficial radiotherapy (Grenz rays) is effective. This is also carcinogenic and is probably best reserved for older patients.

Murray Williams' warts

Multiple seborrhoeic warts occurring in areas of resolved eczema have only occasionally been reported since the phenomenon was described by Williams in 1956 [1,2]. Multiple warts arise in the few months following resolution of the eczema and tend to gradually resolve by 5–6 months.

Lichenification

Definition. Lichenification is a change in appearance and texture of the skin associated particularly with pruritic dermatoses.

Clinical features. Mild or early lichenification presents as a rather subtle coarsening of the skin surface markings on a background of dry and usually erythematous skin. As the condition progresses, the skin becomes markedly thickened and hyperkeratotic (Fig. 23.32). The borderline between lichenification and some prurigos is tenuous, both in nomenclature and in practice. Prurigo nodularis could also be called nodular lichenification.

Histopathology. The variable clinical severity of lichenification is reflected histologically in variable degrees of acanthosis and hyperkeratosis. Additional features specific to lichenified dermatoses are discussed further below.

Aetiology. The features of lichenification are sometimes regarded as developing secondary to excoriation. This may not be entirely accurate, and it seems likely that inflammation associated with the underlying dermatosis often plays an independent role. Lichenification can occur to some degree in all pruritic, and especially eczematous, dermatoses.

Fig. 23.32 Lichenification of the arm in a patient with atopic eczema.

Lichenified dermatoses

In lichen simplex, lichen striatus and notalgia paraesthetica, lichenification is usually the predominant clinical feature.

Lichen simplex

Synonym
- Circumscribed neurodermatitis

Definition. Lichen simplex is an eczematous dermatosis characterized by a small number of heavily lichenified plaques or, very often, a single lesion.

Not all individuals are capable of developing lichenification. Patients with lichen simplex are more readily conditioned to scratch following an itch stimulus than control subjects [1]. Lichen simplex may occur as a manifestation of the atopic state [2], but not all atopics lichenify, and lichen simplex is seen in many individuals who show no stigmata of atopy. There appears to be well-marked racial variation in the capacity of the skin to lichenify; the high incidence of lichenification in oriental people has often been emphasized.

In the predisposed subject, emotional tensions play an important role in favouring the development of lichen simplex and ensuring its perpetuation [3].

Histopathology [4,5]. The histological changes of lichen simplex vary with site and duration. Acanthosis and variable degrees of hyperkeratosis are usually observed. The rete ridges are lengthened. Spongiosis is sometimes present, and small areas of parakeratosis are occasionally seen. There is hyperplasia of all components of the epidermis [6]. The labelling index has been shown autoradiographically to be over 25%, but the transit time is longer than in psoriasis [7].

The dermis contains a chronic inflammatory infiltrate, and in very chronic lesions there may be some fibrosis. Silver impregnation techniques show proliferation of the Schwann cells, which may make up an appreciable proportion of the cellular infiltrate.

Fig. 23.33 Follicular papules of lichenification adjacent to the elbow.

In very chronic lesions, especially in giant lichenification, the acanthosis and hyperkeratosis are gross, and the rete ridges are irregularly but strikingly elongated and widened.

Clinical features [5]. As in all forms of lichenification, pruritus is a prominent symptom, and is often out of proportion to the extent of the objective changes. It may develop in paroxysms of great intensity. Scratching tends to give great satisfaction initially, but is then continued with violence until the skin is sore. There is then a refractory period of some hours until the itch recurs. During the early stages the skin is reddened and slightly oedematous, and the normal markings are exaggerated. The redness and oedema subside, and the central area becomes scaly and thickened, and sometimes pigmented. Surrounding this central plaque is a zone of lichenoid papules, and beyond this an indefinite zone of slight thickening and pigmentation merges with normal skin. These features may be greatly modified by the site and duration of the lesion. In mild cases, follicular eczematous papules may be seen, particularly on the forearms and elbow regions of children (Fig. 23.33).

Lichen simplex is uncommon in childhood. The peak incidence is between 30 and 50 years of age, but it is seen at any age from adolescence onwards. Women are affected more often than men. Single and multiple sites are involved with about equal frequency. Almost any area may be affected, but the commonest sites are those that are conveniently reached. The usual sites are the nape of the neck, the lower legs (Fig. 23.34) and ankles, the sides of the neck, the scalp, the upper thighs, the vulva, pubis or scrotum, and the extensor forearms.

Lichen simplex of the nape of the neck (lichen nuchae) is almost confined to women. The plaque may be limited to a small area around the midline of the nape or may extend some distance into the scalp and over the neck. Scaling is often profuse and psoriasiform, and episodes of secondary infection are frequent. The fold behind the ear may also be involved. Scaling, crusting and fissuring are more evident than the usual changes of lichenification. Other regions of the scalp are less often affected. The presenting manifestation is an area of scaling, with twisted, broken hairs. The epidermal thickening may be great enough to form a nodule.

Fig. 23.34 Lichen simplex. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

In other sites the typical features of lichenification are usually retained, but if the subcutaneous tissues are lax, and excoriation continues for many years, solid, tumour-like plaques may be formed, with a warty, cribriform surface. This, the so-called *giant lichenification of Pautrier* [8], occurs mainly in the genitocrural region.

The descriptive term *pebbly lichenification* has been applied to a distinctive clinical variant, consisting of discrete, smooth nodules, seen occasionally in atopic and seborrhoeic subjects, and in photodermatitis. Clinically it may simulate lichen planus.

A dermatomal pattern of lichen simplex chronicus has been described as the initial presentation of an intramedullary neoplasm with syringomyelia [9].

Diagnosis. The morphological diagnosis of lichenification is not usually difficult—lichen planus, lichen amyloidosus and psoriasis have to be excluded, and typical lesions should be sought in other sites. Sometimes, however, no conclusive diagnosis is possible on either clinical or histological grounds. A patient with psoriasis may develop lichen simplex which combines the histological features of both conditions.

Once the diagnosis of lichenification has been established its causation must be carefully investigated. Secondary lichenification complicates persistent skin lesions of many types. It occurs on the lower leg in the presence of venous insufficiency, in atopic dermatitis, in asteatotic eczema, in low-grade chronic contact dermatitis, and in some chronic infections with *Trichophyton rubrum*. Symmetrical lesions in particular should suggest secondary lichenification of a contact dermatitis. More than one woman with formalin dermatitis of the base of the neck has been referred to a

psychiatrist, when she should have been patch tested and advised merely to discard the offending article of clothing. Similarly, a chronic *T. rubrum* infection of the thighs or feet, with secondary lichenification, responds better to griseofulvin than to tranquillizers.

Treatment. A careful psychological history should be taken, and the patient given some assistance in reducing their tensions. The nature of lichen simplex and the need to break the scratching habit must be explained. Sedation is often needed, and sedative antihistamines may be helpful. A topical antibiotic may be prescribed for a few days if secondary infection is present. A potent or very potent topical corticosteroid can be very helpful in some cases, but seems to have no effect in others.

On an arm or leg it is useful to apply an occlusive bandage which prevents scratching. For very chronic lesions, tar paste medicated bandages can be very helpful. They should be renewed at intervals of 5–7 days. Self-adhesive, steroid-impregnated tape (e.g. Haelan® tape) can often be effective. Alternatively, a potent steroid ointment under polythene occlusion, for short periods, may also be useful. Modest improvement has also been shown with 5% doxepin cream [10].

Circumscribed, chronic lesions can often be effectively treated by dermal infiltration with triamcinolone (10 mg/ml).

Response has been reported to capsaicin cream [11].

Lichen striatus

Synonym
- Linear lichenoid dermatosis

Definition and aetiology. Lichen striatus is a self-limiting, inflammatory, linear dermatitis of unknown origin. The factors determining the linear distribution are unknown, as none of the proposed embryological, neurological and vascular hypotheses is applicable to all cases. It has been suggested that the lesions develop in the lines of Blaschko [1], which are thought to be due to a form of human 'mosaicism' in which different groups of cells behave differently for reasons which are not yet clear. In a series of 26 patients, 80% were atopic [2].

Histopathology [3–5]. The histological appearances are variable, but may be distinctive. They often resemble lichen planus, with a band-like infiltrate in the dermis, and overlying epidermal changes. The earliest change is intercellular oedema, stretching the tonofilament–desmosome complexes and separating the epidermal cells. Like the spongiosis, acanthosis is variable in degree. Dyskeratotic keratinocytes, like the 'corps ronds' of Darier's disease, are seen in about 50% of cases. There is focal liquefactive degeneration of the basal layer. The dermis is oedematous, and the vessels and appendages are surrounded by an infiltrate of lymphocytes and histiocytes, which may be quite dense and extend deeply. Scattered cells often penetrate the epidermis.

Clinical features [2,6]. Over 50% of cases occur in children, usually between the ages of 5 and 15 years, but onset in early infancy and in old age has been reported. Females are affected two or three times as frequently as males. Small, pink, lichenoid papules, discrete at first but rapidly coalescing, appear suddenly and extend over the course of a week or more to form a dull-red, slightly scaly, linear band, usually 2 mm to 2 cm in width, and often irregular. Occasionally, the bands broaden into plaques, especially on the buttocks. The lesion may be only a few centimetres in length or may extend the entire length of the limb, and may be continuous or interrupted (Fig. 23.35). Parallel linear bands or zosteriform patterns have been recorded.

The initial lichenoid papules are pink and not violaceous, and show no umbilication or Wickham's striae. The papules may be hypopigmented in dark-skinned people.

The lesions occur most commonly on one arm or leg, or on the neck, but may develop on the trunk. The abdomen, buttocks and thighs may be involved in single extensive lesions, but multiple lesions are rare, and bilateral involvement is exceptional. Involvement of the nails may result in longitudinal ridging, splitting, onycholysis or nail loss [7–8].

There are usually no symptoms, but pruritus may occasionally occur. The course is variable. The lesion usually reaches its maximum extent within 2 or 3 weeks, but gradual extension can continue for several months. Spontaneous resolution can be expected within 3–6 months in most cases, but some lesions may persist for over a year. Resolution may be followed by temporary hypopigmentation.

Diagnosis. Epidermal naevi, linear or zosteriform, may first appear in childhood or later, and the inflammatory linear epidermal naevus (Chapter 18) in particular has many clinical and histological features in common with lichen striatus, but the naevi persist indefinitely. Linear forms of lichen planus and psoriasis can usually be differentiated clinically, even in the absence of typical lesions in other sites, which should always be sought.

Fig. 23.35 Lichen striatus of the inner thigh in a girl aged 16 years. The histological changes were those of chronic eczema. (Courtesy of Dr R.A. Marsden, St George's Hospital, London, UK.)

Linear porokeratosis must also be considered [9]. Biopsy may be helpful.

Treatment. Usually none is necessary. In the unusual persistent case, infiltration with steroids may be effective. Nail involvement may respond to potent steroid cream under occlusion.

Notalgia paraesthetica

Definition. A localized, pruritic patch of lichenified and often hyperpigmented skin at or near the inferior tip of the scapula. This distinctive pruritic condition seen in adults is thought to result from entrapment of the dorsal nerve root.

Treatment. Capsaicin 0.025% cream applied three to five times daily for 4 weeks proved effective in a placebo-controlled trial [1].

Prurigo [1]

Definition. This term is best used to denote a group of skin diseases characterized by intensely pruritic papules or nodules.

The definition has been the subject of much debate. Some authors have stressed the intense pruritus, others have emphasized visible excoriations, and yet others have suggested that there should be no identifiable local cause for the scratched lesions.

The term was originally introduced by Hebra [1] to denote papules induced by scratching. This definition allows the inclusion of entities such as the papular urticaria caused by insect bites, where dermographism may also be present. Many of the original cases of Hebra's prurigo, described in Vienna in the 19th century, were probably atopic patients in poor social conditions. Flea bites may well have played a part in producing the papular lesions.

The archaic term Besnier's prurigo has been applied to the chronic lichenified flexural form of atopic eczema.

Pruriginous dermatoses

Pruriginous lesions are the characteristic feature of nodular prurigo, chronic prurigo, prurigo pigmentosa, prurigo of pregnancy and actinic prurigo. Dermographic prurigo and neurotic excoriation can present with a similar appearance and are therefore also described here.

Nodular prurigo

Synonym
- Hyde's prurigo

Definition. Nodular prurigo is characterized clinically by chronic, intensely itchy nodules and histologically by marked hyperkeratosis and acanthosis, with downward projections of the epidermis. It is generally regarded as a variety of eczema. In many cases there is a history of atopic dermatitis or another form of eczema.

Aetiology [1]. The cause is unknown. Emotional stress seems to be a contributory factor in some cases, and it can be difficult to determine whether this is the cause or a result of the prurigo. Around 65–80% of patients are atopic. In these patients the age of onset may be earlier [2], even if no eczematous eruption is present. In 20% the condition starts after an insect bite [3].

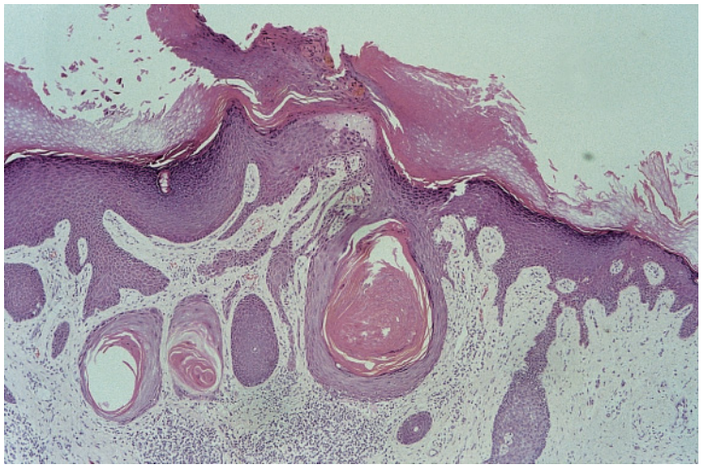

Fig. 23.36 Nodular prurigo. This shows gross accentuation of the changes found in lichenification. The epidermal downgrowth is pseudoepitheliomatous in extent. There is a mixed inflammatory cell infiltrate in the dermis and some sclerosis of the dermal collagen. H&E, ×40. (Courtesy of Dr M.J. Cook, Royal Surrey County Hospital, Guildford, Surrey, UK.)

Fig. 23.37 Nodular prurigo of the arm. (Courtesy of Dr D.A. Burns, Leicester Royal Infirmary, Leicester, UK.)

Histopathology [4,5]. The changes somewhat resemble those of lichen simplex, but the hyperkeratosis may be even greater, and the downward projections of the epidermis so marked as to suggest pseudoepitheliomatous hyperplasia (Fig. 23.36). The dermal infiltrate is dense, and there may be neural and vascular hyperplasia. These changes may arise, in part, as a non-specific reaction to repeated scratching [6]. In some cases the histology is that of chronic eczema. Mast cells are prominent, and there may be striking extracellular deposits of eosinophilic granule proteins such as major basic protein and eosinophil-derived neurotoxin [7], suggesting that mast cells and eosinophils may play a major role.

In the early literature, Pautrier described 'neuromas' in this condition, but these have not been seen in large series of patients [3,8]. There are, however, increased numbers of calcitonin gene-related peptide and substance P immunoreactive nerve fibre bundles in the skin of the nodular lesions, and neuropeptides may play a part in causing the intense itching [9,10]. In 75% of cases an increase in the number of Merkel cells is also seen [11]. Such changes do not occur in the lesions of lichen simplex.

Clinical features. Cases occur at all ages, but mainly from 20 to 60 years. Both sexes are equally affected. The individual lesions range from small papules to hard globular nodules, 1–3 cm in diameter, with a raised, warty surface. The early lesion is red, and may show a variable urticarial component. Pigmentary changes are common. Crust and scale may cover recently excoriated lesions. The intervening skin often shows slight xeroderma, and there is often an irregular ring of hyperpigmentation immediately around the nodules. The number of lesions varies greatly and may be very large. The nodules may be arranged in groups. They usually develop initially on the distal parts of the limbs, and are worse on the extensor surfaces (Fig. 23.37). The trunk, face and even the palms can be affected.

The patient is tormented by crises of intense pruritus. New nodules develop from time to time, and existing nodules may remain pruritic indefinitely, although some may regress spontaneously to leave scars. The disease runs a very protracted course.

Diagnosis. The large, more-or-less symmetrical nodules, and the intense, often distressing pruritus, are the key clinical features. These may also arise as a secondary event in a wide range of cutaneous and systemic diseases, which must be considered carefully before arriving at a diagnosis of idiopathic nodular prurigo.

Skin diseases that may mimic nodular prurigo include hypertrophic lichen planus, especially on the lower legs. The lesions are usually violaceous, and may be associated with more typical lichen planus lesions elsewhere. A variant of bullous pemphigoid called pemphigoid nodularis may present as nodular prurigo for some time before the typical urticated plaques and blisters supervene [12,13]. Immunofluorescence findings are those of pemphigoid, and the disease can be treated as pemphigoid with immunosuppressive therapy. Most cases occur in elderly women, but a juvenile form has been reported [14]. An unusual case of porokeratosis has been described in which some lesions, histologically demonstrating features of porokeratosis, clinically resembled prurigo nodules [15]. Cases are also described in association with oncocerciasis, leech bites, reactive perforating collagenosis and multiple granular cell tumours [1]. Allergic contact dermatitis may also result in a papulonodular eruption, and patch testing can sometimes be helpful [16].

Systemic causes of pruritus which can give rise to lesions resembling nodular prurigo include renal failure [17], liver disease [18], lymphoma [19] and HIV infection [20]. Gluten-sensitive enteropathy has been found in some patients [21,22], but is not present in the majority [3,23].

Treatment. Measures used to reduce excoriation include cutting the nails very short, wearing gloves at night and occlusion of the involved regions of skin with bandages, dressings or steroid-impregnated tape. Sedative antihistamines are often used, and are most helpful at night. Emollients may be helpful when xerosis is present. Topical steroids are not usually effective, but intralesional injection of triamcinolone can be beneficial. Topical capsaicin [24]

has been used with success in some cases. Cryotherapy can be helpful, but may result in pigmentary changes, especially in pigmented skin. Application of the sensitizer DNCB improved nodular prurigo in one case [25].

Systemic agents that can be highly effective include thalidomide, although this is hazardous in fertile female patients due to teratogenicity. This drug can also induce a painful peripheral neuropathy [26,27]. Ciclosporin [28] and azathioprine [29] can also be highly effective, although the disease tends to relapse after the drugs are discontinued. Interestingly, ciclosporin also proved effective in a case associated with uraemia [30].

Nodular prurigo can respond well to PUVA, using local application of psoralen [31]. Oral PUVA is also used on occasions. A pleasing response has been reported to UVB [32], and narrowband UVB may be effective alone and in combination with thalidomide [33].

Assessment of the patient's emotional state is desirable; antidepressants and tranquillizers can prove useful in selected cases [34].

Chronic prurigo of adults

Synonyms

- Chronic papular urticaria
- Subacute prurigo
- Papular dermatitis

These terms are used to denote pruritic papular eruptions, which often appear rather similar to nodular prurigo except that the lesions are smaller and less elevated. Chronic prurigo is regarded as eczematous in nature although, as in the case of nodular prurigo, a similar clinical picture can arise in patients with systemic causes of pruritus. Another similarity with nodular prurigo is the association with stress and other psychological factors in some cases. Neurotic excoriation has previously been included as synonymous with subacute prurigo (see below).

Biopsy shows a non-specific dermatitis.

Treatment is similar to that of nodular prurigo and tends to be difficult. Soothing topical applications such as crotamiton or 0.5% menthol in aqueous cream are often used. Some patients respond well to a course of UVB or PUVA [1].

Prurigo pigmentosa [1–6]

Definition. Irritable, red papules on the trunk and neck which fade to leave reticular hyperpigmentation.

(a) (b)

Fig. 23.38 (a) Prurigo pigmentosa. (Courtesy of Dr M. Aso, Tottori University School of Medicine, Japan.) (b) Prurigo pigmentosa. (Courtesy of Dr L. Chiam, National Skin Centre, Singapore. Published with permission from *Clinical and Experimental Dermatology*.)

Aetiology. The cause is unknown. Some cases have occurred in patients who were diabetic, dieting or anorexic, and it has been suggested that the associated metabolic changes, including ketosis, may play a role [7].

Histopathology. The histology is non-specific, but often somewhat lichenoid. Immunofluorescence is negative. Occasional blood eosinophilia occurs.

Clinical features. The condition is rare in the Western world, but many cases have been described in Japan. The disorder is more common in adult females, with an onset in the spring and summer months. The characteristic lesions are found on the trunk and neck, and present as itchy, red papules, sometimes with vesicles, which coalesce to produce a reticular pattern (Fig. 23.38). Later they are replaced by a reticular hyperpigmentation.

Diagnosis. This is based on the clinical and histological features. Patch testing may be helpful in excluding allergic contact dermatitis.

Treatment. Minocycline 200 mg daily appears to be the treatment of choice [1], as the pruritus and rash disappear within a week in most cases. About one-third of patients will respond dramatically to dapsone. A prompt response to macrolide antibiotics has been reported [8]. Neither the rash nor the itching respond to oral antihistamines or topical steroids.

Prurigo of pregnancy [1,2]

This is regarded as a specific dermatosis of pregnancy (see Chapter 8). It occurs in about one in 300 pregnancies. In some cases it appears to be a manifestation of atopy. Pruritic papules and nodules develop on the abdomen and/or limbs, usually at 25–30 weeks of gestation. These may persist for several weeks after delivery. Skin biopsy reveals non-specific epidermal thickening, parakeratosis and a lymphocytic infiltrate in the upper dermis. Immunofluorescence is negative. The itch is usually improved by potent topical steroids and sedative antihistamines. The condition is not associated with any risk to the pregnancy.

Dermographic prurigo

This is a severe form of symptomatic dermographism in which urticarial weals and excoriations occur at sites of clothing pressure, especially around the edges of a brassière or belt. There may eventually be some pigmentation.

Actinic prurigo

Synonym
- Hutchinson's summer prurigo

This is an uncommon photodermatosis (see Chapter 29).

Neurotic excoriation

This disorder, which predominantly affects middle-aged women who appear to be under emotional stress, has also been called subacute prurigo. This latter term is now more appropriately used synonymously with chronic prurigo of adults. It is not a satisfactory description of neurotic excoriation, as the lesions are excoriated erosions or ulcers rather than papules. This term should be reserved for cases where psychological factors are the primary cause of repeated excoriation. Neurotic excoriation is described further in Chapter 64.

Erythroderma

Definition. Erythroderma is the term applied to any inflammatory skin disease that affects more than 90% of the body surface. The term exfoliative dermatitis is used synonymously, although the degree of exfoliation is sometimes quite mild.

Incidence. A study from the Netherlands estimated the annual incidence at 0.9 per 100 000 population [1].

Aetiology [2–6]. The main causes of erythroderma in adults are listed in Table 23.9 and are discussed below. The figures vary somewhat with the age of the population, and are based on several published studies. In younger people, for example military personnel, there will be a larger proportion due to drug allergies [6]. Drugs commonly causing erythroderma are listed in Chapter 75. In some communities, the incidence of erythroderma may be higher because of self-medication and use of traditional remedies [7]. The use of herbal remedies, such as St John's wort [8], may trigger this reaction.

The causes of erythroderma in the newborn are considered in Chapter 17.

Other, rare causes of erythroderma include sarcoidosis [9], Hailey–Hailey disease [10], pemphigoid [11], toxic shock syndrome [12], lupus erythematosus [13], angioimmunoblastic lymphadenopathy [14] and dermatomyositis [15]. Graft-versus-host disease may progress to erythroderma in some cases. A related disorder was reported in Japan, where cases of fatal erythroderma occurred following major surgery. It was suggested that these cases were examples of post-transfusion graft-versus-host disease [16].

Erythroderma has occasionally been reported with seroconversion following HIV infection [17]. In established AIDS, erythroderma may arise from a variety of causes. Some are examples of severe seborrhoeic dermatitis, others are associated with lymphoma, and some are of unknown cause [18]. However, it should be noted that $CD4^+$ T lymphocytopenia has been caused by erythroderma in the absence of HIV infection [19].

Males are affected between two and three times more frequently than females and, if the hereditary disorders and atopic dermatitis are excluded, most are over 45 years old.

Table 23.9 Causes of erythroderma and relative prevalence in adults.

Condition	Prevalence (%)
Hereditary disorders	1.0
Ichthyosiform erythroderma	
Pityriasis rubra pilaris	
Psoriasis	25.0
Eczema of various types	40.0
Drugs	10.0
Especially organic arsenic, gold, mercury	
Occasionally penicillin, barbiturates, etc.	
Pemphigus foliaceus	0.5
Lymphoma and leukaemias	15.0
Other skin diseases	0.5
Lichen planus	
Dermatophytosis	
Crusted scabies	
Dermatomyositis	
Unknown	8.0

Histopathology. Histopathology can help identify the cause of erythroderma in up to 50% of cases, particularly if multiple skin biopsies are examined [20]. The histological appearances vary depending upon the severity and duration of the inflammatory process. In the acute stage, spongiosis and parakeratosis are prominent, and a non-specific inflammatory infiltrate permeates, to a variable depth, a grossly oedematous dermis. In the chronic stage, acanthosis and elongation of the rete ridges become more prominent.

In erythroderma due to lymphoma, the infiltrate may become increasingly pleomorphic, and it may eventually acquire specific diagnostic features, such as a band-like lymphoid infiltrate at the dermoepidermal junction, with atypical cerebriform mononuclear cells and Pautrier microabscesses [21]. In other cases, however, it remains non-specific throughout its course, and the distinction can be difficult. Patients with Sézary syndrome often show some features of chronic dermatitis, and benign erythroderma may occasionally show some features suggestive of lymphoma.

Immunophenotyping of the lymphoid infiltrate may not solve the problem, as it generally shows features of mature T cells in both benign and malignant erythroderma [22].

In psoriasis, papillomatosis and clubbing of the papillary zones may be seen, and in pemphigus foliaceus, superficial acantholysis will be present. In ichthyosiform erythroderma and pityriasis rubra pilaris, repeated biopsies from carefully selected sites may reveal their characteristic features.

Clinical features. Erythroderma developing in primary eczema or associated with a lymphoma is often of sudden onset. Patchy erythema, which rapidly generalizes, may be accompanied by fever, shivering and malaise. Hypothermia may develop.

The erythema extends rapidly, and may be universal in 12–48 h. Scaling appears after 2–6 days, often first in the flexures, but it varies greatly in degree and character from case to case. The scales may be large, or fine and bran-like. At this stage the skin is bright red, hot and dry, and palpably thickened. The intensity of the erythema may fluctuate over periods of a few days or even a few hours. Irritation is sometimes severe, but a sensation of tightness

is more characteristic. Many patients complain of feeling cold, especially when the erythema is increasing.

When the erythroderma has been present for some weeks, the scalp and body hair may be shed and the nails become ridged and thickened, and may also be shed. The periorbital skin is inflamed and oedematous, resulting in ectropion, with consequent epiphora. In very chronic cases there may be pigmentary disturbances, especially in black people, in whom patchy or widespread loss of pigment is often seen.

The degree of enlargement of the lymph nodes in the absence of an underlying malignant lymphoma is variable. They are usually slightly or moderately enlarged and of rubbery consistency, but in some cases the enlargement may be gross. It is important that this dermatopathic lymphadenopathy is not mistaken for lymphoma. In difficult cases, lymph node biopsy may be advisable, but the pathologist must be told that the patient is erythrodermic for a reliable histological interpretation to be made.

The general picture is modified according to the nature of any underlying disease, and the patient's age and general physical condition.

Fig. 23.39 Erythrodermic psoriasis.

Fig. 23.40 Widespread drug rash. This will rapidly progress to erythroderma if the drug is continued.

Eczematous dermatoses

Generalization of an eczema occurs most frequently in the sixth and seventh decades when venous eczema is a common precedent. However, atopic erythroderma may occur at any age. Exacerbation of existing lesions usually precedes the generalization, which follows the usual pattern. Pruritus is often intense. Some elderly patients have increased serum IgE and lactic dehydrogenase levels, with eosinophilia [23].

Psoriasis

In erythrodermic psoriasis (Fig. 23.39) the clinical picture may be highly desquamative but when the erythroderma is fully developed the specific features of psoriasis are often lost. In some cases, crops of miliary pustules may develop at intervals, and transition to generalized pustular psoriasis may occur, especially in cases treated with potent topical steroids, or systemic steroids [24]. Emotional stress, intercurrent illness and phototherapy overdosage may also precipitate erythroderma.

Drugs

A wide range of drugs can cause erythroderma. Among the more commonly implicated are pyrazalone derivatives such as phenylbutazone, hydantoin derivatives, carbamazepine, cimetidine, gold salts and lithium [25]. The eruption may start as a generalized eczema, or scarlatiniform or morbilliform erythema, often accompanied by some irritation, which increases steadily in severity. Erythema may first appear in the flexures, or over the whole skin (Fig. 23.40). This group has the best prognosis of all the causes of erythroderma [2,26], often resolving in 2–6 weeks [27]. However, it is important to remember that the cutaneous manifestations of drug hypersensitivity may be accompanied by involvement of other organs, for example haematological abnormalities, hepatitis or nephritis. An example is the syndrome known as DRESS (drug reaction with eosinophilia and systemic symptoms). This term is used for a group of severe, multisystem drug reactions characterized by later onset than most manifestations of drug hypersensitivity. Exposure to the causative drug may last for 2 weeks to several months before the reaction emerges. DRESS may also persist for a long time and even worsen after withdrawal of the causative agent. Multisystem involvement may include fever, eosinophilia, lymphadenopathy, hepatitis, renal dysfunction and pneumonitis.

Fig. 23.41 Erythroderma in Sézary syndrome. (Courtesy of Dr B. Dharma, University Hospitals Coventry and Warwickshire, UK.)

Lymphoma, leukaemia and other malignancy

Cutaneous T-cell lymphoma (Fig. 23.41) is the commonest malignancy to cause erythroderma, followed by Hodgkin's disease. Non-Hodgkin's lymphoma, leukaemias and myelodysplasia have also been reported as causes. Association with other internal malignancies has been observed less often [5].

The clinical picture follows the pattern already described, but the accentuation of certain features should arouse suspicion that a lymphoma is associated, even if repeated investigations over a period of months fail to provide convincing confirmatory evidence. In many such cases the underlying disease will eventually be detected. Pruritus is often very severe. The erythroderma is universal, and the infiltration of the skin may be so severe that the patient's features are deformed. Rubbing and scratching may produce secondary lichenification. Enlargement of the lymph nodes may be considerable, even if they are histologically not involved by the lymphoma.

Biopsy of involved skin may show only non-specific features initially, and may need to be repeated several times before infiltration with atypical lymphocytes becomes evident. The use of a skin biopsy for analysis of T-cell receptor gene rearrangement, to determine whether clonality is present in the infiltrate, may prove to be a useful investigation in these circumstances [28,29]. Lymph-node biopsy may be diagnostic of lymphoma, but often shows only the features of dermatopathic lymphadenopathy. There may be hepatosplenomegaly. A differential white blood cell count should be performed, and the blood examined for abnormal cells. Eosinophilia may suggest Hodgkin's disease. Atypical lymphocytes with cerebriform nuclei (Sézary cells) are often observed in erythroderma regardless of cause. When they constitute more than 20% of the circulating peripheral blood mononuclear cells they become diagnostic of the leukaemic variant of cutaneous T-cell lymphoma known as the Sézary syndrome. Large Sézary cells (15–20 μm in diameter) are diagnostic even in small numbers [30]. The demonstration of a clonal T-cell population in the peripheral blood by analysis of T-cell receptor genes, using PCR, appears to offer high diagnostic specificity for Sézary syndrome. The sensitivity also appears high, but on occasions the test may need to be repeated if initial results are negative and this diagnosis is still suspected [30].

Pemphigus foliaceus

Moist, crusted lesions on the face and upper trunk often precede the development of the erythroderma. Scaling is conspicuous, moist and adherent. Crops of thin-walled bullae may erupt, especially on the limbs.

Ichthyosiform erythroderma

This condition is usually present from birth or early infancy.

Pityriasis rubra pilaris

The erythrodermic forms may begin in childhood or adult life. The presence of follicular, horny plugs on the knees and elbows, and on the backs of the fingers and toes, is distinctive. In many cases, islands of normal skin persist in the erythrodermic regions, and horny plugs may be evident around their margins. These normal pale 'islands' are very suggestive of the diagnosis, and the skin on the palms and soles often has an orange discoloration.

Lichen planus

Erythrodermic lichen planus is very rare, but lichenoid reactions to gold, quinine and other drugs are not uncommon. As the initial erythema and oedema subside, individual violaceous papules may be revealed. The buccal mucous membrane may show typical lacy, bluish-white streaks.

Dermatophytosis

Generalized erythroderma has very rarely resulted from chronic infection with organisms such as *Trichophyton violaceum*.

Norwegian scabies

The heavily crusted hands and feet, with thickened nails, so characteristic of Norwegian scabies, may occasionally be accompanied by generalized erythema and scaling. The condition is often mistaken for erythrodermic psoriasis. The occurrence of scabies in others in the same environment, or in the medical or nursing staff caring for the patient, will soon make the diagnosis clear.

Erythroderma of unknown origin

The percentage of cases in which no underlying disease is demonstrable diminishes with the thoroughness of investigation and the duration of observation, but in any series of cases it is rarely below 10% [3,4,27]. The cutaneous changes may precede any other evidence of a lymphoma by many months or years. If these cases are excluded, the hard core of chronic erythrodermas of unknown origin consists mainly of elderly men, in whom the condition runs a very long course with partial and temporary remissions. These have been labelled the 'red-man syndrome'. It is characterized by marked palmoplantar keratoderma, dermatopathic lymphadenopathy and a raised serum IgE [23,31]. It is important to note that

this condition is not established erythrodermic cutaneous T-cell lymphoma, which is occasionally referred to as 'l'homme rouge'.

The three commonest causes of idiopathic protracted erythroderma are probably atopic eczema of the elderly, intake of drugs overlooked by the patient and pre-lymphomatous eruptions [3].

Secondary haemodynamic and metabolic disturbances. Chronic, generalized erythroderma is associated with profound metabolic disturbances [11,32–34]. The blood flow through the skin is markedly increased, and this can result in high-output cardiac failure, especially in elderly patients [35,36]. The increased skin perfusion may lead to hypothermia [37]. When the body temperature is raised, heat loss is further increased. The regulation of temperature is grossly disturbed, and the patient behaves like a poikilothermic animal, tending to adopt the environmental temperature. The excessive loss of heat leads to compensatory hypermetabolism and a raised basal metabolic rate.

Fluid loss by transpiration is much increased and is roughly proportional to the basal metabolic rate. The loss of exfoliated scale may reach 9 g/m^2 of body surface or more each day [38].

Hypoalbuminaemia is common, and probably has several causes. Dilution by increased plasma volume may be one cause [39], but is likely to be less important than a lowered total albumin mass due either to a decrease in synthesis or an increase in metabolism [40,41]. There is also, of course, an increased protein loss via scaling and exudation. Oedema is common. Occasionally, the increased capillary permeability is severe enough to justify plasma infusions as well as parenteral steroids.

Immune responses may become altered, reflected by an increase in gammaglobulins; occasional patients have been described with very high levels of serum IgE [42], and $CD4^+$ T lymphocytopenia may occur in the absence of HIV infection [19].

Elderly patients living alone may already be malnourished prior to developing erythroderma. Any exudative or extensive scaling condition will intensify this.

Diagnosis. The recognition of erythroderma is easy, but the diagnosis of the underlying cause may be very difficult. The difficulty of exact classification of some of these cases is illustrated by the report of seven patients with erythroderma who were followed for 3–16 years before they developed the Sézary syndrome (cutaneous T-cell lymphoma). Four of these patients had multiple contact allergies or drug reactions, and one had severe atopic dermatitis [43].

The history is often helpful in identifying the hereditary disorders, drug reactions, psoriasis, etc., but in some cases the erythroderma is of sudden onset and the history may not be helpful. Multiple biopsies are usually, but not invariably, helpful [44], and the eczematous erythrodermas and those associated with lymphoma may not show any distinctive histological features.

Treatment. Treatment in hospital is frequently necessary, especially in acute and fulminant cases, because some patients may develop serious general medical problems. In these cases the protein and electrolyte balance, circulatory status and body temperature require continual surveillance. The environmental temperature must be carefully regulated. Cooling and overheating must both be avoided by the use of extra blankets or fans, respectively.

Urea and electrolyte levels and fluid balance should be monitored. Adequate fluid intake must be maintained, but if there is oedema, diuretics and/or plasma infusion should be considered. Cardiac failure must be treated if it develops.

The possibility that the erythroderma is due to a drug reaction should be considered in every case, and all non-essential drugs should be withdrawn.

The cutaneous inflammation should be treated in the first instance with soothing emollient creams, or a mild topical steroid. The majority of patients will improve over a week or two on this regimen, during which time the diagnosis of the underlying condition will probably be established.

If active topical medication is applied it must be remembered that the barrier function of erythrodermic skin is greatly reduced. This is potentially hazardous because topical application of medications, such as salicylic acid, corticosteroids or vitamin D analogues, will result in much higher systemic exposure than might be expected in other circumstances.

Many dermatologists prefer to avoid systemic steroids if possible, because of the dangers of fluid retention, secondary infection, diabetes, etc., but in severe persistent cases they may become necessary. There is some evidence that the use of systemic steroids or potent topical steroids in psoriatic erythroderma may provoke the development of pustule formation [24]. In such cases, low-dose methotrexate, acitretin or ciclosporin [33] may be safer alternatives. Topical tar and UV therapy should also be avoided on erythrodermic psoriasis.

Antibiotics will be required to control secondary infection. Heng [45] has suggested that colonization of the skin by *Staphylococcus aureus* may actually cause erythroderma, which will clear with appropriate antibiotic therapy.

The optimum treatment of erythrodermic cutaneous lymphoma is still debated. Options include systemic steroids, PUVA, total body electron-beam irradiation, topical nitrogen mustard and systemic chemotherapy [46]. The use of methotrexate has appeared beneficial in a retrospective study on 29 patients [47]. However, diagnostic histology was only obtained in 13 of these cases, so they may have been a somewhat heterogeneous group. Extracorporeal photopheresis has been advocated [48] but it is not yet clear whether this prolongs survival.

Prognosis and complications. Erythroderma is a serious condition in itself, quite apart from hazards associated with the underlying disease, and is sometimes fatal despite skilled management. It is particularly dangerous in elderly people. Reported death rates have varied from 18 to 64% [2,4,6], but with modern therapy the rate is probably lower.

The commoner forms of erythroderma—eczematous, psoriatic or of unknown origin—may continue for months or years, and tend readily to relapse [24]. As the patients are often elderly, the prognosis must always be guarded. The metabolic disturbances involve a serious risk of hypothermia, cardiac decompensation, peripheral circulatory failure and thrombophlebitis. Cutaneous, subcutaneous and respiratory infections are common, and the majority of patients who die do so from pneumonia [24].

The treatment can also be hazardous, especially when systemic steroids and immunosuppressants are required.

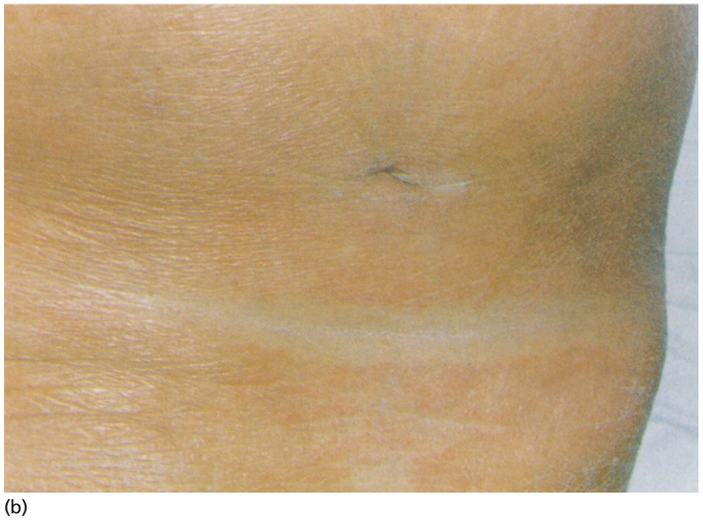
Papuloerythroderma of Ofuji [1–5]



This distinctive pattern of erythroderma was described by Ofuji in 1984 [1]. It differs from ordinary erythroderma in that papulation is prominent, it tends to spare the face and flexures, and it is consistently and, often intensely, pruritic.

It is not yet clear whether this represents a distinct disease or a reaction pattern. Although most cases have been seemingly 'idiopathic', several have been reported in association with other diseases.

Pathology. Histological features are usually non-specific. In the epidermis there are variable, but most often mild, degrees of acanthosis, spongiosis, hyperkeratosis and focal parakeratosis. There is marked lymphohistiocytic infiltration of the dermis, predominantly perivascular in distribution, with a variable, and often conspicuous, number of eosinophils. A mild degree of epidermotropism has occasionally been observed and, rarely, plasma cells and multinucleate giant cells. Immunofluorescence is negative.

(b)

Fig. 23.42 Papuloerythroderma of Ofuji. (a) The papules. (b) The 'deck-chair' sign (sparing of the body folds). (Courtesy of Dr M.J. Tidman, Edinburgh Royal Infirmary, Edinburgh, UK.)

Clinical features. Papuloerythroderma has been observed entirely in an elderly population, with ages at diagnosis ranging from 57 to 100. Many cases occur in the eighth or ninth decades. Males are predominantly affected, the male : female ratio being estimated at 4.7 : 1 [2].

The erythroderma typically begins with an eruption of brownish-red, flat-topped papules which become confluent (Fig. 23.42a). The limbs and trunk are affected, but the face and flexures, especially axillary and inguinal regions, tend to be spared. A characteristic and distinctive pattern of sparing of the abdominal flexures has been termed the 'deck chair sign' [3], indicating the similarity to the distribution of sunburn in one who has been sitting out in a deck chair for too long (Fig. 23.42b). The lesions sometimes develop along scratch marks. Pruritus is a consistent feature and ranges from moderate to extremely severe. Additional features often observed include hyperkeratosis and fissuring of the palms and soles, and benign lymphadenopathy.

There is usually circulating eosinophilia and a raised IgE. There is often a mild degree of absolute or relative lymphocytopenia.

Reports of papuloerythroderma occurring in association with malignancies, which have included T-cell [4,5] and B-cell lymphomas [5], gastric [5], lung [5], colon [6], prostate [2] and hepatocellular carcinomas [7], would suggest that this eruption may sometimes occur as a paraneoplastic phenomenon. There are also several reports that papuloerythroderma may progress into mycosis fungoides [2,8,9], in one case 11 years after the onset of symptoms [10]. In some cases, papuloerythroderma therefore seems to be a presentation of cutaneous T-cell lymphoma. One case developed into psoriasis [2]. Papuloerythroderma has also been reported in association with HIV infection [11,12], and, in one case, biliary sepsis [13].

Treatment. Emollients, topical corticosteroids and antihistamines have produced a slow response in some cases. The condition can respond well to oral prednisolone, although high doses are sometimes required. PUVA, including bath PUVA, has proved effective in several reports. Azathioprine [14], ciclosporin [15] and etretinate [16] may be effective. In view of the possible associations with malignancy and HIV infection, and as some cases progress to cutaneous T-cell lymphoma, the use of retinoids or PUVA would seem preferable to immunosuppressant drugs. However, papuloerythroderma is sometimes very refractory to treatment. It typically persists for many years, but some cases have remitted.

Definition

Atopic dermatitis is a difficult condition to define because it lacks a diagnostic test and shows variable clinical features. The following definition seems to be in accord with most consensus groups. Atopic dermatitis (which is synonymous with atopic eczema) is an itchy, chronic, or chronically relapsing, inflammatory skin condition. The rash is characterized by itchy papules (occasionally vesicles in infants) which become excoriated and lichenified, and typically have a flexural distribution. The eruption is frequently associated with other atopic conditions in the individual or other family members [1–3].

Atopic and non-atopic dermatitis

One of the difficulties in defining atopic dermatitis arises from the impreciseness of its association with atopy and the nature of atopy itself. Atopic dermatitis and disorders resulting from anaphylaxis, for example those resulting from insect stings and food allergies, may be associated with IgE antibodies and therefore grouped with the atopic diseases. Such grouping is not completely acceptable, as 20–40% of individuals with atopic dermatitis can have a normal total or specific IgE level [4], and it is rarely attributable to a specific allergic reaction; the IgE antibodies present in the blood often appear to be incidental to the condition.

It is still a matter of debate whether the group with dermatitis and normal IgE levels, termed intrinsic atopic dermatitis or non-atopic dermatitis, can be distinguished clinically, immunologically, and prognostically from extrinsic or atopic dermatitis [5]. Up to 50% of infants have been reported to have intrinsic dermatitis [6], but with time atopic features become more prevalent and the intrinsic form may be found in only 5.4% of adult patients [7].

Terminology

Debate has added to the already wide variety of historical names for the condition. Currently, atopic dermatitis and atopic eczema are the most widely used. The World Allergy Organization has suggested that 'eczema' should be used as an umbrella term, and subdivided it into atopic eczema and non-atopic eczema [8]. Historical terms such as Besnier's prurigo, disseminated neurodermatitis, Spatexudativ Ekzem and prurigo diathesique are now

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

little used. We continue to use the term atopic dermatitis until the clinical relevance of dividing the disease into subgroups is confirmed.

Diagnostic criteria

Hanifin and Rajka [1] proposed major and minor diagnostic criteria based on their clinical experience. These criteria allow a uniformity of diagnosis for hospital-based and experimental studies but were considered not helpful for population-based studies [2]. Consequently, Williams coordinated a UK working party to attempt to refine the criteria of Hanifin and Rajka into a repeatable and validated set of diagnostic criteria for atopic dermatitis [3,4] (Table 24.1).

These diagnostic guidelines appear to be valid for adults, children and non-white ethnic groups suffering from atopic dermatitis [3], and have been validated in a population setting [4]. They were primarily developed for epidemiological studies and, of necessity, exclude some signs that could be useful for diagnosis in individuals but are not common enough for use when assessing large populations.

More recently, other modifications of the diagnostic criteria have been proposed, but these have been less rigorously validated [5,6].

Table 24.1 The UK refinement of Hanifin and Rajka's diagnostic criteria for atopic dermatitis. (From Williams *et al*. [4].) Scabies should be excluded.

In order to qualify as a case of atopic dermatitis with the UK diagnostic criteria, the child must have:

- An itchy skin condition (or parental report of scratching or rubbing in a child)

Plus three or more of the following:

1 Onset below age 2 years (not used if child is under 4 years)
2 History of skin crease involvement (including cheeks in children under 10 years)
3 History of a generally dry skin
4 Personal history of other atopic disease (or history of any atopic disease in a first-degree relative in children under 4 years)
5 Visible flexural dermatitis (or dermatitis of cheeks/forehead and outer limbs in children under 4 years)

Prevalence

Although it is accepted that atopic dermatitis is a common disease, precise measurement of its frequency is difficult because different methods of assessment have been used. For example, some studies have based information purely on questionnaire results without objective validation of the quality of responses. Other studies have used clinical examination by dermatologists to supplement and confirm data from interview and questionnaire. Detailed reviews of the prevalence studies are to be found in McNally and Phillips [1] and Williams [2]. The international study of asthma and allergies in childhood (ISAAC) used cross-sectional questionnaires to sample school children of 6–7 years and 13–14 years in 56 centres throughout the world [3]. A history of an itchy relapsing rash affecting skin creases in the previous 12 months was a main outcome measure.

Overall, from the ISAAC study data and many other studies, a pattern emerges that atopic eczema is most prevalent in the most developed Westernized countries, and least prevalent in the most non-Westernized and underdeveloped countries. Thus, in Norwegian children from 7 to 13 years of age, the cross-sectional prevalence was 19.7% [4]. In Danish children up to 7 years of age, the lifetime prevalence was 22.9%, whereas in Germany and Sweden 13.1% and 15.5%, respectively, were reported [5]. In England, the point prevalence in 3- to 11-year-old children was found to be 11.5–14% [6] and the 1-year period prevalence was reported as 11.5% [7]. In Japan, figures of 9.5 and 20% have been reported for elementary school children and 3 year olds, respectively [8,9]. In contrast, in Tanzania, a point prevalence in 7–8 year olds was found to be only 0.7% [10].

Studies of migrants show some interesting patterns. There are reports comparing the frequencies of atopic eczema in particular ethnic/genetic groups in their homeland with those in their adopted new homeland. For example, children who migrated to New Zealand from Tokelau have a much greater prevalence of atopic eczema than those in their country of origin [11]. Immigrant populations appear to develop a prevalence of atopic eczema even greater than that of the indigenous population of their adopted homeland. Thus, black Afro-Caribbean children residing in London were shown to have twice the prevalence (16.3%) of atopic eczema of their Caucasian counterparts (8.7%) [6]. A study from Sweden showed that immigrant Turkish children had a signifi-

cantly higher prevalence of atopic disease (32.4%) than Swedish children (6%) [12].

These observations clearly reflect the fact that environmental factors play a large part in determining the expression of atopic diseases. The tantalizing question is whether the Westernized countries have an environment that actively promotes the atopic phenotype or whether the underdeveloped world has factors that actively suppress the expression of the atopic phenotype.

There is accumulating evidence that the prevalence of atopic diseases in general, and atopic eczema in particular, have been increasing over the last three to four decades. Among the epidemiological experts, there is concern that changing methods of assessment and methodological errors may have distorted the true picture [13]. However, a composite picture from many studies suggests that the cumulative incidence in children up to 7 years of age was less than 3% if they were born before 1960, 4–8% for those born between 1960 and 1970, and 8–12% for those born after 1970.

In the elegant twin studies by Shultz Larsen the cumulative incidence was shown to rise progressively from about 3% for twins born between 1960 and 1964, to 12% for those born between 1975 and 1979 [14,15]. Selnes surveyed large numbers of Norwegian children (7–13 years of age) in 1985 and 1995, and found the cumulative incidence of atopic eczema had risen from 13.2% to 19.7% over the intervening 10 years [4]. The reason for this steady rise in the prevalence of atopic diseases is not clear, but there are a number of possible environmental candidates (see below).

The consequence of the rising prevalence of atopic eczema is a heavy burden on medical services and budgets. In Britain, the annual cost of atopic dermatitis was estimated as about £465 million [16], and in the USA, insurance payouts to cover the costs of atopic eczema have been estimated at between $0.9 and $3.8 billion [17].

Aetiology

Recently, there has been a growing realization that the atopic state and the syndromes of atopic eczema and asthma involve abnormalities not only of immune regulation but also a range of primary functions of the epidermis and bronchial epithelium. It is not clear whether these are independent or whether there is an interplay in which the epithelia and the immune system regulate each other.

Genetic influence

The importance of genetic factors in determining the expression of the atopic phenotype is reflected in data from twin studies. Thus, monozygotic twins have a concordance rate of 0.72, whereas dizygotic twins have a concordance rate of only 0.23 [1–3].

Four genome screens have been reported from German/Scandinavian (n = 839) [4], British (n = 383) [5], Swedish (n = 470) [6] and Danish (n = 424) [7] populations. These have identified susceptibility loci on 1q21 [5], 3p24–22 [6], 3q21 [4] and 17q25 [5] in association with atopic dermatitis. A number of other associated loci have also been reported by further association with disease severity, or IgE, or concurrent asthma: 3p26–24 [7], 3q14 [6], 4p15–14 [7], 13q14 [6], 15q14–15 [6], 17q21 [6], 18q11–12 [7], 18q21 [6], 20p [5]. Genome screens for asthma report some overlapping loci: 13q [8] and 20p [5]. Interestingly, many loci associated with atopic dermatitis overlap with known psoriasis loci (1q, 3q, 17q and 20p [5]), which is unexpected because the two conditions are almost mutually exclusive in clinical practice. This information suggests that genetic influences on these two conditions may overlap in the targeting of the epidermis. Clearly, overlapping loci of association do not imply the same causative genetic factors, but even if the same gene were to be implicated by such a study, it would be important to investigate the effects on gene expression and protein function in that setting, which could be very different for the two diseases.

Recently, studies of genetic linkage have identified a number of genes related to the expression of different atopic syndromes, IgE levels and cytokines relevant to the regulation of IgE levels. A polymorphism in the gene encoding the β chain of the high affinity IgE receptor FCεR1β has demonstrated a highly significant association with atopic dermatitis [9]. Genes on chromosome 5q encoding the cytokine gene cluster have been linked to atopic mucosal

syndromes [10] and include associations with polymorphisms in the IL-4 gene with atopic dermatitis [11–14]. A gene at 16p11.2–12 encoding the α chain of the IL-4 receptor has been linked to atopy [15–17]. The gene encoding mast cell chymase has been linked to atopic eczema [18,19], but this association has not been confirmed [20,21]. Variants in the RANTES gene promoter region have also been reported to be associated with atopic eczema [22], and further studies have demonstrated this variant to be associated with enhanced RANTES production [23].

Abnormal epidermal barrier function is a well recognized clinical association of atopic eczema, and until recently it was not clear whether the dry skin was only a consequence of the underlying immune inflammatory process. However, loss-of-function mutations have been described in the filaggrin gene, which is part of the so-called epidermal differentiation complex on chromosome 1q21 [24–26]. These genetic defects predict early onset of atopic eczema, a worse prognosis and persistence of the disease into adulthood [26]. It is very interesting that, even though filaggrin is not expressed in bronchial epithelium, filaggrin gene mutations are also associated with atopic asthma, being linked to asthma severity independently of eczema [27]. Another genetic influence contributing to abnormal barrier function is *SPINK5* which encodes LEKTI, a serine protease inhibitor expressed at epithelial and mucosal surfaces. Although mutations in this gene determine Netherton's syndrome, variants in the gene have also been associated with atopic eczema [28–30].

Maternal factors and inheritance

There is accumulating evidence that atopic disorders are more frequently transmitted by mothers than by fathers. A number of population–based surveys have shown that the risk of children developing atopy is significantly higher when the mother is atopic than when the father is [1,2]. Cord blood IgE is high in babies whose mothers are atopic or have high IgE, whereas paternal atopy or raised IgE are not associated with raised cord blood IgE.

Genes encoding IgE responsiveness, located on chromosome 11q13, are more frequently inherited from the maternal side [3,4]. Thus, of 203 sib pairs analysed, 62% shared the maternal allele whereas 38% did not. Of the alleles that were paternal, the proportion shared with the offspring was close to 50%.

Pregnancy/intrauterine factors

The question arises of how maternal factors can modify the expression of atopy. One possible mechanism is through so-called genetic imprinting—in which paternal genomic effects are suppressed. Another possible mechanism is intrauterine programming—a major factor of which is the balance between fetal nutrition and growth rate. A number of non-dermatological conditions are programmed in fetal life. For example, death rates from coronary heart disease fell progressively between those who were less than 5.5 lb (2.5 kg) at birth and those who were more than 9.5 lb (4.3 kg) [5]. For atopy, there is a positive correlation between increasing birth weight and prevalence of atopic eczema [6–8]. A third possible factor is the onset of immunological sensitization through intrauterine exposure to food and environmental allergens. Cord blood IgE levels and the presence of antigen-specific T lymphocytes in cord blood indicate that immune sensitization occurs in fetal life. The concentration of IgE in cord blood is a predictor for subsequent development of atopy [9]. Maternal exposure to a number of agents, including antigens, alcohol, cigarettes and other pollutants, has attracted attention, but none has emerged as a major regulatory factor.

Environmental factors

The rate of increase in the prevalence of atopic eczema is too rapid to be accounted for by change in population genetics. Therefore, environmental factors are the most likely modulating influences. The two principal aspects that have attracted attention are 'pollution' and microbes.

A different prevalence in populations of the same genetic background separated only by geographical factors is well documented in developed countries. The fall of the Berlin wall separating East and West Germany provided an opportunity to examine the role of industrial pollution by comparing the 'dirty' East with the 'clean' West. Cohorts of pre-school children from comparable cities in the East (Halle) and West (Duisberg) and a rural area (Borken) were recruited. Questionnaires assessed the personal and family history of atopic disease as well as many of the relevant factors such as socio-economic status. All the children were examined by dermatologists. The levels of airborne pollutants were compared, and sulphur dioxide was fourfold higher in Halle, whereas dust and nitrogen oxides were comparable between the cities. The prevalence of atopic eczema was 17.5% in Halle but only 5.7–7.3% in Duisberg [1]. However, conflicting findings emerged in the study comparing the prevalence of atopic disease in Leipzig (East Germany) and Munich (West Germany). A slightly lower prevalence was observed in Leipzig compared with Munich [2]. For comparison, prevalence in rural Ethiopia was estimated to be 0.3% [3], yet this was significantly lower than the urban population of the same country (1.5%).

The identification of relevant pollutants that might contribute to the expression of the atopic phenotype is still confused. Indoor pollution levels from cigarette smoke or nitrogen oxides in the gas exhaust from cookers and heaters are difficult to quantify.

Environmental microbes—the hygiene hypothesis [4,5]

Interaction with environmental microbes may be important in the causation of atopic eczema in a number of ways. First, early life exposure may condition the maturation of the immune system so that the apparent dysregulation associated with production of IgE antibody and formation of allergies does not occur. Secondly, in individuals with the atopic phenotype, eczema may be induced or exacerbated by staphylococcal toxins or by the presence on the skin of *Malassezia* yeasts. The possible role of microbes in the early maturation of the immune system may be the major factor that could explain the differences between the Western world and the developing world regarding the incidence of atopy and allergic diseases. This idea was initially proposed as the 'hygiene hypothesis' [5] and remains controversial [6]. Indirect support for this hypothesis derives from the observations that allergic sensitization is greatest in first-born children and is less frequent in children from large families [5]. However, numerous epidemiological studies have failed to demonstrate a reduced infection rate in children who go on to develop atopic dermatitis [7–15].

Many studies have examined the effects of particular organisms or routes of infection, and a preponderance of findings suggest that microbes entering via the faecal–oral route have a greater protective effect against the development of atopic allergic diseases than those entering via respiratory routes. Thus, early exposure to hepatitis A virus, *Helicobacter pylori* or *Toxoplasma gondii* is reported to reduce the risk of atopy by more than 60% [16]. In contrast, it seems that exposure to respiratory pathogens is not associated with this effect [16].

Significant differences have been observed in the prevalence of allergies between rural and urban areas within one country, which could also reflect different levels of exposure to microbes. Moreover, there are differences in the prevalence of allergic diseases among children living on farms and in those living in the same rural environment, but not on farms [17–20]. This difference suggests that contact with livestock and poultry is a key factor and, although the levels of aero-allergens are likely to be higher in the farm environment, the levels of bacterial endotoxin are also much higher in the household dust from farms [19,21]. However, it is of

considerable interest that the reported differences only apply to respiratory diseases and not to eczema.

The potential importance of endotoxins lies in the powerful effects they can have in regulating the responses developed by the immune system (see below). The possibility that microbial endotoxins play a major role in driving the immune system towards productive/protective responses and away from non-productive/nuisance responses associated with allergy, suggests that what matters is the immunological outcome following exposure to stimulatory microbial factors, rather than particular infections themselves. The effects of bacterial endotoxins on immune function will be discussed in the following section on immune dysregulation.

Immune dysregulation

T lymphocytes

The fetal immune system is normally weighted towards generating Th2 responses, which is necessary to reduce the chance of the fetus and mother reacting against each other, with subsequent spontaneous abortion. This is reflected in the production of low basal levels of interferon-γ. In the post-natal period the immune system appears to mature and production of interferon-γ increases. However, in infants destined to develop infantile atopic eczema, the basal production of interferon-γ is particularly low [1] and Th2 dominant responses persist [2]. This could reflect an intrinsic defect in T-cell function.

Biopsy of developing lesions of atopic dermatitis reveals that T cells infiltrate the skin early in the disease process [3,4]. The cellular infiltrate in atopic dermatitis is predominantly T lymphocytes ($CD4^+$:$CD8^+$ ratio 7:1) but eosinophils are also present, albeit at lower frequencies [5,6]. A large fraction of lesional T cells are CLA^+ (skin homing receptor) and predominantly $CD45RO^+$, suggesting previous encounter with antigen [7,8]. Markers of activation, such as IL-2Rα (CD25) and HLA-DR, are also prominent [9].

In situ hybridization experiments reveal an increased number of cells expressing IL-4 and IL-13, but not IL-5 or IFN-γ mRNA, in non-lesional atopic dermatitis skin than in normal control skin [10,11]. The same authors demonstrated significantly greater numbers of IL-4, IL-5 and IL-13 mRNA-expressing cells in lesional skin than in non-lesional or control skin. IFN-γ mRNA expression was not detected in acute atopic dermatitis but only in chronic skin lesions in which there were significantly fewer IL-4 and IL-13 mRNA-expressing cells. In chronic as opposed to acute lesions, IL-5, GM-CSF, IL-12 and IFN-γ mRNA-expressing cells predominate. Both IL-5 and GM-CSF production are important in promoting the growth and survival of eosinophils and macrophages, whereas IL-12 and IFN-γ promote the Th1 polarization of T lymphocytes. These data, suggesting a role for both classical Th1 and Th2 cytokines, have been supported by serial investigations using application of allergen to the skin of atopics in an atopy patch test model. Investigation using this method and serial biopsies reveal a biphasic pattern of cytokine release [3,4]: IL-4 expression is predominant early in the process and begins to decline after 24 h, whereas IFN-γ expression peaks at 48–72 h. Thus, although development of acute lesions of atopic dermatitis is characterized by Th2 cytokines, persistence to chronic disease is associated with Th1 production as well.

Further evidence of the role of Th2 cells is derived from demonstration that allergens evoke Th2 responses in atopic subjects [12,13]. Furthermore, Th2 cell numbers increase in target organs of allergic disease [14–16], modulating Th2 responses towards Th1 can be associated with disease improvement [17–20], and transfer and correction of atopy may be achieved by bone marrow transplantation [21–23].

There is evidence that activation signalling in T cells may be different in atopic individuals (see below). Thus, constitutional

over-activity of cyclic AMP phosphodiesterase is associated with blunted or attenuated cAMP-mediated signalling. This has been shown to tie up with differentiation of atopic T cells towards a Th2 phenotype [24]. In addition, T cells from atopic donors respond to allergens such as Der p1 from dust mites with an increased production of Th2-type cytokines, and IL-13 in particular [25]. This could be blocked with an inhibitor of adenylate cyclase—the kinase that transduces cAMP-induced signals to more downstream targets. Paradoxically, it was also blocked by rolipram, an inhibitor of type IV cAMP phosphodiesterase which, by inhibiting breakdown of cAMP, augments intracellular cAMP levels and therefore has the exact opposite effect of inhibiting cAMP breakdown.

Chemokines are cytokine-like molecules which are essential for cellular recruitment to tissues in response to injury or infection. Chemokine–receptor interactions have been implicated in atopic dermatitis by demonstration of a significant role in skin homing of T cells. Demonstration of raised lesional mRNA levels correlating with atopic dermatitis severity include eotaxin (CCL11) and CTACK (CCL27).

The reasons why the atopic immune system responds with ready generation of Th2 lymphocytes are not clear, but a hypothesis attracting much attention is the so-called hygiene hypothesis (see above). This proposes that exposure in early life to microbes of various types, but especially those possessing lipopolysaccharide (LPS) endotoxin such as *E. coli* and other enteropathogens, is critical in pushing immune responses towards a Th1 type. The LPS activates production of IL-12 by DCs, which promotes production of interferon-γ and hence can deviate T-cell activation induced by any other antigen present at the same time towards a Th1 response.

Regulatory T cells in atopic disease. Over-active Th2 responses are critical to the manifestation of allergic disease. The mechanisms whereby similar responses do not occur in allergen-exposed, unaffected individuals are not clear. Interest in the role of regulatory cells in atopic dermatitis and allergy stems from two observations: firstly, that murine models of autoimmune disease can be prevented by adoptive transfer of regulatory T cells (Tregs) [26–28] and, secondly, that genetic disorders with resultant lack of regulatory T cells (immune dysregulation polyendocrinopathy enteropathy X-linked syndrome (IPEX syndrome) due to mutations in the forkhead box protein P3 (FoxP3) gene [29]) are associated with spontaneous dermatitis, hyper-IgE and food allergy, amongst other defects.

Evidence exists for the role of Tregs in inhibiting antigen-specific Th2 responses in various clinical allergy settings: allergen-specific immunotherapy (SIT) of hymenoptera venom [30]; aeroallergen sensitivity [31–33]; cow's milk allergy [34]; and allergic contact dermatitis to nickel [35]. Glucocorticoids have been reported to increase the Treg cell population [36,37], and staphylococcal-derived superantigens, which are detected in and correlate with disease severity in atopic dermatitis, can subvert Treg cell function [38]. Furthermore, the role of the epithelium in controlling Treg function has been recently highlighted by demonstration of keratinocyte expression of RANKL, which appears to have a critical role in modulating dendritic cell control of Treg populations [39].

Despite these reports, investigations of peripheral blood Treg number and suppressive function have found them to be normal in individuals with atopic dermatitis [40,41]. Verhagen *et al.* [42] reported that the number of $FoxP3^+$ cells in atopic dermatitis lesional skin was low, yet IL-10 and TGF-β cytokines and their receptors were found to be expressed, suggesting that Tr1 cells may be present in lesions of atopic dermatitis.

Apart from alterations in immune regulatory mechanisms, the allergens themselves seem to evoke different responses in atopic individuals. Thus, both atopic and non-atopic people make IgG antibodies against *Candida albicans*, whereas house dust mite antigen Der p1 evokes IgE antibodies in atopics but IgG antibodies in non-atopics [12,13]. It has been suggested that this property is related to the natural function of many allergens as proteases.

Immunoglobulins

IgE. The main immunoglobulin abnormality is increased production of IgE. This results in the presence of many antigen-specific IgE species to ingested or inhaled antigens and, frequently, an increase in total serum IgE. About 80% of patients with atopic dermatitis have increased amounts of total IgE. If dermatitis is the only clinical manifestation of atopy, the amounts of total IgE may be little above the normal range [1–3] and the patients show no anaphylactic sensitivity to environmental antigens [4,5]. However, even though total IgE levels may be normal, there are almost always specific IgEs directed at environmental aero- and/or food allergens [6–10]. If there is concomitant asthma or allergic rhinitis the concentrations of IgE may be very much above normal [1,3]. Surface-bound IgE on epithelial dendritic cells (DC) by the high affinity IgE receptor (Fc epsilon RI) is an important mechanism of allergen capture and internalization by the DC, which enhances processing and presentation of antigenic epitopes to the adaptive immune system [11,12]. Epithelial DC expression of Fc epsilon R1 is significantly increased in individuals with atopic dermatitis. IgE also increases in amount with increasing severity and extent of the dermatitis, even without respiratory allergy, and patients with high levels are likely to have a poorer prognosis. The converse has also been demonstrated, in that persons who were free of classical signs of atopic dermatitis for a year had normal amounts of IgE, even if they had persistent or recurrent eczema of the hands, or discoid eczema [13].

The production of very large amounts of IgE, equivalent to levels encountered in the hyper-IgE syndrome, may be induced by *Staphylococcus aureus* antigens [14]. Some staphylococcal exotoxins are superantigens [15], which activate a greater number of lymphocytes than those stimulated by specific antigen, resulting in a 'superstimulation' (Chapter 13). One manifestation is an excessive synthesis of IgE. Staphylococci colonize the skin of atopic dermatitis patients, and exotoxins with superantigen properties have been isolated from them [16,17]. One such exotoxin, the toxic shock syndrome toxin I, although inhibiting *in vitro* IgE synthesis by blood mononuclear cells at high concentration, was found to stimulate synthesis of IgE by the mononuclear cells of atopic dermatitis patients at low concentration. This pathway may have contributed to the increased IgE synthesis in this disorder [17].

IgE is involved in autoimmune reactivity in two ways. Firstly, it is an antigenic target for IgG anti-IgE antibodies and, secondly, it can also be autoreactive, with specificity for self proteins. IgE occurs in serum in the form of immune complexes with IgG and C3, but the amounts of precipitable complexes are not related to the concentrations of serum IgE or to the severity of the skin condition [18,19]. As much as 32% of the serum IgE may be in the

high-molecular-weight complexes [20], which should therefore influence the interpretation of serum IgE assays. IgE–anti-IgE complexes also occur, with antibody specificity to the CH_3 and the CH_4 IgE epitopes [19]. The ability of the free IgG anti-IgE antibodies to release histamine and other mediators from mast cells and basophils *in vitro* varies. In some tests no histamine was released [21,22], whereas in others histamine release occurred [23,24]. Similar autoantibody complexes occur in other atopic disorders.

Autoreactive IgE antibodies have been reported to be directed against self-proteins, some of which may be skin-derived [25,26]. This autoreactivity probably develops secondary to the chronic exposure to skin-derived antigens. However, it is thought that once present, the autoreactivity may contribute to the chronicity and severity of the dermatitis.

Other immunoglobulins. The amounts of IgG, IgA and IgM in atopic dermatitis are usually normal but increases have been reported, particularly in severely affected persons. However, in patients with severe eczema complicated by cutaneous infection, an increase in IgG appears to be due to antibodies to bacteria. In other cases the increase is due to antibodies to food antigens. Any change in total IgG is considered to be a secondary or unrelated phenomenon, and not contributory. Furthermore, *in vitro* synthesis of IgG by blood mononuclear leukocytes was less than in cells from normal persons, and attributed to decreased responsiveness of atopic B cells [1].

Although total IgG usually remains within normal limits, some patients show an increase in the subclass IgG4 [2,3]. However, because this subclass is quantitatively the smallest of the four subclasses the increase in IgG4 is unlikely to make a significant difference to the total IgG. IgG4 antibodies were specific for β-lactoglobulin [4] and for egg [5]. No clinical relevance was found on comparison of the amounts of IgG4 antibody with those of IgE, or with skin-test results [5]. In children with eczema complicated by asthma, IgG4 was much increased, usually with increases in total IgE [6,7]. Those who had an increase only in IgE or IgG4 did not have eczema, but asthma alone [6]. There is no clear evidence that IgG4 is anaphylactic, that is mediating mast-cell responses on challenge with antigens, or that it contributes to the clinical changes of atopic dermatitis. It may be protective, because it has been shown *in vitro* that IgG4 will impede sensitization of basophils by IgE [8]; a conclusion supported by the finding of increased amounts of IgG4 and relatively small amounts of IgE antiovalbumin in children with atopic dermatitis [9].

It has been proposed that atopic subjects have an IgA deficiency which permits excessive absorption of allergen through mucosae, resulting in increased production of IgE. A modification of this theory is that the IgA deficiency may be transient, occurring for a few months early in infancy, and that the increased allergen absorption primes the individual to excessive production of IgE later in life.

The contention that a transient IgA deficiency in infants, particularly those born of atopic parents, predisposes the infants to increased production of IgE antibodies and atopic eczema later in life, led to the proposition that the atopic state could be avoided if the infants were not exposed to potent allergens during the susceptible period. The most common allergens are foods, for example milk and eggs, and elimination of potent food allergens

for the first 6 months of life in high-risk infants is reported to reduce the incidence of eczema. However, allergen avoidance by breastfeeding and soya preparations has not been associated consistently with a decreased incidence of atopy, although in these reports complete avoidance is not evidenced during the critical period. Likewise, allergen avoidance by the mother during pregnancy and during breastfeeding has led to modest or equivocal benefit.

Pathogenesis of eczema

The role of allergy

There are many factors, including allergies, infections, emotional, climatic and other environmental influences, that contribute to the causation of atopic dermatitis. In early life, atopic infants develop eczema as the first of the possible atopic syndromes, which include eczema, asthma and rhinitis. There is uncertainty as to whether this is the result of allergic sensitization or the consequence of pro-inflammatory effects of staphylococci and their superantigens.

The epithelia of atopic individuals have significant impairments of innate antimicrobial defences. Thus, in the bronchial epithelium of asthmatics, viral infections do not evoke normal production of interferon-α [1,2]. Epidermal keratinocytes in atopic eczema produce reduced levels of the anti-bacterial peptides human beta defensins (HBD)-1, -2 and -3, and cathelicidin [3,4]. This is apparently not a constitutive deficiency but is the result of the cytokine milieu (high levels of IL-10 in particular) causing downregulation of the production of the antimicrobial peptides [5]. The consequence is reduced defence against *Staphylococcus aureus*, *M. furfur* and probably the herpesvirus family. Colonization of the skin by *S. aureus* exacerbates eczema in two ways. Firstly, the staphylococci often produce superantigens which have the property of driving an inflammatory response and eliciting an eczematous inflammatory reaction. Secondly, invasive infection by staphylococci produces acute, infected flares of eczema.

There is evidence that immune sensitization occurs to food-derived allergens as well as aeroallergens [6–8]. The infantile intestine shows increased permeability to macromolecules and this is greater in atopic infants. This may be due to inherent 'leakiness' and also, because of the transient deficiency of IgA, the IgA-mediated clearance mechanisms are less effective, allowing greater entry of food-derived macromolecules into the systemic circulation where they may induce immunological sensitization. The increased permeability of the intestine may also reflect a general reduction in barrier function that is also seen in the bronchial and epidermal epithelia [9,10]. It is unclear why circulating T cells reactive with food antigens should home to the skin and generate an eczematous process rather than a gut-centred pathology. It may be hypothesized either that food-derived antigens somehow activate immature T cells to become skin-homing or that skin-homing lymphocytes are stimulated as a result of their target antigens reaching the skin via the circulation. Perhaps because the epidermal permeability barrier is disrupted by the eczema, allowing penetration of environmental aeroallergens, during the first few years of life there is progressive development of immune reactivity to aeroallergens, reflected by the presence of specific IgE and T-cell responses [11].

The role of airborne environmental allergens, both in the initial sensitization of atopic individuals and the subsequent elicitation of the clinical features, is becoming clear. Environmental allergen levels are probably the major determinant of whether sensitization of genetically predisposed individuals occurs. Thus, children born just before the birch pollen season in Scandinavia have a higher risk of sensitization to birch pollen than those born after the season [12]. Babies born in autumn, when house-dust mite (HDM) numbers are highest, have a greater risk of sensitization by HDM [13], and avoidance of exposure to HDM and food allergens for the first year of life was associated with significant diminution in the proportions of clinically detectable eczema and asthma [14]. A recent Japanese study showed that if atopic babies (with detectable IgE antibodies to various foods but not HDM) were protected from contact with HDM by encasing their bedding in dust-proof bags, there was significantly less sensitization to HDM, reflected by IgE and prick test response [15]. However, it was not followed through to see whether there was a reduction in associated clinical problems. It has been proposed that the risk of becoming sensitized to HDM is greatly increased by exposure to dust containing 10 μg/g of Der p1, and that even 2 μg/g confers a significant risk [16]. It appears that in some individuals, priming of immune responses to a range of allergens may happen during intrauterine development [17,18]. In others, the induction of sensitization appears to occur postnatally and during childhood. The sensitization is reflected by the presence of antigen-specific helper T lymphocytes and specific antibodies of IgE class.

The role of aeroallergens such as HDM in provoking or maintaining atopic dermatitis has been the subject of controversy and uncertainty. The presence of immune sensitization and allergic reactivity, reflected by the presence of positive responses to skin challenge administered in different ways, can be detected in the large majority of patients with atopic dermatitis. Prick testing with

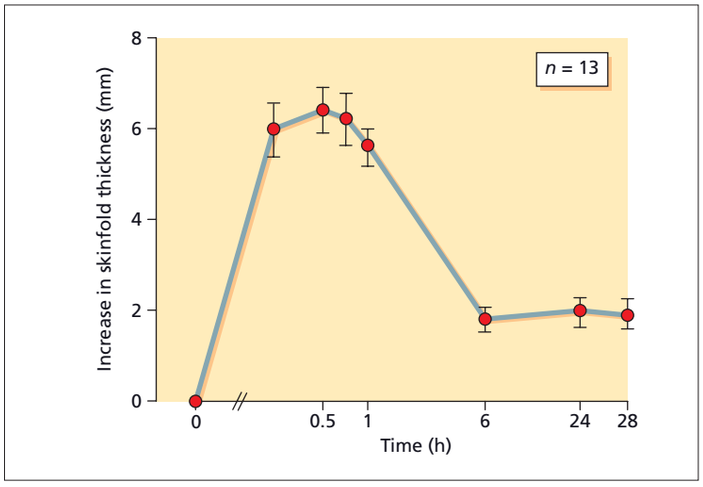

Fig. 24.1 Response elicited by intradermal inoculation of allergen (house-dust mite extract) in individuals with atopic dermatitis. A triphasic allergic response is seen, consisting of an immediate (15-min) weal and flare, a 6-h late-phase response and a 24- to 48-h delayed-type response. (Reproduced with permission from [19].)

aeroallergens, such as Der p1 or extracts of animal fur or pollens, elicits a weal and flare response after 10 to 15 min. This is mediated by specific IgE antibodies on the surface of skin mast cells. When the IgE binds antigen the mast cells are triggered to degranulate, releasing histamine and other mediators. Intradermal or epicutaneous patch challenge on tape-stripped skin elicits a triphasic allergic response [19,20] (Fig. 24.1). There is a 15 min immediate weal and flare due to histamine release from skin mast cells. There is a late-phase response comprising erythema and a deeper oedematous reaction between 6 and 24 h, and there is a delayed response at 48 h. After intradermal challenge, there is an erythematous papular reaction similar to a tuberculin test, but after patch challenge a classical eczematous reaction develops. The proportion of positive responses can be varied by more or less aggressive tape-stripping to disrupt the stratum corneum permeability barrier and by using higher concentrations of allergen [21]. This author (PSF) detected positive patch tests to HDM extract in up to 88% of adults and 60% of children older than 5 years. Others have used the so-called atopy patch test without tape stripping and obtained positive responses to aeroallergens in about one-third of atopic eczema sufferers [22].

Patch test responses can be elicited in atopic eczema sufferers with a range of other allergens, including foods [23] and the ubiquitous skin surface *Malassezia* yeasts [24–26].

The eczematous response developing in allergen-induced patch test reactions has been used to model naturally occurring eczema for investigation of the role of T lymphocytes. From 8 h onwards there is infiltration of $CD4^+$ T cells, 10–20% of which express $CD25^+$, the p55 chain of the IL-2 receptor, indicating that they have been activated through the T-cell receptor by contact with specific antigen. A number of workers have cloned the T cells in the first 12–24 h of such reactions and shown that they are predominantly of the Th2 type, producing IL-4 and IL-5 [27–29]. Also, up to 24 h after intradermal challenge with HDM, IL-4 and IL-5 production has been detected after amplification by polymerase chain reaction (PCR), but at later time points Th1 cells and their cytokines predominate [30–32]. In addition to the lymphocyte infiltration, there is heavy infiltration with eosinophils during the first 6–24 h of patch test challenge in atopic eczema sufferers.

The crucial question is whether allergic reactions induced by any allergen—aero or food—are of pathogenic importance in the causation of lesions of atopic eczema. The strongest evidence that this can be the case derives from studies of the effects of avoidance of house-dust allergens in the domestic environment. A placebo-controlled, double-blind study by Tan *et al*. [33] examined a combination of dust-mite eradication measures (sealed containment bags for the mattress, pillows and bedding top covers, a high power vacuum cleaner and a spray containing agents to kill mites and denature their allergens). It was shown that highly significant reductions in Der p1 load in carpets and beds occurred. This was associated with great clinical benefits in both adults and children (over 6 years old) with severe atopic eczema. These findings were not reproduced in a German study which used an essentially similar design but omitted the acaricidal and allergen-denaturing spray [34], or a Dutch study which used only bedding encasements [35].

The clinical relevance of allergy to *Malassezia* yeast is indicated by studies showing that treatment with itraconazole to eradicate the yeast resulted in improvement of the eczema comparable with that obtained with betamethasone valerate [26]. Hence, there is some compelling evidence that allergic reactions to common allergens may play an important part in the pathogenesis of atopic eczema in many people. However, such reactions do not appear to account for the entire process, and the whole approach suffers from a lack of robustness in the tests to identify those individuals who would benefit from avoiding any particular allergen.

The role of infection

Patients with atopic dermatitis are particularly susceptible to certain cutaneous infections [1]. The most common skin infection is with *Staphylococcus aureus*. However, human papillomavirus-induced warts, fungal infections, viruses (such as HSV1 and 2, vaccinia, coxsackie A and the pox virus of molluscum contagiosum) are also frequent pathogens causing, in some cases, severe complications.

Innate immunity is compromised in atopic dermatitis, as demonstrated by reductions in keratinocyte-derived antimicrobial peptides (cathelicidin LL-37, β-defensin 2 and β-defensin 3) [2,3], neutrophil chemoattractant IL-8 [3], and inducible nitric oxide synthetase (iNOS) [3] which mediates pathogen death through release of NO [4]. Further antimicrobial compromise occurs as a result of defective dermcidin-derived antimicrobial peptides, produced by eccrine glands [5]. Production of IgA, a key epithelial antimicrobial immunoglobulin, is also reduced in the sweat and tears of atopic dermatitis patients [6,7], which may help to explain the concordance between staphylococcal growth on both mucosal and skin surfaces in these patients.

Most individuals with atopic dermatitis have *S. aureus* identifiable on skin swabs, often at very high density, and more often present on lesional than non-lesional skin [8]. Furthermore, *S. aureus* present on the skin of atopics is significantly more likely to express superantigen than in non-atopics, and indeed the levels correlate with disease severity [9–11]. Direct exposure of skin to staphylococcal superantigen in an allergen patch test model has been demonstrated to enhance allergen-specific responses *in vivo* [12]. Further work has demonstrated that keratinocytes show enhanced allergen presentation to T cells following exposure to staphylococcal enterotoxin B (SEB)-stimulated peripheral blood mononucular cells (PBMC) *in vitro* through up-regulation of HLA class II and ICAM-1 expression [13], providing evidence of a potent adjuvant effect of staphylococcal products for human allergen-specific Th2 responses. Furthermore, staphylococcal superantigen has been documented to reduce regulatory T-cell activity in humans [14] and to confer T-cell steroid resistance [15], both of which may contribute to the association with more severe atopic dermatitis.

Altered immune function

The defining characteristic of the atopic immune system is the capacity to generate IgE antibodies in response to allergens. The key disturbance to immune regulation that results in this IgE production appears to be the differentiation pathway followed by $CD4^+$ helper T lymphocytes. Naïve precursor Th0 cells are induced to differentiate into Th2 cells, characterized by the production of interleukins (IL) -4, -5 and -13. Th2 cells 'help' or control the type of immunoglobulin (Ig) that B lymphocytes make, inducing synthesis of IgE.

Cellular mechanisms

The regulatory mechanisms that underlie the preferential development of Th2 cells appear to involve the interaction between dendritic antigen-presenting cells and $CD4^+$ helper T lymphocytes. The question arises of whether there is something different about the dendritic cells (DCs) of atopic individuals and the signals they give to T cells, or whether there is a defect in the T cells themselves.

Dendritic cells. Much work has gone into examining the mechanisms by which DCs regulate the differentiation of Th cells, and there is accumulating evidence that DCs may also subdivide into DC1 that preferentially induce Th1 cells and DC2 that induce Th2 cells [1]. The critical stimulus, signal 1, is given during the presentation of antigenic peptides held in the groove of MHC class II molecules (Fig. 24.2). Secondary signals (signal 2) come via interactions of co-stimulatory surface molecules such as CD 80 and 86 on the DCs, with their counter receptors CD28 and CTLA4 on the T cells. In murine systems, signalling via CD80 can preferentially induce Th1 differentiation, and CD86 can induce Th2 differentiation [2]. There is evidence that signalling through CD28 gives a positive activation signal, whereas signalling through CTLA4 may either give an inhibitory signal or activate T regulatory cells which have inhibitory (suppressor) activities [3]. In addition, binding of CD40 on T cells interacting with CD40 ligand on the DC is one of the strongest signals for the T cell to produce interferon-γ and to differentiate towards a Th1 phenotype [4,5]. Cytokines released from the DCs give 'signal 3' which is also important in determining the final differentiation into Th1 or Th2 cells. IL-12 drives a Th1 response and IL-4 drives a Th2 response (Figs 24.2 & 24.3) [4,6,7].

There is little direct evidence that DC function is altered in atopic individuals. However, it has been observed that monocytes from atopic donors produce greater quantities of prostaglandin E_2 (PGE_2) and IL-10 than cells from non-atopic individuals [8,9]. PGE_2 can suppress production of interferon-γ, a cytokine which is not

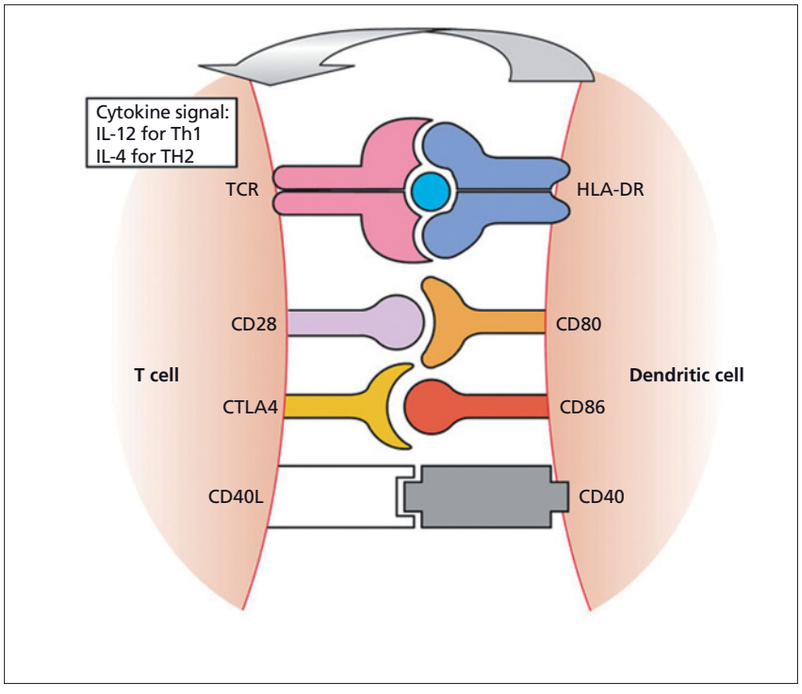

Fig. 24.2 Activation of naïve T lymphocyte by interaction with dendritic antigen-presenting cell. Signal 1 comes from interaction of the T-cell receptor (TCR) with the complex of MHC class II and the antigenic peptide (blue circle) lying within its groove, on the surface of the dendritic cell. Signal 2 results from the interaction of co-stimulatory molecules (CD80, 86 and 40) on the dendritic cell with their counter receptors. CD28 is thought to give positive signals whereas CTLA-4 appears to give negative or inhibitory signals. Signal 3 is given by soluble cytokines including IL-1β and IL-12 which drive T-cell differentiation towards a Th1 phenotype, and IL-4 which favours differentiation towards the Th2 type. Th17 cells are a recently described CD-4 subset, which are characterized by IL-17 production and require IL-23 for expansion and survival. Further Th subdivision arises with differentiation of regulatory T cells, full discussion of which is beyond the scope of this chapter.

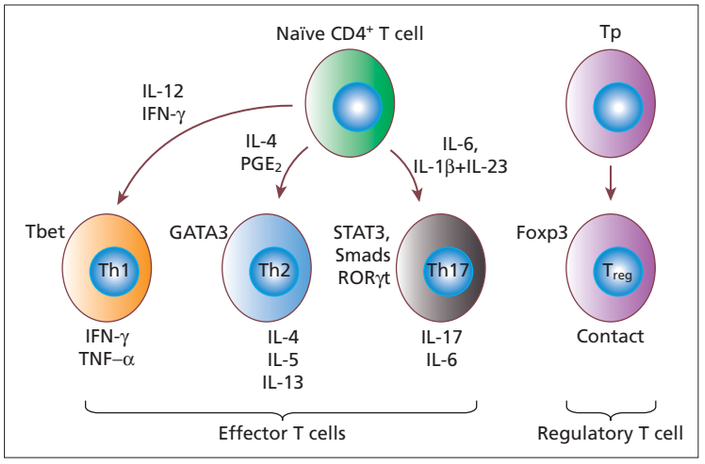

Fig. 24.3 Differentiation of CD4+ T lymphocytes. Precursor naïve T cells have the potential to differentiate into either Th1, Th2 or Th17 cells, depending upon the signals they receive during the interaction with dendritic antigen-presenting cells (APC) (see also Fig. 24.2). Depending upon the cell surface co-stimulatory molecule interactions and the presence of particular cytokines, the differentiation is directed. IL-12 is the critical determinant of Th1 generation, which acts via the transcription factor T-bet, IL-4 drives Th2 formation via GATA-3 and IL-6 and TGFβ drive Th17 cells via STAT3, Smads and RORγt. Atopic monocytes (and hence possible dendritic cells) produce increased amounts of prostaglandin E_2 (PGE_2), which helps drive T-cell differentiation towards the Th2 phenotype. Thymic precursor T cells (Tp) can develop into natural regulatory T cells, which inhibit the actions of effector T cells in a contact-dependent fashion.

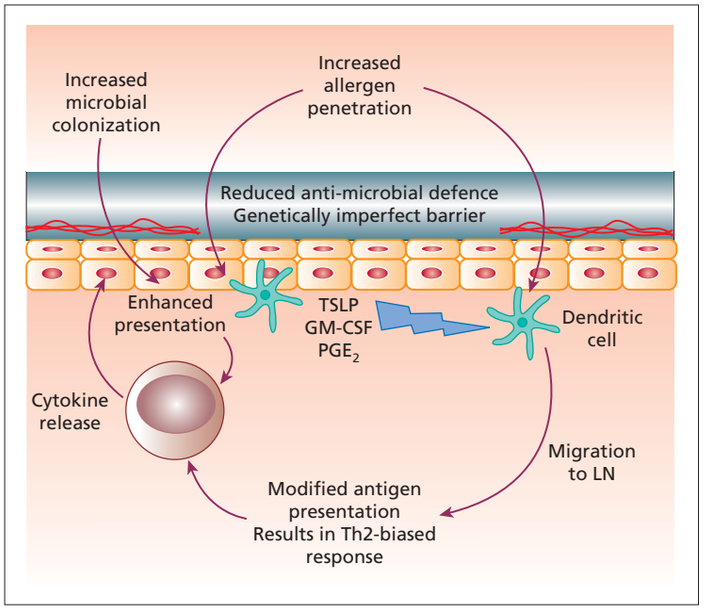

Fig. 24.4 Interaction between epidermis and immune system in atopic dermatitis. The epidermis has increased permeability (genetic abnormalities of filaggrin) and reduced innate antimicrobial defences. In addition, production of thymic stromal lymphoprotein (TSLP) and prostaglandin E_2 conditions dendritic cells to induce Th2 differentiation. Th2-cell re-encounter with antigen in the skin is enhanced by local inflammation induced by factors such as microbial products, and activation results in inflammatory Th2 cytokine release and induces further down-regulation of genes involved in both antimicrobial defence and skin barrier formation.

only produced by Th1 lymphocytes but which also favours the differentiation of naïve Th0 cells towards the Th1 phenotype. Similarly, IL-10 is both a suppressive/regulatory cytokine and also drives Th0 cells towards a Th2 phenotype [10]. Dendritic cells from atopic individuals have yet to be shown to behave similarly.

A property of DCs in atopic individuals that has attracted much interest is the finding that they bear antigen-specific IgE on their surface [11,12]. The IgE is bound to the high affinity receptor for IgE, FcεR1, normally found on mast cells and basophils [13–15]. There is controversy as to whether FcεR1 is expressed exclusively on DCs from people with atopic eczema or whether it can be expressed in atopic individuals without eczema but with active 'allergic' disease such as asthma [15,16]. FcεR1 on DCs differs from that on mast cells and basophils in that it comprises the alpha and gamma chains, but lacks the beta chain [17]. This may alter its capacity either for expression on the cell surface or for activating intracellular signals [17]. FcεR1 is induced on DCs by IL-4 and possibly also by high levels of IgE. The surface-bound IgE on DCs has been shown *in vitro* to perform the function of 'antigen focusing' to allow DCs to present antigens to T cells much more efficiently. Thus, T cells can be activated to respond to one-hundredth to one-thousandth the amount of antigen [18]. However, it is not clear whether or how this is important in the pathogenesis of atopic eczema.

Epidermal modulation of dendritic cell function. Recent findings have produced evidence indicating that the epidermal environment is critically involved in programming dendritic cells to direct the differentiation of Th0 cells towards a Th2 phenotype (Fig. 24.4). Epidermal keratinocytes in atopic eczema produce a cytokine with similarities to interleukin-7 called thymic stromal lymphopoietin (TSLP). This cytokine is also produced by atopic bronchial epithelium, Hassall's corpuscles in the thymus and mast cells that have been activated by cross-linking of the IgE receptors (FcεR1) [19]. Mice that have TSLP over-expressed in the epidermis spontaneously develop an inflammatory skin condition that resembles atopic eczema. The crucial finding is that TSLP conditions dendritic cells so that when they interact with naïve T cells they drive them to differentiate into Th2 cells. Of special relevance is the fact that TSLP-conditioned dendritic cells induce the Th2 cells to produce not only the classical Th2 cytokines IL-4, -5 and -13 but also TNF-α—hence they are called 'inflammatory Th2 cells' [19–21]. So it appears that the immune dysregulation and the epidermal dysfunction may be functionally connected and that the epidermis may actually play an important role in programming the immune system.

Pharmacological and vascular abnormalities

The small blood vessels in atopic dermatitis show a tendency to vasoconstriction responses:

1 Pallor of the skin after stroking – white dermographism
2 Delayed blanch with acetylcholine
3 White reaction to nicotinic acid esters
4 Abnormal reactions to histamine in affected skin
5 Low finger temperature
6 Pronounced vasoconstriction on exposure to cold.

None of these findings is pathognomonic. The delayed blanch phenomenon with acetylcholine [1–3] and related drugs is characteristic for atopic dermatitis, and occurs less regularly with other atopic disorders. Whether these pharmacological changes in atopic dermatitis are secondary to cutaneous inflammation, or the deranged pharmacology and the immune abnormalities are both secondary to a common defect, is not known. However, these patterns in vascular responses led to the so-called β-adrenergic blockade theory proposed by Szentivanyi [4]. Although this theory no longer remains tenable, it has led to observations of abnormalities in a range of intracellular second messenger signalling pathways. In atopic individuals, attenuated cAMP signalling results from overactive cAMP-phosphodiesterase which is associated with several of the phenotypic features. The principal observations, summarized by Hanifin and Chan [5], follow from the well-known increased IgE synthesis that characterizes atopic individuals. *In vitro* this appears linked to reduced IFN-γ production by mixed peripheral blood mononuclear cells (PBMCs) from patients with atopic dermatitis. However, atopic T cells actually show increased production of IFN-γ *in vitro*; hence, it was concluded that the monocytes produce an inhibitor of IFN-γ synthesis. Atopic PBMCs produce increased amounts of PGE_2 and it is the monocytes that are the source [6]. It had been shown by Betz and Fox that PGE_2 inhibits IFN-γ production [7] and Chan *et al*. [6] showed that inhibition of PGE_2 with indometacin results in increased IFN-γ production by atopic PBMC. Atopic monocytes also produce increased amounts of IL-10, which also inhibits production of IFN-γ [8].

Hanifin had previously shown that PBMCs from atopic subjects have blunted cAMP responses to agents acting on adenylyl cyclase such as histamine, isoprenaline or prostaglandins [9]. This was found to be a result of elevated cAMP-phosphodiesterase (PDE) activity [10], so the cAMP was hydrolysed more completely. These abnormalities were also present in people with respiratory atopic disease. Sawai *et al*. [11] showed that there was no correlation between cAMP-PDE activity and severity of eczema. The abnormality has also been shown to be present in cord blood from babies with atopic parents [12,13].

The elevated cAMP-PDE activity was shown to be located predominantly in monocytes [14]. Chan and colleagues went on to type the PDEs in atopic leukocytes [15]. They found three isoforms were common to both monocytes and lymphocytes and all were more active than in cells from non-atopics. However, the atopic monocytes had an additional isoform which was specific for cAMP and was calcium/calmodulin-dependent. Also, the PDE was more susceptible than control PDE to inhibition by Ro20-1724—an inhibitor of PDE type 4 [15,16]. It should be noted that Gantner *et al*. [17] found no differences between PDE expression and activity in cells from healthy and atopic blood donors.

One aspect which makes interpretation of data about levels of PDE activity difficult is that PDE activity is subject to modulation by various factors. Thus, PDE activity is induced by stimuli that increase cAMP, such as long-term administration of β-adrenergic agonists. This has clouded the question of whether elevated PDE is found in atopic asthma, as most patients receive chronic therapy with these agents. In monocytes from healthy subjects PDE activity is increased by cytokines IL-4 and IFN-γ [18]. However, in monocytes from atopic dermatitis patients, IFN-γ at low concentrations was without effect and at higher concentrations it reduced PDE activity [18]. This difference may be because in atopic cells PDE activity is already maximally induced.

The PDEs form a family of at least seven groups [19]. The different types vary in their affinity for cAMP or cGMP, their

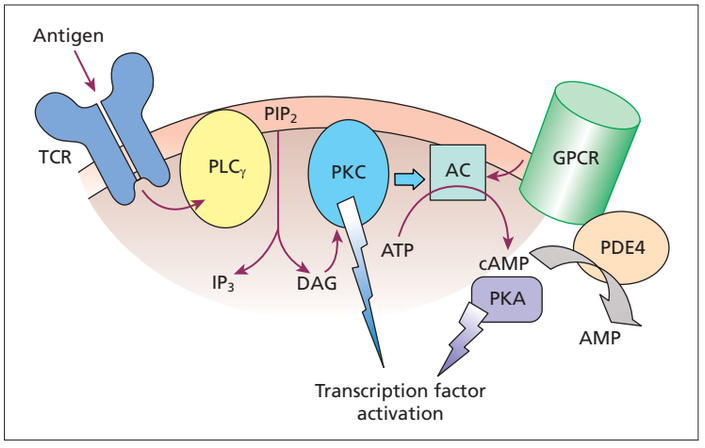

Fig. 24.5 Intracellular signalling that interacts with cAMP in T cells. The T-cell receptor (TCR) receives activating signals from the dendritic antigen-presenting cell. It activates phospholipase Cγ (PLCγ), which cleaves membrane phosphatidyl inositol bisphosphate (PIP_2) to diacylglycerol (DAG) and inositol trisphosphate (IP_3). The DAG activates protein kinase C (PKC), which activates a variety of targets including transcription factors. It can also activate adenylate cyclase (AC), which generates cAMP. Membrane receptors that are coupled to G proteins (G protein-coupled receptors, GPCR) activated by their ligands signal via generation of cAMP, which in turn activates protein kinase A (PKA). cAMP is degraded by the actions of cAMP phosphodiesterase type 4 (PDE4), which is constitutively overactive in atopic cells. This attenuates or switches off cAMP signalling, which may alter the balance of 'cross-talk' between different signalling pathways.

susceptibility to different inhibitors and, in some cases, in their cell/tissue distribution. Type 4 PDE (PDE4) is cAMP-specific and was characterized by inhibition by rolipram and Ro20-1724. PDE type 4 is present in inflammatory cells—mast cells, eosinophils, monocytes, macrophages and lymphocytes.

Several activities of mononuclear cells are mediated via cAMP and can be reduced by inhibitors of PDE4: increased PGE_2 production [8]; spontaneous IgE production by B cells [20] and release of histamine from basophils [8]; increased spontaneous production of IL-10 is reduced as is the anti-CD3-induced increase in IL-4 production [8,21]; migration of eosinophils [22]; *in vitro* transmigration of lymphocytes but not monocytes through a monolayer of endothelial cells [23]; and allergen-induced release of IL-5 [24].

cAMP is a second messenger that lies in the midst of a network of pathways (Fig. 24.5). Different signalling mechanisms are involved depending on which cell surface receptors are activated. The T-cell receptor activates phospholipase Cγ, which in turn cleaves phosphatidyl inositol bisphosphate to release diacyl glycerol (DAG) and inositol trisphosphate (IP_3). These moieties can both act as further signals in different directions; IP_3 activates release of calcium from intracellular stores and DAG activates protein kinase C (PKC). PKC can activate adenylate cyclase, generating cAMP which activates protein kinase A (PKA). The intensity of the effects of cAMP are blunted through the overactivity of PDE4 (see above). The inositol pathway of peripheral blood mononuclear cells shows evidence of chronic activation and hyporesponsiveness to subsequent stimulation [25,26]. Apart from the clear evidence of the effects of the altered second messenger signalling in T lymphocyte differentiation towards a Th2 type (see above and [27]) the further importance of these processes in the wide range of vascular, neural and immune alterations in atopic eczema has yet to be elucidated.

Neuropeptides

Neuropeptides mediate vasodilatation, oedema, itch and pain, the axon-reflex flare, sweat-gland secretion, and have some, probably minor, ability to regulate T-cell activation [1]. Vasoactive and pro-inflammatory neuropeptides mediate tissue change and sensory stimuli in perturbed skin (Chapter 12). Theoretically, neuropeptides could have a significant role in many of the features of atopic dermatitis, including vascular changes, itch, symptoms associated with sweating and leukocyte infiltration. The neuropeptides that have been studied in the lesions are substance P (SP) and calcitonin gene-related peptide (CGRP), often present together in unmyelinated C sensory fibres, somatostatin (SOM), vasoactive intestinal polypeptide (VIP), which coexists with acetylcholine in postganglionic sympathetic fibres, and neuropeptide Y (NPY) in adrenergic fibres. Assays of skin extracts have shown greatly increased amounts of VIP in atopic lesions [2–4], and reduced amounts of SP [3,5], although SP has also been reported to be unchanged in comparison with normal controls in one study [2].

Immunohistochemical examination has revealed NPY-positive dendritic epidermal cells in lichenified atopic dermatitis lesions, but no somatostatin fibres. Healthy, normal control skin showed the opposite—no NPY dendritic cells but a normal network of somatostatin fibrils [6]. Elsewhere, it has been reported that NPY fibres (adrenergic) are fewer than normal, but CGRP and SP (sensory) fibres are increased in number [7].

The skin of atopic dermatitis patients shows altered reactivity to injections of neuropeptides. Intradermal injection of SP induces a weal and flare response—at low doses this is the result of direct effects on vasculature whereas at higher doses SP induces degranulation of mast cells with histamine-mediated weal and flare. Contradictory findings have been reported regarding cutaneous responses to injection of SP in atopic individuals. Coulson and Holden observed greater weal volumes in atopics than in non-atopics, with no difference in the area of flare [8]. In another study, although injection of SP elicited weals of similar size, there was less flare in atopic dermatitis skin than in controls [9]. Injection of neuropeptides was also reported to induce less than normal weal and flare responses [10].

Apart from effects on vascular reactivity and pruritus, neuropeptides can play a part in recruitment of granulocytes by up-regulating expression of adhesion molecules, including VCAM-1 on endothelial cells [11]. They can also modulate lymphocyte function *in vitro*. Thus, SP augments production of interferon-γ and IL-4 by lymphocytes from atopic donors but has little effect on cells from non-atopic donors [1,12]. VIP had no effect on lymphocyte cytokine production [12]. Thus, neuropeptides may contribute to the complex mix of factors regulating lymphocytes in atopic dermatitis.

Pruritus

The major symptom that accompanies the rash of atopic eczema is pruritus. The mediators and mechanisms responsible for this symptom are still totally obscure. Symptoms of itching are induced in patients with atopic eczema by stimuli that induce sweating, both thermal and emotional, as well as contact with fibres, especially wool. Clues regarding mediators come from the effects of therapeutic agents with defined mechanisms of action. Thus, despite the general presumption that mast cell degranulation via IgE-mediated allergen-specific mechanisms is important in atopic eczema, antihistamines are generally of little effect against the pruritus of atopic eczema [1]. The older, sedating H1 antagonists may improve the subjective comfort through sedation and deeper sleep. Ciclosporin causes very rapid cessation of the pruritus—which might indicate the involvement of T-lymphocyte products such as cytokines. However, ciclosporin has effects on cells other than lymphocytes and, for example, may inhibit formation of prostaglandins [2]. As described above, responses to neuropeptides appear altered in atopic eczema. Neuropeptides such as substance P (SP), VIP, somatostatin and neurotensin provoke itch,

together with neurogenic inflammation in the form of erythema and weal and flare [3]. Capsaicin depletes nociceptive nerve endings of CGRP and SP and is reported to reduce pruritus in atopic eczema [4]. Acetylcholine (ACh), the archetypal neurotransmitter, activates both vasodilatation and sweating. ACh is also produced *in vitro* by keratinocytes [5]. ACh levels are raised in lesional skin of atopic eczema, and intradermal injection of ACh elicits pruritus rather than pain in patients with atopic eczema [6]. However, use of anticholinergic agents for treatment of the pruritus of atopic eczema has not become a useful therapeutic measure.

It has been suggested that opioids may play a part in the pruritus of atopic eczema; indirect evidence for this comes from the observation that opioid receptor antagonists such as naloxone or nalmefene can reduce pruritus [7]. However, others have failed to reproduce this observation [8].

Proteases, including tryptase and chymotryptase are released by mast cells, and it has been proposed that they play a part in causing pruritus. Intradermal injection of mast cell tryptase elicits pruritus, erythema, leukocyte infiltration and oedema [9]. Proteases exert a range of effects through activation of protease-activated receptors (PARs) including PAR-2 in particular [10]. PAR-2 receptors are found on endothelial cells, sensory nerves and keratinocytes, and play a part in the inflammatory process resulting from mast cell degranulation. With greater availability of PAR-2 antagonists for use in clinical situations, it will be easier to assess the functional importance of these receptors.

There has been speculation that cytokines may contribute to the pruritus of atopic eczema. Cytokine-rich supernatants from mitogen-stimulated lymphocytes can induce pruritus when injected into atopic eczema sufferers but not healthy controls [11,12]. A wide range of cytokines are released in atopic eczema. They include IL-2, 4, 5, 6, 8, 10, 13, IFN-γ and TNF-α. Most of these have been injected into human skin without producing significant pruritus. The exception is IL-2, which can produce redness and itching when used in the therapy of malignancy [13]. A possibility that has not been explored is that of synergism between some of the above mediators–say cytokines and neuropeptides.

A recently described cytokine, interleukin-31, was overexpressed in the epidermis of transgenic mice. This was accompanied by a progressively worsening itch, excoriation and dermatitis [14–16]. Moreover, IL-31 is strongly expressed by skin-homing, CLA-positive T cells in atopic eczema epidermis [17]. The receptor for IL-31 is expressed by keratinocytes and infiltrating macrophages in atopic eczema [17]. The most potent inducer of increased expression of IL-31 identified so far is staphylococcal superantigen [18].

Sweating

Many patients are aware that sweating induces itching and aggravates their condition. This may reflect altered sensations associated with the neuropeptides released in the neurogenic control of sweat glands. Altered inflammatory responses to acetylcholine are described above, and increased numbers of nerve fibres have been described around the sweat glands in atopic non-lesional skin compared with lesional and healthy control skin [1]. Sweating responses to neurogenic stimuli are altered in atopic eczema sufferers, although there is some lack of agreement between findings, and diverse methods have been used to quantify sweat production. Sweating in response to cholinergic stimulation was found to be reduced in volume by one group [2,3] but normal in volume, although of more prolonged duration, by another group [4]. A possible explanation for differences comes from the study of Eishi *et al*. [5], who measured both direct cholinergic effects on sweat glands and distant effects mediated via the axon reflex. They found that directly induced sweat production hardly differed from that in healthy controls, whereas axon reflex-induced sweating was of lower volume with a longer latency. In a study of the response to adrenergic stimulation, sweating was similar between atopic eczema patients and non-atopic controls at low concentrations of adrenaline, but at higher concentrations sweating in non-atopic individuals was increased, whereas in atopic eczema patients it was decreased [6]. Sweating in response to the thermal stress of sitting in a heated room was found to be reduced

in atopic eczema patients [7]. However, there was no difference in sweating responses induced by hard cycling on a bicycle ergometer between atopic eczema sufferers and healthy controls [8].

Another way in which sweating may induce itching and aggravate eczema is related to the observation that there seems to be an IgE-mediated allergic reactivity to components of sweat [9]. Thus, skin challenges with autologous sweat induced positive responses in 56 of 66 (84%) patients compared with three of 27 (11%) healthy controls. Also, basophils were induced to release histamine in an IgE-dependent process [9]. The nature of the reaction-inducing substances is completely obscure.

Psychological factors

Patients with atopic dermatitis commonly complain that their condition is exacerbated by episodes of psychological stress, a situation that is also found in many inflammatory dermatological conditions. Buske-Kirschbaum *et al.* [1] showed that formal stressing of people who experience recurrent herpes simplex lesions could significantly increase the recurrence rate of cold sores, and that there was also a rise in plasma levels of TNF-α. The role and mechanisms of psychosocial stress on the clinical course of atopic dermatitis still remain to be elucidated. When volunteers are subjected to formal stress tests in the form of public speaking and performance of mental arithmetic, a wide range of endocrinological changes occur. These include increased production of adrenaline, ACTH, corticotrophin releasing factor (CRF) and cortisol, and reduced production of growth hormone, prolactin and progesterone [2]. The stress-induced rise in free cortisol is reportedly lower in patients with atopic dermatitis [3]. White blood cells and various cytokines also change in response to stress tests: increases in lymphocyte, monocyte, neutrophil and basophil numbers were seen 10 min after the stress provocation test and were equal in atopic individuals and healthy controls [4]. Also, although IFN-γincreased and IL-4 decreased in both control and atopic groups, atopic individuals showed a significant increase in eosinophils and IgE in response to stress [4]. Fjellner *et al*. [5] examined itch in response to intradermal inoculation of histamine, but found there was no demonstrable effect of stress.

Another humoral influence that appears to modulate atopic dermatitis is mediated by the sex steroids. One-third of 133 patients questioned claimed there was a significant pre-menstrual flare of atopic eczema [6]. Pregnancy exacerbated eczema in 52% of women, whereas it ameliorated eczema in 24% [6]. It has been proposed that a possible mechanism by which sex steroids alter susceptibility to inflammatory skin diseases is by modification of sensitivity to anti-inflammatory effects of glucocorticoids (GC). In a comparison of differences in susceptibility between men and women, Rohleder *et al*. [7] stressed volunteers as above; women were tested in the luteal phase of the menstrual cycle. Sensitivity to GC was assessed *in vitro* by measurement of dexamethasone inhibition of lipopolysaccharide-stimulated production of IL-6 and TNF-α. Salivary cortisol levels increased equally between the sexes. However, in men, GC sensitivity was markedly increased 1 h after stress, whereas GC sensitivity decreased significantly in women. Similarly, lipopolysaccharide-induced cytokine production decreased in response to stress in men but increased in women. It is not clear whether this is the result of the increased cortisol production suppressing cytokine production in men or of a change in responsiveness to lipopolysaccharide itself. Hence, the premenstrual flares of atopic eczema could reflect the reduced sensitivity to the anti-inflammatory effects of endogenous cortisol.

Clinical features

Atopic dermatitis is an itchy, chronic, fluctuating disease that is slightly more common in boys than girls, with a range of clinical features (Table 24.2). The age of onset is between 2 and 6 months in the majority of cases, but it may start at any age, even before the age of 2 months in some cases. The distribution of the eruption varies with age, as described below.

Infantile phase

The lesions most frequently start on the face (Fig. 24.6), but may occur anywhere on the skin surface. Often, the napkin area

Table 24.2 Clinical features of atopic dermatitis.

Itching

is relatively spared. When the child begins to crawl, the exposed surfaces, especially the extensor aspect of the knees, are most involved. The lesions consist of erythema and discrete or confluent oedematous papules. The papules are intensely itchy, and may become exudative and crusted as a result of rubbing. Secondary infection and lymphadenopathy are common. The disease runs a chronic, fluctuating course, varying with such factors as teething, respiratory infections, emotional upsets and climatic changes.

Childhood phase

From 18 to 24 months onwards, the sites most characteristically involved are the elbow and knee flexures, sides of the neck, wrists and ankles [1] (Fig. 24.7). The sides of the neck may show a striking reticulate pigmentation, sometimes referred to as 'atopic dirty neck' [2,3] (Fig. 24.8). The anatomical basis for this distribution is unknown. Sometimes only one site is involved. The erythematous and oedematous papules tend to be replaced by lichenification. Some patients with atopic dermatitis are apparently unable to lichenify, even after prolonged rubbing (Fig. 24.9), and they may be very difficult to treat. Patients with an extensor distribution of

Fig. 24.13 Adult flexural dermatitis.

eczema in later childhood are uncommon, and may take longer to remit. This distribution is said to be commoner in Asian or black children (Fig. 24.10), but frequently they show the typical distribution [4]. As well as the typical mixture of papules and lichenification, true eczematous lesions with vesiculation may occur, often in discoid patches. Involvement of the hands, often with exudative lesions, and sometimes with nail changes, is common (Figs 24.11 & 24.12). Acute generalized or localized vesiculation should always suggest the possibility of secondary bacterial or viral infection (p. 24.24).

Adult phase (Fig. 24.13)

The picture is essentially similar to that in later childhood [5], with lichenification, especially of the flexures and hands. Localized patches of atopic dermatitis can occur on the nipples, especially in adolescent and young women. Involvement of the vermilion of the lips and the adjacent skin is commonly an atopic manifestation. Follicular lichenified papules are a frequent feature in black people and the Japanese. A distribution on the face, upper arms and back may correlate with areas of maximal thermal sweating or *Malassezia* sensitivity [6]. Photosensitivity is not uncommon, especially in adults with atopic dermatitis. The mechanisms involved are several and complex. Many such cases do not show sensitivity when tested with the monochromator. Rajka [7] has suggested that infrared and UV radiation may both contribute. Management of such cases requires a combination of approaches used for ordinary atopic dermatitis and for photosensitivity, neither alone sufficing.

Atopic hand eczema (Chapter 23)

The prevalence of hand eczema in patients with active atopic dermatitis was 58.9% in a recent study, and the prevalence rises with increasing age [8]. A patchy, somewhat vesicular and lichenified eczema is a common manifestation of atopic dermatitis in childhood. The nails are often involved, resulting in coarse pitting and ridging. A more diffuse, chronic lichenified eczema of the

hands is frequently found in cases of extensive atopic dermatitis which persist into adult life, and atopic dermatitis is frequently a contributory factor in many cases of what usually has to be called constitutional hand eczema [9]. A previous history of atopic dermatitis, and more particularly hand involvement, is a highly significant risk factor for the development of occupational dermatitis [10]. Involvement of the feet is also common and almost half the patients with atopic hand eczema will have eczema on the feet [11].

Associated disorders

Other manifestations of atopy (Fig. 24.14)

Allergic rhinitis (hay fever) and asthma are beyond the scope of this book. They occur in 30–50% of cases of atopic dermatitis [1,2]. Atopic dermatitis is a risk factor for the future development of allergic airways disease, possibly by percutaneous sensitization to protein antigen [2,3]. The age of onset is later than that of the eczema. Latent asthma may be detected by bronchial inhalation tests in a proportion of patients with atopic dermatitis without clinical asthma.

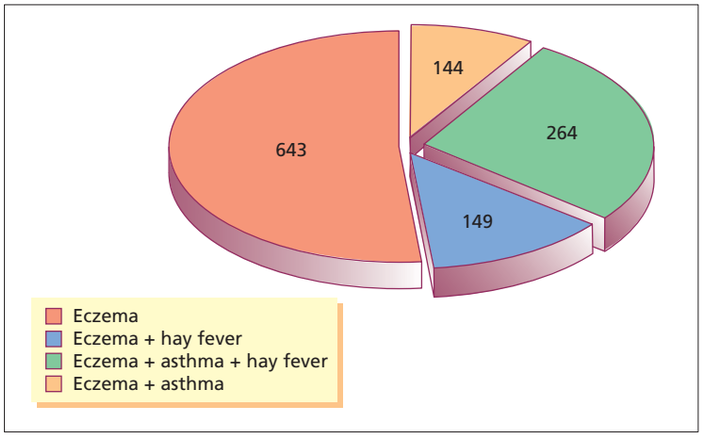

Fig. 24.14 The incidence of atopic respiratory symptoms in 1200 patients with atopic dermatitis. (From Rajka G. Prurigo Besnier (atopic dermatitis) with special reference to the role of allergic factors. *Acta Derm Venereol (Stockh)* 1960–1; **40**: 285; **41**: 363.)

Dry skin

This is a common feature of atopic dermatitis and figures prominently in its management. It is likely that it occurs because of increased transepidermal water loss through an abnormal stratum corneum [4,5], which may also correlate with disease activity [6]. The dry skin may be a consequence of abnormal ceramide synthesis and have an important role in the development of inflammation. Ceramide-containing emollients may be helpful in managing the condition [7]. Ichthyosis vulgaris and keratosis pilaris may also be seen in association with the condition and loss-of-function variants of the barrier protein filaggrin may be the link between these conditions and atopic dermatitis [8].

Other patterns of eczema

Infantile seborrhoeic dermatitis

This condition is discussed in Chapter 17. It normally starts earlier than atopic dermatitis, and it may be possible to distinguish between the two conditions clinically [9]. However, there are a number of children who present with what appears to be seborrhoeic dermatitis and then progress to typical atopic dermatitis [10].

Allergic contact dermatitis

It is clear that atopic dermatitis patients are at greater risk of developing irritant contact dermatitis than non-atopic patients [11]. However, there is a dispute about whether they are at greater risk of developing allergic contact dermatitis [12]. Nonetheless, patients can develop sensitivity to a variety of contact allergens such as topical medicaments, including topical corticosteroids [13,14]. There is also a risk of protein contact sensitivity, such as that associated with latex in rubber gloves [15,16]. The development of contact allergic dermatitis does not seem to adversely affect the prognosis for the atopic dermatitis [17].

Lip-lick cheilitis

Synonyms
- Perioral eczema
- 'Lick eczema'

Moist or fissured eczema around the mouth is common in children with atopic dermatitis. It can also occur as a result of food allergy, and in children with no known atopy or allergy. Frequently spreading some distance around the mouth, it may become secondarily infected and crusted (Fig. 24.15). Its persistence, and perhaps its origin, is attributable to habits of lip licking, thumb sucking, dribbling or chapping. It is easily transformed into true perioral dermatitis by the application of potent corticosteroids (Chapter 43). The regular application of 1% hydrocortisone ointment is usually most helpful. Contact sensitivity, for example to toothpaste ingredients, can occasionally be demonstrated.

Fig. 24.15 Lip-lick cheilitis.

Several other patterns of eczema are seen in individuals with atopy, but they are also seen in non-atopic individuals. These include eczema with a predominantly follicular accentuation, and discoid eczema. Certain well-defined conditions appear more common in atopic individuals; pityriasis alba and juvenile plantar dermatosis are discussed in Chapter 23. Nodular prurigo can quite frequently complicate the atopic diathesis (Chapter 23).

Infra-auricular dermatitis is quite frequently seen in atopic dermatitis patients, and infra-auricular fissures appear to be quite specific to atopic dermatitis [18].

Drug sensitivity

IgE-mediated drug reactions of the anaphylactic type are more common in atopic persons, but anaphylactic reactions to injected antigens can occur in persons with no other atopic manifestations. Anaphylactic reactions to topically applied drugs have been reported [19]. Other types of drug reaction with different immunological mechanisms occur with equal frequency in atopic and non-atopic individuals.

Food allergy

Abdominal symptoms due to food allergy are more frequent in patients with atopic disorders, but are not restricted to them. The role of food allergy in asthma and allergic rhinitis is probably minor. The role of food intolerance in the management of atopic dermatitis is discussed on p. 24.30.

Alopecia areata

There is a statistically significant association between alopecia areata and atopy.

Urticaria

The majority of cases of urticaria cannot be shown to be due to IgE or any other allergic sensitivity. Those cases in which an allergic basis is found occur more often in atopic individuals (Chapter 22). Contact urticaria, for example on the hands, occurs not infrequently in atopic dermatitis, and may present as an acute exacerbation of the dermatitis [20]. It occurs particularly in food handlers and slaughterhouse workers [21], and has been reported in health carers because of latex protein sensitivity [15].

Complications

Psychosocial aspects

Atopic dermatitis has a profound effect, equal to or greater than that of asthma and diabetes, on many aspects of patients' lives and the lives of their families [1–4]. In children, the most troublesome symptoms are itching, distress at bath time and difficulty going to sleep. This can lead to behavioural difficulties in severely affected children [5,6]. The patient's dermatitis promotes family

dysfunction, causing exhaustion, sleep deprivation and emotional distress [7]. Increasingly, a demonstration of improvement in the quality of life of patients forms part of the assessment of new therapies [8] and reveals that advice from experienced teams can improve well-being [7].

Growth delay

Growth delay can be associated with atopic dermatitis [9]. It used to be seen in severe cases before the advent of corticosteroid therapy, and can therefore be attributed to the disease. However, suspicion must also clearly rest on both oral and topical steroid therapy, which can cause growth stunting in any child on long-term therapy [10]. Prepubertal children with atopic dermatitis show features consistent with constitutional growth delay [11].

Bacterial infections

Secondary bacterial infection with staphylococci or streptococci is virtually an integral part of the clinical picture [12]. It contributes to many exacerbations of the disease, even without grossly visible purulent exudate. Widespread impetigo may sometimes closely mimic Kaposi's varicelliform eruption. Indeed, any acute vesicular eruption in an atopic should suggest the diagnosis of secondary bacterial or viral infection.

Viral infections

Patients with atopic dermatitis, both active and quiescent, are liable to develop acute generalized infections with herpes simplex virus (eczema herpeticum), to produce the clinical picture of Kaposi's varicelliform eruption (Fig. 24.16) [13] (see Chapter 33).

Fig. 24.16 Kaposi's varicelliform eruption: eczema herpeticum.

Such episodes may present as a severe systemic illness with high fever and a widespread eruption. However, there may be no systemic disturbance, and at times the eruption may be quite localized, often to areas of pre-existing atopic dermatitis. The individual lesions start as the characteristic viral papulovesicles, but not necessarily with an herpetiform grouping. There may then be rapid evolution to a state in which extensive purulent exudate masks the initial papulovesicles, or superficial scattered erosions may be the only clue to the cause of a rapid deterioration of the dermatitis. The differential diagnosis includes bacterial impetigo and chickenpox. Herpes zoster and chickenpox apparently behave as in normal persons.

There is a lack of agreement about whether viral warts are more prevalent in atopic dermatitis. An initial uncontrolled study suggested an increased frequency of viral wart infections [14], but a more recent epidemiological study has cast doubt on this observation [15].

Similarly, the frequency of molluscum contagiosum in such patients is not clear. However, the clinical impression is that widespread molluscum contagiosum is more common in the atopic child.

An abnormal response to a Coxsackie infection in an atopic has been described [16]. AIDS may aggravate atopic dermatitis, and 'recall' atopic dermatitis has been described in AIDS patients [17]. A condition resembling atopic dermatitis has been seen in association with HTLV-1 infection, although this may be coincidental [18].

Ocular abnormalities (see also Chapter 67)

A number of ocular changes can occur in atopic dermatitis [19]. The Dennie–Morgan fold is often present as a fold of skin under the lower eyelids [20]. However, this change is not specific to atopic dermatitis, and is commonly seen in non-atopic black children [21].

Conjunctival irritation is a common syndrome in atopic persons. As in hay fever it may represent a true allergic reaction, or it may be due to a non-allergic irritability such as occurs in the nose or skin. Keratoconjunctivitis has been recorded [22].

Keratoconus [23,24], or conical cornea, is a rare condition. It may occur in the absence of any other disease or in association with atopic dermatitis. It is due to a degenerative change in the cornea, which is forced outwards by the intraocular pressure, to give rise to marked visual disturbances. Onset is in childhood, and after some years progress of the disease becomes arrested. Contact lenses may be helpful.

Cataract associated with atopic dermatitis (Fig. 24.17) has certain peculiarities which distinguish it from other types of cataract [25]. It occurs in up to 10% of the more severe adolescent and adult cases, but overall it is uncommon. It is associated with atopic dermatitis rather than with other atopic diseases perhaps because of a genetic risk factor [26]. It may start in early childhood or up to the age of 30 years, but the peak incidence is between 15 and 25 years. It is almost always bilateral. The appearances on slit-lamp examination are characteristic but not diagnostic. In the early stages translucent globules and small opacities appear at the pole in front of the posterior capsule and also in the anterior subcapsular zone. Progression may be slow, or alarmingly rapid over a

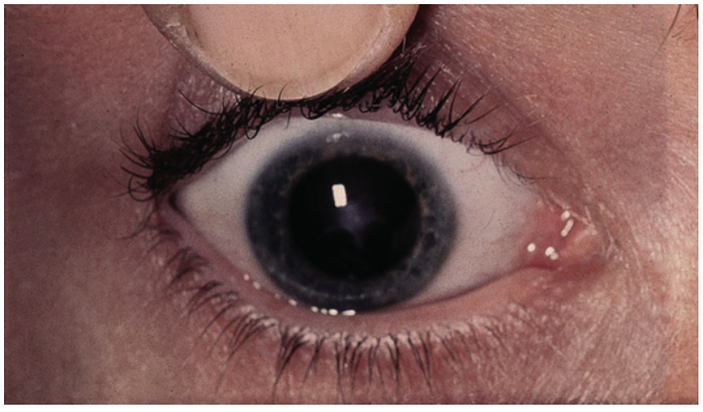

Fig. 24.17 Atopic cataract.

few days, and seems to be related to severe facial involvement [26]. The final appearance may resemble a mature, cortical, senile cataract.

Atopic cataracts may resemble those induced by topical or systemic steroids. The potential for cataract formation is an important reason for examining the eyes of any patient with atopic dermatitis when psoralen and UVA (PUVA) therapy is being contemplated.

Retinal detachment has been reported, particularly in Japanese patients [27], and appears to be identical to the retinal detachment seen following trauma [28].

Miscellaneous

Cartilaginous pseudocyst of the external auricle may be more common in children with atopic dermatitis [29], as may olecranon and pretibial bursitis [30]. A case of Sézary syndrome has been described in a patient with severe atopic dermatitis [31], and lymphomatoid papulosis in a patient receiving ciclosporin for their dermatitis [32]. However, the overall risk of cancer may be reduced in patients with atopic dermatitis [33].

Natural history and prognosis [1–5]

Hospital-based studies suggest the age of onset is less than 6 months in 75% of cases and before the age of 5 years in 80–90%. However, community-ascertained cases may have a later age of onset than that reported in hospital-based studies [6]. The reported prognosis differs considerably according to how the cases are selected, the criteria for diagnosis and many other variables. There is a general tendency towards spontaneous improvement

throughout childhood and often some slight relapse during adolescence. Relatively few typical cases persist over the age of 30 years; perhaps half of all cases clear by the age of 13 years. The reported clearance rates range from 40 to 60% within 10–20 years [2,6]; 84% within 5–20 years [5]; and 50% at 10 years [3].

It is difficult to predict the prognosis in an individual case. However, children with severe disease, starting early, who also have asthma, hay fever and a family history of atopic dermatitis are likely to have more persistent disease [6]. Children with raised IgE antibodies to foods and inhalant antigens at 2 years of age may also have a poorer prognosis [7].

Recently, it has been suggested that involvement of the head and neck of adults implies further prolonged disease [8]. In addition, the atopic patient remains particularly at risk from occupational irritant hand dermatitis as an adult [9].

Diagnosis

The diagnosis of atopic dermatitis is usually based on clinical criteria. The UK refinements of Hanifin and Rajka's diagnostic criteria (see Table 24.1) appear to be valid for both adults and children of white and non-white groups. However, these criteria were developed primarily for epidemiological use and were considered less reliable under 1 year of age.

Differential diagnosis

In the individual patient, one must consider a number of other conditions. Scabies should always be excluded, and can cause confusion when superimposed on pre-existing atopic dermatitis. In the first few months of life the differentiation of infantile seborrhoeic dermatitis from atopic dermatitis can be difficult [1], although with time the distinction becomes apparent. Immunodeficiency states should also be considered in infants in whom the disease is unusually severe, when there are recurrent systemic or ear infections, and if there is failure to thrive, malabsorption or petechiae. Recurrent infected eczema in Jamaican children may be associated with HTLV-1 infection (Chapter 23). An eruption resembling atopic dermatitis, with or without other atopic disorders, and sometimes with raised IgE levels, may be found in several genetic and metabolic disorders (Table 24.3).

Table 24.3 Genetic and metabolic disorders.

Agammaglobulinaemia
Anhidrotic ectodermal defect
Ataxia telangiectasia
Coeliac disease [2]
Cystic fibrosis heterozygote [3]
Experimental histidine depletion [4]
Hearing loss (genetic) [5]
Hurler's syndrome
Jung's disease (Chapter 23)
Nephrotic syndrome [6]
Netherton's syndrome (ichthyosis, bamboo hairs) [7]
Phenylketonuria
Wiskott–Aldrich syndrome (infections and thrombocytopenia)

In adults, flexural eczema may be a consequence of secondary dissemination of other types of eczema, for example in nickel allergy and occupational contact dermatitis [8].

Hyper-IgE syndrome [1–3]

Synonyms
- Job's syndrome
- Buckley's syndrome

This is a syndrome that develops in infants or children. It resembles atopic dermatitis, but tends to involve particularly the scalp, axillae and groins. It may be inherited in an autosomal dominant or autosomal recessive form. In the dominant inheritance the associated features include persistent secondary bacterial infection, fluctuant cold abscesses, contact urticaria, bronchitis and more severe lung damage [1]. The recessive disease has a broader range of bacterial infections along with severe chronic molluscum contagiosum and herpes infections [2]. The key laboratory finding is the great elevation of serum IgE levels (greater than 200 i.u./mL),

often with some eosinophilia. Other immunoglobulins are often normal in the dominant form but elevated in the recessive variant.

Hypereosinophilic syndrome [1–4]

Eosinophilia is a common feature of many diseases, including several skin diseases. In this situation the eosinophilia is reactive and induced as a response to eosinophilopoietic cytokines. However, clonal eosinophilia may present with skin signs, including: a non-specific, itchy, maculopapular eruption; urticaria or angio-oedema; an eruption resembling atopic dermatitis; or erythroderma [3–5]. Only a few such cases can be attributed to an eosinophil leukaemia. The clinical manifestations appear to be attributable to the eosinophilia itself, and include cardiac involvement, and involvement of the nervous system, liver, lungs and gut.

Pachydermatous eosinophilic dermatitis

Nir and Westfried described a generalized rash associated with marked blood and skin eosinophilia, and called it hypereosinophilic dermatitis [1]. More recently, a variant of this disorder has been described in three black South African teenage girls, and designated pachydermatous eosinophilic dermatitis [2]. This condition is thought to resemble severe atopic dermatitis or onchodermatitis. However, the three patients had peculiar hypertrophic genital lesions, peripheral blood eosinophilia and an eosinophil-rich lymphohistiocytic cutaneous infiltrate.

Investigations

The diagnosis of atopic dermatitis is rarely aided by investigations. Estimation of total serum IgE, specific radioallergosorbent tests (RASTs) and prick tests usually serve only to confirm the atopic nature of the individual. It is possible that such confirmation may be of value occasionally in adult-onset dermatitis. However, one must remember that 20% of patients with atopic dermatitis have normal total IgE levels and negative RASTs, whereas 15% of apparently healthy individuals have a raised IgE [1].

The value of investigations in identifying trigger factors in atopic dermatitis is disputed. How helpful specific RASTs to foods or aeroallergens are for disease management is unclear [2–4], although it is suggested that if they are negative allergy is unlikely [5]. It may be that skin prick test positivity to food allergens in young children with severe atopic dermatitis and a high serum IgE indicates a high risk of developing later allergic respiratory disease [6]. Adults with head and neck dermatitis and positive RASTs to *Malassezia* species may benefit from treatment with oral anti-yeast therapies [7].

If one suspects immunodeficiency with atopic dermatitis, then the appropriate investigations should be performed, for example immunoglobulin levels and subclasses, IgE levels, white-cell count, platelets, complement levels and function, and T, B and phagocyte cell numbers and functions. If clinically appropriate, one may also consider testing for HTLV-1 and HIV.

Bacteriology and virology swabs may be helpful in identifying causes for deterioration of atopic dermatitis. Although atopic dermatitis skin is often colonized by *Staphylococcus aureus*, bacterial culture can identify antibiotic resistance and detect β-haemolytic *streptococci*. Herpes simplex is usually readily cultured, but a Tzanck smear, an immunofluorescence slide test or electron microscopy can also be helpful, and will provide more rapid confirmation of infection.

Patch testing may also help to identify a contact allergen responsible for deterioration of the skin condition, particularly in adults [8,9]. The 'atopy patch test' for aeroallergens [4] and foods [10] in atopic dermatitis, and the skin-application food test (SAFT) in the management of the IgE-mediated contact urticaria syndrome in children with atopic dermatitis [11], are recommended by some authorities.
