E-selectin expression is detectable on dermal endothelium in all inflammatory dermatoses, indeed it is preferentially expressed in skin [25]. Cutaneous lymphocyte antigen (CLA) is a glycoprotein molecule expressed on T cells that home specifically to the skin [26]. The expression of CLA by T cells is dependent on induction of glycosylation enzymes that modify pre-existing PSGL-1 during transition of T cells from non-activated to memory phenotype [27,28]. T cells in inflammatory skin disease express CLA, whereas T cells in non-cutaneous inflammation are mainly CLA-negative [27]. The skin specificity of E-selectin–CLA binding makes this an attractive target for biological therapy of inflammatory skin disease [29]. However, a systemically administered antibody directed to E-selectin was ineffective in the treatment of psoriasis [29]. A soluble form of E-selectin is released, which can also induce β2 integrin expression on neutrophils. Levels of soluble E-selectin in plasma are increased in scleroderma, polyarteritis nodosa, SLE, psoriasis and atopic dermatitis [30]. Correlation between levels of soluble E-selectin and disease activity has been observed in atopic dermatitis, psoriasis and palmoplantar pustulosis [31,32]. Whether soluble E-selectin has any direct pathogenic role in psoriasis or is merely a reflection of skin inflammation is debatable.

L-selectin. L-selectin (CD62L, LAM-1, LECAM-1, $gp90^{MEL}$, DREG) is constitutively expressed on the surface of leukocytes during maturation, and expression persists until binding of leukocyte to endothelium [33]. L-selectin is important in the initial phases of leukocyte–endothelial cell binding (Fig. 12.2). L-selectin is unique in that it is the only selectin known to be involved in trafficking of lymphocytes into lymphatic tissue. Upon leukocyte activation (binding), L-selectin is shed from the cell surface [34]. During the later stages of the inflammatory response L-selectin is an important mediator of neutrophil recruitment [35]. Four L-selectin ligands have been identified to date:

1. *Glycosylation-dependent cell adhesion molecule-1* (GlyCAM-1): a secreted protein not found on high endothelial venules (HEV)
2. *Mucosal addressin cell adhesion molecule-1* (MadCAM-1): important in tethering and rolling of lymphocytes in the HEV of Peyer's patches in the gut
3. *CD34*: has a role in lymphocyte rolling in the tonsil
4. *Sgp200*: as for the other two selectins, PSGL-1 may also be a ligand for L-selectin.

Although selectins were originally investigated as adhesion molecules, there is now considerable interest in their role as signalling molecules. For instance, activation via cross-linking of

L-selectin on leukocytes leads to up-regulation of surface expression of β1 and β2 on naïve but not memory T cells, and calcium flux in peripheral blood mononuclear cells [36–38]. In neutrophils in particular, L-selectin cross-linking leads to activation of MAP kinases involving Erk 1 and 2 activation [39].

Down-modulating selectin function has been shown to be an effective therapeutic paradigm, at least in various animal models of inflammation [40–43]. For example, L-selectin diminishes T-cell-mediated allergic reactions during the early sensitization phase of contact dermatitis [44].

Blockers of selectin function have been recently developed for the treatment of various inflammatory dermatoses including psoriasis and atopic dermatitis. β-1, 3-glucan sulphate (PS3) has been shown to have inhibitory activity towards L and P-selectin function [45].

Immunoglobulin superfamily

CAM are the ligands or counter-receptors for the integrins (Table 12.13). They have one or more immunoglobulin-like domains, hence the designation immunoglobulin superfamily, and have repeat sequences resembling those of fibronectin. Their chief function is to bind leukocytes to cells expressing them, or to endothelium to facilitate vascular emigration, or to cytokine-activated fibroblasts and keratinocytes, to aggregate leukocytes at sites of inflammation.

ICAM-1 has five immunoglobulin-like domains, and is expressed weakly on normal endothelium, but is much increased by stimulation by IL-1, TNF-α or the complement component C5a [1]. On other cells (e.g. keratinocytes and fibroblasts) ICAM-1 is not expressed constitutively, but appears following stimulation by TNF-α or IFN-γ. ICAM-2, present constitutively on endothelium, is not increased by inflammatory stimulation. The third member, ICAM-3, contains five immunoglobulin-like domains and is expressed constitutively by resting monocytes, lymphocytes and epidermal Langerhans' cells [2]. Its expression is increased upon stimulation (e.g. treatment *in vitro*) and it binds with LFA-1 (CD11a/CD18). ICAM-1 contributes to leukocyte adhesion via the LFA-1 and Mac-1 β2 integrins (Table 12.13) [3]. The related VCAM-1 molecule expression is increased after cytokine stimulation, and it binds the α4β1 integrin mediating extravascular migration, principally of monocytes and eosinophils. Another variant, the platelet–endothelial cell adhesion molecule (PECAM-1 or CD31), is found in platelets and at the intercellular junctions of endothelium, where it contributes to leukocyte passage from blood vessels (Fig. 12.2) [4].

Table 12.13 The immunoglobulin superfamily of adhesion molecules.

Adhesion molecule	Cells	Ligand/ counter-receptors	Cells
LFA-3 (CD 58)	Most cell types	CD2	T lymphocytes
ICAM-1	Endothelium	LFA-1	Leukocytes
	Fibroblasts	(α1β2)	
	Activated leukocytes	Mac-1	Monocytes
	Activated keratinocytes	(αnβ2)	
ICAM-2	Endothelium	LFA-1	Leukocytes
ICAM-3	Activated leukocytes	LFA-1	Leukocytes
	Dendritic cells		
	Langerhans' cells		
VCAM-1	Endothelium	VLA-4	Leukocytes
	Macrophages	(α4β1)	(not neutrophils)
	Dendritic cells		Langerhans' cells
	Fibronectin		
PECAM-1	Platelets, leukocytes	PECAM-1, CD31	
	Endothelium		

Like the selectins, the extracellular regions of ICAMs and VCAM are released into tissue fluids in a soluble form (sICAM-1, sVCAM). *In vitro* studies of ICAM-1 indicate that its soluble form is released from blood mononuclear cells, but not from epithelium, fibroblasts or endothelium. In normal persons, up to 450 ng/mL sICAM-1 is detectable in serum, but this may be increased two- or threefold in inflammation (e.g. in disorders such as diabetes, idiopathic pulmonary fibrosis and liver disease); sICAM-1 is also detectable in the synovial fluid of patients with rheumatoid arthritis [5]. sICAM-1 is significantly elevated in the serum of a number of dermatological diseases including atopic dermatitis, psoriasis and metastatic melanoma [6–8] and correlates with clinical severity in untreated disease. sICAM-2 does not exist. sICAM-3 is increased in the sera of patients with psoriasis and atopic dermatitis but is less relevant than sICAM-1 to disease activity [9]. sVCAM is present in normal sera, and is increased in cancer and inflammation, including rheumatoid arthritis. Serum levels of sVCAM are elevated in advanced cutaneous melanoma, localized scleroderma, systemic sclerosis and SLE [10–12]. The role of soluble adhesion molecules is poorly understood—they may compete in cell–cell binding or they may activate cells that possess the cognate ligand.

The L1 cell adhesion molecule (L1CAM) belongs to the immunoglobulin superfamily and was originally identified in the nervous system. Recent studies demonstrated L1CAM expression in various types of cancer, predominantly at the invasive front of tumours and in metastases, suggesting its involvement in advanced stages of tumour progression [13].

A new member of the Ig superfamily, activated leukocyte cell adhesion molecule (ALCAM), has been detected in subsets of haematopoietic cells and endothelial cells during embryogenesis. ALCAM supports the development of haematopoietic cells and increases capillary tube formation. The soluble form, sALCAM, also appears to regulate human microvascular endothelial cells (HMVEC), upon TNF-α stimulation. ALCAM significantly enhanced tube formation of endothelial-like cells on Matrigel, and inhibited their migration. sALCAM completely abolished the effects of ALCAM, suggesting a role as a decoy receptor. sALCAM also enhanced migration of HMVEC, suggesting an important role of this adhesion molecule in the regulation of endothelial cell function [14].

CEACAM1 appears to be an essential CAM for the regulation of T-cell function and cytokine regulation. It is also a co-inhibitory receptor after T-cell activation.

Another cell adhesion molecule regulating skin endothelial cell function is CD99, a highly *O*-glycosylated cell-surface protein expressed on most leukocytes. It is also expressed at endothelial cell contacts and participates in the process of transendothelial migration of monocytes and neutrophils. In a mouse model of delayed-type hypersensitivity (DTH) reaction, anti-CD99 antibodies inhibited the recruitment of *in vivo*-activated T cells into

inflamed skin as well as oedema formation, suggesting CD99 to be a potential therapeutic target in skin inflammation [15].

Adhesion molecules regulating leukocyte emigration

Leukocyte emigration at a site of inflammation is regulated by a complex sequence of interacting changes. A leukocyte rolling over endothelium is arrested by an activated endothelial cell, binds to it, and passes through an endothelial intercellular junction, attracted by chemokines and other chemotactic agents [1–4], a process known as the endothelial cell–leukocyte adhesion cascade (Fig. 12.2).

Neutrophils, eosinophils and monocytes in the blood may flow mid-stream, or roll down the endothelium, when both leukocytes and endothelium are unstimulated. Contact between the rolling leukocyte and endothelium is regulated by constitutive L-selectin (neutrophils) or by L-selectin and α4β1 integrins (eosinophils and monocytes). On contact between the leukocyte, and endothelium activated by TNF-α, IL-1, IL-4 or LPS endotoxin, the leukocytes are rapidly activated. Differences in the integrins expressed in the leukocyte types contribute to the selectivity of the resulting leukocyte infiltrate. The initial adhesion is enhanced by other products resulting from endothelial activation: thrombin, histamine, bradykinin, H_2O_2 and LTC_4. Similarly, neutrophils become further activated by endothelial inflammatory products, particularly PAF, enhanced by platelet aggregation.

The rolling activated neutrophil is arrested by the activated endothelium. The L-selectin molecules are shed. P-selectin from endothelium and platelets is rapidly mobilized, linking the neutrophil to the endothelium; adherence is enhanced by E-selectin on the endothelium binding to sialyl Lewis groups on the neutrophils (Fig. 12.2). Arrest is followed by firm adhesion, during which the neutrophil spreads on the endothelium, adhesion forces are progressively increased, and the neutrophil begins to respond to chemokines and other attracting agents. A rapid change occurs in the conversion of LFA-1 integrins to an avid state, to bind with ICAM-1 and ICAM-2 on the endothelium, which increases expression of ICAM-1. A second β2 integrin, Mac-1, also has functional increased activity and binds to ICAM-1 only (Fig. 12.2).

Adherence changes to migration as the neutrophil responds to IL-8, neutrophil activating peptide-2 (NAP-2), growth-regulated gene/melanoma growth stimulating activity (GRO/MGSA), C5a and other attracting agents. Vascular emigration is most evident in the post-capillary endothelium, but occurs elsewhere in the venous system with sufficient loss of vessel wall integrity. Emigration appears to be mediated by the neutrophil flowing over the ICAM molecules and inserting itself into an intercellular junction, where PECAM-1 is localized; this appears essential for passage of the cell (Fig. 12.2).

Emigration of monocytes and eosinophils is similar, but with some differences in the adhesion molecules and chemokines involved. The α4β1 integrin is expressed constitutively, and contributes to leukocyte rolling, and also to adhesion by binding to VCAM-1 [2]. Monocytes express all three of the CD11/CD18 β2 integrins, and also some ICAM-1 [5]. This may regulate the binding of monocytes to unstimulated endothelium, but adhesion to and emigration from stimulated endothelium is much stronger [5]. A greater number of chemokines contribute to monocyte and eosinophil emigration than emigration by neutrophils, particularly RANTES, MIP-1α, MCP-2 and MCP-3, and additionally MIP-1β and MCP-1 attract monocytes.

Detailed knowledge of the adhesion molecules has an application in the development of blocking ligands, which may offer the potential for control of tissue damaging inflammation.

Adhesion molecules on activated keratinocytes

Leukocytes emerging from blood vessels move through tissue and bind to activated cells by the same adhesion molecules. ICAM-1 is expressed on fibroblasts, activated thymic epithelial cells and activated keratinocytes [1–4]. As for endothelial cells, ICAM-1 is inducible on fibroblasts by IL-1, IFN-γ and TNF-α, which are cytokines activated or released in damaged tissue [4,5].

It is well known that adhesion molecules critically regulate immune responses [6], cell proliferation and migration [7], and inflammatory signalling pathways in endothelial and epithelial cells [8].

Normal keratinocytes do not express ICAM-1 when examined by usual immunohistochemical methods, although extremely small amounts are detectable by immunoelectron microscopy; this expression may be sufficient for normal leukocyte and Langerhans' cell migration, but avoids leukocyte-mediated damage [9]. The expression of ICAM-1 on keratinocytes is induced by IFN-γ and TNF-α, which are products released by lymphocytes infiltrating inflamed skin [10]. Activated lymphocyte IFN-γ induces keratinocyte expression of ICAM-1 and HLA-DR, promoting inflammatory and allergic epidermal responses [11,12]. ICAM-1 expression is induced in the basal and lower suprabasal layers; decreased expression in the upper layers is associated with greater differentiation and formation of involucrin [13]. When ICAM-1 is found in the upper suprabasal layers, it probably reflects the presence of relatively undifferentiated hyperproliferative epidermis. Among the disorders in which keratinocytes express ICAM-1 are allergic contact dermatitis [14–16], irritant contact dermatitis [17], psoriasis [18–20], lichen planus, bullous pemphigoid, exanthems and urticaria [21].

Endothelin 1

Endothelin 1 (ET-1), a 21-amino acid peptide, was first identified as a vascular endothelial cell product [1] with potent vasoconstrictor activity, which contributes to endothelial turnover and integrity. It is also synthesized by keratinocytes [2]. ET-1 is mitogenic for fibroblasts [3], smooth muscle cells including vascular cells [3,4], melanocytes, in which it also stimulates tyrosinase activity [5], and renal mesangial cells.

Endothelin (ET-1) has been shown to contribute crucially to UV-induced skin responses such as tanning. ET-1 skin levels in UV-irradiated mice increased substantially and continually in correlation with the levels of UV-induced skin inflammation. Moreover, blockade of ET-1 receptors (ETA) resulted in significantly decreased cutaneous inflammation following UV irradiation. Intracutaneous ET-1 injection caused prominent mast cell degranulation and mast cell-dependent inflammation. ETA blockade did not decrease UV-induced inflammation in mast cell-deficient mice, unless these mice had been adoptively transferred with mast cells before irradiation. This indicates that skin inflammation due to UV irradiation is caused in part by ET-1 acting on skin mast cells [6].

ET-1 has been implicated in diverse physiological or pathological processes, including the vascular changes associated with sepsis. However, the factors that regulate ET-1-associated toxicity during bacterial infections and in other settings are not fully understood. Both the pathology associated with certain allergic and autoimmune disorders, and optimal host defence against bacterial and parasitic infections are mediated by mast cells. *In vitro*, mast cells can produce ET-1, undergo ET-1-dependent

and endothelin-A receptor (ET(A))-dependent activation, and release proteases that degrade ET-1. ET(A)-dependent mast-cell activation can diminish both ET-1 levels and ET-1-induced pathology *in vivo*, and can also contribute to optimal survival during acute bacterial peritonitis. These findings identify a new biological function for mast cells: promotion of homeostasis by limiting the toxicity associated with an endogenous mediator [7].

ET-1 was described over a decade ago as belonging to the group of mast cell-derived and mast cell-bound cytokines. Mast cell subtype- and environment-dependent, ET-1 acts as a potent non-immunological mast-cell activator, which leads to degranulation and mediator release. Studies in mast cell-deficient mice have provided convincing evidence that mast cells counteract the toxicity induced by high concentrations of ET-1, and thereby promote homeostasis [8].

Growth factors from cells other than keratinocytes

Potent cytokines stimulating regeneration of skin are synthesized by cells of the dermis. TGF-α and TGF-β, PDGF and βFGF are synthesized by several types of cell, and the epidermis probably contributes only a small proportion of that synthesized in a healing lesion. Other potent cytokines are EGF, insulin-like growth factor-1 (IGF-1), IGF-2, FGF, αFGF and βFGF.

Overview of structure and function of the immune system

G.P. Spickett, pp. 13.1–13.26

The immune system plays a key role in the protection of an organism against infection and has evolved in parallel with pathogens, which seek to circumvent the organism's defensive strategies. The structure and function of the immune system is complex, rivalled in complexity only by the nervous system with which it shares considerable structural and functional homology. Both organs extend through the body and are reliant on chemical mediators to transmit information between cells. There are complex links between the two systems, manifest by shared receptors and common mediators. The immune system is divided into innate and acquired immunity, which between them provide both immediate defence and long-term immunological memory respectively. Both systems are interlinked to provide effective protection against infection. Disease can arise through immunodeficiency, malignancy and deviation (autoimmunity and allergy).

Traditionally, the immune system is divided into two parts, the innate or non-adaptive and acquired or adaptive, the difference being in the ability of the acquired immune system to learn from exposure to pathogens. The requirement for the innate system is to provide generic protection during the time required for the acquired immune system to generate a specific response. The main feature of the adaptive system is long-lived, specific immunological memory. The two parts are linked through shared mediators (cytokines and chemokines) as well as shared receptors. In many respects, both systems amplify the other's response through released mediators.

In a short chapter it is not possible to give an in-depth view of all aspects of the immune system and the interested reader is directed to more detailed sources of information. A brief overview of the immune system follows as an introduction to the clinical aspects later in the chapter.

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

Innate immunity

Innate immunity describes all of the body's defensive strategies that do not have the capacity for learnt responses or immunological memory. The system includes surface defences, soluble mediators and non-specific cells. These do not operate in isolation but are closely integrated with acquired immunity. Figure 13.1 gives an overview of the main features and how they are integrated.

Non-specific defence mechanisms

The non-specific defence mechanisms include the structural design of the organism, aimed at reducing the capacity for microorganisms to gain entry. These include: the structure of the skin itself, together with the secretions it produces; enzymes in tears and other secretions, such as lysozyme and complement, that have a bactericidal effect; stomach acid, which is extremely effective

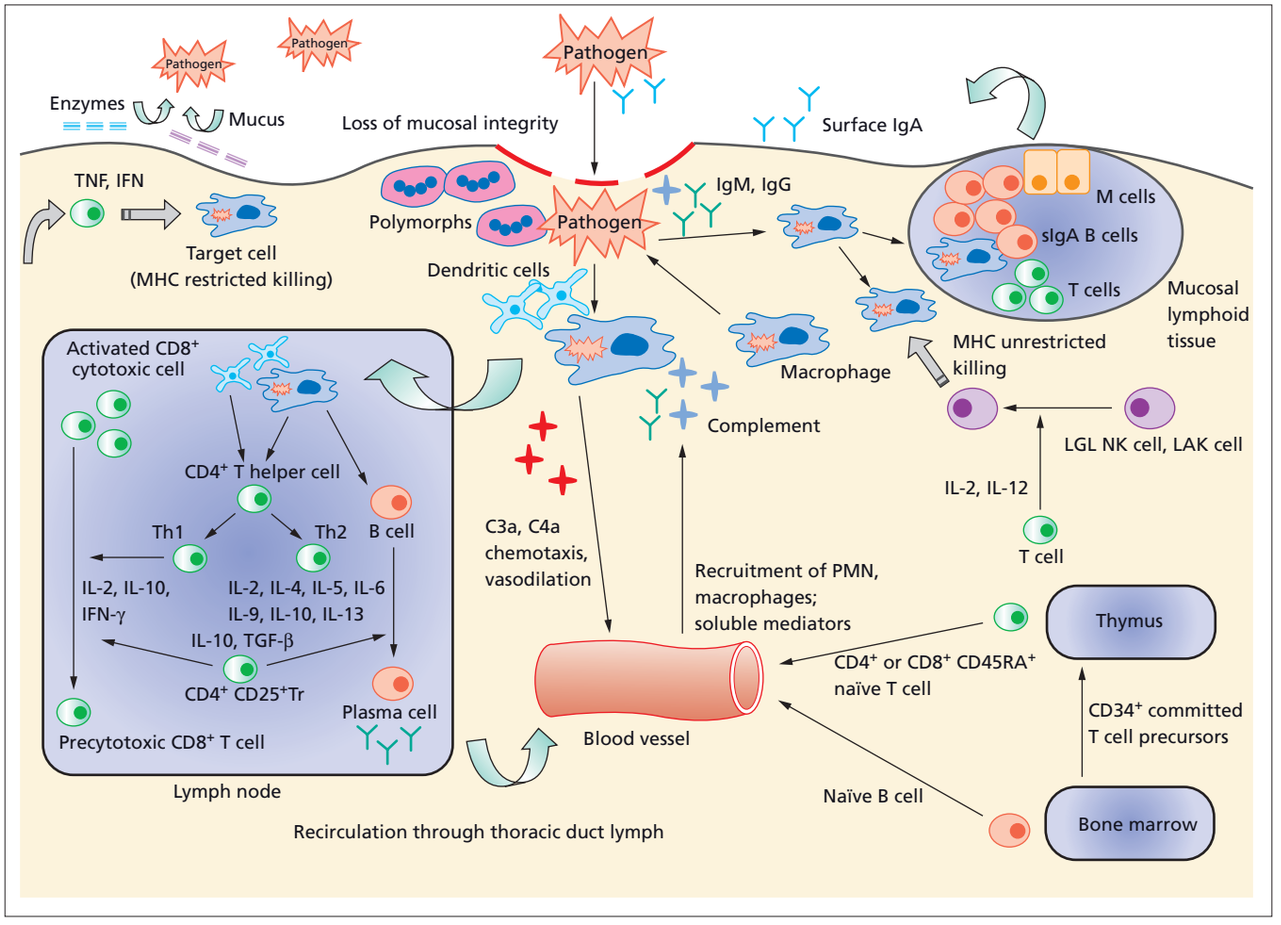

Fig. 13.1 Integration of the various aspects of the immune system, both innate and acquired, in dealing with pathogens. IFN, interferon; IL, interleukin; LAK, lymphokine-activated killer; LGL, large granular lymphocyte; TGF, transforming growth factor.

at reducing bacterial counts entering the upper gastrointestinal tract; and surface mucus in the respiratory tract, which traps bacteria and allows them to be removed by the ciliary escalator. The importance of these mechanisms is demonstrated in illnesses where these protective mechanisms are disrupted, for example: burns lead to easy passage of bacteria into deeper tissues; Sjögren's syndrome, with reduced secretions in eyes, mouth and lungs, is accompanied by increased bacterial infections at all these sites; achlorhydria, either due to gastric atrophy or induced by drugs such as proton-pump inhibitors, is associated with reduced resistance to enteric infections and also to *Candida*; cystic fibrosis and ciliary dyskinesia both disrupt the interaction between mucus and cilia and lead to progressive and severe lung disease due to infection. These examples clearly demonstrate that these non-specific features play a significant role in host defence and cannot be replaced, no matter how effective other aspects of the innate and acquired immune systems might be.

Soluble factors

The main soluble factors involved in host defence are the components of the complement and kinin cascades which are linked, through shared regulatory components, with the clotting cascade. There are three pathways of complement activation (Fig. 13.2): the classical pathway, triggered by interaction of an antibody–antigen complex with C1q; the lectin pathways, triggered by binding of mannose-binding lectin (MBL) to mannose residues on bacterial surfaces; and the alternate pathway, triggered by interaction of lipopolysaccharides of appropriate surface charge with alternate pathway proteins. The alternate pathway is also responsible for the 'tick-over' low-level activation of the complement system. All three pathways converge at the level of C3 to activate the terminal lytic sequence, which inserts a pore comprising the C5–8 proteins and polymerized C9. These pore-forming proteins are structurally very similar to the proteins produced in natural killer (NK) cells and cytotoxic T cells. Complement is a major opsonin, and the presence of C1q and C3 on bacterial surfaces increases phagocytosis through binding to complement receptors. Activation of the complement system also increases recruitment of phagocytic cells by the split products released during activation, that is C4a, C3a and C5a, the anaphylatoxins, which increase vascular permeability and are chemotactic for neutrophils. A specific receptor for C5a (CD88) has been identified, which activates cells via tyrosine phosphorylation and MAP kinases.

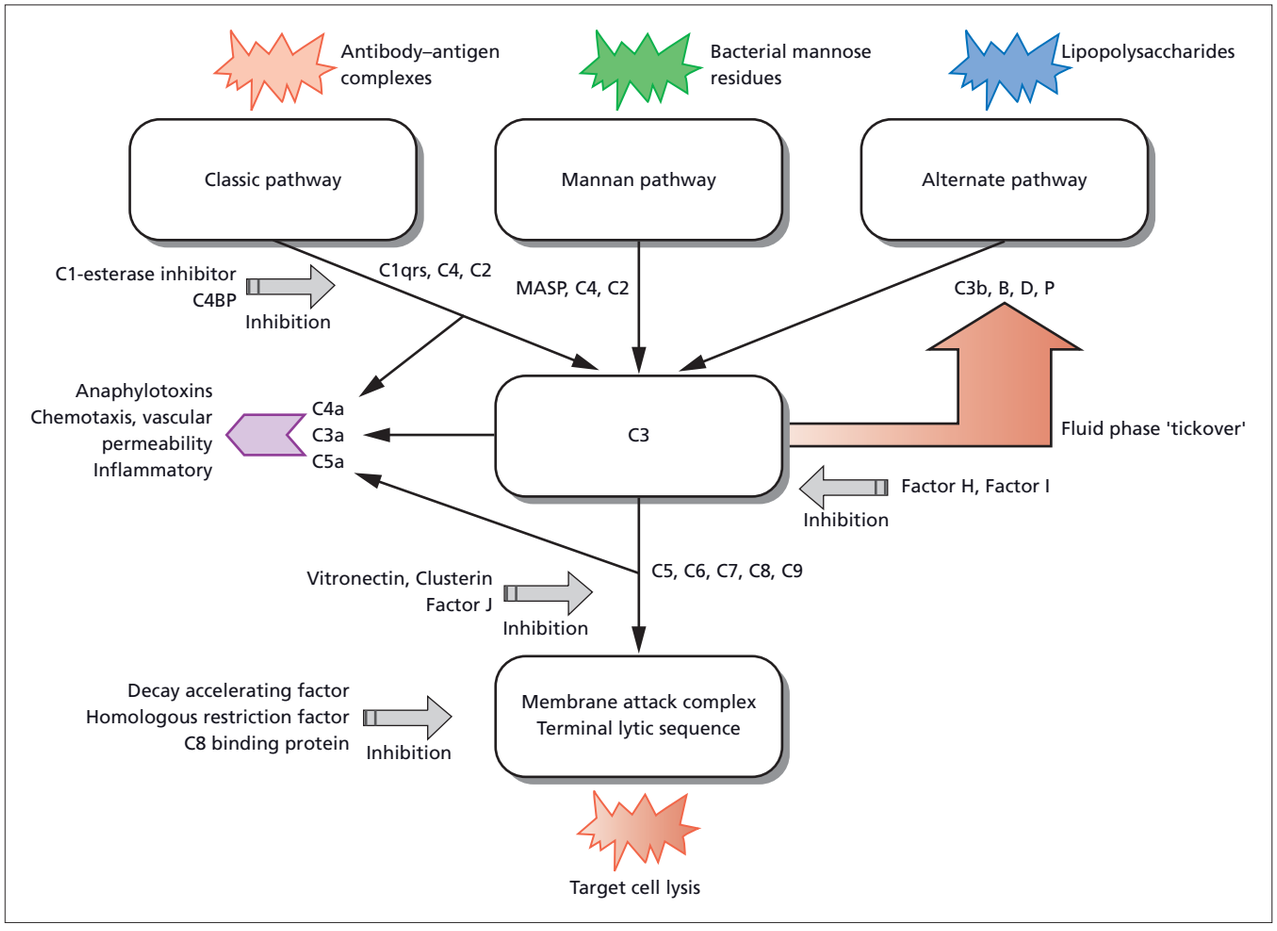

Fig. 13.2 Pathways of complement activation and their control. MASP, mannan-binding protein associated serine protease.

Complement receptors play a crucial role in linking the innate and acquired systems. Complement receptor 1 (CR1, CD35) is widely expressed on neutrophils, macrophages, follicular dendritic cells and B cells. Its presence on phagocytic cells is directly coupled to the process of phagocytosis, while on follicular dendritic cells it plays a pivotal role in antigen trapping and therefore persistence of antigen for subsequent presentation to T cells and B cells to maintain immunological memory. On B cells it is involved in activation and also in presentation of antigen to T cells. It is present on erythrocytes and is therefore involved in the removal of immune complexes to the spleen for subsequent phagocytosis and destruction. CR2 (CD21, EBV receptor) is expressed mainly on B cells, and forms part of the B-cell antigen receptor complex with surface immunoglobulin, CD19 and the immunoglobulin α chain (CD81). CR2 binds C3 degradation fragments iC3b and C3d, and co-ligation of these with antigen to the B-cell receptor reduces the threshold for B-cell activation 100-fold. CD21 is also essential for the development and maintenance of B1 ($CD5^+$) B cells, which are involved in the spontaneous production of IgM and play a role in recognition of lipid antigens. It is also a receptor for soluble CD23, an autocrine B-cell growth factor involved in IgE production. CR3 and CR4 are β integrins, expressed on phagocytic cells and directly involved in signalling for phagocytosis.

The complement system is an enzymatic cascade of proteases, with each step providing amplification. There are key checkpoints at which regulatory proteins act to ensure that the process is controlled. C1-esterase inhibitor inhibits C1r and C1s and also mannan-binding protein (MBP)-associated serine protease from the lectin pathway, as well as acting as a regulatory protein in the clotting and kinin cascades. Factor H is an inhibitor of C3 and C4-binding protein inhibits activated C4; these are both large molecules with multiple binding sites and are therefore capable of inactivating multiple activated complement proteins simultaneously. Both also act as co-factors for factor I, an inhibitor of activated C3 and C4. Deficiency of factor H has been associated with haemolytic–uraemic syndrome. Key molecules involved in the regulation of the classical pathway are CD55 (decay accelerating factor), which binds C4b and C3b, and C4 binding protein (C4bp) which binds C4b. The complement receptor CR1 also inhibits the activities of the convertases. In the alternate pathway, the cell bound molecule CD46 (membrane co-factor protein, MCP), which is similar to DAF, and works in a similar way to Factor H, promotes Factor I inactivation of C3b and C3i.

Newly described regulators of the terminal lytic sequence include vitronectin and clusterin, which interact mainly with C5b67. Host cells also have regulatory proteins CD59 (membrane inhibitor of reactive lysis (MIRL); protectin) and C8-binding protein (homologous restriction factor, HRF) expressed on their surface to prevent accidental bystander destruction by the terminal lytic sequence.

In paroxysmal nocturnal haemoglobinuria, there is a somatic clonal mutation in the *pig*A gene that prevents proteins, such as DAF, MCP and protectin, which contain the glycosylphosphatidylinositol (GPI) anchor, from being expressed through disruption of the transmembrane glycolipid tail. This causes the production of erythrocytes susceptible to complement-mediated lysis and night-time haemolysis, when the blood pH drops.

Deficiency of nearly all components of the complement system has been described, and most lead to increased susceptibility to infection, particularly with *Neisseria* species. The significance of MBP deficiency is uncertain, as deficiency alleles have been identified in healthy subjects. It is thought likely that MBP deficiency is only clinically important when other aspects of the humoral immune system are defective and the levels of MBL are significantly reduced.

The kinin cascade is also a critical pathway in inflammation, particularly in rhinitis and asthma, and also in generation of angio-oedema in hereditary angio-oedema. The end-product of the cascade is bradykinin, which acts through specific bradykinin receptors on smooth muscle, endothelial cells, neurones and synovial cells. C1-esterase inhibitor and α_2-macroglobulin inhibit activated kallikrein and therefore reduce bradykinin production; C1-esterase inhibitor also inhibits factor XIa in the clotting cascade and Hageman factor in the kinin cascade. Carboxypeptidase N breaks down bradykinin to des-arg-bradykinin, which retains some vasoactive properties: deficiency of carboxypeptidase N has been reported as a cause of angio-oedema. Des-arg-bradykinin is inactivated by angiotensin-converting enzyme (ACE), which explains why angio-oedema and cough are common complications of therapy with ACE inhibitors. Experimental drugs such as icatibant and FR173657 are available that block bradykinin receptors, and may therefore have a major role in the management of angio-oedema.

The pentraxin family of molecules includes C-reactive protein (CRP) and serum amyloid A (SAA). These are acute-phase proteins that bind directly to microbial polysaccharides as well as matrix proteins. CRP also scavenges DNA released from dead cells by binding to chromatin. It binds to C1q, thus facilitating the removal of the DNA–immune complex. It acts as an opsonin, but inhibits the convertases that activate the terminal lytic sequence. CRP is clearly an essential molecule, as deficiency has never been reported.

Defensins are newly described, small polypeptide molecules with a direct ability to lyse bacteria. The α-defensins are produced in neutrophils and also in gastrointestinal Paneth cells, while the β-defensins are produced by epithelial cells of the airway and the urothelium.

Many cells of the innate system produce inflammatory compounds derived from the arachidonic acid pathway. These include the prostaglandins, thromboxanes and leukotrienes. These agents have a diverse array of inflammatory properties, including increasing vascular permeability, local blood flow, chemotaxis of neutrophils and smooth muscle constriction, and effects on platelets. The different metabolic pathways include mutually antagonistic agents, prostacyclins and lipoxins. Abnormalities of the enzymes of the synthetic pathways for prostaglandins account for the adverse effects of aspirin in some individuals. The pharmaceutical industry has been active in producing inhibitors of leukotriene synthesis, inhibitors of lipoxygenase (Zileuton) and 5-lipoxygenase activating protein being the most effective, while drugs such as monteleukast and zafirlukast are leukotriene antagonists that are effective in asthma but also in urticaria and other inflammatory conditions.

Cellular components

Polymorphonuclear leukocytes (neutrophils) play a critical role in the immediate defence against bacteria. They develop in the bone marrow under the influence of the specific cytokines SCF, IL-3, G-CSF and GM-CSF. The bone marrow contains a large reserve pool of mature cells, which can be released by stress such as infection; 60% of bone marrow capacity is devoted to neutrophil production. Neutrophils remain in the circulation for only a few hours before emigrating into tissues. Abundant expression of leukocyte adhesion molecules, such as L-selectin, P-selectin and cutaneous lymphocyte antigen (CLA), ensures the margination of neutrophils along the endothelial surface. In the presence of activating and chemotactic factors binding to specific surface receptors such as *N*-formylmethionine-containing peptides derived from bacteria, platelet-activating factor (PAF), the chemokines MIP-1α, RANTES and IL-8, and the anaphylatoxins C3a and C5a, adhesion to endothelium occurs. This process involves integrins of the CD11/CD18 family, with subsequent emigration and migration of neutrophils to the site of inflammation, following the chemotactic gradient. Phagocytosis is stimulated by binding of antibody to Fc receptors and complement to complement receptors, leading to the formation of the phagocytic vacuole. Fusion of the vacuole with the primary neutrophil granules then exposes the bacterium to an array of enzymes and bactericidal proteins, including myeloperoxidase, lysozyme, elastase, cathepsin G, proteinase-3, azurocidin and α-defensins. Three types of granule are recognized: specific granules containing the enzymes, gelatinase granules containing predominantly gelatinase and NADPH oxidase, and secretory granules. Inducible enzyme systems also contribute, producing nitric oxide and superoxide. The oxidative burst that forms superoxide is produced by the NADPH oxidase system, a multicomponent enzyme. Genetic deficiencies of the subunits of this enzyme cause the X-linked and autosomal forms of chronic granulomatous disease. In X-linked chronic granulomatous disease (63% of cases) mutations occur in the gp91-phox protein, while the autosomal forms are due to mutations in p47-phox, p22-phox and p67-phox. Myeloperoxidase is responsible for the production of hypochlorous acid, a potent oxidizing agent formed from hydrogen peroxide and chlorine; myeloperoxidase deficiency has been reported and leads to increased infections. Neutrophils have multiple bactericidal pathways, so defects in one pathway

will not necessarily lead to failure to kill bacteria. Neutrophils are also biosynthetically active, secreting an array of cytokines and chemokines, including tumour necrosis factor (TNF)-α, IL-1, IL-12, interferon (IFN)-γ, transforming growth factor (TGF)-β and IL-8, that amplify the inflammatory response.

Neutrophils

Neutrophils express high levels of pattern recognition receptors (PRR) which recognize cell wall components of pathogens, viral DNA and RNA and lipoproteins. These include CD14, the lipopolysaccharide receptor and toll-like receptors (TLR) of which there are a large number. Binding of antigens activates a cell through complex interlinked cascades. Deficiency of components of the TLR cascades has now been identified as causing increased susceptibility to bacterial infection. Neutrophils also express scavenger receptors which bind low density lipoproteins, particularly if they have been oxidized. In mice, deficiency of these receptors can increase susceptibility to staphylococcal infection.

Macrophage–monocytes

Macrophage–monocytes are mononuclear phagocytic cells, also derived from the bone marrow and under similar differentiation control to neutrophils. They are longer lived than neutrophils and are actively migratory, being found in all tissues in the body. Control of migration is similar to that for neutrophils, although there are a range of chemokines specifically involved in recruitment, such as MCP-1, MDC, PF4 and MIP-1α. As well as expressing complement and Fc receptors, enabling them to phagocytose immune complexes, they also express an array of scavenger receptors, including lipopolysaccharide (LPS) and TLR, which bind LPS complexed with soluble CD14. Other TLR bind proteolytic cleavage fragments from the complement and kinin systems. Activation through TLR leads to oxidative burst and release of the cytokines IL-1 and TNF-α, which drive the systemic inflammatory reaction, stimulating the acute phase response and causing pyrexia via effects on the hypothalamus. Macrophages have similar enzyme systems to neutrophils, although the activity of the NADPH oxidase system is lower. Macrophages can act as antigen-presenting cells (APCs) and major histocompatibility complex (MHC) class II antigens on the cell surface are up-regulated by activation. These cells play an essential role in type IV delayed-type hypersensitivity reactions, as part of granuloma formation, often with cell fusion to create multinucleate giant cells. This is mediated through IFN-γ. Mutations in the IFN-γ receptor, leading to either non-expression or expression but loss of function, have been associated with increased susceptibility to mycobacterial infection, due to failure of macrophage function despite good T-cell immunity. Defects in the receptor for IL-12, which is involved in the induction of IFN-γ, also lead to a similar clinical picture.

Macrophages, together with dendritic cells, form an essential bridge between the innate and acquired immune systems. Phagocytosis of antigen by macrophages leads to internalization, digestion of antigen and re-expression of derived peptides on the cell surface bound to MHC class II antigens. This provides essential stimulation to $CD4^+$ T cells. Dendritic cells have direct phagocytic capacity but acquire antigen through transfer from macrophages, with which they form tight complexes during the immune process.

Eosinophils

Eosinophils are derived from the same bone marrow lineage as neutrophils, but differentiate under the influence of IL-5; their main role in host defence is against parasitic infections. Their granules contain: eosinophil peroxidise; the Charcot–Leyden crystal protein, a cytotoxic phosphatase; eosinophil cationic protein (ECP); major basic protein; and eosinophil-derived neurotoxin. The latter is an important mediator of the neuropathy seen in Churg–Strauss syndrome. Eosinophils have surface receptors for IgE (low affinity, CD23), IgG Fc receptors and complement receptors. Recruitment to sites of inflammation is through similar use of selectins and integrins. The anaphylatoxins and PAF are chemotactic and there are specific eosinophil chemoattractants of the chemokine family, eotaxin-2 and eotaxin-3. Activation of an eosinophil leads to an oxidative burst and production of leukotrienes as well as an array of cytokines, including IL-1, IL-6, TNF-α and the chemokine IL-8, thus promoting an acute inflammatory reaction. Release of eosinophil granule components contributes to bronchial damage in asthma, and promotes the chronic phase of inflammation through the release of cytokines active on lymphocytes. MHC class II is expressed, indicating that the cells can also function as APCs.

Mast cells

Mast cells are derived from a distinct lineage of bone marrow cells and express high levels of high-affinity IgE receptors on their surface. Mast cells also express receptors for C3a and C5a, as well as multiple chemokine receptors, ensuring that they are attracted to sites of inflammation regardless of the initiating event. Similar adhesion molecules are expressed as on neutrophils and eosinophils. Their granules contain large amounts of histamine, heparin, tryptase and TNF-α. Cross-linking of the IgE receptor by allergen triggers degranulation. Mast cells produce both leukotrienes and prostaglandins, contributing to the inflammatory response, and also synthesize IL-3, IL-4, IL-5 and GM-CSF. Mast cells in lung and gastrointestinal mucosa can be differentiated from those in skin and gastrointestinal submucosa by the presence of chymase in the latter.

Basophils

Basophils are circulating cells with similar properties to tissue mast cells and have high-affinity receptors for IgE. Despite this, they are derived from the same bone marrow precursor as eosinophils, whereas mast cells are a distinct lineage. Basophils circulate for several days in the bloodstream. They produce leukotrienes but not prostaglandins. Basophils are about 100-fold more sensitive to activation via the IgE receptor compared with mast cells, and are also more sensitive to non-IgE stimuli, including *N*-formyl-methyonyl-leucylphenylalanine (fMLP), C3a and C5a, and phospholipase A. They appear to be involved in the late phase of allergic reactions in tissues and produce IL-4 and IL-13, which increase synthesis of IgE. Interestingly, the release of these

cytokines is dependent on the calcineurin pathway, which can be inhibited by ciclosporin and tacrolimus, accounting for the effectiveness of these drugs in treating allergic reactions.

Natural killer cells

Natural killer cells are large, granular lymphocytes derived from bone marrow precursors. Their granules contain perforin, a cytotoxic protein closely related to complement proteins of the terminal lytic sequence. Although of lymphocyte lineage, these cells do not express CD3/T-cell receptor (TCR) complexes on their surface, nor do they rearrange their TCR genes. Some cells express CD8, but mainly they express CD16, a low-affinity IgG Fc receptor, and CD56, a variant of the neural cell adhesion molecule. They express a range of specific NK-cell receptors, including NKp46 and NKG2D (binds to MHC class I chain-related A and B molecules, MICA and MICB), and cytotoxicity is enhanced by exposure to IL-2. It is thought that the default for NK cells is to kill cells that they come into contact with, unless the cells express sufficient levels of MHC class I antigens to interact with killer-inhibitory receptors (KIRs) expressed on the surface of NK cells. Binding of MHC class I to KIRs is independent of the presence of bound peptide. There are a variety of different KIRs, some of which recognize non-classical MHC antigens (HLA-E, HLA-G). This reactivity explains the abundance of NK cells in the placenta that express high levels of non-classical MHC as they are involved in tolerance to the fetal allograft. Expression of IgG receptors enables them to kill antibody-coated targets via antibody-dependent cell-mediated cytotoxicity. They produce IFN-γ, TNF-α and granulocyte macrophage colony stimulating factor (GM-CSF), contributing to acute inflammation and stimulating T-helper type 1 (Th1) responses in the acquired system (see below). NK cells contribute to tumour surveillance, seeking out cells with reduced class I expression, and also provide protection against viral infections, as viruses often block surface expression of MHC class I antigens, thereby preventing T-cell recognition. Very rare, primary NK-cell deficiency has been reported, with increased susceptibility to all types of herpesviruses. Functional abnormalities of NK cells are seen in the X-linked lymphoproliferative syndrome, due to signalling lymphocyte activation molecule (SLAM)—associated protein (SAP) deficiency, and in Chédiak–Higashi syndrome.

γδ T cells

γδ T cells are thought to represent an evolutionarily early form of T cell and comprise only a minority of T cells, located mainly in mucosae and skin. They never express αβ TCR and even their γδ TCR are of limited diversity and tend to be more cross-reactive. Their pattern of antigen recognition is more in keeping with other cells of the innate immune system. They do not require antigen processing for recognition. MICA and MICB are targets for NKG2D recognition. Effector functions are similar to $\alpha\beta TCR^+$ T cells.

NK T cells

NK T cells are cells with characteristics of both T cells and NK cells and carry a very limited diversity αβ TCR and also express NKG2D receptors and KIRs. They appear to recognize CD1d, a molecule with similarity to MHC antigens, and interact specifically with dendritic cells. Antigens recognized include glycosylsphingolipids. Their effector functions are more in keeping with NK cells but they may also play a role in limiting autoimmunity.

$CD5^+$ B cells

These cells (B1 cells, see below) comprise a small population of very long-lived B cells that are involved in the production of natural antibodies, predominantly IgM class, with a structure close to germ-line configuration, and are broadly polyreactive. The presence of these natural antibodies may facilitate early antibody-mediated opsonization and lysis, before a more specific immune response can develop. These cells thus act as a bridge between the innate and acquired immune systems. Self-reactivity is a problem with natural antibodies and B1 cells are frequently the cell type identified in chronic lymphocytic leukaemia.

Acquired immunity

The key features of the acquired immune system are: (i) the responses are specific to a particular pathogen or antigen; and (ii) there is long-lived immunological memory that persists after the first encounter. This is manifest in the antibody responses to antigen on first exposure, where the response is small and comprises predominantly IgM (primary immune response), whereas re-challenge after a suitable interval leads to a large and predominantly IgG response (secondary immune response). The process is accompanied by an expansion of the antigen-reactive cells, together with the generation of long-lived memory B cells. A similar process takes place in T cells. During the process somatic mutation takes place in the antigen receptors to enhance their affinity for antigen. The immune system is a dynamic surveillance system, with constant recirculation of the constituent cells through the bloodstream, organs and lymphoid tissue. Lymph nodes and spleen remain the primary sites of encounter with antigen-bearing APCs and are also the sites of major antigen-driven proliferation. The recirculation process is tissue-specific and targeted through specific receptors expressed on vascular endothelium.

Components of acquired immunity

The key components of the acquired immune system are the B cells, which produce antibody, and T cells, which serve helper, cytotoxic and regulatory functions. Both have specific receptors based on recombination of multiple genes to give an enormous range of potential specificities. Both cell types use the recombinase-activating genes (*RAG-1* and *RAG-2*) to carry out this process. The antigen receptors on T and B cells differ in their recognition requirements. Antibody binds to conformational epitopes in whole molecules and these will not usually be contiguous, but are represented as surface binding sites on the target molecule. In contrast, the TCR recognizes short linear peptide sequences (7–15 amino acids), only in the context of binding of the peptide to MHC antigens. These linear sequences may be anywhere in the molecule but are usually deeply buried within the structure and not accessible on the surface. This means that B cells can be stimulated by free antigen whereas T cells in the main require processed antigen, presented by APCs such as macrophages and dendritic

cells. As B cells themselves express MHC class II antigens, they can function as APCs, presenting peptides to $CD4^+$ T cells in return for help through T-cell cytokine production. Both T-cell and B-cell antigen receptors occur in clusters with co-receptor molecules, which confer additional recognition functions (complement, MHC class), and transmembrane signalling molecules linked to cascades of intracellular enzymes. Activation signals are usually delivered by phosphotyrosine kinases, while inhibitory signals dephosphorylate tyrosine.

B lymphocytes

B lymphocytes develop in the marrow and then migrate to secondary lymphoid tissue, where they encounter antigen. Antigen-stimulated B cells develop into plasma cells, producing quantities of serum immunoglobulins that are representative of the surface antibody receptor of the cell. B cells exist in two forms, B1 and B2, distinguished by their pattern of surface antigens. B1 cells have low/absent surface IgD, CD45, CD23 and can be $CD5^+$ (B1a) and $CD5^-$ (B1b). B1 cells are long-lived cells, producing naturally occurring low-affinity antibodies, usually IgM, against bacteria and autoantigens. Early in life a high percentage of cells are B1, but this falls with age; however, it is this population that is expanded in most chronic lymphocytic leukaemias. B2 cells are 'conventional' B cells and have high levels of surface IgM and IgD as well as CD45 and CD23, but do not express CD5.

Immunoglobulins

Serum immunoglobulins comprise five classes, IgM, IgD, IgG, IgA and IgE (in order of expression), determined by the heavy chain. Each can have either κ or λ light chains. IgD operates primarily as a surface receptor and has no known function as a secreted molecule. High levels have been associated with a syndrome of recurrent fevers, arthritis and infections (hyper-IgD syndrome) that appears to be caused by a defect in mevalonate kinase. IgM exists as a membrane receptor and as a soluble pentameric form, in which the five IgM molecules are joined by a J chain. IgM is the antibody produced in the first phase of an immune response. IgG exists as four subclasses, and comprises, by concentration, the major serum immunoglobulin. IgG1 and IgG3 are mainly antiprotein antibodies, while IgG2 is mainly antipolysaccharide. IgG4 is present only in low concentrations and its precise role is uncertain, although deficiency of it and other subclasses do not necessarily give rise to clinical disease; measurement of IgG subclasses is therefore not a useful predictor of underlying humoral immune deficiency. In Sjögren's syndrome, IgG1 is preferentially increased in the polyclonal elevation of IgG seen in this condition; the other subclasses are relatively reduced. IgA exists in two forms, IgA1 (the predominant serum form) and IgA2. IgA is the antibody of mucosal surfaces, and is secreted in the form of dimers and trimers, with an associated J chain. In the process of secretion, which involves active transport through the epithelial cells mediated by the poly Ig receptor, a secretory piece is added, which slows the rate of breakdown. Secretory piece deficiency has been reported very rarely. In the absence of IgA, IgG and IgM can be transported to the mucosal surface and provide effective protection. Thus selective IgA deficiency may be asymptomatic in respect of infection, although it increases the risk of developing a range of autoimmune diseases, including coeliac disease and connective tissue diseases. IgE is primarily involved in antiparasite immunity, acting as a passively adsorbed receptor on mast cells and basophils. Serum concentrations are extremely low in comparison with the other classes of immunoglobulins.

T lymphocytes

Mature T cells develop in the thymus from T-lineage committed precursors derived from bone marrow. In the thymus, the process of development of functional TCRs takes place in an analogous way to the process in B cells. As well as the TCR, the cells also develop the co-receptor molecules of the CD3 complex (five separate chains) and CD4 and CD8 surface expression. In the periphery, T-cell function is defined to a certain extent by expression of CD4 and CD8, which define the class of MHC recognized. $CD4^+$ T cells are 'helper-effector cells', which recognize predominantly MHC class II antigens and thus interact mainly with a restricted array of MHC class II-positive cells, such as B cells and APCs, or other cells which may have induced class II, for example thyrocytes during thyroiditis. Functions ascribed to $CD4^+$ T cells include provision of T-cell help through cognate interactions and cytokine release to B cells and also cytotoxicity towards class II-bearing targets. $CD8^+$ T cells recognize MHC class I antigens, which are expressed on all cells except erythrocytes, and are particularly involved in the recognition of virally infected targets. These cells are actively cytotoxic, using the same enzymes found in NK-cell granules (perforins and granzymes). T cells also perform regulatory functions, cross-suppressing other types of T cells (see below).

Structure and development of the immune system

Although diffused throughout the body, the immune system functions as an integrated organ in much the same way as the nervous system, with which it shares a number of key molecular concepts. However, the immune system has an enormous task as the surface area of the skin is about 2 m^2, that of the lung 100 m^2 (the size of a soccer pitch) and that of the gastrointestinal tract 400 m^2 (four soccer pitches!). The mucosal surfaces have to be 'painted' with a contiguous film of secreted IgA. This explains why the total daily production of IgA is tenfold higher than that of IgG, even though the serum level of IgA is five times less than that of IgG.

Primary lymphoid tissue

The primary lymphoid tissue comprises the sites in which lymphocytes and other cells involved in immunological function develop. In humans this comprises the yolk sac and fetal liver during embryogenesis, with seeding of pluripotent precursors to the bone marrow. These stem cells may be either $CD34^+$ or $CD34^-$, although in clinical transplantation CD34 is used to enrich for stem-cell activity. B-cell development takes place in the bone marrow while committed T-cell precursors, which are $CD7^+$, migrate to the thymus. In birds the bursa of Fabricius and in lagomorphs the sacculus rotundus and the appendix are specific organs involved in the generation of B cells and are analogous to the thymus. However, humans do not appear to have homologous structures. In all these organs there is a complex interaction

between stromal epithelium and developing immunocytes, with production of key growth factors by the epithelial cells and presentation of self-antigens involved in tolerance induction.

B-cell development takes place in the bone marrow in humans, with 10^9 new B cells produced each day. During the process of B-cell development, the immunoglobulin genes undergo rearrangement to form the basis of the enormous repertoire of antibodies. This process is dependent on the presence of the recombinase enzymes *RAG-1/RAG-2*. Recombination occurs first in the heavy-chain genes, involving the V, D and J regions. There is a significant wastage as 50% of cells fail to produce viable recombinations. Initially the cells produce a membrane form of the μ heavy chain, which appears on the surface, coupled with the surrogate light chains, V pre-B and λ5. At the same time the invariant chains Igα and Igβ are also produced and combine on the surface as part of the receptor complex. The role of the surrogate light chains is purely to allow expression of the heavy chain and to permit the continued development of the B cell, with recombinations of the κ and λ light chains, and the expression of a fully formed receptor. During this process, the other components of the receptor complex (CD19 and CD21) also appear, and cells become dual positive for surface IgM and IgD. B-cell development is a complex process, and defects in some of the essential enzymes and genes have been identified as causing primary immunodeficiencies. These include deficiencies of surrogate light chain, μ chain, Igα BLNK (B-cell linker protein) and BTK (B-cell tyrosine kinase), which give B-lineage specific defects, while *RAG-1/RAG-2* defects cause severe combined immunodeficiency (SCID) due to their involvement in TCR rearrangement. Use of knock-out mice has enabled rapid strides to be made in the assessment of the enzymes critical to B-cell development. It is likely that further genetic abnormalities will be described in humans.

Within the thymus, committed T-cell precursors undergo rearrangement first of their TCR β genes; *RAG-1/RAG-2* are critical for this process. In order for the gene product to be expressed a surrogate α chain, invariant TCR pre-α, is produced that permits the next stage of α-chain rearrangement. A small proportion of cells express γδ TCR rather than αβ TCR. Failure to rearrange a functioning β chain leads to cell death. It has been calculated that the process of gene rearrangement can lead to 10^8 potential recombinations. Numerous genes are involved in the control of this process, including *Ikaros* and *Notch-1*. During this process, expression of CD44 (hyaluronate receptor) is lost and expression of CD25 (low-affinity IL-2 receptor) is gained. Cells then express CD3 and both CD4 and CD8 (dual-positive cells), and lose one or the other as development proceeds to become either $CD4^+$ or $CD8^+$ T cells. The enzyme ZAP-70 kinase is essential to this process and its genetic deficiency leads to failure of production of $CD8^+$ T cells and reduced numbers of $CD4^+$ T cells; this disorder is a variant of SCID. T cells leave the thymus in a naïve state. During the process of T-cell development two key events take place: positive selection of T cells that recognize self-MHC and negative selection of those that recognize self-peptides. As the recombination process is essentially random, the majority of developing T cells do not develop appropriate TCRs. Cells that do not recognize MHC die by 'neglect' while those that recognize self-peptides are stimulated to proliferate and die (activation-induced cell death or apoptosis). Accordingly, the thymus has a huge turnover of T cells, the majority of which die *in situ*. Any failure in the process of eliminating self-peptide reactive T cells contributes to later development of autoimmune disease.

Failure of thymic development has been described and is due to as yet uncharacterized gene defects located at chromosome 22q11, which control the development of the branchial arches and pouches; this leads to failure of T-cell production as well as cardiac abnormalities. The severe form with immunodeficiency is recognized as DiGeorge syndrome, analogous to the nude mouse mutation. However, milder variants without immunodeficiency are also identified: velocardiofacial syndrome and conotruncal anomaly face syndrome.

Although early dogma denied the possibility of extrathymic generation of T cells, it is now clear that certain specific classes of T cells can develop independently of the thymus. These include intestinal intraepithelial lymphocytes, which are usually γδ TCR^+ and often express an unusual homodimeric αα CD8. Extrathymic γδ TCR^+ cells appear to have specificity for non-protein phosphate containing antigens, particularly triphosphate nucleic acids and hydrocarbon phosphates derived from mycobacteria. Recognition of these antigens does not appear to require conventional processing and the cells can recognize whole antigen.

Secondary lymphoid tissue

Spleen

The largest lymphoid organ is the spleen, containing about 25% of the body's lymphocytes, and comprises white pulp surrounding central arterioles (peri-arteriolar lymphoid sheath) and red pulp through which blood is filtered. Red pulp contains sinusoids with abundant macrophages, which are important in stripping off immune complexes bound to the surface of red blood cells and also for removing aged red blood cells. The white pulp comprises both T and B cells and also contains follicles consisting mainly of B cells. In primary follicles the B cells are predominantly resting cells, whereas in secondary follicles a change in morphology identifies the presence of germinal centres, where active B-cell development takes place in response to antigenic stimulation. This process is stimulated by the presence of APCs and activated T cells expressing high levels of CD40 ligand (CD154). The marginal zone occurs at the interface of red and white pulp and contains a distinct population of B cells, expressing surface IgM but little IgD.

Lymph nodes

Lymph nodes occur in chains beginning at the extremities and are linked by lymphatic channels that eventually coalesce to form the thoracic duct, which drains into the left subclavian vein. Flow along the lymphatics is centripetal, draining lymph-containing antigen, inflammatory mediators and cells to regional lymph nodes and thence to the general circulation. Lymph enters the cortex of the node, filtering through the kidney-shaped node to leave by the medulla. The cortex comprises the mainly B-cell area with primary and secondary follicles, as in the white pulp of the spleen, while the medullary area comprises mainly T and B cells in the process of emigration from the node. However, T cells and APCs are spread through the whole structure of the lymph node

and the paracortical area surrounding the B-cell follicles is rich in T cells, macrophages and dendritic cells. Specialized follicular dendritic cells are found in the follicles and are responsible for holding antigen on their surface to provide continuous stimulation of B cells recruited into the follicle. These cells have abundant Fc receptors for IgG and use passively bound antibody to sequester antigen in abortive endocytic vacuoles called iccosomes, which protect it from proteolytic degradation. This feature explains why antibody levels decline but not usually to zero after a secondary immune response, as there is continuous restimulation from the sequestered antigen.

Specialized lymphoid tissue is present in the upper respiratory tract, including the tonsils and adenoids (Waldeyer's ring). These are particularly rich in B cells and have a structure similar to lymph nodes. Absence of tonsillar tissue in a small child should always raise suspicion of a B-cell deficiency, particularly a genetic abnormality such as X-linked agammaglobulinaemia, in which mature B cells cannot be produced. The tonsils atrophy in early adult life and it is most unusual to see persistent tonsillar tissue in adults over the age of 25 years. The gut is well supplied with lymphoid tissue in the form of Peyer's patches, located in the lamina propria, particularly around the ileum, and containing many follicles. Isolated follicles also occur scattered through the lamina propria. The surface epithelium overlying the follicles and Peyer's patches is modified with the presence of M cells, which take up particulate antigen and express MHC class II antigens. Peyer's patches contain all the elements found in peripheral lymph nodes, except that a high proportion of the differentiated B cells express IgA. As well as the defined structures, the lamina propria also contains large numbers of free-ranging lymphocytes, including IgA^+ B cells, and specialized intraepithelial lymphocytes, mainly $CD8^+$ or $CD4^-CD8^-$ T cells, γδ T cells and NKT cells. There is an increased proportion of γδ TCR^+ cells with cytotoxic activity. The lymphoid structure in the lower respiratory tract is less well developed, although small aggregates similar to Peyer's patches may be found. The difference is related to the burden of microbes in the two sites, as the lung under normal conditions is relatively free of infection, with most foreign material trapped in the upper airway or removed by the mucociliary escalator.

In the skin, Langerhans' cells are scattered through the epidermis. These are potent APCs, migrating in the lymph to the regional lymph nodes to stimulate B and T cells and secreting IL-1 and chemokines. Keratinocytes are also directly involved in immune responses through the production of cytokines, including IL-1, IL-6, TNF-α and TGF-β. As noted below, blood vessels in the skin express specific receptors for recruiting skin-homing lymphocytes that express CLA.

Lymphocyte trafficking

A key feature of immune function is the traffic of lymphocytes and other cells involved in the immune response from sites of storage or rest to sites of inflammation. As an estimate of the size of the population of cells on the move, the total number of lymphocytes is estimated at 10^{12} while 10^{11} are in circulation at any one time. Recruitment of lymphocytes into secondary lymphoid tissue occurs through specialized vessels in lymph nodes, the high endothelial venule (HEV); 80% of the lymphocytes enter lymph nodes using the HEV, with the remaining 20% arriving in afferent lymph from tissues. Entry is controlled by expression of L-selectin (CD62L) on the lymphocyte and its cognate receptor on the HEV. The integrins of the lymphocyte function associated antigen (LFA-1) family are also crucial in neutrophil trafficking but are less so for lymphocytes, which can use other cognate pairs; clinical deficiency of LFA-1 family members leads to an inability of neutrophils to leave the circulation. A range of different receptors occurs on lymphoid tissue in different tissues and the skin that allow selective recruitment of either naïve cells or cells that have been primed to antigens occurring in these locations. For example, binding of L-selectin to the mucosal addressin MAdCAM causes recruitment of naïve cells to Peyer's patches, while the interaction of an $\alpha_4\beta_7$ integrin with MadCAM and vascular cell adhesion molecule (VCAM)-1 recruits naïve cells to Peyer's patches but memory cells to the lamina propria of the gut. Interaction of CLA and E-selectin on endothelium in skin recruits memory cells to the skin. Binding of lymphocyte very late antigen (VLA)-1 to VCAM-1 attracts lymphocytes to inflammation, as does interaction of lymphocyte-expressed CD44 with hyaluronate. Chemokines and their receptors are also involved, such as secondary lymphoid chemokines, which bind to T cells bearing CCR7; fractalkine, expressed on HEV is also a potent chemoattractant for T cells. T and B cells have discrete and non-overlapping patterns of chemokine responses, and are therefore recruited to different areas within the lymph nodes. Many other molecules involved in cellular adhesion have been identified and it is thought that other molecular pairs exist which confer additional tissue specificity on lymphocytes. Once memory cells are recruited in one area, they are thought to retain that homing response for the reminder of their life.

As well as deficiencies of LFA-1 such as leukocyte adhesion molecule deficiency (LAD)-1, clinical examples of other adhesion molecule deficiencies have been described. LAD-2 is caused by a defect in fucosylation that leads to an inability of the receptors for selectins to bind to their cognate molecules, causing recurrent infections, neutrophilia and mental retardation. These patients can be treated successfully with oral fucose. A clinical deficiency of E-selectin has also been described, with recurrent infections but no neutrophilia.

Lymphocyte function, activation and regulation

Antigen presentation

Professional APCs, including macrophages and dendritic cells, undertake antigen presentation to T cells and B cells that express MHC class II antigens constitutively and to other cells on which class II can be induced by inflammation. Although dendritic cells are not phagocytic, they can take up processed antigen transferred from macrophages via pinocytosis in clathrin-coated pits and receptor-mediated endocytosis. Antigen presentation through the class II (or exogenous) pathway targets antigen to the $CD4^+$ T cells. Newly synthesized class II molecules are directed to the endosomal compartment by the invariant chain Ii where they are loaded with peptides. A peptide sequence in Ii called CLIP blocks the peptide-binding groove in the class II molecule until it reaches the endosome, where the enzyme DM removes it. The peptide-binding groove in class II is open-ended, allowing peptides to

overhang the ends, provided that the correct sequence binds in the middle. Once loaded, the class II molecule is transferred to the cell surface. The process is a continuous one, and class II is recycled off the surface and can be reloaded with peptide.

Antigen presented via the class I (or endogenous) pathway is loaded in a different compartment, the endoplasmic reticulum, with proteolysis taking place in proteosomes in the cytosol and governed by ubiquitin. The peptide-binding groove on class I has closed ends, which means that the peptide has to be exactly the right length and sequence to bind. Trimming of over-length peptides is carried out in the cytosol by leucine aminopeptidase. The proteins involved in peptide loading are the TAP (transporter associated with antigen processing) proteins. Once correctly loaded, the class I molecule is inserted in the endoplasmic reticulum membrane in association with calnexin and then with β_2-microglobulin. Finally, a large multi-molecular complex is formed and transported to the Golgi body and then to the surface membrane. Any class I molecules not loaded with peptide are destroyed prior to transfer to the Golgi. Evidence for recycling is less clear than for class II.

A third pathway of antigen presentation exists, based on the non-MHC molecular family CD1, which is coded separately from MHC but has similarities to class I, including the use of β_2-microglobulin as a light chain. CD1 molecules also present antigen to T cells, although the antigens are predominantly lipids, particularly those derived from mycobacteria. At least four isoforms are known, each with different lipid specificities. Loading of CD1 molecules with lipid takes place in the endocytic pathway.

B cells

Mature B cells leaving the bone marrow circulate through the blood and tissues or enter lymph nodes directly via HEVs, where they form the follicles. On encounter with antigen and with T cells recognizing components of the same antigen, B cells are stimulated to proliferate and to develop further to plasma cells. Two further key processes are involved: class switching, in which the B cell changes the heavy chain associated with a given antibody binding specificity; and somatic hypermutation, which permits an increase in affinity of the antibody (affinity maturation).

Class switching allows the immune system to develop IgG and IgA responses from the initial primary IgM response. This process depends on the interaction of CD40 on the B cell with CD40 ligand (CD154) on activated T cells. Genetic defects in CD154 lead to the X-linked hyper-IgM syndrome, where there is failure of the class switch and IgG and IgA antibody are not produced but high levels of IgM are produced. Deficiency of CD40 itself causes a similar but autosomal disease. CD40 is also expressed on APCs and hence T-cell function is also impaired, leading to the typical occurrence of opportunistic infections such as *Pneumocystis jiroveci* pneumonia and cryptosporidiosis. One of the enzymes involved in class switching is activation-induced cytidine deaminase (AID); mutations in this enzyme give rise to autosomal hyper-IgM syndrome. Other enzymes involved are the Ku family of DNA phosphokinases, which are targets in the autoimmune process in systemic lupus erythematosus (SLE).

Affinity maturation only takes place in B cells proliferating in the germinal centres, and occurs at hotspots within the variable regions of heavy and light chains, targeting residues that form part of the antibody-binding site. The process is random, and it appears that the enzyme AID is also involved in this process. The process is actively driven by exposure to antigen: cells that hypermutate to produce antibodies of lower affinity are less stimulated and will therefore cease to proliferate, whereas those with higher affinity will continue to receive positive feedback stimuli.

Memory B cells have a different phenotype from naïve B cells, expressing high levels of CD27, a member of the TNF-receptor gene family. Conversion to memory phenotype is dependent on the CD40–CD40 ligand interaction in the presence of IL-4. Subsequent activation of memory B cells can take place through interaction of CD27 with its ligand, CD70, expressed on activated T cells; IL-2 and IL-10 augment this process. Naïve B cells can be induced to form plasma cells through OX40 and its interaction with OX40 ligand on T cells.

B-cell responses to antigen have been divided on the basis of requirement for T-cell help. T-dependent antigens include most proteins; T-independent (TI) antigens are mostly polysaccharide antigens. TI-1 antigens include LPS and endotoxin, which at low doses stimulate B cells directly to produce specific antibody, but at high doses stimulate polyclonal B-cell proliferation through interaction with specific receptors. T-independent type 2 (TI-2) antigens such as capsular polysaccharides only stimulate specific antibody production. For all TI responses, however, responses are greater in the presence of T cells, so T-cell independence is relative.

Regulation of B-cell activation takes place through negative feedback loops of cytokines produced by activated B cells. It is also thought that the production of idiotypic antibodies, that is antibodies that bind to the antigen-binding site of other antibodies, form complex regulatory networks that down-regulate antibody production. Rheumatoid factors are antibodies that recognize the Fc regions of other antibodies; these also appear during infections and are thought to play a role in control of the immune response, presumably by forming immune complexes, which are known to switch off antibody production when present in high concentrations. This explains why antibody responses to antigens are reduced in small children when maternal antibody is still present. This normal occurrence of rheumatoid factors during the immune response explains why measurement of rheumatoid factors as a diagnostic screening test is usually unhelpful unless a patient has clinical signs of rheumatoid arthritis.

T cells

Recent T-cell emigrants from the thymus are naïve and are distinguished by expression of high levels of CD45RA. After antigen exposure, the phenotype changes, with reduction in CD45RA and expression of CD45RO. CD45RA and CD45RO are isoforms of the leukocyte common antigen CD45 and are generated by alternate splicing of the RNA transcript. Exposure to antigen via the TCR/CD3 complex must occur in the context of the appropriate co-stimulatory molecules for T-cell activation to occur. If exposure to antigen occurs in the absence of co-stimulation, then non-responsiveness to the antigen is generated (anergy) or the cell is switched to the apoptotic pathway. The best-known co-stimulatory molecule is T-cell CD28. This interacts with B7.1

(CD80) and B7.2 (CD86) expressed on APCs. As noted above, interaction between CD40 and CD40 ligand is also important. Inducible co-stimulator (ICOS) is another T-cell co-stimulatory molecule that interacts with B7RP-1 to activate T cells. Conversely, a related T-cell molecule, cytotoxic T lymphocyte-associated antigen (CTLA)-4, binds to B7.2 and leads to inhibition of T-cell activation. Surface receptors for cytokines are also required for T-cell activation. Mutations in the common γ chain for cytokine receptors lead to SCID. The intracellular kinase cascade is complex, and is being unravelled through studies on knock-out mice and human genetic immunodeficiencies. The kinase JAK-3, linked upstream to cytokine receptors and downstream to signalling transduction and activator of transcription (STAT) kinase, is critical since defects in this molecule also lead to SCID. Other defects in intracellular signal transduction occur in Wiskott–Aldrich syndrome, where mutations in the *WASP* gene interfere with signalling through the rho-GTPases; ataxia telangiectasia, in which a phosphatidylinositol 3-kinase is defective; and the X-linked lymphoproliferative syndrome in which the defect is in the SAP protein. Intracellular calcium is essential for activity of some of the kinases and this is controlled via the calcineurin pathway, which provides the target for ciclosporin and tacrolimus, immunosuppressive drugs that prevent T-cell activation.

Apoptosis plays a key role in the control of lymphocyte activation and the prevention of autoimmunity. Two processes exist: apoptosis triggered by lack of signals (intrinsic cell death pathway, controlled by Bcl) and apoptosis triggered by activation via CD95. CD95 is expressed on T cells activated via the TCR/CD3 complex. Interaction of CD95 ligand with CD95 (fas) on the T cell activates the caspase pathways and leads to DNA fragmentation. The importance of this pathway is demonstrated in the Canale–Smith syndrome, in which there are defects in the apoptotic pathways at the level of either CD95 or the caspases. The syndrome is characterized by excessive, uncontrolled lymphoproliferation accompanied by features of autoimmunity.

$CD4^+$ Th cells have been divided on the basis of cytokine production, and latterly chemokine receptor expression, into Th1 and Th2 cells. Th1 cells are involved primarily in 'help' for cytotoxic or cell-mediated T-cell responses, while Th2 cells are predominantly responsible for the support of antibody-mediated responses, including IgE-mediated allergic responses. There is cross-regulation of the two subsets, with Th1 cytokines down-regulating Th2 cells and vice versa. Th1 cells produce IL-2 and IFN-γ, while Th2 cells produce IL-4, IL-5, IL-9, IL-10 and IL-13. Th1 responses require signalling through the IL-12 receptor and the IFN-γ receptor; in the absence of function in these pathways, Th1 responses essential for handling mycobacteria are abolished and recurrent infection occurs. Polarization of naïve $CD4^+$ T cells to either a Th1 or Th2 response occurs through the release of cytokines from the cells of the innate system, such as macrophages, NK cells, mast cells, eosinophils and basophils. Conversely, the cytokines released by activated Th1 and Th2 cells further stimulate the innate cells. IL-9 appears to have an important role in governing the class switch in B cells to IgE production. In evolutionary terms, the Th2–IgE axis plays an important role in the control of parasitic infections, particularly worm infections of the bowel. One proposal for the increasing prevalence of allergic disease suggests that the disappearance of parasitic worm infections in developed countries releases the IgE system to respond inappropriately to other antigens.

$CD8^+$ cytotoxic T (Tc) cells have also been divided into two populations based on cytokine production: Tc1 produce IFN-γ, while Tc2 produce IL-4 and IL-5. Two discrete mechanisms are used by Tc cells for killing targets recognized via interaction of target cell class I with the CD3/TCR/CD8 complex. Co-stimulation is required for optimum killing activity, especially via CD2 and LFA-1 (CD11a/CD18). The first pathway triggers cell death in the target using the fas–fas ligand pathway of apoptosis, as discussed above. The other pathway uses granzyme and perforin, exocytosed from granules in the Tc. Perforin forms pores in the target cell membrane and allows the entry of granzymes into the cell, which completes cell destruction. Under certain circumstances $CD4^+$ T cells can also be shown to possess cytolytic activity.

Other classes of T cells have been described that play an important role in down-regulation and control of activated T cells. These include Th3, Tr1 and T regulatory (Treg) cells, not to be confused with the old concept of 'suppressor cells'. The role of CTLA-4 in inhibiting activation has already been noted. IL-10 and TGF-β produced by these T cells is also inhibitory. The best documented population of Treg cells is CD4+CD25+FoxP3+; L-selectin and OX-40 are also expressed. FoxP3 is expressed specifically on Treg in the thymus and in the periphery, but is not expressed on other types of T cells. Deficiency of this type of T cell is seen in the IPEX syndrome, an immunodeficiency with high levels of autoimmune diseases.

Overview of immunological disease

Immunological disease can arise as a result of genetic deficiency of key components, hyperreactivity (allergy/hypersensitivity), immune deviation (autoimmunity) and immunological malignancy. In addition, there are changes in immunological function arising from extremes of age, malignancy in other organs, pregnancy and environmental exposures (e.g. cigarette smoke, drug administration).

Understanding immune-mediated disease is dependent on understanding both the development and function of the immune system. However, multiple mechanisms may be active. For example, in primary immunodeficiencies due to genetic defects, there is often aberrant immunological development that leads to autoimmunity and eventually in many cases to lymphoid malignancy.

Immunodeficiency

Immunodeficiency is subdivided into primary and secondary (Tables 13.1–13.3). Over the last 10 years an increasing number of genetic abnormalities of the immune system have been described. A key feature is the lack of correlation between the genetic abnormalities and the clinical phenotype. In some cases this is due to redundancy within the immune system, allowing compensatory mechanisms to provide protection. Some immunological diseases that are classified as 'primary' do not yet have a clearly defined genetic basis, such as common variable immunodeficiency,

Table 13.1 Summary of major immune defects (not exhaustive).

B-cell defects
X-linked agammaglobulinaemia
μ-chain deficiency; surrogate light-chain deficiency
SWAP-70 deficiency
Hyper-IgE syndrome (includes secondary neutrophil disorder)
CD79a (Igα chain) deficiency
BLNK deficiency
ICOS deficiency
TACI deficiency
T-cell defects
Wiskott–Aldrich syndrome (*WASP* gene mutations)
Ataxia telangiectasia (*ATM* mutations)
Chronic mucocutaneous candidiasis (AIRE, FoxP3 deficiency)
X-linked hyper-IgM (CD40 ligand deficiency); autosomal hyper-IgM syndrome (multiple defects)
Cartilage–hair hypoplasia
Idiopathic $CD4^+$ T-cell lymphopenia
Combined defects
Severe combined immunodeficiency (*RAG-1*/*RAG-2* mutations, common γ-chain deficiency; CD3ε deficiency)
Adenosine deaminase deficiency
Purine nucleoside phosphorylase deficiency
DNA repair defects (DNA ligase IV); Bloom's syndrome; xeroderma pigmentosum
Canale–Smith syndrome (autoimmune lymphoproliferative syndromes; fas, fas-ligand, caspase deficiencies)
X-linked lymphoproliferative syndrome (SAP deficiency; includes NK disorder)
MHC class I and MHC class II deficiency
Neutrophil defects
Chronic granulomatous disease (X-linked, autosomal)
Cyclic neutropenia
Leukocyte adhesion molecule deficiency (LAD-1, LAD-2)
Chédiak–Higashi syndrome (including NK cells)
Complement defects
C1–9 deficiency, properdin deficiency
C1-esterase inhibitor deficiency
C4-binding protein deficiency
Factor H deficiency
Chemokine deficiency
WHIM syndrome (CCR7 deficiency)
Toll Receptor Pathway deficiencies
STAT-1 deficiency
IRAK-4 deficiency
Interferon-γ receptor deficiency
Unclassified
Common variable immunodeficiency
Selective IgA deficiency
Specific antibody deficiency
Hyper-IgD syndrome (mevalonate kinase deficiency); periodic fever syndromes (TNF-receptor associated protein deficiency)

selective IgA deficiency and specific antibody deficiency. Most primary immunodeficiencies are rare, in contrast with secondary immunodeficiency, which is common and becoming increasingly so due to widespread use of immunomodulating drugs to control immune-mediated disease.

Primary immunodeficiency

Primary immunodeficiency is defined as immunodeficiency due to genetic defects or where no secondary cause can be identified. Advances in molecular genetics over the last 10 years have meant that clinically well-described syndromes have been identified genetically, increasing our understanding of the immune system through natural knock-out experiments. This has also led to a re-evaluation of some diseases, for example X-linked hyper-IgM syndrome, previously thought to be a B-cell defect, is now known to be a T-cell defect impairing B-cell development.

The type of cell or protein affected by the defect determines the likely clinical sequelae. In most cases this will include infection, although other problems such as autoimmunity and malignancy also arise.

Investigation for primary immunodeficiency is an increasingly complex field and specialist advice from an immunologist interested in this type of disorder is required at an early stage to assist with both diagnosis and management.

Secondary immunodeficiency

Secondary immunodeficiency represents the most likely type of immunodeficiency that will be encountered by clinical practitioners. The causes are extensive but can be categorized according to primary triggers. In most cases the effects are on T and B cells, although some triggers lead to damage to neutrophils and other parts of the innate immune system, leading to a more complex immunodeficiency. The dermatological manifestations tend to be cutaneous infection and an increase in cutaneous neoplastic change, often at multiple sites. Investigation may be required to prove the cause, but in most cases identification of the primary cause is enough to explain the problem.

Autoimmunity and allergy (hypersensitivity)

These represent overactivity of the immune system. In the case of allergy this is directed against external antigens (allergens), while in autoimmunity the targets are host antigens. Gell and Coombs originally classified the pathogenic mechanisms and no one has produced a better classification since (Table 13.4). However, it is worth noting that pathological reactions frequently involve more than one mechanism so the classification represents a simplification of the true nature of immunological disease.

Allergic disease

Atopic disease in particular is now thought to be a complex phenomenon, with both immediate type I and delayed type IV mechanisms active at different times within the evolution of the disease process. This applies particularly to asthma and has important ramifications for therapy. Previously, treatment has focused on the immediate responses in the airway, while ignoring the T-cell-mediated damage, which is not apparent until secondary lung fibrosis occurs due to T-cell-stimulated collagen deposition. Thus although good initial control is obtained, the disease gradually progresses to irreversible lung disease. Adapting treatment to deal with all the pathogenic mechanisms involved is therefore critical.

In clinical practice, classification of a disease is dependent on demonstrating the presence of appropriate components of the

Table 13.2 Dermatological consequences of some primary immunodeficiencies.

	Key clinical features	Dermatological features
B-cell defects		
X-linked agammaglobulinaemia	Bacterial infections of upper and lower respiratory tracts, joints, gastrointestinal tract	Cutaneous bacterial infection
Common variable immunodeficiency	Bacterial infections of upper and lower respiratory tracts, joints, gastrointestinal tract; autoimmunity; granulomatous disease, lymphoma; nodular lymphoid hyperplasia	Cutaneous bacterial infection, vitiligo, alopecia, cutaneous granulomas
Hyper-IgE syndrome	Eczema, staphylococcal infections of skin and lung (pneumatoceles), osteopenia	Extensive impetigo, recurrent boils
T-cell defects		
Chronic mucocutaneous candidiasis (including APCED: autoimmune polyendocrinopathy, candidiasis and ectodermal dysplasia, due to *AIRE* gene mutations)	Chronic candidiasis; endocrinopathy; systemic infections with bacteria, mycobacteria and herpesviruses	Candidiasis of nails, Norwegian scabies
Wiskott–Aldrich syndrome (mutations in *WASP* gene)	Thrombocytopenia, small platelets, recurrent bacterial and viral infections, eczema, lymphoma	Eczema (distribution atypical compared with atopic eczema); often infected; cutaneous viral infections, papillomavirus, molluscum contagiosum (both extensive)
Ataxia telangiectasia	Cerebellar ataxia (progressive), cutaneous telangiectasia, viral and bacterial infections	Cutaneous viral infections, papillomavirus, molluscum contagiosum (both extensive); telangiectasia (conjunctivae, ears especially)
Cartilage–hair hypoplasia	Short-limbed dwarfism, fine hair, recurrent bacterial infections	Abnormal (fine) hair
Combined immunodeficiencies		
Severe combined immunodeficiency (all variants)	Early onset of infections: bacterial, viral, fungal	Rashes (Omenn variant, maternofetal engraftment)
DNA repair defects (xeroderma pigmentosum, Nijmegen breakage syndrome)	Malignancy, recurrent infections	Keratoses, cutaneous malignancy
Neutrophil disorders		
Chronic granulomatous disease	Bacterial and fungal infections	Cutaneous bacterial infections, ulceration of mouth
Cyclic neutropenia	Bacterial and fungal infections	Cyclic mouth ulceration (gingivitis)
Rare disorders		
Chédiak–Higashi syndrome and Griscelli's syndrome	NK cell defect, abnormal neutrophils, recurrent infections, lymphohistiocytosis	Silver streaks in hair, oculocutaneous albinism
Dyskeratosis congenita	Malignancy, bone marrow failure, recurrent infections (bacterial) with hypogammaglobulinaemia	Cutaneous pigmentation, nail dystrophy, oral leukoplakia
Anhidrotic ectodermal dysplasia	Respiratory infections	Hypohidrosis, abnormal dentition
Papillon–Lefèvre syndrome	Recurrent bacterial infections, impaired neutrophil function	Hyperkeratosis and pyoderma
Complement disorders		
C2 deficiency	SLE-like disease, recurrent bacterial infections	Extensive cutaneous lupus erythematosus
C1-esterase inhibitor deficiency	Angio-oedema	Angio-oedema without urticaria
C4-binding protein deficiency	Angio-oedema, features of Behçet's syndrome	Angio-oedema, ulceration

NK, natural killer; SLE, systemic lupus erythematosus.

immune response, such as allergen-specific IgE, autoantibodies and complement abnormalities. However, detection of abnormal T cells is more difficult, except in the context of patch-testing for contact hypersensitivity.

The development of allergic disease is multifactorial. In principle, however, allergens are no different to any other antigen in the way in which they are processed and presented to T cells. The propensity to develop a Th2–IgE response appears to be genetically controlled, although more than one gene is involved. Candidate genes include those for the Th2 cytokines IL-4, IL-5 and their receptors, IgE and MHC antigens. Allergic reactions are commoner in developed countries, although allergic sensitization occurs in all populations. However, in communities in developing countries it appears that the cytokines produced as a result of endemic infections suppress the clinical manifestations of allergic disease. Where food allergens are concerned, it appears that

Table 13.3 Causes of secondary immunodeficiency.

Infection
Human immunodeficiency virus
Epstein–Barr virus and other herpesviruses
Measles, rubella, influenza
Chronic bacterial sepsis, tuberculosis
Parasitic and protozoal infections

Drugs
Immunosuppressive drugs: corticosteroids, cyclophosphamide, azathioprine, ciclosporin A, tacrolimus, sirolimus, mycophenolate (all affect T- and B-cell function)
Biologicals: anti-CD3, anti-CD4, anti-CD52, efalizumab, alefacept anti-TNF (etanercept, infliximab, adalimumab)
Anticonvulsants: phenytoin, valproate, carbamazepine (hypogammaglobulinaemia, neutrophil dysfunction)
Carbimazole (agranulocytosis)
Chloramphenicol, penicillins (aplastic anaemia)
Transfusion therapy (blood components, including intravenous immunoglobulin)

Malignancy
Lymphoma, leukaemia, myeloma and other plasma cell dyscrasias, myelofibrosis (neutrophil dysfunction)
Solid tumours

Physical
Irradiation
Plasmapheresis, immunopheresis
Surgery (especially if thoracic duct damaged)

Medical/metabolic
Diabetes mellitus, glycogen storage disease (neutrophil dysfunction)
Chronic renal failure
Protein-losing enteropathy
Myotonic dystrophy
Nutritional deficiency (iron, zinc, vitamin B_{12})

Miscellaneous
Asplenia
Burns
Toxins (alcohol, cigarettes, solvents)
Extremes of age (prematurity, old age)
Pregnancy

TNF, tumour necrosis factor.

Table 13.4 Gell and Coombs classification of immunological reactions.

Gell and Coombs classification	Immunological mechanisms	Examples of clinical disease
Type I (immediate hypersensitivity)	Allergen-specific IgE, mast cells, histamine, leukotrienes, Th2 cells, cytokines involved in IgE production (IL-4), eosinophil production (GM-CSF, IL-3, IL-5)	Anaphylaxis, urticaria (some types), allergic rhinoconjunctivitis, asthma (immediate but not chronic)
Type II	IgG-antibody mediated, direct effects (complement-mediated lysis), Th2 cells	Antibody-mediated autoimmune disease (thyroid, haemolytic anaemia, thrombocytopenia, myasthenia gravis, etc.)
Type III	Immune complex disease, IgG and IgM antibodies, complement, complement receptors	Serum sickness, SLE (abnormal complement, complement receptors), complement deficiency (abnormal immune complexes)
Type IV (delayed hypersensitivity)	T-cell mediated, Th1 cells, cytokines (IL-2, IFN-γ, TNF-α), macrophages, $CD8^+$ cytotoxic T cells	Contact (delayed-type) hypersensitivity, eczema, graft rejection

GM-CSF, granulocyte–macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; SLE, systemic lupus erythematosus; TNF, tumour necrosis factor.

exposure at times when the immune system is relatively immature in the first 2 years of life can lead to inappropriate responses. This may be augmented by the fact that many of the foods concerned contain naturally occurring lectins (e.g. wheatgerm agglutinin, peanut agglutinin), which have profound proliferative effects on lymphocytes. Exposure to infections in early childhood also has a protective effect against the development of allergic disease, as demonstrated in German children brought up on farms (hygiene hypothesis). Changes in the way we live are also important, for example the move to centrally heated, double-glazed houses with poor ventilation and fitted carpets provide optimum growth conditions for house-dust mites. Keeping pets indoors also contributes, although there is some evidence that keeping pets can have a protective effect against pet allergy. Other environmental factors include changes in diet, for example peanuts are now a common source of protein whereas they were rarely consumed 30 years ago, and the contribution of pollution, especially diesel fumes.

Autoimmune disease

Autoimmunity can arise through failure of the initial negative selection process for T and B cells or it can occur through the breaking of peripheral tolerance. As pathogens have evolved in parallel with humans, and in order to reduce the risk of elimination by the immune system they have developed antigenic structures similar to those present in their preferred host. Accordingly, there is a risk that the immune response may generate both antibodies and effector T cells that are cross-reactive with components of self, for example coxsackieviruses and diabetes mellitus, and *Klebsiella* and $HLA\text{-}B27^+$ arthritis. Evolutionary selection pressure will determine that individuals who can respond to pathogens with an effective immune response will survive, even though this may be at a later cost of autoimmune disease. The pathogen will eliminate those whose immune response fails. The need to present such antigens then drives the evolutionary pressure on the selection of certain MHC haplotypes in stable populations and accounts for the widely differing patterns of MHC antigens in different parts of the world. Today's long-distance travel means that this equilibrium is disturbed: individuals are exposed to pathogens whose antigens cannot be presented effectively because those infected do not possess the appropriate MHC molecules. Other genes also contribute to the generation of autoimmunity, for example there is an increased incidence of autoimmunity in

complement deficiencies and a high incidence of autoimmunity in defects of apoptosis such as fas deficiency and caspase deficiency, deficiencies in Treg cells (IPEX syndrome) and in thymic development (AIRE gene defects). Autoimmunity may also be triggered by the release of sequestered antigen from privileged sites (e.g. the eye) and by the generation of neoantigens by chemicals and toxins (e.g. autoimmune haemolytic anaemia caused by penicillins). One suspects that the root cause of most autoimmune diseases will be infection, although like a hit-and-run accident the culprit is long gone even though the effects of the 'accident' may be lifelong.

Immunity at extremes of age

The immune system is incompletely developed at birth; while all the components are present, the acquired immune system requires antigen exposure to develop the full repertoire of both T- and B-cell antigen receptors through recombination and somatic mutation and class switching. While this process takes place, protection is provided for the first 6 months of life by maternally transmitted antibody, transferred across the placenta by an active process in the last trimester. Breastfeeding also provides important amounts of IgA for protection of the gut. Stimulation to the acquired system can be provided by either natural infection or programmes of immunization. However, virulence factors in certain classes of bacteria, notably pneumococci, *Haemophilus influenzae* and *Neisseria meningitidis*, are capsular polysaccharides. These antigens are difficult for the immune system to recognize in the first 2 years of life, hence the high incidence of invasive disease caused by these organisms in this age group. Normally the bulk of antipolysaccharide antibody is IgG2 subclass. Interestingly, this defect can be bypassed by covalently conjugating the polysaccharide antigen to a protein, with the immune system producing a protective but mainly IgG1 antibody response to the polysaccharide. As the immune system ages, this inability to recognize polysaccharide antigens returns and there is a second peak of disease in the older population.

Ageing of the immune system is not chronologically related. Studies of the immune system in the elderly have been hampered by the need to define healthy elderly, free of other illness and medication. In fact the immune system remains remarkably effective, with good vaccine responses in the healthy elderly. However, protection of at-risk groups is less effective by virtue of their coexisting disease. Thus targeting influenza vaccine at those with, for example, chronic respiratory disease or chronic lymphocytic leukaemia targets the vaccines at those least able to respond. It was previously assumed that beyond the age of about 25 years, the ability of the immune system to reconstitute from thymus and bone marrow declined rapidly. However, newer evidence has shown that thymus is capable of functioning well into old age, albeit with a reduced capacity for generation of mature T cells. Much of the immune dysfunction of the elderly is related to other disease processes, either directly or through their treatment. Immune regulatory function becomes less effective with age and this is manifest by increasing levels of rheumatoid factors and other autoantibodies, usually in the absence of clinical disease. Low-level monoclonal gammopathies also develop due to failure to suppress antibody-producing clones at the end of an immune response (monoclonal gammopathy of uncertain significance; MGUS). These may remain stable for decades, although the current view is that all will eventually develop into myeloma, given sufficient time.

Immunity and malignancy

The immune system has an important role to play in immune surveillance for malignancy through the activities of NK cells (see above) and in control of established tumours by infiltrating cytotoxic T cells. Tumours often escape immune surveillance and cytotoxicity by loss of key antigens on the cell surface or production of immunosuppressive mediators. Tumours of the immune system, either lymphomas (including chronic lymphocytic leukaemia) or myelomas, have a direct effect on immunological responsiveness, with reduction in humoral immunity especially and an increase in bacterial infections. In the case of lymphomas, the abnormalities of humoral immune function may persist for years after apparently curative therapy. The importance of the acquired immune system in tumour control is well demonstrated by the significant increase in cutaneous tumours seen in patients treated with immunosuppressive drugs such as ciclosporin and cyclophosphamide over long periods.

Overview of diagnostic testing for immunological and allergic disease

Accurate immunological diagnosis depends on access to appropriate immunology laboratory services. Such services need to be run to high quality standards, verified by external peer review inspection. In the UK this is carried out by Clinical Pathology Accreditation (CPA); similar organizations exist in other countries. Laboratories are inspected at regular intervals to ensure compliance with agreed standards. These standards verify the organization, testing and reporting of laboratory testing. Participation in external quality assurance for the tests offered is essential, although rarely requested tests may not have national schemes in place. Under these circumstances the laboratory must satisfy itself that it is taking reasonable steps to quality assure the results. In all cases, laboratories should run internal controls with defined parameters and only report results when these internal controls meet their predetermined values. Clinical governance standards require clinicians to assure themselves that they are using appropriate diagnostic services. Where academic departments are providing in-house tests for diagnostic clinical use, they have the responsibility, under product liability legislation, for any errors or problems arising from the assay. It is essential therefore that scrupulous internal quality control data are collected, together with validation data.

Good clinical practice requires that test selection should be appropriate to the disease under investigation. The laboratory is responsible for selecting the most appropriate methodology and ensuring that clinicians have a clear understanding of the performance of the test, through derivation of normal ranges appropriate to the population under study and interpretative comment. Each laboratory for each test should define normal ranges, although in practice nationally established ranges may be used. Ranges should be adjusted for age, sex and racial background.

Table 13.5 Allergy tests.

	Advantages	Disadvantages
Skin prick tests	Cheap Results available in 15 min Useful positive and negative reinforcement Can be used with *ad hoc* allergens (e.g. fresh foods, drugs)	Cannot be done in patients receiving antihistamines, calcium channel blockers, phenothiazines, or those with extensive dermatitis Inadvisable as first-line test in patients with suspected anaphylaxis to test reagents (except where resuscitation facilities available) Requires skilled staff for reproducible results
Radioallergosorbent test (RAST)	Clinically useful for inhalants and some foods only Automated analysis Can be used in patients where skin prick testing is contraindicated	Expense (staff and analyser) Results not immediately available No reinforcement of clinical message Not suitable for many allergens (fruits, drugs)
Flow cytometric tests	Research tools	Very expensive, labour-intensive

Immunochemistry

Immunochemistry covers the measurement and identification of serum proteins, including abnormal ones. Usually this is undertaken using automated analysers, which are readily quality controlled. International standards have been established for all major serum proteins, and there are long-established external quality assurance schemes. Results in principle should vary little from laboratory to laboratory.

Allergy tests (Table 13.5)

Total IgE and allergen-specific IgE are readily measured in the diagnostic laboratory. However, total IgE levels correlate poorly with the allergic symptomatology; elevated levels suggest inheritance of the atopic tendency but do not predict the form this may take. Levels greater than 1000 kU/L are usually seen in atopic dermatitis. Levels more than 50 000 kU/L are seen in the hyper-IgE syndrome. However, levels in the range 10 000–50 000 kU/L may be seen in either condition and the differential diagnosis is then dependent on associated clinical and immunological features. Levels of total IgE within the normal range do not exclude severe allergic disease, although this is usually mono-allergenic. Total IgE levels are geometrically rather than normally distributed and there is considerable variation in ranges with age. It is essential to check that the laboratory has reported the appropriate range for age.

Allergen-specific IgE can be detected by many techniques, although the earliest technique was the radioallergosorbent test (RAST): this acronym has entered common usage as a term for allergen-specific IgE. Few, if any, laboratories use this technique now, having moved to colorimetric or fluorimetric assays. Complex array-based assays, in development, may make detailed screening much more cost effective. These assays tend to be expensive. Direct testing by skin prick is cheaper and is the preferred method of testing, provided that staff experienced in the technique are available. Results of skin prick testing are operator dependent. Correlation between skin prick testing and RAST is dependent on the allergen. For inhalant allergens and strongly allergenic food allergens, such as shrimp, peanut and tree nuts, there is good correlation. In the case of fruit allergens, as seen in the oral allergy syndrome, RAST results are unreliable and should not be used. Of those patients with latex allergy, 15% will have negative RAST results. RAST for drug allergy, with the exception of suxamethonium, is also unreliable and skin prick or intradermal testing is required. Newer assays include the Flow-CAST, and assays of stimulated histamine release compare well in some respects but are very expensive in comparison with existing tests. Allergy testing should be targeted to allergens identified on the basis of clinical symptoms, as routine screening with extended panels often leads to positive results of uncertain clinical significance, which is confusing to clinicians and patients alike. Very high total IgE levels (>1000 kU/L) have always been suspected of causing false-positive reactions in RAST, especially to food allergens, although most modern assays seem to be less susceptible to this effect. Biological cross-reactivity is also common, where similar allergenic proteins occur in many species of plant or animal. This may be clinically relevant, for example prawn allergy in patients allergic to house-dust mite, or irrelevant, as in the detection of IgE to wheat in patients allergic to grass pollen. Interpretation of results is therefore dependent on a clear understanding of the patient's history.

Mast cell tryptase is a useful marker of mast cell degranulation and can therefore be used to discriminate between acute allergic reactions and non-immunological mimics. It is a stable protein whose levels remain elevated for up to 24 h after a reaction and is easily and reliably measured on a clotted blood sample. Eosinophil cationic protein (ECP) has also been used to demonstrate activation of eosinophils, particularly in the context of asthma, where it has been proposed as a useful marker of chronic eosinophilic inflammation. Unfortunately it is less stable than mast cell tryptase, and has a strict sampling protocol involving timed centrifugation, which renders it useless for diagnostic use.

Mast cell tryptase is also helpful in suspected mastocytosis, although 24-h urinary methylhistamine is probably more sensitive, albeit more awkward to collect. At present, the only commercial assay for urinary methylhistamine has been withdrawn by the manufacturer.

Immunoglobulins (Table 13.6)

Automated analysers, using nephelometry or turbidimetry, can measure serum immunoglobulins and IgG subclasses accurately

Table 13.6 Patterns of immunoglobulins.

Pattern of immunoglobulins and electrophoresis	Clinical associations
IgG, IgA, IgM all low; electrophoresis shows agammaglobulinaemia	X-linked agammaglobulinaemia (children), light-chain myeloma (elderly), gross unselective nephrotic syndrome (all serum proteins reduced), burns, immunosuppressive drugs (excess), acute severe bacterial infection
IgG and IgM normal, IgA absent; electrophoresis normal	IgA deficiency; may be associated with IgG subclass deficiency and specific antibody deficiency. Also associated with gluten sensitivity (dermatitis herpetiformis, coeliac disease), connective tissue diseases
IgG and IgA low/absent, IgM normal/low; electrophoresis shows reduced γ region	Common variable immunodeficiency, protein-losing enteropathy; selective nephrotic syndrome (albumin reduced)
IgG and IgA low/absent, IgM high/normal; electrophoresis shows reduced γ region	Hyper-IgM syndrome, acute viral infection (repeat in convalescence)
Raised IgG; IgA and IgM low; electrophoresis shows monoclonal band on background of reduced γ region	IgG myeloma, lymphoma
Raised IgA; IgG and IgM low; electrophoresis shows monoclonal band on background of reduced γ region	IgA myeloma
Raised IgM; IgG and IgA low; electrophoresis shows monoclonal band on background of reduced γ region	Waldenström's macroglobulinaemia, lymphoma
IgG, IgA and IgM low; electrophoresis shows monoclonal band on background of reduced γ region	IgD or IgE myeloma, light-chain myeloma with free light chains in serum (also think of AL amyloid)
Raised IgG, normal/raised IgA, normal IgM; electrophoresis shows polyclonal increase in γ	Chronic infections (bacterial, viral), chronic inflammatory disease (RhA, SLE), sarcoidosis, autoimmune hepatitis
Very raised IgG (predominantly IgG1), raised IgA and IgM; electrophoresis shows polyclonal increase in γ	Sjögren's syndrome, hypergammaglobulinaemic purpura
Very raised IgM, normal IgG or IgA; electrophoresis shows polyclonal increase in γ region with or without small IgM bands	Primary biliary cirrhosis
Very raised IgA, normal/raised IgG, normal IgM; polyclonal increase in γ with β–γ bridging	Liver disease, especially cirrhosis due to alcohol

RhA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

and reproducibly. The only indications for measurement of these parameters are the investigation of suspected immunodeficiency, liver disease, lymphomas and plasma cell dyscrasias. Normal ranges must be age specific and in adults the range for IgM is also modified by sex, with the lower limit of normal for IgM being higher in females than males. Measurement of immunoglobulins should always be accompanied by electrophoresis, both as an internal quality control and also to permit the detection of paraproteins (monoclonal immunoglobulins). If the latter are detected, then immunofixation should be carried out to identify the nature of the band, and urine requested for analysis for free light chains (Bence Jones proteins). Paraproteins may react abnormally with antisera used for the quantification, leading to falsely low or high results. This may be due to polymerization of the paraproteins or the presence of monomeric, as opposed to pentameric, IgM. Paraproteins should therefore also be quantified by scanning densitometry.

Table 13.7 Cryoglobulins.

Type	Composition	Associations
I	Monoclonal immunoglobulin	Myeloma, Waldenström's macroglobulinaemia, lymphoma
II	Monoclonal immunoglobulin with rheumatoid factor activity, precipitate contains both monoclonal and polyclonal immunoglobulins	Myeloma, Waldenström's macroglobulinaemia, lymphoma, mixed essential cryoglobulinaemia (HCV infection), subacute bacterial endocarditis, connective tissue diseases
III	Polyclonal immunoglobulins with rheumatoid factor activity	Chronic infections, chronic inflammatory diseases

HCV, hepatitis C virus.

Cryoglobulins and cryofibrinogen

Cryoglobulins are abnormal immunoglobulins that precipitate at a higher temperature than normal (Table 13.7). Normal immunoglobulins may precipitate from serum that is cooled to 4–6°C, but cryoglobulins precipitate at temperatures found in the extremities, that is above 26°C, causing obstruction to small blood vessels and a vasculitic-looking rash on cooler parts of the bodies, typically the hands and feet but also nose and ears. The higher the temperature at which they precipitate, the worse the symptoms will be. The appearance of cutaneous vasculitis on extremities, particularly in cooler weather, should always raise suspicions of cryoglobulins. The detection of a type II cryoglobulin in the absence of evidence for myeloma should raise the possibility of hepatitis C infection; complement C4 is invariably markedly reduced. Pyroglobulins are extremely rare and precipitate when the temperature is raised. Cryofibrinogen is an abnormal fibrinogen precipitated by cold; the significance of cryofibrinogen is less certain, but it is often associated with malignancy. Cryoglobulins are often

confused with cold agglutinins, which are antibodies that agglutinate erythrocytes in the cold and are strongly associated with *Mycoplasma* infection.

Detection of cryoglobulins requires a clotted blood sample to be taken and kept at 37°C until clot retraction has taken place; in practice this means transporting samples in a vacuum flask containing water at 37°C. Cryofibrinogen can be detected in samples containing ethylenediamine tetra-acetic acid (EDTA); heparin should not be used because some fibrinogens are heparin insoluble.

Specific antibodies

Specific antibodies to bacterial, viral and fungal allergens are useful diagnostic tests for the assessment of the appropriateness of the humoral immune response. Tests can be carried out to exposure antigens and to deliberate challenges with vaccines (no live vaccines should be used in patients with any form of known or suspected immunodeficiency). The use of polysaccharide antigens such as pneumococcal capsular polysaccharide is particularly valuable as a robust test for humoral immune deficiency, as failure of responsiveness may occur even when total immunoglobulins and IgG subclasses are normal.

Precipitating antibodies to fungi are useful as diagnostic tests for fungal infection, although chronic mucocutaneous candidiasis is often accompanied by very high levels of *Candida* precipitins despite poor or absent T-cell responses, demonstrated by delayed hypersensitivity testing or *in vitro* antigen-specific T-cell proliferation (see below).

Complement assays

Complement components C3 and C4 are usually measured routinely by nephelometry or turbidimetry and can be assayed rapidly. Both are acute-phase proteins and will rise in chronic infection or inflammation by about 10%. C4 null alleles are common, resulting in reduced C4; as there is an ancestral gene duplication there are two C4 genes (four alleles), C4A and C4B. As a rule of thumb, two null alleles give a C4 level at the lower end of the normal range, while three null alleles give a level of half the lower end of the normal range, assuming there is no excess consumption. Factor B, from the alternate pathway, can be measured by automated analyser, although in routine practice this adds little useful clinical information. Mannan-binding lectin (MBL) from the lectin pathway can also be readily measured but the clinical utility is uncertain, except in the investigation of recurrent infections, where deficiency in MBL may be a co-factor with other immunological deficiency.

There is no role for measurement of immune complexes, as they can be readily detected in normal healthy individuals and the assays are difficult to standardize. Measurement of stable complement breakdown products such as C3d is more valuable as a determinant of complement turnover (Table 13.8).

Investigation of complement component deficiencies, which are associated with increased susceptibility to neisserial infection and atypical SLE-like disease, should be undertaken with haemolytic assays of complement that test both the classical and alternate pathways: CH_{100}/CH_{50} and $APCH_{100}/APCH_{50}$. These assays demonstrate intact complement cascade pathways through lysis of red cells. In the case of CH_{100}/CH_{50}, antibody-coated red cells are used to fix complement via the classical pathway; for the alternate pathway $APCH_{100}/APCH_{50}$, guinea pig erythrocytes are used, which can uniquely bind the alternate pathway components. Both tests rely on an intact terminal lytic sequence. Both tests must be done in parallel to identify the site of any deficient component. Reduced haemolytic function will be seen where there is excessive complement consumption, although absent haemolysis will be found where there is a component deficiency. The exception is C9 deficiency, which permits slow haemolysis via the membrane attack complex C5–8. This deficiency is rare in Caucasians but is common in Japan. Individual components can then be measured depending on which part of the complement cascade is likely to be affected. It is difficult to identify C2 deficiency, which often presents with atypical cutaneous lupus (Ro antibody positive), because active lupus without C2 deficiency will reduce C2 levels due to activation of the classical pathway by antigen–autoantibody complexes. Ideally one needs to carry out testing at a time when clinical disease is quiescent, although this is often difficult to achieve.

Table 13.8 Patterns of complement abnormalities.

Complement pattern	Associated conditions
C3, C4 raised	Acute phase: infection, inflammation
C3, C4 reduced, C3d increased	Increased complement turnover via classical pathway (antibody or MBP mediated)
C3 reduced, C4 normal/high, C3d increased	Increased complement turnover via alternate pathway (endotoxin) Post-streptococcal glomerulonephritis (up to 6 weeks); C3 nephritic factor (>6 weeks: type II membranoproliferative glomerulonephritis)
C3 normal, C4 reduced, C3d normal	C4 null alleles, C1-esterase inhibitor deficiency, C4-nephritic factor, mixed essential cryoglobulinaemia (HCV)

HCV, hepatitis C virus; MBP, mannan-binding protein.

C1-esterase inhibitor deficiency leads to a clinical syndrome of angio-oedema *without* urticaria, that is hereditary angio-oedema, an autosomal dominant condition. There is no value in screening patients for C1-esterase inhibitor deficiency where typical urticaria is seen. Patients with hereditary angio-oedema all have reduced C4 levels even between attacks; during attacks, C4 levels become undetectable. Measurement of C1-esterase inhibitor is therefore unlikely to be helpful if C4 is normal. Individuals with type I hereditary angio-oedema (85%) have a non-functioning C1-esterase inhibitor gene, while in type II (15%) there is a point mutation at the enzyme active site, leading to loss of function of the protein. Both immunochemical and functional assays for C1-esterase inhibitor are available. Angio-oedema has also been reported as a consequence of the rare deficiency of C4-binding protein and due to gain of function mutations in clotting Factor XII.

Acquired angio-oedema may be seen in the older population, in association with the presence of paraproteins or autoimmune disease (although more commonly it is due to drug treatment,

typically with ACE inhibitors). In such cases checking for autoantibodies associated with SLE and measuring immunoglobulins and performing serum electrophoresis will give clues to the underlying diagnosis. C2 levels are said to be reduced in hereditary angio-oedema but normal in acquired angio-oedema, but this is not reliable.

Acute-phase proteins

Measurement of acute-phase proteins is an essential part of the investigation of sick patients. Measures of the acute phase include erythrocyte sedimentation rate (ESR), plasma viscosity, C-reactive protein (CRP), orosomucoid (α_1-acid glycoprotein), serum amyloid A (SAA) and albumin. However, these measures are *not* interchangeable, and more than one marker is usually required. Albumin is a negative acute-phase protein, that is serum levels decrease during the inflammatory process. Transferrin behaves similarly. Most other proteins increase during an inflammatory process, although the increase may only be of the order of 10%, for example C3 and C4. In selecting suitable measures for clinical use, it is essential to choose markers that are easily measurable (preferably with automated equipment) and cheap and which have a wide dynamic range, that is there is a large difference between normal and abnormal values. The ESR has a dynamic range of 15 (10–150), while the CRP has a dynamic range of 100 (4–400). SAA has a similar dynamic range to CRP but is a less widely available and more expensive test, so has little additional value. Orosomucoid has a dynamic range of 2 so is unsuitable for routine use, although it has been previously supported as a more specific marker in inflammatory bowel disease. There is, however, no evidence that it performs better than CRP. Plasma viscosity has been promoted as equivalent to ESR but also has a poor dynamic range (2); its use is specifically for investigation and monitoring of hyperviscous states occurring in myeloma, especially IgA myeloma, and Waldenström's macroglobulinaemia.

Contrary to popular belief, CRP and ESR are not interchangeable. The relationship between ESR and CRP is similar to that between HbA_{1c} and glucose. The ESR rises only slowly after the onset of an acute insult and remains raised for several weeks after, being largely dependent on serum fibrinogen levels, a long-lived circulating protein. CRP on the other hand rises within hours and has a short half-life (6–8 h), meaning that levels also fall rapidly after a successful therapeutic intervention. Accordingly, CRP is appropriate for day-to-day monitoring, whereas ESR changes little in this time frame. At any given time, CRP gives a picture of events of the previous 12 h, while ESR clarifies events of the previous 2 weeks. There are diseases, such as active SLE, where the two markers move asynchronously, with a significantly elevated ESR but little if any rise in CRP, unless infection is also present. Occasional patients have been described whose CRP range is reset, so that their acute-phase response takes place within the 'accepted' normal range. This is seen sometimes in giant cell arteritis, and makes monitoring difficult.

Detection of autoimmunity

Detection of the presence of autoantibodies can be performed by direct or indirect immunofluorescence (usually the cheapest and easiest method), solid phase assays, enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay and, in some cases, flow cytometry. High throughput analysers using luminex or array-based technology are now increasingly used and may well supplant other techniques, including immunofluorescence. In all cases it is essential that the assay system has an appropriate threshold to reduce the risk of false-positive results. A number of autoantibodies may be found at low levels in apparently healthy individuals (e.g. rheumatoid factors, anti-Ro antibodies) and the prevalence of incidental positives rises with increasing age.

Nuclear and related antigens

A very large range of nuclear antigens have been identified as targets for autoimmune processes. Not all of these have identifiable clinical utility. Table 13.9 identifies the most important antigens and their clinical significance. Most of these can be detected by immunofluorescence using either rodent tissue or a human epithelial cell line (Hep2) (Fig. 13.3). Hep2 cells have the advantage of having a large nucleus in which patterns of staining can be readily identified. Genetically modified Hep2 cells are also available, engineered to have higher levels of expression of Ro antigen. Rodent tissue tends to have low levels of Ro antigen and it is also saline soluble so can be lost during the staining procedure. When rodent tissue was used exclusively for the detection of antibodies to nuclear antigens, this loss of Ro accounted for the high percentage of patients classified as antinuclear antibody-negative lupus. The increased use of Hep2 cells has significantly reduced the number of lupus patients in whom no antinuclear antibodies can be detected. Antibodies to extractable nuclear antigens were originally identified by counter-current immunoelectrophoresis; however, with the availability of cloned recombinant antigens, solid phase assays are widely used to identify specificities of nuclear antibodies. The wide variety of different assays has meant that there is often no good agreement between the different assays and there is no currently accepted 'gold standard'. Similar problems have arisen with antibodies to double-stranded DNA (dsDNA), although here the gold standard has been the Farr assay; ELISA does not always produce satisfactory results due to degradation of dsDNA to single-stranded DNA or reverse-wound DNA (Z-DNA). Immunofluorescence on *Crithidia* has been proposed as a suitable test for dsDNA as its kinetochore contains pure dsDNA. The assay is, however, relatively insensitive and is now less widely used.

Detection of antibodies to nuclear components is diagnostically valuable. However, with the exception of antibodies to dsDNA, serial monitoring of antibody titres or arbitrary ELISA units provides no clinically useful information. Changes in levels of dsDNA antibodies do have some predictive value: a rising titre frequently heralds relapse, while a falling titre is usual where therapy has been successful. However, the absolute value has no relevance to disease activity. It is likely that there are subgroups of dsDNA antibodies, as not all patients with SLE develop renal disease. Currently available diagnostic tests do not yet distinguish these different anti-DNA antibodies.

The significance of the titre of an antinuclear antibody is dependent on the age of the patient: low-titre and clinically insignificant antibodies are seen in healthy elderly patients; conversely,

Table 13.9 Nuclear and related antigens.

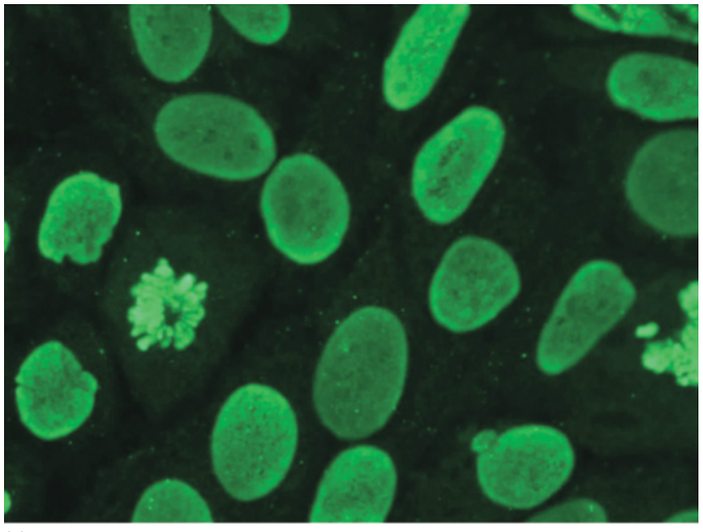
Staining pattern on rodent liver and Hep2 cells	Antigens recognized	Clinical associations
Homogeneous nuclear staining	dsDNA	SLE
	Histones (H2A, H2B)	SLE, drug-induced LE
	Mi-2	Steroid-responsive dermatomyositis
Fine speckled nuclear staining	Ro (52 kDa, 60 kDa antigens, distinguished using immunoblotting)	Sjögren's syndrome, SLE
	La (48 kDa protein)	Primary Sjögren's syndrome, SLE
Coarse speckled nuclear staining	U1-RNP	Undifferentiated connective tissue disease (anti-dsDNA and anti-Sm negative)
	Sm (B′/B and D proteins shared between U1, U2 and U4–U6 RNPs)	SLE
	Nuclear matrix (coarse speckles indicates multiple proteins)	SLE, undifferentiated connective tissue disease
Atypical speckled nuclear staining	Scl-70	Systemic sclerosis (severe form)
Nucleolar staining	RNA Pol I (speckled nucleolar staining)	Diffuse systemic sclerosis
	PM-Scl (PM-1) (homogeneous nucleolar staining)	Myositis–scleroderma overlap
	Fibrillarin (clumpy nucleolar staining)	Systemic sclerosis (lung and heart but few joint problems)
Cell-cycle-specific nuclear speckles	PCNA	SLE
Centromere (dividing cells)	CENA, CENB, CENC	Limited scleroderma (CREST syndrome)
Fine cytoplasmic speckled staining	tRNA synthetases (Jo-1, PL-7, PL-12, EJ, OJ)	Myositis (antisynthetase syndrome)
Coarse cytoplasmic speckled staining	Signal recognition peptide	Myositis
Ribosomal staining	rRNP	SLE (nephritis)
	Ribosomal P protein	SLE (cerebral)

CREST, calcinosis, Raynaud's phenomenon, (o)esophageal involvement, sclerodactyly, telangiectasia; dsDNA, double-stranded DNA; LE, lupus erythematosus; PCNA, proliferating cell nuclear antigen; RNP, ribonucleoprotein; SLE, systemic lupus erythematosus.

low-titre antibodies are often significant in children. Laboratories should provide age-specific ranges.

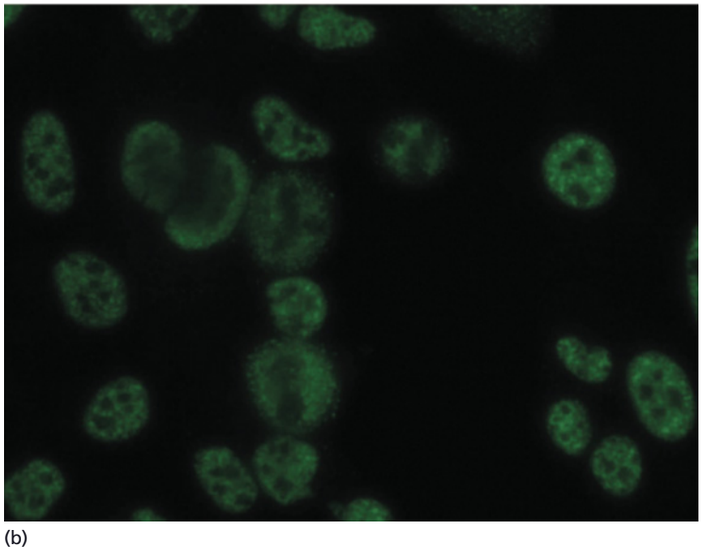
Antinuclear antibodies of varying specificities and sometimes in high titre have been reported in association with infection, especially adenovirus and Gram-negative bacteria. Antibodies to dsDNA are rarely found under these circumstances. It is critically important to interpret the laboratory results in the light of the full clinical picture. Similarly, antibodies can appear in association with malignancy. In some cases, these markers are useful identifiers of paraneoplastic phenomena (anti-Hu, anti-Yo, anti-Ri in neurological disease).

ANCA antigens and the diagnosis of vasculitis



The detection of antineutrophil cytoplasmic antibodies (ANCA) has been an important step forward in the diagnosis of autoimmune vasculitis. The substrate for detection is ethanol-fixed human neutrophils. Other fixation techniques such as formaldehyde and acetone are not reliable and should not therefore be used. Three patterns are recognized: cytoplasmic granular staining (C-ANCA), atypical cytoplasmic staining (X-ANCA) and perinuclear staining (P-ANCA). As the latter can be difficult to distinguish from nuclear staining, Hep2 cells should also be used as a control for the presence of nuclear antibodies. Target antigens have been identified: proteinase 3 is the main target antigen for C-ANCA and myeloperoxidase is the main antigen for P-ANCA. Solid phase confirmatory assays are now available for these antigens. Other target antigens that have been identified include cathepsins, lactoferrin and neutrophil elastase. It is important to identify X-ANCA, as laboratories frequently confuse this pattern (which is not associated with antibodies to proteinase 3) with a true C-ANCA.

Of patients with Wegener's granulomatosis, 85% have C-ANCA, 10% P-ANCA and 5% will be seronegative. Of patients with Churg–Strauss syndrome, 10% have C-ANCA and 60% P-ANCA. In microscopic polyangiitis, 45% have C-ANCA and 45% have P-ANCA.



ANCA may also be seen in non-vasculitic conditions, including inflammatory bowel disease and sclerosing cholangitis. Prolonged neutrophil activation, as in infection, may also cause ANCA to appear, for example in cystic fibrosis. Careful interpretation of results is therefore required. It appears that ANCA do not appear as part of the ageing process, and therefore their detection in the elderly is likely to be significant. There is no correlation between disease severity and ANCA titre, although rising titres are thought to herald relapse. IgA ANCA have been reported in some IgA-related vasculitides such as Henoch–Schönlein purpura and IgA nephropathy, although the significance of this is uncertain.

Rheumatoid factor

As previously noted, rheumatoid factors are seen as part of the normal immune response to infection. They also occur in the

(a)

(b)

Fig. 13.3 (a) Homogeneous antinuclear antibody demonstrated by indirect immunofluorescence on Hep2 cells; (b) Coarse speckled pattern seen with anti-RNP antibodies on Hep2 cells.

ageing population, without clinical significance, and as a specificity of monoclonal proteins (often with cryoglobulin properties). Although the assay is widely requested, its utility as a screening test is nil. Its major value is as a predictor of severe extra-articular disease in those patients with known clinical rheumatoid arthritis, where high levels of rheumatoid factors are predictive. Increasingly, antibodies to cyclic citrullinated peptide (CCP) are being used as an early marker of rheumatoid arthritis, as these are more specific than rheumatoid factor.

Other organ-non-specific antigens

Immunofluorescence using composite tissue blocks containing kidney, liver and stomach will also identify other organ-non-specific antibodies such as mitochondrial antibodies (primary biliary cirrhosis), liver–kidney microsomal antibodies (drug-induced hepatitis), ribosomal antibodies (see Table 13.9), smooth muscle antibodies (autoimmune hepatitis) and gastric parietal cell antibodies (pernicious anaemia).

Table 13.10 Autoimmune syndromes.

Syndrome	Major criteria	Minor criteria
Type I (autoimmune polyendocrinopathy, candidiasis, ectodermal dysplasia)	Candidiasis, adrenal failure, hypoparathyroidism	Gonadal failure, alopecia, malabsorption, chronic hepatitis
Type II (Schmidt's syndrome)	Adrenal failure, thyroid disease, type I diabetes mellitus	Gonadal failure, vitiligo, non-endocrine autoimmunity (myasthenia gravis)
Type III	Thyroid disease	Type I diabetes mellitus *or* pernicious anaemia *or* non-endocrine autoimmunity (myasthenia gravis)

Organ-specific antigens (including skin)

Organ-specific autoantibodies can be detected by direct immunofluorescence on biopsies and also by indirect techniques using animal tissues (primate or rodent). These include autoantibodies against endocrine tissues, as seen in the autoimmune polyglandular syndromes, some of which are associated with chronic mucocutaneous candidiasis (Table 13.10).

Autoantibodies to skin (see Chapter 40) are detected on primate oesophagus by indirect immunofluorescence. Titres and serial monitoring do not appear to have any great clinical significance. The same substrate is also used to detect endomysial antibodies of the IgA class, as a diagnostic test of high sensitivity and specificity in gluten-sensitive enteropathy, including dermatitis herpetiformis. As coeliac disease is associated with an increased incidence of IgA deficiency, screening for such is required; under these circumstances, IgG endomysial antibodies carry the same diagnostic significance. The target antigen has been identified as tissue transglutaminase (tTG), and solid phase assays for antibodies to this enzyme are available. There is no evidence that these are diagnostically superior to endomysial antibodies. Gliadin antibodies (IgG and IgA) are non-specific tests that should not be used for the diagnosis of gluten-sensitive enteropathy. Endomysial and tTG antibodies disappear gradually when strict gluten avoidance is instituted, but reappear after gluten challenge; they are therefore valuable as a tool to monitor compliance.

Autoimmunity in urticaria

It has been claimed that a significant proportion of patients (up to 35%) with chronic urticaria may have autoantibodies to the α subunit of the IgE receptor, and a further 5–10% may have autoantibodies to IgE itself. Unfortunately, the solid phase assays used to demonstrate the presence of these autoantibodies have lacked appropriate controls. Studies using immunoblots have confirmed that such autoantibodies may occur but have shown them to be commonly present in low concentrations in the serum of otherwise healthy individuals and also at higher titre in patients

Table 13.11 Surface markers on leukocytes.

Surface marker	Cell type	Examples of abnormalities
CD19 (or CD20)	B lymphocytes	Absent in X-linked agammaglobulinaemia, BLNK deficiency and B^- SCID; reduced in common variable immunodeficiency
CD16/56	NK cells	Elevated in acute infections; rare deficiency reported
CD3	T cells	Reduced/absent in severe combined immunodeficiency
CD4	T helper cells	Reduced in viral infections including HIV
CD8	T cytotoxic cells	Raised in acute/chronic viral infections; reduced/absent in ZAP-70 deficiency
CD25	IL-2 receptor	Expression measured on $CD4^+$ cells as marker of T-cell activation (inflammation and infection); high levels are expressed on Treg, with FoxP3
MHC class II (DR common)	Constitutively expressed on B cells, activation marker on T cells	Measured on $CD4^+$ cells as marker of T-cell activation (inflammation and infection); absent in class II MHC deficiency
MHC class I (W6/32, common)	All nucleated cells	Absent in MHC class I deficiency
CD45RA	Naïve T cells	Monitoring reconstitution post BMT
CD45RO	Memory T cells	Monitoring reconstitution post BMT
CD11a,b,c/CD18	Adhesion molecules (lymphocytes, neutrophils)	Leukocyte adhesion molecule deficiency type I
CD15	Adhesion molecule (macrophages, neutrophils)	Leukocyte adhesion molecule deficiency type II
CD21/CD35	Complement receptors (with CD11b, c) on phagocytic cells and B lymphocytes	Complement receptor deficiency

BLNK, B-cell linker protein; BMT, bone marrow transplantation; HIV, human immunodeficiency virus; IL, interleukin; MHC, major histocompatibility complex; NK, natural killer; SCID, severe combined immunodeficiency.

with blistering skin diseases and connective tissue diseases. Their clinical utility is doubtful and there are no commercial validated assays available.

A small proportion of patients with chronic urticaria have hypocomplementaemic urticarial vasculitis. These patients have systemic features and may also suffer from angio-oedema, ocular inflammation and chronic obstructive pulmonary disease in the absence of a smoking history. It may be associated with evidence of an underlying connective tissue disorder. C3 and C4 are usually reduced and autoantibodies to the collagenous region of C1q can be demonstrated, although these are also found in patients with SLE (especially if glomerulonephritis is present) who do not have urticarial lesions. However, all patients with clinical features of hypocomplementaemic urticarial vasculitis have the antibody. Routine assays are available for anti-C1q antibodies, although these are prone to interference from immune complexes and DNA fragments.

Cellular tests

Delayed-type hypersensitivity testing

In vivo testing for type IV reactions is commonly practised in dermatology departments in the form of patch testing for contact dermatitis. This is a useful and reliable test, and is the type IV counterpart of skin prick testing. Allergens are applied under aluminium discs taped to the back for 48 h and then removed. Allergen-specific T cells are then recruited by allergen-bearing APCs in the epidermis, accumulating over the next 48–72 h. The infiltrate is palpable, and there is often blistering and inflammation at the site due to cytokine release and recruitment of inflammatory cells. In the case of photoallergy, allergens are applied in duplicate, with one panel being exposed to UV light after removal of the discs, while the duplicate panel is protected from light.

Variants of this type of test include the well-known Heaf test for T-cell immunity to *Mycobacterium tuberculosis*, in which a multipronged applicator introduces purified protein derivative (PPD) into the dermis. Similar tests are used by clinical immunologists to test for T-cell immunity to *Candida* and other protein antigens, as part of the work-up for suspected T-cell immunodeficiency. Access to antigens in a form suitable for (unlicensed) clinical use limits the usefulness of this type of testing.

Cell marker analysis (whole blood) (Table 13.11)

Lymphocyte subpopulations in peripheral blood are readily measurable. This test is carried out by flow cytometry, ideally using a single platform instrument capable of producing absolute counts for the major lymphocyte populations. There is a wide range of available surface markers, but in clinical practice a relatively restricted panel provide all the required information. This type of testing has no intrinsic diagnostic value in the absence of a clear clinical question, such as whether a child has immunological features compatible with SCID. Testing lymphocyte subsets is often carried out as a surrogate (without informed consent) for retroviral disease. As well as being ethically unjustified, this is inappropriate because changes in $CD4^+$ T cells are seen in a wide range of acute and chronic viral infections as well as in acutely sick patients and are not specific to human immunodeficiency virus (HIV) disease. In patients with known HIV infection, monitoring of cell counts provides important information on risks of opportunistic infections, as different infections appear at different points in the decline of the $CD4^+$ T-lymphocyte count. Monitoring is also important in assessing the immune reconstitution seen in response to treatment with highly active antiretroviral therapy. Patients on immunosuppressive therapy with cytotoxic agents should in the first instance be monitored with absolute lymphocyte counts obtained from a standard full blood count, but if very

low counts occur then checking the subpopulations is helpful for determining whether any additional prophylaxis against infection is required.

It is important to remember that analysis of peripheral blood lymphocytes provides a snapshot of lymphocytes in transit only, and gives no information about immunological processes going on in other tissues. Furthermore, there are circadian changes in blood lymphocytes, so the timing of samples has a significant effect on cell counts; this is particularly important for serial monitoring.

More extensive panels are used for the identification of leukaemias and this is usually done in parallel with examination of bone marrow. Here absolute counts are not necessary as the phenotype of the bulk population is required.

In vitro proliferation assays

In vitro T-cell function testing is complex, labour-intensive, time-consuming and difficult to quality control. Lymphocytes must be purified from blood by density gradient centrifugation and set up in sterile culture for periods of 3–7 days. Accordingly, its use is restricted to diagnosis and monitoring of primary immunodeficiencies. Abnormalities in these assays are not necessarily translated into clinical symptoms. The gold standard is still tritiated thymidine uptake. Alternative methods using flow cytometry have been developed based on analysis of cellular DNA content and expression of activation markers such as CD69 and transferrin receptor, but these do not provide the same information or have the same clinical correlations as tritiated thymidine incorporation. Panels of polyclonal stimuli are used that activate T or B cells at different points in the cascade, enabling the cellular location of defects to be identified. These include phytohaemagglutinin A, pokeweed mitogens and concanavalin A, plant lectins that bind to oligosaccharides on cell surface proteins; anti-CD3 (±IL-2), which mimics activation via the TCR; and phorbol esters, which activate the intracellular enzyme protein kinase C in the presence of calcium (calcium ionophores are used). Antigen can also be used but as the frequency of antigen-specific T-cell precursors in peripheral blood is extremely low, responses are very small compared with polyclonal stimuli. Typically, *Candida* antigens, tetanus toxoid and viral antigens such as those from herpes simplex virus (HSV), cytomegalovirus (CMV) and varicella-zoster virus (VZV) are used.

Results are expressed in counts per minute (cpm) and also as a stimulation index (SI) calculated by comparing the control incorporation with the stimulated incorporation. It is essential that a medium control is always performed and that a normal healthy control is run in parallel as a reagent check. There is a large range of normal responses and laboratories should develop their own acceptable ranges. However, as a general principle, polyclonal stimuli should give an SI greater than 10, while for antigen an SI of 2–4 is acceptable.

Other functional assays have been developed for the flow cytometer, including assays for apoptosis, valuable in the Canale–Smith syndrome, and activation-induced expression of CD40 ligand (CD154), valuable in the X-linked hyper-IgM syndrome.

Neutrophil function tests

Robust assays exist for the identification of defects of neutrophil oxidative metabolism. The historic assay is the nitroblue tetrazolium reduction test, which was performed as a slide assay. This has been modified by the application of similar fluorescent dyes for use on the flow cytometer. Similarly, flow cytometric assays exist for measuring neutrophil and macrophage phagocytosis, using fluoresceinated opsonized bacteria. However, these assays are highly susceptible to the clinical state of the patient, and abnormal results are obtained in patients with active or recent infection. Assays of neutrophil chemotaxis are described but these are impossible to standardize and there is such a wide range of 'normal' results that interpretation of clinical results is no better than guesswork.

Cytokine assays

Measurement of cytokines by solid phase assays is well-established as a research tool. However, measurement of cytokines in clinical material has not been shown to be diagnostically helpful as the assays are unreliable when used in this way, mainly due to the natural occurrence of soluble cytokine receptors and anticytokine antibodies in body fluids that interfere with binding. The use of surrogates such as CRP is more robust. Cytokine production *in vitro* can be used as an adjunct to T-cell proliferation assays. Intracellular cytokine production can be measured using the flow cytometer, and cytokine production can be tied to particular cell types by simultaneous surface staining with monoclonal antibodies. There seems to be little gain in clinically useful information over and above that derived from lymphocyte subset analysis.

Molecular immunology

The use of molecular genetic techniques to identify immunoglobulin and TCR gene rearrangements has been essential in developing the understanding of lymphoproliferative conditions. These techniques can be as easily applied to solid tissue extracts as to peripheral blood cells. Flow cytometric methods have also been used to identify clonality of T cells in peripheral blood by examining Vβ chain usage with panels of monoclonal antibodies.

Immunological therapy

Immunological therapy has for many years rested on a small group of cytotoxic drugs supplemented with corticosteroids. These remain important, but advances in our understanding of basic immunology and parallel technical advances have opened the door to new and exciting immunological therapies with potentially fewer side effects. Nonetheless, steroids and cytotoxics will remain important for the foreseeable future.

Corticosteroids

These have both anti-inflammatory and immunosuppressive effects. The anti-inflammatory effect is mediated by increased production of lipomodulin, an inhibitor of phospholipase A_2, the enzyme essential to the formation of the arachidonic acid pathway metabolites involved in inflammation (leukotrienes and

prostaglandins). Phagocytosis is also inhibited, and production of IL-1 and TNF-α is reduced. At higher doses, corticosteroids are lymphotoxic, via increased apoptosis. Lymphocyte proliferation is inhibited and cytokine production is reduced, especially by Th1 cells.

Methotrexate

Methotrexate is a folate antagonist, used in weekly (low) doses as an immunosuppressant. It is converted to long-lived intracellular polyglutamate metabolites, which are potent inhibitors of dihydrofolate reductase; this accounts for the cumulative toxicity. However, it is not clear if this activity accounts for the immunosuppressive and anti-inflammatory activities. One suggested mechanism is blockade of transmethylation reactions, with increased lymphotoxic concentrations of *S*-adenosylhomocysteine (one of the toxic metabolites that accumulates in adenosine deaminase deficiency, a cause of SCID). Another postulated mechanism involves the inhibition of aminoimidazole carboxamide ribonucleotide (AICAR) transformylase, which leads to an increase in cellular AICAR riboside, which also inhibits adenosine deaminase and leads to an increase in adenosine, a powerful inhibitor of lymphocyte proliferation and cytokine production that acts via specific adenosine receptors.

Azathioprine

Azathioprine, a pro-drug of 6-mercaptopurine, inhibits DNA synthesis and also the purine salvage pathway. Its conversion to thio-IMP suppresses the conversion of inosine monophosphate (IMP) to adenosine monophosphate (AMP), and metabolism of thio-IMP to thioguanine leads to the latter's incorporation into, and consequent damage to, DNA. Azathioprine has a broad range of immunological activities: reduced NK-cell function; reduction in $CD8^+$ T cells; inhibition of lymphocyte proliferation and cytokine production; inhibition of antibody responses (primary > secondary) and impaired neutrophil chemotaxis. Side effects are related to levels of the enzyme thiopurine methyltransferase (TPMT). Patients with a homozygous deficiency of TPMT are highly susceptible to prolonged bone marrow toxicity even from tiny doses of azathioprine, whereas heterozygotes can tolerate reduced doses of the drug with care. Checking red cell TPMT levels before treatment allows identification of those who will develop severe toxicity so they can be spared a trial of therapy. Long-term use may cause a persistent profound lymphopenia and severe hypogammaglobulinaemia.

Other drugs operating on these pathways are fludarabine and cladribine. These have been mainly used in the treatment of haematological malignancies, but their potent immunosuppressive effects are likely to be of considerable value in managing autoimmune disease, with appropriate tailoring of the doses.

Mycophenolate mofetil

Mycophenolate is a potent inhibitor of the enzyme IMP dehydrogenase and therefore works on both *de novo* synthesis as well as salvage of purine, that is the same pathways affected by azathioprine. Its range of effects is therefore very similar to azathioprine. In addition, the reduction in the guanine nucleotide pool decreases the synthesis of oligosaccharide chains on surface receptors involved in adhesion and migration.

Cyclophosphamide

Cyclophosphamide is a pro-drug converted by the liver into phosphoramide mustard, an alkylating agent that acts on guanine residues in DNA and which increases cross-linking of DNA strands, thus preventing DNA replication and transcription. It is a potent inhibitor of lymphocyte proliferation, reducing antibody production, particularly primary antibody responses. It is more active against $CD4^+$ T cells, and has minimal effects on NK cells. Significant lymphopenia occurs on treatment with cyclophosphamide, and prophylactic antibiotics to prevent opportunistic infections are recommended.

Leflunomide

This is a pro-drug that is converted *in vivo* into a potent inhibitor of the enzyme dihydro-orotate dehydrogenase, an enzyme required for the synthesis of pyrimidines. It prevents lymphocyte proliferation. As T cells are dependent on *de novo* synthesis of pyrimidines, they are uniquely sensitive to leflunomide. At high doses it is also thought to inhibit tyrosine kinases, inhibiting the cascade linked to the IL-2 receptor. It has a very long half-life, as it is highly protein bound.

Hydroxychloroquine and mepacrine

The actions of the antimalarials are not entirely certain, although they reduce the production of cytokines, particularly the pro-inflammatory cytokines IL-1, TNF-α and IFN-γ. They are also concentrated into lysosomes, where they alter pH and interfere with antigen processing.

Thalidomide

Thalidomide is a potent inhibitor of TNF-α production by monocytes, interfering with gene transcription. It also decreases adhesion molecule expression and inhibits IFN-γ production through preferential stimulation of Th2 cells. Oxypentifylline has similar but weaker properties.

Ciclosporin, tacrolimus and sirolimus

Ciclosporin binds to cyclophilin, an intracellular peptidyl-prolyl *cis-trans* isomerase, and the resulting complex inhibits cytoplasmic calcineurin, a calcium-activated serine–threonine phosphatase. This in turn prevents dephosphorylation of NF-AT (nuclear factor of activated T cells), which normally binds to DNA to enhance the transcription of IL-2 and other cytokines, and CD40 ligand in activated T cells. Dephosphorylation prevents the normal translocation of NF-AT from cytoplasm to nucleus, and inhibits the production of IL-2 and other molecules normally associated with activation of T cells. T cells are particularly sensitive to the effects of ciclosporin, because of low levels of calcineurin. NK cells and B cells are also affected by ciclosporin. The effect is reversible, so overenthusiastic immunosuppression can be rapidly reversed if required. Monitoring of trough blood levels is possible and enables doses to be accurately controlled; levels required for control of autoimmune diseases are lower than those required to prevent allograft rejection.

Tacrolimus binds to a similar peptidyl-prolyl *cis-trans* isomerase, FKBP12, and this has a similar effect on calcineurin. Clinically and immunologically, the effects of tacrolimus are similar to those of ciclosporin.

Sirolimus (rapamycin) also binds to FKBP12, but appears to inhibit an enzyme called mTOR, which is involved in transmission of signals via the IL-2 receptor. Sirolimus and ciclosporin appear therefore to be able to act synergistically by inhibition both of IL-2 production and signalling via IL-2.

Topical formulations of these drugs and related novel compounds are now being introduced for use in immunologically mediated skin disease.

Biological therapy (monoclonal antibodies, chimeric molecules, cytokines, cytokine antagonists, intravenous immunoglobulin; see Chapter 76)

There has been great interest in the use of monoclonal antibodies for the treatment of disease. The first agent used clinically was a murine anti-CD3 (muromonab), although its use was limited by its murine origin, which usually led rapidly to the development of neutralizing antibodies. However, it was recognized as a potent immunosuppressive agent and used in clinical allograft rejection. Genetic engineering of monoclonal antibodies now allows the murine binding site to be inserted into a human immunoglobulin framework, while retaining its original specificity. This reduces, but does not completely abolish, the antimouse response. Antibodies to the pan-leukocyte antigen CD52 are potent immunosuppressive agents (Campath), producing a prolonged lymphopenia. An anti-CD20 (B cell) monoclonal antibody, rituximab, originally introduced to treat lymphomas, has also been found to be a useful therapy in a variety of autoimmune conditions including pemphigus. Many surface molecules are now the targets of experimental monoclonal antibody therapies. A humanized monoclonal antibody to LFA-1 (CD 11a), efalizumab, is a licensed therapy for psoriasis. Particular targets of interest are the co-stimulatory molecules B7–CD28 and CD40–CD40 ligand. Because of its inhibitory nature, CTLA-4 has also been used in the form of a hybrid fusion molecule with human immunoglobulin. Fusion proteins such as LFA-3/IgG (alefacept) and denileukin diftitox have been used to treat psoriasis and cutaneous T-cell lymphoma, respectively.

An alternative strategy has been to target the cytokines or their receptors. The most effective examples of this have been the use of the humanized anti-TNF monoclonal antibody (infliximab), the fully human anti-TNF monoclonal antibody (adalimumab) and the TNF-receptor Ig Fc fusion protein (etanercept), which are highly active in suppressing TNF-based inflammatory reactions such as psoriasis, Crohn's disease and rheumatoid arthritis. There has been concern, however, that use of these agents may increase autoimmunity and also susceptibility to infection, particularly mycobacterial infection. Other cytokine antagonists, such as the naturally occurring IL-1 receptor antagonist, which binds to IL-1 receptor but does not signal, are also being tested in clinical trials. Other targets for monoclonal antibodies in trials include IL-6 and IL-8.

There is a long history to the administration of cytokines in pharmacological doses, starting with IL-2, as adjuncts to chemotherapy for malignant disease. However, the benefits have been small and the side effects considerable. There may be some benefit from IL-2 in common variable immunodeficiency, used in a pegylated form to lengthen the circulating half-life, and in acquired immune deficiency syndrome (AIDS), to improve T-cell function. Administration of IFN-γ has been shown to be beneficial in chronic granulomatous disease, although the precise mechanism of action is unclear. IFN-α is valuable in treatment of chronic hepatitis C infection, with best results coming from combination therapy with the antiviral ribavirin. On the whole, however, cytokine therapy has been a disappointment. This is partly due to the considerable cytokine redundancy, with overlapping functions from multiple cytokines, and partly because most of the cytokines act as short-range messengers; also, the total cytokine and chemokine milieu that a cell experiences determines its response. The same cytokine may therefore have different effects depending on which other cytokines are present. This scenario is difficult to replicate by pharmacological administration of single cytokines.

High-dose intravenous immunoglobulin is widely used as an immunomodulatory agent for autoimmune disease. It is likely that multiple mechanisms of action are involved, including modulation of cytokine release and function, antiproliferative effects, suppression of antibody production via idiotypic antibodies, inhibition of complement-mediated tissue damage and Fc receptor blockade. Problems with this type of therapy are that it is in short supply and has to be derived from human material, which poses risks of infection; the risks of transmission of prion disease are as yet unquantified. It has been widely used, including the treatment of bullous skin diseases, resistant urticaria and atopic dermatitis. None of these uses are yet licensed. In a shortage, priority for supplies should be given to its use in licensed indications and in properly conducted clinical trials.

Physical therapy (plasmapheresis, photopheresis, irradiation, immunoadsorption)

Plasmapheresis provides a rapid way of removing pathogenic autoantibodies. However, it must be combined with immunosuppressive therapy, as there is usually a rebound increase in autoantibody levels immediately following plasmapheresis. Modifications of plasmapheresis include the use of specific immunoadsorption columns in the extracorporeal circuit. These columns comprise a biocompatible substrate to which either protein A or specific antigen is coupled, enabling specific antibodies to be removed without removing essential antibodies necessary for host defence against pathogens. A further development is the use of photopheresis, in which psoralen-like drugs are administered and the extracorporeal circuit is then irradiated with UV light; this provides a potent method of suppression of lymphocytes. The main drawback of these methods is the need for expensive equipment and trained staff.

Low-dose irradiation is also immunosuppressive in doses below those used in the management of malignant disease. This can prove valuable where there is localized immunological disease, for example locally aggressive Wegener's granulomatosis.

Allergy therapy

The mainstay of symptomatic allergy relief is the reduction of mediator output by the use of steroids and mast-cell stabilizing

drugs such as disodium cromoglycate and nedocromil, and the antagonism of released mediators by the use of antihistamines and leukotriene antagonists.

Reduction or abolition of allergic reactivity can be undertaken by specific allergen immunotherapy, using purified and standardized allergen extracts. The precise mechanism by which tolerance is induced is unclear. Initially, IgE levels increase before declining slowly. IgG4 antibodies are also produced and may have a blocking role. Alterations in T-cell function are also likely. The process is slow and optimum schedules have yet to be established. Maintenance therapy is required, usually for several years. Most therapy is given by injection but there is evidence that the sublingual route can be used with good effect, albeit requiring much larger doses of allergen. It is, however, very effective for seasonal allergic rhinitis due to grass and tree pollens, and is also effective for house-dust mite, cats (but less so dogs) and venoms. There is some risk of anaphylaxis and therefore the treatment is suitable only for hospital use by experienced personnel. Current trials are investigating the use of peptides derived from key allergens as a way of inducing T-cell tolerance and therefore abolishing the IgE response. The peptides induce tolerance when injected because they are not presented in the correct way with co-stimulation. This effect may be enhanced by co-administration of IL-12 or IL-18, which induce IFN-γ and bias the immune response towards Th1.

Monoclonal antibodies to IgE have also been introduced into clinical trials with some success. These have been tested first in asthma, where the effects are modest, probably because non-IgE mechanisms are also prominent, but are likely to be more effective in rhinitis. Significant reductions in circulating IgE levels have been documented.

Transplantation

Stem cell transplantation after bone marrow ablative therapy as a treatment for severe autoimmune disease refractory to conventional immunosuppressive therapy is now being undertaken. Diseases include juvenile chronic arthritis and other severe connective tissue diseases such as scleroderma.

Further reading

The field of immunology is a colossal one and provision of up-to-date references in a textbook that takes 2 years from submission to publication is impossible. Accordingly, the list below indicates useful immunological reference works that provide more detailed discussion of the topics covered. Use of PubMed and Medline to obtain the latest information is strongly recommended, particularly in regard to diagnosis and management of clinical conditions.

Photoimmunology

T. Schwarz, pp. 13.26–13.34

It is more than 25 years since the discovery that ultraviolet (UV) radiation can influence the immune system. Since then numerous studies in the field of photoimmunology have tried to identify, first, the biological impacts of UV-induced immunosuppression and, second, the underlying mechanisms. The immunosuppressive effects of solar radiation are mostly due to the medium wavelength range (UVB, 290–320 nm). Accordingly, the vast majority of photoimmunological studies have used UVB. There is also recent evidence that the long wave-length range (UVA, 320–400 nm) can affect the immune system, although its effects are less pronounced and more heterogeneous. Hence, in the following section the term UV refers mostly to UVB. If other spectra, for example UVA or UVC, were used it will be mentioned specifically.

UVB inhibits antigen presentation, induces the release of immunosuppressive cytokines and the generation of T cells with suppressive activities. This does not cause general immunosuppression but rather an inhibition of immune reactions in an antigen-specific fashion, mediated by suppressor/regulatory T cells. UVB-induced DNA damage is a major molecular trigger of UV-mediated immunosuppression. Further studies addressing the molecular mechanisms underlying UV-induced immunosuppression will contribute

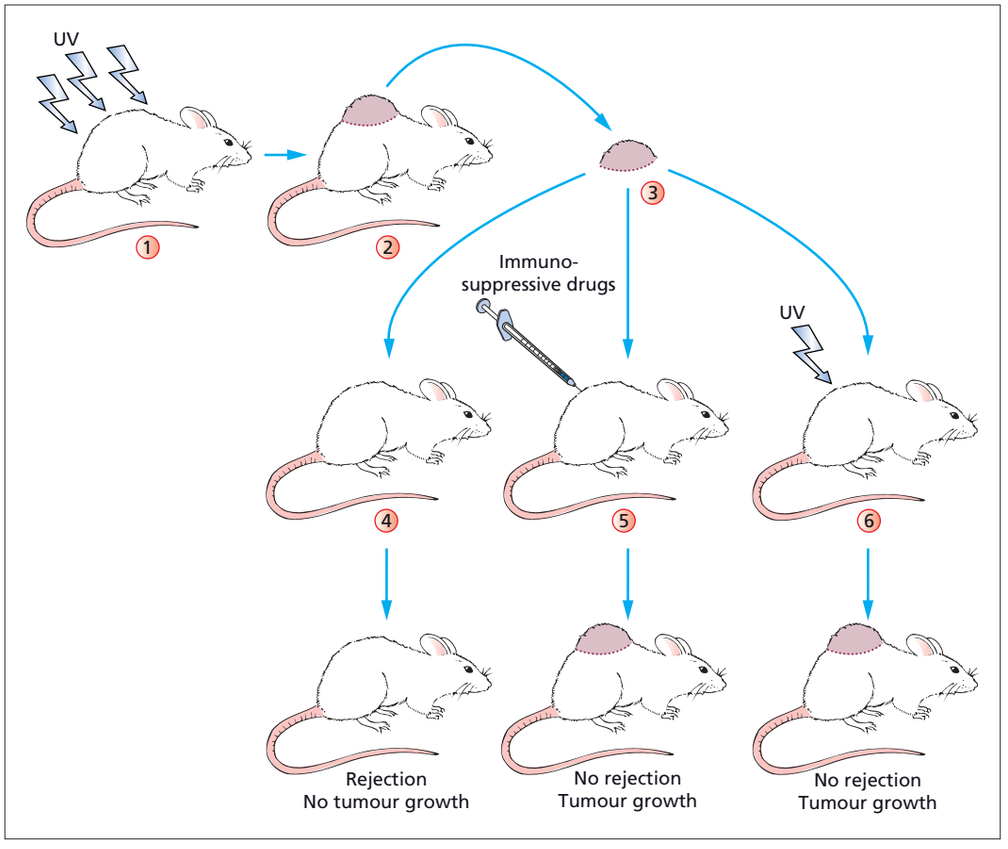

Fig. 13.4 UV radiation inhibits the rejection of immunogenic skin tumours. Chronic UV exposure (1) induces skin tumours (2). Upon transplantation (3) these tumours are rejected by naïve syngeneic recipient mice (4). If recipient mice are treated with immunosuppressive drugs (5) or exposed to UV radiation (6) these tumours are not rejected but grow.

to a better understanding of how UV acts both as a pathogen and as a therapeutic tool.

Until recently, photoimmunology has exclusively concentrated on studying the effects of UV radiation on the acquired immune response. There are very recent indications that UV radiation might also influence the innate immune response. Since these studies are just at the beginning and the impact of the alteration by UV radiation is not yet clear, the following chapter will almost exclusively focus on the effect of UV radiation on the acquired immune response.

UV radiation induces local and systemic immunosuppression

Initial evidence that UV radiation influences the immune system was provided by the observation that UV radiation inhibits the immunological rejection of transplanted tumours. Skin tumours induced by chronic UV exposure in mice are highly immunogenic since they are rejected following transplantation into naïve, syngeneic hosts [1]. However, if the recipient animal is treated with immunosuppressive drugs, the inoculated tumours are not rejected but grow, implying that the rejection is immunological in nature. Rejection can also be prevented when the recipient mice are exposed to UV radiation instead of immunosuppressive drugs, clearly indicating that UV radiation can act in an immunosuppressive fashion (Fig. 13.4).

A similar effect can be observed in another immunological *in vivo* model, namely the induction of contact hypersensitivity (CHS). CHS represents a particular kind of delayed type hypersensitivity response which is induced by epicutaneous application of low molecular weight chemical compounds. Since these substances have to bind to proteins to exert antigenic features they are called haptens. Painting of haptens on areas of skin that have been exposed to low (suberythemogenic) UV doses does not induce CHS, whereas administration of the same compound to an unexposed site causes a normal CHS response [2].

Since the areas of hapten application and UV exposure are identical, this type of immunosuppression is called local (Fig. 13.5). Inhibition of CHS induction by UV radiation is associated with a reduction in the number of Langerhans' cells (LC) at the site of exposure [2,3]. This appeared logical since in those days LC were regarded as the primary antigen-presenting cells in the skin [4] and thus suggested that UV radiation interferes with antigen presentation. However, this concept has recently been challenged by the findings that LC may be dispensable for sensitization [5–7].

Higher doses of UV can also affect immune reactions initiated at distant, non-UV-exposed sites. Accordingly, CHS cannot be induced in mice that are exposed to high doses of UV radiation even if the hapten is applied at unirradiated sites [8]. This type is called systemic immunosuppression (Fig. 13.6). Systemic immunosuppression is certainly mediated by mechanisms other than

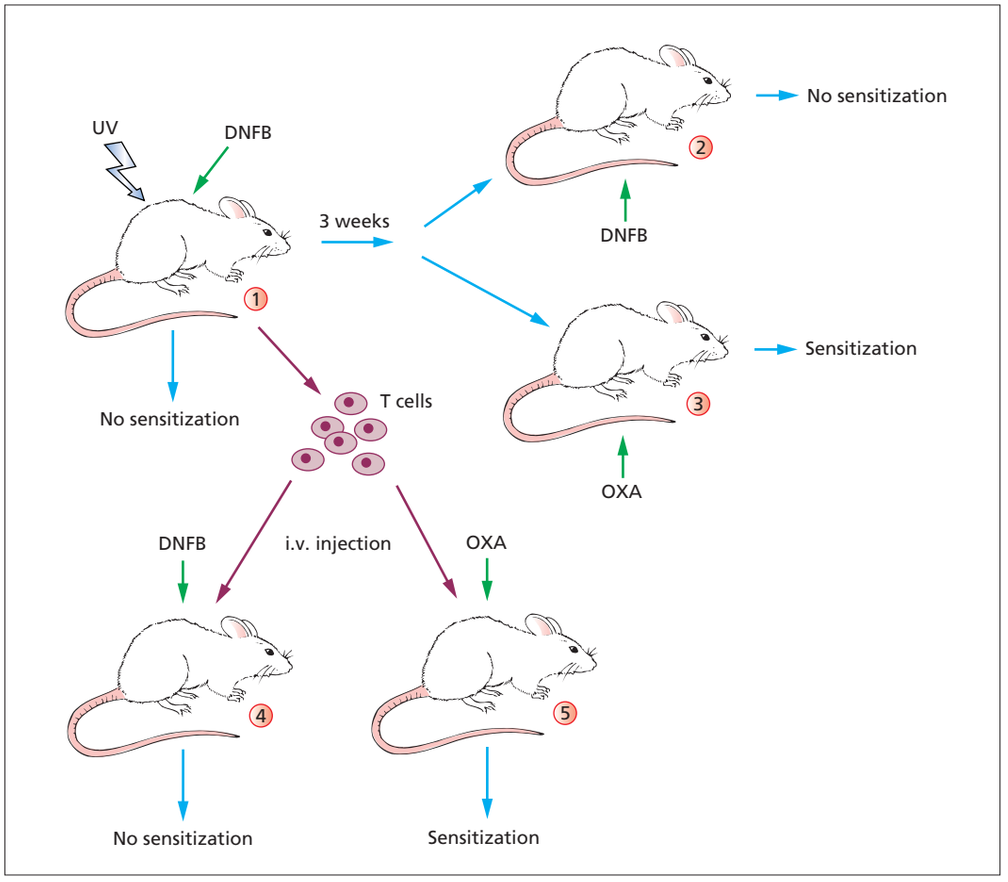

Fig. 13.5 UV radiation induces hapten-specific tolerance which can be adoptively transferred. Application of the hapten dinitrofluorobenzene (DNFB) onto UV-exposed skin does not result in sensitization (1). Reapplication of DNFB onto non-UV-exposed skin of the same mice 3 weeks later again does not cause sensitization (2), indicating that tolerance has developed. However, animals can be sensitized against the unrelated hapten oxazolone (OXA), indicating that tolerance is hapten-specific (3). Intravenous (i.v.) injection of T cells obtained from mice that received DNFB onto UV-exposed skin inhibits sensitization against DNFB of recipient mice (4). However, recipients can be sensitized against OXA (5), indicating that transfer of suppression is hapten-specific.

local immunosuppression. The question as to how UV radiation could interfere with the induction of an immune response at a distant, non-UV-exposed skin area remained unanswered for a long time. It is now clear that UV radiation stimulates keratinocytes to release immunosuppressive soluble mediators which enter the circulation and cause systemic immunosuppression [9].

Effect of UV radiation on antigen presentation

Within the epidermis, LC are the major antigen-presenting cell [10], although other dendritic cells resident in the skin may also be capable of inducing sensitization [5–7]. Exposure of skin to UV radiation results in a profound depletion of LC (Fig. 13.7) which seems to be responsible for inhibition of the induction of contact hypersensitivity following UV irradiation [2]. Depending on the dose of UV applied, the disappearance of LC may be due to either their emigration out of the epidermis and/or induction of apoptotic cell death. UV-damaged LC are still able to migrate into the regional lymph nodes [11] and on their arrival they are still capable of presenting antigen to T cells. Nevertheless, due to the UV stress LC seem to be so damaged that they are unable to present antigen properly, which results in tolerance but not sensitization.

UV radiation certainly alters the antigen-presenting capacity of LC [12]. Inhibition of expression of the adhesion molecule intercellular adhesion molecule-1 (ICAM-1) by UV radiation may be responsible for impaired adherence between LC and T cells. Accordingly, inhibition of antigen presentation by UV radiation was proven both *in vitro* and *in vivo*. Injection of antigen-loaded LC or dendritic cells that have been exposed to UV radiation does not result in sensitization, while injection of antigen-pulsed cells mounts an immune response [13]. In addition, UV-exposed antigen-presenting cells (APCs) are unable to induce a response *in vitro*, for example proliferation in the mixed leucocyte reaction [14]. *In vitro,* UV exposure differentially affects LC in their capacity to stimulate different subsets of $CD4^+$ T-cell clones. While UV-treated LC are unable to stimulate T-cell clones of the Th1 type, their ability to stimulate Th2 clones is unaffected [15]. This may explain why UV radiation preferentially suppresses Th1-mediated immune responses.

UV radiation induces immunologic tolerance

Application of haptens onto UV-exposed murine skin does not result in the induction of contact hypersensitivity. If the same contact allergen is applied, several weeks later, to an area of skin which was not exposed to UV radiation, again no contact hypersensitivity response is induced [1]. This indicates that the initial

application of the hapten onto UV-exposed skin induces long-term unresponsiveness (Fig. 13.5). However, the mice are not generally immunosuppressed by the initial UV exposure since an immune response against another, unrelated, hapten can be induced perfectly in these animals. This indicates that the immunological unresponsiveness caused by UV radiation is hapten-specific, a state called hapten-specific tolerance. Induction of UV-mediated tolerance can be also observed in systemic immunosuppression [2]. Long-term immunosuppression by UV radiation is also observed in the tumour transplantation model. UV exposure suppresses rejection of transplanted skin tumours. If mice are treated for several weeks with repeated doses of UV radiation and then treatment is stopped, the animals remain susceptible to tumour challenge for at least one year, perhaps even for the rest of their lives [3].

The phenomenon of UV-induced tolerance is also demonstrable in humans although some interindividual susceptibility appears to exist. [4]. The fact that UV radiation suppresses the immune system in a specific rather than a general fashion might explain why phototherapy exerts much lower side effects than conventional immunosuppressive drugs which compromise the immune system in a broad manner.

UV radiation induces T cells with regulatory/suppressor activity

UV radiation-induced hapten-specific tolerance appears to be due to the induction of T cells with inhibitory/suppressive activity. Injection of splenocytes from mice which have been tolerized by application of a hapten onto UV-exposed skin into naïve syngeneic mice renders the recipients unresponsive to this particular antigen [1]. Immune responses against other non-related antigens are unaffected (Fig. 13.5). Transfer of suppression is mediated via T cells since their depletion from splenocytes is associated with a loss of transfer. Thus, sensitization in combination with UV exposure induces the generation of T cells with hapten-specific suppressor activity. Transfer of tolerance can be observed both in local [1] and systemic models [2]. Nevertheless, different types of T cells seem to be involved. In the systemic form of UV-induced suppression, transfer of tolerance is mediated by the induction of antigen-specific, $CD3^+CD4^+CD8^-$ suppressor cells [3]; in the local form of suppression, both $CD4^+$ and $CD8^+$ cells appear to be involved. These differences may be due to a variety of factors including: the different systems used; strain of mice; the type of haptens; and the UV doses applied.

Although the adoptive transfer experiments appear convincing, attempts to purify and clone these transferred cells have been unsuccessful. For this reason, the term 'T suppressor cells' was almost banned in general immunology and the entire concept of UV-induced tolerance and suppressor cells was drawn into question by many immunologists [4]. The subject of T suppressor cells experienced a renaissance by the finding that chronic activation of both human and murine $CD4^+$ T cells in the presence of interleukin (IL)-10 induces $CD4^+$ T cell clones which release high levels of IL-10, low levels of IL-2 and no IL-4 [5]. These antigen-specific T cell clones suppress the proliferation of $CD4^+$ T cells in response to antigen, and prevent a T cell-mediated colitis in an immunodeficient mouse model of this condition [5]. This $CD4^+$ T cell subset is referred to as T regulatory cells 1 (Tr1).

Another subset of $CD4^+$ regulatory T (Treg) cells is characterized by the constitutive expression of the α chain of the IL-2 receptor (CD25). After antigen-specific activation, $CD4^+CD25^+$ T cells suppress immune reactions both *in vitro* and *in vivo* in an antigen-non-specific way [6]. There is also evidence that $CD4^+CD25^+$ Treg may be involved in the mediation of UV-induced tolerance. The area of Treg is currently one of the most extensively studied subjects in general immunology and future studies will increase knowledge about the mediation of tolerance and active suppression. Whether these T cells are termed suppressor or regulatory seems to be more of a semantic issue. The term regulatory T cells or Treg is usually preferred, since the existence of these cells is becoming accepted even by those investigators who previously denied the existence of suppressor T cells.

Due to the different tolerance models (local, systemic, induction, memory, high dose, low dose) different subtypes of UV-induced Treg (UV-Treg) may exist. Currently best characterized are the Treg involved in the low-dose suppression of CHS. These cells belong to the $CD4^+CD25^+$ subtype, express CTLA-4, and in contrast to the classical $CD4^+CD25^+$ T cells release high amounts of IL-10 upon antigen-specific activation [7]. Thus, they may represent a separate subtype of Treg since they exhibit characteristics of naturally occurring Treg (expression of CD4 and CD25) but also of type 1 regulatory T (Tr1) cells (release of IL-10).

Intravenous injection of hapten-specific Treg into naïve mice inhibits sensitization in an antigen-specific fashion as immune reactions against other antigens are not suppressed [1]. Treg suppress immune reactions in an antigen-specific manner thus these cells carry quite a therapeutic potential, as via their administration general immunosuppression may be avoided. In comparison with conventional immunosuppressive drugs, this would have great benefits for the patients as the side effects of general immunosuppression, including secondary infections and increased risk of developing malignancies, could be avoided or prevented. Therapeutic administration, however, would only make sense if these cells are able not only to prevent sensitization but also to inhibit the elicitation in sensitized hosts. In general, the aim of immunosuppression is not to prevent but to treat and to cure diseases.

Interestingly, intravenous injection of UV-Treg into naïve mice inhibits the sensitization, but not the elicitation, of CHS when injected intravenously into already sensitized mice [8]. However, upon intracutaneous injection of UV-Treg into the ears of sensitized mice the ear challenge is inhibited [9]. This proves that UV-induced Treg once they have reached the area of inflammation can suppress not only the induction but also the elicitation of

immune reactions. This process is critically dependent on the expression pattern of tissue homing receptors. UV-Treg express lymph node but not skin homing receptors. Hence upon intravenous injection, they migrate into the lymph nodes but not into the periphery and thus only inhibit sensitization but not elicitation. Thus, it is of crucial importance whether it will be possible to manipulate the expression pattern of homing receptors in such a way that Treg can gain access to the periphery. If this proves not to be the case, the therapeutic potential of Treg will be limited.

Cellular-mediated suppression appears to play a role in the inhibition of tumour immune responses by UV radiation. However, in this setting natural killer T (NKT) cells, but not Treg, appear to be involved [10]. UV-induced NKT cells suppress a delayed type hypersensitivity reaction against tumour antigens. In addition, they support the growth of inoculated UV-induced tumour cells which are rejected in normal mice. This indicates that NKT cells may play a critical role in regulating the growth of UV-induced skin cancers.

UV radiation induces the release of immunosuppressive mediators

The finding that mice exposed to higher doses of UV radiation cannot be sensitized, even when the antigen is applied to an area of skin which has not been exposed to UV [1,2], clearly indicates that UV radiation has the capacity to suppress the immune system in a systemic manner (Fig. 13.6). How events at the irradiated site lead to a suppressed response to an antigen applied at a distant area of non-UV-exposed skin remained unresolved for many years. Keratinocytes have been recognized as a potent source of various soluble mediators, including immunostimulatory and pro-inflammatory cytokines. Cytokine release by keratinocytes can be effectively induced by UV radiation [3]. UV radiation, however, may also stimulate the release of immunosuppressive mediators since intravenous injection of supernatants obtained from UV-exposed keratinocytes into naïve mice renders the recipients unresponsive to hapten sensitization [4]. Therefore, UV-induced keratinocyte-derived immunosuppressive mediators may enter the circulation and inhibit immune responses at areas of skin not directly exposed to UV radiation, thereby explaining the phenomenon of systemic immunosuppression.

Several mediators appear to be involved in UV-induced immunosuppression. The major player appears to be IL-10, whose release by keratinocytes is induced by UV radiation [5]. IL-10 abrogates the ability of LC to present antigens [6] and injection of IL-10 into an area of skin where hapten has been applied prevents the induction of CHS and induces hapten-specific tolerance [7]. In turn, injection of an anti-IL-10 antibody into UV-irradiated mice prevents systemic UV-induced suppression of the induction of delayed type hypersensitivity [5]. Furthermore, IL-10 induces a shift from a Th1 to a Th2 response; this may explain why UV radiation inhibits primarily Th1 immune reactions and favours development of Th2 reactions [8].

IL-12 is a cytokine which induces a Th1 immune response and which may be regarded as a counter-balance to IL-10 [9]. Thus, it is not surprising that IL-12 has the capacity to prevent UV-induced immunosuppression. Injection of IL-12 before UV exposure enables sensitization even if the antigen is applied onto UV-irradiated skin [10–12]. Even more importantly IL-12 is able to break established UV-induced tolerance, since its injection into UV-tolerized mice renders these animals susceptible to the antigen against which they were tolerized [10,12].

Other soluble mediators, besides IL-10, which appear to be involved in UV-induced immunosuppression are: tumour necrosis factor-α [13,14]; IL-4 [15]; prostaglandin E_2 [15]; calcitonin gene related peptide [16], α melanocyte stimulating hormone [17]; and platelet activating factor (PAF) [18].

UV radiation induces immunosuppression in humans

The vast majority of studies in the field of photoimmunology have been performed *in vivo* in animal, usually murine, models. Although numerous *in vitro* studies have been performed with human cells, the key question is whether the observations made in animal models are relevant to the human situation and whether humans are immunosuppressed by UV radiation in a similar fashion. UV-induced tolerance has been shown to occur in humans as well as in animals. Upon low-dose UV radiation, about 45% of UV immunosuppressed humans become tolerant. Tolerance is hapten-specific, since the individuals respond normally upon subsequent immunization against other non-related haptens [1]. Higher doses of UV appear to increase the proportion of individuals that can develop tolerance [2]. However, it is unclear whether all humans can be rendered tolerant by UV radiation; this may be critically dependent on the spectrum, the dose, the timing and on individual predisposition. It remains to be determined whether the UV-susceptible population is at higher risk of developing skin cancer. Indeed, sensitivity to sunburn appears to be associated with susceptibility to UV radiation-induced suppression of cutaneous cell-mediated immunity in humans [3]. Recently, UV-induced immunosuppression has started to be used as a tool to evaluate the potency of sunscreens [4,5].

Molecular targets mediating UV-induced immunosuppression

Nuclear DNA is a perfect chromophore for both UVB and UVC radiation. UV radiation primarily induces two types of DNA lesions, pyrimidine dimers and (6-4)-photoproducts. Thus UV-induced DNA lesions have been regarded as the major, and for a long time the only, molecular target via which UV radiation exerts its biological effects. UV-induced DNA damage also appears to be critically involved in signalling photoimmunosuppression. This conclusion is supported by studies using DNA repair enzymes applied topically in a liposome-based cream (Fig. 13.6). Application of T4N5 endonuclease, a bacterial DNA repair enzyme, restores the immune response when applied immediately after UV exposure [1]. Similar findings were obtained in humans when the repair enzyme photolyase was applied topically [2].

Despite clear-cut evidence for the crucial role of UV-induced DNA damage in photoimmunosuppression, there are indications that UV radiation may also affect cytoplasmic and membrane targets [3]. UV radiation can directly trigger surface receptors either by inducing their oligomerization [4] or phosphorylation [5].

In addition, the involvement of *cis*-urocanic acid (UCA) indicates that UV-induced immunosuppression can be mediated independently of DNA damage. UCA is an epidermal chromophore involved in mediating UV-induced immunosuppression [6]. UCA, a metabolite of the essential amino acid histidine, accumulates in the epidermis as epidermal cells are devoid of the necessary enzymes to further catabolize it. Two tautomeric forms of UCA exist, *trans* (E)- and *cis* (Z)-UCA. Upon UV exposure UCA is photoisomerized from *trans*- into *cis*-UCA. Tape-stripping of the epidermis, which removes the majority of UCA, prevents UV-induced suppression of the induction of CHS, indicating that *cis*-UCA is involved in photoimmunosuppression [7]. Furthermore, injection of *cis*-UCA partially mimics the immunoinhibitory activity of UV radiation [8]. *Vice versa*, anti-*cis*-UCA antibodies restore particular immune responses after UV exposure [9]. *cis*-UCA also inhibits the presentation of tumour antigens by Langerhans' cells [10]. This effect can be reversed by IL-12 [11]. In addition, injection of *cis*-UCA antibodies reduces the incidence of UV-induced skin tumours in a photocarcinogenesis model indicating the involvement of *cis*-UCA in the generation of UV-induced skin cancer [11].

UVA-induced immunosuppression

While UVB is universally found to be immunosuppressive, this is not the case for UVA. There are reports that UVA may protect the immune system from the suppressive effects of UVB [1]. This effect seems to be mediated via interferon-γ [2]. Unlike UVB which has a dose response showing increased levels of immunosuppression with increasing dose, UVA, at least under some circumstances, has a bell-shaped dose–response curve so that after the maximum immunosuppressive dose has been reached, higher doses cause lower levels of immunosuppression until a dose is reached which is no longer suppressive [3]. This refers to dose ranges to which humans can be exposed during normal daily outdoor activities. While this might appear to indicate that UVB is the more important waveband in sunlight for causing immunosuppression, solar-simulated UV-induced immunosuppression dose responses have been reported to be identical to UVA, since absorption of UVB from the irradiation source has no discernible effect on solar-simulated UV-induced immunosuppression [4,5]. Furthermore, numerous studies using sunscreens to filter UVB from solar-simulated UV have shown the importance of UVA within the sunlight spectrum for causing immunosuppression in humans and mice [6,7]. Thus, UVA-1 induced immunosuppression has been used to determine the UVA-1 filtering capacity of sunscreens [8].

Implications of UV-induced immunosuppression

The biological implications of UV-induced immunosuppression may be several-fold. In experimental models it has been demonstrated that UV radiation can inhibit the protective immune response against viral, bacterial and fungal infections. The most frequently used infectious agents to study these phenomena are herpes simplex virus, *Listeria*, *Leishmania*, mycobacteria and *Candida* [1]. Based on these studies there is clear cut-evidence that UV radiation can compromise an immune response against these agents both in a local and a systemic fashion. These models have contributed in an essential way to the further understanding of how UV radiation suppresses the immune system. However, from daily clinical practice we know that acute and severe exacerbations of infectious diseases following solar exposure are extremely rare in humans. The only exception is herpes simplex infection, in which recurrences are frequently observed after solar exposure.

In contrast, bacterial infections are only observed rarely. For defence against bacterial infections the innate immune response which involves granulocytes, complement and, in particular, antimicrobial peptides is much more relevant than the classic adaptive immune response [2]. Preliminary data exist that UV radiation might induce the release of antimicrobial peptides. This could explain why bacterial superinfections are not a major problem upon solar and artificial UV exposures. In this context, it is important to mention that vitamin D, the production of which is induced by UV, has been found to exert antimicrobial activity against mycobacteria via the release of the antimicrobial peptide cathelicidin [3]. Therefore, at this stage, the clinical implications of UV-induced immunosuppression for infectious diseases may be limited.

The immune system protects not only against infection but also malignancy. Transformed cells, particularly in the early stages, can be recognized as 'foreign' and attacked by the immune system (tumour immunology). This may specifically apply to both non-melanoma skin cancer and malignant melanoma. There is clear evidence of an association of susceptibility to skin cancer and immunosuppression. Chronically immunosuppressed individuals, like transplant patients, exhibit a significantly increased risk

of developing skin cancer [4]. This risk increases with the cumulative UV load. In addition, the ability of UV radiation to negate host defences against skin tumours has been convincingly demonstrated in various experimental animal models. Furthermore, restoration or even enhancement of an immune response, for example by topical or systemic application of immunomodulators (interferons, imiquimod), has become an established alternative therapeutic option for the treatment of skin cancer [5]. Taken together, the immunosuppressive impact of UV radiation is probably much more relevant for carcinogenesis than for the exacerbation of infectious diseases.

It is striking that UV radiation at low doses can suppress an immune response [6]. Thus, one may speculate that a certain degree of immunosuppression may be beneficial. The skin is an organ that is constantly exposed to potential allergens; in addition autoimmune responses may be generated within the skin [7,8]. Hence, it is tempting to speculate that a certain degree of regular immunosuppression by daily sun exposure may prevent the induction of these immune responses.

The immunosuppressive effects of UV radiation, however, can also be exploited therapeutically. Phototherapy is a major therapeutic strategy in the treatment of inflammatory skin disease (Chapter 29). Although the mechanisms underlying the beneficial effects of solar/UV exposure in certain diseases remain to be determined, it is obvious that the immunosuppressive properties are essential in this respect [9]. Accordingly, the majority of dermatoses, for example psoriasis and atopic dermatitis, which can be treated with immunosuppressive drugs, respond favourably to phototherapy.

Biological aspects of wound healing

E.A. O'Toole, pp. 14.1–14.9

Introduction

Skin, the largest organ in the body, is vital for humans and animals to protect against dehydration, bleeding and environmental microorganisms. Humans and animals have evolved a sophisticated mechanism of wound healing to plug any gap in skin integrity quickly, re-epithelialize over the defect and rapidly replace the lost dermis with new matrix. The final product is not normal skin, for adult human skin does not regenerate, but rather is a repair in the form of a scar, which is visible on the skin surface.

Adult wound repair consists of a series of overlapping stages [1], beginning with aggregation and degranulation of platelets, blood clotting and the formation of a fibrin plug (eschar), which initially fills the wound (Fig. 14.1). This is followed by the inflammatory phase, where initially polymorphonuclear leukocytes appear, which stimulate the recruitment of monocytes, macrophages and lymphocytes that kill microorganisms and secrete a wide variety of growth factors and cytokines, which modulate the remaining wound healing response. These immune cells invade the fibrin-filled wound space and, together with fibroblasts and blood vessels from the deep fascia and surrounding dermis, begin to lay down a temporary matrix of granulation tissue consisting initially of a proteoglycan- and fibronectin-rich tissue, which serves as a guiding substratum for the migrating and proliferating cells. Cellular behaviour and coordination of the wound response is controlled during this granulation phase by a wide range of growth factors, extracellular matrix molecules and their receptors. There are extensive cell–cell and cell–matrix interactions. Epidermal cells proliferate and move down the edge of the wound until they reach the new granulation tissue, where they dissect between the overlying fibrinous eschar and the underlying granulation tissue to close the wound. At the same time, the wound contracts predominantly by forces exerted by contractile elements contained within myofibroblasts. The transitory granulation tissue phase ends as immune cells, fibroblasts and endothelial cells undergo apoptosis, while the remaining fibroblasts lay down collagen (mostly types I and III), a process that continues for some time. In the final remodelling stage of wound healing, the matrix is remodelled with a decrease in the relative levels of fibronectin, proteoglycans and type III collagen and an increase in the levels of predominantly type I collagen, which is organized into thick bundles and extensively cross-linked to form the mature scar.

Acute wound healing proceeds quickly and with few problems in the vast majority of cases. Clearly, the speed of wound healing depends upon many factors, including the size of the wound (incisional or excisional), blood supply to the area, presence of foreign bodies and microorganisms, age and health of the patient, nutritional status of the patient, drugs that the patient may be taking and a variety of systemic diseases. Oxygen plays a critical part in wound healing [2,3], as does nitric oxide [4]. Leptin may be another regulator of wound healing [5]. Wound healing is subject to regulation by a large number of different cytokines and growth factors [6,7]. Oestrogens promote wound healing, while androgens inhibit it [8–11]. Opioid peptides may also favour wound healing [12].

Sometimes, the wound-healing process does not proceed normally and chronic wounds result. The most common forms of chronic wounds in humans include venous ulcers, diabetic ulcers and pressure sores. In each of these cases there is normally an underlying pathology, such as venous insufficiency in the case of venous ulcers, or abnormal microvasculature and high blood sugar levels in diabetic ulcers. These underlying pathologies create a situation where the wound-healing response is impaired. Thus, for example, in the case of venous stasis ulcers, there is often a chronic ischaemia–reperfusion injury resulting in high levels of local cytokines, complex cuffs forming around the blood vessels and increased levels of wound proteases, particularly metalloproteinase-8 (MMP-8), MMP-26 and elastase, and decreased levels of protease inhibitors such as tissue inhibitor of matrix metalloproteinases (TIMP-2) [13–16]. In the case of diabetic ulcers, there are often extensive abnormalities in the microcirculation, thickening of the blood vessel wall, thrombi and areas of focal necrosis [17].

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

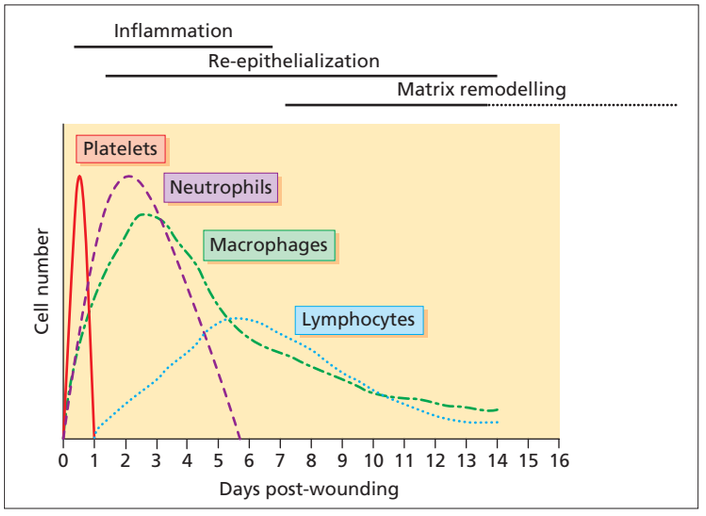

Fig. 14.1 Wound inflammatory cells during the first 2 weeks of wound healing.

In such chronic wounds, it is necessary to treat the underlying pathology if long-term non-recurrent healing of the ulcer is to be achieved. Understanding the molecular pathogenesis of these chronic wound-healing states can lead to novel therapeutic targets for pharmacological intervention (e.g. application of dressings containing protease inhibitors or 'smart matrix'). The wound-healing response can also be disrupted by excessive healing (adverse scarring), which is represented at the extremes by hypertrophic scars or keloids. These excessive wound-healing states result from the abnormal deposition of connective tissue within the healing wound, such that the scar is elevated and may extend beyond the boundaries of the original wound. Excessive scarring shows a clear genetic basis with racial tendencies (e.g. it is more common in black and oriental people than it is in white people).

Finally, the acute wound-healing response varies with the age of the individual. Wounds made on very early embryos heal by complete regeneration, while wounds made on later embryos or early fetuses (in the middle trimester of pregnancy) display scar-free healing but absence of regeneration of dermal appendages. Embryonic wounds exhibit a markedly reduced inflammatory response, alterations in cellular mediators, cytokines, growth factors, extracellular matrix modulators, tyrosine phosphorylation patterns and homeobox gene expression [18]. Wounds in children and young adults often heal quickly with excessive scarring, while elderly patients show specific disruptions in the wound-healing cascade, such as elevated levels of proteases, altered ratios of growth factors and their receptors and a slower rate of healing but often with enhanced quality (reduced scarring). Age-related changes in the inflammatory response to wounding have been reported [19]. Wound healing is impaired by stress, possibly due to increased serum cortisol [20].

Despite the fact that the various phases of wound healing overlap, it is convenient to consider the principal cellular and molecular mechanisms regulating the basic biology of wound healing in three phases: inflammation and the immune response, re-epithelialization, and matrix remodelling (see Fig. 14.1).

Inflammation and the immune response

Following wounding, there is almost immediate release of inflammatory mediators from damaged cells, degranulating platelets or resident tissue macrophages and mast cells. Furthermore, wounding causes a transient permeabilization of cells near the wound margin, with the rapid exchange of extracellular and intracellular ions, resulting in the switching on of early response genes in such cells within seconds following wounding. These mediators initially cause arteriole dilatation, resulting in an increased blood flow into the wound area. This process is further aided by growth factors such as vascular endothelial growth factor (VEGF), which causes hyperpermeability of endothelial cells [1]. This results in an influx of fluid and plasma components into the wound space, while inflammatory cells adhere to the vascular endothelium and migrate through the vascular wall into the wound.

Neutrophils are the predominant, initial inflammatory cells recruited to the wound, which together with platelets release a complex mixture of cytokines and growth factors. These amplify

the inflammatory response resulting in an influx of monocytes and lymphocytes, the proliferation of monocyte precursors within the wound and their differentiation into mature macrophages [2]. The use of knock-out mouse models to dissect the contribution of individual cytokines to wound repair revealed important roles for tumour necrosis factor-alpha (TNF-α), interleukin-1 signalling, CXCR2, IP-10, Smad3 and secretory leukocyte protease inhibitor in the inflammatory cell recruitment in acute wound healing [2,3].

Platelets respond very quickly, and when they reach the wound they adhere through selectin and integrin receptors [4], degranulate and release a variety of factors, including thromboxanes, prostaglandins, 12-lipoxygenase products, serotonin, adhesive glycoproteins including fibrinogen, Von Willebrand factor, fibronectin and thrombospondin and growth factors including platelet-derived growth factor (PDGF), epidermal growth factor (EGF) and transforming growth factor-β1 (TGF-β1). These factors both contribute to the initial fibrin plug that closes the wound and modulate subsequent cellular behaviour, including attachment, migration, proliferation and matrix deposition. However, wound closure, angiogenesis and collagen synthesis are not significantly impaired in thrombocytopenic mice [5].

These signals from the wound site, together with changes in vascular permeability, cause leukocytes to pavement in the blood vessels, undergo rolling and attachment to activated endothelial P- and E-selectins and integrins, for example heterodimers of CD18 (β2 integrin) and variable α subunits [4,6]. Neutrophils, recruited early in wound healing, are responsible for destroying invading bacteria by phagocytosis and release of reactive oxygen species, eicosanoids and proteolytic enzymes (elastase, cathepsin G, urokinase-type plasminogen activator), which may cause further tissue damage and inflammation. Once in the wound, neutrophils may be activated by cytokines such as granulocyte–macrophage colony-stimulating factor (GM-CSF) and tumour necrosis factor-α (TNF-α), complement or proteases such as thrombin. Unless stimuli for neutrophil recruitment persist, after a few days neutrophils are eliminated by macrophage phagocytosis or apoptopic cell death [7]. Monocytes and macrophages are recruited in large numbers to the healing wound as neutrophil numbers begin to decline. Classic studies by Leibovich and Ross [8] demonstrated the importance of these cells in wound healing; experimental depletion of wound macrophages resulted in prolonged inflammation and delays in fibroblast proliferation, matrix deposition and subsequent wound closure. The transition from a resting to an active state in monocytes and macrophages is controlled by cytokines such as TNF-α and IFN-γ, as well as bacterial products such as lipopolysaccharide. Monocytes and macrophages produce a range of cytokines in response to pro-inflammatory signals, including TGF-β and TGF-α, basic fibroblast growth factor, VEGF and PDGF. The interactions between these growth factors and monocyte/macrophage differentiation/activation is complex and often self-regulatory. Thus, TGF-β1 acts as a pro-inflammatory cytokine early in the wound-healing phase, as it is chemotactic to immature monocytes, which are recruited to the wound site, and synthesize and secrete more TGF-β1, due to a self-inducing response element in the TGF-β1 promoter. However, TGF-β1 is anti-inflammatory to mature or activated monocytes/macrophages, because it inhibits their activation and modulates receptor expression. Although wound healing is initially normal in the TGF-β1 knockout mouse, accumulation of inflammatory cells and reduction in angiogenesis and collagen deposition lead to delayed epithelial closure [9].

In addition to the production of cytokines, wound macrophages also produce a range of extracellular matrix molecules, which, together with fibrinogen and fibrin from the blood clot, matrix molecules from degranulating platelets, recruited fibroblasts and endothelial cells, form the granulation tissue or provisional matrix. This provisional matrix is rich in molecules, such as fibronectin, vitronectin, thrombospondin, SPARC (osteonectin), tenascin and proteoglycans such as dermatan, chondroitin and heparan sulphate. It acts as an early scaffold for the re-establishment of the dermis and for the migration of epidermis as it promotes both cell migration and proliferation [10]. Regulation of this provisional matrix is complex, and achieved partially through control at the transcriptional level, for example with alternative splicing of the primary transcript for fibronectin resulting in embryonic-like cellular fibronectins being deposited within the wound space, which better facilitate cell migration and proliferation [11].

Pro-inflammatory cytokines such as TNF-α and IFN-γ can stimulate the production of chemokines by endothelial cells [12]. Endothelial and macrophage chemokines (e.g. IL-8, IP-10, PF-4, MIP-1α, MIP-1β, RANTES and MCP-1) attract lymphocytes to the wound area, and may have a role in the progression of healing to fibrosis [3]. These lymphocytes include both B and T lymphocytes, and there is growing evidence that the particular type of T-lymphocyte response (Th1 or Th2), each characterized by a different profile of cytokine secretion, may be one of the factors underlying abnormal fibrosis and scarring [13]. Human γ/δ T lymphocytes express and synthesize connective tissue growth factor (CTGF), known to regulate fibrogenesis and wound healing, as well as FGF-7, -10 and IGF-1 regulating keratinocyte differentiation and proliferation [14]. In addition, this T-cell subgroup regulates keratinocyte hyaluronic acid deposition in the provisional matrix, and subsequent macrophage infiltration into the wound [15]. The type of T-lymphocyte response itself may be determined by the profile of growth factors in the early wound. Thus, for example, natural killer (NK) cell migration out of blood vessels is promoted by VEGF but inhibited by FGF-2 [16]. IL-6 also has a crucial role in wound healing, probably by regulating early leukocyte infiltration and tissue remodelling in the later stages of wound repair [17]. Recent *in vivo* functional studies reveal the roles of different transcriptional regulators in wound repair. Mice deficient for PU.1 transcription factor, that lack macrophages and functional neutrophils, surprisingly showed normal scar-free healing of incisional wounds [18]. Mice deficient in Nrf2, a leucine zipper transcription factor involved in detoxification of reactive oxygen species, have increased and prolonged macrophage infiltration in wounds, suggesting that Nrf2 regulates resolution of inflammation [19].

These early inflammatory responses clear the wound of foreign antigens such as bacteria and supply combinations of growth factors and extracellular matrix molecules, which orchestrate the subsequent healing of the provisional matrix by providing the signals and scaffold for fibroblast, endothelial and keratinocyte influx. Inflammatory cells such as monocytes and macrophages

decrease towards the end of the inflammatory phase, largely through apoptosis resulting from diminution of the levels of survival factors (e.g. specific cytokines and matrix molecules).

Re-epithelialization

The process of re-epithelialization commences about 24 hours after wounding when keratinocytes migrate from the wound edge or hair follicles across the provisional wound matrix to invade the wound bed, where they proliferate to form new epidermis [1]. Keratinocyte injury alters the ratio of magnesium and calcium ions, which induces keratinocytes to adopt a migratory phenotype [2]. The migrating keratinocyte flattens and elongates with formation of lamellipodia to aid cell movement, loss of cell–cell (desmosomes) and cell–matrix contacts and rearrangement of the actin filament network. The K1 and K10 suprabasal cytokeratin filaments are replaced by the flexible cytokeratins K6 and K16, whose expression is regulated by growth factors such as EGF, TGF-α and TGF-β present at high levels within the provisional matrix [3].

Following wounding, signals from the matrix and growth factors induce phosphorylation of numerous keratinocyte proteins, including focal adhesion kinase, c-Met, the small guanine triphosphatase, Rac, extracellular signal-regulated kinases 1/2, phosphatidylinositol 3-kinase, mitogen-activated protein kinase kinase kinase 1 and p38 mitogen-activated protein kinase, and the downstream AP-1 and Stat3 families of transcription factors which regulate many of the genes involved in keratinocyte migration, for example integrins, MMPs and growth factors [4–10]. TNF-α stimulates transcription of the PPARβ/δ (peroxisome-proliferator-activated receptor β/δ) gene, also via an AP-1 site in its promoter, with subsequent up-regulation of the expression of integrin-linked kinase and 3-phosphoinositide-dependent kinase-1, which activates the anti-apoptotic protein, Akt [11]. Keratinocytes in the basal layer some 300–400 cell diameters away from the wound margin proliferate extensively; such proliferation peaks within 1–2 days post-wounding and then falls back again to reach basal levels about 14 days post-wounding. The transcription factor, c-Myc, is a potent regulator of keratinocyte proliferation during wound healing [12]. Suprabasal cells derived from this extensive proliferation roll over the attached basal cells to form new basal cells at the wound margin, a process repeated by successive basal cells until re-epithelialization is complete.

To reach the wound bed, migrating keratinocytes express metalloproteinases (MMPs) (enzymes that degrade basement membrane components and interstitial collagens) and urokinase-type plasminogen activator, an enzyme which activates plasmin for fibrinolysis of fibrin [13,14]. Up-regulation of MMP-9 and urokinase plasminogen activator, induced by hypoxia, result in increased keratinocyte migration [15,16]. This up-regulation is mirrored by the concurrent up-regulation of plasminogen-activator inhibitors, which control the extent of plasminogen activation [16]. This suggests a key role for the plasmin–plasminogen system in wound healing, an assertion given experimental weight by wound-healing studies on mice with targeted disruption of the plasminogen gene [17]. These mice show substantial delays in wound re-epithelialization and the aberrant persistence of fibrin within the wound matrix, demonstrating the importance of the plasminogen–plasmin system for fibrin removal during wound healing. Syndecan-1 is a cell-surface proteoglycan that enhances keratinocyte proliferation and re-epithelialization [18].

During wound healing, the migrating keratinocytes come into contact with dermal collagens and the fibrin clot constituents fibrin, fibronectin and vitronectin. Thus, α5, β1, αV and β5 integrins, the primary keratinocyte receptors for fibronectin and vitronectin, are up-regulated in migrating keratinocytes during re-epithelialization [19]. Expression of these integrins may be induced by TGF-β1 [20]. Once re-epithelialization is complete, the keratinocytes switch from the vitronectin/fibronectin receptor (αVβ5) to the tenascin/fibronectin receptor (αVβ6), a switch that may be involved in the redifferentiation of the epidermis, as the β6 integrin has been associated with epithelial remodelling during

development and tumourigenesis [21]. Because keratinocytes do not express the fibrin-specific integrin, αVβ3, instead of invading the fibrin clot, the migrating cells dissect the fibrin clot from the wound bed [22].

A number of growth factors secreted by keratinocytes, fibroblasts or inflammatory cells promote keratinocyte proliferation and migration (see Table 14.1 and Table 14.2 and references [23–26]). Fibroblast growth factor-7 (FGF-7/KGF) stimulates hyaluronan synthesis, which also promotes keratinocyte migration [27]. The antimicrobial peptides, human beta-defensins, stimulate epidermal keratinocyte migration, proliferation and production of pro-inflammatory cytokines [28]. Secreted heat shock protein-90α induced by TGF-α, promotes both epidermal and dermal cell migration [29]. Keratinocytes can stimulate FGF-7 production by underlying dermal cells, which then acts specifically on the overlying epidermal cells expressing the FGF-7 receptor [30]. During wounding, cells come into contact with human serum, which promotes keratinocyte motility via p38 MAP kinase and induction of epidermal MMP expression [31].

In normal skin, the basement membrane separates the epidermis from the dermis. Following wounding, this dermal–epidermal junction must be reconstituted as part of the re-epithelialization process. Basal lamina components, such as type IV collagen, laminin and heparan sulphate, are synthesized and deposited into the dermal–epidermal junction by both the fibroblasts and the keratinocytes, and a scanty basement membrane is usually present by 7 to 9 days after wounding [32,33]. Maturation of anchoring fibrils may take up to 3 years [34].

Angiogenesis

Formation of new blood vessels within the provisional matrix is stimulated by day 2 of the inflammatory stage of wound healing. Immediately following injury, angiogenic growth factors including VEGF, PDGF, FGFs and TGF-β are secreted by platelets, fibroblasts, wounded keratinocytes and macrophages [1,2]. Vascular endothelial growth factor induces endothelial cell proliferation and migration through three receptors, VEGFR-1/Flt1, VEGFR-2 and Neuropilin-1 [3,4]. Periostin, a known inducer of VEGFR-2 expression which plays a role in regulating vascular smooth muscle cell migration, was recently shown to be 96-fold upregulated in wound vessels compared to normal blood vessels [5]. The sprouting endothelial cells participate in granulation tissue formation (the capillary loops within the provisional matrix give granulation tissue its red granular appearance). Hypoxia and reactive oxygen species also regulates VEGF expression via the activation of hypoxia-inducible factor-1α, which is strongly expressed by keratinocytes at the wound edge, and the Sp1 transcription factor, respectively [6,7]. Endothelial cells from nearby blood vessels and, in larger wounds, endothelial progenitor cells from bone marrow, activated by VEGF and mobilized by the CXCR4 ligand, SDF-1 (stromal cell-derived factor 1), move to the wound bed [8].

Laminin 411 (laminin 8) and laminin 511 (laminin 10) are the major laminin isoforms in the basement membrane of dermal microvascular endothelial cells [9]. Laminin 8 promotes endothelial cell attachment, migration and tubule formation. Endothelial cells use both β1-containing and αvβ3 integrins in their interactions with the G1-3 domains of the α4 chain of laminin 8 [10,11]. Proteolytic enzymes, for example MMPs, are released at the growing tips of capillaries, degrading the ECM for forward movement [12]. Ephrin ligand–receptor interactions guide the patterning of vascular loops and tubes [13].

Adequate revascularization of the wound is essential for healing; ineffective angiogenesis results in impaired wound healing. At the end of the provisional matrix phase, the numbers of blood vessels within the healing wound decrease by a process of apoptosis,

probably induced by depletion of vascular survival factors, such as VEGF, and the appearance of pro-apoptotic factors such as TGF-β [14].

Fibroblast recruitment, matrix synthesis and scarring

The fibroblasts migrate into, and proliferate within, the provisional wound matrix, depositing additional extracellular matrix molecules. Most wound fibroblasts are derived from proliferation of fibroblast progenitor cells in the deep dermis and the septae of the underlying fat; relatively few cells are derived from the margins of the surrounding dermis [1]. Like the keratinocytes, they alter their integrin profile, expressing receptors for fibronectin, fibrin and vitronectin and down-regulating receptors for collagen during the early phases of migration [2,3]. During the early stages of provisional matrix deposition, collagen synthesis in the surrounding unwounded skin is suppressed, while fibronectin synthesis is enhanced [2]. Fibroblasts within the provisional matrix secrete and assemble a complex extracellular matrix. Initially, this consists predominantly of fibronectin and proteoglycans, but later consists of mature type I collagen bundles. The ratio of collagen types during wound healing varies, the early wound being characterized by elevated levels of type III collagen, whereas later in wound healing type I collagen predominates. Minor collagens, such as types 12 and 14, as well as proteoglycans such as decorin, are also present in the early healing wound and play a key part in collagen fibril organization. The degree of collagenous cross-linking also varies with time after wounding: the early wound has fewer and more immature cross-links compared with the later wound, which has extensive mature cross-links, resulting in a more insoluble collagenous matrix. Both mesenchymal and epidermal secreted factors stimulate fibroblast proliferation, migration and extracellular matrix synthesis in a paracrine and autocrine fashion, including the TGF-β family, IGF-1, PDGF, CTGF and hypoxia-induced heat shock protein 90 [4–6]. There is extensive cross-talk between the extracellular matrix-derived signals and growth factor signalling in this process. Thus, for example, clustering of integrin receptors on the fibroblast leading edge leads to associated clustering of growth factor receptors, which then interact with the growth factors bound to the matrix.

The early granulation tissue is characterized by transformed wound fibroblasts called myofibroblasts, which show elevated levels of α-smooth muscle actin and are morphologically and functionally intermediate between fibroblasts and smooth muscle cells. Differentiation into myofibroblasts is induced by growth factors such as TGF-β1 and IL-6, coagulation protease factor (F)Xa, extracellular matrix proteins such as the fibronectin splice variant ED-A FN and tenascin, and the mechanical microenvironment [7,8]. Myofibroblasts may contribute to the contractile forces involve in wound contraction, and their persistence can lead to abnormal scar contracture. They are preferentially eliminated during the apoptopic phase of wound healing which may be induced by wound relaxation [7]. The Smad family of proteins mediates signal transduction of the TGF-β superfamily, including induction of CTGF expression and synthesis of collagens and TIMP-1, and TGF-β induces fibroblast contraction necessary for efficient wound healing [9]. Turnover of the extracellular matrix is facilitated by a range of proteases and protease inhibitors, including plasmin, matrix metalloproteinases, hyaluronidase and elastase [10]. Levels of these active proteases are carefully and focally controlled both by growth factors, for example, IL-6, and by proteolytic inhibitors such as TIMP and syndecans [11,12]. IL-10 and bFGF both regulate remodelling of the ECM during wound healing [13,14].

As healing proceeds, the numbers of fibroblasts, endothelial and inflammatory cells decrease, and the predominantly collagenous matrix becomes organized into thicker, more heavily cross-linked bundles. This marks the establishment of the mature scar. Scars continue to remodel for a long time after wounding, and cannot be considered to be in a steady-state condition until at least 2 years post-wounding. Cutaneous scarring is defined as a macroscopic disturbance of the normal structure and function of the skin architecture, resulting from the end-product of a healed wound [15]. Scarring may manifest itself as an elevated or depressed site, with an alteration of skin texture (e.g. hard), colour (e.g. hyperpigmentation or erythema), vascularity, nerve supply, reflectance and biomechanical (e.g. elasticity) properties. Histologically, dermal scars are characterized by thickened epidermis with a flattened dermal–epidermal junction, and an abnormal organization of the dermal matrix into parallel bundles of scar-tissue collagen, as opposed to the normal basket-weave appearance of dermal collagen. The scar collagen fibres are usually smaller, more densely

packed and often have higher proportions of type III collagen and fibronectin compared with surrounding normal skin. Elastin appears early in the wound-healing process but then disappears (presumably because of the activity of elastase) to reappear again later in the scar [16]. However, the elastin is abnormally organized into fragmented and chaotic structures, as opposed to the normal elastin fibre arcades that characterize normal dermis [16]. Epidermal appendages such as hair follicles and sebaceous glands do not regenerate in scars, although experimental addition of dermal papilla fibroblasts to a wound can induce hair follicle formation [17]. Recent evidence from a mouse model suggest that wounding, in association with Wnt signalling, can induce hair follicles from epidermal progenitor cells [18]. Proliferative scarring or chronic wounds may result from overexpression or dysregulated activity of the fibrogenic isoforms of TGF-β (1 and 2) [19,20]. All three isoforms of TGF-β, and its receptors, are strongly expressed in adult wounds, but not in fetal wounds, which do not scar [21].

The severity of scarring can be assessed clinically using visual analogue scales, and the severity of macroscopic scarring correlates with histological abnormalities predominantly in the epidermis and in the papillary dermis [22]. Scar redness or erythema lasts on average for about 7 months after excisional wounding [23]. The initial inflammatory phase of wounding is thought to be critical to the morphology and severity of scarring. Application of antiscarring therapies, such as neutralizing antibodies to the profibrotic TGF-β isoforms, TGF-β1 or TGF-β2, or exogenous TGF-β3, which is elevated in non-scarring fetal epidermis, is necessary at the time of, or shortly after, wounding to achieve maximum antiscarring effect [24,25]. Smad3 is a key mediator of the TGF-β pathway and the Smad3 null mouse exhibits impaired wound healing, suggesting that inhibition of TGF-β may not always have beneficial effects [26]. Mannose-6-phosphate, an inhibitor of activation of TGF-β1 and TGF-β2, has been reported to reduce scarring in mouse models, and provides a further therapeutic approach [27].

Gap junctions, intercellular communication channels composed of connexin isoforms, are present in epidermis. Application of Connexin 43 antisense oligonucleotides reduced the inflammatory cell infiltrate with accelerated healing in murine wounds and reduced scarring after cutaneous thermal injury [28,29]. Short bioengineered peptides derived from the Cx43 carboxyl terminus accelerate wound healing and reduce scarring [30]. Scarring of skin is a major clinical problem resulting in adverse cosmesis, loss of function particularly if over joints, and interference with growth in children. Strategies to reduce scarring in skin may also be beneficial in the eye, the central nervous system and other organs where cytokine secretion or gap junction communication play a role in fibrosis.

Age-related changes in wound healing

Wounds even of a very substantial size created in certain lower vertebrates (e.g. amphibians) heal by complete regeneration. Similarly, wounds made in early (first-trimester) embryos also heal by complete regeneration [1]. However, these wounds tend to be made before the skin has established even a simple differentiated structure. During the second trimester, experimental studies in numerous animals have shown that late embryonic and early fetal dermal wounds heal with the absence of scarring, but without the regeneration of dermal appendages such as hair follicles or sebaceous glands [2]. This scar-free embryonic wound healing then gradually turns into a scarring healing phenotype during the last trimester and after birth. Scar-free embryonic wounds lack fibrin clots and platelet degranulation, have altered matrix components, including increased tenascin-C and hyaluronic acid, and have a sparse, poorly-differentiated inflammatory response [3]. Consequently, the growth factor profile at the embryonic wound site is different, with reduced levels, for example, of TGF-β1 and TGF-β2, but increased levels of TGF-β3 [4]. Early fetal dermal fibroblasts also display a differential gene response to TGF-β1 compared with postnatal fibroblasts [5]. These observations of scar-free fetal healing have led to experimental studies to manipulate TGF-β isoforms to try and mimic the fetal situation with good results [6]. These interesting experimental findings have now been translated into possible therapies, which are undergoing evaluation in clinical trials.

Interestingly, ageing during adult life also brings alterations to the wound-healing process [7]. Many studies of human age-related changes in the wound-healing profile are methodologically flawed because of failure to control for concurrent morbidity and disease. However, experimental investigations on health status in defined human subjects of varying ages have shown profound alterations in the wound-healing process with age [7]. Elderly subjects heal their wounds more slowly, with a reduced inflammatory response, an altered cytokine profile and an increased level of active proteases [8–10]. Of major interest is the observation that, in normal ageing skin, the levels of proteases such as matrix metalloproteinases and elastase increase, while the levels of proteolytic inhibitors (e.g. TIMP) decrease, tipping the balance towards proteolytic digestion of the dermis [11]. This may account for some of the age-related changes seen in normal skin structure. It may also predispose certain individuals to ulcer formation, as chronic venous ulcers are characterized by an excessive proteolytic profile [12]. By contrast, the quality of wound healing in elderly subjects is markedly improved with reduced scarring. In part, this correlates with the altered inflammatory and growth factor response, which to some extent mimics that seen in embryonic skin [8]. These ageing studies have also shown marked differences between how males and females heal their wounds, and between the healing of pre- and postmenopausal females [13,14]. In general, postmenopausal women heal more slowly but with a better scar quality than premenopausal women. Exogenous therapeutic addition of topical oestrogen to the healing wounds of postmenopausal women causes a marked acceleration of wound healing and reverses the age-related changes in speed and quality [15]. Selective oestrogen receptor modulators, such as tamoxifen, appear to act as oestrogen receptor agonists in skin, accelerating cutaneous wound healing in a murine model [16]. These results have significant implications for the treatment of wounds in older individuals.

Clinical aspects of wound healing

J.E. Mellerio, pp. 14.9–14.25

Acute wounds result from a breach in the integrity of the skin, which occurs with incisional and excisional surgical wounds and traumatic skin injury including burns. At a cellular level, acute wounding results in activation of mitogen-activated protein kinase pathways and activator-protein 1 [1].

Healing by primary intention refers to wounds where the edges have been brought into apposition by sutures, which is possible when there is a good blood supply and no contamination or necrotic debris. Optimal healing requires the wound edges to be everted, carefully aligned and free from tension. Epidermis will

cross the gap by 24 h, but by 5 days the tensile strength is only about 5% that of normal skin. Thus, sutures help to take some tension off the wound. Buried absorbable sutures are helpful in reducing dead space and supporting the wound for longer, as the tensile strength is still only about 20% that of normal skin at 3 weeks [2]. Staples or clips may be used for primary wound closure, especially post-operatively, and have the advantage of producing a good cosmetic result. Tissue adhesives and sterile skin closure strips may also be used, particularly for traumatic lacerations where sutures would increase tissue tension and threaten viability, and have the advantage of not requiring suture removal.

Healing by secondary intention occurs when a wound is allowed to heal from the edge without surgical closure [3], so re-epithelialization is a crucial process. This technique is often used when there is wound contamination and a risk of infection, for example following excision of a pilonidal sinus or hidradenitis suppurativa. The depth of the wound is critical to the manner of healing. In a partial-thickness wound, not only will part of the dermis remain intact, but retention of critical regions of hair follicles and other skin appendages will also provide a rapid source of epidermal regeneration. The density of skin appendages therefore influences the rate of healing. In contrast, full-thickness wounds will have lost dermal and appendageal components and can only be healed from the wound edge, requiring a stimulation of granulation tissue; a mixture of proliferating microvasculature, fibroblasts and the deposition of matrix components. Wound contraction occurs after 1–2 weeks, via activated fibroblasts or myofibroblasts, which decreases the surface area to be closed. Different body sites vary in the results of secondary intention healing, concave surfaces being better than convex, and the face being better than extremities.

In open wounds, the normal water-retaining properties of the skin are lost, and the inflammatory exudate on the surface dries to form a crust or scab. This acts as a barrier to external infection, but it prevents epidermal migration across the surface of the wound. A wound that is kept moist by an appropriate dressing will epithelialize faster than a wound that has been allowed to form a crust. Accelerated epithelial healing under an occlusive non-permeable dressing is associated with a gelatinous coagulum containing fibrin and fibronectin, which provides a suitable matrix for epidermal cell migration [4].

Tertiary healing or delayed primary closure [5] involves allowing some healing by secondary intention and then closing the wound primarily. This may be indicated when infection is present and needs to be cleared by antibacterial treatment, or if skin grafting is intended. Delaying primary closure in this way reduces morbidity, but does not delay the development of wound strength [6]. Indeed, there is some evidence that by the 60th day, wounds healed by delayed primary closure are considerably stronger than those closed immediately [7]. This may be because of better oxygenation and blood flow with delayed closure [8].

Burns

Burns may be classified according to the depth of thermal injury: partial-thickness burns affect the epidermis only (superficial or first-degree burns) or involve the epidermis and dermis (second-degree), where they may be superficial or deep dermal. Full-thickness (third-degree) burns extend to the subcutaneous tissues [1] (Fig. 14.2). Most burns have a mixture of different depths of involvement within them which requires careful assessment. Superficial burns are red, moist and blanche easily, but deeper dermal burns are mottled red, dry and non-blanching. Full-thickness burns are dry, chalky white or charred. More superficial burns are extremely painful whereas full-thickness burns are anaesthetic. The extent of injury is determined by the rule of nines [1,2]. The head and upper limbs are each 9% of the total body surface area (TBSA), whereas each lower limb, the anterior and posterior trunk is 18% TBSA. A minor burn is either superficial or involves less than 20% TBSA. The speed of healing of dermal burns depends on the number of viable hair follicles and other appendages. Deep burns result in longer healing times, severe scarring and contractures, so surgical practice has evolved to excise burn wounds and close with a skin graft as soon as practicable, usually within the first 5 days after the injury.

Wound healing in burns is affected by particular complications of the burn injury in the cutaneous vasculature [3]. The depth of burns tends to increase after 24–48 h as a result of progressive vascular occlusion. Thermal injury produces a zone of coagulative

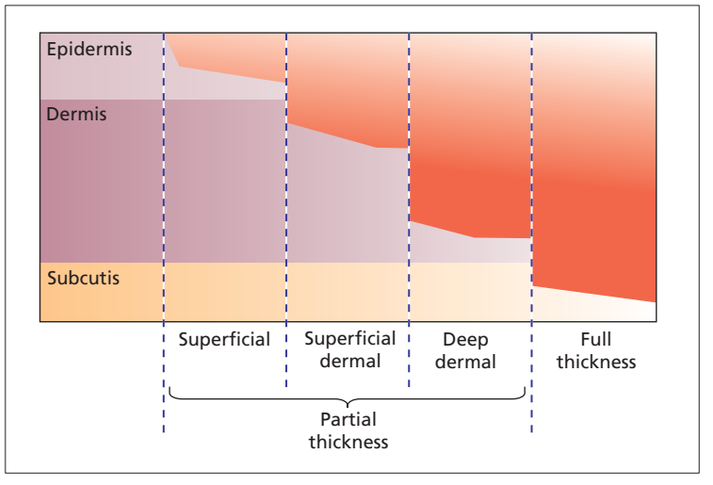

Fig. 14.2 Different depths of cutaneous burns.

necrosis surrounded by an area of hyperaemia, as histamine release after burning gives initial vasodilatation followed by bradykinin-mediated vasoconstriction. Leukocyte adhesion to vessel walls produces progressive thrombotic occlusion, which causes extension and deepening of the burn. Continued leukocyte activation leads to free-radical-mediated tissue damage, and produces prolonged inflammation for 1–4 weeks, which prevents healing. Release of proteases from leukocytes, keratinocytes and macrophages also delays healing by inactivating growth factors, and by destroying newly regenerating tissue.

Early management of thermal burns [4] includes removal from the heat source and immersion in or irrigation with tepid (15°C) water for at least 20 min to limit further thermal damage, minimize oedema and provide analgesia. Polyvinyl chloride (PVC) film (Clingfilm) may be placed over the wound as an initial wound covering, or hands and feet placed in a clear plastic bag. A variety of dressings (e.g. Vaseline impregnated gauze or soft silicone dressings (e.g. Mepitel®)) may be used for the first 24–48 h until wound depth can be clarified. Biological dressings such as human allografts, porcine heterografts or synthetic skin equivalents are very effective in reducing pain. Occlusive dressings may be helpful on small burns, but are not practical for large surface-area burns. One per cent silver sulfadiazine cream is widely used in burns units to reduce the risk of secondary infection, especially *Pseudomonas* species. Dressings are generally changed every 3 to 5 days, or more frequently if there are signs of infection.

Chemical burns resulting from contact with corrosive substances tend to be deep because coagulative necrosis of tissues usually continues until the chemical is removed. Alkalis, such as cement, and acids such as hydrofluoric acid used in glass etching, are commonly implicated. Clothing over affected sites should be removed and the area thoroughly irrigated with water before undertaking assessment and management as for thermal burns [5].

In a deep dermal or full-thickness circumferential burn, early escharotomy may be needed to prevent ischaemia in a limb or respiratory compromise with extensive chest burns. Surgical excision down to bleeding with immediate grafting is the treatment of choice on any burn not likely to heal in 2–3 weeks. Tangential excision and split-thickness sheet or mesh grafts are generally used, either autologous grafts, cadaveric allografts or cultured epithelial autografts. Synthetic skin equivalents (e.g. Integra®, TransCyte®, Apligraf®) may be particularly useful if the extent of the burns limits suitable autologous donor skin, but are costly. Cultured autologous epithelial suspensions which can be applied to the wound bed (e.g. ReCell®) are a further option which has become available recently [6]. There may be significant blood loss (200 mL/1% TBSA) from wound bed excision, which must be replaced. Pressure garments are widely used to prevent excessive scarring, as are silicone gel sheets and occlusive membranes.

Chronic wounds

The series of biological events that close any defect in the skin may be impaired by factors interfering with inflammation, angiogenesis, re-epithelialization and wound remodelling. Most wounds will have a tendency to heal, however long standing, but this process may be very slow and suffer from many complications. Recurrent injury over a previous scar, as in a leg ulcer or pressure sore, and recurrent breakdown following healing, can give rise to chronic skin wounds or ulcers that appear to have lost the capacity to heal. Although the mechanisms of skin ulceration are understood, the biological profile of the chronic wound is not clear.

The chronic wound environment may, for example, be deficient in stimulatory growth factors, growth factor receptors or proteolytic enzymes required for growth factor activation, or may be overproducing any of these factors [1–3]. Growth activation in the edge of a wound bed is particularly associated with overexpression of TGF-α, heparin-binding epidermal growth factor (HB-EGF) and EGF receptor [4]. The chronic wound may produce a hostile microenvironment to cells requiring activation in the wound-healing process. Chronic wound fluid has been shown to decrease proliferation of fibroblasts, endothelial cells and keratinocytes, in part mediated through Ras- and mitogen-activated protein kinase (MAPK) signalling pathways [5–9]. In contrast, acute wound fluid stimulates growth of these cells [10]. Wound fluid from venous ulcers contains active collagenases and degraded fibronectin and vitronectin, and decreases cell adhesion. Fibrin accumulates in chronic wounds (unlike acute wounds), and forms complexes that may bind or inactivate other molecules such as growth factors.

Metalloproteinases (MMPs) are pro-enzymes requiring activation [11]. Three classes of MMPs are collagenases, gelatinases and stromelysins, single-chain proteins the production of which is stimulated by soluble factors and matrix proteins, and inhibited by TIMP [12,13]. There may be abnormalities of MMPs and TIMP in the chronic wound [2,14,15]. Collagenases are probably important in tissue remodelling following healing. Keratinocytes in the edge of a chronic wound are stimulated to produce collagenase by type I collagen.

Keratinocytes in chronic wounds fail to migrate across a wound bed despite a hyperplastic epithelium, and may lack specific matrix proteins in the wound bed to permit cell movement. Keratinocytes migrate most effectively on fibronectin, usually present in the wound bed, and on type I and IV collagens, but not on laminin [16]. Keratinocyte mesenchymal interactions therefore require a vascularized appropriate matrix, and they are impaired in chronic persistent wounds.

The chronic wounds that pose the most significant clinical problems are chronic leg ulcers and pressure sores. These wounds are also of high economic importance, as caring for them consumes a huge amount of health-care resources [17].

Leg ulcers

Leg ulcers are becoming more common as the population ages, as they particularly afflict the elderly. Prevalence figures suggest up to 1% of the population may be affected [1–4]. The health-care cost of non-healing ulcers is immense, in view of the high use of community nursing resources, consuming an estimated 1–2% of the annual health-care budget of European countries [5,6]. Chronic leg ulcers also cause significant morbidity and reductions in quality of life for those affected [7–10]. The most common cause of leg ulcers (80–85%) is chronic venous insufficiency, with arterial disease and diabetic neuropathy accounting for the majority of the remainder (Table 14.3).

Venous ulcers result from valve incompetence in the perforating veins connecting superficial and deep venous systems, so that venous pressure does not fall during exercise and as a result capillary proliferation occurs [11]. An increased permeability to macromolecules produces a pericapillary fibrin cuff, which binds growth factors and matrix proteins and may impede oxygenation [12]. Trapped leukocytes occluding capillaries may add to tissue ischaemia through the release of inflammatory mediators that increase vascular permeability [13]. The skin develops purpura resulting from extravasated red cells, and pigmentation from collections of haemosiderin and melanin. There may be pitting oedema, or changes of lipodermatosclerosis, with induration and fibrosis of the dermis and subcutaneous tissues, skin atrophy and pigmentation. Eczematization is also commonly observed. Ulceration typically develops in the gaiter area above the malleoli with irregular, gently sloping edges. Ulcers usually heal initially but there is a high recurrence rate. The resultant scarring, repeated episodes of infection and chronic lymphoedema tend to promote the chronicity of ulceration [14,15] (Fig. 14.3). The most important factor in the aetiology of venous ulcers is venous hypertension, resulting from valve incompetence, loss of calf muscle pump, or both. Venous thrombosis may also lead to venous hypertension.

Table 14.3 Causes of leg ulcers.

Venous (chronic venous insufficiency)
Arterial
Atherosclerosis
Hypertensive
Trauma (+above)
Mixed arteriovenous
Vasculitis (arteritis and allergic vasculitis)
Pyoderma gangrenosum
Bacterial infections (including tropical ulcer, acid-fast bacilli, ecthyma)
Malignancy
Necrobiosis lipoidica
Vasospastic (including sickle cell anaemia, cryoglobulinaemia)

Fig. 14.3 Chronic venous ulcers with surrounding chronic edge.

In familial cases of venous leg ulcers there may be an inherited resistance to activated protein C, leading to thrombosis and subsequent ulceration. Most cases of activated protein C resistance are caused by a specific mutation in exon 10 of the clotting factor V gene, known as the factor V Leiden mutation [16]. Less commonly, a polymorphic variant in the prothrombin gene (G20210A) may also be associated with increased risk of venous leg ulceration [17]. Management of venous leg ulcers centres around the use of appropriate compression bandaging or hosiery to reduce the effects of venous hypertension, suitable wound dressings and treating infection, when present [18,19].

Arterial ulceration tends to occur in patients with other symptoms and signs of peripheral vascular disease, such as intermittent claudication, rest pain and loss of peripheral pulses. The ulcers tend to occur at acral sites such as the tips of toes or over bony prominences. They are punched out with a demarcated border which may be haemorrhagic, usually with a dry, necrotic base. Surrounding skin may be smooth, hairless, cool and demonstrate reduced capillary refill. Ischaemic ulcers are extremely painful, especially at night. Besides local wound care, management may include surgical intervention to increase arterial perfusion, modification of risk factors for peripheral vascular disease, and increasing exercise to encourage collateral circulation to the legs and feet.

Diabetic ulcers are most commonly associated with diabetic neuropathy, although microvascular occlusive disease may also contribute [20–22]. They often result from unnoticed injury on the plantar surface of the foot, particularly over bony prominences, and are prone to infection. Healing tends to be slow and difficult to achieve; underlying osteomyelitis may occur and amputation is an unfortunately common outcome. Neuropathy may be associated with paraesthesia, anaesthesia and pain. Light touch, vibration and then position sense are usually lost in the affected foot. Little is known about how endothelial and metabolic abnormalities in diabetes affect wound repair. Hyperglycaemia may affect neutrophil activity. Loss of neuropeptide homoeostasis may be relevant, as intact neurosensory activity is essential for inflammation. Management of diabetic ulcers requires a multidisciplinary approach, and should address wound management, glycaemic control, arterial disease, infection and orthotics for relief of pressure areas [23,24].

Pressure ulcers

Pressure ulcers (bed sores, decubitus ulcers) are areas of localized tissue necrosis caused by pressure, friction or shearing forces, acting alone or in combination, resulting in soft tissue compression between a bony prominence and a rigid external surface [1–4]. The presence of moisture, from wound exudate or urinary or faecal incontinence, further exacerbates damage to the tissues. The overall prevalence of pressure ulcers in hospital inpatients has been estimated to be as high as 30% and is associated with a significant morbidity, mortality and economic cost [5–7].

The mean capillary pressure in healthy individuals is 25 mmHg, and external compression with pressures of 30 mmHg will occlude blood vessels so that tissues become anoxic and undergo ischaemic necrosis. Toleration of high tissue pressures depends on the patient's health and the extent and time of application, but short intervals of pressure relief will allow longer resistance. Any patient who is severely and acutely ill can develop pressure sores, because dehydration and hypotension will add to tissue destruction. Patient immobility is the major risk factor, but loss of sensory perception, including loss of consciousness, will contribute. Factors predisposing to pressure ulcers are listed in Table 14.4.

The depth of ulcer is used to classify pressure sores, and there are a number of classification systems, for example the European Pressure Ulcer Advisory Panel (EPUAP) scheme (Table 14.5). Eighty per cent are superficial and 20% deep, but even superficial sores will progress if left unrelieved. The most common sites are the areas of highest compression in the supine patient: 60% of all

Table 14.4 Factors predisposing to pressure ulcers.

Immobility especially post-operatively
Hypotension
Dehydration
Reduced sensory perception including neurological disease and spinal injury
Loss of consciousness
Elderly
General ill health
Ischaemic heart disease
Peripheral vascular disease
Smoking
Pyrexia
Poor nutrition especially hypoalbuminaemia and low zinc
Drugs reducing mobility, sensation or blood flow

Table 14.5 Staging of pressure sores (EPUAP classification scheme).

I	Non-blanching erythema of intact skin
II	Partial-thickness skin loss involving epidermis and/or dermis
III	Full-thickness skin loss with necrosis of subcutaneous tissue down to but not through underlying fascia
IV	Full-thickness with penetration to fascia, muscle, bone

sores are over the sacrum (Fig. 14.4a), while the ischial tuberosities, greater trochanter and heel (Fig. 14.4b) account for 15%. Less common sites are elbows, knees, ankles and occiput. Heels erode when individuals sit immobile with heels supported.

Assessment of at-risk patients should be undertaken and may help prevent pressure ulcers. A variety of tools exist which assess factors such as age, mobility, level of consciousness, nutritional status, continence and severity of illness, although these should be used in conjunction with clinical judgement [8–10]. Patients considered to be at risk of developing pressure ulcers should be encouraged to mobilize regularly or, where this is not possible, should be turned or repositioned at least every 1–2 hours. Care should be taken when moving patients not to increase shearing or frictional forces on the skin. A variety of pressure-relieving devices such as static or dynamic mattresses and mattress overlays are available and may be indicated in those at particular risk of developing pressure ulcers or those with established areas of ulceration [11]. Faecal or urinary incontinence should be managed to reduce moisture at pressure sites as much as possible. Existing pressure ulcers should be managed with appropriate dressings but deeper or extensive lesions may require surgical intervention with debridement, with or without reconstuction.

Early active mobilization not only relieves pressure, but also increases blood flow and muscle tone. When pressure is relieved, sores go through a process of debridement, where necrotic slough forms a hard dry black eschar. This later separates by natural proteolysis, followed by wound contraction, re-epithelialization and scar remodelling. The pathology of the pressure ulcer shows wedge-shaped infarcts of the subcutaneous tissue, capillary obstruction by microthrombi, and endothelial cell swelling and necrosis, with widespread inflammation.

Infection and osteomyelitis may follow wound breakdown, but significant tissue infection will be associated with redness, heat, oedema and tenderness, and systemic features such as leukocytosis, fever and pain, with an offensive exudate. Rapid debridement is particularly important in those at increased risk of infection, such as diabetics and the immunosuppressed.

Complications of wound healing

Hypertrophic and keloid scarring

Keloids and hypertrophic scars are abnormal fibrous reactions to trauma, inflammation, surgery or burns in predisposed individuals, particularly in Afro-Caribbean skin, and most occur between the ages of 10 and 30 years. Hypertrophic scars remain restricted to the original wound, but keloids extend beyond the original wound and rarely regress. Trauma, skin tension and hormones are aetiological factors. Most keloids commence within a year of trauma in areas of highest skin tension: on the upper back, shoulders, anterior chest and upper arms. Reducing wound tension by orientating the wound along lines of relaxed tension may reduce scar formation. Familial predisposition to keloid formation is suggested by reports of recessive and dominant inheritance. Although no human leukocyte antigen (HLA) association or polymorphic variants in TGF-β genes have been found [1], linkage studies have identified susceptibility loci on chromosomes 2p23 and 7p11 in two families with autosomal dominant keloids [2]. Some skin diseases give keloidal scarring, including acne conglobata, acne keloidalis nuchae, hidradenitis suppurativa and certain infections such as chickenpox.

Keloids present clinically because they are disfiguring, painful or pruritic, especially when actively growing. The clinical course is variable, with keloids appearing from weeks to months after the initiating lesion, growing to exceed the wound limits and then stabilizing. Suppurative necrosis occasionally complicates the lesion from vascular damage or pilosebaceous occlusion, particularly in acneiform lesions. Keloids seldom regress spontaneously, but may soften in the elderly.

Hypertrophic scars are distinguished from keloids by growth course and outcome. They occur soon after the trauma or inflammation, are limited to the site of the wound and regress in months to years, but may be difficult to distinguish from keloids in their early actively growing phase. Pathological distinction is not easy. Normal healing involves fibroplasia following the inflammatory phase. In keloids, this is progressive and forms nodular vascular proliferations surrounded by fibroblasts. These nodules transform into avascular collagenous bundles with persistent swirls of fibroblasts; myofibroblasts are prevalent in active keloids. The collagen bundles are randomly aligned and not orientated to the skin surface, whereas in normal scars the bundles lie parallel to the epithelial surface. There are suggestions from *in vitro* studies that abnormal collagen cross-linking, degradation or regulation by TGF-β may be involved in the pathogenesis [1,3–5]. Other cellular changes identified include alterations in α1β1 integrin collagen receptor expression [6] and in the regulation of fibroblast apoptosis [7]. *In vitro* studies also suggest that keloid keratinocytes may also influence keloid fibroblasts (and normal fibroblasts) to increase procollagen I and III gene and protein expression [8]. Increased fibronectin gene expression and expression of IL-6 have been demonstrated in keloid fibroblasts, in addition to increased vascular endothelial growth factor (VEGF) in keloid keratinocytes [9–12].

Treatment of keloids and hypertrophic scars initially involves intralesional corticosteroid injection, although hypopigmentation and local subcutaneous atrophy are possible local side effects. Mechanistically, triamcinolone acetonide has been shown to directly stimulate basic fibroblast growth factor (bFGF) expression and to inhibit TGF-β1 production [13], changes that are both recognized to reduce scarring. However, repeated injections of corticosteroids are always necessary, and seldom completely successful. Surgical therapy with excision or enucleation has a high recurrence rate in the absence of adjunct therapy, such as intralesional steroids, radiotherapy, pressure devices, silicone gels or other less proven agents including intralesional IFN-γ, IFN-α2 and retinoids. Prevention by minimizing trauma and surgery in predisposed individuals is important, as most treatments are unsatisfactory, although surgery combined with radiation has the lowest recurrence rates [14,15]. Other possible treatment options include laser therapy (585-nm pulsed-dye or Nd:YAG), electron beam irradiation, cryotherapy, intralesional 5-fluorouracil, intralesional verapamil and topical imiquimod [16–27]. *In vitro* studies suggest that the anti-inflammatory drug lysine acetylsalicylate also decreases proliferation and extracellular matrix gene expression (procollagen I and II) in keloid fibroblasts [28].

Wound infection

Wounds may be contaminated or colonized with microorganisms without overt infection or impairment of healing, although multiplication of these organisms may lead to critical colonization and frank infection. This mediates adverse events in the wound following binding of microorganisms to tissue and triggering of a host immune response. Wounds that contain more than 10^5 bacteria per gram of tissue are likely to lead to clinical infection [1,2]. Bacteria compete for metabolites (glucose and oxygen), release toxins and proteases (leading to cell damage), and activate complement (prolonging inflammation). Patients with systemic problems such as diabetes mellitus, steroid therapy, increasing age, local ischaemia and oedema, and immunosuppression are more prone to develop infection. Fibronectin in the wound bed is known to predispose to bacterial adhesion. Foreign material, such as necrotic eschar, non-vital tissue, dressing fibres or sutures further predispose to bacterial contamination.

Failure of a chronic wound to decrease in size may be the first clinical sign of infection [3]. Exudate will typically increase in quantity, first clear or serous but becoming purulent or haemorrhagic as infection progresses. Commonly, Gram-positive organisms such as *Staphylococcus aureus* are isolated (56% leg ulcers and 51% pressure sores [4]). Infections with Gram-negative bacilli and anaerobic organisms, particularly *Pseudomonas* and *Proteus*, are also commonly implicated, especially in more chronic wounds (greater than a month in duration), and give a characteristic offensive odour. Friable or beefy red granulation tissue in the wound bed is suggestive of superficial wound infection. Indicators of deeper infection include increasing pain, warmth, swelling and pyrexia [5]. In deeply infected wounds, there may be probing to underlying bone, and, in such cases, it is necessary to consider the possibility of osteomyelitis. Whilst more superficial wound infections will usually respond to topical antimicrobial agents, signs of deeper or systemic infection necessitate systemic antimicrobial therapy.

The gold standard for identifying causative organisms in wound infections is a biopsy of the wound bed for culture and sensitivity of organisms, although this is seldom practicable in standard clinical practice. Rather, a bacteriology swab should be taken from the wound base after removal of slough and exudate, rotated through 360° and sent to the laboratory in transport medium. Culture and sensitivity will identify pathogenic organisms, including resistant bacteria, and guide the choice of antimicrobial therapy. Bacterial counts are often elevated under occlusive dressings, and there is no good explanation for the low incidence of clinical infection, although limiting exogenous pathogenic organisms by the barrier of the dressing may play a part [6–8].

In recent years, emergence of multiple antibiotic resistance of methicillin-resistant strains of *Staphylococcus aureus* (MRSA) has become a major clinical problem worldwide [9–12]. Although hospital-acquired MRSA infections have been implicated in causing many nosocomial infections, community-acquired reservoirs of MRSA are now identified in a greater number of wound infections [13]. MRSA bacteraemia rates have increased worldwide over recent years, and are associated with a higher mortality than bacteraemias of methicillin-sensitive *Staphylococcus aureus* [14]. At a cellular level, the key determinant of the broad-spectrum beta-lactam resistance in MRSA strains is the activity of the penicillin-binding protein 2a (PBP2a) [15]. Patients with chronic wounds are also frequently treated with oral antibiotics when suspected of clinical infection, which predisposes to the development of resistance of other organisms. Notably, widespread use of ciprofloxacin for its anti-*Pseudomonas* activity has given rise to resistant isolates from leg ulcers [10,12,16].

Other local factors influencing wound healing

Desiccation of the wound allows the formation of a dry eschar, leading to slower re-epithelialization. Indeed, covered acute wounds resurface up to 40% faster than those exposed to the air [1–3]. A moist wound environment also encourages more rapid angiogenesis and dermal repair [4–6]. Occlusion of chronic wounds may also increase healing rates over the first 4 weeks.

Haematoma formation may impede wound healing because of local tissue hypoxia as well as providing a medium for accumulation and growth of bacteria and other microorganisms [7]. Haemostasis is therefore important in surgical procedures, as is good wound handling because crushed tissue or over-tight sutures may cause ischaemia and promote inflammation and secondary infection.

Foreign bodies in wounds tend to lower pH, reduce oxygen tension and activate complement, thereby delaying wound healing [3,7].

Contact dermatitis may develop to a variety of topical preparations applied to wounds. There is a tendency towards a greater incidence with increasing age and many patients will have positive patch tests to multiple allergens [8–11]. Commonly identified medicament allergens include aminoglycoside antibiotics, fragrance allergens, lanolin, topical corticosteroids, rubber accelerators and hydrocolloid gels. Contact allergy or cell toxicity to a number of herbal or complementary wound preparations are also recognized [12–15]. Superimposed contact dermatitis usually delays wound repair and some vehicles of topically applied medications may also affect epithelialization [16].

Wound healing and ageing

Wound healing in the elderly progresses more slowly, and it is thought that all phases of the wound-healing process are affected, with decreased proliferative responses, delayed angiogenesis, delayed remodelling and slower re-epithelialization [1–6]. Age-related reductions are seen in keratinocyte and fibroblast migration (especially in poorly oxygenated wounds), integrin function, actin cytoskeletal organization and inflammatory chemokine responses [7–11]. Incisional wounds in older individuals have a lower tensile strength, and postoperative surgical dehiscence rates are higher [12]. However, elderly patients do successfully heal after major surgery, such as open heart surgery, and so the differences from younger individuals are not contraindications to surgical procedures. Other factors adversely affecting wound healing, such as peripheral vascular disease, cardiac problems, diabetes mellitus and poor nutrition, are also more likely to occur in the elderly.

Superficial wounds heal more slowly among the elderly, with unroofed blisters and split-thickness wounds, such as donor sites, showing the same pattern [3,13]. Meshed autografts greatly accelerated healing (10 days) compared with Vaseline gauze (10–36 days) in the treatment of donor sites in the elderly, which suggests that reducing the need for re-epithelialization is of considerable benefit [14]. New techniques of wound healing, such as cultured epidermal grafts, are particularly applicable to the elderly, but care must be taken to treat vigorously underlying medical conditions.

Systemic factors affecting wound healing

Systemic diseases, including vascular disorders (e.g. congestive cardiac failure, hypertension, atherosclerosis, venous insufficiency or lymphoedema), as well as metabolic disorders (e.g. chronic renal failure, chronic liver disease or diabetes mellitus) may all interfere with wound healing.

Underlying unrecognized or untreated diseases may also retard healing. For example, ulceration of the skin may result from ischaemic necrosis secondary to a primary vasculitis such as polyarteritis nodosa, rheumatoid vasculitis or neutrophilic inflammation such as pyoderma gangrenosum. Although the early stages of such lesions often have a prominent haemorrhagic component, they may result in indolent chronic ulcers. The site and distribution of lesions are often a clue to the underlying pathology, as are signs of inflammation, haemorrhage or undermining of the edge. Vasculitic lesions particularly affect acral sites and areas of impaired vascularity, and signs of livedo or palpable purpura may be present. Although lesions in necrotizing venulitis may be in the stasis areas, they will also occur on arms, legs and buttocks. Active treatment of the underlying disease will often stimulate surprisingly rapid healing, and intralesional steroids in the edge of a chronic wound help even chronic pyoderma gangrenosum lesions. Genetic abnormalities may also contribute to impaired wound healing, in particular abnormalities of connective tissue, as found in Marfan syndrome, Ehlers–Danlos syndrome and prolidase deficiency, and defects of the epidermis and appendages, such as epidermolysis bullosa and ankyloblepharon–ectodermal dysplasia–clefting syndrome.

Malignancy may be relevant to impaired wound healing, either because of ulceration occurring within a tumour or because malignancy arises on a background of chronic ulceration. Non-melanoma skin cancers, both basal cell and squamous cell carcinomas, as well as malignant melanoma, may ulcerate. Many of these lesions will be on sun-exposed sites, but they may be extensive in patients exposed to carcinogens, and lesions on the legs may be misdiagnosed, although this is a common site of actinic lesions in women. A malignant ulcer will continually grow in size, be irregular in shape and usually have a thickened edge. The site may be atypical for a chronic ulcer, which provides an important clue. A diagnostic biopsy of the edge should always be considered in any ulcer increasing in size. Excision and grafting will often be required on the lower leg. Malignant change can develop in a chronic non-healing ulcer, particularly following burns or pressure ulcers: this is referred to as a Marjolin ulcer. Suspicion is raised by failure to heal, progressive enlargement and changes in the ulcer edge, and a diagnostic biopsy is indicated. Tumours arising in chronic ulcers are usually squamous cell carcinomas and are typically aggressive with frequent local and distant metastasis, and an accompanying poor prognosis [1–3].

Protein malnutrition is a major factor affecting wound healing, and malnourished patients have an increased risk of surgical complications [4]. Surgery, trauma or sepsis may lead to relative protein deficiency and a negative nitrogen balance. This is particularly the case for patients following burns in whom nitrogen loss, malnutrition and loss of trace elements can be profound and have a negative effect on wound healing, morbidity and mortality if not adequately and promptly addressed [5,6]. Protein malnutrition causes inhibition of angiogenesis, and impairment of fibroblast proliferation and collagen synthesis; these abnormalities are reversed on protein replacement. Nutritional support also maintains immune function, decreases the risk of infection and facilitates wound healing [7]. Serum levels of albumin, transferrin and IGF-1 are indicators of the status of protein stores [8].

Vitamin deficiency may have adverse effects on wound healing, particularly in the case of vitamins A, C and K. Vitamin A modulates cell differentiation and can reverse inhibitory effects of glucocorticoids on healing of some wounds. Lack of vitamin A also compromises epithelialization, collagen synthesis and inflammation [9]. Vitamin C deficiency seriously impairs the speed and strength of wound healing because of markedly reduced collagen synthesis, formation of fragile capillaries and decreased resistance to infection [10]. Supplementation may improve rates of healing of chronic wounds [11]. Vitamin K is essential in the synthesis of blood clotting factors II, VII, IX and X. Deficiency of vitamin K impairs haemostasis and may result in haematoma formation.

Trace element deficiency usually occurs in combination with other deficiencies, particularly in chronic malabsorption and alcoholism. Zinc is a component of many coenzyme complexes, and severe deficiency results in abnormal lymphocyte function, increased susceptibility to infection and delayed wound healing [12,13]. Zinc-deficient wounds are also abnormally weak. Although zinc metabolism and distribution may be abnormal in patients with non-healing leg ulcers, oral zinc supplementation probably only accelerates healing in individuals with zinc deficiency. Topical zinc, however, may reduce infections and promote wound healing [13]. Iron deficiency interferes with wound healing by causing anaemia and tissue hypoxia, but also interferes with bacterial killing, increasing the risk of wound infection. Clearly, most deficiency states are multiple and it is difficult to distinguish which deficiency is causing the problem in healing. Local nutritional problems are also of importance in consideration of delayed healing, and loss of an adequate blood supply accounts for the bulk of the 'non-healing wounds' seen in clinical practice,

including decubitus ulcers and ulcers of the lower legs resulting from various types of vascular disease.

Drugs, such as corticosteroids, reduce DNA synthesis in the epidermis and induce morphological changes in fibroblasts [14,15]. In addition, it is well established that they induce dermal atrophy (probably by inhibiting synthesis of collagen) and retard re-epithelialization. It is therefore not surprising that long-term administration of these drugs either systemically or topically impedes the healing of wounds, and predisposes both to wound dehiscence and to chronic ulceration. Other drugs such as anticoagulants, cytotoxic agents, aspirin, colchicine, penicillamine, ciclosporin and phenylbutazone [16–18] may have adverse effects on wound healing, from direct effects on cells taking part in the healing process (as in cytotoxic agents), effects on vascularization or the enhancement of infection.

It is well-established that cigarette smoking has an adverse effect on wound healing [19]. It causes restriction of cutaneous blood flow and carboxyhaemoglobin further limits oxygenation of the skin. There are also reductions in dermal fibroblast proliferation and migration which impair healing and cause increased scarring. Surgical scars, flaps and grafts are at particular risk of breakdown and smokers should therefore be encouraged strongly to stop smoking before elective procedures [20].

Principles of treating wounds

Assessment and wound bed preparation

Assessment of any wound should include investigation of possible primary pathology, such as Doppler studies of arterial pressure if ischaemic aetiology is suspected. Any potential factors that may be delaying healing, for example poorly controlled diabetes mellitus, malnutrition or systemic corticosteroid use, should also be explored and corrected where possible. It is important to be able to assess wounds objectively so that progress can be monitored at successive visits. Accurate wound measurement to establish the area, shape and volume of the wound, however, is often difficult. Serial photography and computerized planimetry are not practicable to use in standard practice in the community, but a simple photographic record with a scale measurement included can provide a useful reference in the patient's clinical records over successive visits. Alternatively, in approximately circular wounds, the longest diameter in one direction may be multiplied by the diameter at 90 degrees to give an approximation of wound size. In more irregularly shaped wounds, tracings on gridded acetate films can be used and the area approximated by counting squares within the grid. This technique is prone to error, however, since it may not take account of islands of re-epithelialization within the wound, nor encompass wound depth. Since this technique also involves direct wound contact, it may be unacceptably painful to use. Deep, flask-shaped pressure ulcers are particularly difficult, but the volume of fluid under an occluding membrane can be roughly measured. Research studies may use a variety of techniques, including laser Doppler assessment of blood flow, ultrasound measurement of depth, optical coherence tomography, wound pH and direct measurement of arterial or venous pressures [1–3].

Thorough assessment of chronic wounds is fundamental to establishing potential causes of delayed healing and many tools for recording features such as size, exudate, wound bed and edge exist. A number of different schemes have been employed to use information from these clinical signs to address factors that are impeding healing. One that is commonly used is the TIME system, which examines a number of parameters that need to be optimized to prepare the wound bed for healing (Tissue, Infection/Inflammation, Moisture, Edge) [4,5]. Tissue in the wound bed is assessed for viability: necrotic tissue, slough or adherent eschar delays healing and acts as a focus for microorganisms, and needs removal before healing can progress. Infection and inflammation will also impair healing, so if infection is present, as assessed clinically and microbiologically, it should be treated with appropriate topical or systemic antimicrobial agents. Moisture balance is extremely important in chronic wounds: a desiccated wound will have delayed healing, but, similarly, excess exudate will cause maceration of surrounding skin with the potential for extension

of the wound. A variety of topical agents and dressings are available to achieve good moisture balance in different types of wound. The wound edge should be assessed if it is failing to advance or is undermined, and options such as debridement or grafting considered to encourage healing.

In addition to the wound itself, assessment of surrounding skin is essential to identify changes such as cellulitis, eczema or maceration. If callus is present it should be debrided to prevent increased tissue breakdown and ulceration underneath it. Pain should also be assessed: this may be procedural related to dressing changes or bathing, or constant, particularly if there is ischaemia, infection or neuropathy. A variety of pain assessment tools exist to record the nature, site and severity of pain.

Compression bandaging

Compression bandaging and elastic stockings are of proven benefit in reversing the effects of chronic venous hypertension, by raising the local hydrostatic pressure and reducing superficial venous pressure [1–4] (Table 14.6). Indeed, a systematic review of venous leg ulcer compression bandaging trials has found that compression increases ulcer healing rates compared with no compression, that multilayered systems are more effective than single layer dressings, and that high compression is more effective than low compression [5]. The compression increases flow velocity, and results in the restoration of fibrinolysis and breakdown of fibrin cuffs. The optimal external pressure of 35–40 mmHg may not be tolerated, but lower pressures may enhance ulcer healing. It is essential not to deliver such levels of pressure to an ischaemic leg, as necrosis or gangrene may result [6]. For this reason, Doppler pressures should always be measured and compression dressings only used if the ankle brachial pressure index is greater than 0.8.

Fig. 14.5 Application of a four-layer bandage.

Traditional crêpe bandaging, etc., provides little external compression, but newer short-stretch and high-performance bandages are much more effective. There is variation in pressure according to the technique of the user. A large community programme tested a four-layer bandaging technique (Fig. 14.5) designed to deliver sustained, consistent compression for a week between dressing changes (crêpe/Velband/Elset/Coban) [1]. The excellent healing rate (80% of ulcers in 12 weeks) in this study has led to the widespread adoption of the technique in the UK, but the success rates depend on the local clinical profile; specialist wound-care units often collect patients who have failed all conventional treatments. Combining compression therapy with surgery to correct superficial venous reflux does not lead to improved healing rates compared with compression alone, but reduces ulcer recurrence and increases ulcer-free time [7].

Table 14.6 Compression hosiery and bandages.

	Class	Ankle pressure (mmHg)	Indication
Compression hosiery	1	14–17	Varicose veins
	2	18–24	Mild oedema and prevention of recurrence venous ulcers in slim legs
	3	25–35	Oedema and chronic venous insufficiency in large legs
Single-layer bandages	3a	14–17	Uncomplicated venous leg ulcers, e.g. Elset, K-Plus
	3b	18–24	Venous leg ulcers and lymphoedema, e.g. Coban
	3c	25–35	Venous leg ulcers and lymphoedema in large legs, e.g. Tensopress, Setopress
	3d	36–50	Extensive venous leg ulcers, ulcers secondary to lymphoedema, venous insufficiency following venous thrombosis in very large or oedematous legs, e.g. elastic web bandages
Multilayer bandages		36–50	Venous leg ulcers and ulcers secondary to lymphoedema, e.g. Padding, crepe plus Class 3a and 3b bandages

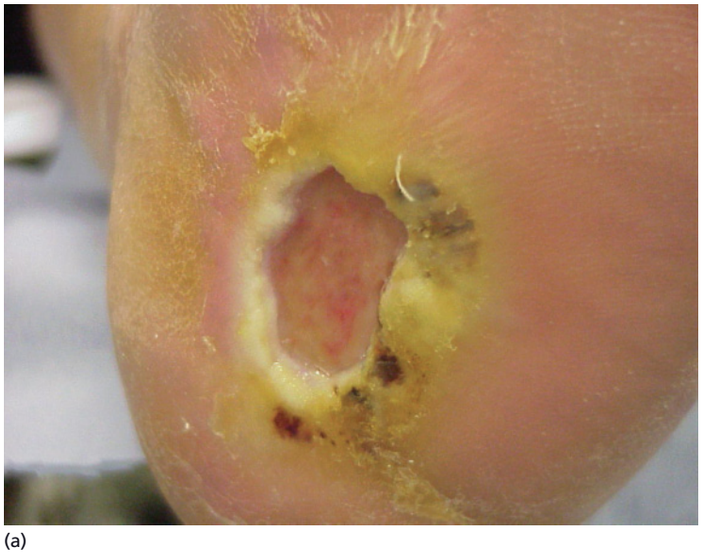
Organization of wound care services

Over the last couple of decades, there has been a move towards managing chronic wounds in community-based settings with district nurses providing the vast majority of care for patients. Admission for inpatient care and leg elevation is not practical due to lack of inpatient beds and high cost. Furthermore, leg ulcers healed by intensive inpatient treatment tend to recur following discharge, and admission is associated with a loss of independence in this largely elderly group. Using a research-based approach to optimize leg ulcer management, community leg ulcer clinics have increased wound healing rates as well as reducing costs for this care. This model also ensures that only patients with wounds requiring special expertise, such as skin grafting, vascular surgery or medical treatment, are referred to more expensive hospital facilities. Schemes, such as the Leg Club Foundation in the UK, provide valuable community-based treatment for patients, as well as education and social support (www.legclub.org).

Topical therapy

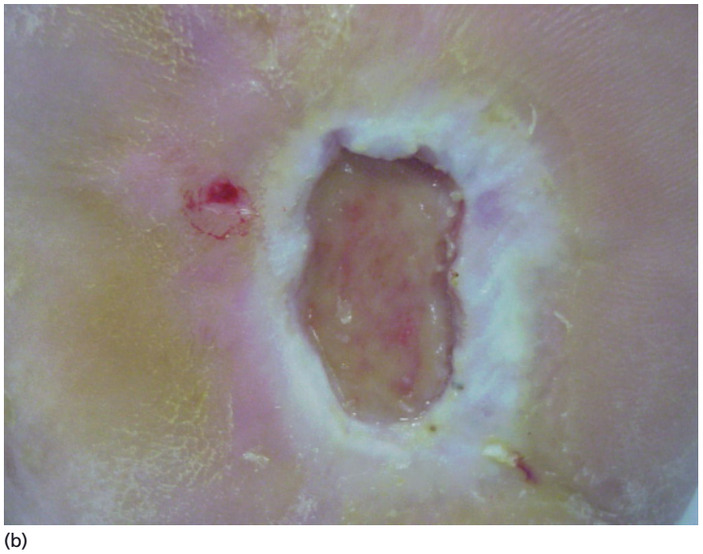
Antiseptics. Antiseptic antimicrobial agents have been widely used to cleanse infected wounds for many years. The advent of systemic antibiotics for infection control has led to a reappraisal of antiseptic usage, as they have now been shown to retard re-epithelialization and slow healing [1,2]. However, this must be balanced against the emergence of bacteria resistant to systemic and topical antibiotics, in which setting appropriate use of antiseptic preparations may be extremely useful.

Saline dressings can be used to irrigate and clean a wound, removing cellular and bacterial debris, and are safe but pharmacologically inactive. Hexachlorophene and chlorhexidine are tissue toxic, and tend to be painful to apply to open wounds. Hydrogen peroxide is rapidly broken down to give molecular oxygen and, as with sodium hypochlorite, is rapidly inactivated by tissue exudate, although the physical effervescence may help surface debridement. A cream formulation of stabilized hydrogen peroxide has broad antimicrobial effects and, in addition, improves the microcirculation in chronic venous ulcers with a beneficial effect on healing [3]. Povidone–iodine solution is also toxic in high concentrations, but can maintain bactericidal activity at low concentration. Its effect on wound healing is not clearly established, but there is some evidence to suggest a beneficial effect on chronic wounds [4,5]. Cadexomer-iodine has beneficial effects in wound healing through its antimicrobial action, although it also increases levels of VEGF in wounds [6,7]. As iodine can cause contact dermatitis, it should be used with caution.



Silver sulfadiazine compounds are widely used in burn care, being effective against *Staphylococcus aureus* and *Pseudomonas aeruginosa*, and possibly having an effect by enhancing epithelialization [8].

Antibiotics. Topical antibiotics have also been used to reduce tissue infection in wounds and are often incorporated into dressing materials, but they are frequent causes of contact dermatitis, particularly neomycin and gentamicin. Use of systemic antibiotics for true tissue infection is now preferred, particularly with the development of antibiotic-resistant organisms. Mupirocin appears to sensitize infrequently but, as it may be effective in multiresistant *Staphylococcus aureus* (MRSA), it should not be generally used. Topical antibiotic use should be strictly limited to appropriate clinical settings and not used for prolonged periods of time.



Traditional. Honey mixed with butter was applied to wounds by the Ancient Egyptians as 'Balm of Gilead', and both honey and cane sugar are still used as wound dressings [9,10]. Honey stimulates tissue growth and epithelialization, as well as reducing inflammation and infection, debriding and deodorizing wounds [11]. It is also effective against antibiotic resistant bacteria, including MRSA [12]. A systematic review of randomized trials of topical honey in superficial burns and wounds has concluded that honey may be a useful treatment [13]. Cane sugar containing sucrose, which is not metabolized outside the gastrointestinal tract, prevents bacterial growth by decreasing available water, and it has also been claimed that it might stimulate granulation tissue [14].

Wound debridement

When there has been necrosis or progression in a chronic ulcer, necrotic debris which accumulates on the surface of or around a wound may impair healing by forming a physical barrier to re-epithelialization, as well as acting as a focus for infection. Debridement is the removal of this tissue and can be undertaken using a variety of techniques [1]. Surgical debridement under local or general anaesthetic may be required to promote healing, and entails removal of necrotic tissue and a margin of viable tissue. This may need to be repeated at intervals. Conservative sharp dissection does not usually require anaesthetic as it involves removal of necrotic tissue only, without viable wound margin (Fig. 14.6).

Non-surgical methods of debridement include irrigation with water or saline, which can also be performed under pressure in a whirlpool. Wet-to-dry dressings involve application of saline-soaked gauze to a wound and removal when it has dried out, taking with it adherent slough and necrotic tissue. This may be painful for the patient, however, limiting its usefulness. Autolytic debridement exploits the presence of endogenous collagenases and proteases present in a wound to break down necrotic tissue. Appropriate dressings to maintain a moist wound environment, such as hydrogels, films and hydrocolloid dressings in dry wounds, and foams, alginates or hydrofibres in more sloughy wounds, may be used. Care must be taken to protect surrounding skin from damaging effects of these enzymes, however.

Proteolytic enzymes can also be applied to wounds to facilitate debridement, and, again, care must be exercised to protect surrounding tissues. The two enzymes most commonly used in Europe are fibrinolysin/desoxyribonuclease and collagenase. Studies in necrotic ulcer animal models have shown the effectiveness of collagenase in wound debridement, but no clinical efficacy for fibrinolysin/DNAse in this model [2]. Streptokinase/streptodornase is the topical enzyme preparation most commonly used in the UK. Proteolytic enzymes derived from Antarctic krill have also been shown to be effective in wound debridement [3], and papain is also used in some countries.

Larval therapy has made a reappearance on the therapeutic scene [4]. Sterile maggots of the green bottle fly, *Lucilia (Phaenicia) sericata*, are used for debridement. Up to 1000 maggots are introduced into the wound and left for 1–3 days before a dressing change. Secretions from the maggots have a proteolytic effect and their movement in the wound bed is thought to stimulate granulation tissue. It is now also possible to use maggots contained in mesh bags for application to the wound bed which appears effective and may be more acceptable to the patient. One advantage of this therapy is that the maggots effectively separate necrotic from living tissue, thereby making subsequent surgical debridement unnecessary or much easier [5].

Wound dressings

Wound dressings protect the surface of wounds and prevent bacterial and viral contamination of healing wounds. Studies have shown that occlusive dressings maintaining a moist environment have beneficial effects on wound healing through accumulation of endogenous growth factors in wound fluid, and other biological effects on angiogenesis, generation of granulation tissue and re-epithelialization [1–5]. The main concern about wound occlusion has been a perceived increased risk of tissue infection, and indeed

occlusion of wounds can lead to higher bacterial counts. However, rates of tissue infection are low and there appears to be no impairment of re-epithelialization [6].

An ideal dressing should be able to maintain a good moisture balance at the wound bed, be easy to remove without damaging the wound or surrounding skin, be impermeable to bacteria, confer mechanical protection to the wound and be non-toxic and non-allergenic. Comfort for the patient, conformability, cost-effectiveness and a long shelf life are other important considerations. There are many different types of synthetic dressing available with different physical properties, depending on their composition. These comprise: polyurethane films, hydrogels, hydrocolloids, foams and alginates. In addition, newer dressings have emerged that have specific clinically relevant qualities, including collagens, hydrofibres, antimicrobial dressings, debriding agents, odour-absorbing dressings, biosynthetic dressings and hyaluronic acid dressings [7]. A dressing should be selected according to the properties of the wound it is to be applied to, and this choice may need to be re-evaluated depending on how the wound progresses.

Clinical indications for optimal selection of appropriate dressings are outlined in Table 14.7.

Semipermeable films (e.g. Biocclusive®, Opsite®, Tegaderm®) are thin polyurethane transparent sheets that are often coated with adhesive to stick to the margins of the wounds, although they do not adhere to the wound itself. They are impermeable to bacteria and fluids but are air and water vapour permeable. Films allow inspection of the wound without need for removal and can be left *in situ* for up to several days at a time. They promote a moist wound environment but are not able to cope with large amounts of exudate and provide little mechanical protection of the wound. Films are useful for superficial wounds or as dressings around catheter sites. Care must be taken when removing film dressings because new epithelium can easily be stripped [8–10].

Low-adherence dressings (e.g. Bactigras®, Jelonet®, Mepitel®, NA Ultra®, Urgotul®) maintain a moist wound environment, but allow exudate to pass through from the wound to a secondary dressing. They have very low adherence to the wound bed and surrounding skin, so are a valuable choice in patients with fragile skin. Low-adherence dressings may come in the form of tulles, textiles or perforated or layered plastic films.

Hydrogels (e.g. ActiformCool®, Intrasite®, Sterigel®) are translucent, jelly-like non-adhesive matrices of insoluble polymers. They are able to donate water to the wound surface to maintain a moist environment, but, since they are only partially hydrated, can also absorb low to moderate amounts of exudate. They are semipermeable to gas and water vapour. Hydrogels are usually used in gel form, in sheets or impregnated into gauze with a secondary dressing applied over them. They often have a soothing, cooling and analgesic effect because the cross-linked polymers tend to entrap water and reduce the skin surface temperature by up to 5°C. Hydrogels are useful in superficial wounds as well as deeper wounds, sinuses and cavities, although care must be taken to avoid maceration of surrounding skin [11].

Hydrocolloids (e.g. DuoDERM Extra Thin®, Granuflex®, Tegasorb®) comprise an opaque mixture of adhesive absorbent polymers and gelling agents such as gelatin, pectin and sodium carboxymethylcellulose. They adhere well to the wound edge and have an impermeable polyurethane backing. Hydrophilic particles in the dressing interact with the wound exudate to form a yellow gel next to the wound. This can be confused with a purulent wound discharge, but the acidic microenvironment forms an antibacterial and antiviral barrier and is helpful in autolytic wound debridement. Hydrocolloid dressings can adhere to any dry or moist site, allowing the patient to bathe or shower. They are widely used in shallow or cavity wounds, especially on difficult areas to dress such as the sacrum and heels. Side effects from these dressings include an increased amount of granulation tissue and tissue maceration [12,13].

Hydrofibres (e.g. Aquacel®) are composed of carboxymethylcellulose fibres in a non-woven sheet that form a soft gel when exposed to heavily exudative wounds. They are extremely absorbent, up to three times more so than alginates (see below). They are well-suited to flat, cavity or sinus wounds and require a secondary dressing.

Alginates (e.g. Kaltostat®, Sorbsan®) are made from brown seaweed and are highly hydrophilic, changing from fibrous to gel form on absorbing water. Indeed, alginates can absorb up to 20 times their own weight. The ingredients include calcium salts of alginic, mannuronic and guluronic acids. When exposed to sodium-rich solutions (such as wound exudate) calcium and sodium ions interchange resulting in increased amounts of free calcium. This leads to amplification of the normal wound clotting cascade. Alginates are available in sheets or rope forms and are suitable for dressing heavily exudative wounds, deep wounds and cavities. In addition, they can be easily moved without damage to

Table 14.7 Selection of appropriate wound dressings.

Types of wound	Suitable dressings
Acute	
Abrasions, lacerations	Films, hydrocolloids, thin foams
Catheter or cannula sites	Films
Burns	Hydrocolloids, hydrogels, biosynthetic dressings
Donor sites	Films, hydrocolloids
Dermabrasion, chemical peels	Hydrogels
Surgical wounds	Films, hydrocolloids, hydrogels, alginates
Chronic	
Venous ulcer	
Heavy exudates	Foams, alginates, hydrofibres
Moderate exudates	Hydrocolloids, foams
Mild exudates	Hydrogels, hydrocolloids
Malodorous	Foams, alginates, hydrocolloid charcoal
Arterial	Hydrogels
Neuropathic	
Moist	Hydrogels, alginates, hydrofibres
Dry	Hydrogels, hydrocolloids
Pressure ulcers	
Stage I	Films, thin hydrocolloids
Stage II–III	Hydrocolloids, foams, hydrogels, debriding agents
Stage IV	Alginates, hydrofibres, debriding agents
Fungating	Hydrocolloids, hydrogels, alginates, foams, charcoal

the wound surface when well hydrated [13]. They require a secondary dressing and should be changed daily.

Foams (e.g. Allevyn®, Mepilex®) are absorbent, opaque polyurethane or silicone sheets that are permeable to gas and water vapour. They may be of variable thickness and are suitable for moderately or heavily exudative wounds. Foams often have a semi-permeable backing to prevent exudate seeping through. Conventional foam dressings may stick and be difficult to remove if the exudate dries out, but silicone-coated foams avoid this problem and protect surrounding skin.

Collagen dressings (e.g. Catrix®, Promogran®) are made from cowhide and are available as sheets, pads, particles or gels. Sometimes they are also combined with alginates or hydrogels. These dressings accelerate wound healing by providing a collagenous matrix to enhance cell migration during wound healing.

Antimicrobial dressings (e.g. Acticoat®, Aquacel Ag®, Inadine®, Iodosorb®) are designed to counter the anti-healing effects of bacterial colonization and infection in chronic wounds. While it is recognized that topical antimicrobials in high concentration interfere with wound healing, antiseptics such as povidone–iodine 0.001% have been shown to maintain bactericidal activity but without any cytotoxic effects on the healing wound. Slow-release iodine preparations such as cadexomer–iodine are suitable for chronic venous ulcers [14]. Thyroid function may be affected and should therefore be monitored in patients using iodine dressings. Silver compounds have also been shown to prevent chronic wound colonization by bacteria and are now widely available in a variety of different wound dressings including low adherence dressings, hydrofibres, hydrocolloids, alginates and foams [15]. Metronidazole gel is commonly used with other dressings to control odour and infections from anaerobic organisms that may be particularly problematic in fungating malignant wounds.

Debriding dressings in the form of chemical or enzymatic looseners can be used to remove necrotic tissue, often to supplement hydrocolloid dressings.

Odour-absorbing dressings (e.g. CliniSorb®, Lyofoam C®) are based on activated charcoal that absorbs bacterial breakdown products. These dressings are often combined with foam, alginate or hydrocolloid dressings.

Hyaluronic acid dressings (e.g. Hyalofill®) are made of biodegradable absorbent bipolymers that form a hydrophilic mesh with the wound exudate. Hyaluronic acid accelerates granulation tissue formation and re-epithelialization and these dressings help stabilize the clot and attract inflammatory cells crucial to the wound healing process.

Other pharmacological and physical modalities

Pentoxifylline increases fibrinolysis, decreasing blood viscosity, increasing red cell deformity and inhibiting platelet aggregation. It is used to reduce symptoms of ischaemia in patients with occlusive arterial disease, and a number of studies indicate it may be beneficial with or without concurrent compression in the treatment of chronic venous leg ulcers [1].

Prostaglandins E1 and I2, iloprost and calcium-channel blockers such as nifedipine, show conflicting results in peripheral vascular disease and venous ulceration [2], although some calcium-channel blockers may have a direct effect on keratinocyte migration [3]. The serotonin antagonist, ketanserin has been shown to be of benefit when applied topically to diabetic foot and leg ulcers [4,5].

Ascorbic acid is a co-factor for proline hydroxylase necessary for collagen synthesis, but it is of doubtful benefit in patients who are not vitamin deficient. In accordance with the Pauling concept that most individuals do not have enough vitamin C in their diet, large dietary supplements of ascorbic acid were given to a group of patients with pressure sores in a double-blind study; considerable increase in the rate of healing was noted in the treated group [6]. Ascorbic acid has also been shown to have an important function in the preparation of *in vitro* skin substitutes, with direct effects on epidermal barrier formation, basement-membrane integrity and the quality of skin contracture after grafting [7].

The precise role of zinc in wound healing is unclear at present. Early studies claiming that systemic zinc therapy accelerated wound healing in humans and other animals have been supported by some workers and refuted by others [8,9]. This discrepancy may be partly explained by studies that have shown that systemic zinc reduces the healing time in patients with venous and arterial leg ulcers, but only if the patients are initially zinc deficient. Topical zinc may be beneficial in wound healing through local actions reducing infection and promoting epithelialization [9–11]. Zinc also appears to have an important antioxidant role in skin [12], and mutations in the zinc transport gene, *SLC39A4*, have recently been demonstrated in the zinc-deficiency disorder,

acrodermatitis enteropathica, an autosomal recessive condition associated with chronic superficial skin ulceration and poor wound healing [13].

Treatment of wounds with oxygen has been considered to be helpful in some wounds, although recent studies have focused on the state of the redox environment of wounds and the role of nitric oxide in wound repair [14,15]. Nitric oxide is a small radical, formed from the amino acid L-arginine by three distinct forms of nitric acid synthase. The inducible form (iNOS) is synthesized in the early stages of normal wound healing, and experimental knockout of the gene leads to delayed wound healing. By contrast, improved wound healing can be obtained by the addition of nitric oxide or arginine to wounds. Nitric oxide has also been shown to regulate collagen synthesis, cell proliferation and wound contraction [14]. Hyperbaric oxygen therapy increases wound nitric oxide levels which is thought to promote healing of chronic wounds, particularly diabetic foot ulcers [16–18]. Although not yet of practical widespread therapeutic value, manipulation of nitric oxide in skin using hyperbaric oxygen or other means may have future relevance to improving normal or abnormal wound healing.

In vacuum-assisted closure, negative pressure is used to assist wound closure, particularly deep wounds, chronic leg ulcers and diabetic ulcers [19,20]. It helps remove wound fluid and is thought to promote healing by increasing local tissue oxygenation, blood flow and formation of granulation tissue. Low-frequency, non-contact ultrasound has also been used to promote healing in chronic wounds and pressure ulcers, although efficacy of this modality has not hitherto been confirmed [21,22].

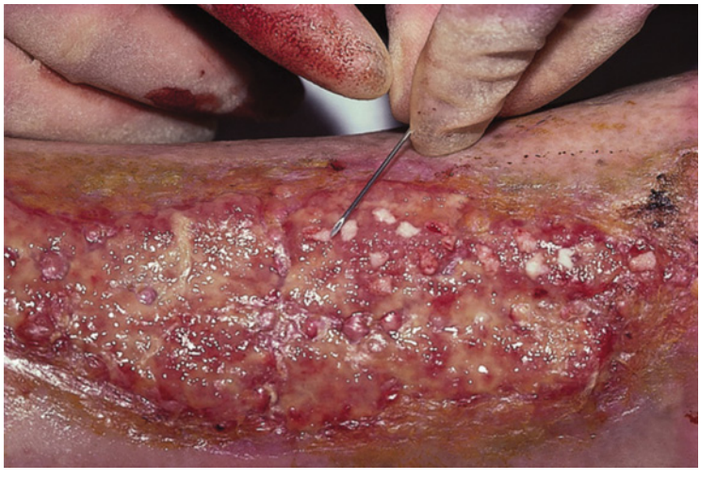
Skin grafts

E.A O'Toole, pp. 14.25–14.27

Pinch grafts and split-thickness skin grafts

For pinch grafts, small (2–3 mm^2) pieces of partial-thickness skin can be removed under local anaesthetic, as an outpatient procedure or by a specialist nurse within the home, and planted across the wound bed to form islands for re-epithelialization with greatly increased healing (Fig. 14.7). The time-consuming nature of the procedure is the major problem, but repeated grafts can be performed, and the donor sites heal very rapidly. The approach may benefit both arterial and venous leg ulcers, and its suitability for primary care settings has been demonstrated [1].

For split-thickness skin grafts, a large sheet of partial-thickness skin is removed using a dermatome. The plane of cleavage may be variable, either within the papillary or reticular dermis. The graft is usually meshed before application as this tends to reduce the chances of the graft subsequently detaching as a result of the wound exudate. Split-thickness skin graft donor sites are often painful.



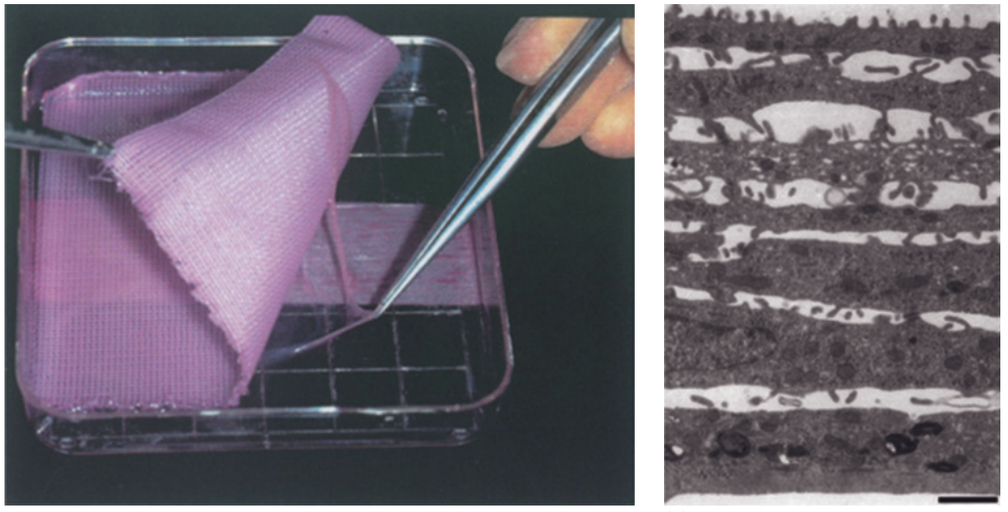


Fig. 14.7 Application of pinch grafts to a leg ulcer.

(a) (b)

Fig. 14.8 (a) Cultured keratinocyte allograft prepared for clinical use. (b) Ultrastructure of allograft.

In vitro-prepared skin grafts

The feasibility of growing human keratinocytes in culture was first established in 1975 [2] and the possibility of expanding a small donor site up to 10 000-fold led to the application of cultured keratinocytes for grafting [3]. Grafts established from the patient's own skin (autografts) or from allogeneic donors (allografts) have subsequently been formulated for clinical use (Fig. 14.8).

The earliest clinical use was to treat major burns patients, and the translucent sheets became a permanent stable epidermis, visible after 12–14 days [4]. The resulting graft remained fragile, and remodelling of the dermis occurred slowly [5]. Without a well-vascularized dermis, cultured keratinocytes alone are of limited use, and provision of a dermal equivalent in the graft on the wound bed appears to enhance graft take [6]. Cultured epidermal autografts have also been used to treat epidermolysis bullosa wounds [7], wound beds of congenital naevi [8], and chronic leg ulcers [9], where repeated grafting from passaged cultures is a major advantage. Preparation of a cultured keratinocyte sheet can take 2–3 weeks. Keratinocytes can also be suspended in fibrin and sprayed onto wounds or delivered on polymer carrier systems, such as hyaluronate membranes, allowing earlier grafting than previously possible [10–11]. Allografts of cultured keratinocytes do not survive long term [12–13], but have been shown to have a wound-healing effect in chronic leg ulcers [14], probably because of the production of appropriate growth factors and extracellular matrix proteins.

The field of tissue engineering to generate skin in the laboratory using keratinocytes, fibroblasts, growth factors and biomaterials has advanced considerably [15,16]. Available products can be categorized into three groups: (i) epidermal substitutes, (ii) dermal substitutes and (iii) combined epidermal and dermal substitutes (Fig. 14.9). Full-thickness wounds require replacement of both the epidermis and dermis. Current skin substitutes lack a vascular plexus, a major challenge for this area of research.

Pluripotent stem cells, such as mesenchymal cells from bone marrow, are recruited into the dermis during wound healing [17,18]. Stem cells derived from bone marrow or adipose tissue accelerate wound healing in both murine and human wounds, providing an exciting prospect for future therapy [19,20].

Growth factors to augment wound healing

All cells involved in the wound-healing process (inflammatory cells, epidermal keratinocytes and mesenchymal cells) can synthesize a wide range of membrane-bound and free growth factors, whose effects are mediated by specific growth factor receptors for each family of growth factor. Growth factors are multifunctional and have differing effects on different cell types, and can induce expression of other cytokines and their receptors in an autocrine and paracrine fashion. Growth factor activity can also be regulated via ECM components and proteolytic activation. The addition of exogenous growth factors in pharmacological amounts may have measurable effects in wound-healing models, but can be disappointing in the clinical arena [1–3]. Furthermore, elevated metalloproteinases and bacterial superinfection of wounds may completely obliterate any possibility of a useful therapeutic response from exogenous growth factors because of rapid degradation of the recombinant protein [4].

In animal models, a number of growth factors have positive effects on granulation tissue formation and angiogenesis, including PDGF, FGFs and TGF-β [5,6]. EGF family members appear to enhance re-epithelialization, as well as having mesenchymal effects [7–9]. Repifermin, a truncated form of recombinant KGF-2 (FGF-10), showed promise in a Phase 2A randomized clinical trial on venous ulcers [10], but in a subsequent trial failed to meet its primary endpoint [11]. PDGF (becaplermin gel) is currently the only licensed recombinant growth factor for treating recalcitrant wounds, and its usefulness in the management of chronic neuropathic diabetic ulcers has been demonstrated in clinical trials [12]. However, use of becaplermin is limited by cost and the requirement for daily applications.

The clinical success of delivery of growth factors to wounds has been disappointing. Gene therapy is a promising method of delivery of growth factors to epithelium. In a rabbit ischaemic ear wound model, one injection of an adenoviral vector containing DNA for human PDGF-AA increased wound closure and re-epithelialization compared to both ischaemic and non-ischaemic controls [13]. The promising results of the first human gene therapy trial using PDGF have recently been reported [14].

Genetics and disorders of the skin

Progress in the field of genetics in medicine continues rapidly. Most of the known single-gene disorders (e.g. genodermatoses) have at least been mapped to a particular chromosomal region and, in ever-increasing number, the causal genes have been isolated and studied [1]. In contrast, progress towards unravelling the molecular genetic basis of the more common and complex disorders (e.g. psoriasis and atopic eczema) has been somewhat slower. However, recent progress with the human sequencing effort together with radically improved computerized analytical strategies offer the prospect of progress in understanding the pathogenesis of these important dermatological disorders. The extraordinary rate of such developments has contributed to the parallel progress in understanding of the fundamental aspects of human skin characteristics. In combination, this revolution offers enormous opportunity and excitement for future research, together with the prospect of improved therapies for skin disease.

The Human Genome Project, an international effort to describe the entire human genetic sequence (3×10^9 bases), has hit targets ahead of expectation, and the release of the first draft [2] has necessitated a radical readjustment of the likely number of human genes within the genome (20 000–25 000). The genome sequences of a range of other organisms, including the nematode worm *Caenorhabditis elegans*, the fruit fly *Drosophila melanogaster* and the mouse, have now been completed. These act as important models for exploring gene structure and function in relation to tissues or the whole organism and have been extensively investigated in relation to a number of important genodermatoses.

The Internet provides the most satisfactory window on all this activity and a number of the more informative sites are listed below.

- UK Human Genetics Unit (http://www.hgu.mrc.ac.uk). Access to a wide range of databases and resources for genetic studies.
- The National Center for Biotechnology Information (http://ncbi.nlm.nih.gov/guide/). Main entry point for information about the Human Genome Project.
- Mutation Database, Cardiff (http://www.hgmd.cf.ac.uk/ac/index.php).
- Online Mendelian Inheritance in Man (OMIM) (http://www.ncbi.nlm.nih.gov/omim/). OMIM is a catalogue of over 12 000 known human Mendelian characters, and was created by Dr Victor McKusick of Johns Hopkins Hospital, Baltimore, USA. OMIM is an excellent starting point for acquiring up-to-date information on human Mendelian characters or *phenotypes*. Each character is given a six-digit MIM number, which is widely used to identify inherited disorders in the medical literature. The first digit of the MIM number indicates the mode of inheritance (historical): 1, autosomal dominant; 2, autosomal recessive; 3, X-loci or phenotype; 4, Y-loci or phenotype; 5, mitochondrial loci; and 6, autosomal loci or phenotypes added after 1994.

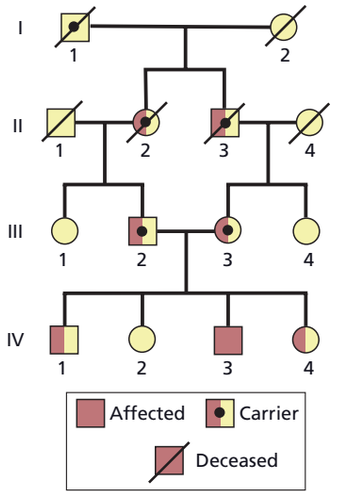
Nosology of genetics in skin disease

The terms 'familial', 'inherited' and 'congenital' are frequently misunderstood and misused. *Familial* refers to the clustering of a disorder, with more close relatives affected than predicted by the population prevalence of the condition. *Inherited* disorders require the transmission of genetic variants from one generation to the next. The term *congenital* simply means that the character was present at or detectable before birth; such abnormalities may not be genetically determined, and include developmental defects due to environmental infectious agents (e.g. rubella) and deformations arising from physical insults (e.g. amniotic bands). Only a proportion of inherited disorders reveal themselves at birth (i.e. are congenital), with many having their onset in later life. Such age dependence may result from a wide number of factors, including maturation of cells or tissue-specific functions, exposure to exogenous agents or accumulation of a noxious substance. A further and important example of adult age of onset is provided by hereditary cancer syndromes, such as neurofibromatosis (NF) type 2, in which a second mutation impacting upon the normal allele of a so-called *tumour-suppressor gene* (e.g. *Merlin*) is required to lead to tumour formation. Such a mutation occurs as a 'somatic' change.

Of the inherited skin abnormalities, the largest group is the single-gene disorders, which require an alteration in the function of a gene and are known commonly as the genodermatoses. The inheritance patterns for classical genodermatoses are illustrated in Figs 15.1–15.4. Each disorder is relatively uncommon, and more detailed descriptions of a number of important examples are presented in this chapter and elsewhere. Predisposition to the more common skin disorders, including atopic eczema and psoriasis, is determined by the action of more than one gene, with significant evidence for further modulation by environmental factors. Such disorders display complex patterns of clustering in families, and are referred to as *multifactorial*. Chromosomal abnormalities, either in number (*aneuploidy*) or form (*translocation*, *complex rearrangements* or *microdeletions*) are important to the clinician, particularly if the patient presents a range of abnormalities including mental retardation. However, chromosomal anomalies rarely present solely with dermatological problems and hence are only briefly mentioned.



The study of rare disorders, including the genodermatoses, has also provided insight into fundamental aspects of human genetic principles and mechanisms. Essential terms and principles are described, with the intention of helping the reader understand relevant genetic concepts referred to throughout this book and to aid in the interpretation of the rapidly emerging literature in this field [1–4].

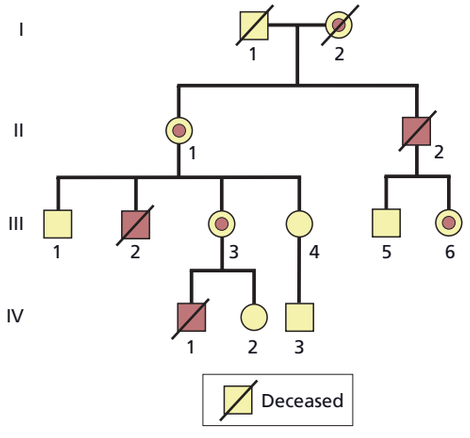
Principles of medical genetics

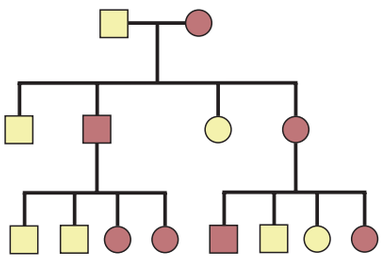


Inherited characteristics are transmitted from one generation to the next by chromosomes, composed of double-helix strands of DNA. A *gene* is a sequence of bases in DNA encoding a polypeptide. The precise position of the gene on a genetic map is known as its *locus*. In females, the 46 chromosomes found in most somatic cells present in homologous pairs; hence two copies of every gene exist, one maternal and the other paternal in origin. In males, the Y chromosome only pairs with the X chromosome at the pseudo-

1 AR disorders affect both males and females.
2 Affected individuals are homozygous for an abnormal allele and typically are born to unaffected parents.
3 On average, 1 in 4 of the children of heterozygous parents will be affected.
4 Typically, no family history is seen.
5 Consanguinity increases the risk of an AR disorder because both parents are more likely to carry the same mutant allele, inherited from a common ancestor.
6 The offspring of an affected person will be healthy heterozygotes and can be affected only if the other parent is also a gene carrier. This is unlikely except in consanguineous marriages or in ethnic groups in which particular alleles are common (e.g. isolated populations).
7 AR disorders are often severe; for example, many of the inborn errors of metabolism are AR.

Examples:
epidermolysis bullosa (the more severe forms)
ichthyosis (the more severe forms)
acrodermatitis enteropathica
phenylketonuria
xeroderma pigmentosum

Fig. 15.2 Autosomal recessive (AR) inheritance.



1 Usually only males are affected.
2 The disorder is transmitted through healthy female carriers; occasionally a heterozygous female may show some features of the condition (as a result of non-random X inactivation).
3 A female carrier will transmit the disorder to half her sons, and half her daughters will be carriers.
4 When a male is affected, all his daughters will be carrier heterozygotes.
5 The trait cannot be transmitted from father to son.
6 An XLR condition should be considered when the family history indicates affected males in different generations of the same family. Family history is not always positive as new *de novo* mutations are fairly common.

Examples:
anhidrotic ectodermal dysplasia
Fabry's disease
Menke's syndrome
ocular albinism

Fig. 15.3 X-linked recessive (XLR) inheritance.

autosomal region. *Meiosis* is the process of cell division by which male and female gametes (germ cells) are produced. Alternative genes at a single locus are called *alleles*. An individual with two different alleles at a particular locus is *heterozygous*; where both alleles are identical, the individual is described as *homozygous* at that locus. Genes on the X chromosome are not one of a pair in males and when such a gene is abnormal in a male, the term *hemizygous* is used. Nuclear DNA accounts for 99.995% of the total genetic pool. As with all complex mammalian genomes, the human sequence is made up of considerable amounts of repetitive DNA (Fig. 15.5). The total number of genes is now estimated to be approximately 20 000, with an average size, including introns, of between 10 and 15 kb.

An allele is regarded as *dominant* (Fig. 15.1) if it manifests as a phenotype when present on only one member of the chromosome pair (heterozygous state) and as *recessive* (Fig. 15.2) if it must be present at both corresponding loci (homozygous state) before it can exert its full effect. Hence, it is apparent that the terms 'domi-

1. An XLD disorder will give rise to a disorder in both hemizygous males and heterozygous females.
2. Affected males will transmit the disorder to their daughters, but not to their sons.
3. Affected females will transmit the disorder to half their sons and half their daughters.
4. In some disorders the condition is lethal in hemizygous males; so only female patients are encountered in clinical practice.

Examples: incontinentia pigmenti
X-linked form of oro-facial-digital syndrome

Fig. 15.4 X-linked dominant (XLD) inheritance.

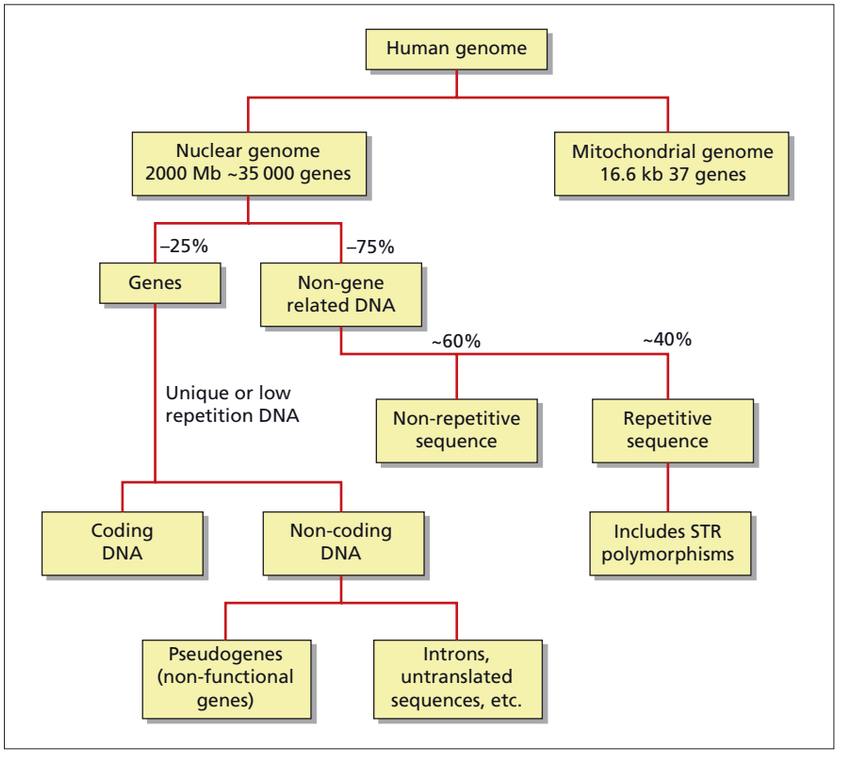


Fig. 15.5 Human genome organization.

nance' and 'recessivity' refer to a phenotypic characteristic rather than a gene [1].

Those genes borne on chromosomes other than the sex chromosomes (X and Y) are known as *autosomal*. Characters controlled by genes borne on the X or Y chromosomes are termed *sex-linked* (Figs 15.3 & 15.4). The Y chromosome is much smaller than the X chromosome. The great majority of sex-linked genes are exclusive to the X chromosome, having no active counterpart on the Y chromosome. For these traits the term 'recessive' applies to males who carry only one (mutant) allele. Females who carry X-linked mutations are typically heterozygous and with rare exceptions, including markedly skewed X inactivation, display no clinical abnormalities.

A region of homology sufficient for pairing between the X and Y chromosomes exists on the end of the short arm of the X chromosome, known as the *pseudo-autosomal region*, enabling sex-linked transmission comparable to autosomal traits [2]. Genes that are Y-linked are primarily involved in male sex determination (e.g. *SRY* gene controlling the testis determining factor) or spermatogenesis. Girls affected with MIDAS syndrome (microphthalmia, dermal aplasia and sclerocornea) and showing anomalies of the genitalia may display an *SRY*-positive status, indicating a translocation between the pseudo-autosomal region of Xp and Yp [3]. Hairy pinnae is another phenotype that is Y-linked [4].

The effects of a mutant allele are not necessarily constant; the degree to which the effects are variable is a measure of the *expression* of the character in question, and the frequency with which a gene produces any effect at all is a measure of its *penetrance*.

In addition to nuclear DNA, mitochondria contain a circular chromosome comprising 14 protein-coding regions [5]. The mito-

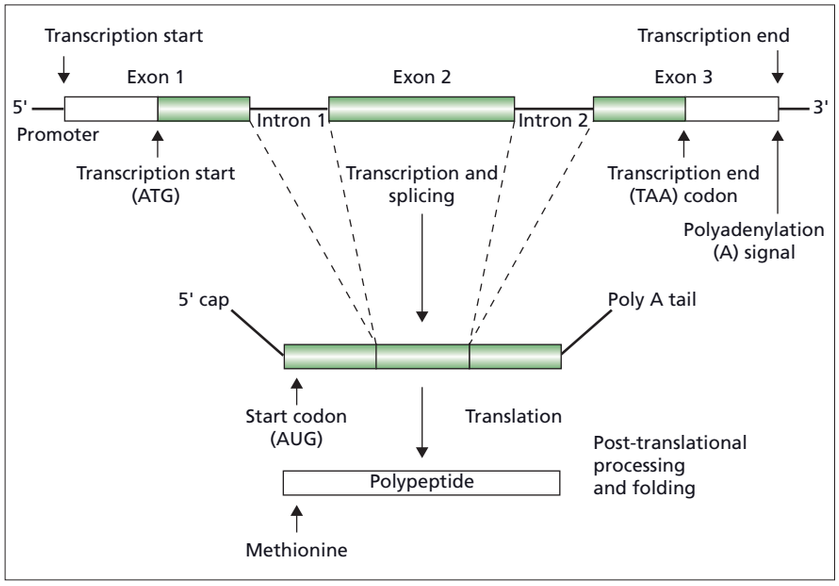

Fig. 15.6 Features of a typical human structural gene.

chondrial DNA codes for enzymes involved in the respiratory chain and oxidative phosphorylation. Mitochondrial disorders are essentially muscular, neurological and ophthalmological diseases and transmission is almost exclusively matrilineal [6].

Genetic heterogeneity

Genetic heterogeneity is the term used to describe clinically similar disorders (phenotypes) that result from different genetic defects. The concept of genetic heterogeneity is important for several reasons: (i) disorders that appear the same can be due to entirely different molecular defects, with a different natural history and requiring different treatment; (ii) for accurate genetic counselling, as defects may have different inheritance patterns; and (iii) because genetic heterogeneity plays a significant role in common complex disease states. Different alleles at the same locus (allelic) and genes at different loci (non-allelic) can give rise to similar phenotypes. Recognizing this, one can differentiate similar disorders by careful clinical distinction, as Wells and Kerr [7] did in distinguishing between autosomal dominant and X-linked ichthyosis. The use of both clinical findings and family history has helped to delineate heterogeneity in the epidermolysis bullosa and Ehlers–Danlos syndromes. Xeroderma pigmentosum illustrates phenotypic homogeneity but with marked genetic heterogeneity, with at least seven different genetic variants.

Mutations and disease

Most mutations are spontaneous and unexplained; however, certain factors such as mutagenic chemicals and ionizing radiation can increase the rate. In the absence of such agents, the mutation rate is of the order of 1 base pair (bp) substitution for every 10^9–10^{10} bp replicated. If a mutation occurs in a somatic cell (*somatic mutation*), only the descendants of that cell are affected and there will be no transmission of the abnormality to further generations. Only mutations occurring in the gametes or their precursors can be transmitted to offspring.

Normally, replication of DNA is accurate but mutations can occur, either induced by exposure to mutagenic agents or spontaneously through errors in the process of DNA replication and repair during meiosis.

Mutations that impinge on the function of a gene most commonly occur within the coding regions (exons) and may alter the amino-acid sequence and hence structure and function of the protein (Fig. 15.6). In addition to gross structural chromosomal changes, submicroscopic alterations including substitutions (replacement of a single nucleotide by another), deletions (loss of one or more nucleotides) and insertions (addition of one or more nucleotides) may occur. Single-base substitutions, often referred to as point mutations, have been most extensively characterized (see Cardiff Human Mutation Database). The majority are either missense or nonsense mutations. These mutations alter a codon so that either a different amino acid is encoded (missense), or a codon specifying an amino acid in a normal individual is altered to code for the stop codon TGA, leading to premature termination of the protein (nonsense). Deletions and insertions (up to 20 bp of DNA) other than multiples of three will lead to disruption of the reading frame for RNA translation, resulting in a frameshift mutation and premature termination (Fig. 15.6). Point mutations may also affect splicing, the process by which mature messenger RNA (mRNA) is produced from RNA that has been transcribed directly from the gene [1].

Two-hit progression to tumour formation

Through pioneering observations on the familial and sporadic occurrence of rare tumours, Knudson [8] proposed that germ-line mutation of one allele of a tumour-suppressor gene, although required to explain an autosomal dominant pattern of inheritance, was not in itself sufficient to lead to tumour formation. Hence, in a target tissue, acquired mutations known as somatic mutations need to occur and lead to complete loss of function of the gene. Molecular genetic evidence to support this important concept has

recently emerged for a number of disorders, including NF1 and tuberous sclerosis.

Contiguous gene syndromes

Large genome deletions may involve several neighbouring genes, for example a well-established 'set' of contiguous gene disorders involve the steroid sulphatase locus (Xp22.3). Deletions of different sizes and location within Xp22.3 give varying combinations of X-linked ichthyosis, Kallman's syndrome (hypogonadotrophic hypogonadism and anosmia), chondrodysplasia punctata, ocular albinism, mental retardation and short stature [9].

Functional impact of mutations and polymorphisms

Mutations exert their effects by leading to a loss or gain of function of the gene's protein product. In general, loss-of-function mutations lead to either reduced activity or complete loss of the protein. Gain-of-function mutations result in either increased levels of expression or the acquisition of a new function of a protein. The term 'mutation' has traditionally been applied to genetic variation causative of a Mendelian disorder. As further studies are undertaken to unravel the genetic contribution of common and complex disorders, understanding the subtle functional consequences of all genetic variation, including polymorphisms, will be increasingly important [1].

High-throughput genetic analysis

Studies of human genetic disease have been substantially facilitated by the introduction of rapid and increasingly low-cost methods of DNA analysis. Genome-wide screens of polymorphic markers and global analysis of gene transcripts can readily be achieved. DNA microarray represents one emerging technology likely to impact on the application of molecular genetics to clinical dermatology. A microarray or DNA chip represents multiple DNA sequences immobilized on a solid surface, using either a photolithographic process or simple 'spotting' of DNA sequences onto a glass slide. Such chips allow high-throughput parallel analysis, which can be used to uncover point mutations in single genes or larger genomic deletions, as well as detecting changes in gene expression associated with disease states or response to treatment.

Mosaicism, lyonization and the lines of Blaschko

Mosaicism describes an individual with two or more cell lines of different genotypes derived from the same zygote. In health, all females exhibit functional mosaicism with regard to their X chromosomes. One of the two X chromosomes in the cells of normal females undergoes inactivation at an early stage of embryonic development (12–16 days after fertilization), a process known as lyonization [10]. The inactive X remains condensed as a densely stained mass of chromatin known as the Barr body. For each somatic cell it is random whether the paternal X or the maternal X is inactivated, but the choice is fixed for all subsequent descendants of that cell. Thus, a female has a mixture of two populations of cells, some of which have an active paternal X chromosome and some of which have an active maternal X chromosome. The relative proportions vary from female to female (even in identical twins) due to the randomness of the inactivation process. As a result of lyonization, the heterozygous state of various X-linked gene defects may give rise to a mosaic pattern of cutaneous lesions, which conforms to the system of lines on the skin first described by Blaschko in 1901 [11] (Fig. 15.7). The original description by Blaschko referred to a 'system of lines on the human skin which the linear naevi and dermatoses follow'. Many naevoid skin lesions display an arrangement following these lines. The lines do not correspond to any known nervous, vascular or lymphatic structures, but represent the developmental growth pattern of the skin [12].

Many genetic skin diseases reflect mosaicism, with mutation occurring after fertilization (post-zygotic). Important features to be considered in mosaicism and their impact on phenotype relate to the proportion of cells that harbour the mutation and tissue distribution. In general, the greater the proportion of cells that are abnormal, the greater the severity of the resultant phenotype. Furthermore, phenotype is influenced by the portion of mutant cells in a specific tissue. If a mutation has little impact on the normal function of the tissue, the phenotypic consequences are likely to be minimized. Women heterozygous for the gene of X-linked recessive ichthyosis do not display any mosaic pattern of skin changes, and it has been suggested that some genes on the X chromosome may escape inactivation [13,14].

It is likely that all naevi reflect genetic mosaicism [15]. Streaky or patchy pigmentary skin changes may be a clue to the presence of mosaicism. The pigmentary patterns associated with mosaicism are reviewed by Happle [16].

Gonadal mosaicism and recurrence risk

An autosomal dominant trait may occur in more than one sibling, even though both parents are apparently unaffected. This phenomenon may be explained by gonadal mosaicism, due to the presence of a mutation in germ-line but not somatic cells [17]. Evidence of gonadal mosaicism exists in tuberous sclerosis [18], bullous ichthyosiform erythroderma [19] and NF1 [20]. Gonadal mosaicism for the X-linked disorder incontinentia pigmenti has been reported in a healthy male [21].

Genomic imprinting

This term is used to describe the phenomenon whereby a DNA sequence derived from one parent acts in a different way compared with that derived from the other parent [22,23]. Imprinting (coding or non-coding) carries a signal or imprint that indicates to nuclear transcription machinery the parent of origin for that sequence. For the majority of the human genome, no distinction is made between paternal and maternal copies, with the exclusion of polymorphic variation. The molecular basis of imprinting is thought to be methylation, the process whereby a methyl group (CH_3) is added to DNA nucleotides (typically cytosine). Methylation is usually associated with reduced levels of expression of a gene, and for certain genes is applied exclusively to either the paternal or maternal copies. Examples of dermatological disorders subject to imprinting include familial glomus tumour [24] and Albright's hereditary osteodystrophy [25], and the phenomenon may also play a role in the genetic basis of atopy [26,27] and psoriasis [28].

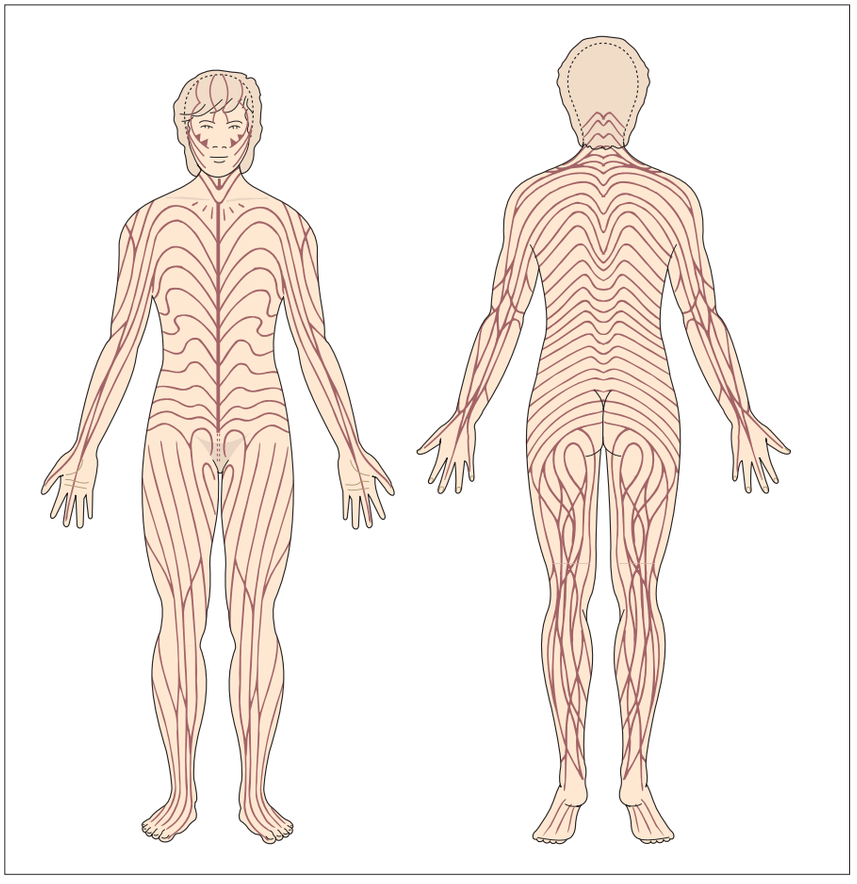

Fig. 15.7 Blaschko's lines as illustrated in his 1901 article 'A system of lines on the surface of the human body which the linear naevi and dermatoses follow'.

Uniparental disomy

For the vast majority of individuals, one chromosome of a pair has been inherited from each parent. Rarely, uniparental disomy may occur when an offspring receives both copies of a chromosome pair from one of its parents. For some chromosomes this results in recognizable phenotypes, for example uniparental disomy of the maternal copies of chromosome 15 leads to Prader–Willi syndrome. For other chromosomes, uniparental disomy does not appear to be of obvious phenotypic value, unless by chance the identical chromosomes harbour a recessive mutation, which would then be present in the homozygous state [29,30].

Twin spotting

This hypothesis has been proposed, based on the genetic concept of somatic recombination, to explain the frequent coexistence of two separate and distinct naevi, for example a telangiectatic naevus and naevus anaemicus and phacomatosis pigmentovascularis [31–33]. Twin spotting has been extensively studied in plants and animals.

Genome sequence and analysis of inherited disorders

Completion of the human genome sequencing effort has led to phenomenal progress in gene mapping techniques, with thousands of DNA markers now available, each defined and covering all chromosomes. These markers have greatly facilitated linkage studies within families with Mendelian disorders. Linkage analysis questions whether each DNA marker co-inherits with the disease more often than expected by chance. The statistical test of linkage is the logarithm of the odds (lod) score. A lod score of 3 or greater is accepted as significant evidence of linkage, whereas a score of –2 excludes linkage at that location. The traditional DNA marker is a *restriction fragment length polymorphism* (RFLP) analysed by Southern blotting of restricted (digested) DNA, with the fragments detected by a radioactive probe. Most genetic markers are now detected rapidly by polymerase chain reaction (PCR)-based methods of analysis, exploiting an abundant class of DNA sequence variation known as simple tandem repeats or single nucleotide polymorphisms. *Gene tracking* is the term given to the use of a known linkage between a marker and a disease locus to predict the genotype at the disease locus in a particular family member, such as in asymptomatic carrier testing or prenatal diagnosis. Linkage studies are just the first step in positional cloning of a disease gene.

Genetic linkage, linkage disequilibrium and disease association

Alleles at gene loci residing close to each other on the same chromosome remain linked in transmission so long as the chromosome remains intact; however, during reduction division (meiosis), such linkages may be disrupted if *crossing-over* occurs. The closer two

gene loci are situated on a chromosome, the less likely they are to be separated by crossing-over and the more likely they are to be inherited together. Two such gene loci are said to be linked and it is possible to demonstrate genetic linkage in a family using appropriate genetic markers. When two alleles occur together more frequently, or less frequently, in a population than would have been expected from the individual allele frequencies, they are said to be in *linkage disequilibrium*. This may arise as a result of a recent mutation or for a particular combination of DNA sequences, which may have, for example, a selective advantage and hence achieve disequilibrium by natural selection. Linkage disequilibrium is one important cause of disease association.

The nail–patella syndrome is a clinical example of a disorder that shows genetic linkage with the blood group ABO locus; the ABO and the disease gene loci are both situated on chromosome 9. Because of eventual crossing-over, over a number of generations recombination will occur, leading to different affected families; alternatively, independent mutations causing nail–patella syndrome may arise *de novo*. Thus, there is genetic linkage between the loci for blood groups and nail–patella syndrome, but no association with a particular blood group. Genetic linkage is a phenomenon demonstrable within families. In contrast, association due to linkage disequilibrium is a phenomenon demonstrated by comparing a population of affected individuals with a control population [1].

Histocompatibility antigens and disease association

Human leukocyte antigens are glycoproteins on the cell surface of most nucleated human cells. These differ in subtle ways from person to person and uniquely fingerprint each person's cells. These fingerprints allow a person's immune system to recognize if a given cell is its own. The importance of the human leukocyte antigen (HLA) system has been highlighted by the need to match donors and recipients in the transplantation of human tissues.

The HLA region is located on the short arm of chromosome 6, referred to as the major histocompatibility complex (MHC). A person inherits HLA as a set, one set (haplotype) from each parent. There are at least four or five genetic loci that produce HLA, termed A, B, C, D and DR (in order of their discovery not their location), and their gene products are called HLA-A, HLA-B, HLA-C, HLA-D and HLA-DR. Each locus has multiple allelic determinants (polymorphism). Each allele at each locus controls an antigen, which is identified by a number placed after the letter of that series, for example HLA-A1, HLA-B5. The letter 'w' in front of a number indicates that its specificity was studied in an international workshop, and continues to undergo further definition.

HLAs that code at the A, B and C loci are determined by serological cytotoxicity methods, whereas those occurring at the D locus are detected by the mixed lymphocyte reaction. The HLA-DR antigens are serologically determined and are similar, if not identical, to the D locus antigens. DNA-based methods for typing at all HLA loci are now available.

The association of an HLA with a given disease means that there is a higher incidence of that antigen in a group of patients with the disease than in a group of people without the disease. There are various ways in which the presence of a particular HLA might be involved in the pathogenesis of a disease.

1 *Molecular mimicry*. An infective agent may have a similar configuration to the HLA, so that the agent is then not attacked by the body's defence system. Alternatively, the agent might differ only slightly from the HLA, so that antibodies are produced that attack both the infective agent and the cells containing the HLA, thus inducing autoimmune damage.
2 *Receptor effects*. Many chemicals, including drugs and toxins, bind to the cell surface before they are taken into the cytoplasm. As HLAs are present on the cell surface, they could modify the binding of these potentially toxic substances, and the specificity for such binding may be determined, at least in part, by DNA variation for HLA molecules.
3 *Genetic linkage*. The HLA may be close to another gene on the same chromosome that produces a disease, either directly (e.g. due to an enzyme deficiency) or indirectly due to an effect on the immune response, which may be abnormally enhanced, leading to autoimmunity, or abnormally decreased, leading to infection.

The association between an HLA and a particular disease is rarely absolute. Ankylosing spondylitis is strongly associated with the B27 antigen, but some patients with this disease are B27 negative and many patients with B27 do not develop ankylosing spondylitis. There are many possible explanations for this, including the role of environmental factors or triggers, such as chemicals or infective agents, in disease causation. Non-HLA-linked genes are probably also important, including some that may confer resistance to disease. The relative risk is the numerical answer to the question 'How many times is a person with a given HLA phenotype more likely to develop a given disease than a person without that HLA phenotype?' The relationship between HLA and skin disease is the subject of several reviews [1–4] (Table 15.1).

Table 15.1 Some skin diseases known to be associated with particular human leukocyte antigens (HLA).

Disease	Antigen	Relative risk
Dermatitis herpetiformis	B8	15
	Dw3/DRw3	>15
Pemphigus	DRw4	10
Reiter's disease	B27	35
Behçet's disease	B5	10
Psoriasis	B13	4
	B17	5
	B37	5
	Cw6	12
	Dw7	10
Psoriatic arthropathy (central)	B27	10
Psoriatic arthropathy (peripheral)	Bw38	9

There is a genetic predisposition to pemphigoid (herpes) gestationis; 90% of patients express either HLA-DR3 or HLA-DR4 [5].

Genetic counselling [1–3]

Advice to parents or prospective parents must be based on an accurate diagnosis and a detailed family history. It is essential to establish a diagrammatic representation of the family pedigree. Genetic counselling depends upon the recurrence risk to parents of having an affected child. The risk that any pregnancy will produce a child with a serious abnormality is about 1 in 50 (2%). A risk greater than 10% is high, whereas a risk of less than 5% is considered low. However, the impact such a risk has upon a couple or extended family depends on the severity of the disorder and any prior experience relatives may have of a condition. The offspring and recurrence risks for known forms of Mendelian disorders are illustrated in Figs 15.1–15.4.

Many different definitions of genetic counselling have been proposed, but all include the concept of a process of communication, where patients or relatives are informed of the probability of developing or transmitting a genetic disorder. This process should also include discussion about the consequences of such disorders and the possibilities for disease prevention. Hence, it is apparent that counselling is a complex process that requires a range of skills, which increasingly includes integration of complex information regarding DNA analysis. However, it remains important to realize that it is the burden of disease rather than the precise numerical value of risk that concerns most patients and prospective parents. Genetic counselling has recently emerged as a distinct specialty in medicine and many dermatology centres work in close collaboration over the provision of accurate and comprehensive advice.

Chromosomal disorders

Chromosomal disorders may be due to abnormalities of chromosome number or structure and may involve autosomes or sex chromosomes. Somatic cells are *diploid*, with a complement of 46 chromosomes, whereas gametes (ova and sperm) are *haploid*, with only 23 chromosomes following reduction division in meiosis. Numerical abnormalities that involve the gain or loss of one or

more chromosomes are known as aneuploidies. Structural chromosome rearrangements result from chromosome breakage with subsequent reunion in a different configuration. They may be balanced or unbalanced, depending on whether or not gain (or loss) of genetic material occurs. Approximately 7.5% of all conceptions have a chromosomal disorder, but most of these are spontaneously aborted, so the birth frequency is 0.6%. Among early spontaneous abortions, the frequency of chromosomal disorders is 60%, whereas in late spontaneous abortions and stillbirths the frequency is 5%. Chromosomal abnormalities generally cause multiple congenital malformations. Children with more than one physical abnormality, particularly if retarded, should undergo chromosomal analysis as part of their investigation. Chromosomal disorders are incurable but can be reliably detected by prenatal diagnostic techniques. Amniocentesis or chorionic villous sampling should be offered to women whose pregnancies are at increased risk, namely women over the age of 35 years and couples with an affected child.

Autosomal chromosome defects

Down's syndrome [1–3]

Synonym
- Trisomy 21

Down [1] described this syndrome in 1866. In 1959, it became the first recognized chromosomal anomaly [4]. It is the most common autosomal abnormality, with a frequency of about 1 per 700 live births [5].

Aetiology [2]. Most cases (95%) result from trisomy of chromosome 21, in which the extra chromosome is derived by nondisjunction at meiosis, usually from the mother; the incidence of this type rises with maternal age. Less common, and clinically indistinguishable, is the type that shows no relation to maternal age and is sometimes familial. The affected child has the normal number of 46 chromosomes but one of the clinically normal parents carries a translocation of part of chromosome 21. A few patients are themselves mosaics and tend to have less marked physical stigmata and higher intelligence [6].

Pathology. Congenital heart defects are common and the brain is small with flat convolutions. Renal tract anomalies are less common.

Immunological defects are frequent. Autoimmune disease is common in Down's syndrome, T-cell function is impaired and the atopic state is often associated [7]. There is an increased risk of developing acute leukaemia, usually under the age of 5 years.

The lichenified patches of skin show no distinctive pattern, with hyperkeratosis, acanthosis and a dermal inflammatory infiltrate.

Clinical features [8]. The facial appearance often permits a clinical diagnosis. The head is small, the face flat, the nose short and squat and the ears small and misshapen. The eyes are usually conspicuously mongoloid, with slanting palpebral fissures. The eyelids are thickened and the eyelashes short and sparse. Epicanthic folds are frequent in early childhood but tend to become less noticeable with age. The iris tends to be hypoplastic and may show light areas in its outer third (Brushfield's spots). The limbs are stumpy and the joint ligaments lax. The fingers are short and cone-shaped and are sometimes webbed. The little finger is often curved. The presence of these features varies in affected individuals, and a diagnostic index has been proposed [9].

Mental retardation is a serious complication: the IQ is usually less than 50, and if it is not mosaicism should be suspected. Congenital heart malformations, especially endocardial cushion defects, are present in 40%, and duodenal atresia may occur. Other complications include cataracts (2%), epilepsy (10%), hypothyroidism (3%), leukaemia (1%), atlantoaxial instability (2–3%) and recurrent respiratory infections. When serious malformations are present, death during infancy is usual, but otherwise life expectancy is little reduced. Down's syndrome accounts for about one-third of all moderate and severe mental disability in children of school age. Most will walk and develop simple language. Puberty is often delayed and incomplete, with adult heights about 150 cm. Presenile dementia commonly supervenes after 40 years of age.

The skin is normal at birth and in early childhood is soft and velvety [8,10]. Between the ages of 5 and 10 years it becomes increasingly dry and less elastic, and by the age of 15 over 70% show generalized xerosis of mild to moderate degree, with evidence of accelerated skin ageing [11]. Patchy lichenification is present in some 30% under 10 years and more than 80% over 20 years of age. The patches resemble lichen simplex and most commonly occur on the upper arm, the wrists, the fronts of the thighs, the back of the ankle and the back of the neck, and are probably correctly regarded as manifestations of atopic dermatitis, the incidence of which some authorities [10] have considered to be low.

A chronic follicular papular eruption of the presternal and interscapular regions is frequently present, consistent with *Malassezia* folliculitis. In a clinical trial, oral itraconazole produced a significant clinical improvement accompanied by a decrease in the skin *Malassezia* count, but relapse occurred when therapy was discontinued and was accompanied by a return of the *Malassezia* yeasts [12].

The hair may be normal but is often fine and may be hypopigmented. The prevalence of alopecia areata is high and it tends to be extensive and persistent [7,13]. The teeth are hypoplastic and late to erupt. Fissuring and thickening of the lips are frequent and increase in prevalence and severity with age [14]. The tongue is scrotal in almost all cases. Elastosis perforans serpiginosa [15,16] and syringomas, especially in adult females with Down's syndrome [17,18], occur more often than in normal subjects.

Skin infections, angular cheilitis, chronic blepharitis and a purulent nasal discharge are common. There is a high prevalence of onychomycosis [7,19]. The cheeks are often red. The peripheral circulation is poor, acrocyanosis is frequent and livedo reticularis is often conspicuous throughout the year, on the thighs, buttocks and trunk.

Dermatoglyphic features include a single flexion crease on the fifth finger, the simian palmar crease and an increased incidence of ulnar loops on the fingers.

There is no evidence that the prevalence of other dermatoses is significantly different in individuals with Down's syndrome

compared with individuals with mental retardation from other causes. Psoriasis runs its normal course, although an unusual hyperkeratotic form has been described [20]. Acral lentiginous melanoma has been described in association with Down's syndrome [21].

Trisomy 18 [1–3]

Synonym
- Edwards' syndrome

This is the second most common multiple malformation syndrome. It occurs in about 1 per 3000 live births; 95% of affected fetuses abort spontaneously. Parental non-disjunction at either the first or second meiotic division results in the extra copy of chromosome 18. Rarely, a parental translocation is responsible. Occasionally, mosaicism is seen with a milder phenotype and can give rise to pigmentary skin changes, as seen in hypomelanosis of Ito [4,5]. The syndrome comprises severe mental deficiency, a characteristic skull shape with a small chin and prominent occiput, low-set malformed ears, clenched hands with overlapping index and fifth fingers, single palmar crease, 'rocker-bottom' feet and a short sternum. Malformations of the heart, kidneys and other organs are frequent. Cutaneous features include cutis laxa of the neck, hypertrichosis of the forehead and back, and capillary haemangiomas. Fingerprints show a distinctive low-arch dermal ridge pattern. Death within a month occurs in 30%. Only 10% survive beyond the first year and these infants show profound developmental delay.

Trisomy 13 [1–4]

Synonym
- Patau's syndrome

The incidence of trisomy 13 is 1 per 5000 live births. Non-disjunction at either the first or second meiotic division in either parent may cause trisomy 13. In about 20% of cases, one parent is a translocation carrier. In about 5% of patients, mosaicism is present. The characteristic features of the syndrome are mental retardation, sloping forehead reflecting underlying holoprosencephaly (a developmental defect of the forebrain), eye defects including microphthalmia or anophthalmia, cleft palate and cleft lip, low-set ears, 'rocker-bottom' feet, cardiac defects and a variety of other visceral abnormalities. Survival for more than 6 months is unusual. Cutaneous features include vascular anomalies, especially of the forehead, hyperconvex nails and localized defects of the scalp. Cutis laxa of the neck has also been reported. The palm print shows a distal palmar axial triradius.

Other autosomal abnormality syndromes

Although the syndromes to which these autosomal abnormalities give rise include distinctive craniofacial malformations, they do not exhibit constant or frequent dermatological features, apart from abnormal dermatoglyphics. Other chromosomal disorders are reviewed elsewhere [1,2].

Chromosome 4, short-arm deletion syndrome [3]
These children have microcephaly, mental retardation, hypospadias and multiple malformations, such as cleft lip and/or palate, low-set ears and pre-auricular pits. There are scalp defects in some cases.

Chromosome 5, short-arm deletion syndrome [4–6]

Synonym
- *Cri du chat* syndrome

This is a clinically heterogeneous syndrome. The patients are mentally deficient microcephalics with a cat-like cry. In some cases a pre-auricular skin tag accompanies low-set malformed ears. There may be premature greying of the hair.

Long-arm 18, deletion syndrome [7]
Hypoplasia of the mid-face gives these children deep-set eyes. The antihelix is very prominent and there are multiple skeletal and ocular abnormalities. Eczema has been reported to occur in 25% of cases.

Sex chromosome defects

Turner's syndrome [1,2]
Turner's syndrome is defined as a gonadal dysgenesis due to a missing or structurally defective X chromosome. In 1938, Turner described this syndrome in seven girls [1].

Aetiology [2]. The frequency of Turner's syndrome is 1 per 2500 female births [3]. In some 80% of cases there are 45 chromosomes with an X0 sex chromosome complement. Such cases are chromatin negative in buccal smears. It is assumed that the missing chromosome was lost before or at fertilization. The incidence of 45X was reported to be increased in the offspring of teenage mothers [4], but in a study from Denmark there was no significant relation between mother's age and risk of Turner's syndrome [5].

Most of the remaining 20% of cases are chromatin positive. Some have 46 chromosomes but with partial deletion of one X chromosome [6]. Such individuals may not differ significantly in their phenotype from the common X0 but they may be less severely affected [7]. Other cases have shown mosaicism of various types (XX/X0 or XXX/X0) [8].

Pathology [8]. In place of the normal gonads, ovarian streaks are present that are composed of stroma-like cells and quiescent germinal epithelium without follicular activity or germ cells. However, both follicles and germ cells have occasionally been present.

Lymphangiographic studies have shown hypoplasia of cutaneous and subcutaneous lymphatics [9].

A lack of feedback inhibition by hormones from the defective ovaries produces elevated levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in the serum by 5 days of age [10].

Clinical features [7,11–13]. Turner's syndrome results in early spontaneous loss of the fetus in over 95% of cases. Severely affected fetuses who survive to the second trimester can be detected by ultrasonography, which shows cystic hygroma, chylothorax, ascites and hydrops.

Growth failure is a consistent finding at birth in infants with Turner's syndrome, which begins in early gestation and is well established by mid-pregnancy [14]. The diagnosis may be suggested in the newborn by redundant neck skin and peripheral oedema. However, the diagnosis is usually made later as a result of investigation for short stature and primary amenorrhoea.

The characteristic clinical features of Turner's syndrome include: small stature; a broad shield-shaped chest with widely spaced nipples; a wide carrying angle of the arms; a webbed neck (pterygium colli); a low posterior hairline; low, misshapen ears; high, arched palate; cutis laxa, especially on the neck and buttocks; short fourth, and sometimes fifth, metacarpals and metatarsals; hypoplastic nails; and a tendency to keloidal scar formation.

Individuals with Turner's syndrome have increased numbers of melanocytic naevi and therefore have an increased risk for melanoma [15]. Lymphangiectatic oedema of the hands and feet may be present at birth and clear in the first 2 years. Skeletal abnormalities are a common feature [6], but are also very variable. Among the most frequent are cubitus valgus, kyphoscoliosis and epiphyseal defects and pathological fractures. Cardiovascular abnormalities [16] are present in some 25% of cases, especially coarctation of the aorta. Ocular defects, squints or ptosis, are also a feature of some cases. Intelligence is usually normal, although a few girls have educational problems.

Endocrinological investigations reveal an increased output of pituitary gonadotrophins accompanied by low oestrogen levels. Thus there is usually primary amenorrhoea with failure to develop full secondary sexual characteristics. Some patients menstruate and, exceptionally, may be fertile. Adrenal androgens are present, and pubic and axillary hair may be present in the absence of other manifestations of normal pubertal development. A few examples are known [17] in which otherwise typical Turner's syndrome (X0 chromosome complement) is accompanied by some degree of genital virilization and hirsutism.

Diagnosis. Diagnosis may be made prenatally by amniocentesis [5]. The somatic abnormalities may suggest the diagnosis in infancy or childhood, but if they are inconspicuous or absent, the diagnosis may be unsuspected until puberty. Increased urinary excretion of FSH supports the diagnosis, which can be confirmed

by examination of buccal smears supplemented by chromosome studies.

Treatment. Oestrogen replacement will allow the development of secondary sexual characteristics but does not seem to influence stature or infertility. Treatment with human growth hormone may improve the ultimate adult height; long-term, randomized, controlled studies are in progress [18]. Melanocytic naevi may grow more rapidly during growth hormone therapy [19]. Therefore, individuals with Turner's syndrome, especially those on growth hormone therapy, should have periodic skin examinations and be advised on the regular use of sunscreens [15].

Klinefelter's syndrome [1,2]

Aetiology. The frequency of Klinefelter's syndrome is 1 per 600 male births [2]. In buccal smears the nuclei are chromatin positive and indistinguishable from those of the normal female, but in cultures there are seen to be 47 chromosomes with an XXY sex chromosome complement [3]. The differentiation of the developing gonad proceeds along male lines but the testis fails to develop fully, and many seminiferous tubules are replaced by fibrous tissue. Leydig cells are present in normal or increased numbers.

Clinical features [1,2,4–6]. There are no clinical manifestations before puberty, which occurs at the normal age. The testes are small and fail to produce adult levels of testosterone, which leads to poorly developed secondary sexual characteristics and infertility. Hair growth on the trunk, limbs and face tends to be below average. Psychiatric disorders are common but mental deficiency is not. Some patients retain eunuchoid body proportions. They are tall, obese and may develop gynaecomastia. Associated features include osteoporosis [7] and taurodontism (vertical enlargement of the molar pulp chamber) [8]. Various minor dermatoglyphic changes have been recorded [9].

An association between systemic lupus erythematosus (SLE) and Klinefelter's syndrome has been postulated [10], and this is interesting in view of the fact that SLE is more frequent in women than men and that oestrogens may provoke SLE in some patients [11]. In a case report of SLE in a hypogonadal male with Klinefelter's syndrome treated with testosterone in doses sufficient to normalize the serum level of this hormone to the adult male range, haematological and serological abnormalities, including elevated levels of anti-DNA antibodies and depressed complement levels, returned to normal within 9 months of increasing the testosterone dose [12].

There are two reports of incontinentia pigmenti in boys with Klinefelter's syndrome [13,14]. As incontinentia pigmenti trait is usually lethal in males, it has been proposed that the second X chromosome protects against fetal death.

Patients with Klinefelter's syndrome have an increased risk of developing leg ulcers, especially in combination with hyperpigmentation or atrophie blanche [15,16]. Some authors have attributed the cause of leg ulceration to venous insufficiency, others have implicated increased activity of plasminogen activator inhibitor 1 [17]. It seems likely that androgens may protect against the development of leg ulcers, because ulcers are more common in women than men, and it may be relevant that men who do develop leg ulcers tend to be taller, heavier and less fertile than age-matched control subjects [18].

Testosterone replacement therapy will improve secondary sexual characteristics, but infertility is the rule, except in mosaic patient.

Diagnosis. The association of gynaecomastia with small testes and otherwise apparently normal genitalia should suggest the diagnosis, which is supported by finding an increased urinary excretion of gonadotrophin. The diagnosis is confirmed by chromosome studies.

Other abnormalities of the sex chromosomes

XXYY [1]

These individuals show many of the main features of Klinefelter's syndrome, including sparse body hair. Additional features reported are multiple cutaneous angiomas, acrocyanosis and early peripheral vascular disease.

XYY syndrome [2]

These patients are phenotypic males, often tall and with, perhaps, an increased incidence of severe acne (see Chapter 42). They may be mentally retarded, and have a reputation for aggressive behaviour [3], not accepted by all authorities. There is no evidence of increased secretion of FSH or LH [4].

XXXXY syndrome [5]

These patients, of low birth weight, are slow to grow physically and are mentally defective. There are multiple skeletal defects, of which limited elbow pronation is the most characteristic. The ears are large, low-set and malformed. There is hypogenitalism. No consistent dermatological defects are reported, but some patients have hypotrichosis.

Fragile X syndrome [6–8]

Fragile X syndrome is associated with a folate-sensitive fragile site in band Xq27.3 due to a triplet DNA repeat that is expanded and unstable. Subjects have mental retardation and mild dysmorphic features, with mild connective tissue abnormality that leads to fine skin, hyperextensible joints and flat feet. Males are more commonly affected than females. The disorder is common, with about 1 in 2000 children affected.

Noonan's syndrome (MIM 163950) [1,2]

This autosomal dominant syndrome, which occurs in both sexes, phenotypically resembles Turner's syndrome. Clinically, patients are of short stature and have a broad short neck, which may be webbed. The facies are characteristic and have an association of hypertelorism, blepharoptosis, epicanthic folds and a small chin. Skeletal defects, including spinal deformity in 30%, are frequent [3]. Congenital heart defects, such as pulmonary stenosis and cardiomyopathy, may be present. Intelligence may be normal but some degree of intellectual impairment is usual. Children with Noonan's syndrome (NS) tend to be clumsy, stubborn, irritable and have communication difficulties [4]. In 70% of males, the testes are undescended.

Dermatological manifestations are common. Lymphoedema of the feet and legs is common and more severe than in Turner's syndrome [5]. Orbital oedema is sometimes seen and can be an unusual presentation of NS [6]. Widespread leukokeratosis of the lips and gingiva has been described [7]. The hair is usually coarse, light coloured and curly, with a low posterior hairline. Downy hypertrichosis may occur on the cheeks or shoulders. Pubic hair is scanty in the male and beard growth is poor [8]. Ulerythema oophryogenes may be a cutaneous marker for NS [9,10].

The genetic basis of NS in many cases is now known to be due to mutations in *PTPN11*, a gene encoding the non-receptor protein tyrosine phosphatase SHP2, which contains two Src homology-2 (SH2) domains [11]. Tartaglia *et al.* [11] found that mutations in the *PTPN11* gene accounted for about 50% of the patients studied. Mutations in the neurofibromin gene (*NF1*), which is the site of mutations causing classic NF1, have been found in neurofibromatosis–Noonan syndrome. Acute leukaemia has been reported in a few cases of NS [12]. After germ-line mutations in *PTPN11* were demonstrated in NS, a search has been performed for defects in *PTPN11* in myeloid disorders, including cases of juvenile myelomonocytic leukaemia (JMML) in children with NS. Specific mutations in *PTPN11* associated with isolated JMML occur as somatic

changes and have never been observed as germ-line defects, leading to speculation that these molecular defects have a greater functional impact and may be associated with embryonic lethality.

Patients with overlapping features of NF1 and NS have also been described (see p. 15.20), and in some of these cases mutations in the *NF1* gene have been detected.

In contrast with Turner's syndrome, short stature and infertility are not constant features. The diagnosis of NS must be suspected in all patients labelled as Turner's syndrome if they are of normal height, intellectually impaired, have a cardiac valve defect or manifest normal gonadal function. Individuals with NS who are of short stature may benefit from treatment with growth hormone [13].

Less common forms of Noonan's syndrome

De novo germline mutations of the *KRAS* gene have also been found in individuals with a variant of Noonan's syndrome (designated NS3; MIM 609942), but these account for less than 5% of Noonan's syndrome cases [14]. Although this mutation was initially identified in an individual with juvenile myelomonocytic leukaemia-like myeloproliferative disorder, further screening of NS cases revealed additional mutations in this gene in the absence of myeloproliferative problems.

Mutations in the *KRAS* gene have also been found in cardiofaciocutaneous syndrome [15].

Further uncommon forms of Noonan's syndrome have been designated NS4 and NS5. NS4 (MIM 610733) is caused by gain-of-function mutations in the *SOS1* gene, which may account for up to 28% of all cases of NS and is therefore the second most common gene defect in NS [16,17].

Some genotype–phenotype correlations are emerging in NS, in that those patients with *SOS1* mutations (NS4) appear to have a more frequent occurrence of pulmonary stenosis compared with NS patients in general, and a lower incidence of atrial septal defects compared with those with *PTPN11* mutation [16]. Additionally, ectodermal features including keratosis pilaris and curly hair were significantly more prevalent among individuals with *SOS1* mutation compared with other Noonan patients. Reduced height, seen in 70% of the general Noonan population, occurred in relatively few patients with *SOS1* mutations (height below the third percentile in only two of 15 individuals with a *SOS1* mutation). In contrast, macrocephaly was overrepresented among those with *SOS1* mutations. Only one individual with an *SOS1* mutation had mental retardation, potentially attributable to critical illness as a newborn. In comparison, 30% of all children with Noonan's syndrome require special education [16].

NS5 (MIM 611553) is caused by mutations in the *RAF1* gene [18], a serine–threonine kinase that activates MEK1 and MEK2. Pandit *et al*. [18] sequenced the *RAF1* gene in 231 individuals with Noonan's syndrome who did not have mutations in the *PTPN11*, *KRAS* or *SOS1* genes. These authors identified 13 different missense mutations in 18 unrelated patients with NS and found that hypertrophic cardiomyopathy was present in 94% of patients carrying a mutation in one of two hotspots. Simultaneously with this report, another group sequenced the *RAF1* gene in 30 patients with NS and again found a strong association with cardiomyopathy [19].

Familial multiple tumour syndromes

The neurofibromatoses

The neurofibromatoses comprise several distinct genetic disorders that lead to the formation of tumours surrounding nerves and many other pathological features. The two main forms are NF1 and NF2. The most common type (NF1) is characterized by multiple café-au-lait macules and the occurrence of neurofibromas along peripheral nerves. The second type (NF2) is characterized by vestibular schwannomas (acoustic neuromas), usually bilateral, as well as meningiomas and other tumours of the nervous system. NF2 does not have significant cutaneous manifestations and is not reviewed here. The spectrum of these disorders has been reviewed [1–6].

Neurofibromatosis 1 (MIM 162200)

Synonym

- von Recklinghausen's neurofibromatosis

Fig. 15.8 Neurofibromatosis: axillary freckling and multiple neurofibromas. (Courtesy of Professor J. Harper, Great Ormond Street Hospital, London, UK.)

Fig. 15.9 Neurofibromatosis: extensive neurofibroma of the foot. (Courtesy of Professor J. Harper, Great Ormond Street Hospital, London, UK.)

Fig. 15.10 Neurofibromatosis: Lisch nodules (pigmented iris hamartomas). (Courtesy of Professor J. Harper, Great Ormond Street Hospital, London, UK.)

Definition, history and aetiology [7–9]. In 1882, Friedrich von Recklinghausen published a monograph describing this disease and pointing out that the skin tumours were derived from peripheral nerves [10]. In retrospect, Virchow [11] first reported a family with more than one affected member. It is now recognized that NF1 is an inherited neuroectodermal abnormality, characterized by the presence of six or more café-au-lait spots, axillary freckles, multiple neurofibromas and Lisch nodules (pigmented iris hamartomas) (Figs 15.8–15.10). The mode of inheritance is autosomal dominant, with almost 100% penetrance by the age of 5 years [9,12]. Sporadic cases result from a high gene mutation rate and account for up to 50% of all cases [7–9]. The prevalence of NF1 has been estimated at about 1 in 2500–3300 births [9]. Incomplete or monosymptomatic forms are frequent.

The gene for NF1 is located on chromosome 17 [13,14]. The *NF1* gene has now been cloned and encodes a protein named neurofibromin [15–17]. The gene spans 335 kb and has at least 59 exons, producing four major alternatively spliced transcripts. It is widely expressed in a variety of human tissues. The neurofibromin protein shows significant regions of similarity to the GTPase-activating protein and is capable of down-regulating Ras activity. The majority of *NF1* germ-line mutations alter the reading frame or insert a premature stop codon. No hotspot for mutations has been identified, making the genetic screening highly challenging as each affected individual and family has specific mutations. The impact of these mutations is effective haploinsufficiency for neurofibromin, that is only 50% of the normal protein is produced by cells. Further investigation supports the contention that the *NF1* gene acts as a suppressor of tumour activity, with a variety of somatic inactivating mutations identified in neurofibromas, in keeping with the classical Knudson 'two-hit' hypothesis of tumour genesis. The random acquisition of somatic mutation partly explains the delayed age of onset of the tumours associated with NF1 and the variability of expression [18]. Mouse models with disrupted *NF1* genes have been shown to have an increased susceptibility to certain tumours, giving further support to the role of the *NF1* gene as a tumour suppressor [19,20]. Neurofibromin has been shown to be present in both keratinocytes and melanocytes in normal adult human skin [21].

Mast cells are increased in neurofibromas and may be involved in the development and growth of these tumours by producing

several growth factors, such as histamine and tumour necrosis factor-α (TNF-α) [22,23].

Pathology. Cutaneous neurofibromas are derived from peripheral nerves and their supporting structures, including neurilemmal cells. Ultramicroscopically, they are seen to consist of arborizing Schwann cells in collagenous interstitial tissue. The fibroblast-like cells in cutaneous neurofibromas are thought to be derived from factor XIIIa and HLA-DR-positive connective tissue cells in peripheral nerves [24]. In both café-au-lait spots and clinically unaffected skin, giant pigment granules are occasionally found in epidermal cells and melanocytes [25–29]. They are rarely found in McCune–Albright syndrome, and never in normal skin. They can, however, be found in other conditions, and their presence cannot be regarded as pathognomonic.

Clinical features [7,8,30–32]. The National Institutes of Health Consensus Development Conference Statement, developed in 1988, has proved to be very useful and is widely employed in clinical practice [33]. This requires two or more of the following criteria to be fulfilled.

1. Six or more café-au-lait macules of over 5 mm in greatest diameter in prepubertal individuals and over 15 mm in greatest diameter in postpubertal individuals
2. Two or more neurofibromas of any type or one plexiform neurofibroma
3. Freckling in the axillary or inguinal regions
4. Optic glioma
5. Two or more Lisch nodules
6. A distinctive osseous lesion such as sphenoid dysplasia or thinning of the long bone cortex with or without pseudoarthrosis
7. A first-degree relative (parent, sibling, offspring) with NF1 by the above criteria.

Café-au-lait macules (CALMs) are sharply defined, light-brown patches that vary in size from 0.5 to 50 cm, although the majority are 10 cm or less in size. CALMs are the first feature of the disease to appear in all children [8,34]. In a population study, parents noted café-au-lait macules for the first time at 4 years of age or less in all affected children and within the first year of life in 82%. The macules increase in size and number during the first decade.

Cutaneous neurofibromas (previously termed mollusca fibrosa) are soft, lilac-pink tumours, sessile and dome-shaped, sometimes pedunculated. These lesions are most numerous on the trunk and limbs; hundreds may be present, ranging from a few millimetres to several centimetres in diameter. In women, they are prominent on the areola of the breast. Small, firm nodules may develop in relation to peripheral nerves. Blue–red macules and pseudoatrophic macules also occur [35] and are often variants of neurofibromas.

The plexiform neurofibroma is a diffuse elongated fibroma along the course of a nerve, frequently involving the trigeminal or upper cervical nerves and usually noticeable within the first 2 years of life. Plexiform neurofibromas have a distinctive 'bag of worms' feeling on palpation. Elephantiasis neurofibromatosa is a similar diffuse neurofibromatosis of nerve trunks associated with overgrowth of the subcutaneous tissue and of the skin, which is wrinkled and pendulous and may produce gross disfigurement. Neurofibromas may also involve the viscera and blood vessels.

Freckling occurs frequently in the axillae, when it is virtually pathognomonic (Crowe's sign) [36]. It is present in about 70% of affected subjects and appears a little later than the café-au-lait spots, the youngest case in one series being 3 years old [34]. It may also occur in other intertriginous areas, especially the groin. There may also be darker pigmented patches over an underlying plexiform neurofibroma, and if these extend to the midline of the spine, it may indicate that the tumour involves the spinal cord [37].

Lisch nodules (pigmented iris hamartomas) appear as dome-shaped lesions found superficially around the iris on slit-lamp examination. They occur in over 90% of patients and increase in incidence with age [8,34]. They are asymptomatic but help to confirm the diagnosis. They do not occur in segmental or bilateral acoustic NF [31].

Oral lesions are present in 5–10% of cases, as papillomatous tumours of palate, buccal mucous membrane, tongue and lips, or as macroglossia, which is usually asymmetrical [38].

Skeletal abnormalities are well described in NF1, possibly due to a defect in osteoblast differentiation secondary to NF1 ± status [39]. Kyphoscoliosis occurs in 2% of cases. Early-onset, high-level lesions may progress inexorably, leading to cardiorespiratory disease, unless aggressive surgery is performed. Pseudoarthrosis involving the tibia or radius occurs in 1%, but may be asymptomatic [31]. Sphenoid wing dysplasia is a characteristic abnormality.

Recently, in addition to the well characterized skeletal abnormalities, a generalized bone metabolic defect due to loss of the function of neurofibromin has been identified [40]. Early identification of NF1 patients with osteoporosis may permit more timely and aggressive treatments to prevent the likely substantial morbidity associated with increased fracture risk later in life. Short stature and macrocephaly [41] are also uncommon features of the condition.

Other organs: the severity of cutaneous involvement gives no reliable indication of the extent of the disease in other organs. Between 25 and 30% of children may exhibit learning difficulties [34,42] and physical development may be impaired. Speech impediments, hypertelorism and headaches are also common [31,43].

Endocrine disturbances of many types may be associated [44]: precocious puberty, acromegaly [45], Addison's disease, hyperparathyroidism, gynaecomastia and phaeochromocytoma. Renovascular hypertension may occur in children [46,47]. Osteomalacia when present is the result of a congenital defect of the renal tubules.

Involvement of the lower urinary tract [48] may give rise to urinary symptoms. Constipation occurs due to dysfunction of the colonic musculature. Gastrointestinal lesions may also cause recurrent haemorrhage or obstruction. There is a high prevalence of cardiovascular abnormalities [49,50] and NF1 can be complicated by pulmonary hypertension [51].

Neurological manifestations are found in some 40% of patients [38,52]. The most common solitary intracranial tumour is an

optic nerve glioma; astrocytomas and schwannomas also occur. Tumours may arise in peripheral nerves and within the spinal cord. Intracranial tumours may cause epilepsy, although fits may occur in the absence of any demonstrable focal lesion.

Sarcomatous change within a neurofibroma varies from 1.5 to 15% of cases, more often in deeper than in cutaneous lesions [34,53]. It is rare before the age of 40 years, but has occurred in early childhood. Growth is often slow and metastasis late, but local recurrence is frequent. In contrast, malignant peripheral nerve sheath tumours (MPNST) are highly aggressive [54]. MPNST associated with NF1 have a poorer prognosis than spontaneous MPSNT [55]. Malignant change may occur simultaneously in several lesions. Enlargement or pain should suggest the possibility of malignant change, although rapid enlargement may also occur secondary to intralesional haemorrhage.

Other malignant diseases associated with NF include Wilms' tumour, rhabdomyosarcoma, several types of leukaemia [56], retinoblastoma [57] and malignant melanoma [58].

Pruritus may be a symptom of NF. The presence of large numbers of mast cells in the skin in this condition, and the response of the itching to antihistamines, suggest that histamine is the cause of the pruritus [37]. In addition, a beneficial effect of the mast cell blocking agent ketotifen has been reported [22].

Course and prognosis [7,31,38,59]. The course of the condition varies considerably in individual patients and the majority will have a benign course without developing major complications. In fact, a diagnosis of NF1 is often made in middle age or later in life. The wide variability in presentation appears to be at least partially genetically determined and is unrelated to the unaffected NFI allele [60].

Characteristically, café-au-lait spots are present at birth or, more commonly, develop in early childhood and increase in number throughout life. Cutaneous neurofibromas appear during childhood and increase rapidly in number at puberty, suggesting a possible hormonal influence. However, lesions may be present at birth and become progressively more extensive. Although early onset and rapid progression before puberty usually indicate a poor prognosis, minimal cutaneous involvement in the young child does not necessarily imply a favourable course, although many cases remain limited. Extensive involvement of the urinary or gastrointestinal tract or the central nervous system carries a poor prognosis.

Pregnancy, in which unexplained hypertension frequently occurs, sometimes appears to induce rapid progression of existing lesions and the development of new ones [31,61], again suggesting hormonal sensitivity.

At presentation, a detailed clinical assessment is essential and must include examination of all other members of the family. Suggested investigations should include a neurophysiological assessment, a skeletal survey, audiography and slit-lamp ocular examination. Parents and siblings should also have their eyes examined for the presence of Lisch nodules. It is recommended that individuals with NF1 have an annual clinical review, which must include measurement of blood pressure. Further investigations will depend upon the detection of complications. Magnetic resonance imaging (MRI) should be performed in children who have macrocephaly or who demonstrate focal neurological signs or symptoms. Routine cranial imaging is the subject of debate. The detection of an asymptomatic brain lesion will increase patient and parental anxiety and would not alter clinical management. Patients with NF should be monitored by a number of different specialists, with one physician acting as the coordinator. The ideal situation is a multidisciplinary clinic, now established in a number of centres [62].

Long-term follow-up information on cohorts of NF1 patients has shown a reduced life expectancy related to the development of malignancy and other complications, such as hypertension due to renal artery stenosis or phaeochromocytoma [63–65].

Diagnosis. Diagnosis is established on the basis of clinical criteria. Molecular genetic testing is feasible, but the large size of the gene and wide range of pathogenic mutations have so far impeded the widespread diagnostic use of genetic testing [66]. Cutaneous neurofibromas are clinically and histologically distinctive, although a plexiform neurofibroma in an infant can clinically resemble a congenital melanocytic naevus. Café-au-lait spots, usually the earliest manifestation in children, are present in 10–20% of normal individuals and about 35% of patients with McCune–Albright syndrome [7,25]. If only one or two are present, they have little diagnostic significance in the absence of other signs or of a family history of the disease; if six or more are present, the probability of NF is high. Identification of the *NF1* gene means that prenatal/presymptomatic diagnosis for this disease is now possible, with greater than 95% accuracy in families with a suitable structure [34]. However, in a disorder showing such varied expression and complications, the decision to undergo prenatal diagnosis is far from clear. Prenatal diagnosis is also not an option for the approximately 50% of cases who represent new mutations.

Treatment. Treatment is symptomatic. The more disfiguring lesions can be excised if not too diffuse [67]. Carbon dioxide laser surgery is a treatment modality for cutaneous neurofibromas, but hypertrophic and atrophic scars can result and a preliminary test treatment is recommended [68]. Surgery is also indicated when an increase in size and pain suggests possible malignant change. Epilepsy should be thoroughly investigated, as neurosurgical relief is sometimes practicable. Prolonged follow-up with routine checks every 6–12 months is advisable.

NF1 has a significant impact on quality of life through alteration of health and appearance [69]. Adolescence is a particularly difficult time when neurofibromas may grow rapidly in response to hormonal changes.

Genetic counselling is important. Informing families about the varied complications of NF1 is a difficult counselling task, and there is a fine balance between providing adequate information and causing unnecessary alarm. It should be made clear to patients that 50% of their children are likely to be affected and the disease may be severe. First-degree relatives (e.g. siblings and offspring) who have no stigmata of the disease are unlikely to carry the gene and the risk for their offspring is small but not absent, as gonadal mosaicism has been observed [70,71].

NF1, juvenile xanthogranulomas and juvenile chronic myeloid leukaemia

The association of juvenile xanthogranulomas with NF1 has been noted in many patients [1]. It is now recognized that children with NF1 and juvenile xanthogranulomas have a 20–32-fold higher risk for juvenile chronic myeloid leukaemia than do patients with NF1 who do not have juvenile xanthogranulomas [2]. Juvenile chronic myeloid leukaemia is a rare type of leukaemia and accounts for about 1–2% of childhood leukaemias. A rare association of NF1, juvenile xanthogranulomas, and juvenile myelomonocytic leukaemia (JMML), initially presenting with features of haemophagocytic lymphohistiocytosis has been described [3].

Segmental neurofibromatosis [1–7]

This condition is characterized by café-au-lait spots, cutaneous neurofibromas and sometimes visceral neurofibromas, limited to a circumscribed body segment. The condition probably represents a somatic mosaicism of the *NF1* gene. Rubenstein *et al.* [8] reported two patients with segmental NF in which signs of generalized NF appeared in a single member of the next generation. It is difficult, in the light of these and other anecdotal examples, to reassure patients with apparent segmental NF that there is no risk of NF1 occurring in their offspring, although the risk is small.

Café-au-lait spots and pulmonary stenosis (MIM 193520) [1,2]

Synonym
- Watson's syndrome

In three families, café-au-lait macules were associated with pulmonary stenosis and low intelligence. Some affected individuals also had freckling in the axillae, perineum and elsewhere. There was no other evidence of NF [2]. Café-au-lait spots are present in about 60% of patients with this syndrome [1]. Allanson *et al.* [3] demonstrated linkage with markers for the *NF1* gene, and Tassabehji *et al.* [4] identified an *NF1* mutation in a family with features of Watson's syndrome and NS. The pathogenesis of this distinct phenotype is as yet unclear.

Neurofibromatosis–Noonan syndrome (MIM 601321)

Patients with features of both NF1 and NS have been described, although considerable variability of phenotypic expression exists. Whether a specific NF–NS phenotype exists is unclear at present. In a survey of the Noonan phenotype in a series of NF1 patients, it was concluded that this was not a distinct syndrome [1]. More recently, De Luca *et al.* screened a case collection with clinically well-characterized NF–NS for mutations in the entire coding sequence of the *NF1* and *PTPN11* genes [2]. Heterozygous *NF1* defects were identified in 16 of the 17 unrelated subjects studied, thus providing evidence that mutations in *NF1* represent the

major molecular event underlying this condition. Several in-frame defects affecting exons 24 and 25, which encode a portion of the GAP-related domain of the protein, were observed. On the other hand, no defect in *PTPN11* was observed and no lesion affecting exons 11 through 27 of the *NF1* gene was identified in 100 *PTPN11* mutation-negative subjects with NS, providing further evidence that NF–NS and NS are genetically distinct disorders. These results support the view that NF–NS is a variant of *NF1* and is caused by mutations of the *NF1* gene, some of which have been demonstrated to cause classic *NF1* in other individuals.

Diffuse neurofibroma [1]

Diffuse neurofibroma is a relatively recently recognized distinct clinical entity. A report of four adult cases [1] described 3–8-cm, hard, sclerotic plaques with an irregular surface but without protruding nodules, present for 1–12 years. Histologically, the tumours consisted of spindle cells with wavy fibrillar cytoplasm and elongated nuclei. Electron microscopy and special stains confirmed their neural origin. Excision revealed infiltration well beyond the clinical margins, and malignant transformation in one. Early diagnosis is important, as prompt surgical treatment is recommended.

NF1-like syndrome (MIM 611431)

Synonym
- Legius syndrome

In 2007, an important disorder that closely resembles NF1 was described. The cardinal features are multiple CALMs, macrocephaly and axillary freckling. Five families that were negative for *NF1* gene mutational analysis were used for linkage analysis and a region identified on chromosome 15; subsequently, mutations in the *SPRED1* gene were identified [1]. Legius syndrome appears to be distinguished clinically by the absence of Lisch nodules or neurofibromas and genetically by the absence of *NF1* gene mutations.

Tuberous sclerosis complex (MIM 191100)

Synonyms
- Epiloia
- Bourneville's disease

Definition, history and aetiology. Tuberous sclerosis complex (TSC) is now the preferred name for the condition previously known as tuberous sclerosis and represents a genetic disorder of hamartoma formation in many organs, particularly the skin, brain, eye, kidney and heart. Characteristic skin lesions are numerous and include angiofibromas, the shagreen patch, periungual fibromas and 'ash-leaf' white macules, classically, although not invariably, seen in association with epilepsy and mental retardation. The term 'complex' emphasizes the multisystem involvement and highly variable expression of the disease.

TSC was first recognized in the 19th century [1]. Rayer [2] gave the first description of the fibrovascular papules, and Bourneville [3] reported the case of a mentally retarded girl who also suffered from hemiplegia and epilepsy. He did not recognize her facial eruption or kidney tumour as being part of the disease. Sherlock [4] coined the now outmoded term 'epiloia', a contraction capturing the diagnostic clinical triad of *epi*lepsy, *l*ow *i*ntelligence and *a*denoma sebaceum.

Early population studies greatly underestimated the prevalence of TSC. More recent studies have shown the incidence to be 1 in 10 000 in the Oxford region [5] and 1 in 27 000 in the west of Scotland [6]. Osborne *et al.* [7] have estimated that the birth incidence may be in the region of 1 in 5800, which makes TSC, along with NF1, one of the more common single-gene disorders.

The inheritance of TSC is determined by a single autosomal dominant gene, showing great variability of expression, even within a single family. Genetic linkage studies first mapped the *TSC* gene to chromosome 9 [8,9]. It is now recognized that about half the TSC families are linked to 9q34 (*TSC1*) and the other half to 16p13 (*TSC2*) [10,11]. The proportion of families who do not link to either chromosome 9 or 16 is small. *TSC1* encodes hamartin and the *TSC2* gene encodes a protein named tuberin. Tuberin shows one area of homology to the catalytic domain of the GTPase-activating protein Rap1. Rap1 is a member of the same group of GTPases as *RAS* and is involved in the regulation of cell proliferation and differentiation. This suggests that some of the biological functions of tuberin and neurofibromin are similar.

Loss of tuberin activity is thought to lead to activation of Rap1 in tumours of patients with TSC [12]. Further support for a putative tumour-suppressor role is derived from the study of loss of heterozygosity studies for the *TSC1* and *TSC2* gene regions in various hamartomas from TSC patients [13–15]. No obvious phenotypic differences have been found between families linked to *TSC1* and *TSC2* [16]. Analysis of deletions of the *TSC2* locus has identified one specific correlation, namely severe polycystic kidney disease, for which the causal gene is contiguous [17].

Approximately 60–70% of TSC cases are thought to be the result of new mutations, but before genetic counselling of the normal parents of an affected child, both parents should be fully investigated, including a full skin examination using the Wood's lamp, and possibly computed tomography (CT) [18], renal ultrasound or intravenous pyelography, and expert ophthalmological examination. A study using these investigations showed that about 30% of apparently unaffected parents had TSC [19].

Pathology [20]. The defect in organogenesis may affect almost any tissue. Most of the lesions are hamartomas, and in many organs the cells resemble embryonic cells, suggesting that the defect occurs at an early stage in embryogenesis. In many lesions, for example angiomyolipoma of the kidney, there is malformation of vascular and mesenchymal tissue. The lesions are slow growing and tend to produce symptoms by pressure effects, although occasionally there is haemorrhage from a vascular lesion.

Most of the cutaneous lesions show an excess of collagen. The shagreen patches show no other change and cannot be identified on the histological findings alone. Angiofibromata (formerly misnamed adenoma sebaceum) consist of hyperplastic blood vessels and sebaceous glands of immature hair follicles. Collagen synthesis is increased in the angiofibroma, although total collagen content is decreased, suggesting that there may be an increased turnover of collagen [21]. Histopathology of the periungual fibromas shows a distal part with loose collagen and many blood vessels and a larger proximal part composed of dense collagen bundles and fewer capillaries [22]. The white ash-leaf-shaped macules contain abnormal melanocytes with reduced tyrosinase activity [23], and electron microscopy shows defective melanization of melanosomes [24,25].

The characteristic tuberosclerotic nodules of glial proliferation may occur anywhere in the cerebral cortex, basal ganglia and ventricular walls, but are rare in the cerebellum, medulla or cord [20]. Gliomas are not uncommon and almost always develop in the striothalamic region. Renal tumours of embryonic type, usually multiple, subcapsular and benign, are found in about 80% of cases at post-mortem but are frequently asymptomatic. The angiomyolipoma is the characteristic lesion but cystic renal disease also occurs [26]. The so-called congenital rhabdomyoma of the heart is an abnormal and premature differentiation of embryonic myocardium into atypical Purkinje cells. The lungs may show interstitial fibrosis or fibroleiomyomatosis with cystic changes [27–29]. Lymphoblastoid cell lines and fibroblasts from patients with TSC are abnormally sensitive to radiation and radiomimetic chemicals [30].

Clinical features [31–36]. The characteristic features of the syndrome are skin lesions, mental retardation and epilepsy, but these show very wide variation in age of onset and severity. Onset before the age of 5 years with cutaneous changes or with epilepsy is usual, although the disease may remain latent until adolescence or adult life. Diagnostic criteria determined by a committee of the then US National Tuberous Sclerosis Association (now the TS Alliance) [37,38] have since been modified [39,40]. A definitive diagnosis of TSC requires two major features (Table 15.2). Brain MRI or non-enhanced CT, renal ultrasound or echocardiogram may be necessary.

Skin lesions are found in 60–70% of cases. Lesions of four types are pathognomonic.

1. Angiofibromas (Fig. 15.11) may rarely be present at birth or develop in infancy, but usually appear between the ages of 3 and 10 years, and sometimes later. They often become more extensive at puberty and then remain unchanged. Firm, discrete, red-brown, telangiectatic papules, 1–10 mm in diameter, extend from the nasolabial furrows to the cheeks and chin, and are occasionally found in the ears. They may be numerous and conspicuous, and very rarely may form large cauliflower-like masses. In many cases they are easily overlooked, being confined to a small area on each side of the nose or the chin.
2. Periungual fibromas (Koenen's tumours) appear at or after puberty as smooth, firm, flesh-coloured excrescences emerging from the nail folds. They are usually 5–10 mm in length, but may be very large. This can be the only clinically evident abnormality.
3. The shagreen patch is an irregularly thickened, slightly elevated, soft, skin-coloured plaque, usually in the lumbosacral region.
4. White ovoid or ash-leaf-shaped macules [23,41–43] 1–3 cm in length, most easily detectable by examination under Wood's light, are frequently present on the trunk or limbs. They are a valuable physical sign, as they may be found at birth or in early infancy, some years before other signs of the disease develop, and may suggest the correct diagnosis in infants with convulsions. However, it is important to appreciate that hypopigmented macules are seen in 2–3 per 1000 of apparently normal newborn babies and therefore alone their presence is not indicative of TSC [44].

Table 15.2 Revised diagnostic criteria for tuberous sclerosis complex [39,40].

Major features
Facial angiofibromas or forehead plaque
Non-traumatic ungual or periungual fibroma
Hypomelanotic macules (more than 3)
Shagreen patch (connective tissue nevus)
Multiple retinal nodular hamartomas
Cortical tuber*
Subependymal nodule
Subependymal giant cell astrocytoma
Cardiac rhabdomyoma, single or multiple
Lymphangiomyomatosis†
Renal angiomyolipoma†
Minor features
Multiple randomly distributed pits in dental enamel
Hamartomatous rectal polyps‡
Bone cysts§
Cerebral white matter migration lines*§¶
Gingival fibromas
Non-renal hamartoma‡
Retinal achromic patch
'Confetti' skin lesions
Multiple renal cysts‡
Definite TSC: either 2 major features or 1 major feature with 2 minor features
Probable TSC: 1 major feature and 1 minor feature
Possible TSC: either 1 major feature or 2 or more minor features

* When cerebral cortical dysplasia and cerebral white matter migration tracts occur together, they should be counted as one rather than two features of TSC.

† When both lymphangiomyomatosis and renal angiomyolipomas are present, other features of TSC should be present before a definitive diagnosis is assigned.

‡ Histological confirmation is suggested.

§ Radiographic confirmation is sufficient.

¶ One panel member recommended three or more radial migration lines constitute a major feature.

Fig. 15.11 Tuberous sclerosis: angiofibromas. (Courtesy of Professor J. Harper, Great Ormond Street Hospital, London, UK.)

Fig. 15.12 Tuberous sclerosis: fibromatous nodule on the forehead. (Courtesy of Professor J. Harper, Great Ormond Street Hospital, London, UK.)

Other cutaneous manifestations include firm fibromatous plaques, especially on the forehead [45] and scalp (Fig. 15.12), soft pedunculated fibromas around the neck and axillae, and poliosis [46].

Fibromatous tumours are occasionally present on the gums and palate and rarely are found on the tongue, larynx and pharynx [47]. Small pits commonly occur in the tooth enamel in adult patients; although less obvious in the deciduous teeth, these pits have been used as an early diagnostic sign in children with TSC [48].

Learning difficulties is present in 60–70% of cases and may be progressive, but if mental development has been normal throughout childhood subsequent deterioration is uncommon [34]. Some cases have presented gross behaviour disorders, although they have been of normal intelligence. In particular, self injury behaviour is quite common, occurring in up to 10% of patients [49]. Psychotic symptoms, including schizophrenia, sometimes develop [50].

Epilepsy [51] is seen in almost all mentally retarded patients and in some 70% of those with average intelligence. It usually begins in infancy or early childhood, thus often preceding the skin lesions by many years. Less frequently, the onset of epilepsy is delayed until puberty or adult life. The attacks may be focal and often become progressively more frequent and severe, but there may be long remissions. Treatment can be quite challenging and in some cases requires surgery. Intracranial malignant change occurs in a few patients. Symptoms and signs of raised intracranial pressure usually result from obstruction by a tumour at the foramen of Monro. Very rarely, cord lesions produce focal neurological signs.

Ocular signs [52,53] occur in 50% of cases but may be hard to detect. Retinal phacomas are seen as white streaks along the vessels or as small, rounded tumours near the disc. Pigmentary and other retinal abnormalities can occur. Symptoms are rare but there may be scotomas or amaurosis. Hypopigmented spots in the iris also occur and these may be analogous to the ash-leaf macule in the skin [54].

Cardiac and renal tumours are often asymptomatic unless by reason of their size or site. Cardiac rhabdomyomas, detected by echocardiography, occur in over 50% of infants [55–57]. These tumours may result in early death; however, recent evidence suggests that in the majority these tumours regress in early infancy and again in adolescence [57]. Prenatal detection of these tumours is now possible by fetal echocardiography [58,59] and is often the initial clue to the diagnosis. Renal involvement includes angiomyolipoma [60], a benign tumour of the renal parenchyma and, less commonly, renal cysts [61,62]. Rarely, the presenting symptoms may be of renal origin, usually haematuria [63].

Pulmonary changes [28] are rare and seldom cause symptoms, but if extensive can result in increasing dyspnoea and recurrent spontaneous pneumothorax. Lymphangioleiomyomatosis is occasionally seen. These respiratory complications occur much more frequently in females and tend to become clinically manifest in the second decade [27,29]. They may result in death from tension pneumothorax or cor pulmonale. The rare association of TSC with chylothorax resulting from lymphangiomyoma appears to be significant [64].

Gastrointestinal tumours may occur [65]. These are usually hamartomatous colonic polyps. Colonoscopy should be considered in the investigation of patients with TSC.

Endocrine and other metabolic disturbances may be present [66]. Most frequently reported are pituitary–adrenal dysfunction, thyroid disorders and premature puberty.

Associated abnormalities. These include primary localized gigantism [67,68] and diffuse cutaneous reticulohistiocytosis [69].

Partial forms. In some cases, only one component of the syndrome is clinically evident, although post-mortem findings in such cases often show involvement of other organs. Unilateral, multiple, facial angiofibromas have been reported in two patients and the authors hypothesized that this represented a mosaic form of TSC [70].

Radiological findings [71]. These are delineated below.

Skull. Calcification is seen on plain skull X-ray in about 50% of patients, although it is not usually apparent until later

childhood or adult life. Investigation should now include CT and MRI [72]. The characteristic CT findings include periventricular (subependymal) nodules, parenchymal hamartomas (cortical tubers), ventriculomegaly and, rarely, subependymal giant cell astrocytomas. The typical CT appearance of TSC consists of calcified periventricular nodules that project into the lateral ventricles and hypoattenuated parenchymal lesions. MRI is more sensitive in the detection of parenchymal lesions. The periventricular lesions may not be seen initially and can progress to calcified lesions with time. This is also true of the parenchymal lesions.

Hands and feet [73]. Cyst-like lesions of the phalanges and irregular thickening of the cortex of metatarsals and metacarpals have been reported, and similar lesions localized in vertebrae, pelvis or long bones are not uncommon.

Lungs. There may be irregular reticulation of the lung fields, not radiologically distinguishable from other types of interstitial fibrosis.

Kidneys. Investigation includes ultrasound and CT [74]. Angiography is helpful in differentiating renal hamartomas from other lesions [75].

Electroencephalographic findings. The proportion of cases showing abnormal findings is high and increases with age, but there is no diagnostic pattern.

Course and prognosis. The expectation of life for a severely affected infant is poor: 3% die in the first year, 28% under 10 years and 75% before age 25 years. Death is usually due to epilepsy or intercurrent infection, but occasionally it is due to a tumour, cardiac failure or pulmonary fibrosis. The prognosis for the older child or young adult with the cutaneous stigmata and epilepsy is unpredictable. Each case must be investigated in detail and individually assessed.

Diagnosis [36]. The telangiectasia and the lack of comedones and pustules distinguish angiofibromas from acne vulgaris. The firm, skin-coloured papules of epithelioma adenoides cysticum must also be differentiated. The full syndrome presents few problems. Difficulties arise in infancy when the classical triad is not evident. The identification of white ash-leaf-shaped macules under Wood's light, in the presence of unexplained epilepsy, retinal phacomas, or radiological or electroencephalographic findings, or a positive family history will help establish the diagnosis. The partial forms are often unsuspected until post-mortem. Any child of a person diagnosed as having TSC has a 50% chance of inheriting the disease. Family screening and genetic counselling should be carried out by referral to a clinical genetics service. DNA testing is available in 85% of cases and should be discussed. Gonadal mosaicism is possible in around 3% of families where parents are not known to have overt TSC. Prenatal diagnosis is not an option for the 60–70% of cases who represent new mutations.

Treatment. The cosmetic appearance may be improved by treating angiofibromas with the pulsed dye vascular laser (wavelength 585 nm), which reduces redness. The more papular/nodular lesions are best treated with the carbon dioxide laser or other débriding techniques in the first instance [76]. The treatment of lesions in other organs is unsatisfactory, and surgical procedures may be required for relief of symptoms. Neurosurgery should be considered when epilepsy is uncontrolled by drugs and there is a fixed, circumscribed, electroencephalographic focus [77].

Gardner's syndrome (MIM 175100)

Aetiology. The syndrome comprises multiple epidermoid cysts, fibrous tissue tumours, osteomas and polyposis of the colon; its inheritance is determined by an autosomal dominant gene of variable expressivity [1–4]. The Gardner's syndrome gene is located on chromosome 5q, near bands 5q21–q22 [5,6]. It is now thought that Gardner's syndrome and familial polyposis coli are allelic disorders, caused by mutation in the *APC* (adenomatous polyposis coli) gene.

Congenital hypertrophy of the retinal pigment epithelium is a frequent finding in Gardner's syndrome and is a valuable clue to the presence of the gene in persons who have not yet developed other manifestations [7,8].

Turcot's syndrome, in which polyposis of the colon is associated with malignant tumours of the central nervous system [9], was present in the uncle of a patient with gastric polyposis and multiple epidermoid cysts [10]. It has been suggested that Turcot's syndrome represents a variant of Gardner's syndrome.

Pathology. The pathology and natural history of the polyposis are essentially similar to familial polyposis coli. The syndrome in which polyposis of the colon is associated with perifollicular fibrosis is probably distinct [11]. Several groups have reported the association of hepatoblastoma with polyposis coli [12,13].

Histology and immunohistochemistry of cutaneous cysts suggest that these are derived from follicular stem cells [14].

Clinical features [3,11,15–17]. Polyposis of the colon or rectum usually arises during the second decade, but may occur in early childhood. It is present in about 50% of cases by the age of 20 years. There are few symptoms and intussusception is not a feature. Malignant change develops some 15–20 years later in over 40% of reported cases.

The variable expressivity of the gene must be remembered when a family is investigated [18]. Cutaneous and skeletal changes may be present without polyposis, and polyposis may be present when one or more of the other features of the syndrome is lacking [19].

Epidermoid cysts, which may be numerous, are usually irregularly distributed on the face, scalp and extremities, and are less frequent on the trunk. They may first appear between the ages of 4 and 10 years, but often considerably later, and are ultimately present in almost all cases.

Osteomas develop mainly in the maxilla, mandible and sphenoid bones, but also in other bones of the skull and, less frequently, in the long bones. They are usually small, multiple and present in some 50% of cases. The age of onset is often not accurately known, but they may be present at puberty.

Fibromas or desmoid tumours are less frequently present. They are usually poorly localized tumours in incisional scars of the abdomen, but may occur at other sites. Fibrosarcomas have also been associated with the syndrome. Fibromatous growths of the mesentery may be discovered at operation, and severe peritoneal scarring may follow surgery. A very large desmoid tumour extensively involving the chest wall and the left anterior abdominal wall has been described in a patient with a family history of Gardner's syndrome. The desmoid arose at the site of a thoracotomy scar following the removal of a large aneurysm of the left atrial appendage 5 years before [20].

Lipomas in the subcutaneous tissues, and in other organs, have frequently been noted.

Leiomyomas of the stomach or ileum, or retroperitoneal tissue, are sometimes present.

Diagnosis. Because multiple epidermoid or sebaceous cysts may be inherited as an isolated abnormality and may thus have no sinister significance, their discovery is an indication for a detailed family history and a careful examination for osteomas, including radiological examination of the skull, and for other dermal tumours. The cutaneous lesions are an important indicator of possible asymptomatic polyposis.

Cowden's disease (MIM 158350)

Synonyms

- Cowden's syndrome
- Multiple hamartoma syndrome

Definition. In this rare disorder, multiple hamartomatous lesions of ectodermal, endodermal and mesodermal origins are associated with a predisposition to malignant tumours, particularly of the breast. Cowden was the name of the family in whom the disease was first described [1].

The condition is characterized by mucosal and cutaneous papillomatosis and fibromatosis, with fibrocystic breast disease in the female and thyroid goitre or adenoma.

Aetiology. Inheritance of the disease is determined by an autosomal dominant gene of variable expressivity. Germ-line mutations of the *PTEN1* gene, located on chromosome 10, have been identified in a proportion of kindreds. However, Cowden's disease, like so many other inherited disorders, shows locus heterogeneity,

with some families developing the disease due to heterozygous mutation of the transforming growth factor (TGF)-β type 1 receptor, known as bone morphogenetic receptor type 1 (*BMPR1A*). Both genes encode proteins required in regulation of cell proliferation, and loss of the wild-type allele has been detected in tumour tissue, in accord with the Knudson 'two-hit' hypothesis [2]. About 100 cases have been reported [3].

Pathology [4,5]. The skin lesions around the mouth, eyes and chin are trichilemmomas [6]. The breast lesions are fibroadenomas, which are liable to undergo malignant degeneration. A unique fibroma on the face and other sites has been described [5,7], composed of broad acellular collagen bundles in a lamellar or whorl-like pattern with occasional giant cells. This has been referred to by Barax *et al.* [3] as 'Cowden's fibroma'. An immunohistochemical study of the sclerotic fibroma has shown strong staining with an antibody directed at human type I procollagen [8]. There is a report of amyloid in association with multiple hamartoma syndrome [3].

Clinical features [9–14]. Mucocutaneous lesions have been present in all reported cases of this disease, but they have varied in their distribution, extent and age of onset. Skin-coloured, lichenoid papules up to 4 mm in diameter, tending to coalesce to give a cobblestone appearance, are distributed on and around the eyes and mouth. On the dorsa of hands and wrists are lesions like those of acrokeratosis verruciformis. On palms and soles and on palmar and plantar aspects of fingers and toes are small translucent keratoses. Multiple angiomas and lipomas have been found in several cases. Malignant melanoma has occurred [15].

Verrucous and papillomatous lesions are seen in some patients on the labial and buccal mucosa, fauces and oropharynx, and may extend to the larynx.

In a series of 21 patients [14], craniomegaly was noted to be the most frequent extracutaneous finding, affecting 70% of patients.

Of the many other abnormalities that have been reported in this syndrome, the most frequent involve the thyroid and breasts. Approximately 30% of reported female cases developed breast cancer [14]. Fibrocystic disease of the breast sometimes leads to massive hyperplasia. Goitre or thyroid adenoma is present in many cases and thyroid carcinoma has been reported [7,9]. Adenocarcinoma of the uterus has been reported in 6% of women with multiple hamartoma syndrome [14]. Less frequent associations include adenoid facies, high-arched palate, vitiligo, café-au-lait spots, skeletal abnormalities, retinal glioma, pseudotumour cerebri, gastrointestinal polyposis and various gynaecological disorders (menstrual irregularity, uterine fibroids). An association with renal cell adenocarcinoma and primary neuroendocrine carcinoma of the skin (Merkel cell carcinoma) in one patient has been documented [16].

Ruschak *et al.* [17] described a patient with this syndrome who had a deficiency of T-lymphocyte function, with recurrent cellulitis and abscess formation, and the eventual development of acute myeloid leukaemia.

Differential diagnosis. The combination of clinical and histological findings is pathognomonic. It seems possible that the skin lesions have in the past been confused with Darier's disease, and some cases may have been reported as TSC with mucosal involvement [7]. The relationship between Cowden's syndrome and gingival fibromatosis with hypertrichosis [18] is uncertain, but they are probably separate conditions.

Treatment. Cosmetic surgery may be helpful. The possibility of carcinoma of breast or thyroid must be borne in mind. Female patients with this syndrome should avoid oestrogen therapy and should have frequent breast investigations, including mammography, or even prophylactic mastectomy [19].

Ectodermal dysplasias

The ectodermal dysplasias are a complex and highly diverse group of heritable disorders. By some authors' estimations the broader definition of ectodermal dysplasias encompasses some 170 to 200 individual conditions. Any approach to summarizing current knowledge about this group of conditions presents several challenges. Firstly and most importantly, how is an ectodermal

dysplasia defined, and which distinct conditions are encompassed by this broad term? The history of the terminology throughout the literature is instructive. The first clinical cases with features of what would now be classified as ectodermal dysplasia were reported as early as 1792, when Danz described two Jewish boys with congenital absence of hair and teeth [1]. In 1875 Charles Darwin reported the case '. . . communicated to me by a Mr. Wedderburn, of a Hindoo family in Scinde in which ten men, in the course of four generations, were furnished, in both jaws taken together, with only four small and weak incisor teeth and with eight posterior molars. The men thus affected have very little hair on the body, and become bald early in life. They also suffer much during hot weather from excessive dryness of the skin.' [2]. This family would now be recognized as having X-linked hypohidrotic ectodermal dysplasia but the term 'ectodermal dysplasia' did not appear until 1929 [3]. Prior to this report a small series of cases with hypotrichosis, hypodontia, onychodysplasia and anhidrosis had been described under various names such as 'dystrophy of hair and nails', 'imperfect development of skin, hair and teeth', and 'congenital ectodermal defect'. The designation outlined by Weech specified three essential aspects of ectodermal dysplasias: (i) most of the disturbances must affect tissues of ectodermal origin; (ii) these disturbances must be developmental; and (iii) heredity plays a causal role. Weech had in mind the X-linked anhidrotic form (Christ–Siemens–Touraine syndrome (CST) or hypohidrotic ectodermal dysplasia (HED) MIM: 305100) in males but noted that it had also been reported in females; he also noted that this pattern of involvement was occasionally inherited as a non-sex-linked trait. For some authors and clinicians, the term ectodermal dysplasia is still used specifically with reference to CST syndrome and the autosomal dominant and recessive forms of HED. As more clinical reports of patients with similar but subtly distinct patterns of anomalies were recorded, the term 'ectodermal dysplasia' became extended to include many different genetic entities. In an attempt to encapsulate this heterogeneity and diversity of symptoms seen, Touraine [4] suggested the expression 'ectodermal polydysplasia'. Attempts at more formal classification soon followed; initially conditions were classified as hidrotic or anhidrotic, but this simple classification failed to reflect the complexity of nail, hair and dental anomalies associated with the various forms of ED.

Currently, the most widely accepted and used definition of the ectodermal dysplasias is of a group of inherited disorders that share in common developmental abnormalities of two or more of the following: hair, teeth, nails, sweat glands and other ectodermal structures. Other structures derived from embryonic ectoderm include the mammary gland, thyroid gland, thymus, anterior pituitary, adrenal medulla, central nervous system, external ear, melanocytes, cornea, conjunctiva, lacrimal gland and lacrimal duct. There are merits and demerits of this approach to definition. One definite benefit is that the problems encountered by many patients and families are similar regardless of the specific subtype of ED; parents and children can benefit by being part of larger support networks exemplified by the Ectodermal Dysplasia Society (UK-based; URL: http://www.ectodermaldysplasia.org) and the National Foundation for Ectodermal Dysplasias (US-based; URL: http://www.nfed.org). This wide-ranging classification is also helpful in concentrating the minds of research workers in the field and several EDs are now known to have shared genetic mechanisms. Although the broader definition has the benefit of reach and inclusivity, many conditions encompassed by this broad definition are not usually considered as primarily ectodermal dysplasias. For example, inherited conditions as diverse as incontinentia pigmenti, dyskeratosis congenita, trichothiodystrophies, cardiofaciocutaneous syndrome, pachyonychia congenita and Goltz syndrome by this definition are ectodermal dysplasias, but common practice has been to consider many of these as separate entities. In excess of 190 different conditions come under the umbrella term of 'ectodermal dysplasia', if the widest definition of 'an inherited disorder involving two or more of the following ectodermal appendages: teeth, hair, eccrine sweat glands' is used. For a recent detailed summary of most of these conditions see Table 15.3.

Classification: clinical approaches

Having accepted the broadest definition of an ectodermal dysplasia, the second challenge presented by this group of conditions is that of designing a meaningful and functional classification system. Until the end of the 20th century, classification systems for ectodermal dysplasias were, due to lack of molecular understanding, based on clinical manifestations. Several authors addressed the issue of delineating nosological groups of conditions linked by shared phenotypic traits. The most comprehensive accounts of clinical phenotypes and inheritance patterns of ectodermal dysplasia were produced by Freire-Maia and Pinheiro in their classic monograph [5] and in subsequent writings [25]. Their classification designated conditions by groups depending on presence of hair, nail, tooth or sweat gland abnormalities, and assigned conditions to groups using a '1-2-3-4 system' to collate conditions that had involvement of hair (1), teeth (2), nails (3) or sweat glands (4). This classification was a comprehensive attempt to bring order to an unwieldy group of conditions but was difficult to use and grouped together disparate clinical entities such as Goltz syndrome and pachyonychia congenita. In common with any other classification of ectodermal dysplasias based on clinical findings, this system is confounded by the subtleties of inheritance such as incomplete penetrance and variable expressivity of phenotype. This is especially true in the ectodermal dysplasias, in which sweating is often not formally measured and tooth or nail anomalies may be subtle. For a comprehensive contemporaneous consideration of the breadth of ED conditions in the tradition of Freire-Maia and Pinheiro please see [26]. Clinical classifications now need to become more focused, user-friendly, and better integrated with emerging molecular data. Difficult decisions will need to be made to balance inclusiveness (of every possible ectodermal dysplasia) with accessibility and practicality of usage.

Classification: molecular approaches

The last decade has seen several important insights into the molecular basis of a number of the ectodermal dysplasias. In some cases the molecular data have confirmed clinical impressions, for example Hay–Wells syndrome and ectrodactyly, ectodermal dysplasia, clefting (EEC) syndrome have ectodermal dysplasia and clefting of the palate and lip as common clinical findings and these

Table 15.3 The ectodermal dysplasias. (Modified from Harper J, Oranje A, Prose N, eds. *Textbook of Pediatric Dermatology*, 2nd edn. Blackwell Publishing, with permission.)

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Absence of dermal ridge patterns, onychodystrophy, and palmoplantar anhidrosis (Basan syndrome)	129200	AD	Fingernails attached distally to the hyponychium; rough in texture; horiz & vert grooved	Normal	Normal	Palmoplantar anhidrosis	**Skin:** at birth, multiple milia (on chin); several vesicular/bullous lesions (on fingers & soles); leather-like texture & callosities in adults; simian creases in some patients
Ackerman syndrome (dento-oculocutaneous syndrome)	200970	AR?	Horiz ridging of the fingernails with dist onychoschizia	Scanty body hair; vellus hairs in the moustache & beard areas	Taurodontia, pyramidal or fused molar roots	Normal	**Skin:** indurated & hyperpigmented over the interphalangeal joints of the fingers **Face:** upper lip characterized by abs of 'Cupid's bow'; thickening & widening of the philtrum; ectropion of both lower lids **Other:** complete sensorineural hearing loss; juvenile glaucoma; syndactyly (third & fourth fingers); clinodactyly of the fifth finger
Acro-dermato-ungual-lacrimal-tooth syndrome (ADULT syndrome)	103285	AD	Finger- & toenail dysplasia	Frontal alopecia	Hypodontia; loss of permanent teeth	Normal	**Skin:** intensive freckling **Other:** lacrimal duct atresia; ectrodactyly, syndactyly; hypoplastic breasts & nipples
Acrorenal field defect, ectodermal dysplasia, lipoatrophic diabetes (AREDYLD syndrome)	207780	AR	Normal	Scalp hypotrichosis, scant axillary & pubic hair; normal eyebrows & lashes	2 natal & 4 deciduous teeth with enamel dysplasia; abs of permanent teeth buds; anodontia by 11 years	Normal	**Skin:** hypoplastic & hypopigmented areolae; abs of DIP extension & flexion creases **Face:** prom forehead & bridge of nose; sl mongoloid slant of palpebral fissures; short nasal septum with flat tip of nose; short upper lip; relatively flat philtrum; prom chin with mandibular prognathism; posteriorly angulated auricles with broad intertragal incisure; hypoplastic tragus & small groove at antitragus **Other:** short stature; difficulty in grasping with left hand; limb abnormalities; lipoatrophic diabetes; hypoplasia of mammary gland; lumbar scoliosis; hyperostosis of cranial vault; cranial dysostosis; prom subcutaneous leg veins; hypoplasia of the middle right major renal calyx & hypotonia of the right ureter
Agammaglobulinaemia–dwarfism–ectodermal dysplasia (Swiss type ectodermal dysplasia); ? same as cartilage–hair hypoplasia (see below)	200900	AR?	Normal	Slow growing, in one family failed to grow after initial pelage	No data	No data	**Skin:** erythroderma; mild hyperkeratosis; generalized scaliness; ichthyosiform lesions; redundant, esp on the limbs, suggesting cutis laxa; biopsy showed keratosis, fissuring of keratotic layer, & thickening of granular layer **Other:** dyschondroplastic (short-limbed) dwarfism; lymphopenia; gammaglobulinaemia; prom eosinophilia; hypoplastic thymus; microscopic alterations of thymus, spleen, lymph nodes, gastrointestinal tract, bones

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Alopecia–anosmia–deafness–hypogonadism (Johnson neuroectodermal syndrome)	147770	AD	Normal	Abs or sp scalp hair, eyebrows & lashes, axillary & pubic hair	Carious, leading to extensive premature loss	Hypohidrosis	**Skin:** multiple café-au-lait spots **Other:** conductive hearing loss; hypogonadism; occas cong heart defects; cleft palate; choanal stenosis; anosmia or hyposmia; mental retardation; speech impairment; hypodontia; unilateral facial palsy; retro/micrognathia
Alopecia–onychodysplasia–hypohidrosis	F-M & P [5]	NK	Severely dyst (thick & yellow)	Abs scalp & body hair; no eyebrows or lashes; virtually no body hair	Normal	Hypohidrosis with hyperthermia	**Skin:** thick, scaly skin in patches over most of the body (the scalp, soles & legs are more severely affected); eczema; scaly lesions with crusting & some open sores most pronounced around orifices **Other:** photophobia; horiz nystagmus, legal blindness; short stature; low IQ, seizures; hypospadias; non-palpable testes
Alopecia–onychodysplasia–hypohidrosis–deafness	F-M & P [5]	NK	Normal fingernails; thick, sl deformed toenails, with subungual hyperkeratosis; cong anonychia	Extensive scalp hypotrichosis; abs of eyebrows	Normal	Hypohidrosis	**Skin:** hyperpigmented, dry & sl rough, with hyperkeratosis of palms, soles, knees & elbows; dermatoglyphics with extensive ridge dissociation **Face:** unusual, with prom nose; sl anteverted auricles with broad upper antihelical region; mongoloid palpebral slanting & narrow palpebral fissures **Other:** sensorineural deafness; bilateral ectropia; photophobia; short stature; pectus excavatum; retarded bone age
Alopecia universalis–onychodystrophy–total vitiligo	Lerner [6]	AR?	Dyst fingernails & toenails with transverse ridging	Prog loss of body & scalp hair, eyebrows, & lashes	Normal	Hyperhidrosis	**Skin:** total vitiligo; skin becomes light & translucent & prone to sunburn
Amelo-cerebrohypohidrotic syndrome	226750	AR?	Normal	Normal	Yellow due to enamel hypoplasia	Hypohidrosis	**Skin:** Scarce sebaceous glands & nerve fibres **Other:** Myopia, prog CNS degeneration with severe epileptiform seizures appearing between 11 months & 4 years of age; muscle spasticity; abn EEG
Amelo-onychohypohidrotic dysplasia	104570	AD	Onycholysis with subungual hyperkeratosis	Normal	Hypocalcified-hypoplastic enamel	Hypohidrosis	**Skin:** gen xerotic with keratosis pilaris over the buttocks & extensor surfaces of the limbs; seborrhoeic dermatitis of scalp
Ankyloblepharon-ectodermal defects—cleft lip and palate (AEC) syndrome	106260	AD	Severe dystrophy	Hypotrichosis; abs or scanty eyebrows & lashes	Poorly formed & pointed; widely spaced; carious; severe hypodontia	Hypohidrosis; no hyperthermia	**Skin:** dry & smooth; palmoplantar hyperkeratosis with obliteration of dermatoglyphic patterns; occas reticulate hyperpigmentation; supernumerary nipples, severe recurrent scalp pustulation **Face:** ankyloblepharon filiforme adnatum with partial fusion of eyelids at birth; broad nasal bridge; hypoplastic maxilla; auricular abnormalities; cleft lip **Other:** lacrimal duct atresia; photophobia

Anonychia–onychodystrophy with brachydactyly type b and ectrodactyly	106990	AD	Anonychia; onychodystrophy	Normal	Normal	Normal	**Limbs:** ectrodactyly; absent/hypoplastic metacarpals; absent/hypoplastic distal phalanges; hypoplastic metatarsals
Anonychia with bizarre flexural pigmentation	106750	AD	Gen abs on the fingers & toes; in a few instances rudimentary	Slow growing & coarse scalp hair, thinning early in adult life	Highly carious	Mild hypohidrosis without hyperthermia	**Skin:** hypo- & hyperpigmentation, particularly in the groins, axillae, & breasts; distortion of epidermal ridges on palms & soles; mild palmoplantar hyperkeratosis; increased palmar markings; distorted fingertip patterns; small macular telangiectases in a few regions
Arthrogryposis and ectodermal dysplasia (trichooculodermovertebral syndrome)	601701	NK	Abs at birth; later normal length; tendency toward longitudinal breaks	Hypotrichosis of scalp (atrichia at birth) & body; scanty eyebrows & lashes	Enamel hypoplasia	Hypohidrosis	**Skin:** dry; tendency to excessive bruising & scarring after injuries & scratching **Other:** bilateral epicanthic folds; sl mongoloid slant; short stature; probable low–normal intelligence level; arthrogryposis of all joints; bilateral clinodactyly; sl bilateral syndactyly of second & third toes; diabetes mellitus
Autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED) syndrome; autoimmune polyendocrinopathy syndrome, type I	240300	AD	Thickened & dystrophic	Occas alopecia areata	Normal	Normal	Oral candidiasis; autoimmune endocrinopathies (hypergonadotropic hypogonadism, insulin-dependent diabetes mellitus, autoimmune thyroid diseases & pituitary defects); autoimmune or immunomediated gastrointestinal diseases (chronic atrophic gastritis, pernicious anaemia & malabsorption); chronic active hepatitis; autoimmune skin diseases (vitiligo & alopecia); keratoconjunctivitis; immunological defects (cellular & humoral); asplenia & cholelithiasis
Baisch syndrome	Baisch [7]	NK	Almost total abs of the finger & toenails	Normal	Delayed eruption; abs of lateral incisors	Normal	**Limbs:** polydactyly with syndactyly in the hands (6/7 fingers); hypoplasia of the dist interphalangeal joints of fingers & toes; short & wide hands & feet; adduction of feet; delayed bone age
Blepharocheilodontic syndrome (clefting, ectropion, and conical teeth syndrome)	119580	AD	Normal	Normal	Conical teeth	Normal	Cleft lip & palate; hypertelorism; ectropia; euryblepharon
Book dysplasia	112300	AD	Normal	Normal	Hypodontia of the premolar region	Palmoplantar hyperhidrosis	**Eyes:** blue irides
Brachymetapody–anodontia-hypotrichosis–albinoidism (oculo-osteocutaneous syndrome; Tuomaala syndrome)	211370	AR	Normal	Poor hair growth	Cong anodontia	Normal	**Skin:** albinoidism **Other:** multiple ocular abnormalities including strabismus, nystagmus, distichiasis, lenticular opacities, high-grade myopia; mandibular prognathism; short stature; short metacarpals

(Continued)

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Camarena syndrome	F-M & P [5]	AD? XD?	Dysplastic	Thin; hypopigmented & very sp; poor growth	Anodontia	Abs of sweat glands in the scalp; anhidrosis on face & scalp	**Skin:** thin & smooth; palmoplantar erythema; nevus vascularis on the right lid & above the nose; euhidrosis on the rest of the body; mild 'cara de vieja' (old woman's face) **Other:** hypertelorism; abn auricles; micrognathia; microstomia; bilateral clinodactyly of the fifth fingers; high arched palate
Cardiofaciocutaneous syndrome	115150	AD	Normal	Sparse, slow-growing curly hair; absence of eyebrows & eyelashes	Normal	Normal	**Skin:** severe atopic dermatitis, ichthyosis; multiple palmar & plantar creases, hyperkeratosis (especially extensor surfaces), keratosis pilaris **Face:** coarse facial features, similar to Noonan syndrome; relative macrocephaly; prominent forehead; bitemporal narrowing; shallow orbital ridges; prominent philtrum; posteriorly rotated ears; down-slanting palpebral fissures; hypertelorism; exophthalmos; short upturned nose; depressed nasal bridge; submucous cleft palate; high-arched palate **Other:** postnatal short stature; hearing loss; nystagmus; strabismus; atrial septal defects; pulmonary stenosis; splenomegaly; hyperextensible fingers; mild to moderate mental retardation; seizures; hypotonia or hypertonia; hydrocephalus; cortical atrophy; frontal lobe hypoplasia; brain stem atrophy
Carey syndrome	F-M & P [5]	NK	Dyst from early childhood	Thin, hypopigmented & very sp	Discoloration; microdontia; hypodontia	Decreased number of sweat pore openings	**Skin:** aplasia cutis congenita-like scalp defects **Other:** moderate conductive hearing loss; abs of tear ducts; displacement of the inner canthi; U-shaped mouth; flat nasal bridge; maxillary hypoplasia; incomplete 2–3 toe syndactyly; cleft palate
Cartilage–hair hypoplasia syndrome	250250	AR	Normal	Sp eyebrows, eyelashes, beard, lt coloured hair	Normal	Normal	Increased malign risk; short-limbed dwarfism, mild scoliosis, short hands, limited elbow extension; Hirschsprung's disease, oesophageal atresia

Cataract–alopecia–sclerodactyly syndrome	212360	AR	Normal	Total alopecia	Normal	Normal	**Skin:** sclerodactyly, hyperkeratosis **Other:** congenital bilateral cataracts; contractures digits; pseudoainhum; patients from Rodrigues in the Indian Ocean
Cataract, hypertrichosis, mental retardation syndrome (CAHMR syndrome)	211770	AR	Normal	Gen hypertrichosis	Normal	Normal	Mental retardation; cong lamellar cataracts
Cleft lip/palate–ectodermal dysplasia syndrome (CLEPD1; Roselli–Gulienetti syndrome; Zlotogora–Ogur syndrome) (allelic to Margarita Island ectodermal dysplasia, see below)	225000	AR	Subungual hyperkeratosis, sulci; transverse & longitudinal striae; irregularities of free margins; hallucal nails with abs of the lamina	Woolly, thin, coarse, opaque, & short	Hypodontia; transverse striation; irregularities of the free margins	? mild tendency to perspiration	**Skin:** tendency to desquamation with erythematous patches **Face:** cleft lip; hypoplasia of the auricular lobes; flat nasal pyramid **Other:** cleft palate; malformation of the genitourinary system; abs or fusion of the last lumbar vertebra; aplasia or hypoplasia of thumb
Coffin–Siris syndrome	135900	AR? AD?	Abs to hypoplastic fifth fingernails & toenails; other nails occas hypoplastic or abs	Sp scalp hair; bushy eyebrows & lashes; hirsutism of limbs, forehead & back	Delayed eruption; microdontia	Normal	**Skin:** dermatoglyphic changes; simian crease **Other:** coarse face with thick lips, wide mouth & nose, anteverted nostrils, & low nasal bridge; retardation of psychomotor & growth development; hypotonia; lax joints; clinodactyly of the fifth fingers; general abs of terminal phalanges of fifth fingers & toes; general aplasia or variable hypoplasia of middle & prox phalanges of other fingers & toes; bilateral or unilateral dislocation of the radial heads; small or abs patella; frequent respiratory infections; umbilical & inguinal hernias; cleft palate; feeding problems in infancy; six lumbar vertebrae; short sternum; microcephaly
Conductive deafness, with ptosis and skeletal anomalies	221320	AR	Normal	Delayed hair growth	Dysplastic teeth	Normal	**Other:** conductive hearing loss from combined atresia of the external auditory canal & the middle ear space, complicated by chronic infection; ptosis; thin, pinched-nose facial appearance **Skeletal:** internal rotation of hips; dislocation of the radial heads & fifth finger clinodactyly
Congenital hypotrichosis with juvenile macular dystrophy (HJMD)	601553	AR	Normal	Cong hypotrichosis; normal eyelashes/ eyebrows	Normal	Normal	Juvenile macular dystrophy

(Continued)

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Congenital insensitivity to pain with anhidrosis (CIPA; familial dysautonomia, type II)	256800	AR	Normal	Hypotrichosis in areas of the scalp	Enamel aplasia	Hypohidrosis with hyperthermia	**Skin:** dry; scars from self-inflicted bites may be present on the fingers & arms; chronic sores are common on the hands, feet, & pressure points, such as the buttocks **Other:** irregular lacrimation; mental retardation; multiple fractures from trauma resulting in deformities; joint degeneration (Charcot joints); universal sensory loss; abs pain perception & physiological responses to painful stimuli; impaired temperature & touch perception; diminished tendon reflexes; occas encopresis & enuresis; ulceration of the mouth & scars from biting the tongue & lips
Cook's syndrome	106995	AD	Onychodystrophy; anonychia	Normal	Normal	Normal	Fifth finger brachydactyly; digitalization of thumbs; absent/hypoplastic distal phalanges of hands & feet
Corneodermatoosseous syndrome	122440	AD	Distal onycholysis	Normal	Soft teeth; early tooth decay	Normal	**Eyes:** corneal dystrophy; photophobia; burning/watering of eyes **Skin:** palmoplantar hyperkeratosis, erythematous scaly skin; generalized erythroderma **Other:** brachydactyly; short distal phalanges; short stature; medullary narrowing of hand bones
Cranio-ectodermal syndrome (Levin syndrome I; Sensenbrenner syndrome)	218330	AR	Broad & short	Thin, sp & slow-growing; abn structure	Microdontia; hypodontia; widely spaced; enamel hypoplasia; taurodontism	Normal	**Skin:** dimples over elbows & knees; bilateral hallucal creases; single flexion crease on each toe; bilateral single palmar creases **Skeletal:** rhizomelic shortness (greatest in upper limbs); disproportionate shortness of the fibulae; pronounced shortness of middle & dist phalanges of toes & fingers; cutaneous syndactyly; clinodactyly; increased space between first & second toes; hallux valgus; dolichocephaly; gen osteoporosis; highly arched palate; sagittal suture synostosis; short & narrow thorax; pectus excavatum **Other:** hyperopia; myopia; nystagmus; frontal bossing; epicanthal folds & antimongoloid slant; full cheeks; posteriorly angulated pinnae with hypoplastic antihelix; hypotelorism; broad nasal bridge; anteverted nares; everted lower lip; capillary naevus on the forehead; multiple oral frenula; cong heart defects

Curly hair–ankyloblepharon–nail dysplasia (CHANDS)	214350	AR	Hypoplastic finger & toe nails	Curly	Normal	Normal	**Eyes:** fused eyelids at birth (ankyloblepharon)
Deafness and onychodystrophy (DOOR syndrome)	220500	AR	Hypoplastic & dyst finger & toenails; anonychia	Normal	Hypoplastic & discoloured; irregular placement	Normal	**Skin:** dermatoglyphic abnormalities **Other:** sensorineural deafness; apparently low-set ears; seizures & mental retardation; triphalangy of both thumbs & halluces; hypoplasia or aplasia of terminal phalanges of fingers & toes; occas clinodactyly & camptodactyly
Deafness and onychodystrophy (Robinson syndrome)	124480	AD	Hypoplastic & dyst finger & toenails	Normal	Coniform; hypodontia, delayed primary & secondary dentition	Normal	**Other:** syndactyly of toes; severe sensorineural hearing loss (high frequency)
Dermo-odonto-dysplasia	125640	AD	Dysplastic; brittle	Dry; slow-growing (scalp, moustache & beard); circumscribed area of alopecia; normal eyebrows & lashes; sp axillary & pubic hair	Hypodontia; microdontia; persistence of deciduous teeth	Normal	**Skin:** dry & thin to variable degree (esp. on palmoplantar regions); simian crease **Face:** left palpebral ptosis; prognathic mandible
Dermotrichic syndrome ? related to IFAP syndrome (308205) (see below)	F-M & P [5]	XR	Dyst & hyperconvex fingernails	Gen atrichia from birth	Normal	Hypohidrosis without hyperthermia	**Skin:** gen ichthyosiform lesions; including palmoplantar area & scalp **Face:** prom forehead; large ears; small nose with mildly low nasal bridge; blepharophimosis **Other:** severe psychomotor retardation; abnormal EEG; frequent apyretic seizures; short stature; hemivertebrae at the dorsolumbar region; cong aganglionic megacolon; narrow arched palate; positive Benedict & glucoseoxydase tests; discrete increase of tyrosinaemia; discrete anaemia

(Continued)

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Dubovitz syndrome	223370	AR	Normal	Sp scalp hair, sp lateral eyebrows	Delayed eruption; caries	Normal	**Skin:** eczema **Face:** elongation of face with age; shallow supraorbital ridge; facial asymmetry; micrognathia; high, sloping forehead; prom ears; short palpebral fissures; ptosis; blepharophimosis; microphthalmia; broad nasal tip; high-arched palate; submucous cleft palate; velopharyngeal insufficiency **Other:** growth retardation; short stature; microcephaly; mild mental retardation with behaviour problems; high-pitched voice; recurrent infections; hypogammaglobulinaemia; IgA deficiency; neoplasia including aplastic anaemia; acute lymphatic leukaemia, lymphoma & neuroblastoma
Dyskeratosis congenita (X-linked) (Zinsser–Cole–Engman syndrome)	305000	XR	Dystrophy with late onset paronychia occas leading to anonychia; hypoplasia	Hypotrichosis; loss of cilia due to blepharitis & ectropion; abs of eyebrows & lashes; premature canities	Poorly aligned; early carious degeneration	Gen hyperhidrosis elsewhere	**Skin:** hyper- & hypomelanosis, telangiectatic erythema; ulcers; dry desquamation; atrophy; hyperkeratotic plaques (palmoplantar & over joints); premalignant lesions; abs fingerprints **Eyes:** blepharitis; ectropion of the lower lids; obliteration of the punctalacrimalia; bullous conjunctivitis; continuous lacrimation **Other:** sharp facial features; occas mental & growth retardation; Fanconi-like pancytopenia; premalignant leukoplakia on lips, mouth, anus, urethra & conjunctiva; frail skeletal structure; genital anomalies; oesophageal dysfunction and/or diverticulum; atrophic lingual papillae; gingivitis
Dyskeratosis congenita (autosomal dominant/ Scoggins type)	127550	AD	Dystrophic	Hypotrichosis	Carious	No data	**Skin:** hyper- & hypomelanosis, telangiectatic erythema; ulcers; dry desquamation; atrophy; hyperkeratotic plaques (palmoplantar & over joints); premalignant lesions; abs fingerprints **Eyes:** Blepharitis; ectropion of the lower lids; obliteration of the puncta lacrimalia; bullous conjunctivitis; continuous lacrimation **Other:** sharp facial features; occas mental & growth retardation; Fanconi-like pancytopenia; premalignant leukoplakia on lips, mouth, anus, urethra & conjunctiva; frail skeletal structure; genital anomalies; oesophageal dysfunction and/or diverticulum; atrophic lingual papillae; gingivitis

Dyskeratosis congenita (autosomal recessive)	224230	AR	Dystrophic	Hypotrichosis	Carious	No data	**Skin:** hyper- & hypomelanosis, telangiectatic erythema; ulcers; dry desquamation **Other:** pancytopenia; thrombocytopenia; small platelets; T-cell abnormalities; dystrophic fingers & toes
Ectodermal defect with skeletal abnormalities	Wallace [8]	NK	Finger & toenails poorly developed & foreshortened	Scalp hair is sl coarse; very sp axillary hair	Hypodontia; hypoplastic teeth	Normal	**Skin:** thin, fine & dry; fine, light, granular pigmentation; translucent appearance; rudimentary nipples **Face:** striking appearance; central portion is relatively underdeveloped; the cheeks, upper jaw & nose are sunken with the 'inverted, dish-shaped deformity' & somewhat prom eyes **Other:** low intelligence; short metacarpals; some absorption of the terminal tufts of the dist phalanges; flexion anomalies of hands & feet, abs of breasts; narrow & highly arched palate
Ectodermal dysplasia with natal teeth (Turnpenny type)	601345	AD	Normal	Thin scalp hair; scanty body hair	Oligodontia by late adolescence	Variable heat tolerance	**Skin:** flexural acanthosis nigricans
Ectodermal dysplasia with palatal paralysis	Wesser & Vistnes [9]	NK	No data	Abs of frontal hair, eyebrows & lashes	Stunted & peg-shaped; enamel hypoplasia	Anhidrosis on face (abs sweat glands)	**Skin:** abs of sebaceous glands on the face **Other:** conductive loss; otitis; frontal bossing; depressed nasal bridge; highly arched palate; palatal paralysis; diminished sensation in the palate, the posterior pharyngeal wall & the tonsillar pillar area; abn & distorted speech with a marked nasal component
Ectodermal dysplasia with severe mental retardation	Kirman [10]	NK	Almost abs from fingers & toes	Abs scalp (except for a small wisp in the centre of the head) & body hair	Normal	Hypohidrosis without hyperthermia	**Skin:** fine, thin & shiny with some desquamation over the hands, feet & the top of the head; abs of both nipples **Other:** blindness with bilateral cataract; abn ears; severe mental retardation; abs of menstruation; prepubertal vulva
Ectodermal dysplasia with mental retardation and syndactyly	600906	NK	Severe onychogryphosis	Short, abundant, & stiff, sparse eyebrows	No data	Hypohidrosis	**Skin:** dry **Other:** syndactyly involving the third & fourth fingers & the second & third toes; mild mental retardation; large scalp defect, a peculiar face with large palpebral fissures, broad nasal bridge & constantly open mouth, abnormally modelled ears; mild, & toes

(Continued)

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Ectodermal dysplasia with syndactyly	Wiedemann *et al.* [11]	AR	Yellowish & partially thickened	Hypotrichosis; brittle scalp hair; pili torti; sp eyebrows & lashes	Severe crown hypoplasia; delayed & atypical eruption of permanent teeth	Normal	**Skin:** dry with hyperkeratosis, esp at the dist third of the trunk, lower limbs, & palmoplantar regions (axillae & elbows are normal); transverse crease on both palms **Other:** mild crowding of the lenses; discrete hypermetropia; syndactyly on both fingers & toes to variable degrees; lordosis; highly arched palate
Ectodermal dysplasia syndrome with tetramelic deficiencies	F-M & P [5]	NK	Platonychia; mildly dysplastic toenails	Scalp hypotrichosis; sp eyebrows & lashes	Hypodontia; peg-shaped teeth	Normal	**Skin:** hypoplastic areolae & nipples **Limbs:** bipartite right clavicle; short & distally curved left clavicle; coxa valga; steep femoral necks; synostosis of cuboid & lateral cuneiform bones; cutaneous syndactyly **Other:** esotropia; malformed auricles; protruding lips; wide nasal root; mild mental retardation; short stature; microcephaly; constant tearing & repeated infections of the conjunctivae; atresia of the naso-lacrimal ducts
Ectodermal dysplasia with adrenal cyst (odonto-onycho-hypohidrotic dysplasia with mid-line scalp defect)	129550	AD	Dyst fingernails	Alopecia cutis verticis	Delayed eruption; diastemata; minor shape alterations	Hypohidrosis as determined by pilocarpine iontophoresis	**Skin:** midline scalp defect (aplasia cutis verticis); hypoplastic areolae & nipples **Other:** breast hypoplasia (inability to lactate); hypertension of undetermined pathogenesis
Ectodermal dysplasia with distinctive facies & preaxial polydactyly	129540	AD	Rounded nails	Scalp alopecia; body alopecia; sp eyebrows; sp eyelashes	Thin enamel; dental caries	Normal	Micrognathia; flat philtrum; malar hypoplasia; dystopia canthorum; flat nasal bridge; thin upper lip; thickened frenulum; fifth finger clinodactyly; preaxial polydactyly; duplicated halluces; duplicated first metatarsals; language delay
Ectodermal dysplasia with ectrodactyly & macular dystrophy	225280	AR	Dysplastic	Hypotrichosis	Normal	Normal	Ectrodactyly; syndactyly; cleft hand; macular dystrophy
Ectodermal dysplasia, pure hair & nail type	602032	AD	Congenital onychodystrophy; micronychia; onycholysis; onychorrhexis	Brittle hair; temporal hypotrichosis	Normal	Normal	**Skin:** folliculitis decalvans of neck
Ectrodactyly–ectodermal dysplasia–cleft lip/palate (EEC) syndrome	129900	AD	Dysplastic, thin, pitted, brittle & striated	Hypotrichosis of scalp & body; fair & dry; scanty or abs eyebrows & lashes	Anodontia; hypodontia; microdontia; enamel hypoplasia; poorly formed; peg-shaped incisors	Occas hypohidrosis without hyperthermia	**Skin:** dry, translucent, palmoplantar hyperkeratosis; eczematous patches; pigmented naevi **Face:** cleft lip; broad nose; defective auricles; pointed chin; malar hypoplasia **Other:** conductive hearing loss; tear duct anomaly or malfunction; speckled iris; photophobia; strabismus; blepharitis; clouding of the cornea; cong adhesions between the eyelids; ectrodactyly; syndactyly; clinodactyly; cleft palate; renal abnormalities; rhinitis; respiratory infections; genital anomalies

Ectrodactyly–ectodermal dysplasia (possible variant expression of EEC, see below)	129810	AD	Normal	Hypotrichosis	Normal	Abnormal dentition	**Other:** no clefting of the lip or palate, as seen in classic EEC syndrome
Ellis–van Creveld syndrome (chondroectodermal dysplasia, mesoectodermal dysplasia) See Weyer's acrofacial dysostosis, below	225500	AR	Dysplastic (brittle, furrowed & underdeveloped)	Thin, brittle, & hypochromic; abs or scanty eyebrows & lashes	Natal teeth; precocious exfoliation; hypodontia; occas hypoplastic enamel	Normal	**Skin:** eczema, petechiae are described in different patterns **Other:** occas strabismus, cataract, coloboma of the iris, microphthalmia; exophthalmia; short-limbed dwarfism; bilateral postaxial polydactyly (gen of the hands); brachymetacarpy; thick & short bones of limbs; fusion of the hamate & capitate; clubfoot; genua valga; syndactyly; occas mild mental retardation; cong heart disease; respiratory difficulties; gingivolabial fusion; cleft palate; epispadia; hypospadias; hypoplastic genitalia **Face:** broad nose; occas cleft lip, frontal bossing & hypertelorism
Fischer syndrome (Fischer–Volavsek syndrome)	Fischer [12]	AD	Onychogryposis; onycholysis	Sp scalp hair, eyebrows, & lashes	Normal	Palmoplantar hyperhidrosis	**Skin:** occas xeroderma; palmoplantar keratosis **Other:** eyelid oedema; occas mental deficiency; clubbing of dist phalanges of the fingers & toes; syringomyelia; apathy
Focal dermal hypoplasia syndrome (Goltz syndrome)	305600	XL	Thin, spooned, narrow, grooved hypopigmented or abs	Hypotrichosis	Hypodontia; microdontia; enamel hypoplasia; delayed eruption; irregular placement	Hypohidrosis or hyperhidrosis	**Skin:** abs of skin from various parts at birth; areas of underdevelopment or thinness; linear hypo- or hyperpigmentation; telangiectasia; herniation of subcutaneous fat; multiple papillomas of mucous membranes and periorificial skin; follicular hyperkeratotic papules; angiofibromatous nodules around lips & anus; palmoplantar hyperkeratosis; occas dermatoglyphic changes **Other:** occas hearing loss; colobomas; microphthalmia; irregularity of pupils; clouding of cornea or vitreous; blue sclerae; lip papillomas; malformed auricles; asymmetry & notching of the alae nasi; pointed chin; triangular face; hypertelorism; mental retardation; short stature; syndactyly; polydactyly; hypoplasia of the external genitalia; umbilical and/or inguinal hernia; vertebral anomalies (scoliosis, spina bifida etc) highly arched palate; gum papillomas; small breasts

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Focal facial dermal dysplasia, type I (FFDD-type I, focal facial dermal dysplasia, bitemporal aplasia cutis, Brauer syndrome) ? same as FFDD type II	136500	AD	Normal	Alopecia areata; gen sp eyebrows & lashes or multiple rows of lashes on upper lids; normal to abs lashes on lower lids	Normal	Localized hypohidrosis (scarce to abs sweat glands in the focal lesions)	**Skin:** round, focal temporal lesions that have a smooth or wrinkled surface & may be hyperpigmented; occas multiple vertic linear depressions on the lower forehead; abs of sebaceous glands in the temporal lesions **Eyes:** chronic bilateral blepharitis in a few cases **Face:** leonine appearance; wrinkles periorbitally; wide nasal bridge; fleshy nose with the tip bent down; bilateral epicanthic folds
Focal facial dermal dysplasia, type II (FFDD-type II, facial ectodermal dysplasia, bitemporal forceps marks syndrome, Setleis syndrome) ? same as FFDD type I	227260	?AR	Normal	Alopecia areata; gen sp eyebrows & lashes or multiple rows of lashes on upper lids; normal to abs lashes on lower lids	Normal	Localized hypohidrosis (scarce to abs sweat glands in the focal lesions)	**Skin:** round, focal temporal lesions that have a smooth or wrinkled surface & may be hyperpigmented; occas multiple vertic linear depressions on the lower forehead; abs of sebaceous glands in the temporal lesions **Eyes:** chronic bilateral blepharitis in a few cases **Face:** leonine appearance; wrinkles periorbitally; wide nasal bridge; fleshy nose with the tip bent down; bilateral epicanthic folds
Fried tooth and nail syndrome	Fried [13]	AR	Small, thin & sl concave	Fine & short; scanty eyebrows	Hypodontia; peg-shaped teeth	Normal	**Face:** prom lips & chin **Other:** branchial cyst on the left side of the neck
Gingival fibromatosis and hypertrichosis	135400	AD	Normal	Gen hypertrichosis; black & coarse	Delayed eruption; occas microdontia & premature exfoliation	Normal	**Skin:** occas pigmented nevi & hyperelasticity **Other:** occas large ears, peculiar nose & coarse features; mental retardation; epilepsy; gingival fibromatosis; occas hypoplastic breasts
Gingival fibromatosis–sparse hair–malposition of teeth	Jorgenson [14]	AR	No data	Excessively thick in childhood; begins to thin out during early teens; sp later	Malpositioned & malformed; serrated incisors	No data	**Face:** coarse appearance; protruding lips (secondary to gingival fibromatosis); prognathic mandible; broad & flat nasal alae **Other:** alternating strabismus; rotating nystagmus; myopia; abn EEG; low IQ; large hands; broad & relatively short feet; highly arched palate
Gorlin–Chaudhry–Moss syndrome	233500	AR?	No data	Hypertrichosis	Hypodontia; microdontia; some pulp chambers small or missing	Normal	**Face:** characteristic with 'dished out' appearance of middle face; ectropion of lower lid; antimongoloid slant; short stature **Other:** mild bilateral conductive loss; hyperopia; microphthalmia; horiz nystagmus; corneal ulcers; defective eyelid development; craniofacial dysostosis; patent ductus arteriosus; hypoplasia of labia majora; highly arched palate; mild umbilical hernia

Growth retardation–alopecia–pseudoanodontia–optic atrophy (GAPO)	230740	AR	Hyperconvexity on fingers & toes is referred to in two patients	Generalized atrichia	Pseudoanodontia of both primary & permanent dentition with abs of alveolar ridges	Normal	**Skin:** Dry; redundant; fragile with inadequate wound healing (small, depressed scars); depigmented areas; unusual wrinkles; leatherlike & thick on nape & upper back; abn dermatoglyphics **Face:** 'small' & 'characteristic'; asymmetrical; craniofacial dysostosis; micrognathia; protruding & thickened lips; protruding auricles; prom supraorbital ridges; depressed nasal bridge; minor auricular malformations **Other:** sensorineural hypoacusia; optic atrophy; glaucoma; keratoconus; nystagmus; photophobia; dwarfism; occas mental retardation; symmetrical prox shortening of humeri; hyperextensible fingers; second & third toes smaller than the fourth; wide gap between hallux & second toes; wide anterior fontanelle; prom scalp veins; hepatosplenomegaly; bilateral choanal atresia; hyperplasia of sublingual connective tissue; hypoplasia of mammary glands; pectus excavatum; umbilical hernia; delayed bone maturation through childhood & adolescence
Hallerman–Streiff syndrome (Francois dyscephalic syndrome)	234100	AR Heterogeneity? AD?	Normal	Thin & light; gen or sutural alopecia of scalp	Natal; supernumerary; hypodontia; deciduous; premature caries; coniform teeth; hypoplastic enamel	Normal	**Skin:** cutaneous atrophy largely limited to the face and/or scalp; telangiectases; xerosis **Face:** characteristically bird-like; the head has an abn shape, usually brachycephalic or scaphocephalic with frontal & parietal bossing; micrognathia; microstomia with thin lips; apparently low-set ears; 'double chin' **Other:** bilateral microphthalmia; cong cataract; cong corectopia; occas nystagmus; strabismus; blue sclerae; optic disc coloboma; various chorioretinal pigment alterations; occas syndactyly; winging of the scapulae; proportionate short stature; intelligence ranges from normal to mental retardation; narrow & highly arched palate; delayed ossification of craniofacial sutures; microcephaly; cardiac defects; hypogenitalism; cryptorchidism; vertebral anomalies; funnel chest

(Continued)

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Hayden syndrome	F-M & P [5]	NK	Severe pachyonychia (hands & feet)	No scalp hair, eyebrows, or lashes; virtually no body hair	Normal	Severe hypohidrosis	**Skin:** follicular & plaque-like hyperkeratosis; ichthyosis-like hyperkeratosis on the shins; extremely severe palmoplantar hyperkeratosis to the point of almost complete stiffness of the fingers & toes; severe chronic scalp infection with many pustules **Other:** Chronic external otitis leading to virtual deafness; severe chronic conjunctivitis leading to virtual blindness; saddle nose; narrow palpebral fissures
Hereditary mucoepithelial dysplasia	158310	AD	Chronic monilial nail infection	Non-scarring alopecia	Gingival inflammation	Normal	**Skin:** flat red periorificial mucosal lesions; follicular keratosis **Other:** photophobia; nystagmus; keratoconjunctivitis; keratitis; pannus; cataracts; repeated pneumonia; fibrocystic lung disease; cor pulmonale; mucocutaneous candidiasis; diarrhoea in infancy; T & B cell abnormalities; abnormal PAP smears; vulvovaginal erythema
Hidrotic ectodermal dysplasia (Clouston syndrome/ED2)	129500	AD	Variable degrees of dystrophy; thickened & sl discoloured; paronychia	Dry, fine, usually blonde, slow-growing; hypotrichosis; abs/scanty eyebrows & lashes	Occas hypodontia, anodontia, widely spaced; natal teeth; caries	Normal	**Skin:** dry & rough; tendency toward scaliness; hyperpigmentation of some areas; thick dyskeratotic palms & soles **Other:** occas strabismus, cataract & myopia; occas mental deficiency & short stature; speech difficulties; tufting of terminal phalanges; clubbing of fingers; thickening of skull bones
Hidrotic ectodermal dysplasia, Christianson–Fourie type	601375	AD	Dystrophic thickened nails; unattached distal half of nails	Short, thin, sp, pale scalp hair; absent eyebrows; short, sparse eyelashes; sp axillary & pubic hair	Normal	Normal	Episodic supraventricular tachycardia; bradycardia
Hypertrichosis and dental defects	F-M & P [5]	AD	Normal	Generalized hypertrichosis (except on palms, soles & mucous membranes)	Occas persistence of deciduous teeth, delayed eruption, hypodontia, anodontia	Normal	

Hypohidrotic ectodermal dysplasia–X-linked (ED1; Christ–Siemens–Touraine (CST) syndrome)	305100	XR	Gen normal; sometimes dyst or abs at birth and/or fragile & brittle with incomplete development & celonychia	Fine & dry; hypochromic; hypotrichosis of scalp & body; abs or scanty eyebrows & lashes; moustache & beard gen normal	Hypodontia; peg-shaped incisors and/or canines; persistence of deciduous teeth; delayed eruption; occas anodontia	Hypohidrosis with or without hyperthermia; abs or decreased number of epidermal ridge sweat pores	**Skin:** thin, smooth & dry due to hypoplasia or abs of sebaceous glands; occas pigmentation & dermatoglyphic changes; abs or supernumerary nipples & areolae **Face:** highly characteristic in persons who are severely affected (gen males) with thick & prom lips, depressed nasal bridge (saddle nose), frontal bossing, hypoplasia of the maxilla, wrinkles beneath the eyes, or around the eyes, nose & mouth & minor alterations of the auricles; the periorbital region is often more darkly pigmented than the rest of the body **Other:** occas conductive loss; photophobia; decreased function of the lacrimal glands; aplasia or hypoplasia of the lacrimal ducts; atrophic rhinitis; otitis media; decreased sense of taste and/or smell; atrophied mucous glands of the upper respiratory tract; respiratory difficulties; chronic pharyngitis & laryngitis; aplasia or hypoplasia of the mammary glands
Hypohidrotic ectodermal dysplasia–autosomal dominant (EDA3); includes Jorgenson syndrome	129490	AD	Gen normal; sometimes hypoplastic	Sp, fuzzy, lightly pigmented scalp hair; abs or scanty eyebrows, lashes & body hair	Hypodontia; anodontia; conical teeth	Hypohidrosis with hyperthermia	**Skin:** smooth, thin, dry & hypoplastic **Other:** photophobia; hypoplasia of lacrimal ducts; decreased function of the lacrimal glands; saddle nose; thick & protruding lips; frontal bossing & prom auricles; chronic rhinitis, frequent respiratory infections
Hypohidrotic ectodermal dysplasia (autosomal recessive)	224900	AR	Gen normal; sometimes hypoplastic	Sp, fuzzy, lightly pigmented scalp hair; abs or scanty eyebrows, lashes & body hair	Hypodontia; anodontia; conical teeth	Hypohidrosis with hyperthermia	**Skin:** smooth, thin, dry & hypoplastic **Other:** photophobia; hypoplasia of lacrimal ducts; decreased function of the lacrimal glands; saddle nose; thick & protruding lips; frontal bossing & prom auricles; chronic rhinitis, frequent respiratory infections
HED with immune deficiency	300291	XD	Gen normal; sometimes hypoplastic	Sp, fuzzy, lightly pigmented scalp hair; abs or scanty eyebrows, lashes & body hair	Hypodontia; anodontia; conical teeth	Hypohidrosis with hyperthermia	Milder ectodermal dysplasia features than classic HED; failure to thrive, recurrent infections of digestive tract; recurrent respiratory infections; dysgammaglobulinaemia

(Continued)

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
HED with immune deficiency, osteopetrosis and lymphoedema	300301	XD	Gen normal; sometimes hypoplastic	Sp, fuzzy, lightly pigmented scalp hair; abs or scanty eyebrows, lashes & body hair	Hypodontia; anodontia; conical teeth	Hypohidrosis with hyperthermia	Milder ectodermal dysplasia features than classic HED; failure to thrive, recurrent infections of digestive tract; recurrent respiratory infections; dysgammaglobulinaemia; osteopetrosis Generally more severe phenotype than 300291
HED with deafness	125050	AD	Gen normal; sometimes hypoplastic	Sp, fuzzy, lightly pigmented scalp hair; abs or scanty eyebrows, lashes & body hair	Hypodontia; anodontia; conical teeth	Hypohidrosis with hyperthermia	Progressive hearing loss
Hypohidrotic ectodermal dysplasia with hypothyroidism and ciliary dyskinesia (possibly a CGS with 225040, see below) (? same as ANOTHER syndrome)	225050	NK	Dyst, ridged finger- & toenails with a shrivelled appearance	Scanty & wispy scalp hair with a hard, hay-like consistency; scanty eyebrows & normal lashes	Normal	Hypohidrosis with hyperthermia; low number of sweat gland pores in the palms	**Skin:** poorly developed palmar dermal ridges; mottled brownish skin pigmentation of the trunk during the first months of life; urticaria pigmentosa-like skin & mucosal pigmentation **Other:** lacrimal ducts frequently blocked with resultant bilateral epiphora; frequent conjunctivitis; short stature; structural ciliary abnormalities of the respiratory tract; recurrent & severe upper & lower respiratory infections; severe cow's milk intolerance in infancy; elevated thyrotrophin; decreased thyroid hormone production from early childhood; no evidence of thyroid tissue shown by radiolabelled iodine studies
Hypohidrotic ectodermal dysplasia with hypothyroidism and agenesis of the corpus callosum	225040	NK ?CGS	Dyst, ridged finger & toenails with a shrivelled appearance	Scanty & wispy scalp	Normal	Hypohidrosis with hyperthermia	**Other:** severe mental retardation; agenesis of corpus callosum; primary hypothyroidism; absent normal thyroid & ectopic goiter on technetium 99 thyroid scintigram
Hypohidrotic ectodermal dysplasia with papillomas and acanthosis nigricans (Lelis' syndrome)	Lelis [15]	AR?	Short & dyst	Gen hypotrichosis; scalp hair is dry, fine, lustreless & slow growing; also scanty axillary, pubic hair, moustache/ beard, eyebrows & lashes	Hypoplastic & carious	Hypohidrosis, small number of sweat glands (detected by biopsy)	**Skin:** dry; palmoplantar hyperkeratosis; hyperpigmented & hyperkeratotic skin with wrinkles, papillomas & acanthosis nigricans in the neck, axillae, & genito-femoral regions; increased cornification & presence of follicular plugs on the 'normal' skin; unusual wrinkles around lips **Other:** plicate tongue with papillomatosis

Hypotrichosis-osteolysis-periodontitis-palmoplantar keratoderma syndrome	607658	AD?	Onychogryphosis	Hypotrichosis; pili torti et annulati	Caries & periodontitis	Normal	**Skin:** striate palmoplantar keratoderma; acroosteolysis; psoriasis-like skin lesions **Other:** periodontitis
Ichthyosis follicularis, atrichia, and photophobia syndrome (IFAP) ? related to dermotrichicic syndrome (see below)	308205	XR ? CGS	Normal	Cong atrichia	Enamel dysplasia	Hypohidrosis	**Skin:** ichthyosis follicularis **Other:** photophobia; short stature; mental retardation; seizures; congenital aganglionic megacolon; inguinal hernia; vertebral anomalies; renal anomalies; recurrent respiratory infections
Incontinentia pigmenti (familial male-lethal type IP, Bloch–Sulzberger syndrome)	308300	XL	Dyst in all or most of the fingers & toes in about one tenth of cases	Scarring alopecia in one third	Hypodontia; anodontia; peg-shaped; delayed eruption; both deciduous & permanent teeth are affected	Normal	**Skin:** vesicular-bullous eruption in the neonatal period followed or accompanied by verrucous lesions & bizarre pigmentation; pigmented macules may be present **Other:** occas cong hearing loss; ophthalmological alterations in about one fifth of the patients include blindness, strabismus, cataract, uveitis, retrolental fibroplasias, optic nerve atrophy, microphthalmia; occas clubfoot, cleft palate, microcephaly; about one-third of the cases present severe CNS anomalies: spastic tetraplegia, hemiplegia, diplegia; epilepsy; mental retardation; occas short stature
Johanson–Blizzard syndrome	243800	AR	No data	Sp, dry & fine or coarse; marked frontal upsweep	Oligodontia of both dentitions; peg-shaped teeth	Normal	**Skin:** pale & smooth; café-au-lait spots on lower limbs & abdomen; patches of vitiligo on the lower back & abdomen; midline scalp defects (aplasia cutis congenita); tiny nipples with almost no areolae; transverse palmar creases **Other:** cong sensorineural deafness; aplasia of the inferior puncta; strabismus; aplastic alae nasi, beak-like appearance to nose; severe mental retardation; occas akinetic seizures; microcephaly; hypothyroidism; pancreatic dysfunction; imperforate anus; genitourinary defects; failure to thrive/oedema; malabsorption; epiphyseal dysgenesis; nasolacrimocutaneous fistulae; highly arched palate; delayed bone age; hyperextensibility

(Continued)

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Keratitis ichthyosis and deafness (KID) syndrome, incorporates hystrix-like ichthyosis with deafness (HID) syndrome 602540	148210	AD	Abs at birth; delayed development; leukonychia & thickening (most marked in the fingernails); destructive dystrophy	Hair loss varies from alopecia to fine, thin scalp hair; scanty or abs eyebrows & lashes; occas trichorrhexis nodosa in some scalp hairs	Delayed eruption of deciduous teeth; brittleness; tendency to develop caries; unspecified defects	Hypohidrosis (with hyperthermia)	**Skin:** ichthyosiform erythroderma with sebaceous dysfunction; furrowing around mouth & chin; erythematous hyperkeratotic plaques on elbows, knees, & the dorsa of hands & feet; marked thickening (leather-like consistency) of palms & soles; increased susceptibility to squamous cell carcinoma **Other:** cong sensorineural deafness; vascularisation of the cornea with pannus formation resulting in loss of vision; keratitis; occas decreased tear production; photophobia; bilateral flexion contractures at knees & elbows with tight heel cords
Kirghizian dermato-osteolysis	221810	AR?	Some dyst fingernails	Normal	Hypodontia; abnormally shaped	Normal	**Skin:** multiple ulcerations on face, trunk, & limbs, with healing of the more superficial ones & fistulous cicatrisation of the deeper ones **Other:** recurrent keratitis with corneal scarring leading to visual impairment; acromegaloid enlargement of hands & feet; claw hands; enlarged & deformed joints; short fingers; flexion contractures in some fingers
Limb–mammary syndrome	603543	AD	Nail dysplasia	Normal	Variable degrees of hypodontia	Hypohidrosis	Hypoplasia/aplasia of the mammary glands; cleft lip/palate +/– bifid uvula; lacrimal duct atresia
Margarita Island ED (allelic to cleft lip/palate–ectodermal dysplasia syndrome (CLEPD1))	225060	AR	Dysplastic	Sp, short scalp hair; sp eyebrows	Hypodontia, esp upper lateral incisors	Normal	Cleft lip/palate; syndactyly of fingers;
Marshall syndrome (allelic to Stickler syndrome (108300), but no ectodermal dysplasia in Stickler syndrome)	154780	AD	Normal	Sparse scalp hair & eyelashes in some families	Occas hypodontia, microdontia, abnormalities of eruption, & malposition	Occas mild hypohidrosis	**Face:** characteristic, with cong & persistently severe flat nasal bridge, anteversion of nostrils, malar hypoplasia, frontal bossing, & sometimes hypertelorism **Other:** occas mental retardation; short-to-normal stature; hypoextensible joints; cranial & spondyloepiphyseal abnormalities; prog cong sensorineural deficit; myopia; fluid vitreous; cong & juvenile cataracts with spontaneous & sudden maturation & absorption
McGrath syndrome (ectodermal dysplasia–skin fragility syndrome)	604536	AR	Thickened & dystrophic	Short & sparse, some improvement with time	Normal	Hypohidrosis, some improvement with age	**Skin:** at birth blistering & desquamation especially on the face, limbs, & buttocks; lifelong fragility, with trauma-induced tearing & blisters on the pressure points of the soles after prolonged standing or walking; plantar hyperkeratosis

Melanoleucoderma	246500	AR	Normal	Dry & abundant scalp hair; sp lateral eyebrows; normal eyelashes; axillary & pubic hair almost normal in women, abs in men	Delayed eruption of deciduous & permanent teeth; hypodontia	Mild palmoplantar hyperhidrosis	**Skin:** pale, thin, dry, smooth, pliable & feminine; gen mottled dyschromia consisting of various shades of hyper- & hypopigmentation; anetopoikiloderma-like lesions over the elbows, knees & prox phalangeal articulations; pyoderma over the lower regions of the legs leading to atrophic scars; palmoplantar hyperkeratosis **Face:** typical 'family' face with flat saddle nose, thick lips with sl telangiectasia & deep furrows around the eyes & mouth **Other:** mental retardation; short stature; hyperextensibility of the fingers; slender legs; sexual underdevelopment in men (hypospadias, small penis & scrotum, atrophy of the testes, abs of secondary sexual characteristics)
Mesomelic dwarfism–skeletal abnormalities–ectodermal dysplasia	Brunoni *et al.* [16]	NK	Hypoplastic toenails	Hypotrichosis	Dysmorphic; irregular eruption; malpositioned	Normal	**Skin:** extremely hypoplastic papillary dermal ridges; bilateral transitional palmar flexion creases **Face:** depressed nasal root; micrognathia; hypertelorism; antimongoloid palpebral slanting; epicanthal folds; long philtrum; thin lips **Limbs:** short forearms & hands; broad thumbs; brachymesophalangy; camptodactyly of both fifth fingers; short legs; flattened acetabular margins; broad halluces **Other:** esotropia; short stature; mild psychomotor retardation; brachycephaly; narrow & highly arched palate; retarded ossification of the anterior fontanelle with the presence of Wormian bones
Mikaelian syndrome (ectodermal dysplasia and neurosensory deafness)	224800	AR	Normal	Coarse & brittle; hypotrichosis of scalp	Caries	Normal	**Skin:** hyperkeratotic; increased melanin in the basal layer **Other:** bilateral sensorineural loss; coarse facial features; arachnodactyly; kyphoscoliosis
Monilethrix	158000	AD	Occas dystrophic	Brittle, beaded, highly variable degrees of alopecia	Normal	Normal	**Skin:** keratosis pilaris, especially over nape of neck

(Continued)

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Naegeli–Franceschetti–Jadassohn syndrome	161000	AD	Normal	Normal	Carious & yellowish spotted	Hypohidrosis; discomfort in heat	**Skin:** reticular cutaneous pigmentation (appearing at age 2 & disappearing with age), palmoplantar hyperkeratosis, absent dermatoglyphics
Oculo-dentodigital (ODD) syndrome	164200	AD	Normal	Brittle, sp & dry; slow-growing	Generalized enamel hypoplasia; occas hypodontia; microdontia, & premature loss	Normal	**Eyes:** microcornea; microphthalmia with small orbits; reduced lid apertures; occas findings: optic atrophy, synechiae, disc coloboma, persistence of papillary membrane, nystagmus, cong cataract, glaucoma, strabismus & epicanthal folds **Limbs:** syndactyly & camptodactyly of the fourth & fifth fingers & of one or more toes; occas ulnar clinodactyly of the fifth fingers & syndactyly of the third & fourth toes; hip dislocation; cubitus valgus **Other:** face characterized by a thin nose, hypoplastic alae & narrow nostrils; cleft lip; orbital hypotelorism; occas micrognathia & mild pinna defects; microcephaly; cranial hyperostosis; cleft palate; osteopetrosis; occas conductive impairment
Oculotrichodysplasia	257960	AR	Brittle finger & toenails	Generalized hypotrichosis, sparse scalp, axillary & pubic hair; scanty eyelashes & sparse eyebrows in distal 2/3	Hypodontia; carious with extensive extractions	Normal	**Other:** retinitis pigmentosa
Odontomicronychial dysplasia	601319	AR	Short, thin, slow growing nails	Normal	Precocious eruption & shedding of deciduous teeth; precocious eruption of secondary teeth	Normal	
Odonto-onychodermal dysplasia	257980	AR	Dystrophic	Dry & sparse with thinning of eyebrows in some	Misshapen teeth; peg-shaped incisors	Hyperhidrosis	**Skin:** thickening of the palms & soles; erythematous lesions of face; thickening of the palmar skin with painful chafing **Other:** mild mental deficiency

Onychotrichodysplasia and neutropenia	258360	AR	Hypoplastic finger & toenails; koilonychia; onychorrhexis	Dry, fine, lustreless, short, curly, sp on scalp, eyebrows & lashes; trichorrhexis; abs axillary & pubic hair	Normal	Normal	**Skin:** thin & wrinkled on the palms & soles; pustules on the palms **Other:** chronic irritative conjunctivitis; delayed psychomotor development; mild generalized hypotonia; chronic neutropenia; recurrent infections (mainly tonsillitis, sinusitis, & otitis)
Orofaciodigital (OFD) syndrome type I	311200	XD	Normal	Dryness and/or variable degree of alopecia (65%)	Abs of the lower lateral incisors (50%); malposition; occas supernumerary canines & enamel hypoplasia	Normal	**Skin:** evanescent facial milia **Face:** broad nasal root; hypoplasia of alae nasi; median cleft of the upper lip; occas short philtrum, frontal bossing; ear abnormalities **Limbs:** several types of malformations including brachydactyly, clinodactyly, syndactyly, polydactyly **Other:** dystopia canthorum; occas mental retardation (usually mild), trembling & short stature; multiple hypertrophied lingual & labial frenula; lateral grooving of maxillary alveolar process; grooved ankyloglossia; cleft palate; hypoplasia of malar bone; hypoplasia of the base of the skull; renal abnormalities
Pachyonychia congenita type 1 (Jadassohn–Lewandowsky type)	167200	AD	Severe wedge-shaped thickening	Usually normal	No natal teeth	Palmoplantar hyperhidrosis	**Skin:** Focal palmoplantar keratoderma; verrucous lesions on the knees, elbows, buttocks, ankles, & popliteal regions; follicular keratoses/keratosis pilaris **Other:** oral leukokeratosis; hoarseness
Pachyonychia congenita type 2 (Jackson–Lawler type)	167210	AD	Severe wedge-shaped thickening	Usually normal	Natal teeth	Palmoplantar hyperhidrosis	**Skin:** focal palmoplantar keratoderma; verrucous lesions on the knees, elbows, buttocks, ankles & popliteal regions; follicular keratoses/keratosis pilaris; multiple pilosebaceous cysts (steatocysts) with onset at puberty distinguish this form from PC type 1 **Other:** oral leukokeratosis; hoarseness
Palmoplantar hyperkeratosis and alopecia	104100	AD	Short & dyst with onycholysis	Hypotrichosis to alopecia; abs of eyebrows & lashes; hypotrichosis of axillae & pubic regions	Normal	Normal	**Skin:** palmoplantar hyperkeratosis

(Continued)

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Papillon–Lefèvre syndrome	245000	AR	Occas dyst (spoon-shaped & striated; onychogryphosis)	Occas thin & loose	Periodontal degeneration with consequent shedding of all teeth	Palmoplantar hyperhidrosis; occas gen hypohidrosis	**Skin:** Hyperkeratosis of the palmar & plantar surfaces with a tendency towards fissuring & cracking; dry & dirty-appearing on the dorsal surface of the arms & the ventral surface of the legs; occas eczema & erythema of the face as well as of the sacral & gluteal regions **Other:** severe gingivostomatitis; occas intracranial calcifications; abn liver function; renal abnormalities; gen osteoporosis
Pili torti and developmental delay	261990	AR	Normal	Pili torti	Normal	Normal	Growth & developmental delay, mild to moderate neurological abnormalities
Pili torti and onychodysplasia (Beare type)	Beare [17]	AD	Short, fragile & brittle	Initially normal, followed by hypotrichosis on the scalp, axillary & pubic areas; pili torti	Normal	Normal	**Skin:** normal, dry or greasy; sl atrophy on the top of the scalp **Other:** low IQ; severe mental retardation; 'irresponsible personality'
Pili torti and onychodysplasia	Calzavara-Pinton *et al.* [18]	AD	Distal nail dystrophy	Pili torti of scalp, beard, pubic & axillary hair; absent eyebrows, eyelashes & body hair	Normal	Normal	
Pilodental dysplasia with refractive errors	262020	AR	Normal	Scalp hypotrichosis; pili annulati	Hypodontia, abnormally shaped teeth	Normal	Follicular hyperkeratosis of trunk & limbs & marked hyperopia
Poikiloderma with neutropenia (Navajo poikiloderma)	604173	AR	Thickened & dystrophic	Normal	Normal	Normal	**Skin:** eczematous rash at birth, becomes poikilodermatous over first 2 years of life **Other:** non-cyclical neutropenia, recurrent upper respiratory tract infections & chest infections Similarity to Rothmund–Thompson syndrome (see below) but no mutations in *RECQL4*
Polyposis, skin pigmentation, alopecia and fingernail changes (Cronkhite–Canada syndrome)	175500	?AD	Onychodystrophy	Alopecia	Normal	Normal	**Skin:** hyperpigmentation **Other:** cachexia; cataracts; xerostomia; glossitis; diminution of sense of taste; gastrointestinal hamartomatous polyps (stomach, small bowel, colon); gastrointestinal carcinoma; protein-losing enteropathy; malabsorption; haematochezia; clubbing of fingers; peripheral neuropathy; thromboembolism; hypocalcaemia; hypomagnesaemia; hypokalaemia

Rapp–Hodgkin syndrome	129400	AD?	Small narrow & dysplastic	Coarse & stiff on scalp; pili torti; abs or scarcity on scalp & body; sp eyebrows & lashes	Conically shaped; short, square incisors & canines; hypoplastic enamel; extensive caries; hypodontia	Hypohidrosis; lower number of sweat glands	**Skin:** dry & coarse; thickened over the extensor surface of the elbows & knees; hypoplastic dermatoglyphics **Face:** cleft lip; hypoplastic maxilla; mild frontal prominence; microstomia; mildly depressed nasal bridge; prom & malformed auricles **Other:** conductive loss (secondary to otitis media); chronic epiphora; corneal opacities; photophobia; atresia of puncta; ectropion; lacrimal papillae; short stature; occas syndactyly Absence of ankyloblepharon & severe erosive scalp dermatitis may distinguish Rapp–Hodgkin syndrome from AEC syndrome (see above)
Rothmund–Thomson syndrome	268400	AR	Frequently dyst	Hypotrichosis of scalp & body; eyebrows & lashes usually fall out during the first year of life & remain sp or abs	Hypodontia; microdontia; supernumerary teeth; pronounced caries; delayed eruption	Normal	**Skin:** poikiloderma including atrophy, irregular pigmentation & telangiectasias beginning during the first 3–6 months; palmoplantar hyperkeratosis; sensitivity to sunlight; initial rash is red, elevated with oedematous patches appearing symmetrically on the cheeks, hands, forearms & buttocks & subsequently on the trunk & lower limbs; after a few years dry, scaling & atrophic skin develops with areas of hyperpigmentation, hypopigmentation & telangiectasia **Other:** cataract, usually bilateral (onset 3–6 years); occas degenerative lesions of the cornea; small hands & feet; short terminal phalanges, syndactyly: abs of metacarpals, rudimentary ulna & radius; increased risk of osteosarcoma; short stature; occas mental retardation; hypogonadism; cryptorchidism; skull abnormalities; scoliosis
Sabinas brittle hair and mental deficiency syndrome (?same as those described elsewhere as the Pollitt syndrome, MIM #275550)	211390	AR	Dyst (splitting & cracking proximally)	Dry, brittle, coarse, wiry in texture; reduced eyebrows & lashes; abs of axillary & pubic hair	No data	Normal	**Skin:** scalp hyperkeratosis on exposed areas **Other:** pigmentary retinopathy; unilateral cong tortuosity of the retinal vessels; pale optic discs & hyperopic astigmatism; maxillary hypoplasia; mental retardation; delayed bone age

(Continued)

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Scalp–ear–nipple syndrome (Finlay–Marks syndrome)	181270	AD	Brittle fingernails	Congenitally denuded areas on scalp, sp axillary & secondary sexual hair	Widely spaced/ missing teeth	Reduced apocrine secretion	**Skin:** raised firm scalp nodules **Other:** small tragi; cupped & protruding ears; absent/rudimentary nipples; breast aplasia; partial third/fourth finger syndactyly
Schinzel–Giedion midface-retraction syndrome	269150	AR?	Narrow, deeply set, triangular & hyperconvex	Gen hypertrichosis	Delayed eruption	No data	**Skin:** abundant on the neck; hypoplastic nipples; hypoplastic dermal ridges; simian creases **Face:** saddle nose with depressed root & short bridge; high/protruding forehead; orbital hypertelorism; small/malformed auricles; anteverted nostrils; midface hypoplasia; facial haemangiomata **Limbs:** mesomelic brachymelia; hypoplasia of dist phalanges in hands & feet; short metacarpals of thumbs; talipes **Other:** severe mental retardation; growth retardation; abn EEG & seizures; spasticity; recurrent apnoeic spells; multiple Wormian bones; wide cranial sutures & fontanelles; broad ribs, broad cortex & increased density of long tubular bones & vertebrae, hypoplastic/aplastic pubic bones; choanal stenosis; short & broad neck; short penis with hypospadias
Schopf–Schulz–Passarge syndrome (cystic eyelids–palmoplantar keratosis–hypodontia–hypotrichosis)	224750	AR	Brittle with longitudinal & oblique furrows; onycholysis	Generalized hypotrichosis of scalp & body	Extensive hypodontia; persistence of deciduous teeth	Normal	**Skin:** palmoplantar keratosis; telangiectatic facial skin; papules; multiple tumours with follicular differentiation **Other:** bilateral early senile cataract; arteriosclerotic fundi; myopia; cysts of eyelids developing late
Sener syndrome (frontonasal dysplasia and dilated Virchow–Robin spaces)	606156	NK	Dystrophic nails	Thin hair	Hypodontia; dental occlusion; natal teeth	Normal	**Face:** hypertelorism with a wide mouth, long, smooth philtrum & small posteriorly rotated ears **Other:** multiple cystic areas within the white matter radiating from the ventricles into oval lobes with sparing of the basal ganglia, brainstem, & corpus callosum
Sensorineural hearing loss, enamel hypoplasia & nail defects (Heimler syndrome)	234580	AR	Beau's lines (toenails); leukonychia (fingernails)	Normal	Gen enamel hypoplasia	Normal	Sensorineural hearing loss

Skeletal anomalies–ectodermal dysplasia–growth and mental retardation	Schinzel [19]	NK	Hypoplastic toenails	Almost complete abs of body hair; a few curled hairs are present in the parieto-occipital & pubic regions	Normal	Normal	**Skin:** dry & hyperkeratotic with rhomboid type of scaling, esp on the lower legs; abs of flexion creases on thumbs; fifth fingers with single flexion creases **Face:** large, prom nose; upslanting palpebral fissures; short upper lip; large, poorly formed ears **Other:** microbrachycephaly; multiple uni- or bilateral fusion of vertebral bodies in the lower thoracic & upper lumbar regions; multiple limb abnormalities; syndactyly; bone fusions
Taurodontia, absent teeth, and sparse hair (?Same as Witkop syndrome 189500, see below)	272980	AR	Slow-growing nails; thin, spoon-shaped nails	Sparse hair; slow-growing hair	Congenital hypodontia; taurodontia	Normal	
Tetramelic deficiencies, ectodermal dysplasia, deformed ears, and other abnormalities (odontotrichomelic syndrome)	273400	AR	Hypoplastic?	Severe hypotrichosis of scalp & body	Hypodontia; microdontia; coniform teeth; persistence of deciduous teeth	Normal	**Skin:** thin, dry & shiny; an unusual number of wrinkles are formed when patients smile or grimace; dermatoglyphic disturbances; hypoplastic nipples; hypoplastic or abs areolae **Face:** protruding lips; enlarged nose; large, thin, prom & deformed auricles; incomplete right cleft lip in one patient **Other:** EEG abnormalities; growth retardation; extensive tetramelic deficiencies; metabolic abnormalities; ECG abnormalities
Thumb deformity and alopecia	188150	AD	Normal	Alopecia	Single central upper incisor	Normal	Hypoplastic thumbs; short stature; mental retardation; increased groin pigmentation with raindrop depigmentation
Trichodental dysplasia	601453	AD	Normal	Fine & lustreless appearance; relatively thin shafts with a sl beading effect; scanty or abs dist eyebrows & sp eyelashes	Hypodontia; peg-shaped teeth; retained deciduous teeth	No data	

(Continued)

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Trichodentoosseous syndrome	190320	AD	Flat, thickened, misshapen & striated; brittle	Dry, thick, tough with short curls, often straightens in childhood; balding may occur with age in men	Thin enamel; small, widely spaced teeth; teeth pits; taurodontism; periapical abscesses	Normal	**Face:** occas frontal bossing **Others:** occas clinodactyly; some of the calvarial sutures show evidence of premature fusion leading to mild to moderate dolichocephaly
Tricho-odonto-onychial dysplasia (tricho-odonto-onychial dysplasia with amastia)	129510	AR?	Variable degree of dystrophy of finger & toenails	Alopecia totalis; peripheral fringe of hair on the temporal & occipital regions, sp eyebrows & eyelashes	Enamel hypoplasia in both dentitions; secondary anodontia	Normal	**Skin:** increased number of pigmented naevi; supernumerary nipples; keratotic actinic lesions; crusts, ephelides in the scalp; mild palmoplantar hyperkeratosis; dermatoglyphic alterations **Other:** one patient had a mixed mild hearing deficit on the left; short stature
Tricho-odonto-onycho-dermal syndrome	Pinheiro *et al.* [20]	NK	Severely dyst or abs finger & toenails	Parieto-occipital hypotrichosis; aplasia cutis congenita; sp eyelashes; sp & irregular eyebrows	Hypodontia; persistence of deciduous teeth; enamel hypoplasia; delayed eruption	Normal	**Skin:** dry with hypochromic, atrophic & poikiloderma-like spots; irregular areolae; wrinkled back of hands; palmar keratosis; dermatoglyphic alterations; aplasia cutis congenita of the scalp **Face:** long philtrum; microstomia with thin lips; hyperpigmented eyelids & periorbital regions **Limbs:** bilateral clinodactyly; syndactyly; hypoplastic thumb; pronounced manus cava; hypoplastic dist & middle phalanges of both second fingers; abs middle phalanges of all toes **Other:** mild asymmetry of the skull; cong hypertrophy of the frenum linguae
Tricho-odonto-onychial dysplasia	275450	?AR	Dystrophic	Severe hypotrichosis	Enamel hypoplasia; secondary anodontia	Normal	**Skin:** supernumerary nipples; naevus pigmentosus **Other:** bone deficiency in the frontoparietal region
Tricho-onycho-dental (TOD) dysplasia	Koshiba *et al.* [21]	AD	Thin with longitudinal striations & cracks	Scanty, fine, curled; sp eyebrows & lashes	Taurodontic molars; hypoplastic–hypomature enamel; hypodontia	Hypohidrosis with hyperthermia	**Skin:** fine textured

Trichorhinophalangeal syndrome types I & III	190350 190351	AD	Occas thin, short, with long longitudinal grooves; flattened, koilonychia-like & normal in colour, racket thumbnails	Fine, usually blond & sp (esp in the fronto-temporal areas); sp or abs eyebrows	Occas supernumerary incisors; microdontia; poorly aligned	Normal	**Other:** pear-shaped nose; long & wide philtrum; large, prom ears; occas exotropia & photophobia; short stature; increased susceptibility to upper respiratory tract infections; narrow palate; scoliosis; lordosis or kyphosis; pectus carinatum **Limbs:** brachymesophalangy; brachymetacarpy; brachymetatarsy; peripheral dysostosis with type 12 cone-shaped epiphyses at some of the middle phalanges of the hands (the joints are thickened); ulnar & radial deviation of the fingers; occas clinodactyly; winged scapulae; coxa valga; Perthes-like abnormalities (Type III: severe brachydactyly, short metacarpals, severe short stature)
Trichorhinophalangeal syndrome type II (Langer–Giedion syndrome)	150230	AD	Occas thin, short, with long longitudinal grooves; flattened, koilonychia-like & normal in colour; racket thumbnails	Fine, usually blond & sp (esp in the fronto-temporal areas); sp or abs eyebrows	Occas supernumerary incisors; microdontia; poorly aligned	Normal	As above plus multiple cartilaginous exostoses; mental retardation is common
Trichorrhexis nodosa syndrome (Pollitt syndrome) (? same as Sabinas brittle hair and mental deficiency syndrome (211390))	275550	?AR	Hypoplastic nails; spoon-shaped nails	Trichorrhexis nodosa; short, woolly hair; stubby eyebrow hair	No data	Normal	**Skin:** ichthyotic skin, flexural eczema; photosensitivity **Other:** mental retardation; hypotonia; titubation; spastic diplegia; extensor plantar reflexes; absent deep tendon reflexes; partial agenesis of the corpus callosum; central nuclear cataracts; jerky ocular pursuit movements; growth retardation; microcephaly; receding chin; protruding ears
Ulnar mammary syndrome (Schinzel syndrome)	601621	AD	Normal	Sparse axillary hair; scant lateral eyebrows	Ectopic upper canines; hypodontia	Axillary apocrine gland hypoplasia	**Other:** delayed growth; obesity; subglottic stenosis; hypoplastic scapula; hypoplastic clavicle; breast hypoplasia; nipple hypoplasia; anal atresia or stenosis; pyloric stenosis; small penis; delayed puberty; shawl scrotum; imperforate hymen **Limbs:** hypoplastic/absent/deformed ulna; hypoplastic/absent/deformed radius; hypoplastic humerus; absent 3rd, 4th, & 5th ulnar rays; postaxial polydactyly; short fourth & fifth toes

(Continued)

Table 15.3 *Continued*

Name (alternative names)	MIM number/ primary ref.	Inh	Phenotypic characteristics				
			Nails	Hair	Teeth	Sweat glands	Other
Uncombable hair, retinal pigmentary dystrophy, dental anomalies, and brachydactyly (Bork syndrome)	191482	AD	Normal	Uncombable hair; congenital hypotrichosis	Oligodontia; supernumerary inferior lateral incisors; microdontia	Normal	Juvenile cataracts; retinal pigmentary dystrophy; brachymetacarpy; mild mental retardation
Walbaum–Dehane–Schlemmer syndrome	Walbaum *et al.* [22]	AR	Normal	Initially thin & blond; alopecia later; hypotrichosis of body	Hypodontia; supernumerary teeth; microdontia; malposition	Normal	**Skin:** abn dermatoglyphics **Face:** Swollen, with flat nasal bridge & enlarged tip of nose **Other:** Mild gingival hypertrophy; growth retardation
Weyer acrofacial dysostosis (? milder AD form of Ellis van Creveld, MIM 225500, see above)	193530	AD	Hypoplastic/ dysplastic	Normal	Incisors abnormal in shape & number; single central incisor; conical	Normal	**Other:** short stature; postaxial polydactyly; short limbs; acrofacial dysostosis; abnormal mandible; hypotelorism; prominent ear antihelices
Witkop syndrome (tooth and nail syndrome) (? same as taurodontia, absent teeth, and sparse hair 272980, see above)	189500	AD	Koilonychia; longitudinal ridging; nail pits, toenails more affected than fingernails	Normal	Partial or total anodontia	Normal	Lip eversion
Woolly hair, hypotrichosis, everted lower lip, and outstanding ears (Salamon syndrome)	278200	AR	Highly dyst; brittle; ungues plicatae; toenails more severely affected; onycholysis	Gen hypotrichosis of scalp & body; woolly hair	Extensive hypodontia (rudimentary permanent teeth); persistence of deciduous teeth	Normal	**Skin:** palmoplantar keratosis; telangiectatic facial skin; papules; multiple tumours with follicular differentiation **Other:** bilateral early senile cataract; arteriosclerotic fundi; myopia; eyelid cysts; everted lower lip; protruding ears
Xeroderma–talipes–enamel defect (XTE syndrome)	Moynahan [23]	NK	Deformed on fingers +/– toes	Coarse & dry; slow-growing; hypotrichosis; no lashes on lower lids	Poorly formed; yellow enamel	Hypohidrosis	**Skin:** gen dry, scaling with numerous bullae on face & limbs; scanty hair follicles **Other:** photophobia; hypoplasia of the ocular puncta leading to epiphora & blepharitis; EEG alterations; mild mental retardation; bilateral club foot; cleft palate
Zanier–Roubicek syndrome (? same as AD HED (129490), see above)	Zanier & Roubicek [24]	AD	Occas brittle	Hypotrichosis; normal eyebrows & lashes	Hypodontia; conical teeth; early loss of deciduous teeth	Hypohidrosis, often severe hyperthermia in infancy	**Skin:** smooth & dry **Other:** reduced lacrimation; normal or sl reduced stature; hypoplasia of the mammary glands

Abn: abnormal; abs: absence; AD: autosomal dominant; AR: autosomal recessive; CGS: contiguous gene syndrome; cong: congenital; dist: distally; dyst: dystrophic; esp: especially; gen: generally/generalized; horiz: horizontal; inh: inheritance; lt: light; malign: malignancy; NK: not known; occas: occasionally/occasional; MIM: Mendelian Inheritance in Man; prog: progressive; prom: prominent; prox: proximal; ref: reference; sl: slight; sp: sparse; vert: vertical; XL: X-linked.

conditions are now known to be allelic [27]. Prompted by the great advances in molecular knowledge, several authors have proposed new molecular-based approaches [28–30]. These proposed approaches classify conditions based on the class of molecule responsible for the disorder, for example categorizing together those with mutations in structural or developmental molecules. This approach has many advantages, especially for characterization of defects in preparation for molecular diagnostics and, hopefully, molecular therapy. These systems, however, need to be integrated with clinical findings and need to be accessible to all clinicians involved in the care of these patients. Importantly, it has to be realized that currently it is not possible to provide a molecular diagnosis for all patients, even in those with classical clinical features of conditions well characterized at a molecular level. Molecular factors, such as unusual mutation mechanisms, can frustrate conventional mutation identification as can health-care service delivery factors such as access to and affordability of molecular diagnostics; these and other confounders are likely to remain the case in the foreseeable future.

The following section reviews some of the commoner ectodermal dysplasias, considered by their genetic mechanisms, namely ectodermal dysplasias due to mutations in tumour necrosis factor (TNF)-like/NF-κB signalling pathways, the p63-related ectodermal dysplasias, ectodermal dysplasias due to other transcription factors and ectodermal dysplasias due to mutations in gap junction proteins.

Ectodermal dysplasias due to mutations in TNF-like/NF-κB signalling pathways

The transcription factor NF-κB regulates the expression of multiple genes with functions in controlling the immune and stress responses, cell adhesion, protection against apoptosis and inflammatory reactions [1,2]. NF-κB is composed of homo- or heterodimers of five proteins belonging to the Rel family. NF-κB is usually maintained in an inactive state within the cytoplasm by association with inhibitory proteins of the IκB family: IκBα, IκBβ and IκBε. IκB molecules are phosphorylated on two critical serine residues in response to multiple stimuli such as cytokines, various stress signals, and viral and bacterial infections. Phosphorylation at these sites enables recognition of IκB molecules by a ubiquitation complex. Following polyubiquitation, IκBs are degraded by proteasomes, thus releasing free NF-κB to enter the nucleus and activate target genes [3]. The kinase that phosphorylates IκB has been designated IκK (for IκB kinase) and has been shown to consist of two catalytic subunits (IκKα/IκK1 and IκKβ/IκK2) and a third component IκKγ (more usually known as NEMO) that provides a structural and regulatory function to the complex. Cell lines lacking NEMO are unable to activate NF-κB in response to most stimuli [4]. Extensive work with mouse models has confirmed the centrality of the NF-κB pathway in apoptosis, inflammatory and immune functions [5]. Complete absence of NF-κB leads to prenatal death due to massive TNF-induced liver apoptosis and more subtle knockouts that alter NF-κB activity all lead to immune defects. The NF-κB pathway has recently generated

much interest in the ectodermal dysplasias and defects at various levels have been identified in several EDs. In many cases these predominantly phenotype-driven, mouse–human comparison studies have yielded significant new insights into molecular pathways [1]. One of the best characterized pathways in NF-κB activation is the ectodysplasin pathway, an upstream activator. Since 1997, defects in this pathway have been demonstrated in the X-linked, autosomal dominant and recessive subtypes of hypohidrotic ED. Subsequently, mutations in downstream components have been shown to underlie familial incontinentia pigmenti and HED associated with immunodeficiency and/or osteopetrosis.

The X-linked HED gene, *EDA*, which maps to Xq12-13.1 and is also mutated in the mouse orthologue *tabby* [6], was first described in 1996 [7]. *EDA* encodes two isoforms of a trans-membrane protein, ectodysplasin-A, that has homology to the tumour necrosis factor (TNF) family. The extracellular domain of ectodysplasin-A has a collagen-like repeat and a furin cleavage site, unique in TNF proteins. Cleavage is necessary to enable solubility and functionality of EDA. The two longest isoforms, EDA-A1 and EDA-A2, bind to two different receptors: EDA-A1 binds to the EDAR protein and EDA-A2 binds to another X-linked receptor, XEDAR [8]. Mutations have been identified in all domains of ectodysplasin-A in patients with HED, and many of these mutations are thought to have an effect on solubility or cleavage of ectodysplasin-A, rendering it non-functional [9]. The physiological role of EDA in hair follicle morphogenesis was reinforced by the isolation of the gene for autosomal dominant/recessive HED. Patients with autosomal dominant or recessive HED are phenotypically identical to those with X-linked HED. The mutated gene, named *downless* (*DL*) after the mouse homologue, encodes a member of the tumour necrosis-factor receptor (TNFR) superfamily which functions as an ectodysplasin receptor (EDAR) [10]. Loss-of-function mutations throughout *dl* have been reported in autosomal recessive HED and dominant negative mutations have been reported in autosomal dominant HED within the death domain of this trans-membrane protein [11].

The EDA:EDAR pathway was further refined when the molecular basis of a third mouse homologue was identified. The *crinkled* mouse (*cr*) is a spontaneous mouse mutant with an identical phenotype to *downless* and *tabby*. Using positional cloning techniques, the causative gene was identified in an adapter protein (EDAR-associated death domain, termed EDARADD) for the EDA:EDAR complex [12]. The same group also identified mutations in a family with autosomal recessive HED [12]. The EDARADD interacts with the intracellular death domain of EDAR, linking it to downstream signals, leading to NFκB activation [12]. EDARADD associates with TRAF 1, 2 and 3. NFκB activation by the EDAR pathway is NEMO-dependent [13], and the relevance of this interaction to human ectodermal dysplasias became clarified when loss-of-function mutations were identified in the IKKγ gene (more usually known as *NEMO*) in incontinentia pigmenti [14]. This discovery was followed by identification of less critical mutations in *NEMO* in several male patients with an unusual phenotype of HED associated with immune deficiency (EDA–ID) [13,15]. Mutations in the coding region are associated with the EDA–ID phenotype and specific mutations in the stop codon of *NEMO* cause a more severe syndrome of osteoporosis and/or lymphoedema associated with EDA–ID [13].

Two other EDAR-related members of the TNFR superfamily, X-linked ectodysplasin-A2 receptor (XEDAR) [8] and TROY/TAJ [16,17] have been reported. Signals from each of these receptors were shown to activate NFκB, providing further candidate genes and candidate signalling systems for human HED. The TNFR-associated factor 6 *(TRAF-6)* is a cytoplasmic adapter protein that links signals from members of the TNFR superfamily to activation of transcription factors such as NFκB through IKK activation. TRAF-6 –/– mice display HED, revealing yet more complexity to these signalling systems [18]. It is likely that several of these genes will, in time, be shown to have relevance in human HED.

X-linked, autosomal dominant and recessive hypohidrotic ectodermal dysplasia

The phenotypic appearances of the X-linked (MIM 305100) and autosomal types (MIM 129490 and 224900) are identical.

Definition. X-linked HED is the most common of the ectodermal dysplasias and is characterized by hypotrichosis, hypodontia, hypohidrosis and distinctive facial features. Autosomal recessive HED is clinically identical to X-linked HED and females are as severely affected as males.

Pathology. The epidermis is thin with effacement of rete ridges. Affected males have absent or sparse eccrine glands and ducts [19,21]. Hair follicles and sebaceous glands are variably reduced in number [19–21]. Apocrine glands may be absent, sparse or even normal. Mucous glands of the upper respiratory tract may be sparse or absent [19]. Light and scanning electron microscope findings of hair shaft abnormalities are variable and include longitudinal clefts or grooves and transverse fissuring. The bulb of the hair shaft is dystrophic in some individuals [22]. Radiographs of the mandible reveal dental hypoplasia or aplasia [19,23].

Clinical features

Hair. Scalp hair is sparse, fine, lightly pigmented and grows slowly. Eyebrows are scanty or absent; occasionally just the outer two-thirds are missing. The eyelashes may be normal, sparse or completely absent. Secondary sexual hair in the beard, pubic and axillary regions is variably present and may be normal. Hair on the torso and extremities is usually absent [19,20,24,25]. Approximately 70% of obligate female carriers of X-linked HED describe their hair as being sparse or fine [24].

Teeth. A wide range of dental abnormalities may be associated, ranging from complete absence of teeth (anodontia) to sparse, abnormally shaped teeth. Studies reveal a mean of 24 missing teeth, out of a total of 28, in affected males [24,26]. Dentition is delayed and the erupted teeth tend to be small, widely spaced and frequently conical or peg-shaped (Fig. 15.13). Both deciduous and permanent teeth are affected. The alveolar ridges are hypoplastic, which gives rise to full, everted lips [23,27]. About 80% of obligate female carriers of X-linked HED have distinct dental abnormalities including absent permanent teeth and small or peg-shaped teeth [24].

Fig. 15.13 Conical teeth in X-linked hypohidrotic ectodermal dysplasia. (Courtesy of Professor J. Harper, Great Ormond Street Hospital, London, UK.)

Nails. The nails are normal in most individuals.

Sweat glands. Sweating is severely diminished or absent due to a paucity or absence of eccrine glands. An absence of sweating leads to an inability to thermoregulate by evaporative cooling, and hyperthermia can occur with physical exertion or in a warm environment. Due to a lower body surface area ratio, thermoregulation is most problematic in infants and young children who may experience recurrent bouts of fever as high as 42°C. Heat intolerance does occur in older children and adults, but is less problematic as they are better able to control their body temperature by drinking cold liquids, wetting their skin or clothing and seeking out cool surroundings [24]. Up to 25% of heterozygote females experience heat intolerance and almost half notice their ability to sweat is reduced [24]. The hypohidrotic areas of skin in carrier females of X-linked HED occur in defined linear patterns corresponding to the lines of Blaschko [28].

Skin. At birth, affected males may demonstrate marked scaling or peeling of their skin which may be mistaken for a collodion membrane [29]. In children and adults, the skin is fine, smooth and dry. Periorbital hyperpigmentation and fine wrinkling around the eyes are characteristic features of the disorder. Eczema is common and is prominent in flexural areas [25,30]. Small milia-like papules may be found on the face [21,31].

Other ectodermal structures. Diminished or absent salivary glands and mucous glands of the nose, mouth and ears cause numerous otolaryngological complications including nasal obstruction caused by thick, fetid nasal discharge and adherent nasal crusts, sinusitis, recurrent upper respiratory tract infections, feeding problems in infancy, xerostomia, hoarse voice and impacted cerumen [21,30–32]. Diminished production of tear film from the lacrimal glands may cause dry eyes, photophobia and corneal damage [31,33]. A third of affected males have abnormalities of the nipples including absent, simple or accessory nipples [24,34]. Female carriers may also be affected with marked breast asymmetry, inadequate breast milk production or absence of the breast (athelia). Both pituitary and adrenal insufficiency have been reported [31].

Craniofacial features. Affected patients have a distinctive facies with relative frontal bossing, concave midface, saddle nose and everted lips [19,21,23]. Around 30% of affected males have ears that are described as simple or satyr [24]. The distinctive facial features may not be obvious at birth, but become more noticeable with age. Carrier females may exhibit similar facial features.

Other clinical features. Diminished or absent mucous glands of the tracheal, bronchial, oesophageal, gastric and colonic mucosa cause problems with recurrent bronchitis, pneumonia, dysphagia and gastro-oesophageal reflux and constipation [24,29,31]. Reactive airways associated with wheezing is a common problem [24].

Prognosis. Failure to thrive occurs in up to 40% of affected males [24]. Height and weight are compromised in early childhood but appear to normalize with time. Mortality in infancy and early childhood is historically 25%, primarily due to hyperthermia, failure to thrive and respiratory infections [27], but these figures are likely to have greatly improved in recent years.

Differential diagnosis. Affected infants with scaling skin may be misdiagnosed as collodion babies with lamellar ichthyosis. Once the characteristic facies and lack of sweating are evident, there are very few disorders to consider in the differential diagnosis. HED with hypothyroidism displays hypohidrosis with hyperthermia and hypotrichosis, but the teeth are normal, the nails are significantly dystrophic and the skin has mottled-brown areas of pigmentation [35]. Fried tooth and nail syndrome manifests hypotrichosis, hypodontia and prominent everted lips, but the sweating is normal [35]. Basan syndrome is characterized by hypotrichosis, hypodontia and hypohidrosis, but also by severe nail dystrophy and congenital absence of dermatoglyphics [24]. For the purposes of genetic counselling and reproductive planning it is possible to perform DNA-based molecular genetic diagnosis in a large number of patients. This can help to conclusively distinguish between X-linked and autosomal forms where there is no family history to indicate the mode of inheritance.

Treatment. A multidisciplinary approach is best [35]. Early diagnosis facilitates avoidance of life-threatening complications in infancy and planning of long-term management. Accurate diagnosis enables informed genetic counselling for families [36]. Female carriers may be detected in most cases by careful clinical examination for patchy distribution of scalp and body hair, sweat pores and hypodontia [30]. DNA-based molecular diagnosis on affected families can detect female carriers of X-linked HED. DNA-based prenatal diagnosis is also possible in families at risk for the disorder, but it is not widely practised.

Prevention of hyperthermia is critical. This is done by avoiding heat and physical overexertion, cooling the body with wet clothing and cool drinks and by air-conditioning home and school environments. Early dental restoration with bonding, overdentures or implants is imperative [32,37,38]. Nasal crusting and

discharge can be managed with saline nose drops and a home humidifier. Consumption of large amounts of liquids or artificial saliva preparations minimize dry mouth and swallowing difficulties [39]. Dry eyes may be treated with artificial tears. The daily use of lubricating drops facilitates the removal of impacted ear wax. Pulmonary difficulties are managed by avoidance of smoky, dusty environments, adequate humidification, and the use of chest physiotherapy and antibiotics when appropriate [40].

Future treatments may involve gene correction or administration of recombinant EDA protein. Proof of principle has been achieved in a dog model for this approach [41].

Hypohidrotic ectodermal dysplasia with immunodeficiency (EDA–ID; MIM 300291); hypohidrotic ectodermal dysplasia with immunodeficiency, osteopetrosis and lymphoedema (EDA-ID-OP; MIM 300301)

The observation of unusually severe recurrent infections in a small subset of patients with otherwise typical HED features led to the suggestion that there may be a specific syndrome of HED and immunodeficiency (EDA–ID). The EDA–ID syndrome was first reported in a boy with miliary tuberculosis [42], and the second reported case had recurrent life-threatening infections caused by *Pseudomonas aeruginosa*, *Mycobacterium avium* and cytomegalovirus [43]. A third child had a milder phenotype with repeated infections due to *Staphylococcus aureus* and *Streptococcus pneumoniae* [44], and three further siblings from a different kindred had recurrent severe infections with *Streptococcus pneumoniae*, with impaired response to polysaccharide antigens [45]. All of these cases were in males, suggesting X-linked inheritance. Further cases have extended knowledge of the phenotype, and severe life-threatening or recurrent bacterial infections have been reported in the lower respiratory tract, skin, soft tissues, bones and gastrointestinal tract, as well as meningitis and septicaemia in early childhood. Overall, the causative pathogens have most often been Gram-positive bacteria (*S. pneumoniae* and *S. aureus*), followed by Gram-negative bacteria (*Pseudomonas* spp. and *Haemophilus influenzae*) and mycobacteria. Most patients have severe hypogammaglobulinaemia, with low serum IgG levels and varied levels of other immunoglobulin isotypes (IgA, IgM and IgE) [4]. Some patients have massively elevated IgM levels [13,15,46], and an impaired antibody response to polysaccharides is the most consistent feature of this condition [4]. Impaired NK cell activity is reported in some, but not all, patients with EDA–ID [47,48]; the degree and range of immunological abnormalities seen may relate to the type of *NEMO* mutation involved.

Familial incontinentia pigmenti (incontinentia pigmenti type 2; MIM 308300)

Please see Chapter 58 for a full discussion of this condition.

TP63-related phenotypes: overview of molecular pathway

The *p53* gene family is a key regulator of the cell cycle and is mutated in more than 50% of human cancers. *p63* and *p73* are related genes that share high amino acid identity with *p53* [1–5]. The role of p63 and p73 in human cancers has been extensively studied but neither molecule is felt to play a significant role in tumorigenesis. Both p63 and p73 are distinct from p53 in that they each have a C-terminal protein–protein interacting motif (sterile-alpha-motif; SAM domain) that is not present in p53. The *p63* and *p73* genes also differ from *p53* in that they each can encode several different isoforms by utilizing two different transcription initiation sites (for review see [6]). The expression of *p63* is more restricted than the ubiquitous nature of *p53* expression and is restricted to the embryonic ectoderm and the basal regenerative layers of epithelial tissues in adults (skin, cervix, tongue, oesophagus, mammary glands, prostate and urothelium) [5]. *p63* –/– mice die at birth and have truncation of limbs (especially the forelimbs, with complete absence of phalanges and carpals), and absence of ectodermal derivatives including the epidermis and appendages (whiskers, hair etc.), the prostate, lacrimal, breast and urothelial tissues [7,8]. Limb defects are best explained by a failure of the apical ectodermal ridge to develop [8].

Mutations in *p63* have now been identified in five distinct human phenotypes, all of which have ectodermal dysplasia as a key feature. Some genotype–phenotype correlation is possible in that there is clustering of mutations in some of the phenotypes to specific sites of the p63 molecule (for review see [6]). *p63* mutations account for most cases of ectrodactyly, ectodermal dysplasia, clefting syndrome (EEC syndrome). In an authoritative paper, van Bokhoven *et al.* [9] were able to demonstrate mutations in 40 out of 43 families with EEC; all but one of these mutations were sited within the DNA-binding domain, and five amino acid residues accounted for 75% of all mutations. In ankyloblepharon–ectodermal dysplasia–clefting syndrome (AEC syndrome, also known as Hay–Wells syndrome), where the limb abnormalities are absent or minimal, mutations have been exclusively detected within the SAM domain and are associated with complex gain-of-function as well as loss- and change-of-function effects [9]. In limb–mammary syndrome (LMS), *p63* frameshift mutations leading to truncations of p63 protein have been reported in exon 13 in two unrelated patients [9], and an N-terminal mutation in a further family [6]. Mutations in acro-dermato-ungual-tooth syndrome (ADULT syndrome) have yielded interesting insights in that the first mutation was identified in exon 3′, which is only expressed in the transactivating (TA) isotypes of p63 and causes an amino acid substitution outside the DNA binding domain [10]. A subsequent report has demonstrated a mutation that confers significant transactivation activity on ΔN-p63γ, an otherwise inert isoform of p63 [6]. Non-syndromic split-hand split-foot syndrome (SHFM) is a genetically heterogeneous group of conditions, but some cases (possibly around 10%) are attributable to *p63* mutations [9]. Some of these mutations seem specific for SHFM but others underlie both EEC and SHFM [6].

The clustering of mutations in specific sites observed in the TP63-related syndromes suggests that the mechanism is due to gain-of-function rather than loss-of-function [11]. Although clustering of mutations is determined in part by the characteristics of the mutated residue, whether it is a CpG site, etc., the degree of clustering in this group of conditions suggests that each condition has a specific pathogenetic mechanism. This site-specificity also presumably suggests that the p63 protein has several functions, each with a specific site within the molecule, and that each of these functions can be disturbed in isolation from the others.

Ankyloblepharon–ectodermal dysplasia–clefting syndrome (MIM 106260)

Synonym
- Hay–Wells syndrome

Definition. Ankyloblepharon–ectodermal dysplasia–clefting (AEC) syndrome is characterized by cleft lip/palate, severe scalp erosions and abnormalities of the epidermal appendages, including hypotrichosis, hypodontia, absent or dystrophic nails and mild hypohidrosis. One distinctive feature is ankyloblepharon filiforme adnatum—partial thickness fusion of the eyelid margins.

History. In 1976, Hay and Wells described seven patients from four families with an inherited disorder characterized by congenital filiform fusion of the eyelids, dysplasia of the epidermal appendages and cleft lip/palate. Five of these original seven patients had ankyloblepharon filiforme adnatum and one had small nodules removed from her eyelids as a child, presumably remnants of spontaneously lysed ankyloblepharon [12].

Pathology. Scanning electron microscopy of the affected hair shaft shows various defects including fractures of the cuticle and pili torti, none of which is specific for the disorder [13]. Skin biopsy of involved scalp tissue shows a thin granular layer and stratum corneum. Hair follicles are reduced in size and arrector pili muscles appear hypertrophic [14]. Sweat stimulation tests reveal a patchy loss of sweat glands over most of the body [12].

Clinical features

Hair. Scalp hair is wiry, coarse and sparse; alopecia is common. The eyebrows and eyelashes are short, brittle and sparse. Body, pubic and axillary hair may be sparse or absent [12,13,15].

Teeth. Hypodontia is common. Those teeth that are present are frequently small, conical and discoloured [12,13,15,16].

Nails. Nail abnormalities are variable, even within an individual, and include distal hypoplasia and thickened hyperconvex plates. Complete absence of nails is a frequent finding [12]. Chronic paronychia has been reported [13].

Sweat glands. Heat intolerance is described by a significant number of individuals, but hyperpyrexia is not a problem [15]. Sweat pores are reduced in number in affected individuals [12].

Skin. At birth, over three-quarters of affected newborns have red, eroded, peeling skin like a collodion membrane (Fig. 15.14) [15]. This resolves over the first few weeks and the underlying skin is dry (Fig. 15.15). Over two-thirds of individuals have chronic problems with severe, recurrent scalp erosions and scalp infections which are a major feature of AEC syndrome (Fig. 15.16) [15]. Palmoplantar keratoderma was reported in four of the original seven patients described by Hay and Wells [12]. It is not a common finding in affected children but may be more pronounced in adults.

Other ectodermal structures. Ankyloblepharon filiforme adnatum (strands of epithelial tissue between the eyelids) are a cardinal feature of the disorder but are noted in only 70% of patients (Fig. 15.17) [12,13,15]. The strands may lyse spontaneously and may be difficult to detect. Lacrimal duct atresia or obstruction occurs in over half of affected individuals [15]. Supernumerary nipples may be present [13,15].

Craniofacial features. Typical craniofacial features include a broadened nasal bridge and maxillary hypoplasia (Fig. 15.18) [17]. The ears may be small and low-set, with deformities of the auricle [15]. The ear canals may be webbed and abnormally shaped [13].

Fig. 15.14 Peeling, red, parchment-like skin in a newborn with AEC syndrome. (Courtesy of Dr V.P. Sybert, Seattle, WA, USA.)

Fig. 15.15 The parchment skin resolves over the first few weeks of life and the underlying skin is dry as seen in this 1-month-old baby with AEC syndrome. (Courtesy of Dr V.P. Sybert, Seattle, WA, USA.)

Cleft lip is a variable feature but cleft palate is seen in most individuals [12,13,15].

Other abnormalities. Other features seen occasionally in AEC syndrome include cutaneous syndactyly of the second and third toes, hypospadias and vaginal dryness and erosions [15].

Prognosis. Abnormalities of the external ear canals and palate frequently cause problems with chronic otitis media and secondary hearing loss. Atresia of the lacrimal duct can lead to epiphora,

Fig. 15.16 Severe scalp erosions and extensive granulation tissue in a 5-year-old girl with AEC syndrome. (Courtesy of Dr V.P. Sybert, Seattle, WA, USA.)

Fig. 15.17 Ankyloblepharon filiforme adnaturm (strands of epithelial tissue between the eyelids) in a newborn with AEC syndrome. (Courtesy of Dr V.P. Sybert, Seattle, WA, USA.)

chronic conjunctivitis and photophobia. Scalp erosions and chronic scalp infections may be severe enough to warrant surgical intervention with skin engraftment [15]. Prenatal diagnosis may be possible in affected families by ultrasound of cleft palate/lip [18].

Differential diagnosis. CHANDS is a rare autosomal recessive ectodermal dysplasia with curly, kinky hair, hypoplastic nails and the defining feature of ankyloblepharon. It can be distinguished from AEC by absence of cleft palate and lack of typical craniofacial

Fig. 15.18 The characteristic craniofacial features of a broad nasal bridge and maxillary hypoplasia are seen in this young girl with AEC syndrome. (Courtesy of Dr V.P. Sybert, Seattle, WA, USA.)

features [19,20]. In the newborn period, the eroded, peeling skin seen in AEC syndrome may be mistaken for epidermolysis bullosa [21].

Treatment. Emollients are appropriate for the collodion-like membrane in the newborn. Neonates with AEC often have extreme skin fragility and they should be handled with extreme care. Neonatal intensive care nursing protocols such as those used for neonates with epidermolysis bullosa should be used. The ankyloblepharon filiforme adnatum may require surgical correction or may lyse spontaneously. The lacrimal duct atresia may be surgically correctable [22]. The scalp requires aggressive wound care and treatment with topical or systemic antibiotics as warranted [15]. Other abnormalities such as cleft lip/palate, hypospadias and the maxillary hypoplasia may be surgically corrected [17]. Teeth preservation and restoration is imperative [16].

Ectrodactyly, ectodermal dysplasia, clefting syndrome (EEC syndrome; MIM 12990)

Definition. The main features of the EEC syndrome are ectrodactyly (split hand or foot deformity), cleft lip/palate, tear duct anomalies and abnormalities of the epidermal appendages including hypotrichosis, hypodontia, dystrophic nails and occasional hypohidrosis.

History. The association of ectrodactyly, cleft lip/palate and ectodermal dysplasia was initially described by Rüdiger *et al*. [23] who recognized this combination of defects represents a specific syndrome termed EEC syndrome. Over 150 cases have subsequently been described [14].

Pathology. Radiographs of hand or foot deformities show missing or hypoplastic metacarpals and metatarsals [24]. Scanning

electron microscopic studies of hair shafts of affected individuals show longitudinal grooves, distorted bulbs and cuticular defects [25,26]. These findings can be seen in a number of other ectodermal dysplasias and are not specific to EEC syndrome.

Clinical features

Hair. The scalp hair is fine and sparse, light-coloured and may be wiry in texture. Eyebrows and eyelashes are short, thin and sparse. Axillary, pubic and body hair may also be affected [23–25,27].

Teeth. Teeth may be small, abnormally shaped or missing [23–25,27]. Premature loss of secondary teeth is common, presumably due to multiple caries from enamel hypoplasia.

Nails. The nail plates may be dystrophic, hypoplastic or completely absent, even when there are no bony defects of the involved digit [27,28].

Sweat glands. Sweating is usually normal, but heat intolerance is noted by a few individuals [24,27,29].

Skin. Dry skin and hyperkeratosis, particularly of the legs, are reported in some individuals [30,31]. Scalp dermatitis is seen rarely [25,31].

Other ectodermal structures. Atresia or hypoplasia of the lacrimal duct are seen in over 90% of affected individuals [14,30,32]. Secretions from the lacrimal gland may be diminished [32]. Nipple anomalies are reported in a few individuals [30].

Craniofacial features. The nose may be broad, and the chin pointed, and there may be minor variable ear anomalies, but the facies are not distinct. Cleft palate, with or without cleft lip, occurs in three-quarters of affected individuals and is a major feature of this disorder [30]. Choanal atresia has been reported [33].

Other abnormalities. Ectrodactyly (lobster claw deformity) is a major feature of this disorder and occurs in over 90% of affected individuals (Fig. 15.19). About three-quarters of individuals with ectrodactyly have both hand and foot involvement [30]. Structural abnormalities of the genitourinary tract occur in about one-third of individuals; the most common structural finding is megaureter [34,35]. Abnormalities of the external genitalia have also been described [35]. Mental retardation is a variable and uncommon feature of the disorder, occurring in less than 10% of affected individuals [30], and may be limited to those with chromosomal deletions as part of a contiguous gene syndrome. Hearing loss occurs in about 15% of individuals [30]. It is uncertain whether this is primary or secondary to recurrent otitis media. Isolated growth hormone deficiency has been reported in one individual [36].

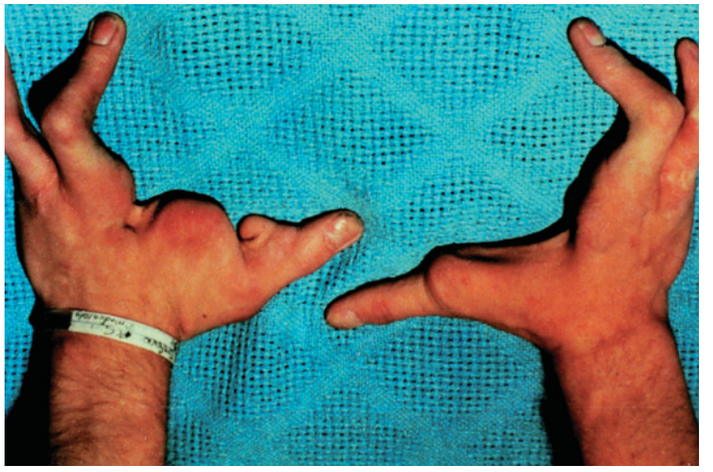

Fig. 15.19 Ectrodactyly of the hands in a young man with EEC syndrome. (Courtesy of Dr V.P. Sybert, Seattle, WA, USA.)

Prognosis. A significant number of affected individuals experience epiphora, conjunctivitis and blepharitis as a result of lacrimal duct hypoplasia. Photophobia, corneal ulcers and corneal scarring and perforation, may occur as a result of lacrimal gland hypoplasia [32]. Recurrent urinary tract infections, both symptomatic and asymptomatic, may be a problem in individuals with genitourinary anomalies [34].

Differential diagnosis. A few other ectodermal dysplasias manifest limb abnormalities and cleft palate/lip. Although clefting is not a constant feature, odentotrichomelic syndrome may be differentiated by severe tetramelic reductions and autosomal recessive mode of inheritance [14]. Other rare syndromes such as Martinez syndrome, Zlotogora–Ogur syndrome and Rosselli–Gulienetti syndrome can be differentiated from EEC by specific limb abnormalities and mode of inheritance (see Table 15.3).

Treatment. Treatment involves surgical correction of the cleft lip/palate, lacrimal duct, limb defects and genitourinary abnormalities, as indicated. DNA-based prenatal diagnosis is available for selected families where the gene defect is known.

Acro-dermato-ungual–tooth (ADULT syndrome; MIM 103285)

Acro-dermato-ungual–tooth syndrome is a rare condition distinguished from EEC syndrome by an absence of facial clefting. Patients have, in addition, excessive freckling and exfoliative dermatitis of the digits [37].

Limb mammary syndrome (LMS; MIM 603543)

This previously unrecognized autosomal dominant syndrome was reported in a Dutch family with a constellation of features that had not previously been reported. The major features were a combination of hand and foot anomalies and mammary gland aplasia/hypoplasia. The skin and hair were normal in all affected individuals, but some had lacrimal duct atresia, nail dysplasia, hypohidrosis, hypodontia or cleft palate [6]. LMS is distinguished from EEC syndrome by the consistent finding of mammary anomalies in LMS (infrequent in EEC) and the much more frequent finding of skin, nail and tooth anomalies in EEC syndrome. The clefting in LMS is of the palate only, whereas in EEC syndrome the lip and palate are affected [6].

Non-syndromic split hand–split foot syndrome (SHFM; MIM 183600)

This condition has no dermatological features and therefore is not discussed in detail here.

Defects in transcription factors other than p63

In addition to the p63 pathway, several other EDs have now been attributed to defects in transcription factors that control the expression of several target genes important in ectodermal morphogenesis. In many cases, positional cloning studies have yielded the primary mutation in a specific gene but the detailed molecular signalling pathways have yet to be delineated. Ellis van Creveld syndrome (EvC) is a recessive ED that is characterized by a skeletal dysplasia with short limbs, short ribs, postaxial polydactyly and congenital heart defects [38]. The gene has recently been identified [39] and the function, although not fully characterized, is most likely a transcription factor, given the hypothetical structural characteristics (nuclear localization, two DNA-binding domains, leucine-rich zipper domain). Witkop syndrome (MIM 189500) is an autosomal dominant ED with primary manifestation in the teeth (taurodontia, partial or complete anodontia) and nails (koilonychia, longitudinal ridging, and nail pits) [40]. Mutations have been identified in the *MSX1* gene, a member of the homeobox gene family and an important regulator of transcription [40].

Of the EDs more likely to be seen by a dermatologist, trichodentoosseous (TDO) syndrome and trichorhinophalangeal (TRPS) syndrome have both been attributed to mutations in transcription factors. The causative gene for TDO is *DLX3* [41], a homeodomain transcription factor that is developmentally expressed in many structures derived from epithelial–mesenchymal interactions, such as teeth, hair follicles and limb buds [42]. The *TRPS1* gene underlies TRPS types I and III [43], and a microdeletion syndrome (8q42.11 to 8q24.1), that includes *TRPS1* and *EXT1*, underlies TRPS type II [44,45]. Computer analysis of *TRPS1* suggests that it is a novel transcription factor with an unusual composition of nine putative zinc-finger motifs of four different types [46]. All of the mutations in *TRPS1* probably act as loss-of-function mutations, meaning that haploinsufficiency is the likely mechanism in TRPS.

TDO and TRPS are discussed in detail below.

Trichodentoosseus syndrome (MIM 190320)

Definition. TDO syndrome is a well-defined ectodermal dysplasia, with kinky hair, hypoplasia of tooth enamel and asymptomatic sclerotic bone changes.

History. Lichtenstein *et al.* [47] defined the features of this disorder in 107 individuals and proposed the name tricho-dento-osseous (TDO) syndrome. Robinson and Miller [48] were the first authors to describe this syndrome, but did not detect bone involvement as part of the disorder. Some authors argue that the clinical manifestations observed in some families are varied enough to suggest genetic heterogeneity, and they classify TDO syndrome into three subtypes differing from each other primarily by the degree of bone involvement [49,50]. Other authors consider that variable expression of a single gene seems a more plausible explanation [51].

Pathology. On dental radiographs, unerupted teeth and taurodontia (increased size of the tooth pulp chamber) are found [52]. Scanning electron microscopic analysis of affected teeth shows pits and depressions in the tooth enamel, uniformly thin tooth enamel, and an abnormal collagenous membrane around the open apices [53]. Radiographs of the skull reveal sclerosis and sometimes thickening of the calvarium. The long bones may also be sclerotic [51].

Clinical features [47,48,50,51,53]

Hair. At birth, the scalp hair is thick and kinky or curly; it may straighten in later life. The eyelashes may also be curly.

Teeth. Teeth abnormalities are present in all patients and include pitted, hypoplastic enamel with brownish-yellow discoloration of both primary and permanent teeth, and taurodontia. Tooth eruption may be delayed, and abscesses are common. Dental caries occurs and leads to early loss of teeth.

Nails. Fingernails are thin, brittle and peel readily. Toenails may be thickened or normal.

Sweat glands. Sweating abnormalities are not found in this disorder.

Skin. The skin is normal and other ectodermal structures are normal.

Craniofacial features. There is frontal bossing, the jaw is square and the head is elongated. Partial premature fusion of the cranial sutures occurs in three-quarters of affected individuals. The bones of the skull are radiographically dense and may be thick. This is not problematic for the patient and may be found incidentally when radiographs of the skull are obtained for unrelated reasons.

Other abnormalities. Clinodactyly is rarely seen.

Prognosis. Affected individuals are healthy, but lose most of their teeth by the age of 30 years [47].

Differential diagnosis. Curly hair and nail dysplasia is also seen in CHANDS syndrome (curly hair, ankyloblepharon and nail dysplasia), but ankyloblepharon makes this disorder distinct. Tooth and nail syndrome lacks kinky or curly hair.

Treatment. This includes appropriate dental restoration.

Trichorhinophalangeal syndrome type I (MIM 190350), type II (MIM 150230) and type III (MIM 190531)

Synonyms

- Langer–Giedion syndrome; MIM 150230
- Sugio–Kajii syndrome; MIM 190531

Definition. The trichorhinophalangeal syndrome (TRPS) is characterized by sparse scalp hair, bulbous, pear-shaped nose, small teeth with dental malocclusion, thin nails, cone-shaped epiphyses, short stature and occasional skeletal abnormalities.

Clinical features [54,55]

Hair. The hair is usually fine, blond and sparse; the most prominently affected areas are the fronto-temporal areas. The eyebrows are sparse or absent.

Teeth. Dental abnormalities are frequent, with supernumerary incisors, microdontia and poorly aligned teeth.

Nails. The nails are occasionally thin and short, with long longitudinal grooves. They can be flattened, koilonychia-like and normal in colour. 'Racket' thumbnails have been described.

Sweat glands and skin. There are no abnormalities of sweat glands or skin.

Other ectodermal structures. There is occasional exotropia and photophobia.

Craniofacial features. Many patients have a characteristic facies, with a pear-shaped nose, a long and wide philtrum, and large, prominent ears. A narrow palate is often noted.

Other features. Short stature is common, and a wide range of skeletal abnormalities have been described including brachymesophalangy, brachymetacarpy, brachymetatarsy and peripheral dysostosis, with type 12 cone-shaped epiphyses on some of the middle phalanges of the hands. Joints are often thickened, ulnar and radial deviation of the fingers is seen, and there are occasional abnormalities such as clinodactyly, winged scapulae and coxa valga. Perthes-like abnormalities have been reported in a few cases [56]. Chest wall deformities, such as pectus carinatum, lordosis or kyphoscoliosis are occasional features.

Type II TRPS shares many characteristics with types I and III, but is more significantly associated with mental retardation. In addition, there are multiple cutaneous exostoses and markedly redundant or loose skin, and more marked joint laxity. Type III TRPS differs from type I by the presence of severe brachydactyly, due to short metacarpals, and more severe short stature [57,58]. There is an emerging genotype–phenotype correlation in that mutations in the GATA DNA-binding zinc finger seem to predict a type III phenotype, whereas mutations elsewhere in *TRPS1* are associated with TRPS type I [59].

Defects in gap junction proteins

Gap junctions facilitate efficient cell–cell communication between all cells in multicellular organisms. This system facilitates a synchronized cellular response to a variety of intercellular signals by regulating the direct passage of low-molecular-weight metabolites (<1000 Da) and ions between the cytoplasm of adjacent cells [1]. In humans, gap junction channels are formed by a polygenic family of 20 different connexin proteins with a predicted molecular mass of 25–62 kDa. Six connexin units oligomerize to rosette-like hemichannels (connexons) that dock end-to-end with an opposing cell. Connexins are integral membrane proteins that couple with four α-helical transmembrane domains, two rigid extracellular domains that couple with those of a partner connexon, and three cytoplasmic portions of variable length and sequence that determine connexin specificity and selective channel properties. Gap junction channels may be composed of two similar hemichannels formed by the same type of connexin (homotypic) or two distinct hemichannels, each formed by a different connexin protein (heterotypic). In addition, each connexon could be assembled from different connexin subunits (heterotypic heterochannels). Each combination of connexins has different qualities of permeability and this is likely highly significant in terms of function. Most cell types express more than one type of connexin, but the skin and inner ear have a particularly high number of gap junctions and utilize up to 10 of the 20 different connexin proteins. In the skin, they appear to have a role in the coordination of keratinocyte growth and differentiation [2]. Connexins may be classified in three major groups (*GJA*, *GJB* and *GJC*) based on sequence homology. Mutations in connexins result in hereditary peripheral neuropathy, complex conotruncal heart malformations, autosomal dominant forms of cataract and hearing loss. The first connexin mutations associated with skin disease were identified in *GJB3*, encoding Cx31, leading to erythrokeratoderma variabilis [3]. Mutations associated with distinct skin phenotypes were subsequently identified in three additional connexins, *GJB3*, *GJB4* and *GJB6*, encoding the β connexins Cx26, Cx30.3 and Cx30, respectively [4,5]. Most of these connexins are also expressed in the inner ear, and the relationship between epidermal disease and deafness is complex—three out of the four autosomal dominant connexin mutations that are associated with epidermal disease are also associated with hearing loss.

In 1996, Clouston's syndrome was linked to chromosome 13q11-q12.1 [6], and subsequent studies have shown genetic homogeneity to this locus [7–9]. Mutations in *GJB6*, encoding the connexin Cx30, were identified in all available kindreds [10]. Several dominant-negative mutations have now been identified within the amino-terminus and transmembrane domains of Cx30. Mutations in *GJB6* had previously been identified in a small family with dominant non-syndromic hearing loss [11], emphasizing the complexity and diversity of phenotypes caused by dominant-acting connexin mutations. Several dominant-negative mutations have

been reported within the first extracellular loop and in the cytoplasmic aminoterminus of the closely related Cx26 in patients with the keratitis–ichthyosis–deafness (KID) syndrome [12]. A D50N mutation in Cx26 is particularly common. Mutations in Cx26 had previously been documented in patients with the mutilating keratoderma Vohwinkel's syndrome (see below). To emphasize the overlap in genotype–phenotype correlation in the connexin disorders, patients carrying identical mutations in Cx30 (V37E) have been shown to have classical Clouston's syndrome [13] and a KID syndrome-like phenotype. The role of connexins in ectodermal dysplasias was further expanded with the identification of mutations in the α connexin, *GJA1*, encoding Cx43 in oculodentodigital dysplasia [14].

Clouston's syndrome (MIM 129500)

Synonym
- Hidrotic ectodermal dysplasia

Definition. Hidrotic ectodermal dysplasia is an autosomal dominant ectodermal dysplasia defined by generalized hypotrichosis, dystrophic nails and hyperkeratosis of the palms and soles.

History. This distinct ectodermal dysplasia is named after Clouston, a doctor in Quebec, Canada, who defined much of what we know about the disorder [15,16]. Several reports describe a large kindred originally from France, who then migrated to Canada, the USA and Scotland [15–19]. Five generations of a large Malaysian-Chinese kindred have also been reported [20].

Pathology. Various abnormal physical properties of the hair shaft have been found, including low disulphide-bonded protein content, increased water content, altered birefringence in polarized light, reduced elastic modulus and reduced tensile strength. The hair shaft is abnormally shaped; it may be twisted, small, have longitudinal grooves and be square in cross-section. The pigment may be absent [21]. Cells of the cuticle are atrophic or even absent near the tips of the hair shafts, although relatively normal near the base. The cortex of the hair shaft is more fibrillar, coarse and disorganized compared with normal hair shafts [21]. Hair follicles in skin biopsies are reduced in number, and when present may appear dystrophic, with thickened connective tissue sheaths surrounding them [22]. Sebaceous glands are sparse and apocrine glands are sparse or absent. Eccrine glands are normal in number; in one affected individual, a single, rather than a double, layer of eccrine ductal cells was present [22]. Skin biopsy of the palmoplantar thickening shows acanthosis, orthohyperkeratosis and hypergranulosis [22].

Clinical features

Hair. Scalp hair is sparse, fine, brittle, pale in colour and slow growing (Fig. 15.20). Hair loss may become more pronounced over time and total alopecia can occur. The eyebrows and eyelashes are thin or absent. Body, pubic and axillary hair are also affected.

Teeth. The teeth are normal but caries is common.

Fig. 15.20 The scalp hair is sparse, fine and brittle in this woman with hidrotic ectodermal dysplasia. (Courtesy of Dr V.P. Sybert, Seattle, WA, USA.)

Fig. 15.21 The nail plates are thick, short and discolored in this individual with hidrotic ectodermal dysplasia. (Courtesy of Dr V.P. Sybert, Seattle, WA, USA.)

Nails. Nail dystrophy is characteristic of HED but can be variable. Generally, the nail plate is short, thick, slow growing and discolored (Fig. 15.21). The nail plate may be completely absent. Frequent infections of the nail folds can occur.

Sweat glands. Sweating is normal in affected individuals.

Skin. The skin tends to be dry and rough; it is unclear how this is related to the paucity of sebaceous glands described in some

Fig. 15.22 Diffuse palmoplantar hyperkeratosis is seen frequently in hidrotic ectodermal dysplasia. This individual exhibits mild plantar hyperkeratosis. (Courtesy of Dr V.P. Sybert, Seattle, WA, USA.)

affected individuals. Diffuse, stippled palmar and plantar hyperkeratosis is a frequent finding (Fig. 15.22), and can be severe. It may extend onto the dorsum of the hands and feet, and fissuring can occur. The skin may also be thickened over the knees, elbows, joints of the fingers and knuckles. Localized hyperpigmentation of the skin is a striking finding and may occur over the knuckles, elbows, axillae, areolae and bony prominences. In the original kindred, cutaneous carcinomas of the nail bed and palmar tissue were observed in several affected individuals [15,16].

Other ectodermal structures. Various eye abnormalities have been described, including conjunctivitis, strabismus and congenital cataract. In one family, five affected individuals developed bilateral premature cataracts [23]. Oral leukoplakia has been described in a number of families [24,25]. Diffuse eccrine poromatosis was reported in one patient [26]. Sensorineural hearing loss has rarely been reported.

Craniofacial features. There are no characteristic craniofacial features. Thickened skull bones have been described.

Other features. Tufting of the terminal phalanges was described in Clouston's original report [15].

Prognosis. The nail and skin dystrophies can become more pronounced over time. Physical development and life span are unaffected.

Differential diagnosis. Pachyonychia congenita shares the features of palmoplantar hyperkeratosis, oral leukoplakia and thickened, discolored nails, but the hair is usually normal and the teeth erupt prematurely [24,27]. Individuals with Coffin–Siris syndrome have sparse hair and absent or hypoplastic nails, most notably the fifth fingernail and toenail. They lack the palmoplantar hyperkeratosis, their facial features are characteristic and they have associated mental retardation [24].

Treatment. Nail ablation may sometimes be necessary, emollients for hyperkeratosis sometimes helpful and artificial hair pieces useful in some individuals.

Keratitis ichthyosis and deafness syndrome (MIM 242150)

Definition. The constellation of vascularizing keratitis, ichthyosiform hyperkeratosis and neurosensory deafness are the characteristic features of KID syndrome. This was probably first reported as early as 1915 [28], with the acronym being coined relatively recently in 1981 [29]. There is a broad clinical spectrum of manifestations.

Pathology. Biopsy of skin shows non-specific acanthosis with papillomatosis and basketweave hyperkeratosis. Hair follicles may be atrophic.

Clinical features

Hair. Alopecia occurs in 80% of patients, ranging from minimal loss of eyebrows or eyelashes to total scalp alopecia; in 25% of patients, the alopecia is congenital. An additional 17% of patients have sparse, fine hair without frank alopecia.

Teeth. No abnormalities.

Nails. Nails are dystrophic in the majority of patients.

Sweat glands. Sweating may be decreased or absent.

Skin. Patients with KID syndrome are usually born with erythematous or erythrokeratodermatous skin that is mildly scaling; in 7% of patients these skin features develop during the first 4 weeks of life [30]. The sharply demarcated, erythematous plaques are symmetrically distributed on the face and extremities. The characteristic thick, leathery skin with tiny stippled papules develops during the first year of life, particularly during the first 3 months. Well-defined, verrucous, hyperkeratotic plaques develop in 90% of patients, often localized to the face and limbs. Diffuse palmoplantar hyperkeratosis with a stippled or leathery pattern also occurs in almost all patients; occasionally, knuckle pads are noted. After puberty, follicular occlusion syndrome, occasionally with severe acne, may develop, accompanied by sinuses in the axillae, groins and perianal region.

Other ectodermal structures. Ophthalmological features are progressive, and most commonly develop in childhood or early adolescence, although photophobia from birth has been described. The keratoconjunctivitis sicca with corneal vascularization leads to pannus formation and markedly decreased visual acuity.

Craniofacial features. There are no characteristic cranioectodermal features.

Other features. The hearing loss is neurosensory, congenital and non-progressive. It can be detected in the neonate by brainstem-evoked auditory potential testing. Approximately 45%

of patients have recurrent infections, especially bacterial and candidal infections of the skin, auditory canals and eyes. Some patients have shown evidence of immunodeficiency, with moderate increases in IgE levels, defective chemotaxis, and absent lymphocyte proliferative responses to *Candida albicans* [31]. Squamous cell carcinoma of the skin and of the tongue have been described in more than 10% of patients, and may occur during childhood.

Prognosis. Ophthalmological manifestations are progressive. The hearing loss is generally not felt to change with time, but in this author's experience progressive hearing loss may occur. Vigilance is required for development of squamous carcinoma.

Differential diagnosis. The stippled palmoplantar keratoderma and alopecia are reminiscent of Clouston's syndrome.

Treatment. Therapy is supportive. Corneal transplants have been successfully performed to treat corneal vascularization. Cochlear implants [32] have been used to treat the hearing loss, but the sustainability of these in persons with such abnormally healing skin has yet to be proven. Oral fluconazole therapy of recalcitrant fungating candidiasis resulted in complete resolution and remission for at least a year [33].

Syndromes associated with DNA instability

Xeroderma pigmentosum (MIM 278700, 278720, 278730, 278740, 278750, 278760, 278780 and 610651)

Definition [1]. Xeroderma pigmentosum (XP) is a rare autosomal recessive disease characterized by photosensitivity, pigmentary changes, premature skin ageing, neoplasia and abnormal DNA repair. Some patients with XP also have neurological complications.

Aetiology. The initial report of this disorder was made by Hebra and Kaposi in 1874 [2], and the term 'xeroderma pigmentosum', meaning pigmented dry skin, was introduced in 1882 [3].

XP is found worldwide in all races, with an equal sex incidence. It occurs with a frequency of approximately 1 in 250 000 in Europe and the USA [4]. In Japan, the frequency has been reported to be higher (1 in 40 000) [5].

Inheritance is autosomal recessive; parents of affected individuals, who are thus obligate heterozygotes, are clinically normal. XP demonstrates considerable genetic heterogeneity; there are at least eight different subtypes recognized, designated complementation groups A–G and XP variant (Table 15.4).

Table 15.4 Nucleotide excision repair disorders. (Data compiled from published literature by A.R. Lehmann, Genome Damage and Stability Centre, University of Sussex, UK.)

Complementation group	Gene	Chromosome localization	Size of gene product (amino acids)	Activity	Comments
Xeroderma pigmentosum (XP)					
XP-A	*XPA*	9q22	273 (31 kDa)	Binds damaged DNA	Most common group; severe skin and neurological abnormalities
XP-B	*XPB*	2q21	782 (89 kDa)	Helicase; part of TFIIH	Rare; only three kindreds, two with XP/CS, one with TTD
XP-C	*XPC*	3p25	940 (106 kDa)	Damage recognition	Common; severe skin abnormalities
XP-D	*XPD*	19q13	760 (87 kDa)	Helicase; part of TFIIH	Common; severe + neurological abnormalities; also includes two cases of XP/CS and most cases of TTD
XP-E	*XPE*	11p12	427 (48 kDa)	Damaged DNA binding	Rare; mild features
XP-F	*XPF*	16p13	905 (103 kDa)	Nuclease subunit with ERCC1	Rare; fairly mild
XP-G	*XPG*	13q33	1196 (133 kDa)	Nuclease	Rare; severe + neurological abnormalities; half of cases have XP/CS
XP-V	*POLH*	6p21	713 (78 kDa)	Postreplication repair	20% of XP cases; mild skin abnormalities
*Cockayne syndrome (CS)**					
CS-A	*CSA*	5q12–q31	396 (44 kDa)	Transcription-coupled repair	Rare; milder features
CS-B	*CSB*	10q11	1493 (168 kDa)	Transcription-coupled repair	Common; more severe features
Trichothiodystrophy (TTD)					
Most TTD patients are in XP-D group, less commonly XP-B group. TTD-A group have mutations in *TFB5* subunit of TFIIH. Non-photosensitive TTDs have no repair defect but mutations in *TTDN1* gene.					

* CS also found rarely in combination with XP in XP-B, XP-D and XP-G groups.

Cleaver first reported in 1968 [6], and in subsequent studies [7–9], that fibroblasts from most patients with typical XP lack the normal capacity to repair UV radiation damage to DNA. In 1970, Epstein *et al.* [10] showed that DNA repair was defective *in vivo*. Approximately 80% of patients with XP show a defect in the initiation of DNA excision repair of UV photoproducts [11–13]. In these patients, repair replication is reduced in all cell types examined—epidermal cells, dermal fibroblasts, lymphocytes, conjunctival cells, corneal cells, liver cells, basal cell carcinoma cells and amniocytes [14,15].

The unscheduled DNA synthesis assay (following UV irradiation of cells in culture) is the standard laboratory method for diagnosis of XP [16]. The complementation group can be determined by using cell fusion techniques to identify the XP repair defect [17]. Cultured fibroblasts from two different patients with XP are fused so that their nuclei coexist in the same cytoplasm (forming a heterokaryon). If both nuclei have the same defect, then the heterokaryon shows defective DNA repair after UV irradiation and the patients are in the same complementation group. If the nuclei have different defects, then each will supply what the other is lacking and DNA repair within the heterokaryon will be normal. Seven distinct complementation groups are recognized in XP patients (A–G).

Nucleotide excision repair [18–19]. This process, whereby damaged DNA is removed and replaced with new DNA using the intact strand as a template, involves the products of some 30 genes [20]. The genes involved in nucleotide excision repair (NER) have now been cloned (Table 15.4). The excision repair cross-complementing (ERCC) genes are so called because of their ability to complement DNA repair in mutant rodent cells. The names of the XP genes have superseded those of the corresponding ERCC genes. The complete process of NER has now been reconstructed [21] (Fig. 15.23). The initial step in the process involves recognition of damaged DNA by the XP-C protein together with its partner HR23B [22]. This results in the recruitment of the dual function transcription factor TFIIH, composed of at least six subunits, including XP-B and XP-D proteins, which both have helicase activity. These helicases open out the structure at the site of DNA damage. The exact function of XP-A protein is not clear, but it seems to have a role in verifying the positions of the other proteins on the damaged structure, enabling the structure-specific nucleases to incise the DNA. ERCC1-XP-F and XP-G are both structure-specific nucleases, which cut the DNA on either side of the damage. The repair–synthesis step requires DNA polymerase ε (polε), the replication accessory factor proliferating-cell nuclear antigen (PCNA) and replication factor C (RFC); the new DNA is then joined to the old by DNA ligase. As well as these proteins, the incision reaction is stimulated by the product of the *XPE* gene, which is the smaller subunit of a dimeric protein that binds specifically to UV-irradiated DNA and is thought to assist in the early recognition of cyclobutane pyrimidine dimers.

Deficiency of NER is also associated with Cockayne's syndrome (CS) and trichothiodystrophy.

XP variant [23]. Twenty per cent of patients have XP variant, with normal NER but a defect in an alternative repair process, known as post-replication or daughter-strand repair. This manifests as a

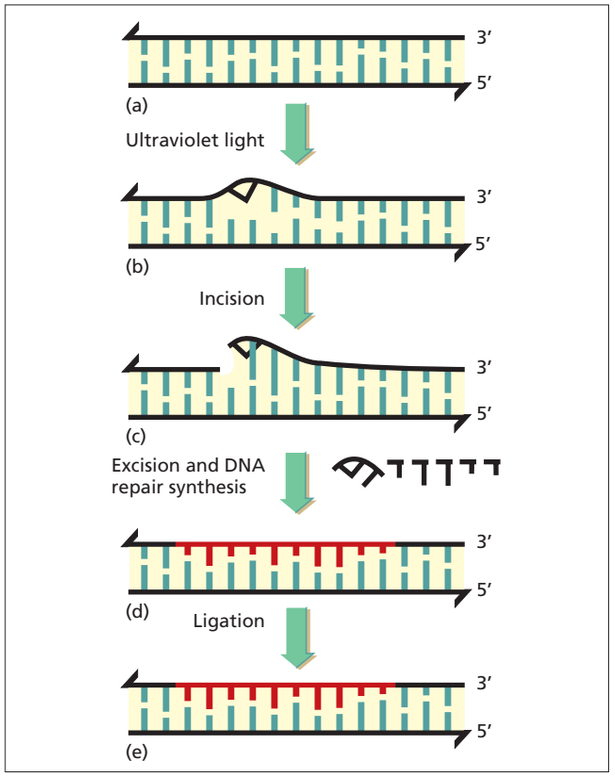

Fig. 15.23 Excision repair of pyrimidine dimers. Distortion in DNA double helix by pyrimidine dimer is located (b), the damaged strand excised (c), the dimer removed together with neighbouring nucleotides and the gap filled with new DNA (d); ligation (e) completes repair. (From Pawsey *et al.* [1].)

reduced molecular weight of newly synthesized DNA in UV-irradiated cells and a delay in the production of intact high-molecular-weight DNA strands following UV irradiation [24]. The genetic defect in XP variant is in *POHL* which encodes a DNA polymerase, designated polη, which is able to replicate DNA past UV-induced cyclobutane thymine dimers and some other types of DNA damage, in most cases inserting the 'correct' nucleotides opposite the damaged bases [25–27]. This property contrasts with that of the DNA polymerases that carry out normal DNA replication. These are extremely accurate, but are blocked by most types of DNA damage.

Clinical diversity. Despite substantial increases in our understanding of the genetic mechanisms underlying different forms of XP, the reasons for marked clinical variability have not been fully elucidated. Different subtypes of XP show clinical and epidemiological differences. Most patients are in group C, which is most common in Europe and the USA, and show no neurological defects. However, those in group A tend to develop neurological disease before the age of 7 years, and those in group D usually develop neurological problems after this age. There is evidence of genotype–phenotype correlation in some XP groups, with more severe phenotypes resulting from truncating mutations in critical domains of the relevant gene, whereas missense mutations in less critical regions tend to result in milder disease [28,29].

Skin photosensitivity. XP is very variable in expression of sun sensitivity and this is reflected in tests for light sensitivity. Some cases of typical XP show a papular and vesicular reaction, mainly to light in the 290–320 nm range [30]. The minimal erythema dose may be reduced or normal.

XP and neoplasia. Cultured dermal fibroblasts from XP patients exhibit increased UV-induced mutagenesis. The neoplasms in XP patients, which occur predominantly on sun-exposed surfaces, are thought to be the result of UV-induced mutations [16]. Indeed, skin tumours from XP patients carry mutations bearing a 'UV signature' in the *p53* and *PTCH* genes [31,32]. UV exposure also triggers a complex series of signal transduction pathways that result in immunosuppression of the skin, which may also be an important factor [33,34].

Pathology. The histological changes in the fully developed atrophic stage closely resemble those of senile skin. The epidermis is thin and flattened, and dermal collagen shows basophilic degeneration. Irregular proliferation of rete pegs, heavily laden with pigment, is a distinctive feature. The keratoses and the malignant tumours that ultimately complicate all but the mildest cases show no specific histological characteristics.

Electron microscopic studies [35] show shrinkage of keratinocytes and their nuclei, and abnormalities of nuclear morphology. Melanocytes are also abnormal, with polymorphic melanosomes, and there may be giant pigment granules in melanocytes or keratinocytes. There are also abnormalities of desmosomes, the endoplasmic reticulum and mitochondria. Dermal fibroblasts appear to behave like macrophages and engulf melanosomes within vacuoles. In hypopigmented macules the melanocytes are scanty, but Langerhans cells are numerous [36].

Clinical features [4,37] (Fig. 15.24). The skin is normal at birth; the first symptoms are noticed between the sixth month and the third year in over 75% of cases, but may appear in very early infancy or later childhood. Although the disease always advances through its successive stages, the rate of progression is unpredictable and bears no constant relationship to the age of onset. Most cases beginning in early childhood reach the tumour stage before the age of 20 years, although a few run a more benign course and some cases of later onset may develop multiple tumours within a few years.

Freckling and increasing dryness on light-exposed surfaces are usually the earliest manifestations; they may follow an acute sunburn or more persistent erythema. Freckles appear first on the face and hands and later on other exposed parts, the neck and lower legs, lips and conjunctivae; in severe cases the trunk is affected. Varying in colour from light to dark brown and in size from a pinpoint to a centimetre or more, they may fuse to form irregular patches of pigmentation. Fading at first in the winter months, they soon become permanent. As they increase progressively in number, telangiectases and small angiomas appear interspersed among them. Telangiectases and angiomas on unexposed skin and on the lingual and buccal mucous membranes have been reported. Small, round or irregular, white, atrophic macules also develop. Some follow crusted vesiculobullous lesions; others arise

Fig. 15.24 Xeroderma pigmentosum. (From Harper J. *Handbook of Paediatric Dermatology*, 2nd edn. Oxford: Butterworth-Heinemann, 1990.)

independently. Superficial ulcers, slow to heal, leave disfiguring scars, and on the eyelids may produce ectropion. Keratoacanthomas may form, even in the mildest cases, and resolve spontaneously in a few months. Actinic keratoses are frequent; they may resolve spontaneously or may undergo malignant change.

The first malignant tumours may develop as early as the third or fourth year, with a median age of onset of 8 years. Patients up to the age of 20 years have a 1000 times greater incidence of melanoma and non-melanoma skin cancers than the general population [38]. Basal cell carcinoma is common, and large numbers, sometimes pigmented, may appear over the course of years. Squamous cell carcinoma is also common and may arise on the anterior tongue, in the portion that may be exposed to UV radiation [38,39]. Melanomas may be multiple; they may lead to early death from widespread metastases or run a more benign course, even in adults, although histologically malignant. Other malignant tumours, such as angiosarcoma and fibrosarcoma, may rarely occur.

The disease is often fatal before the age of 10 years, and worldwide two-thirds die before 20 years of age. These statistics have improved in countries where children are adequately protected from the sun. Multiple metastases of squamous cell carcinoma or melanoma are one cause of death, but many patients die from infection, to which they are abnormally susceptible, or from neurological complications [40]. Survival beyond middle age is sometimes possible in mild cases or with adequate treatment. Striking interfamily variation in expectation of life has been reported.

Ocular lesions [4,37]. The eyes are affected in some 80% of cases. Photophobia and conjunctivitis are common early symptoms. Ectropion and destruction of the lower lids expose the bulbar conjunctiva, and symblepharon and ulceration may occur. Pigmented macules on the conjunctiva are common. Vascular pterygium, corneal opacities and epitheliomas of the lids, conjunctiva or cornea may also develop.

Neurological complications. Progressive neurological abnormalities occur in approximately 20% of XP patients [37,41], with one or more of the following: mental retardation, areflexia or hyporeflexia, spasticity, ataxia, sensorineural deafness, peripheral neuropathy, dysphasia and abnormal electroencephalographic findings. Patients with neurological abnormalities usually have group A or D XP, although a few have been reported with group C, group G or XP variant disease [37,41]. Neurological involvement is thought to arise from accumulation of DNA damage in the absence of adequate NER, ultimately leading to neuronal death. The severity of neurological disease depends on the complementation group and the failure of recovery of RNA synthesis in XP fibroblasts after UV irradiation, but does not necessarily correlate with the severity of skin disease [41].

De Sanctis–Cacchione syndrome [42]. This term has been applied to XP with severe, early onset neurological involvement and can arise in the context of several different complementation groups, but most notably complementation group A. It has also been described in siblings with a homozygous mutation in the CS gene, *CSB* [43]. Microcephaly, severe mental deficiency, dwarfism, hypogonadism, deafness, choreoathetosis and ataxia have been reported. Post-mortem findings show cerebral and olivopontocerebellar atrophy from neurone loss, without primary damage to white matter, or gliosis.

XP with CS. Rarely, CS can occur in combination with XP in XP-B [44], XP-D [45], and XP-G [46,47]. These patients have variability in clinical features and severity which are not fully understood, but generally, those with CS and XP-B have milder disease than those with XP-D and XP-G [48].

Autosomal dominant XP. An autosomal dominant form of XP has been described in two kindreds [49,50]. These patients had a mild clinical course and, in one family, there was reduced fibroblast DNA repair synthesis after UV exposure [50].

Diagnosis. In the fully developed case, the diagnosis of XP is unmistakable. Mild or early cases must be differentiated from ordinary freckling. Other forms of photosensitivity and premature ageing, including progeria, acrogeria, Rothmund–Thomson syndrome, Bloom's syndrome, CS, Hartnup syndrome and hydroa vacciniforme, must be excluded.

Prenatal diagnosis by assessment of UV-induced DNA repair synthesis from cultured amniocytes or chorionic villi is possible [51].

Treatment. As soon as the diagnosis is established, patients must be protected from sunlight by every possible means. They must not go outdoors during daylight hours, except in the early morning or evening, and even then they should wear two layers of clothing and a broad-brimmed hat. All uncovered skin surfaces must be

protected by a total sun-block cream, and sunglasses with side shields should be worn. UV radiation is harmful up to at least 320 nm, and some fluorescent lights can emit radiation below this wavelength. Chemical light screens can combine a cosmetic and protective function.

Early and adequate excision of all tumours is essential, and is to be preferred to radiotherapy because of the atrophic and degenerate state of the skin. Topical 5-fluorouracil may be useful for early or premalignant lesions. Chemical peeling and dermabrasion can also be helpful [52]. Plastic surgery and grafting of large areas of facial skin may sometimes be required [53]. Photodynamic therapy should not be used as the irradiation involved is likely to result in further skin damage and carcinogenesis [54].

There is now substantial evidence to suggest that oral retinoids reduce the occurrence of skin cancer in XP [55,56]. A trial of prophylactic therapy should therefore be considered.

The eyes may need to be treated with artificial tears, soft contact lenses or even corneal transplant. The relatives of known cases should be carefully examined and tested [30] so that mildly affected individuals may be detected at the earliest possible stage.

A clinical trial used the microbial enzyme T4 endonuclease V applied regularly as a topical liposome lotion. This enzyme is able to bypass the defect in XP cells. Employed over a period of 1 year, it significantly reduced the onset of both new basal cell carcinomas and actinic keratoses [57].

In vitro and *ex vivo* experiments have established that correction of the underlying genetic defect in different forms of XP is possible. Animal studies using viral vectors have also established that gene therapy approaches for patients with this disease should soon become possible [58,59].

Cockayne's syndrome (MIM 216400 and 133540)

Definition. An inherited syndrome characterized by short stature, mental retardation, photosensitivity, premature skin ageing, disproportionately large hands, feet and ears, ocular defects and extensive demyelination.

Aetiology [1]. In this rare autosomal recessive syndrome skin fibroblasts are abnormally sensitive to UV irradiation [2–4]. Unlike XP, the global NER process occurs normally in CS cells *in vivo* and *in vitro*. However, CS cells are defective in an important subpathway of NER. Following DNA damage, it is of prime importance for the cell to remove damage from actively transcribed regions of DNA, and in human cells repair is more rapid in transcribed than in untranscribed regions. This preferential repair is referred to as transcription-coupled repair, and it is this rapid preferential repair that is specifically defective in CS cells [5]. The associated failure of cells to restore normal levels of RNA synthesis after UV irradiation [6] has provided a means for carrying out complementation tests on CS cells, and two complementation groups have been identified, CS-A (accounting for approximately 20% of CS patients) and CS-B [7] (Table 15.4). The products of the two known CS genes, *CSA* (chromosome 5) and *CSB* (chromosome 10q11–q21), are envisaged to fulfil a transcription-coupled repair function [8]. CS can rarely be found in combination with XP (see p. 15.73).

Clinical features [9–11]. Although very early onset has been reported in a significant minority of cases, the child usually appears normal for the first year, when facial erythema in the butterfly distribution develops after exposure to sunlight. The sensitivity to light is eventually lost, but not before mottled pigmentation and atrophic scars have given the patient a prematurely senile appearance, which is enhanced by the progressive loss of subcutaneous fat on the face and the sunken eyes. The skin elsewhere shows little change. The ears tend to protrude, and hair is normal or sparse and has sometimes been prematurely grey. In contrast with XP, patients with CS do not have an increased incidence of skin cancer or infection [10].

Physical and mental development are greatly delayed and the child remains growth retarded. The limbs are disproportionately long, with large hands and feet that may be blue and cold. Skeletal deformities and flexion contractures of the limbs commonly develop [12]. Sexual maturation occurs in some cases [13]. Optic atrophy, retinal degeneration and cataracts [14] lead to loss of vision, and progressive deafness is usual but variable in degree. There is extensive, diffuse demyelination of the peripheral nerves and the central nervous system [10]. Survival beyond the second decade is unusual, although two affected brothers, aged 42 and 55 years, have been reported [15]. In general, CS-A is milder in clinical course than CS-B, but within each type no clear genotype–phenotype correlation has been established [16].

Diagnosis. Progeria has frequently caused confusion, as dwarfism and a prematurely senile appearance are characteristic of both syndromes, and in both the child appears normal in its first year. The light sensitivity, ocular defects, normal hair and disproportionately large extremities are typical of CS. In Rothmund–Thomson syndrome, the cutaneous changes begin in early infancy and affect the buttocks and extremities as well as the face. In Bloom's syndrome, the erythema of face and hands is associated with growth retardation, but mental development is normal. The condition is distinguished from XP by the unusual facies, the

demyelination with delayed nerve conduction velocity, the lack of cutaneous malignancy [10] and the normal level of global NER. Prenatal diagnosis is possible by amniocentesis [16–18] or from chorionic villus samples [19], using the RNA synthesis recovery test.

Bloom's syndrome (MIM 210900) [1]

Synonym
- Congenital telangiectatic erythema and stunted growth

Definition. The syndrome is characterized by photosensitivity, telangiectatic facial erythema, proportionate pre- and postnatal growth deficiency, distinctive facies, abnormal immune response and predisposition to malignancy.

Aetiology. Bloom's syndrome is a rare autosomal recessive disorder. Cultured lymphocytes and fibroblasts from patients show a high incidence of chromosomal aberrations and cells with abnormally high rates of sister-chromatid exchange (SCE) are uniquely characteristic of Bloom's syndrome [2,3]. The gene for Bloom's syndrome (*BLM*) has been mapped to chromosome 15q26.1 [4] and encodes a DNA helicase, RecQ protein-like-3 [5,6]. This helicase is thought to be involved in resolving abnormal structures that can arise during DNA replication, and may additionally be involved in transcriptional regulation [7]. Bloom's syndrome occurs with greater frequency in Ashkenazi Jews; a common ancestral mutation has been identified in most of these patients along with other founder mutations in patients from other geographical regions [8,9].

Clinical features [2,10–14]. Bloom's syndrome patients have a characteristic appearance. There is moderate and proportionate growth deficiency both *in utero* and postnatally. Patients have a narrow, slender, delicate facies with a relatively prominent nose. They may have mild microcephaly with dolichocephaly (the head is proportionately longer and narrower than expected). Telangiectatic erythema of the face develops during infancy or early childhood as red macules or plaques, which may simulate lupus erythematosus. They are most numerous on the 'butterfly' area of the nose and cheeks, but may involve the margins of the eyelids, the forehead and the ears, and sometimes the dorsa of hands and forearms. There may be slight scaling. Exacerbation after exposure to sunlight is usual but not invariable, and light may also provoke bullae, bleeding and crusting of the lips.

Other associated abnormalities include café-au-lait patches, clinodactyly, syndactyly, congenital heart disease, bronchiectasis, annular pancreas and a high-pitched voice, possibly due to the craniofacial anatomy and high-arched palate [12,15]. Many associated developmental defects have been reported.

Testicular atrophy is common and adult male patients are infertile. Although the tubular elements of the testes function poorly, the androgen-secreting portions are spared, thus permitting normal puberty [16]. Fertility in female patients appears reduced, although full-term pregnancies have been reported [17,18]. Bloom's syndrome patients have an increased incidence of type II diabetes mellitus [19]. Neurological development is normal.

The mortality from neoplastic disease, particularly acute leukaemia, during the second or third decade is significantly increased [3–5,20]. Cancers of the types and sites seen in the general population arise frequently and unusually early, as do rare malignancies of early childhood [20]. They are predominantly internal rather than cutaneous malignancies [14]. Reported associations include B-cell [21] and Hodgkin's lymphoma [13], and Wilms' tumour [22,23]. Ionizing radiation from cancer surveillance or treatment may predispose to further DNA damage and carcinogenesis in Bloom's syndrome patients and should therefore be minimized as much as possible [24]. There is no increased frequency of malignancies in heterozygote carriers of *BLM* mutations.

Prenatal testing for Bloom's syndrome has been successfully undertaken by SCE analysis in chorionic villus cell cultures [25].

Werner's syndrome (MIM 277700)

Definition. The syndrome is characterized by premature ageing with sclerodermatous skin changes, subcutaneous calcification, short stature, prematurely aged facies, premature arteriosclerosis, diabetes mellitus and a predisposition to malignancy.

Aetiology. Werner's syndrome is a rare autosomal recessive disorder caused by mutations in *WRN (RECQL2)*, a DNA helicase gene on 8p12–p11.2 [1–5]. There is an increased incidence of spontaneous chromosomal deletions and rearrangements in cultured cell lines from affected individuals [6,7]. The mechanism for DNA instability in Werner's syndrome appears to be due to replication-associated telomere loss that is greatly increased in the absence of WRN helicase activity [8]. Clinically normal heterozygous carriers of *WRN* mutations have also been shown to have increased genetic instability compared with normal controls [9,10]. Werner's syndrome occurs worldwide, but there appears to be a higher frequency of reported cases from Japan, where the incidence is estimated at approximately 3 per million [11,12].

Clinical features [11–13]. The cutaneous features of Werner's syndrome include sclerodermatous skin changes, particularly on the face and extremities, and subcutaneous calcification. The face has a prematurely aged appearance with beaking of the nose. Hair may be sparse and prematurely grey. Stature is short with slender limbs. Patients tend to develop early arteriosclerosis, diabetes mellitus, osteoporosis and hypogonadism, and are at risk of cataracts and retinal degeneration. Importantly, Werner's syndrome patients are predisposed to developing malignancies, in particular myeloid disorders, meningiomas, melanomas, thyroid cancers and osteosarcomas [12].

A subset of patients have been described with 'atypical' Werner's syndrome, in whom clinical features have been more severe. In this group, heterozygous mutations of the lamin A/C gene (*LMNA*) have been identified [14], and therefore this should probably be more correctly considered a milder, later onset variant of Hutchinson–Gilford progeria syndrome [15].

Poikilodermatous syndromes

Dyskeratosis congenita: X-linked recessive (MIM 305000), autosomal dominant (MIM 127550) and autosomal recessive (MIM 224230)

Definition. Dyskeratosis congenita (DKC) is a group of rare inherited disorders characterized by pigmentation and atrophy of the skin, nail dystrophy, leukoplakia, bone marrow failure and a predisposition to malignancy. Genes known to be mutated in this heterogeneous disorder have an important role in maintaining telomere length during cell division [1]. DKC therefore appears to be a disorder of telomere maintenance.

Aetiology. DKC is rare, but distributed worldwide. It was first described in 1906 by Zinsser [2], and later by Cole *et al.* [3] and Engmann [4]. X-linked recessive DKC is the most common form [5,6] although autosomal inheritance, both dominant [7–10] and recessive [11], is observed in other pedigrees. The clinical severity, somatic and haematological abnormalities, age at onset and age of death vary greatly in different individuals with DKC; in general terms, the X-linked recessive form is more severe than autosomally-inherited disease. In a significant number of families with DKC, the underlying genetic defect remains to be elucidated [1,11].

Telomeres consist of nucleotide repeats and a protein complex at the ends of chromosomes that are required to maintain integrity of the chromosomes. A number of different proteins are involved in telomere maintenance, including telomerase reverse transcriptase (encoded by *TERT*), its RNA component (*TERC*) and a number of proteins that form a complex known as shelterin that recognizes telomere DNA and telomeres from DNA repair pathways [12–14]. With every cell division, telomeres are shortened by loss of nucleotide repeats. If this shortening becomes critical, cells may undergo senescence with apoptosis, genetic instability or reduced potential for proliferation [15]. In DKC, the telomeres are greatly shortened (< 1st percentile), a phenomenon also observed in inherited and acquired haematological diseases such as some inherited bone marrow failure, aplastic anaemia and myelodysplasia [1]. The first mutations in patients with X-linked DKC were identified in 1998 by Heiss *et al.* [16] in the dyskerin gene, *DKC1*. Dyskerin is a component of H/ACA small nucleolar ribonucleoprotein (snoRNP) particles and is involved in modification of ribosomal RNA, and is also a component of the telomerase complex; one or both of these mechanisms may be affected by *DKC1* mutations in X-linked DKC [17,18]. Female carriers of X-linked DKC show skewed X-inactivation, suggesting that wild-type haematopoietic cells have a growth and survival advantage over cells carrying *DKC1* mutations [19]. More recently, mutations in *TERC*, *TERT* and *TINF2* (which encodes a component of shelterin) have been delineated in families with autosomal dominant DKC [10,20,21]. In addition, there is evidence of anticipation in families with *TERC* mutations, which has been attributed to progressive telomere shortening in successive generations [9]. *TERC* and *TERT* mutations have also been demonstrated in families with adult-onset aplastic anaemia and shortened telomeres but no other features of DKC [9,22–24].

Fig. 15.25 Dyskeratosis congenita: reticulate pigmentation on the neck.

Mutations in two other components of telomerase and snoRNP complexes, *NOP10* and *NHP2*, have been identified in a subset of patients with autosomal recessive DKC [11,25], although the causative molecular pathology in many other cases remains elusive.

Pathology. The cutaneous changes are not pathognomonic and are unimpressive. The epidermis is flattened; the dermis is vascular and contains pigment-laden macrophages and an inconstant lymphocytic infiltrate. The connective tissue is usually normal.

Clinical features [6,26–30]. The essential features of the syndrome are reticulate pigmentation and atrophy of the skin, nail dystrophy and mucosal leukoplakia. The nail changes are usually the first to appear. Between the ages of 5 and 13 years, the nails become dystrophic and are shed; they may be reduced to horny plugs or be completely destroyed. There may be recurrent episodes of suppurative paronychia.

The pigmentary changes may appear simultaneously or 2 or 3 years later, and reach their full development in 3–5 years. Fine, reticulate, grey–brown pigmentation is most conspicuous on the neck (Fig. 15.25) and thighs, but involves the greater part of the trunk. The skin is atrophic, and telangiectases may be sufficiently numerous to give a poikilodermatous appearance. The skin of the face is red and atrophic, with irregular macular pigmentation, and that of the dorsa of the hands and feet is diffusely atrophic, transparent and shiny. The palms and soles may be thickened and hyperhidrotic, and may form bullae with trauma. Premature cavities and cicatricial alopecia have occasionally been noted [28]. The teeth tend to be defective and irregularly implanted, and periodontal disease and early caries are usual.

The onset of the mucous membrane lesions may coincide with, or follow, the nail and skin changes. Small blisters and erosions of the lingual and buccal mucous membranes are succeeded by irregular patches of leukoplakia (Fig. 15.26). Similar changes on the tarsal conjunctiva may obliterate the lacrimal puncta, resulting in epiphora, and soreness and scarring of the lids. Anorectal, oesophageal or urethral leukoplakia may produce stenosis. Similar changes may occur throughout the gastrointestinal tract and on the urogenital mucous membranes. Pulmonary and hepatic fibro-

Fig. 15.26 Dyskeratosis congenita: the development of leukoplakia.

sis have also been described [10]. Interestingly, mutations in *TERC* and *TERT* have also been identified in some patients with isolated pulmonary fibrosis [31,32].

General physical and mental development is sometimes delayed, and osteoporosis may occur. Immunodeficiency, intrauterine growth retardation, microcephaly, cerebellar hypoplasia and intracranial calcification have also been reported, particularly in the Hoyeraal–Hreidarsson syndrome, a severe form of X-linked DKC [33]. Revesz syndrome is characterized by nail dystrophy, fine hair, cerebellar hypoplasia, exudative retinopathy, growth retardation and bone marrow hypoplasia [34]. Identification of a mutation in *TINF2* in an individual with Revesz syndrome supports it as a variant of DKC [21].

Malignancy. The incidence of carcinoma in the areas of leukoplakia appears to be high; it may prove fatal between the ages of 30 and 50 years. Carcinoma has also developed on other mucosal surfaces and in atrophic skin. Other neoplasms reported include pancreatic carcinoma and Hodgkin's disease. In a review of 104 cases [35], 12% had developed one or more tumours at the time of reporting (mean age of patients at reporting was 21 years).

Haematological abnormalities. The incidence of bone marrow failure in DKC is high: in one series, it arose in 93% of patients and pancytopenia was the cause of death in 71% [6]. The timing of onset is variable but the risk increases from age 10 years. Myelodysplasia and acute myeloid leukaemia have been reported in other patients. Bone marrow and stem cell transplantation have been undertaken in many patients over recent years, although short- and long-term complications occur with high frequency, particularly hepatic and pulmonary complications as a result of conditioning radiotherapy and chemotherapy [36–40].

Prognosis. The prognosis is usually poor, as either the blood dyscrasia or carcinoma may prove fatal. However, in some patients only nail dystrophy and pigmentation are present [41], and in such cases the expectation of life is normal.

Diagnosis. Because of the relatively late onset of the characteristic features of this syndrome, their relationship may be overlooked for some years and diagnosis delayed. It has often been confused with Rothmund–Thomson syndrome. In this, erythema of the face, buttocks and limbs in infancy is progressively succeeded by poikiloderma, nail changes are unusual, and leukoplakia does not occur. In anhidrotic ectodermal dysplasia the dental changes, distinctive facies, sparse or absent hair and normal nails provide points of differentiation.

Treatment. The aplastic anaemia associated with DKC can be successfully treated by allogeneic bone marrow transplantation; however, this approach does not reverse the other systemic manifestations of the syndrome [36–40]. Granulocyte colony-stimulating factor has been used successfully to improve haematological parameters in the short term [41].

Retinoids have been reported to cause regression of lesions in leukoplakia [42], and so may reduce the incidence of malignancy.

Rothmund–Thomson syndrome (MIM 268400)

Synonym
- Poikiloderma congenitale

Aetiology. Rothmund–Thomson syndrome (RTS) is a rare autosomal recessive disorder. The initial description by Rothmund [1] referred to children with cataracts and a peculiar degeneration of the skin. Thomson [2] described sisters with similar skin changes, and subsequently [3] labelled the disorder as 'poikiloderma congenitale'. Cataracts were not a feature of his cases. Taylor [4] reviewed the literature and proposed the eponym of Rothmund–Thomson syndrome. Kitao *et al.* [5] reported three patients with RTS who carried two types of compound heterozygous mutations in a DNA helicase gene, known as *RECQL4*, on chromosome 8q24.3. Subsequently, many more *RECQL4* mutations have been identified in individuals with RTS, although in around 40% of patients with this clinical diagnosis, no mutations have been identified, indicating a degree of genetic heterogeneity [6,7]. It has been suggested that patients can be classified depending on the presence or absence of *RECQL4* mutations: patients with RTS type I have poikiloderma and may have juvenile cataracts but the gene defect(s) has not been identified; in RTS type II, in which *RECQL4* mutations are found, patients have the typical poikiloderma and an increased risk of osteosarcoma [7]. Identification of *RECQL4* mutations in patients with a clinical diagnosis of RTS, therefore, may have implications for the need for ongoing surveillance for malignancy. Trisomy 8 mosaicism has also been described in some Rothmund–Thomson patients [8,9].

Mutations in *RECQL4* have also been identified in two other disorders which exhibit some clinical overlap with RTS. Firstly, Baller–Gerold syndrome (BGS) (MIM 218600), which is characterized by craniosynostosis and radial defects, and in which poikiloderma may be a feature. It has been proposed that the clinical and genetic similarities between RTS and BGS may indicate that these are a single entity [10]. Secondly, RAPADILINO syndrome (MIM 266280), which encompasses growth retardation, bony abnormalities, particularly radial defects, and an increased risk of certain malignancies, but no poikiloderma [11]. Genotype–phenotype correlation has been shown for a number of families with these disorders and *RECQL4* mutations [7].

The *RECQL4* protein is essential for the initiation of DNA replication and is necessary for efficient removal of UV-induced DNA damage [12]. Reduced DNA-repair capacity and increased sensitivity to UVC have been reported in individual patients with RTS [13,14].

Pathology [15]. In childhood, the histological changes are flattening and atrophy of the epidermis, with oedema of the dermal–epidermal junction. There may be some vasodilatation and perivascular lymphocytic infiltration in the dermis. In adults, exposed skin shows a combination of fragmentation of elastic tissue in the dermis and patchy Bowenoid dyskeratosis of the epidermis.

Clinical features [4,16–20]. The skin appears normal at birth. The earliest lesions usually develop between the third and sixth month, but sometimes as late as the second year. Plaques of erythema and oedema, or more transitory diffuse erythema, are succeeded by varying combinations of atrophy, telangiectasia, pigmentation and depigmentation. The pigmentation, dull brown in colour,

irregularly macular or reticulate, develops later than the atrophy and telangiectasia on which it is superimposed, although it may extend much beyond these areas, especially on the neck and trunk, where it may be the only change. On the face and hands telangiectasia predominates. Ultimately, the lesions closely resemble chronic radiodermatitis.

The cheeks are first and most severely involved, but the forehead, chin and ears seldom escape. The hands, forearms and lower legs are next affected, and the buttocks and thighs are frequently involved. Light sensitivity is a feature of many cases, and exposure to sunlight may extend the distribution of the eruption on the upper trunk; however, it is not limited to light-exposed skin, and the poikiloderma may develop without preceding erythema. Light sensitivity may be so severe that a bullous response is elicited, and although this tends to diminish after early childhood, it may persist into adult life [15,17].

Once they have reached their full development in early life, the skin lesions tend to remain unchanged, but in many cases keratoses develop on exposed skin from adolescence onwards, and large warty keratoses of hands, wrists, feet, ankles and elsewhere may restrict the patient's activities [21]. Squamous or basal cell carcinoma may develop in the keratoses or in the surrounding atrophic skin [22].

Scalp hair is often sparse and fine, and may be absent. Eyebrows and eyelashes, and pubic and axillary hair are often sparse or absent. Nails are normal or small and dystrophic. Teeth are often normal, but microdontia and early caries have been reported.

Bilateral cataracts have developed, usually between the fourth and seventh year, in 10–40% of reported cases, and are more frequent in some families than in others.

Physical development is frequently delayed; most patients are of proportionate small stature, with slender delicate limbs, small hands and feet, and short fingers. The skull may be small and the features bird-like, sometimes with a saddle nose. Hypogonadism of slight or severe degree is frequent, and the incidence of hyperparathyroidism appears also to be increased [23]. The association of RTS and Addison's disease has also been reported [24].

Skeletal abnormalities include radial ray defects [25], which may present as thumb hypoplasia with an abnormal radial head, or complete absence of the radius. There is a recognized risk of osteosarcoma, notably in patients with *RECQL4* mutations, especially in the bones of the lower leg, which can present in childhood [7,18,26–28]. In a series of 41 patients with RTS, Wang *et al.* [29] identified osteosarcoma in 32% (higher than previous estimates) and radial defects in 20% [29].

Other associations reported include myelodysplastic syndrome [30], malignant eccrine poroma [31], malignant fibrous histiocytoma [32] and annular pancreas with duodenal stenosis [33].

Individuals with Rothmund–Thomson syndrome are usually of normal intelligence. Life expectancy depends on the development of an associated malignancy; otherwise it appears to be normal.

Diagnosis. The essential features in differential diagnosis are the age of onset, the distribution of the lesions and the combination of atrophy, telangiectasia and mottled pigmentation, most intense on light-exposed skin but not necessarily confined to it.

In Werner's syndrome, the skin changes are essentially sclerodermatous, and both skin and ocular lesions develop later than in RTS. In DKC, reticulate pigmentation develops between the ages of 5 and 13 years, and is most marked on the neck, trunk and thighs. Atrophy and telangiectasia may appear later. The nail changes are constant and severe. In progeria, the child is often small but otherwise normal during the first year; thereafter, development is delayed. Scalp hair, eyebrows and eyelashes are lost and the skin assumes an increasingly senile appearance. In CS, light sensitivity is a conspicuous feature after the first year, but there is no poikiloderma. Hypohidrotic ectodermal dysplasia should be identified by the association, in variable combinations, of conical teeth, hypotrichosis and partial or complete anhidrosis. The skin is atrophic but not poikilodermatous. XP should not cause confusion: in mild forms, only freckle-like macules are present, whereas in mild forms of RTS, telangiectasia is the conspicuous feature. Telangiectasia, often irregular, linear and present at birth, is a feature of focal dermal hypoplasia. In Bloom's syndrome, erythema, and not poikiloderma, is the essential change.

Treatment. Protection against sunlight is important. Careful supervision is essential to ensure detection of malignancy. Baseline radiography of the long bones by the age of 5 years has been recommended, because underlying skeletal dysplasias can make X-ray interpretation difficult if there is later suspicion of osteosarcoma [29]. It is not known whether patients with RTS have increased sensitivity to chemotherapy and radiotherapy. Improvement of cutaneous changes has been described with retinoids [34]. Telangiectasia, especially on the face, can be improved significantly by treatment with the vascular pulsed dye laser [35].

Acrokeratotic poikiloderma of Weary (MIM 173700) [1]

Synonym
- Hereditary sclerosing poikiloderma

This syndrome, probably determined by an autosomal dominant gene, appears to be a distinct entity that has been described in a handful of families [1–3]. It is characterized by generalized poikiloderma with accentuation in the flexures and sparing of the face, scalp and ears, sclerosis of the palms and soles, linear hyperkeratosis and sclerosis of the flexures, and finger clubbing. Tissue calcinosis, Raynaud's phenomenon and cardiac abnormalities have also been described [1,3].

Kindler's syndrome (MIM 173650) [1]

Kindler's syndrome is an autosomal recessive disorder characterized by trauma-induced blistering, sun sensitivity, skin atrophy, poikiloderma and mucosal inflammation [1,2]. Although it is now considered to be a form of epidermolysis bullosa, it is clinically and pathologically distinct [3]. Loss-of-function mutations in the gene encoding fermitin family homologue 1 (kindlin 1) (*FERMT1*) on chromosome 20p12.3 have been identified in many affected families [2,4,5]. This is an actin cytoskeleton-associated protein which links the actin cytoskeleton to the extracellular matrix via focal adhesions, with a role in keratinocyte adhesion, migration and proliferation [2]. In the past there has been some confusion between Kindler's syndrome and acrokeratotic poikiloderma of Weary, although these are now considered distinct entities.

Pathology. Histopathology of poikilodermatous areas of skin shows hyperkeratosis, epidermal atophy, loss of rete ridges, dermal pigmentary incontinence, colloid bodies and blood vessel ectasia. Ultrastructurally, there may be reduplication of the lamina densa and clefts around the basement membrane zone, which may be at the level of the basal keratinocyte, within the lamina lucida, or beneath the lamina densa [6].

Clinical features. In neonates and infants, skin fragility and blistering are the most prominent findings, and the condition may be mistaken for other forms of epidermolysis bullosa [2,7]. The blistering tends to improve through childhood, as does the photosensitivity that is a feature in the majority of cases. There is progressive poikiloderma and atrophy, particularly on sun-exposed sites such as the dorsa of the hands and face [1,5,7]. Many patients have nail dystrophy and pseudosyndactyly of the digits. Periodontal disease with erosive gingivitis occurs early [4,8]. Oesophageal, anal, urethral and vaginal stenosis may occur, and an increased risk of squamous cell carcinoma of the skin or mucosae is also well recognized [9–11]. A number of patients have also had colitis and diarrhoea as a feature of their disease [12].

Differential diagnosis. In infancy, the main differential diagnosis is epidermolysis bullosa, although the development of photosensitivity and poikiloderma means that it should be possible to distinguish between these conditions. However, the presence of pseudosyndactyly, scarring, mucosal stenoses and mucocutaneous squamous cell carcinoma may overlap considerably with dystrophic epidermolysis bullosa. Later, Kindler's syndrome must be distinguished from other poikilodermatous conditions.

Treatment. The management of Kindler's syndrome centres around protection of the skin from mechanical trauma, as well as sun avoidance in view of the photosensitivity and predisposition

to skin cancer. Close attention should be paid to oral hygiene to minimize dental loss from periodontal disease. Mucosal strictures may require dilatation, although, generally, non-essential instrumentation should be avoided to minimize the risk of worsening stenoses.

Miscellaneous syndromes

Bazex–Dupré–Christol syndrome (MIM 301845)

Synonyms
- BDC syndrome
- Bazex syndrome
- Follicular atrophoderma and basal cell carcinomas

First described by Bazex *et al.* in 1964 [1,2], the mode of inheritance is now known to be X-linked dominant with evidence of linkage to Xq24–q27 [3]. This represents the identification of a gene presumed to be involved in hair follicle development and skin tumour formation. Several large family pedigrees have been studied [4–7]. The essential features are follicular atrophoderma, present from birth, and the development of multiple basal cell carcinomas of the face from adolescence onwards. In infancy and childhood, milia are often present. The follicular atrophoderma affects the dorsa of the hands and feet, and sometimes large areas on the extensor surfaces or lower back are affected. The exaggerated follicular funnels ('ice-pick' marks) are caused by deep and lax follicular ostia rather than a true atrophy. The basal cell carcinomas present as lightly-pigmented papules, which resemble melanocytic naevi.

Inconstant features include facial hypohidrosis with or without generalized hypohidrosis [8]; congenital hypotrichosis, which in males is diffuse and affects all scalp hairs, whereas females tend to have normal hairs intermingled with abnormal hairs; and hair-shaft abnormalities, such as pili torti and trichorrhexis nodosa [6,9]. Genital trichoepitheliomas and hidradenitis suppurativa have also been described [10]. There is some clinical overlap with Rombo syndrome, characterized by facial follicular atrophy, multiple milia and hypotrichosis. However, these cases also show erythema, telangiectases and dermal collagen or elastin abnormalities, and the inheritance pattern appears to be autosomal dominant [11,12]. Bazex–Dupré–Christol syndrome is easily distinguished from Gorlin's syndrome (see Chapter 52). It must not be confused with a completely different disorder, acrokeratosis paraneoplastica, a cutaneous marker of malignancy, that has also been labelled as Bazex syndrome [13].

Focal facial dermal dysplasia (MIM 136500)

Synonym
- Bitemporal aplasia cutis

The focal facial dermal dysplasias (FFDDs) are a genetically heterogeneous group of disorders characterized by congenital,

bitemporal, round, scar-like lesions with or without associated facial anomalies. Kowalski and Fenske [1] proposed a classification for this group of disorders: type 1, autosomal dominant; type 2, autosomal recessive; and type 3 with other facial features (Setleis syndrome). The genetic basis for the FFDDs is not clear, but it has been suggested that all forms represent a single autosomal dominant disorder with variable penetrance and expression [2].

Brauer [3] originally reported a large kindred with autosomal dominant inheritance. The facial lesions were described as scar-like and varied in size. Hair was absent in the lesions and no sweating could be demonstrated. Apart from the temporal defects, no other abnormalities were noted.

Setleis *et al.* [4] subsequently described five children from three apparently unrelated Puerto Rican families with scar-like defects on each temple and other features including an aged, leonine appearance, absent or multiple rows of eyelashes, eyebrows that slanted sharply upwards and outwards, puckered skin around the eyes, a scar-like median furrow on the chin and a rubbery nose and chin. Histology revealed a thin epidermis and dermis with little elastic tissue and an absence or scarcity of adnexae. Inheritance was assumed to be autosomal recessive.

McGeoch and Reed [5] documented 31 affected persons in six generations of an Australian family with pigmented atrophic lesions on the temples and linear radiating depressions on the forehead. In addition, clefting and hairless depressions on the chin were described. Autosomal dominant inheritance was clearly demonstrated.

A number of cases of FFDD have been described in whom the atrophic, round areas of skin, with or without a hair collar, were located on the cheeks and extended from the preauricular area towards the chin [1,6,7]. The position of these lesions has led to the suggestion that they may result from incomplete maxillary and mandibular ectodermal fusion during embryonic development.

Focal dermal hypoplasia (MIM 305600)

Synonyms
- Goltz syndrome
- Goltz–Gorlin syndrome

Definition and aetiology. Focal dermal hypoplasia (FDH) is a rare multisystem condition in which developmental defects of the skin are associated with ocular, dental and skeletal abnormalities. Over 200 cases have been reported, although the incidence is likely to be underestimated, as mildly affected subjects may go unrecognized. FDH is an X-linked dominant disorder, although rare male cases have been reported, as has father to daughter transmission, thought to reflect paternal X chromosome mosaicism [1–3]. The causative gene in this disorder has been identified as *PORCN* on chromosome Xp11.23 [4,5]. This is thought to encode an *O*-acyltransferase involved in Wnt signalling which is important in ectodermal–mesodermal development during embryogenesis. In a number of affected individuals, heterozygous deletions involving *PORCN* have been identified, whereas nonsense, missense and splice site mutations have been implicated in other patients [4–7]. Skewed X-inactivation has been observed in some patients with FDH, indicating a survival advantage for cells expressing the normal X chromosome over those carrying a *PORCN* mutation or deletion [3–5].

Pathology [8,9]. The foci of dermal hypoplasia show extreme reduction in thickness of the dermis, so that subcutaneous fat is situated almost immediately beneath the epidermis. There is debate about whether the defect is primarily an atrophy of the dermis, with secondary fat 'herniation', or a complex developmental abnormality of connective tissue causing both dermal hypoplasia and the development of fat hamartomas [10]. Wnt signalling is known to promote fibroblast proliferation [11] but also inhibit adipogenesis [12]. Inhibition of Wnt signalling pathways resulting from *PORCN* mutations might, therefore, favour mesodermal development of adipocytes in preference to dermal fibroblasts. Papillomatous lesions of FDH show markedly acanthotic epithelium overlying a core of vascular connective tissue.

Clinical features [6–8,13,14]. Findings vary from easily overlooked, mild skin atrophy to severe limb deformity and life-threatening complications. Skin involvement has been present in all but two of the reported cases [15] and is usually regarded as essential for the diagnosis. It remains possible that undiagnosed gene carriers occur with non-cutaneous features alone.

The typical skin lesions, which are present at birth, consist of asymmetrical linear streaks of atrophy and telangiectasia that follow Blaschko's lines. In racially pigmented skin, the lesions may be hypopigmented or hyperpigmented rather than erythematous. Soft reddish-yellow nodules represent the so-called 'fat herniations' (Fig. 15.27). Raspberry-like papillomas are common on the lips, perineum and at other sites, including the ears, fingers, toes, buccal mucosa and oesophagus [16]. Multiple giant papillomas have been reported [17]. In addition, generalized dryness of the skin and pruritus may be features. Nails may be absent or dystrophic. The hair is usually sparse and brittle, and there may be patchy alopecia of the scalp or pubic area. A case of FDH presenting as congenital localized alopecia has been reported [18]. Dental abnormalities are relatively frequently seen and include enamel hypoplasia, hypodontia, microdontia and irregular spacing of the teeth, with malocclusion [19].

Short stature and slender build are usual, and mental development is sometimes delayed. The facial features are characteristic: the skull is small and rounded, the chin is pointed and the facial

Fig. 15.27 Focal dermal hypoplasia: herniation at the site of skin atrophy.

outline is triangular, with protruding ears. The alae nasi may be asymmetrical and notched. The face, trunk and limbs may be asymmetrical. Other skeletal malformations include scoliosis, but most characteristic are syndactyly, polydactyly, ectrodactyly or absence of one or more digits. Facial clefting has also been described [20,21]. Ocular defects [16,22,23] are frequent and include microphthalmos, anophthalmos, coloboma, strabismus, keratoconus and corneal opacification. Intestinal malrotation and mediastinal dextroposition have been described in association with FDH [24].

On radiological examination, osteopathia striata, seen as fine, parallel, vertical, radio-opaque stripes in the metaphyses of the long bones, is found in a large proportion of cases [25,26]. This finding is not pathognomonic, but is present in approximately 20% of gene carriers and can be a useful feature, particularly if the condition is suspected in minimally affected subjects. Skeletal lesions, including giant cell tumours and osteochondromas, are also seen in some cases [27–29].

Diagnosis. The presence of the lesions from birth and the association of linear streaks of atrophy and telangiectasia with soft fatty nodules and malformations of the digits confirms the diagnosis. MIDAS syndrome (*mi*crophthalmia, *d*ermal *a*plasia and *s*clerocornea) has been reported as distinct from focal dermal hypoplasia [30,31].

Treatment. Patients with FDH often require reconstructive surgery for anatomical abnormalities. Intubation for general anaesthesia must be undertaken cautiously, as papillomas may be present in the upper respiratory tract [32].

Airway papillomas have been treated successfully with endoscopic laser treatment [33], and similar cutaneous lesions may respond to curettage and photodynamic therapy [34]. The telangiectatic skin lesions can be improved cosmetically with the vascular pulsed dye laser [35].

Nail–patella syndrome (MIM 161200)

Synonym
- Hereditary onycho-osteodysplasia (Hood) syndrome

First described by Turner in 1933 [1] and Aschner in 1934 [2], nail–patella syndrome was the first human disorder to be mapped by linkage [3]. Linkage to the ABO blood group was subsequently narrowed to an interval on chromosome 9q34.1 [4,5]. The condition shows autosomal dominant inheritance with variable expressivity but high penetrance. The causative gene, *LMX1B*, encodes an LIM-homeodomain protein, a presumed transcription factor with a role in dorsal/ventral limb patterning, and the development of the glomerular basement membrane, the anterior segment of the eye, and serotoninergic and dopaminergic neurones. Heterozygous loss-of-function mutations have been described in many families with nail–patella syndrome [6–10].

The syndrome combines nail and skeletal defects [10–14]. The nails are dystrophic in 95% of cases, either from birth or early childhood. The thumbnails are most severely involved and may be absent or small, thickened and depressed. Nails of other fingers, and sometimes of the toes, may also be affected. The lunulae are often triangular and may be the only nail change seen.

In only 20% of cases is there aplasia of the patella, but in another 70% there is subluxation of the patella. Other skeletal defects include the presence of posterior iliac horns [15,16], clavicular horns [17], dislocation of the radial heads, scoliosis and thickened scapulae [18–20].

Various renal abnormalities have been recorded, with glomerulonephritis seen most commonly, in 30–55%. It may remain asymptomatic for many years, although end-stage renal failure may occur [21–24]. In cases with glomerulonephritis, there is damage to the basement membrane, with deposition of C3 and IgM in the mesangium. Genotype–phenotype correlation for *LMX1B* mutations has been demonstrated: mutations within the homeodomain are associated with more frequent occurrence and greater levels of proteinuria compared with individuals with mutations in the LIM domains [10].

Hyperpigmentation of the pupillary margin of the iris (Lester iris) occurs in approximately half of all cases. Glaucoma and ocular hypertension may also occur [14,25].

Other features described in nail–patella syndrome include a 'glove and stocking' distribution of numbness or tingling, epilepsy, poor peripheral circulation [14] and sensorineural hearing loss [10]. Reduced bone mineral density compared with controls has been suggested to account for an increased risk of skeletal fractures and scoliosis [26].

Clubbing of the fingers and toes (MIM 119900)

Synonyms
- Hippocratic fingers
- Acropachy

Definition. Clubbing results from swelling of the soft tissues of the terminal phalanx of a digit that obliterates the angle between the base of the nail and the digit [1]. Hypertrophic osteoarthropathy (HOA) (see below) is often associated with clubbing, but can occur without it. In thyroid acropachy, clubbing is associated with thickening of the soft tissues of the hands and feet, and periosteal new bone formation occurs in the hands and feet rather than the long bones [2].

Aetiology. Clubbing may occur early as a hereditary defect in otherwise healthy individuals, or in association with underlying systemic disease. Autosomal inheritance with variable penetrance and expressivity has been proposed in familial cases [3,4], and there is suggestive evidence [5] that hereditary predisposition may play some part in the more common acquired forms. Recently, Tariq *et al.* [6] identified a homozygous missense mutation in the *HPGD* gene in a consanguineous family with isolated congenital clubbing. This gene, on chromosome 4q34–q35, encodes NAD^+ dependent 15-hydroxyprostaglandin dehydrogenase, an enzyme involved in the regulation of prostaglandin metabolism. Mutations in the same gene have also been identified in families with primary hypertrophic osteoarthropathy [7].

Acquired clubbing may be associated with pulmonary (empyema, lung abscess, cystic fibrosis, bronchial carcinoma, etc.), cardiovascular (cyanotic heart disease, subacute bacterial endocarditis, atrial myxoma, etc.), gastrointestinal (inflammatory bowel disease, coeliac disease, etc.) or metabolic (thyroid acropachy, Grave's disease) disease [8–10].

Pathology and pathogenesis. Increased fibrous tissue separates the nail from the phalanx, and there may be perivascular lymphocytic infiltration. The bone is not usually affected, but spurs of bone may occasionally form on the terminal phalanx. Many studies have shown that the blood flow to clubbed fingers is increased, except in hereditary clubbing [10]. The flow returns to normal if the clubbing improves after elimination of the underlying pathology. It is possible that the increased blood flow travels through the central Suquet–Hoyer canals of the digital arteriovenous anastomoses. There is at present no single satisfactory theory to account for the hyperaemia and soft-tissue overgrowth, and there may be several mechanisms. Identification of *HPGD* mutations in isolated clubbing and primary hypertrophic osteoarthropathy may support a role of prostaglandins in the aetiology of clubbing [6,7], although other vasodilators have been proposed, including ferritin [10], bradykinin and serotonin [11]. Tissue hypoxia [10] and neural factors [6] have also been suggested.

Clinical features [1,5]. The normal nail projects from the digit at an obtuse angle of about 160°, most clearly seen on the thumbs. In clubbing, this angle is obliterated, and sometimes reversed. The nail plate usually shows increased curvature in one or both planes and the volume of the distal phalanx may be increased.

In hereditary clubbing, these changes may be congenital [6,12] or begin gradually at, or soon after, puberty. They commonly involve all fingers and toes, particularly the thumbs, although occasionally some digits may be spared. In acquired clubbing, the onset is usually insidious and may occur at any age, but even in severe cyanotic congenital heart disease it is seldom noticeable before the second year. It may be bilateral or unilateral, or may affect only one or two digits. In malignant pulmonary disease, the onset may be rapid and painful.

Diagnosis. The distinction between hereditary and acquired clubbing may be of great clinical significance, as clubbing may precede any other evidence of pulmonary neoplasm by many months. Hypertrophic osteoarthropathy always shows bone and often joint changes, and clubbing is merely one feature of the syndrome. Familial osteoarthropathy [13], a manifestation of avascular necrosis of phalangeal epiphyses, presents before puberty as enlargement and impaired mobility of interphalangeal joints.

Pseudoclubbing may be produced by shortening of the fingernail, which accompanies osteolysis of the terminal phalanges, such as has occurred in workers engaged in the polymerization of vinyl chloride [14].

Unilateral or unidigital clubbing is usually due to a vascular abnormality, such as an aneurysm in the affected limb. Unilateral clubbing can also be caused by neural damage, for example a Pancoast tumour, or prolonged hemiplegia.

Treatment. The secondary form may show some regression if the provocative disease is treated [15].

Pachydermoperiostosis (MIM 167100, 1259100)

(see also Chapters 45 & 62)

Synonym
- Hypertrophic osteoarthropathy

Definition and terminology. Pachydermoperiostosis is a syndrome characterized by hypertrophic changes involving predominantly the skin and bones of the extremities. The term 'cutis verticis gyrata' describes a folded hyperplasia of the scalp that may accompany pachydermoperiostosis but also has other causes.

Aetiology [1–4]. *Primary pachydermoperiostosis* (synonym Touraine–Solente–Golé syndrome) is a rare inherited disorder that has been reported in many ethnic groups and which occurs predominantly in males. In some families, autosomal dominant inheritance with incomplete penetrance and variable expressivity has been proposed [3]. In other families, however, autosomal recessive inheritance has been demonstrated [3,4], and mutations in the *HPGD* gene, encoding NAD^+ dependent 15-hydroxyprostaglandin dehydrogenase, have been identified [4]. Affected individuals with homozygous truncating mutations of *HPGD* have been found to have greatly increased levels of urinary prostaglandin E2; a number of these patients also had a persistent patent ductus arteriosus, presumed secondary to the elevated prostaglandin levels [4]. Heterozygous carriers of *HPGD* mutations may have mild clubbing of the digits [4].

Cranio-osteoarthropathy shares some features with primary pachydermoperiostosis, namely clubbing and hypertrophic osteoarthropathy, but patients do not have pachydermia. They typically present earlier in childhood and have delayed neurocranial ossification, with delayed closure of the fontanelles, and may also have congenital heart disease. The overlap of clinical features suggests that primary pachydermoperiostosis and cranio-osteoarthropathy are allelic in some cases, and this has been confirmed by the identification of homozygous missense mutations in *HPGD* in two families with the latter condition [4].

Secondary pachydermoperiostosis (synonym secondary hypertrophic osteoarthropathy) is usually provoked by severe pulmonary disease, adenocarcinoma or epidermoid carcinoma of the bronchus, pleural mesothelioma, bronchiectasis, lung abscess or, less often, carcinoma of the stomach, oesophagus or thymus. In cyanotic congenital heart disease with clubbing, bone changes rarely develop.

Pathology [2,5]. Proliferative periostitis of the leg bones, especially in the diaphyses of the tibia, fibula, radius and ulna, leads to diffuse irregular periosteal ossification, increasing the circumference of affected bones without increasing their length. In severe cases, almost all bones may be involved, and ligaments, tendons and interosseous membranes may ossify. Abnormal ossification of the skull has been reported [6]. In the early stages, but not the later stages, there is increased blood flow to the clubbed fingers [7,8]. The skin shows hypertrophy of collagen and of epidermis and epidermal appendages, and an increase of acid mucopolysaccharide.

Clinical features [3,4,9–12]. Primary pachydermoperiostosis usually begins soon after puberty. The skin of the face, forehead and scalp becomes grossly thickened and thrown into folds. The folding of the scalp produces one of the forms of cutis verticis gyrata. The skin of the hands and feet is also thickened, but usually not folded. Seborrhoea of the face and scalp, and hyperhidrosis of hands and feet may be troublesome.

Thickening of the phalanges and of the bones of the limbs produces spade-like hands and feet with increased circumference of arms and legs. The fingers and toes are clubbed. Acro-osteolysis of the fingers and toes may occasionally occur [8].

Skin and bone changes become progressively more severe for 5–10 years and then usually remain unchanged throughout life; exceptionally, they may continue to progress and the degree of sebaceous hyperplasia may become extreme. Sparse facial and pubic hair and gynaecomastia are present in some cases, but evidence of endocrine disturbance is equivocal. Many patients have learning difficulties, which may be profound. Expectation of life is reduced in such patients, although reliable figures for the less severely affected are not available. Cranio-osteoarthropathy is characterized by clubbing, hypertrophic osteoarthropathy, delayed cranial ossification and closure of the fontanelles, and, in some cases, congenital heart disease, but not by the skin changes seen in primary pachydermoperiostosis [12–14]. These changes usually start early in childhood.

Secondary pachydermoperiostosis occurs predominantly in men aged 30–70 years. The bone changes are the most obvious feature, develop more rapidly, and are often painful. The skin changes may be absent and are often relatively mild. If the primary disease can be treated effectively, the bone and skin changes will regress.

Radiological changes. The greatest periosteal thickening is seen in the diaphyses of metatarsals and metacarpals and the long bones of the limbs. There is some thickening of the cortex (Fig. 15.28).

Diagnosis. The primary and secondary forms of pachydermoperiostosis must be differentiated by the age of onset, the rate of progression and the presence of underlying pulmonary pathol-

Fig. 15.28 Pachydermoperiostosis: radiograph of the ankle. (Courtesy of the late Dr J. Savin, Edinburgh, UK.)

ogy. Although skin changes are more frequent in the primary form, their presence does not exclude a tumour.

In acromegaly, the facial skeleton, jaw and skull as a whole are enlarged, and visual defects may be detectable. In thyroid acropachy, enlargement is confined to hands and feet, and exophthalmos and pretibial myxoedema are often present, with other signs of hyperthyroidism.

Cutis verticis gyrata

This condition is characterized by convoluted ridges and folds of skin affecting the scalp. It may occur as a primary condition, either in isolation (rarely) or in association with other abnormalities, notably impaired cognition and learning difficulties, cerebral palsy, schizophrenia, microcephaly, deafness, cataracts, retinitis pigmentosa and strabismus. Cutis verticis gyrata may also be secondary to a number of other diseases including cerebriform intradermal naevi, cylindromas, neurofibromatosis, dermatofibromas, connective tissue naevi, acromegaly, inflammatory conditions of the scalp, Noonan's and Turner's syndrome, and acanthosis nigricans.

Acromegaloid phenotype with cutis verticis gyrata and corneal leukoma (MIM 102100) [1]

Synonym
- Rosenthal–Kloepfer syndrome

In this rare, autosomal dominant syndrome, there are acromegaloid facial features but the sella turcica is normal in size. There may be hyperplasia and folding of the facial skin. The scalp is enlarged, causing gyrate folds in the skin, and the dermal ridges in the palms are split longitudinally. During the first decade of life, the cornea becomes opaque, often bilaterally. No endocrine abnormality has been detected.

Table 15.5 The main craniosynostosis syndromes.

Syndrome	Other features in addition to craniosynostosis	Chromosomal localization	Gene	Reference
Apert	Mid-face malformations, syndactyly of hands and feet, acne	10q26	*FGFR2*	[2]
Crouzon	Proptosis, acanthosis nigricans (AN)	10q26	*FGFR2*	[3]
		4p16.3	*FGFR3* (with AN)	[4]
Pfeiffer	Broad halluces and thumbs	8p11.2–11.1/10q26	*FGFR1/FGFR2*	[5,6]
Saethre–Chotzen	Ptosis, facial asymmetry, low hairline	7p21	*TWIST*	[7,8]
Beare–Stevenson	Cutis gyrata	10q26	*FGFR2*	[9]

FGFR, fibroblast growth factor receptor gene; *TWIST*, the human counterpart of the murine *Twist* gene, a basic helix–loop–helix transcription factor.

The craniosynostoses

Craniosynostosis is the premature fusion of skull sutures in infancy causing craniofacial malformation, often in association with other abnormalities. More than 100 syndromic forms of craniosynostosis have been described [1]. Most notable are the eponymously named, autosomal dominantly inherited syndromes of Apert, Crouzon, Pfeiffer, Saethre–Chotzen and Beare–Stevenson. There have been significant advances in understanding of the genetic basis of many of these disorders, especially in relation to fibroblast growth factor receptor genes (Table 15.5). This group of disorders displays allelic heterogeneity in addition to phenotypic variability and overlap.

Apert's syndrome (MIM 101200) [1–4]

Synonym
- Acrocephalosyndactyly

Apert's syndrome is characterized by craniosynostosis, mid-facial malformations and a characteristic syndactyly of the hands with a 'mitten-like' appearance caused by fusion of the fingers (and sometimes the thumb). Moderate or severe acne develops in all cases at puberty, with comedones on the arms and forearms as well as in the commonly affected sites [5,6]. Hyperhidrosis is common, and excess wrinkling of the forehead skin is also described [6]. In a report by Henderson *et al.* [7], severe acne in two patients with Apert's syndrome responded well to isotretinoin therapy. Immunohistochemical studies of the skin showed no difference in the number of cells expressing androgen receptors between the patients with Apert's syndrome and controls.

Most cases of Apert's syndrome are sporadic, although autosomal dominant transmission is reported. The vast majority of cases result from one of two missense mutations in the *FGFR2* gene [8–10]. One of these recurrent mutations has also been identified in lesional skin from an acneiform naevus, indicating somatic mosaicism [11].

Crouzon's syndrome (MIM 123500) [1]

Synonym
- Craniofacial dysostosis

Crouzon's syndrome is characterized by craniosynostosis, maxillary hypoplasia, shallow orbits and ocular proptosis. Like Apert's syndrome, it is an autosomal dominant disorder resulting from mutations in the *FGFR2* gene [2]. Some patients with features of

Crouzon's syndrome also have acanthosis nigricans, which is of early onset before puberty, and wide in its distribution (neck, axillae, chest, abdomen, perioral, periorbital and nasolabial folds). There is a female preponderance for this disorder [3]. Patients with this form of Crouzon's syndrome have been shown to have a specific missense mutation in the *FGFR3* gene [4].

4 Meyers GA, Orlow SJ, Munro IR *et al.* Fibroblast growth factor receptor 3 (FGFR3) transmembrane mutation in Crouzon syndrome with acanthosis nigricans. *Nat Genet* 1995; **11**: 462–4.

Pfeiffer's syndrome (MIM 101600)

In 1964, Pfeiffer [1] described a syndrome comprising craniosynostosis, broad thumbs, broad great toes and, in some, partial soft-tissue syndactyly of the hands. Other features may include umbilical hernia, malpositioned anus, bifid scrotum, widely spaced nipples, proptosis of eyelids, pre-auricular tag, absent external auditory canals, bifid uvula, supernumerary teeth and gingival hypertrophy. There is evidence of genetic heterogeneity, with the majority of cases caused by mutations in *FGFR2* [2], but some resulting from *FGFR1* mutations [3].

Saethre–Chotzen syndrome (MIM 101400)

This syndrome is characterized by a broad and variable pattern of malformations, including craniosynostosis, low-set frontal hairline, facial asymmetry, ptosis, deviated nasal septum, brachydactyly, partial cutaneous syndactyly, especially of the second and third fingers, and various skeletal anomalies [1,2]. Women with the disorder may be at increased risk of breast cancer [3]. It results from mutations in the *TWIST* transcription factor gene [4,5].

Beare–Stevenson cutis gyrata syndrome (MIM 123790) [1]

Beare–Stevenson cutis gyrata syndrome is characterized by cutis gyrata, acanthosis nigricans, craniosynostosis, craniofacial dysmorphism, digital anomalies, umbilical and anogenital abnormalities and early death. *FGFR2* mutations have been identified in some but not all patients with the syndrome, indicating possible genetic heterogeneity [2].

Craniosynostosis and porokeratosis (MIM 603116)

Synonym
- CDAGS syndrome

This rare disorder comprises craniosynostosis, anal and genitourinary abnormalities, clavicular hypoplasia and skin eruptions. In most cases, the cutaneous abnormality is porokeratosis with onset in infancy, although more psoriasiform or lichenoid changes have also been reported [1]. The eyebrows and eyelashes tend to be sparse. This autosomal recessive condition has been mapped to 22q12–q13.

Cornelia de Lange syndrome (MIM 122470)

Synonym
- Typus amstelodamensis

Aetiology. This syndrome was originally described in 1933 by Cornelia de Lange [1]. Recently, it has been shown to arise from mutations in genes involved in the cohesin complex that has a role in chromosomal cohesion and coordinated segregation of sister chromatids. Approximately half of all cases result from autosomal dominant mutations in the *NIPBL* gene on 5p13.1, that encodes a cohesin regulator protein [2,3]. Milder cases of Cornelia de Lange syndrome may result from mutations in cohesin complex protein genes, *SMC1L1* on Xp11.22-p11.21 [4], or *SMC3* on chromosome 10q25 [5].

Clinical features [2–13]. The syndrome is characterized by distinctive facial features that can be used in many cases to make the diagnosis [6]. The face is often expressionless, with arched eyebrows, long eyelashes, a long philtrum with a thin upper lip and down-turned angles of the mouth, and a small nose with a depressed bridge and anteverted nostrils. The teeth are small and widely spaced. Microcephaly, micrognathia and low-set, posteriorly-rotated ears are found. There is marked pre- and postnatal growth retardation, and limb reduction abnormalities are common. Cognitive impairment and learning disability are usually severe. Other features described include cleft and high-arched palate, cardiac septal defects, hypoplastic genitalia, gastrointestinal disorders and a variety of skeletal abnormalities. Respiratory and feeding difficulties are frequent in infancy and the cry is weak and low-pitched.

The hairline is low on the neck and forehead and there is hypertrichosis, which may be prominent on the forehead, the sides of the face, the back, shoulders and extremities. Cutis marmorata is common and persistent, and the skin around the eyes and nose may show a bluish tinge.

Life expectancy is generally poor and most patients die in infancy or childhood, often from infections to which they are susceptible. However, some mildly affected individuals have shown relatively normal development.

Rubinstein–Taybi syndrome (MIM 180849) [1–3]

Synonym
- Broad thumb–hallux syndrome

Aetiology. Rubinstein–Taybi syndrome is an autosomal dominant disorder that, in the majority of cases, arises in the context of cytogenetic abnormalities involving chromosome 16p13.3 [4–6]. The causative gene at this locus, *CREBBP*, encodes CREB-binding protein (CBP), a nuclear protein that participates as a coactivator in cyclic AMP-regulated gene expression [7]. Less commonly, individuals with this condition have been found to harbour mutations in the *EP300* gene on 22q13 that encodes a histone acetyltransferase involved in regulation of transcription [8].

Clinical features. The essential features of this complex and variable developmental syndrome are impaired cognition and learning difficulties, microcephaly, growth retardation, broad thumbs and great toes, and facial abnormalities. The palate may be high and narrow, and teeth crowded and irregular [9]. Syndactyly of the hands and accessory nipples may also occur.

A capillary naevus of the forehead or nape has been noted in over 50% of cases, and about the same proportion are said to develop hypertrichosis, especially of the back. The eyebrows may be heavy and highly arched, and the eyelashes long. Dermatoglyphic abnormalities are common. Patients with Rubinstein–Taybi syndrome seem to be prone to develop keloids [10–12]. There have been individual case reports of this syndrome associated with multiple pilomatricomas [13] and piebaldism [14].

Approximately one-third of cases have cardiac defects [15], and the use of neuromuscular blocking agents such as succinylcholine during anaesthesia can provoke cardiac arrhythmias [16]. Joint laxity and dislocations [17], and an increased risk of tumours, especially of the nervous system, have also been reported [18].

Cartilage–hair hypoplasia (MIM 250250)

Synonym
- Metaphyseal chondrodysplasia of McKusick

This autosomal recessive syndrome was first identified in Amish communities of the USA, among whom it occurs in around 1 in 700 live births [1]. It has also been described in other communities and its prevalence is high in Finland [2].

It is characterized by a high degree of dwarfism, abnormal bone and cartilage development giving rise to multiple skeletal deformities, abnormal hair, and a variable degree of defective immune function giving rise to an increased susceptibility to infection as well as a predisposition to cancers, particularly non-Hodgkin lymphoma [1,3–6]. There may be gastrointestinal tract involvement and anaemia [1,3,7].

The hair is sparse, short, of very fine calibre and lighter in colour than in unaffected siblings, and is often very brittle [8,9]. Some affected individuals are almost bald. The filamentous and matrix proteins of the hair have no gross structural defects; decreased reactivity of some disulphide bonds may account for its abnormal biophysical and biochemical properties [8,10].

Cartilage–hair hypoplasia is caused by mutations in the *RMRP* gene [11]. This nuclear gene encodes RNA rather than DNA. The RNA is not translated but is an essential component of an RNA-processing enzyme, RNase MRP, that is required for copying mitochondrial DNA [12], and for protein translation from ribosomal RNA [13]. Investigation of different *RMRP* mutations reveals genotype–phenotype correlation, with some mutations predisposing to more severe skeletal effects, and others to immune deficiency, hair abnormalities and cancer [14].

Van der Woude syndrome (MIM 119300) [1]

Synonyms
- Cleft lip/palate with mucous cysts of the lower lip
- Lip-pit syndrome

This is an autosomal dominant condition in which there are lower lip pits, cleft lip and/or palate and hypodontia [2]. The penetrance is close to 100%, with variable expression [3,4]. It is the commonest form of syndromic clefting, accounting for approximately 2% of all cases of cleft lip and/or palate. Clefting occurs in around one-fifth of affected individuals [3]. Lip pits are the most common manifestation of the syndrome, present in almost 90% of affected cases, and are the only manifestation in over 60% [3]. The pits, which vary from mere depressions to deep channels, may secrete small quantities of viscous saliva. Other developmental defects, for example syndactyly, are sometimes associated.

Popliteal pterygium syndrome (MIM119500) is another autosomal dominant disorder with variable expressivity that shares phenotypic overlap with van der Woude syndrome. In addition to clefting and lower lip pits, features of the syndrome include lower limb pterygium formation, syndactyly, cryptorchidism, hypoplasia or aplasia of the labia majora, hypoplasia or agenesis of digits and filiform ankyloblepharon [5–9]. In around one-third of patients, there is a pyramidal skin fold over the nails, particularly affecting the great toes. Underscoring their phenotypic similarities [10], these syndromes are allelic, resulting from mutations in the *IRF6* gene on 1q32–q41, that encodes interferon regulatory factor-6, a transcription factor with a role in orofacial development [11]. Interestingly, polymorphisms in *IRF6* have been associated with cases of non-syndromic cleft lip and palate [12,13].

The recognition of lip pits, or a family history of lip pits, in association with clefting is important for genetic counselling because a diagnosis of van der Woude syndrome indicates a higher recurrence risk compared with non-syndromic clefting [14].

Dowling–Degos disease (MIM 179850) [1,2]

Synonym

- Reticular pigmented anomaly of the flexures

This rare autosomal dominant condition usually presents postpubertally with multiple small, round pigmented macules that resemble freckles. They become progressively more numerous and may become reticulate with time. The axillae and groins are the usual sites, although other areas may be involved, including the intergluteal and inframammary folds, neck, scalp, trunk and arms [1–3]. Involvement of the genitalia, particularly pigmented lesions of the vulva, has been described [4]. Pigmentation is symmetrical and progressive, but is otherwise asymptomatic. The degree of pigmentation varies, but in some patients the lesions are almost confluent, giving a brown or black lace-like pattern. Dark brown papules may also develop at affected sites. Nails and hair are normal. Other features that may be present include scattered comedo-like lesions (dark dot follicles) and pitted acneiform scars near the angles of the mouth. Dowling–Degos disease may be associated with hidradenitis suppurativa [5,6].

The histology is diagnostic, with a distinctive form of acanthosis, characterized by an irregular elongation of thin branching rete ridges, with a concentration of melanin at the tips. The condition involves the follicular infundibulum, and in some cases there is follicular plugging. The melanocyte count is normal [7,8].

Dowling–Degos disease is caused by loss of function mutations in the keratin 5 gene (*KRT5*) situated in the keratin gene cluster on 12q13, resulting in haploinsufficiency [9]. Similar pigmentary changes are observed as a result of a specific *KRT5* mutation in epidermolysis bullosa simplex with mottled pigmentation (MIM 131960) [10], underscoring a function of this basal epidermal keratin in melanosome uptake and transport.

Histology of Dowling–Degos disease distinguishes it from conditions such as acanthosis nigricans, multiple basal cell papillomas, epidermal naevi and the axillary freckles of neurofibromatosis. There is clinical overlap between the disease and two other autosomal dominant conditions, reticulate acropigmentation of Kitamura [11–14] and Haber's syndrome [15,16].

The latter is characterized by a rosacea-like eruption with keratotic plaques and pitted scars.

Dyschromatosis symmetrica hereditaria (MIM 127400)

Synonym
- Reticulate acropigmentation of Dohi

This is an autosomal dominant disorder that occurs worldwide but is mostly described in Japanese and Chinese individuals. It comprises hyper- and hypopigmented macules on the dorsa of the extremities and the face, with onset in infancy or childhood [1–3]. Ultrastructurally, there is increased melanin pigment in the basal layer and enlarged melanocytes with long dendrites in pigmented skin, but reduced numbers of melanocytes in hypopigmented areas [4]. The differential diagnosis includes forms of xeroderma pigmentosum, although patients with dyschromatosis symmetrica hereditaria have normal DNA repair and no increased susceptibility to cutaneous malignancy. It is caused by mutations in the *ADAR1* gene on chromosome 1q21.3 that encodes a double-stranded RNA-specific adenosine deaminase [4,5].

Dyschromatosis universalis hereditaria (MIM 127500)

This is another autosomal dominant pigmentary condition described predominantly in Japanese families [1,2]. In contrast with dyschromatosis symmetrica hereditaria, hyper- and hypopigmented macules arise mainly on the trunk and the onset is usually earlier, in the first year of life. Light and electron microscopy demonstrate differences in fully melanized melanosomes in affected areas of skin rather than altered melanocyte numbers [2]. The condition has been linked to 6q24.2–q25.2 in two Chinese families [3]. Autosomal recessive inheritance with linkage to 12q21–q23 has also been described in one pedigree [4].

Chronic, infantile, neurological, cutaneous, articular (CINCA) syndrome (MIM 607115), Muckle–Wells syndrome (MIM 191900) and familial cold autoinflammatory syndrome (MIM 120100)

Chronic, infantile, neurological, cutaneous, articular syndrome was originally described by Ansell *et al.* in 1975 [1], and later termed CINCA syndrome by Prieur *et al.* [2]. It is characterized by a triad of rash, arthropathy and CNS involvement. The rash, which usually starts from birth, is persistent, urticarial and migratory, with perivascular polymorphonuclear inflammation histologically. Arthropathy may be severe and progressive, with epiphyseal abnormalities, periosteal elevation along the shafts of the long bones and early patella ossification radiologically. There is chronic meningitis, with progressive hearing loss. Other features include short stature, delayed fontanelle closure, frontal bossing and a broad nasal bridge.

Muckle–Wells syndrome and familial cold autoinflammatory syndrome (synonym familial cold urticaria) have overlapping clinical features, including episodic inflammatory rash, arthralgias and fever [3,4]. Late-onset sensorineural deafness and renal amyloidosis may occur but are more common in Muckle–Wells syndrome.

These three syndromes with phenotypic similarities have been shown to be allelic, caused by heterozygous mutations in the CIAS1 gene, *NLPR3*, on 1q44, that encodes a pyrin-like protein mainly expressed in peripheral blood leukocytes [5–8]. Interleukin-1 antagonists are emerging as a potentially effective therapy for all three syndromes [9,10].

Dermo-chondro-corneal dystrophy (MIM 221800)

Synonym
- François' syndrome

Patients with this very rare disorder have firm nodular skin lesions on the dorsa of the hands and on the nose and ears, osteochondrodystrophy of the bones of the hands and feet, resulting in limitation of movement and deformity, and corneal dystrophy with white or brownish opacities. A number of case reports suggest autosomal recessive inheritance [1–5], although non-familial cases with marked gingival involvement have also been described [6,7]. The underlying defect has not been identified.

Congenital scalp defects with distal limb anomalies (MIM 100300)

Synonym
- Adams–Oliver syndrome

Individuals with this disorder have congenital scalp defects, often involving the underlying bone, and limb malformations, ranging from hypoplasia of the fingers and toes to absence of the legs below the knees [1–4]. Variable features include vascular defects, cutis marmorata telangiectatica congenita, cardiac defects and central nervous system anomalies [5–8]. The inheritance pattern in the majority is autosomal dominant with variable expression, although autosomal recessive inheritance has also been proposed, especially in patients with CNS involvement [8,9].

FG syndrome-1 (MIM 305450)

Synonym
- Opitz–Kaveggia syndrome

The FG syndrome is an X-linked recessive syndrome comprising a number of congenital anomalies and developmental delay, first described by Opitz and Kaveggia [1]. The major features are impaired cognition and learning disability, mild facial dysmorphism, 'cowlicks' of the hairline, congenital hypotonia, relative macrocephaly and constipation [2]. Elia *et al.* [3] reported a boy with FG syndrome, who also had gingival hyperplasia and keloids. Hyper- and hypopigmented streaks on the trunk have also been reported in some cases [4]. A recurrent mutation in the *MED12* gene on Xp13 that encodes a thyroid hormone receptor-associated protein has been identified in some families [5]. Other forms of FG syndrome with linkage to other loci on the X chromosome have been described: these share phenotypic features with FG syndrome-1.

Future directions

Every attempt has been made to provide an up-to-date overview of progress in the field of clinical and molecular genetics relevant to contemporary dermatological practice. However, no other field of medicine is changing more rapidly than our understanding of the genetic basis of human diseases. The interested reader is strongly encouraged to consult the online information sources described, as these sites are continually updated.

Through information gained from our rapidly increasing knowledge of genetic diseases comes greater awareness about the structure, development and function of the skin and other organs. It also opens the possibility for translational benefits for patients and families, including better means of diagnosis, assessing prognosis, and novel therapeutic options for this wide range of disorders.

Prenatal diagnosis in practice

In most countries, sustained improvements in obstetric and perinatal care have meant that congenital malformations, single-gene defects and chromosomal abnormalities are increasing in their relative importance as causes of infant mortality and morbidity. Up to 5% of live-born infants may be affected by congenital defects or hereditary disease, and approximately 20% of all infant deaths today are the result of such disorders. Congenital defects and hereditary diseases can have a huge impact on individual sufferers and families at risk of genetic disease as well as creating substantial health, economic and financial burdens for health-care providers and society in general.

Over the last 30 years, there have been major advances in defining specific structural, biological, chemical and, in particular, molecular pathologies that either cause certain inherited skin diseases or which act as pathognomonic markers of these disorders [1]. This plethora of information provides new opportunities to improve diagnostic accuracy, to refine genetic counselling, and to provide a rationale for the development of new treatments, including gene, protein and cell-based therapies. The discoveries also make feasible a choice of options for prenatal testing in families at risk of recurrence for several forms of inherited skin disease [2].

Today, any couple planning to have a child cannot afford to ignore these new advances. Prenatal diagnosis with appropriate counselling should be an integral part of the management of individuals or couples at risk of having children with a congenital or genetic disorder. Access to genetic counsellors is important for anyone seeking information about these risks, and the available management options after the risk has been determined.

The purpose of prenatal diagnosis is the detection or exclusion of a hereditary disease or congenital defect *in utero*. The option of an elective abortion of affected pregnancies can help parents at risk of having affected children to produce normal offspring. A consequence of early prenatal diagnosis is that many pregnancies can proceed to term with the delivery of a normal child, instead of being terminated on the basis of a high risk.

The prenatal diagnosis of several genodermatoses is now well established. Over the past three decades, the techniques used have changed from being heavily reliant on the analysis of fetal skin biopsy samples acquired during the second half of the mid-trimester, to the examination of fetal DNA from first-trimester chorionic villus samples [3]. Preimplantation genetic diagnosis (PGD) and preimplantation genetic haplotyping (PGH) are additional options that have been recently introduced [4].

Further technical advances are likely to lead to the development of less invasive forms of fetal screening, such as analysis of free fetal DNA in the maternal circulation [5]. Advances in technology, however, also bring with them new financial costs as well as fundamental ethical and moral considerations, all of which need to be considered carefully in discussing and planning appropriate strategies for prenatal diagnosis in inherited skin diseases.

DNA-based methods

At present, the majority of prenatal diagnosis tests for inherited skin disorders are performed by analysis of fetal DNA that is usually extracted from chorionic villi [1]. After implantation of the embryo, the chorionic plate, which is derived from the trophoblast layer of the blastocyst, attaches to the uterine wall. Chorionic villi are of fetal origin and therefore a useful source of fetal DNA, as

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

Fig. 16.1 Chorionic villi for DNA-based prenatal diagnosis.

are amniotic cells that are released from various fetal epithelia [2]. Chorionic villus biopsy can be performed either transcervically or by the transabdominal route. These procedures allow for approximately 10–50 mg of tissue to be biopsied or aspirated. The risk of fetal loss following chorionic villus sampling (CVS) (performed after 10 weeks) is approximately 1–2%. Initially, some reports suggested that CVS might increase the risk of severe limb reduction defects, but this has not been borne out in subsequent, more extensive international studies [2]. Nevertheless, it is recommended that CVS is not performed before 10 weeks. Tissue obtained from CVS needs to be cleaned under a dissecting microscope to exclude maternal cells (decidua, blood) that could contaminate polymerase chain reaction (PCR) or biochemical analyses (Fig. 16.1).

It is also important that villi are collected in an appropriate medium. For example, the presence of heparin (beyond the initial cleaning phase) may inhibit the activity of the Taq polymerase enzyme that is fundamental to PCR amplification. Chorionic villi can also be cultured for diagnostic confirmation of the findings obtained from direct analysis of the villi. It usually takes about 2 weeks to culture chorionic villi for the confirmatory tests: this may improve diagnostic accuracy but there is an inevitable delay that adds to the gestational age at final diagnosis.

Apart from CVS, fetal DNA can also be extracted from fetal cells obtained by amniocentesis, usually performed at about 16 weeks' gestation [3]. Amniocentesis is a means of obtaining amniotic fluid and its cells for morphological, cytogenetic, biochemical or molecular analysis. Amniotic fluid cells are derived from fetal epidermis, alimentary and genitourinary mucosa, and amnion. These cells have been used to assess diseases associated with abnormalities of DNA synthesis and repair, as well as metabolic disorders that result in abnormal protein synthesis. However, now that the molecular basis of nearly all these conditions is known, such approaches are rarely necessary and the vast majority of prenatal tests can be performed by direct analysis of genomic DNA pathology in fetal DNA following CVS or amniocentesis [4].

Faced with a couple who have had a previously affected child with any form of inherited skin disease and who wish to consider prenatal diagnosis in the next pregnancy, it is vital to have an accurate diagnosis of the condition and to be aware of the pattern of inheritance that will determine the genetic risk. Involvement of specialist dermatology centres, clinical geneticists and genetic counsellors is helpful in determining the feasibility of prenatal diagnostic testing. In preparation for DNA-based prenatal testing, DNA samples should be available from both parents and the affected family member(s) to screen for the pathogenic mutations or informative genetic markers. The possibility of *de novo* mutations, non-paternity, uniparental disomy and germline mutations must all be considered in determining the suitability of the prenatal test. Uniparental disomy refers to the inheritance of both copies of a chromosome pair from just one parent (paternal or maternal). In essence, uniparental isodisomy allows two copies of a recessive mutation to be transmitted from a heterozygous carrier parent. Uniparental disomy has been reported in both junctional and recessive dystrophic epidermolysis bullosa (EB), emphasizing the importance of screening DNA from both parents to check carrier status [5,6]. It is also important to stress that delineation of informative gene mutations or genetic markers should be determined in advance of all requests for prenatal testing. It is not appropriate to undertake a DNA-based test without prior knowledge of the genetic information that is pertinent to a particular case or family.

Table 16.1 lists the disorders for which DNA-based prenatal testing has been performed. It is likely that the number of conditions tested for in this way will expand over the next few years, given that the molecular basis of over 350 single gene disorders with a skin phenotype has now been determined [7]. Over the last 15 years, the most common indications for DNA-based prenatal testing have been Hallopeau–Siemens recessive dystrophic EB and Herlitz junctional EB [4].

Because mutations in only one gene (the type VII collagen gene, *COL7A1*) are known to cause both recessive and dominant forms of dystrophic EB, prenatal diagnosis can be performed by linkage analysis using a combination of intragenic and flanking markers for the gene locus on chromosome 3p21 [8]. These genetic markers can be combined with microsatellite markers for haplotype analysis in predicting whether the fetus carries one, two or neither mutant *COL7A1* allele (Fig. 16.2).

A potential pitfall of haplotype analysis using polymorphic markers is the possibility of a *de novo* mutation or parental germline mosaicism in one of the alleles inherited in a previously affected sibling. To increase the accuracy of the test, DNA analysis of pregnancies at risk of recessive dystrophic EB should also, where possible, be based on direct mutation screening of both *COL7A1* alleles (Fig. 16.3).

Under optimal conditions, the DNA analysis of key family members, including testing for informative polymorphic and microsatellite markers, in addition to mutational analysis, can be completed within 2 weeks. The analysis of fetal DNA can sub-

sequently, in most cases, be accomplished within 48–72 h after its receipt in the laboratory.

Because junctional EB shows considerable molecular heterogeneity (see Table 16.1), DNA-based prenatal diagnosis of this disorder is dependent on direct mutation analysis instead of genetic linkage [9]. In pregnancies at risk for the Herlitz form of junctional EB, prenatal testing includes analysis of the relevant one of the three laminin-332 genes, *LAMA3*, *LAMB3* and *LAMC2*. Mutations in other genes encoding molecular components of the hemidesmosome-anchoring filament complex are also known to cause subtypes of EB. For example, mutations in the genes encoding the α6 or β4 integrin chains (*ITGA6*, *ITGB4*) underlie a form of junctional EB associated with pyloric atresia and defects in the type XVII collagen gene, *COL17A1*, cause a non-Herlitz variant of junctional EB. Clues to the relevant candidate gene/protein in individual cases of junctional EB can usually be derived from immunolabelling of the skin of the previously affected child using antibodies to these different proteins [10].

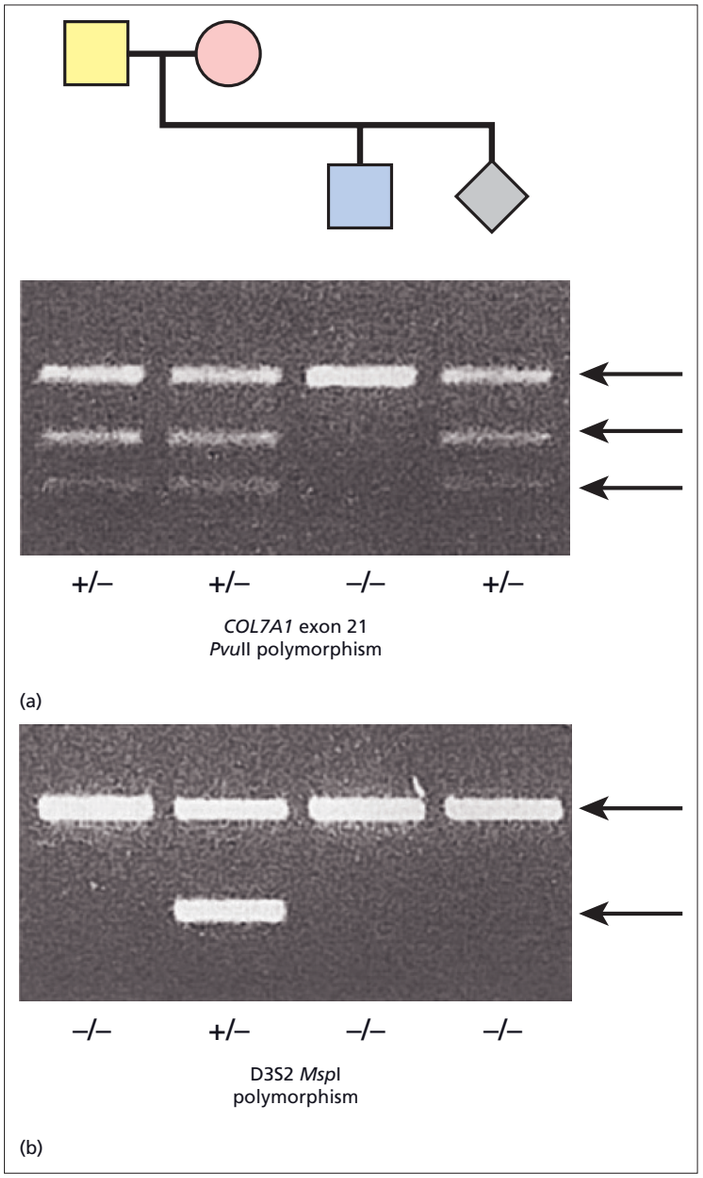

Fig. 16.2 Prenatal exclusion of dystrophic epidermolysis bullosa by linkage analysis. (a) *Pvu*II restriction endonuclease digestion for an intragenic *COL7A1* polymorphism in exon 21 shows a +/– haplotype in the maternal, paternal and fetal DNA in contrast to a –/– haplotype in the previously affected child's DNA. (b) *Msp*I restriction endonuclease digestion for a flanking polymorphism (D3S2) shows a +/– haplotype in the maternal DNA in contrast to a –/– haplotype in the paternal, previously affected child and fetal DNA. These findings indicate that the fetus has inherited the normal paternal *COL7A1* allele and the mutant maternal *COL7A1* allele, and is therefore predicted to be an unaffected carrier of one mutant *COL7A1* allele. (From McGrath *et al.* [11].)

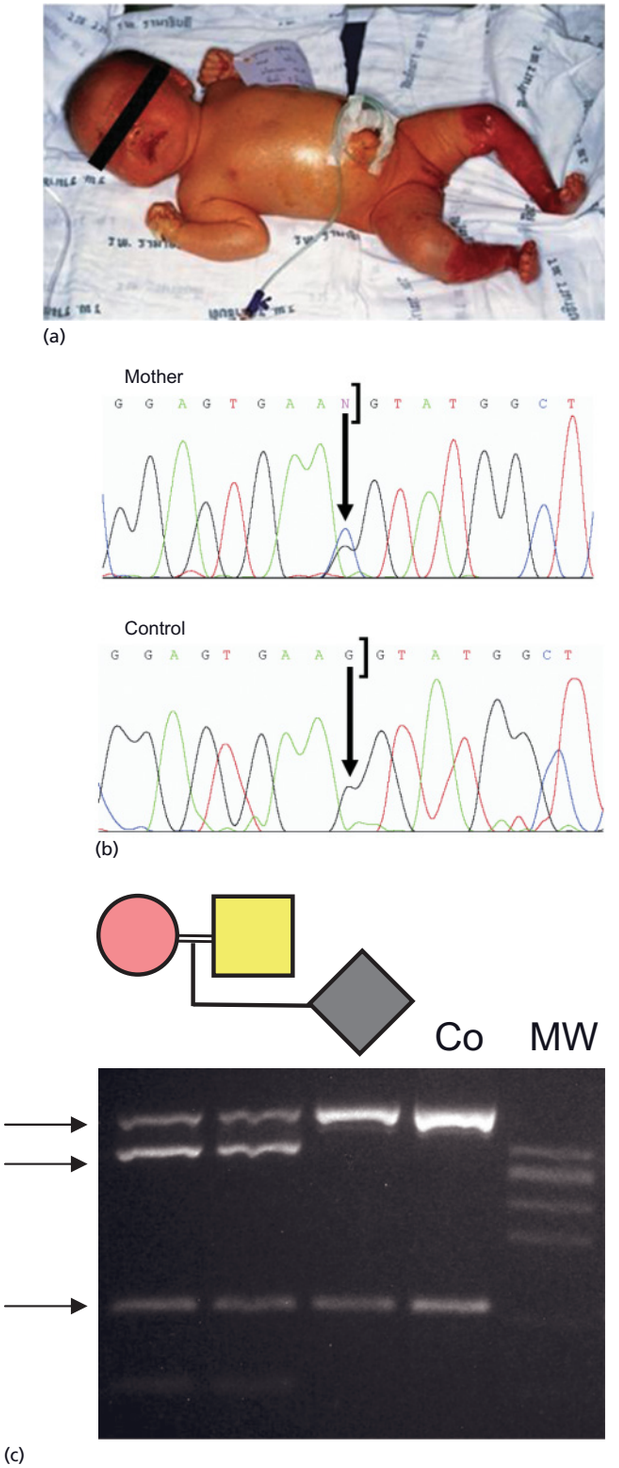

Fig. 16.3 Prenatal exclusion of dystrophic epidermolysis bullosa by mutation analysis. (a) Blistering and erosions in the previously affected child with recessive dystrophic epidermolysis bullosa. (b) Nucleotide sequencing of the PCR products from both parents (here illustrated in the maternal DNA) shows a heterozygous G > C substitution at the end of exon 18 of the *COL7A1* gene: the mutation is designated +/– c.2440G→C. (c) Restriction endonuclease digestion with *HpyCH4*IV and prenatal diagnosis. The mutation introduces a novel cutting site for *HpyCH4*IV. In control DNA (Co), the PCR product is cleaved into two clear fragments. In contrast, in both parents who are heterozygous carriers of c.2440G→C, additional digested bands are present. However, the fetal PCR products are digested similarly to the control DNA, indicating that the fetus has inherited two wild-type *COL7A1* alleles with respect to this mutation and is therefore predicted to be clinically unaffected with RDEB. MW = ΦX174 *Hae*III molecular weight marker.

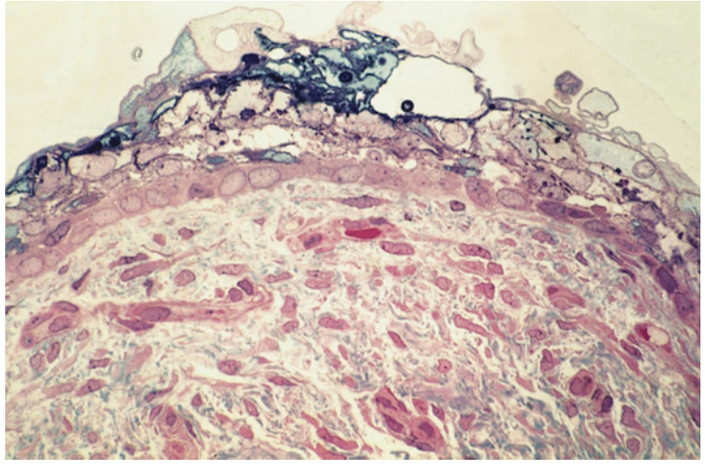

Fig. 16.5 Photomicrograph of a semithin section of a skin sample from 20-week fetus affected with bullous congenital ichthyosiform erythroderma. Note that severe vacuolation of the intermediate cell layers is present, even before the stratum corneum is formed. Periderm blebs are still evident at the epidermal surface (×380).

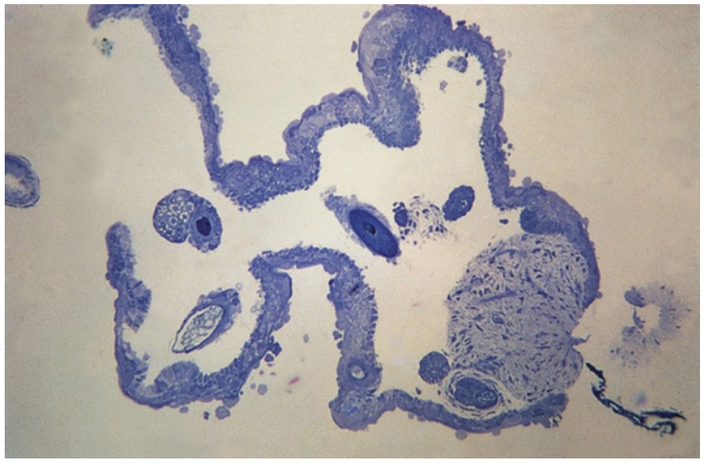

Fig. 16.7 Photomicrograph of a fetoscopic skin sample from an 18-week fetus affected with recessive dystrophic epidermolysis bullosa. Note the extensive dermal–epidermal separation. Subsequent electron microscopy confirmed that the split was beneath the level of the lamina densa. Richardson's stain (×150).

Fetoscopy and fetal skin biopsy

Fetoscopy involves the insertion of a fibreoptic endoscope into the pregnant uterus (Fig. 16.4), using sedation and local anaesthesia, normally at 16–20 weeks' gestation.

The main indications for fetoscopy have been to enable direct visualization of the uterine contents, fetal blood sampling (usually from the umbilical cord) and tissue biopsy (e.g. from skin, liver or other organs). Direct inspection has been of particular value in identifying defects of facial features, limbs and digits, head and spine, anterior abdominal wall and genitalia. With respect to inherited skin disorders, in current clinical practice, fetoscopy has a limited use.

Biopsies of fetal skin represent the earliest form of prenatal testing for inherited skin diseases but this approach has largely been superseded by DNA-based methods. Fetal skin biopsy was first performed in the early 1980s for the diagnosis of congenital bullous ichthyosiform erythroderma (Fig.16.5) and Herlitz junctional epidermolysis bullosa (EB) [1,2].

These initial biopsies were performed with the aid of a fetoscope to visualize the fetus. However, with improvements in sonographic imaging, biopsies of fetal skin started to be taken under ultrasound guidance [3]. Fetal skin biopsy samples obtained during the early 1980s could be examined only by light microscopy and transmission electron microscopy (Figs 16.6 and 16.7).

However, the introduction of a number of monoclonal and polyclonal antibodies to various basement membrane components during the mid-1980s led to the development of immunohistochemical tests to help complement ultrastructural analysis in establishing accurate diagnoses [4], especially in cases of EB, which has been the main clinical indication for performing fetal skin biopsies over the last 25 years [5] (Fig. 16.8).

In such cases, fetal skin biopsy samples are usually obtained between 15 and 22 weeks' gestation. It has been normal practice to take four full-thickness pieces of skin: two for electron microscopy and two for immunofluorescence microscopy. The sites most commonly biopsied are the buttocks, back or thorax. Indirect immunofluorescence microscopy using an antibody (or

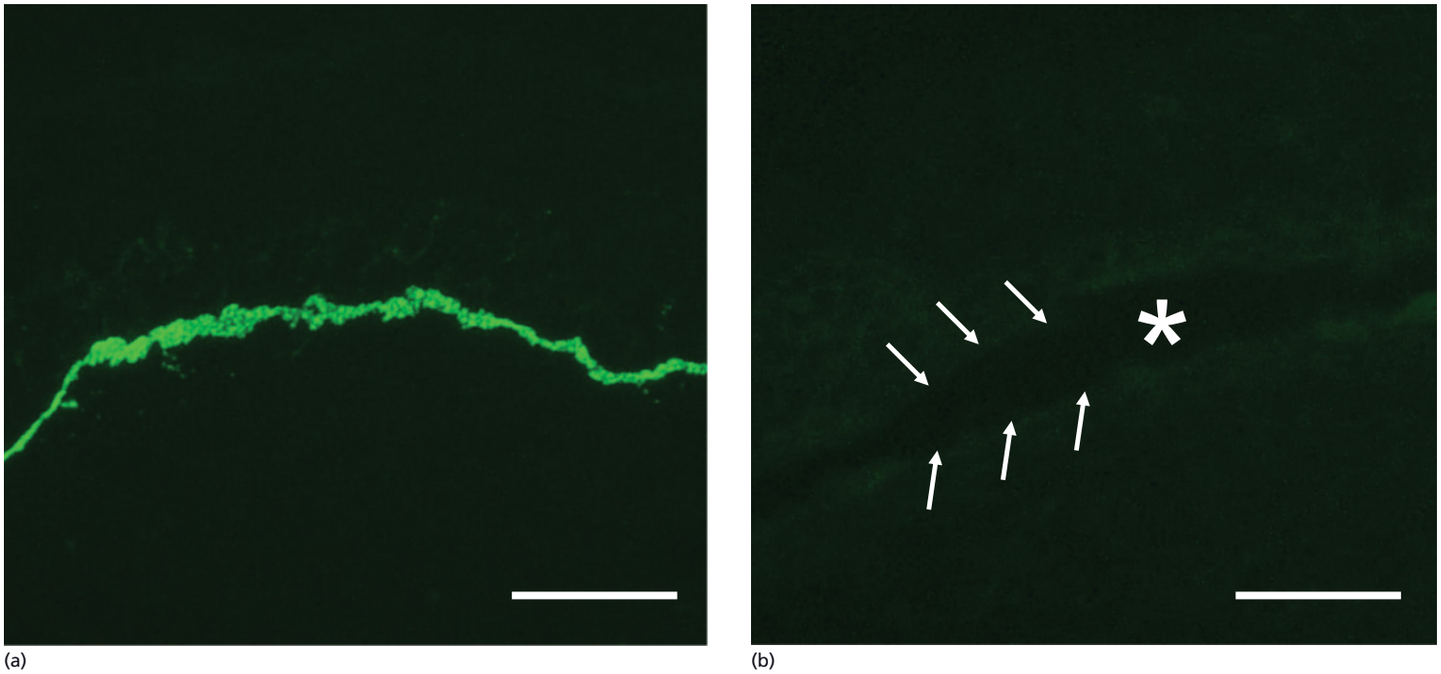

Fig. 16.8 Immunofluorescence microscopy following fetal skin biopsy using an antibody to type VII collagen. (a) In normal fetal skin at 16 weeks' gestation there is bright linear labelling at the dermal–epidermal junction; (b) in contrast, in a fetus affected with severe recessive dystrophic EB there is a complete absence of type VII collagen immunoreactivity (asterisk depicts blister cavity and arrows indicate roof and base of blister at the dermal–epidermal junction). Bar = 25 μm.

antibodies) to specific structural components of the dermal–epidermal junction, that is to those proteins that had shown absent, attenuated or altered immunostaining patterns in the previously affected child, is also part of the prenatal testing for EB.

Historically, another major indication for prenatal testing by fetal skin biopsy has been ichthyosis, especially harlequin ichthyosis. In sampling fetal skin at risk for harlequin ichthyosis, biopsies are not usually taken before 22 weeks' gestation because the structural abnormalities only start to appear at this stage in the pregnancy [6]. Slightly earlier diagnosis, at 19 weeks' gestation, has been attempted by examining keratinized hair canals and amniotic fluid cells [7]. With the discovery of mutations in the *ABCA12* gene as the molecular basis of harlequin ichthyosis, however, most cases can now be considered for much earlier DNA-based prenatal diagnosis instead [8]. Fetal skin biopsies have also been used in the diagnosis of oculocutaneous albinism. During the second trimester, melanogenesis is more active in hair bulbs than in interfollicular epidermis, and therefore fetal skin biopsies are preferentially taken from hairy regions, such as the fetal scalp or eyebrows [9]. Ultrastructural assessment of oculocutaneous tyrosinase-negative albinism has also subsequently been assisted by immunohistochemical methods in which skin samples were incubated with L-DOPA solution to assess tyrosinase activity [10], but DNA-based diagnosis is now also feasible [11].

For all fetal skin biopsy tests, sampling error, inadequacy of samples for analysis, and difficulty in interpreting the morphological and immunohistochemical features can pose problems, according to the experience of the obstetrician and microscopist. Artefact caused by the biopsy procedure, and by processing the very small fetal skin samples, can be severe or mimic true pathology. Nevertheless, fetal skin biopsy has an excellent track record, with a high degree of sensitivity and specificity of the analytical techniques used. Postnatal scars from prenatal skin sampling are usually inconspicuous. The rate of fetal loss is probably no more than 1% over the background incidence of spontaneous abortions. However, the procedure is invasive, which will always be a concern to both the medical team and the patient. Since the mid-1990s, the number of fetal skin biopsies performed has fallen by more than 95%, largely due to the introduction of alternative molecular screening methods [5]. The current indications for fetal skin biopsies, however, are:

1. Where the causative gene is unknown but prenatal diagnosis has been shown to be possible in similar cases using fetal skin biopsies
2. Where the causative gene is known, but informative DNA markers are unavailable, perhaps because an affected offspring had died before appropriate DNA samples could be obtained
3. Where previously attempted DNA-based prenatal diagnosis has been equivocal or technically unsatisfactory.

Fetal ultrasound

Ultrasound images of the fetus and other uterine contents can be very informative in the detection of heart, bone or central nervous system abnormalities but the gross pathology of most inherited skin disorders is usually too subtle and beyond the resolution of this approach. Nevertheless, the 'snowflake sign' in the amniotic cavity may be a marker of fetal skin sloughing in certain disorders, including junctional EB with pyloric atresia and harlequin ichthyosis [1,2]. Three-dimensional ultrasound, however, enables a greatly improved analysis of morphology and has been used in the prenatal diagnosis of harlequin ichthyosis by screening for atypical facial dysmorphism, abnormal ear morphology, a wide open mouth with protruding tongue, large joint contractures and flexion deformities of the fetal digits [3]. Other cutaneous abnormalities diagnosed prenatally by this method include hypohidrotic ectodermal dysplasia, linear naevus sebaceus and cutis verticis gyrata [4–6]. Fetal ultrasonography can also be used for prenatal diagnosis of genodermatoses by identification of associated non-cutaneous features, such as gastric dilatation and associated polyhydramnios in junctional EB with pyloric atresia [7], and, in one case, a combination of severe oligohydramnios, hydrops fetalis and a large nephrogenic cyst in ectrodactyly–ectodermal dysplasia–clefting (EEC) syndrome [8]. These examples illustrate the value of ultrasonography in the prenatal diagnosis of some cutaneous disorders. However, at present this technique can only be used as a prenatal diagnostic tool after about 18 weeks' gestation, often too late in pregnancy to become an acceptable and established method of assessment. With further refinement, non-invasive ultrasound examination of the fetus may become more useful earlier in pregnancy for conditions characterized by gross morphological abnormalities, but for now it has a limited role in clinical practice with regard to inherited skin diseases.

Preimplantation genetic diagnosis

For some couples, termination at any stage of pregnancy is unacceptable. Others may find the stress of abortion after skin biopsy prenatal testing in the mid-trimester or even after chorionic villus biopsy in the first trimester is too great to bear, especially if they have experienced a termination previously. Preimplantation genetic diagnosis (PGD) is an alternative method that is able to provide information about the genetic status of an early embryo [1]. PGD refers to the removal of a single cell from an embryo generated *in vitro* for genetic testing to diagnose a recurrent, serious, heritable condition and thereby to avoid the implantation of affected embryos (Fig. 16.9).

The procedure involves assisted conception techniques to generate embryos *in vitro* (Fig. 16.10). A single cell is then sampled as tissue representative of the whole embryo (Fig. 16.11) and is analysed for the presence of a specific genetic or chromosomal abnormality.

Only embryos found to be free of a specific genetic defect are then implanted in the uterus. The technique was developed in the UK in the late 1980s and was first used to avoid transmission of adrenoleucodystrophy and X-linked mental retardation [2]. Selection of female embryos to avoid X-linked disease was first carried out by polymerase chain reaction and then subsequently by fluorescence *in situ* hybridization (FISH), which can also be applied to testing for chromosomal rearrangements and translocations [3]. Successful clinical application of PGD for an inherited skin disorder has also been described. In that case, PGD testing was performed in embryos at risk of the autosomal recessive disorder, ectodermal dysplasia-skin fragility syndrome (OMIM604536). Testing involved direct sequencing of family-specific mutations in the *PKP1* gene encoding the desmosomal protein plakophilin 1 [4].

Other testing protocols have also been established for dystrophic EB. A generic test based on amplification of microsatellite markers centromeric and telomeric to the *COL7A1* gene is available for clinical use [5]. Tests that can screen for junctional EB resulting from mutations in the *LAMA3* or *LAMB3* genes (which encode the α3 and β3 polypeptide chains of laminin-332, respectively) are also in clinical practice. The tests for junctional EB involve recent technological advances in which template DNA

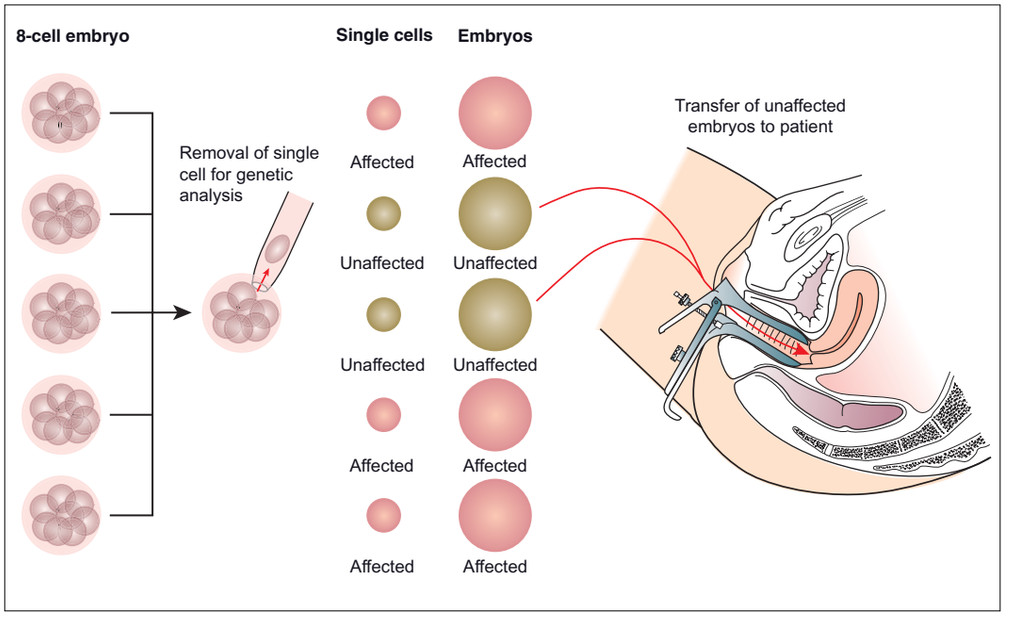

Fig. 16.9 Approach to PGD. Embryos are created with the use of *in vitro* fertilization. On the third day after fertilization, a single cell is removed from each embryo for genetic testing. Up to two mutation-free embryos are considered for transfer back to the uterus.

(typically approximately 6 ng from a single cell) can undergo initial whole genome amplification through multiple displacement amplification to create a much larger amount of DNA (approximately 6 µg) for genetic testing. This means that more markers of mutant or wild-type alleles can be examined, which improves both diagnostic scope and accuracy. The approach is known as preimplantation genetic haplotying (PGH) [6]. The main advantage of PGH is that it does not require precise details of the mutation to be known: only the gene which is implicated and the mode of inheritance are required. This makes the development of a specific test for a disease faster and the diagnosis from a single-cell biopsy more secure.

The clinical success of PGD/PGH is most strongly related to the number of embryos available for biopsy, which in turn is related to the number of good quality eggs obtained after gonadotrophin stimulation. If suitable embryos are available, clinical pregnancy rates are usually about 25% in most centres [7].

In the UK, there are strict regulations governing PGD. In 1990, the UK government passed the Human Fertilization and Embryology Act which gives some protection to human embryos. It limits the time they can be kept *in vitro* to 14 days and requires licences to be obtained for assisted reproductive therapy and for the storage of embryos and research involving them. The Act also established the Human Fertilization and Embryology Authority (HFEA) as

the appropriate regulatory agency and the HFEA is responsible for granting licences for PGD tests for specific diseases. The HFEA decides whether a disease is sufficiently serious to warrant interference with embryos and whether the licence applicants are competent to carry out the testing. In 2006, the HFEA also provided instruction and guidance on PGD testing for genetic susceptibility to certain diseases [8]. Approval was granted for certain subtypes of breast cancer, ovarian cancer, hereditary non-polyposis colon cancer and familial adenomatous polyposis, in which these potentially serious genetic conditions could be predetermined on the basis of single gene tests. Skin conditions such as psoriasis or atopic dermatitis, in which several genes may be implicated and for which medical treatments are available, are not currently deemed appropriate for PGD susceptibility screening. Whether the recent discovery of specific, frequent filaggrin gene mutations in individuals with (usually more severe) atopic dermatitis will challenge the recent testing boundaries, however, remains to be seen. Regulation of PGD varies throughout the world, and this method of prenatal testing is not permitted in several countries (e.g. Argentina, Austria, Switzerland or Taiwan) and is restricted in others (e.g. France or Germany).

Non-invasive molecular strategies

Currently available methods for prenatal testing of fetal DNA or skin all involve invasive procedures and therefore attempts are also being made to develop less invasive screening strategies. One approach that is still at an experimental stage is assessment of fetal DNA in the maternal circulation by means of a simple blood test. This involves isolation of fetal cells in the maternal circulation or analysis of free fetal DNA in the maternal plasma.

In the late 19th century, placentally-derived trophoblasts were first demonstrated in pregnant mothers and in the 1960s it was established that nucleated fetal cells could be isolated from the maternal circulation [1]. Several fetal cell populations can be present in maternal peripheral blood, including erythrocytes, lymphocytes and trophoblasts but typically there is only about one fetal cell per ml of maternal blood. This makes isolation and detection of these fetal cells very difficult, despite the more recent introduction of laboratory techniques such as fluorescence- or magnetic-activated cell sorting, or microdissection, to improve fetal cell capture. Sensitivity rates for fetal cell detection in maternal blood are only approximately 40% and false positive detection rates are often more than 10%. Nucleated fetal cells may also persist in the maternal circulation for months or years, thus rendering their detection of dubious value for prenatal testing [2].

In 1997, it was established that cell-free circulating fetal DNA was also present in the maternal circulation [3]. This fetal DNA constitutes approximately 3–6% of cell-free DNA in the maternal plasma (which corresponds to 25–50 genome equivalents per ml) and mostly consists of short fragments (80% is shorter than 200-bp in length and all is shorter than 300-bp) [1]. It is detectable as early as 4 weeks' gestation and its concentration increases as gestation progresses. Unlike nucleated fetal cells, there is no long-term persistence of free fetal DNA in the maternal circulation. Indeed, free fetal DNA is cleared rapidly with a mean half-life of 16 minutes [4]. The main source of free fetal DNA in the maternal plasma is the placenta, from syncytiotrophoblasts in the form of apoptotic fragments packaged into microvesicles [5]. Normal cell turnover events in the placenta may be responsible for its release into the circulation, which provides an explanation for raised circulating free fetal DNA levels in multiple pregnancies and in pregnancy-associated disorders such as pre-eclampsia.

The main limitation of using free fetal DNA for prenatal diagnosis is its very low concentration in the maternal plasma. One approach to selectively enrich fetal DNA is by using gel electrophoresis to separate the smaller molecular weight fetal DNA from the maternal plasma [6]. An alternative method is to try to reduce the release of maternal DNA from cells during venepuncture. This can be done by collecting the blood in tubes containing formaldehyde; background maternal DNA levels are thereby reduced [7]. This approach, however, has not been widely employed and most maternal blood samples for free fetal DNA extraction are collected in standard EDTA tubes.

Once free fetal DNA is isolated, chromosomes, genes or genetic polymorphisms and mutations, inherited from the father, can be targeted. It is important to remember, however, that fetal cell or cell free DNA cannot be used to screen for maternal alleles because of masking of the maternal allele by maternal DNA. Nevertheless, prenatal diagnosis, based on screening for paternally-derived mutations, has been reported for some types of muscular dystrophy and beta thalassaemia [6]. Moreover, the use of free fetal DNA is now the basis of a widely used clinical assay to test for Rhesus blood group antigen D (i.e. from a RhD positive fetus in the plasma of a RhD negative mother) [8], as well as fetal sex determination in women at high risk for X-linked conditions or congenital adrenal hyperplasia. Current testing by this method is usually carried out at about 7 weeks' gestation and false-positive rates (for fetal sexing) are approximately 2%. As yet, however, there are no maternal blood testing methods currently in use for prenatal testing of severe inherited skin disorders.

In 2000, fetal RNA was also identified in maternal plasma [9]. The placenta is the main source of circulating fetal RNA and so

far approximately 10 specific placental transcripts (i.e. expressed in the placenta but absent in the maternal blood cells) have been characterized. Unlike most RNA, fetal RNA is surprisingly stable against RNase digestion. In future, it may be feasible to detect aneuploidies via the quantitative assessment of placentally-derived cell-free mRNA of certain chromosomes (e.g. chromosome 21-specific genes such as *PLAC4* in the detection of trisomy 21) [10]. Another approach may be to try to establish epigenetic signatures for fetal DNA (e.g. based on differential DNA methylation status) which will allow for the detection of both maternal and paternal markers. Copy numbers of free fetal placental-derived mRNAs could also provide a basis for novel non-invasive disease screening. There is also interest in post-genomics technologies that explore the proteins (proteomics) and transcripts (transcriptomics) released by the placenta to try to identify new biomarkers of disease [11].

Analysis of cell-free fetal DNA in maternal plasma provides a potential opportunity to develop reliable, timely, safe and cost-effective prenatal diagnosis for single gene disorders. To date, non-invasive first-trimester analysis for these conditions has been limited by assay sensitivity and specificity, mostly due to the background maternal DNA. However, the identification of fetal RNA in the maternal circulation and the detection of fetal epigenetic markers has greatly increased the number of molecular markers that could be developed for prenatal diagnosis and monitoring [12]. When testing very early in gestation, however, it is important to perform careful ultrasound examination to determine the number of gestational sacs because of the risk of discordant pregnancies. Nevertheless, overall, it is likely that in the future these basic molecular biology and technical advances will be translated into clinical prenatal tests for couples at reproductive risk of severe inherited skin disorders, thus increasing screening choice for couples at risk.

Ethical aspects of prenatal diagnosis

There is currently a lack of regulatory controls for prenatal diagnostic testing. In the UK, the only statutory requirement is that physicians report the occurrence of any subsequent pregnancy termination and the reasons for it. Termination may be performed at any time during the gestation if 'there is a substantial risk that if the child were born it would suffer from such physical or mental abnormalities as to be severely handicapped'. The upper age limit for abortions, which was set at 28 weeks in the 1967 Abortion Act, was changed to 24 weeks in the 1990 Human Fertilization and Embryology Act, but the change of timing does not apply 'in cases in which the child could have serious mental or physical handicaps'.

In contrast, there are very tight regulatory controls and cumbersome licensing requirements for any work that interferes with 3-day-old eight-cell embryos, which includes all PGD/PGH analyses. Additional restrictions also apply for using human embryos for research, including dissection of the inner cell mass to extract embryonic stem cells.

Present and future trends in prenatal and preimplantation diagnosis are bound to raise questions concerning moral, ethical, legal and economic aspects of these procedures. Major questions concern the degree of fetal abnormality and the consequent level of physical or mental disability that may be considered as a justification for abortion. Further issues will be raised now that preimplantation diagnosis is feasible for genetic susceptibility to certain disorders, usually malignancies, that occur in adult life [1,2]. Familial melanoma is not yet a licensed indication but if a specific single susceptibility gene abnormality is identified in some individuals then it may well become a feasible and licensed screening test. Likewise, psoriasis or atopic dermatitis families with clear single gene causation might also be candidates for preimplantation diagnosis for genetic susceptibility in the future.

For inherited skin diseases such as the various forms of EB, genetic tests are now available for variants of this disorder that generally might be regarded as mild, certainly in comparison with those associated with greater clinical severity or worse prognosis. For example, prenatal testing is now possible for the Weber–Cockayne form of EB simplex. However, such a test has not yet been reported, probably because it has not been requested. Most health-care personnel may feel that aborting a fetus that has tested positive for one of the 'milder' disorders is unjustified [3]. However, society might say that any couple at risk has the right to know what options are available and possibly the right to have prenatal diagnosis with the intention of terminating an affected pregnancy. Ethical implications on informed choice will also need to be considered. It is evident that although informed choice is highly valued in Western, individualistically orientated countries,

it is less highly valued in non-Western, more collectivist countries [4]. How these and other issues are to be resolved based on moral, ethical and legal considerations is by no means clear and will continue to be debated, along with other major issues involving genetic testing, created or influenced by recent advances in biomedical technology and reproductive medicine. For example, the introduction of new technologies for prenatal testing, such as non-invasive approaches, may raise further concerns about the appropriateness (or not) of screening for sex selection, paternity testing, particular physical traits or other genetic information [5].

Skin disorders in the neonate

D. Paige, pp. 17.1–17.48

Nomenclature

The neonatal or newborn period is the first 4 weeks of extrauterine life, whereas infancy is the whole first year.

Infants born alive before the 37th week of gestation (i.e. 37 weeks after the first day of the mother's last menstrual period) are considered to be premature or preterm. Infants born with a birth weight of less than 2500 g are considered to be low-birth-weight infants; this state may be the consequence of prematurity, a less than expected rate of intrauterine growth (small for gestational age), or a combination of both. The term intrauterine growth retardation is used when birth weight is low for gestational age; such infants are commonly described as dysmature or small-for-dates.

Infants born after 42 weeks' gestation are described as post-term, irrespective of birth weight. This expression is often used synonymously with postmature. Because the true period of gestation may not be known exactly by dates, the diagnoses of prematurity, smallness-for-dates and maturity are made principally on clinical grounds; the relevant cutaneous features are considered later.

Skin function in the neonate

Barrier function

Great interest has focused on skin barrier function, both in preterm and full-term neonates, because of the evidence that both are at high risk of toxicity from topically applied substances [1].

It is believed that the normal full-term infant has a completely functional stratum corneum, with fully developed barrier function [2–6]. Toxicity resulting from percutaneous absorption in the full-term neonate is therefore more often related to: (i) the greatly increased ratio of surface area to volume; (ii) the frequent presence of occlusive conditions, such as exist under waterproof nappy covers; and (iii) high ambient temperatures and humidity, than to any impairment of barrier function *per se*.

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

There is, in contrast, definite evidence of impaired barrier function in preterm infants, especially those of less than 34 weeks' gestation, mirroring the anatomical immaturity of the epidermis and stratum corneum [3–5,7–11]. Percutaneous absorption correlates inversely with gestational age, but barrier function appears to improve rapidly after birth in the preterm infant, and will generally be normal by the end of the second or third week after birth [3,5,10,12].

It is clear that nothing should be applied to the skin of any baby without careful consideration of the potential hazards of percutaneous absorption, particularly in those with skin diseases. In the case of small, preterm neonates, one should be hesitant to apply anything at all to the skin. The best documented hazards relate to aniline dyes [13], hexachlorophene and related antiseptics [14–17], alcohol [18–21] and corticosteroids [22]. A number of other substances should never be used in neonates, especially not in preterm neonates; these include neomycin [23], boric acid [6,24–26], resorcinol (e.g. in Castellani's solution) [27,28], γ-benzene hexachloride [6,29], benzyl alcohol [30], benzyl benzoate [6], urea [31] and salicylic acid [6,32]. Antiseptics such as chlorhexidine [7] and iodine [33–35] should be used with the greatest caution and alcohol-based products should be avoided in view of the risk of 'chemical burns' [36,37]. Low-dose (0.25%) aqueous chlorhexidine applied to term babies has been shown to decrease mortality from sepsis in a study of 17 500 neonates from Nepal but only in low-birth-weight babies, and no differences were seen in those with birth weights over 2500 g [38]. Care should also be taken with agents used to launder, sterilize or mark nappies and bed linen [13,39–42], also with mothballs used in their storage [43].

Even the routine use of topical petrolatum-based emollients in preterms has been challenged recently, as whilst they can reduce transepidermal water loss (TEWL), a Cochrane review of four studies showed their use was associated with increased coagulase-negative staphylococcal infection and nosocomial infection [44]. Further studies in Bangladesh have confirmed this increase in nosocomial infection in preterm infants with use of petrolatum emollients, but have shown a significant reduction in infections with use of sunflower oil as an alternative [45,46]. No data yet exist on the use of emollients in preterm infants with severe skin disease, such as Netherton's syndrome or harlequin ichthyosis, where nosocomial infection is such a common problem and often lethal.

In view of the risk, it is of concern that a study undertaken in the USA a few years ago revealed that parents had applied over 48 different chemicals in over-the-counter preparations to the skin of their 1-month-old babies [47].

Conversely, the increased permeability of the skin in the preterm neonate has potential value for percutaneous administration of drugs [48].

TEWL is greatly increased in preterm compared with full-term babies [3,49–51]. The resulting outward passage of water can lead to high rates of heat loss by evaporation, which may even exceed the baby's resting rate of heat production. These losses can be reduced by increasing the ambient humidity [49,46,52], although this leads to an increased risk of infection, by covering the child with a plastic bubble blanket [53,54], a Perspex shield [55], or by applying a lipid barrier [56,57]. Whilst nursing the child in a high relative humidity environment helps lessen TEWL in the acute stage, it slows down the maturation and recovery of the skin barrier, so that abnormal TEWL takes longer to recover than in those nursed in low relative humidity environments [58].

It has been shown that oxygen absorption and carbon dioxide excretion rates through intact skin during the first few days of life are inversely correlated with gestational age [59]. There is, however, no increase in gas exchange in full-term neonates compared with adults, and rates in preterm neonates rapidly fall within 2 weeks of birth to those observed in full-term neonates. These studies raise the possibility of utilizing this increased gas permeability of preterm neonatal skin to deliver oxygen in the respiratory distress syndrome, particularly where there is severe pulmonary hypertension, when adequate oxygenation is exceedingly difficult to achieve.

It is possible that immaturity of the skin also predisposes the premature neonate to penetration of the skin by microorganisms, leading to systemic infection. This may be the reason that the premature infant with congenital cutaneous candidiasis is at greater risk of disseminated candidiasis [60].

Eccrine sweating

A full complement of anatomically normal eccrine sweat glands is present by the 28th week of gestation [61], but these appear to be functionally immature in neonates born before the 36th week, in terms of their responses to intradermal injection of acetylcholine and epinephrine (adrenaline) [62], and to thermal stress [63]. However, responsiveness usually develops in such babies by 2 weeks after birth [62,64]. Neonates born after the 36th week of gestation sweat in response to thermal stress from birth [65,66], although such sweating is initially relatively inefficient as a thermoregulatory mechanism. Care must therefore be taken not to overheat any neonate, but particularly the preterm neonate, and although severe overheating leading to hyperpyrexia is probably rare, lesser degrees of iatrogenic overheating appear to be common and may even induce apnoeic attacks [67].

The forehead appears to be the principal site of thermally induced sweating in the neonate [66]. The palms and soles, however, are sites of 'emotional' sweating, occurring in response to arousal, which appears to be well developed at birth in full-term but not preterm neonates [63]. The rate of such 'emotional sweating' can provide a measure of stress in small babies [68].

Sebaceous gland secretion

The secretions of the fetal sebaceous glands make a significant contribution to the vernix caseosa [69]. Vernix caseosa acts as a naturally occurring 'barrier cream' which also contains antimicrobial peptides and is formed from week 24 gestation [70,71]. Sebum secretion rates are high in neonates compared with older pre-adolescent children [72], and it is assumed that this sebaceous gland activity reflects stimulation by placentally transferred maternal androgen, particularly by dehydroepiandrosterone [72]. Sebaceous gland activity decreases from about the end of the first month to reach a stable level by the end of the first year [72].

The appearance of neonatal skin

A variety of skin lesions commonly seen in the newborn are regarded as 'physiological'. Their frequency has been studied by several authors, and varies somewhat in different racial groups [1–5].

At birth, the skin is covered with a whitish, greasy film, the *vernix caseosa*. The vernix may cover the entire skin surface, or it may be present only in body folds such as the groins. It normally dries rapidly and starts to flake off within a few hours of birth. The vernix appears to be comprised of lipids [6,7]. Little is known of its function, though recent evidence of its content of the peptide antibiotic LL-37 and of lysozyme support an antimicrobial role [8]. Its colour may reflect intrauterine problems, such as haemolytic disease of the newborn and postmaturity, both of which result in golden yellow staining. Fetal distress *in utero* may lead to staining of the vernix by the bile pigments present in meconium.

Peripheral cyanosis (or acrocyanosis) is a feature of the newborn, particularly the full-term newborn, and is usually particularly marked on the palms and soles and around the mouth. In the absence of cyanosis of warm central parts such as the tongue, this may be regarded as normal during the first 48 h or so. It is made more obvious by hypothermia, and is improved by warming.

A few hours after birth, many babies develop a striking generalized hyperaemia usually known as *erythema neonatorum*, which fades spontaneously within 24–48 h.

In as many as 15% of neonates, a vivid colour difference may appear along the midline at some time during the first week of life [9–12]. This phenomenon occurs when the baby is lying on its side, the upper half of the body becoming pale, the lower half a deep-red colour, with a sharp midline demarcation between the two. The duration of the attack is highly variable, but generally is between half a minute and 20 min. If the baby is turned on the other side, the colour change may reverse. An individual neonate may have only a single episode, or it may recur on several occasions. This curious phenomenon has been called *harlequin colour change*. It appears to have no pathological significance in the great majority of cases, and is considered to reflect immaturity of hypothalamic centres responsible for the control of peripheral vascular tone [9]. If it persists beyond the end of the fourth week, it may be associated with hypoxia due to cardiovascular anomalies [13].

Newborn infants who are subjected to cooling will show distinct marbling of the skin. Although this more or less disappears on rewarming, many normal neonates demonstrate faint marbling, even under optimal environmental conditions. The marbling comprises a reticulate blue vascular pattern, which has often been called *cutis marmorata*. This response is a physiological one, and may be seen throughout infancy. *Cutis marmorata telangiectatica congenita* is an entirely distinct vascular developmental disorder, and is easily distinguished (see Chapter 18). Cutaneous marbling may be seen in older children with a variety of disorders, particularly athyrotic (congenital) hypothyroidism [14], the de Lange syndrome, the Adams–Oliver syndrome, in trisomy 18, trisomy 21, homocystinuria and the Divry–Van Bogaert syndrome (see Chapters 15 and 18).

Rather superficial cutaneous desquamation, often termed physiological scaling of the newborn, occurs in up to 75% of normal neonates [5,15]. This usually first appears around the ankles on the first day of life, and is most commonly more or less confined to the hands and feet [5]. It may remain very localized or may gradually become more widespread, usually reaching its maximum extent and intensity by the eighth day. Although it has been reported that this type of desquamation is unusual in babies born earlier than the 39th week of gestation, and that it occurs with increasing frequency the greater the gestational age [15], this was not confirmed in a later study, in which it was found to occur with equal prevalence at all gestational ages [5]. It tends always to be more severe in neonates who are small-for-dates, whatever their gestational age. Physiological scaling may occasionally be fairly pronounced, not generally sufficiently so to lead to confusion with any of the more serious types of congenital ichthyosis, but milder varieties of ichthyosis, such as ichthyosis vulgaris, may be difficult to distinguish, and it should be borne in mind that X-linked hypohidrotic ectodermal dysplasia may present with scaling of the skin in the neonatal period [16].

One or two solitary blisters or erosions are occasionally present at birth on the fingers, lips or forearms, and are believed to be caused by vigorous sucking *in utero*; hence the term sucking blister is often applied. These heal rapidly without sequelae [17].

The scalp hair is shed synchronously during the fifth month of fetal life, and having regrown enters telogen in a wave from front to back, starting about 12 weeks before term. After shedding of the telogen hairs from the frontal and parietal areas, the roots again enter the anagen phase in a similar wave from front to back [18–20]. The roots in the occipital area do not enter telogen until term, and therefore rather conspicuous alopecia may appear at this site at birth or within the first 2 months ('neonatal occipital alopecia') [21].

There appear to be two waves of hair loss and regrowth from front to back during early infancy, but by the end of the first year the typical mosaic pattern of hair growth is established [22]. In some babies, there is unusually synchronous hair loss during the neonatal period, resulting in obvious diffuse alopecia (telogen effluvium of the newborn), but, by the end of the first 6 months of life, most babies have a full head of hair [23]. At this stage, the hairline often extends to the lateral ends of the eyebrows, but the terminal hairs comprising this extension gradually convert to vellus hairs during the remainder of the first year of life, causing the hairline to recede to its characteristic childhood position.

Sebaceous gland hyperplasia is a physiological event in the newborn, reflecting the influence of maternal androgens. It is visible to the naked eye in the great majority of infants as multiple, uniform, pinpoint, yellowish papules that are most prominent on

the nose, cheeks, upper lip and forehead, but may also be visible on the upper trunk, especially the areolae, the genitalia and the limbs. The phenomenon is associated in about 40% of infants with *milia*, which represent minute follicular epidermal cysts [24]. The number of milia present may vary from one or two to many hundreds. They comprise 1–3 mm, white, globular papules, which occur at the same sites. Rather larger and usually single milia, often termed pearls, are seen sometimes on the areolae, scrotum and labia majora. Both the sebaceous gland hyperplasia and the milia tend to disappear spontaneously during the first weeks of life, though a few may persist longer. Milia which are exceptionally extensive or persistent, or whose distribution is atypical, may be features of the orofacial–digital syndrome type I, Marie–Unna type congenital hypotrichosis or the X-linked Bazex–Dupré–Christol syndrome, which features hypotrichosis and milia [25] (see Chapter 15).

The influence on the fetus of maternal and placental hormones gives rise to a group of phenomena, varying greatly in degree, sometimes described as 'miniature puberty'. In the newborn female, the genitalia appear succulent, and the size of the clitoris in particular may lead the inexperienced to suspect intersex. A mucoid vaginal discharge is common. Vaginal smears at this stage may be indistinguishable from those of pregnant women. A few days after birth, the hyperplastic vaginal epithelium desquamates to leave a more normal infantile mucosa; this desquamation may be manifest as a creamy white discharge. Frank withdrawal bleeding may occur from the uterus on the third of fourth day, usually lasting 2 or 3 days. The male genitalia appear similarly large and well-developed at birth.

Both sexes show hypertrophy of the mammary glands at birth. After 2 or 3 days the breasts may become engorged and lactation of so-called 'witch's milk' may occur. The swelling subsides during the second week and has usually become undetectable by the end of the fourth week. In some girls, however, it may be more persistent, and it is these girls in particular who are at risk of infection because of the presence of stagnant milk, leading to mastitis and abscess formation.

In about 8% of babies, the linea alba becomes pigmented, and this pigmentation may persist for 2 or 3 months. Mongolian spots occur in about 85% of oriental neonates [2,26], and the frequency in black babies is also high [27]. Mongolian spots are rare in white neonates, around 3% [27]. Exaggerated pigmentation of the scrotum occurs in about 30% of oriental neonates [26]. A rare type of congenital linear and/or reticulate pigmentation has been reported on the limbs and/or trunk of black neonates [28].

One or more 1–2 mm, yellowish white, keratinous cysts, known as *Epstein's pearls*, may be seen in the mouths of up to 85% of all neonates, along the alveolar ridges and/or in the midline at the junction of the hard and soft palate [5,29,30]. These generally disappear without treatment within a few weeks. Other common oral findings in the neonate [30] include rather succulent gums, analogous to the hypertrophic gingivitis often seen in pregnant women, a whitish hue to the oral mucosa (termed 'leukoedema', but probably synonymous with what other authors have called 'suckling pads' [31]), alveolar lymphangioma [32], ankyloglossia, commissural lip pits [33,34] and a median alveolar notch.

The appearance of the preterm neonate

The skin of the preterm neonate tends to have a rather translucent, gelatinous quality, and the so-called 'miniature puberty' features are much less prominent.

Preterm infants are often covered in quite obvious lanugo hairs, which tend to be most dense on the face, limbs and trunk. This hair would normally be shed *in utero* about 1 month before term [1], to be replaced by a second coat of shorter lanugo, which is present at birth in full-term infants. Like the terminal scalp hair, this downy lanugo is shed during the first months of life and is itself replaced by vellus hair.

Appearance of small-for-dates and postmature neonates

The small-for-dates or dysmature neonate presents a characteristic appearance due to relative prenatal malnutrition. The baby is small and, from the dermatological point of view, the most striking feature is the lack of subcutaneous fat, which causes the baby to look thin and wrinkled. Vernix is absent in the extremely immature infant, but may be profuse nearer to term. The skin and vernix are often stained yellowish green by meconium. After birth, the skin dries quickly and becomes 'crazed' with long transverse splits on the trunk. It then peels off to reveal more normal-appearing skin beneath. The fingernails are often long.

The postmature infant is longer, but of otherwise similar appearance to the small-for-dates neonate, having also experienced intrauterine malnutrition due to placental insufficiency. Vernix is often absent [1].

Toxic erythema of the newborn

Synonym

- Erythema toxicum neonatorum

Terminology. The most widely used term for this condition is inappropriate in view of the complete absence of any evidence of a toxic cause.

Aetiology. The cause of toxic erythema of the newborn is unknown. It was at one time believed that the frequent finding of an associated blood eosinophilia implied an allergic origin, but there has never been any convincing support for the view that the condition is a manifestation of hypersensitivity to milk or drugs transmitted to the infant before birth via the placenta, or to vaginal secretions. Furthermore, the demonstration that tissue eosinophilia is a non-specific feature of inflammatory responses in neonates [1] adds little weight to such a view.

The intrafollicular location of mature pustules has led to the suggestion that the inflammatory response is elicited by some component of sebum [2].

Attempts to culture pathogenic bacteria from the lesions have always proved fruitless [3].

The suggestion has been made that toxic erythema of the newborn might represent a mild and self-limited, acute graft-versus-host reaction due to maternal lymphocyte transfer to the neonate [4], but evidence for this is poor; in particular the histopathological features do not resemble those that have been demonstrated in acute graft-versus-host reactions in the skin.

Pathology [5,6]. Histologically, the macular erythema shows oedema in the upper dermis, associated with a sparse and largely perivascular inflammatory infiltrate comprising principally eosinophils. Papular lesions are characterized, in addition, by eosinophil infiltration of the outer root sheath of one or more hair follicles, above the point of entry of the sebaceous duct. Pustular lesions show intrafollicular accumulation of eosinophils immediately below the stratum corneum. Smears of the pustule contents demonstrate inflammatory cells, more than 90% of which are eosinophils [7,8].

There is an associated blood eosinophilia of up to 20% of the white cell count in around half the cases, and this is generally more marked when there is a prominent pustular element to the eruption [3,7].

Clinical features [3,7–11]. Up to 50% of full-term infants of all racial types will manifest some degree of toxic erythema during the first few days of life [9,12–15]. The incidence appears to decrease with both prematurity and smallness-for-dates [16]. In the majority of cases, the onset is during the first 48 h after birth, but it may occur at any time until about the fourth day. It is in rare instances present at birth [9,17,18].

Most commonly, the eruption initially takes the form of a blotchy, macular erythema, the number of individual lesions varying from one or two to several hundred. They are most profuse on the trunk, particularly the anterior trunk, but also commonly appear on the face and proximal parts of the limbs, especially the thighs. Lesions have been recorded, however, at almost any site except the palms and soles. In the mildest cases, these macules fade within a day. In more severe cases, urticarial papules arise within the erythematous areas, or, occasionally, independently of them (particularly on the back and buttocks). These papules are, in about 10% of cases, surmounted by small pustules 1–2 mm in diameter.

Presentation with scrotal pustules present at birth has been reported more recently [18].

The infant appears well, and unperturbed by the eruption. Spontaneous recovery occurs rapidly, usually within 3 days, but recurrences are occasionally seen, and have been reported as late as the sixth week of life [19,20].

Diagnosis. Toxic erythema of the newborn has to be distinguished from several other disorders featuring pustular lesions during the neonatal period, particularly miliaria, transient neonatal pustular melanosis, incontinentia pigmenti, and, most importantly, herpes

simplex virus (HSV) infection, varicella, impetigo neonatorum and *Malassezia furfur* pustulosis. Of these, perhaps pustular miliaria is the one most often confused clinically with toxic erythema. Toxic erythema can be rapidly distinguished from all of these by microscopic examination of a smear of pustule contents, stained with Giemsa, and by bacterial and viral culture.

Treatment. No treatment is required.

Miliaria

Aetiology. Miliaria occurs when the flow of eccrine sweat is impeded by obstruction of the intraepidermal portion of the sweat duct. Its aetiology and pathogenesis are presumed to be similar at all ages and are considered in Chapter 44. Relative immaturity of the sweat duct may be an important predisposing factor in early infancy, as may a tendency for infants to be nursed in excessively warm and humid conditions.

Miliaria crystallina appears to reflect obstruction of the sweat duct within the stratum corneum itself. It is particularly common during the neonatal period, probably principally because of delayed patency of the sweat pore.

Fig. 17.1 Miliaria crystallina on the upper arm of a 7-day-old infant.

Miliaria rubra appears to be caused by sweat duct obstruction deeper within the epidermis, induced perhaps by increased activity of the intraductal microflora [1,2].

Pathology. Miliaria crystallina is characterized by the presence of intracorneal or subcorneal vesicles in communication with sweat ducts [3]. In miliaria rubra, focal areas of spongiosis and spongiotic vesicle formation are seen in close proximity to sweat ducts, which often contain an amorphous, periodic acid–Schiff (PAS) stain-positive plug [1,4].

Clinical features [5]. Miliaria crystallina presents as crops of clear, thin-walled, superficial vesicles 1–2 mm in diameter, without associated erythema (Fig. 17.1), resembling drops of water. These are exceedingly delicate, and generally rupture within 24 h, and are followed by branny desquamation. They arise most frequently during the first 2 weeks of life, and are particularly likely to be seen on the forehead, scalp, neck and upper trunk. Though rare during the first 4 days, congenital cases have been reported [6,7].

Miliaria rubra ('prickly heat') comprises erythematous papules and papulovesicles about 1–4 mm in diameter, on a background of macular erythema. Sometimes, quite large, weal-like lesions occur. Frequently, some of the lesions are pustular (*miliaria pustulosa*), but this does not necessarily indicate secondary infection. Nevertheless, staphylococcal secondary infection of miliaria (periporitis) is not infrequent, and may lead to sweat gland abscesses.

Miliaria rubra is common and, although it may be seen throughout infancy, it probably occurs most frequently during the neonatal period. Crops of lesions arise fairly symmetrically, most often in flexural areas, especially around the neck and in the groins and axillae. The face, scalp and upper trunk are also frequently affected. It may also occur rather locally at sites that have been occluded, for example where there has been direct contact between skin and a plastic mattress cover or plastic pants. Where the eruption is profuse, the child may be restless and distressed. Each crop of

lesions will subside within 2–3 days, but recurrences are common, unless the provocative environmental conditions are modified.

Recurrent bouts of miliaria pustulosa appear to be a rather specific finding in type 1 pseudohypoaldosteronism [8,9].

Diagnosis. Miliaria crystallina is distinguishable from viral infections of the skin by the lack of background erythema, and by the absence of inflammatory cells or giant keratinocytes on cytological examination of vesicle contents. When it occurs during the first few days of life, miliaria rubra is often confused with toxic erythema. However, miliaria rubra can generally be distinguished by its flexural predominance, by the frequent presence of vesicular lesions and by its tendency to recur. Where pustular lesions are seen in toxic erythema, a smear of their contents will reveal large numbers of eosinophils.

When pustular lesions are prominent in miliaria, there may be confusion with infantile acne or with folliculitis, but careful clinical examination of the individual lesions will show that they do not have a follicular distribution.

Transient pustular melanosis

Synonym
- Transient neonatal pustular melanosis

Terminology and aetiology. Despite having first been described more than 30 years ago [1], whether this is really an entity remains unresolved. Nothing is known of its aetiology other than that it would appear, like toxic erythema of the newborn, to be non-infectious. It was first reported in black Americans, and appears to be commoner in, but not confined to, black neonates (4.4% in black US neonates against 0.6% in white US neonates) [1]. This probably reflects the fact that its diagnosis is currently based on the appearance of typical macular post-inflammatory pigmentation, as the name seems to require. It has been suggested that it is merely a variant of toxic erythema of the newborn [2].

Pathology [1]. Pustular lesions show intra- or subcorneal collections of neutrophils and a few eosinophils. The underlying dermis may show no abnormality, or a sparse perivascular and perifollicular inflammatory infiltrate, also mainly of neutrophils with a few eosinophils.

The pigmented macules demonstrate basal and suprabasal increase in pigmentation only, apparently without pigmentary incontinence.

Smears of pustular contents show predominantly neutrophils, and bacterial culture is negative.

Clinical features [1,3–7]. Lesions are almost invariably present at birth. The most characteristic component of the eruption is 1–3 mm flaccid, superficial, fragile pustules, with no surrounding erythema. These pustules may occur at any site, but favour the chin, neck, forehead, back and buttocks. Sites where they have ruptured are marked initially by a detachable brown crust, and subsequently by a small collarette of scale, which may surmount a pigmented macule. Sometimes, pigmented macules are already present at birth. The pigmented macules are a prominent element in black infants, and are seen more rarely in other races [5]. The pigmentation may persist for about 3 months. Affected infants are otherwise entirely well.

It has been suggested that this condition is responsible for the freckling or '*lentigines neonatorum*' that have been reported in some 15% of black neonates [8].

Diagnosis. It remains to be established whether this is really just an early-onset variant of toxic erythema of the newborn occurring in the dark-skinned. Stained smears and microbiological studies will distinguish staphylococcal and herpetic infections. The differential diagnosis of neonatal pustular eruptions is given in Table 17.1.

Infantile acropustulosis

Aetiology. Infantile acropustulosis is an uncommon disorder of unknown aetiology. It occurs in all races [1], though it was first described in black infants [2,3]. It has been suggested that eosinophilic pustular folliculitis and infantile acropustulosis may be different manifestations of the same disease [4,5]. It has also been suggested that, at least in some cases, infantile acropustulosis occurs following successful treatment of scabies [6–8]. Interestingly, it has been reported in a 2-month-old infant whose mother was treated for scabies 4 months previously [9]. It has also been reported in siblings [9], and in only one of a pair of identical twins [10].

Pathology [2,11–13]. Biopsies of fully developed pustules have revealed well-circumscribed subcorneal or intraepidermal aggregations of neutrophils, with a sparse perivascular lymphohistiocytic infiltrate in the underlying papillary dermis. Biopsy of pre-pustular lesions shows focal intraepidermal vesiculation [13,14] with keratinocyte necrosis. This intraepidermal vesicle is subsequently invaded by neutrophils and/or eosinophils. The pustule starts its life deep in the epidermis, but does not become clinically fully developed until it reaches a subcorneal location.

Direct and indirect immunofluorescence is negative in lesional, perilesional and normal skin [1,3,15].

Stained smears of pustule contents generally show a predominance of neutrophils, but there may be a preponderance of eosinophils early in the course of the disorder [3]. The pustules are sterile [2,11,16]. Peripheral blood eosinophilia has been reported [14,17,18], but is not invariable [9,13,17].

Clinical features [2,3,9,12,15,19,20]. Recurrent crops of intensely itchy, 1–4-mm vesicopustules appear principally on the soles and sides of the feet, and on the palms, but may also occur on the dorsa of the feet, hands and fingers, and on the ankles, wrists and forearms. Scattered lesions may also be seen on the face, scalp and trunk, but a predominantly acral distribution is characteristic. Mucosal lesions do not occur.

Individual lesions appear to start as tiny, red papules, which evolve into vesicles and then pustules over about 24 h. Excoriation results in erosions and then crusts. Healing is frequently succeeded by macular post-inflammatory hyperpigmentation.

Pruritus may be intense, with restlessness, loss of appetite and interference with sleep.

In the majority of cases, the onset is in the first year of life, particularly during the first 6 months [9]; lesions may be present at birth. Each crop lasts for 7–14 days. They tend to occur at intervals of 2–4 weeks in most cases, often being more frequent and more numerous in the summer months. The attacks occur with gradually diminishing numbers of lesions, and with decreasing frequency, until they cease altogether, usually within 2 years of the onset [8].

Treatment. The early use of fairly potent, topical corticosteroids with [9] or without [12] occlusion appears to abort attacks.

The intense pruritus may be lessened by large doses of oral antihistamines [2].

Though rarely justified, dapsone is usually effective in controlling this condition in a dose of 1–2 mg/kg/day in two divided doses [3], and usually reduces pruritus within 24 h. Higher doses are occasionally required [17]. Too hasty withdrawal of treatment may provoke severe exacerbations [11].

Diagnosis. The predilection for the palms and soles and the recurrent attacks differentiate this disorder from most other pustular eruptions seen in the neonatal period, particularly toxic erythema, miliaria and transient pustular melanosis.

Persistent palmoplantar pustulosis may be similar histologically but characteristically has a much later onset, a more persistent course, and the skin surrounding the pustules is dusky red and glazed.

Subcorneal pustular dermatosis may also resemble infantile acropustulosis histologically, and has occasionally had its onset during the first 3 months of life [21]. It is, however, likely to be associated with fever and neutrophilia, and has a different distribution, favouring the proximal flexures, although lesions on the palms and soles have been described.

Scabies may initially be extremely difficult to exclude, and where there is any doubt a therapeutic trial of an appropriate acaricide is clearly justified. The persistence of acral pustulosis for many months in children aged less than 3 years, and previously treated for scabies, has been reported [22].

Eosinophilic pustulosis

Synonym
- Eosinophilic pustular folliculitis

Aetiology. This entity is now recognized as a characteristic skin disorder of infancy, with typical cases described from many different countries [1–5]. Its aetiology and its relationship to eosinophilic pustular folliculitis of adults [6] are unknown. It has been suggested that this condition and infantile acropustulosis may be different manifestations of a single disorder [5,7].

Pathology. Biopsy shows a dense perifollicular infiltrate of eosinophils, with some lymphocytes and histiocytes, in the mid- and upper dermis. The hair follicles themselves show spongiotic degeneration of the outer root sheath, and infiltration with eosinophils. The centre of the follicles is necrotic, and filled with eosinophils and eosinophilic debris. Smears of pustule contents show plentiful eosinophils. There is mild to moderate peripheral blood eosinophilia, and occasionally, neutrophilia.

Clinical features. The condition generally has its onset in infancy. Lesions occur predominantly in the scalp [2,4,5,7], comprising mildly pruritic, 1–3-mm-diameter pustules on an erythematous base, with prominent secondary crusting. However, pustules may also occur at almost any other site except the mucosae, occasionally even in areas lacking hair follicles [3]. Annular lesions resembling those seen in adults were reported in a 5 year old [8], but this is perhaps more likely to have been an early case of the adult form of eosinophilic pustular folliculitis. Patients are not systemically unwell.

A pattern of cyclical recurrences is characteristic, but the likely duration of the disease is unknown.

Diagnosis. Conditions that need to be considered in the differential diagnosis include infections, particularly impetigo and candidosis, and other non-infective pustuloses of infancy, particularly toxic erythema, infantile acropustulosis and transient neonatal pustulosis.

Infections are principally excluded by the sterile pustule contents, the absence of eosinophils in smears of pustule contents, and the lack of peripheral blood eosinophilia. While toxic erythema may initially be clinically and histologically similar, it does not show any predilection for the scalp, and lacks the cyclical recurrent course. Similarly, the pustular phase of transient neonatal pustulosis is confined to the neonatal period. Also, the pustules contain neutrophils rather than eosinophils. The lesions of infantile acropustulosis, while they do generally occur in recurring crops, tend to be larger and are located principally on acral sites including the palms and soles, rather than in the scalp.

Treatment. There is some evidence that higher-potency topical corticosteroids and oral erythromycin may have some suppressive effect on the lesions seen in infants [3,4], but little treatment is required since the prognosis for spontaneous remission appears excellent.

Neonatal pustulosis of transient myeloproliferative disorder

There have been several reports of neonates with trisomy 21 (and mosaic trisomy 21) developing pustules and vesicles (on an erythematous background), predominantly on the face, as part of congenital leukaemia or transient myeloproliferative disorder (TMD) [1,2]. They may also pustulate at sites of trauma, such as venepuncture sites or under adhesive tape. There is an associated high white blood cell count, often with the presence of blasts. Skin biopsy shows intraepidermal pustules with a perivascular dermal infiltrate of neutrophils, eosinophils and atypical mononuclear cells. The lesions often resolve spontaneously over a few weeks paralleled by a decreasing white cell count.

Mutations in the transcription factor GATA1 seem to underlie TMD but a second genetic hit is needed to develop leukaemia [3].

Up to 20% of patients with TMD will go on to develop an acute megakaryoblastic leukaemia within the first 4 years of life.

Congenital erosive and vesicular dermatosis healing with reticulated supple scarring

Synonym

- Extensive congenital erosions and vesicles healing with reticulate scarring

This is a rare disorder of unknown aetiology [1–6]. There is no evidence of genetic transmission. It appears possible that the condition reflects an as yet unidentified intrauterine infection.

The majority of affected infants have been premature. Some have also had microcephaly and neurological problems, including convulsions and developmental delay.

At birth, there are extensive, superficial erosions, with scattered vesicles and bullae, affecting up to 75% of the body surface [1–6]. These heal fairly quickly within the first few weeks of life, leaving rather characteristic soft, reticulated scarring. The trunk and limbs tend to be more severely affected than the face and scalp. Following healing of the skin lesions, there may be residual loss of eccrine sweating in scarred areas, with the potential for hyperthermia under appropriate conditions, patchy alopecia, partial loss of eyelashes, and absence or hypoplasia of nails. Teeth have been normal. Mild, localized, recurrent vesiculation may occur [6].

Biopsies of vesicular areas have shown spongiosis or epidermal necrosis with dermal haemorrhage and inflammation [6]. In another report, an eroded area showed loss of the epidermis with a superficial and deep dermal inflammatory infiltrate comprising mostly neutrophils [4]. Scarred areas have shown an increased density of dermal collagen, and absence of eccrine sweat glands [1,5]. Direct immunofluorescence does not show any specific pattern of deposition of immunoglobulins, C3 or fibrin [4]. Electron microscopy and immunohistochemical mapping of perilesional skin have shown nothing to suggest that this is a variant of epidermolysis bullosa [5].

'Cradle cap'

This term is applied, rather loosely, to almost any situation in which there is adherent scaling of the scalp during infancy. This type of scaling is very common, particularly on the vertex, during the first few weeks of life, and is generally believed to represent persisting vernix.

However, there is little doubt that such scaling may appear in early infancy in babies in whom the scalp was clear at birth [1]. The eyebrows are frequently affected in this acquired type of cradle cap, and lesions may also appear on the forehead and temples, the retroauricular area and the folds of the neck. This rash is generally considered to be a manifestation of infantile seborrhoeic dermatitis.

If scaling or crusting is present during the neonatal period, the scalp should be regularly oiled with olive oil or arachis oil. In the more refractory case, Emulsifying Ointment BP, Aqueous Cream BP or any other water-dispersible emollient should be massaged into the scalp once or twice a day, left for several hours, and then rinsed out. Applications containing salicylic acid, and shampoos containing potentially toxic substances, such as selenium sulphide, should not be used on the scalp in neonates because of the dangers posed by their percutaneous absorption.

Complications of prematurity

Anetoderma of prematurity [1]

A series of infants have recently been described in whom nummular areas of cutaneous atrophy appeared on the trunk and/or proximal limbs within a few weeks or months of birth. All these babies had been born between the 24th and 29th weeks of gestation and in almost all cases the lesions had first appeared while the child was still in the neonatal intensive care unit. Histologically, these lesions demonstrated reduction or absence of elastic tissue, consistent with anetoderma. An aetiological role for trauma resulting from care procedures seems likely and two cases have been described in association with the use of gel ECG electrodes [2].

Complications of medical procedures on the fetus and neonate

Scarring following antenatal procedures

Amniocentesis comprises the insertion of a needle into the amniotic sac through the abdominal wall for the removal of amniotic fluid. Punctate scars and dimples may result from accidental puncture of the fetal skin during the procedure [1–4], although the frequency of such lesions can be greatly reduced by the routine use of ultrasound guidance. Generally, injuries are minor, but more substantial trauma can occur.

Other antenatal procedures on the fetus that may result in scarring include biopsies of skin, liver or tumours, aspiration of fluid

collections, and a variety of therapeutic procedures, all of which are undertaken with ultrasound guidance.

Scarring acquired due to procedures during delivery

Scalp electrodes are very widely employed to monitor fetal heart rate during labour. The most commonly used type of electrode is curved and is implanted by being 'screwed' into the scalp. Lacerations are not an uncommon sequela [1]. Although these generally heal rapidly, they may leave localized areas of permanent scarring in the scalp, which may later be confused with cutis aplasia. Cephalohaematoma has also been reported [2].

Scalp blood samples are also often taken to establish fetal acid–base status; these are taken via small incisions using a special lancet. Either type of injury can lead to abscesses in up to 4% of neonates [3], usually becoming evident by the third day of life. These are generally a minor problem [4], but osteomyelitis [5] and necrotizing fasciitis [6] may, however, occur. Infecting bacteria have included group A streptococci and *Neisseria gonorrhoeae* [7]. HSV infection may also occur at the site of electrode implantation, reflecting infection of the mother's genital tract [8]. Vesicles appear within 4–10 days of birth. Recognition of such lesions is important, as localized infection of this type has occasionally been complicated by meningoencephalitis [9,10] and by lethal dissemination [11].

Forceps delivery may occasionally result in local subcutaneous fat necrosis. Vacuum extractors (ventouse) may rarely cause permanent alopecia, most typically in a circle that clearly corresponds to the site of its application. Marked caput succedaneum is usually present at delivery [12]. Scalpel laceration during caesarean delivery may require suturing and will generally result in scarring.

Complications of phototherapy

Phototherapy with blue light at 420–460 nm leads to the transcutaneous photo-oxidation of bilirubin, and has become firmly established as a safe and effective treatment for neonatal jaundice [1].

A number of minor cutaneous side effects have been described. Some babies develop a macular erythematous rash as the serum bilirubin level falls [2].

Darkening of treated areas of skin lasting for several months has been reported in racially black babies [3]. This effect may initially be due to the immediate pigment-darkening reaction, which is induced by visible as well as by long-wave UV radiation. However, the persistence of hyperpigmentation in these babies over several months implies that increased melanogenesis must also occur.

Unexplained UV burns have also been reported after phototherapy for neonatal jaundice [4].

Phototoxic reactions

Phototoxic reactions to a number of drugs given to the neonate, or injected into the amniotic cavity, may occur following phototherapy for neonatal jaundice. The best known of these drugs is furosemide [5].

Methylene blue is sometimes injected into the amniotic cavity to detect premature rupture of the fetal membranes at the end of pregnancy. Methylene blue is a photosensitizing compound, and the use of phototherapy for hyperbilirubinaemia in a neonate that has been exposed *in utero* can lead to erythema and blistering [6].

'Bronze baby' syndrome

This is a rare complication of neonatal phototherapy, in which a dark-grey-brown ('bronze') pigmentation of the skin, serum and urine follows phototherapy, and remains as the hyperbilirubinaemia fades [7,8]. Hepatic disease appears to be a prerequisite for the development of this complication, and is thought to cause abnormal accumulation of the responsible pigment. This pigment has not yet been precisely identified, but it has been suggested that it might be a photoisomer of bilirubin [9]. The abnormal hepatic function also leads to increased serum levels of porphyrin and copper, which in turn form copper–porphyrin complexes.

Photodestruction of these complexes leads to the production of brown pigments, which might also be responsible for the 'bronze' colour [10]. A third suggestion has been that the pigment is biliverdin, which might accumulate as a consequence of reduced conversion of haem to bilirubin [11].

In making the diagnosis, other causes of similar pigmentation need to be considered, particularly central cyanosis secondary to congenital heart disease, the 'carbon baby' syndrome [12] and the 'grey baby' syndrome, due to chloramphenicol overdosage [13]. These can be ruled out, where appropriate, by skin biopsy, serum chloramphenicol level, blood gas analysis and serum spectophotometry [7].

The bronze pigmentation gradually fades after discontinuation of phototherapy, but death has been reported in several affected neonates, either from kernicterus or from extrahepatic biliary duct atresia [14].

Bullous and purpuric eruptions resulting from transient porphyrinaemia

Bullous photosensitivity reactions may be seen in neonates with congenital erythropoietic porphyria, hepatoerythropoietic porphyria, erythropoietic protoporphyria and harderoporphyria [1,2].

It is clear that under certain, probably exceptional, circumstances, a bullous eruption closely resembling epidermolysis bullosa may develop following phototherapy in a neonate, due to transient porphyrinaemia [3]. The circumstances in which porphyrinaemia may occur in neonates who do not have inborn errors of porphyrin metabolism are not fully defined, but probably include prematurity, cholestasis, disturbed hepatocellular function and renal failure.

More recently, localized purpuric eruptions have been described at exposed sites in a number of neonates who had all been transfused prior to phototherapy; it was proposed that the cause may also have been transient porphyrinaemia [4,5].

Umbilical artery catheterization

Umbilical artery catheters are often used in neonatal intensive care, for frequent blood sampling, for continuous Po_2 and blood pressure monitoring, for administration of fluids and drugs, and for exchange transfusions. Vascular complication may ensue, including aortic thrombosis, embolization and spasm. These may result in lower limb ischaemia, which may progress to gangrene or necrosis [1–7]. Analogous ischaemic changes may occur in the lower arm or hand following cannulation of the brachial and radial arteries, respectively.

Transcutaneous oxygen monitoring

Transcutaneous oxygen monitoring is frequently used in neonatal intensive care. This uses an electrode applied to the skin and maintained at 44°C in order to increase cutaneous blood flow. This generally causes a superficial burn, which usually resolves within 60 h [1], but occasionally, after longer periods of monitoring, there may be a more severe burn [2], sometimes with vesiculation [3]; such lesions may result in permanent scarring [2]. Measures have been recommended to reduce the risk of these injuries [4], but the transcutaneous Po_2 monitor has now been largely superseded by pulse oximetry, which uses an unheated sensor with no risk of burning.

Electrocardiographic electrodes [1]

Raised, skin-coloured lesions, approximately 5 mm in diameter, on the forehead have been described at the age of 3 months following the use of electrocardiographic electrodes in intensive care monitoring of premature neonates. Biopsy demonstrated reduction of elastic fibres; hence the lesions were interpreted as an iatrogenic form of anetoderma, possibly provoked by hypoxia secondary to skin pressure.

Transillumination blisters [1]

Transillumination is used in neonatal intensive care units as a way of diagnosing pneumothorax and for finding arteries and veins for blood sampling. Occasionally, this procedure provokes discrete 2–4-mm blisters with necrotic bases in acral locations close to common venous access sites, such as the wrists and the lateral malleoli. The occurrence of such lesions should arouse suspicions that the transilluminator unit may be faulty, or that the infrared filters might be missing or switched off.

Cutaneous necrosis following extravasation of intravenous medications

Leakage of total parenteral nutrition and of a variety of medications have led to local skin and subcutaneous tissue necrosis in the neonate [1–4]. It appears that the risk is highest when intravenous cannulae are inserted in the lower limbs, particularly above the ankle. Severe lesions may lead to joint contractures requiring plastic surgical correction. Alopecia may result from extravasation from cannulae placed in the scalp.

Iatrogenic dystrophic calcification

Iatrogenic dystrophic cutaneous calcification has been reported in three situations:

1 On the heel due to heel pricks during neonatal care [1–3]
2 At the site of extravasation of calcium-containing solutions given intravenously or by intramuscular injection [4–6]
3 On the scalps of children who have undergone electroencephalography with calcium chloride-containing paste on abraded skin [7].

Needle marks [1]

Children who have received neonatal intensive care will frequently have punctate white scars at sites of needle insertion. Individual lesions will generally be imperceptible, but groups of lesions at particular sites may be more apparent, resulting in curious speckled scarring.

Cutaneous necrosis following chemical burns

Cutaneous necrosis has been reported following skin contact with a variety of antiseptics in premature neonates, reflecting the increased rate of percutaneous absorption that is a feature in this age group [1–5]. The alcohol base can also have a directly toxic effect on the skin so this can occur around a surgical site (e.g. umbilical catheter) and often on the back or buttocks where the cleanser has pooled or soaked onto drapes [6].

Medallion-like dermal dendrocyte hamartoma
Congenital infection (HSV and VZV; maybe zosteriform)
Focal dermal hypoplasia of Goltz
Neonatal lupus erythematosus

Atrophic lesions of neonates

There are a number of causes of atrophic lesions in neonates (Table 17.2).

Medallion-like dermal dendrocyte hamartoma

First described in 2004 in female neonates, this rare condition presents with a reddish-brown, congenital, atrophic lesion of the skin on the upper trunk or neck. Lesions are typically round or oval, measure 2–6 cm across and persist. They may show a slight increase in hair growth and visible underlying blood vessels under a wrinkled epidermis [1–3]. Histology differentiates this disorder from other causes of neonatal cutaneous atrophy such as aplasia cutis congenita, congenital dermatofibrosarcoma protuberans (in early life before it becomes nodular), morphoea, cutis marmorata telangiectatica congenita and anetoderma of prematurity. It shows epidermal atrophy, spindle cell proliferation in the dermis and to a lesser degree the subcutis, and reduced adnexal structures. Spindle cells stain positive for CD34, Factor X111a, vimentin and fascin, suggesting a dermal dendritic origin. Atrophic DFSP is also CD34 positive, but is factor X111a negative.

Congenital annular limb lesions/amniotic bands

Congenital annular limb lesions usually cause constrictions and may lead to limb malformations, lymphoedema and even ischaemia and autoamputation ('congenital pseudoainhum'). They may occur in a number of conditions, including Michelin tyre baby syndrome and amniotic band syndrome. The latter occurs due to premature rupture of the amniotic sac which fails to grow normally and leads to fibrous strands developing on the outer amnion and chorion. The fetus can get 'trapped' in the bands and oligohydramnios can cause further compression. If this occurs early *in utero* malformations tend to be more extensive and include alopecia, aplasia cutis, neural tube defects, craniofacial defects as well as limb constriction bands [1].

Treatment is difficult and is by surgical correction when possible [2].

Raised limb bands occurring later in infancy seem to behave in a more benign fashion even if associated with amniotic bands [3,4].

Neonatal adnexal polyp

Solitary, self-healing, polypoid lesions have been observed in some 4% of neonates in a Japanese survey [1,2]; their occurrence in other racial groups has yet to be documented. These lesions are firm, pink, polypoid nodules, about 1 mm in diameter, usually found close and medial to one or other nipple. Histology shows a normal epidermis, a vascular dermis containing prominent hair follicles with vestigial sebaceous glands and well-developed eccrine glands. These lesions generally separate from the skin spontaneously after a few days.

Infantile pedal papules

Infantile pedal papules [1,2] are a common finding in neonates (6%) and infants (39%). They are benign, asymptomatic, flesh-coloured nodules (0.5–1 cm) on the medial aspect of the foot often anterior to the heel. They are frequently symmetrical and usually disappear by age 3 years. They have been described under various different names: precalcaneal congenital fibrolipomatous hamartomas, adipose plantar nodules, congenital piezogenic-like pedal papules and bilateral congenital fatty heel pads.

Disorders caused by transplacental transfer of maternal autoantibodies

Clinical manifestations in the neonate have now been reported in a number of maternal disorders that are believed to be induced by circulating autoantibodies. Of particular interest to the dermatologist are those reports concerning lupus erythematosus (LE)

(see below), pemphigus vulgaris [1–5], pemphigus foliaceus [6,7], herpes gestationis [8] and aphthosis [9].

Because IgA, IgM and IgE antibodies do not cross the placenta in significant amounts, this phenomenon is restricted to diseases caused by autoantibodies of IgG class. Where complement is also involved in pathogenesis, this must be provided by the fetus, as it does not pass across the placenta. Complement can be detected in the fetus from about the 11th week of gestation [9]. Maternal IgG is catabolized more or less completely within the first 3–6 months of life, and antibody-mediated transplacental diseases can be expected to remit spontaneously within this period.

Neonatal lupus erythematosus

Definition. Neonatal LE is a rare syndrome comprising transient skin lesions resembling subacute cutaneous LE, and/or congenital heart block, occurring in the babies of mothers with clinical or subclinical autoimmune connective tissue disease, and associated with the transplacental passage of maternal autoantibodies to the ribonucleoproteins (RNPs), Ro-SSA, La-SSB or U_1-RNP [1].

Aetiology. It is now accepted that this disease is provoked in the fetus or newborn infant by maternal IgG autoantibodies that have crossed the placenta [2,3]. In 95% of cases, these are of IgG1 class [4] and are directed against the Ro RNP antigen [5]. These antibodies are relatively prevalent in young women, and appear to be compatible with apparently normal health. For these reasons, neonatal LE is seen more commonly than neonatal pemphigus vulgaris or neonatal herpes gestationis. La, anti-native DNA, anticardiolipin or antinuclear antibodies, or rheumatoid factor, may be present in addition to Ro antibodies [6,7]. A small proportion of affected infants do not have detectable Ro antibodies but do have La, U_1-RNP (nRNP) antibodies [6–8]. Many affected infants fail to demonstrate a significant titre of circulating antinuclear antibodies, unless human tissue is used, when a speckled fluorescence pattern will be seen [9].

The presence of Ro and La antigens has been demonstrated in fetal skin and cardiac conducting tissue [10,11].

Up to 60% of the mothers of infants with neonatal LE have no clinical evidence of connective tissue disease at the time of the birth [3,7,12]. However, there is a substantial risk of subsequent development of symptoms of autoimmune connective tissue disease [13]. About 40% of the mothers do have signs or symptoms of systemic lupus erythematosus (SLE), subacute cutaneous LE or the sicca syndrome [14–17], although these may be minimal. More recently, it has been recognized that about 5% of women of child-bearing age who present with leukocytoclastic vasculitis will have Ro antibodies [18], and it is probable that about 5% of babies with neonatal LE have mothers with leukocytoclastic vasculitis [13,19].

Pathology. Skin biopsy specimens from infants with cutaneous lesions generally demonstrate the features of LE, that is epidermal atrophy, liquefaction degeneration of basal keratinocytes, colloid bodies and a perivascular and periappendageal lymphohistiocytic inflammatory infiltrate in the dermis [14,20,21].

Direct immunofluorescence is positive in about 50% of cases, showing dermal–epidermal junction and perivascular deposition of IgG, IgM and C3 [14,21].

Autoimmune haemolytic anaemia and thrombocytopenia are seen in a small proportion of affected infants [14].

Cardiac abnormalities occur in about 60% of infants with neonatal LE [1], although there appear to be some racial differences in this frequency, which is reported to be smaller, for example, in Japan [22]. Fibrosis of the conducting tissue of the heart commonly results in congenital heart block. It has recently been shown that anti-Ro antibodies can bind to cardiac conduction cells during mid- to late fetal development, leading to altered membrane repolarization and selective damage to the atrioventricular (AV) node [23]. Other developmental abnormalities of the heart may also occasionally occur, including subendocardial fibroelastosis and fibrinous pericarditis [24,25].

Asymptomatic central nervous system vasculopathy has been demonstrated in neonatal LE by ultrasound and colour Doppler flow imaging, but its longer term significance is unknown [26].

These antibodies disappear from the infant's serum within about 6 months, but are more persistent in the mother [14,21,27].

Clinical features [9,14–17,22,28–31]. Most infants with neonatal LE have either skin lesions or cardiac lesions; approximately 10% have both [13,32]. About 90% of infants with neonatal erythematosus have only skin lesions.

In about two-thirds of those infants who develop cutaneous lesions, these are already present at birth [15,30]. In the remainder, the lesions appear during the first 2–3 months, although their appearance may be delayed as long as 5 months [13].

The skin lesions of neonatal LE generally take the form of well-defined areas of macular or slightly elevated erythema, frequently annular, occurring predominantly on the face, particularly the forehead, temples and upper cheeks, and on the scalp and neck (Fig. 17.2). A 'spectacle'-like distribution of lesions around the eyes is especially characteristic. The chest, back or limbs may also be affected.

Fig. 17.2 Neonatal lupus erythematosus (LE): fading facial lesions in characteristic periorbital distribution, with residual atrophy, in a 4-month-old infant.

Less commonly, lesions take the form of annular erythema without an epidermal component; this type of presentation has predominantly been reported in Japanese infants [22,27].

Subcutaneous lesions have also been described [33].

Occasionally, neonatal LE presents as extensive reticulate erythema with atrophy, closely resembling cutis marmorata telangiectatica congenita [34,35].

Depigmentation may be very prominent in racially pigmented infants [36].

Provocation or exacerbation of lesions by sun exposure has been reported in some cases.

Follicular plugging is not prominent, but scaling is a common early feature, and a degree of atrophy and/or telangiectasia are frequent long-term sequelae. Permanent hair loss may occur.

Lesions resembling morphoea have been reported [37].

In most cases, the skin lesions have resolved within the first year, but areas of atrophy and/or telangiectasia may be more persistent [38,39]. Long-standing depressions have followed subcutaneous lesions [33]. The most frequent sites for such lesions are the temples and scalp.

Systemic features are detectable in over half of all affected infants, of which cardiac involvement is the commonest, occurring in about 50% of cases. Cardiac involvement tends to affect a different group of infants, heart and skin abnormalities occurring together in only about 10% [9,13,32]. The reasons for this are unclear. Congenital heart block can be detected as early as the 18th week of gestation by ultrasound or electrocardiography [40]. The block is generally permanent, and is not associated with structural cardiac abnormalities such as septal defects. About a half of affected infants require pacemakers [29,40].

A smaller proportion of infants have combinations of hepatomegaly, splenomegaly, lymphadenopathy, autoimmune haemolytic anaemia, thrombocytopenia and pneumonitis, which are generally mild in degree and fairly transient.

Prognosis [41]. Infants with skin lesions alone, or with skin lesions and systemic features other than heart block, generally show little sign of residual disease after the age of 1 year. However, their long-term prognosis must remain slightly guarded in the light of reports of the later development by some of full-blown connective tissue disease [25,29,42–44]. Conduction defects of the heart tend to be permanent, and when severe are associated with a significant mortality [13,29,45].

The risk of recurrence in further pregnancies appears to be about 25% [13,46]. This risk appears to be influenced by immunogenetic factors [47]. Spontaneous abortion and stillbirth do not appear to be more frequent in further pregnancies of mothers who have had a previous child with neonatal LE [13]. Mothers with Ro antibody may experience recurrent fetal loss if they do not have SLE, but do not appear to do so if they do have SLE [48].

Diagnosis [7]. The lesions of congenital rubella or cytomegalovirus infection may need to be considered, although these are of purplish colour and purpura is generally prominent. Congenital syphilis may also need to be excluded, but whereas mucosal, periorificial, and palmar and plantar lesions are common in congenital syphilis, these features are rare in neonatal LE. However, confusion may be caused by the false-positive antibody tests that are as much a feature of neonatal as of acquired LE.

Atrophy and telangiectasia of the cheeks is seen with photosensitivity in Bloom's syndrome, and without photosensitivity, in most cases, in the Rothmund–Thomson syndrome (see Chapter 15). In these disorders, skin lesions are not present at birth and generally appear later than in neonatal LE.

A skin biopsy will usually allow an accurate diagnosis of neonatal LE, particularly if combined with direct immunofluorescence studies, and tests for the appropriate circulating autoantibodies in both the mother and the child.

Treatment. The skin lesions of neonatal LE require no treatment, but sun protection is essential. Occasionally, thrombocytopenia, haemolytic anaemia or hepatitis may warrant systemic steroid therapy [49]. Up to 50% of infants with cardiac involvement will require a pacemaker [22].

The pregnancy of a woman who has Ro, La or U_1-RNP antibodies should be monitored to detect a slow fetal heart rate [50,51]. Treatment with high-dose systemic steroids may be indicated for fetal bradycardia where there are signs of heart failure [52].

Neonatal pemphigus vulgaris

Pemphigus vulgaris is unusual in pregnancy, because it is largely a disease of an older age group and because affected individuals receiving systemic treatment rarely become pregnant. Nevertheless, several cases of transplacentally transmitted pemphigus vulgaris have been reported [1–6]. Not all mothers have had clinically apparent disease during pregnancy [7]; in other cases the disease has been mild [8].

Affected infants have had cutaneous and/or mucosal erosions or bullae. Several have been stillborn [1,6]. Direct immunofluorescence has been positive in skin biopsies from all affected infants, and circulating IgG pemphigus antibodies have been found in the majority.

No treatment is required; lesions have resolved spontaneously within about 3 weeks, and circulating IgG antibodies have become undetectable by the end of the second month of life.

Transplacental pemphigoid (herpes) gestationis

Cutaneous lesions occur in about 10% of infants born to mothers with pemphigoid gestationis, although maternal IgG antibasement-membrane autoantibody can be found in all infants of affected mothers [1,2]. The lesions may be present at birth or they may appear at any time up to the third day of life [3,4]. These lesions may vary from evanescent, non-specific, erythematous or urticarial papules to fully developed bullae [5,6]. Lesions in the infant may be extensive [7]. Spontaneous regression of lesions within 3 weeks is the rule. Direct immunofluorescence is normal by the end of the first month, and circulating IgG anti-basement-membrane-zone antibody can no longer be found.

Earlier reports of increased fetal and infant morbidity and mortality when mothers have pemphigoid gestationis [8] have not been confirmed [9–11]. However, there does appear to be an increased risk of premature delivery when a mother has herpes gestationis [10,11]. The risk of adrenal insufficiency should be considered in neonates whose mothers have been treated with prednisolone for prolonged periods.

Transplacental transfer of maternal malignant disease

Transplacental transfer of maternal malignant disease is fortunately extremely rare, despite the fact that malignancy occurs in 1 in 1000 pregnancies [1,2], and it is well established that maternal cells regularly reach the fetus [3].

The malignancy transferred in this way has been malignant melanoma in about 90% of cases, although this particular malignancy accounts for only about 8% of those occurring in pregnant women [4]. Malignant melanoma transmitted in this way may result in the appearance of nodular skin deposits in the neonate. Spontaneous regression of transplacentally transferred malignant melanoma has been reported [5,6].

Transplacental transmission of acute monocytic leukaemia [7] and of natural killer (NK) cell lymphoma [8] have also been reported.

Disorders caused by transfer of toxic substances in maternal milk

When considering the cause of any rash in a young infant, the possibility that it reflects exposure of the mother to a toxic substance that has been transferred in her milk needs to be borne in mind. A good example is provided by two reports of bromoderma occurring in neonates whose mothers had taken bromide medicinally [1] or had been accidentally exposed in a photographic laboratory [2].

'Collodion' baby

Synonym

- Lamellar desquamation/exfoliation of the newborn

Aetiology and nomenclature. This term describes a highly characteristic clinical entity. It precedes the development of one of a variety of ichthyoses, the commonest of which are the autosomal recessive ichthyoses termed lamellar ichthyosis and non-bullous ichthyosiform erythroderma [1–3] (see Chapter 19). The collodion baby phenotype has been reported in the rarer autosomal dominant form of lamellar ichthyosis [4] and a possibly autosomal

dominant form of non-bullous ichthyosiform erythroderma [5]. It is also characteristic of the trichothiodystrophy–ichthyosis syndrome [6,7].

There are other ichthyoses in which an initial collodion baby phase has occasionally been reported. These include ichthyosis vulgaris [2], X-linked ichthyosis [8], Netherton's syndrome [9], neutral lipid storage disease [10] and the Sjögren–Larsson syndrome [2], but the great majority of neonates with these disorders do not demonstrate the collodion baby phenotype. A transient collodion membrane has also been reported in two neonates with Gaucher's disease [11,12].

In at least 10% of cases, the collodion baby phase is followed by a relatively mild ichthyosis of lamellar type; this may be so mild as to be considered more or less normal [2,3,13–19]. Autosomal recessive inheritance has been reported in this type of case [17], but it remains possible that these cases are genetically heterogeneous.

Pathology [1,2,20,21]. It was at one time popular to regard the collodion membrane as retained periderm (epitrichium) [22]. Histologically, however, the membrane is essentially orthokeratotic, rather than parakeratotic like the periderm [1,2,16,21], making this a highly improbable explanation. Apart from a compact, thickened orthokeratotic stratum corneum, the epidermis is fairly normal, similarly the dermis.

Although the histology of the skin is identical at birth whether the child later develops a severe ichthyosis or not, at about 15 days it may be possible to make a prediction on histological grounds [16], even though the clinical features are still indistinguishable.

Electron microscopy of the epidermis at 2 days in a baby whose skin later became clinically normal showed several distinctive features [14]. The upper two-thirds of the stratum corneum were of abnormal appearance; the corneocytes were convoluted and irregular in shape, and contained unusual, small, dense intracellular granules. There were large numbers of intercellular lamellar (Odland) bodies and exceptionally well-preserved desmosomes.

Clinical features [1–3,9,21,23,24]. The severely affected infant is bright red and encased in a taut, glistening, yellowish translucent covering resembling collodion (Fig. 17.3). The face is immobilized; tension on the skin results in ectropion, eversion of the lips (eclabion), producing a rather fish-like appearance of the mouth, and effacement of the nose and ears. The nostrils may be blocked. The skin over the fingers, hands, toes and feet may result in immobility and may interfere with blood flow, occasionally resulting in the loss of parts of digits.

Within hours, this membrane dries and cracks, and bleeding may occur along the resulting fissures. Within 1 or 2 days, it starts to peel off, either in extensive sheets or as large, light-brown scales, but may reform several times. The shedding will generally be more or less complete within 4 weeks. Subsequently, the typical features of one of several varieties of ichthyosis gradually emerge over a period of weeks or months.

During the first day or two, tightness of the skin on the thorax may interfere with respiration, and very occasionally, respiratory distress may be caused by nasal obstruction.

Fig. 17.3 Lamellar desquamation of the newborn in a 7-day-old infant. This child required peritoneal dialysis for acute renal failure secondary to inadequate hydration. A year later, the skin was normal apart from minimal fine scaling.

Diagnosis. The appearance of the collodion baby is unmistakable.

A degree of cracking and desquamation is a characteristic cutaneous finding in babies who are small for gestational age and/or post-term, presumably due to placental insufficiency, but this is unlikely to be mistaken for true lamellar desquamation of the newborn because of the lesser severity of the skin changes and the presence of other clinical features of these two states. Babies who are erythrodermic at birth, due, for example, to Netherton's syndrome, or to the Conradi–Hünermann syndrome, may be mistaken for collodion babies, but careful examination will reveal no collodion membrane.

The appearance of the neonate with harlequin ichthyosis (see below) has much in common with the collodion baby, the principal difference being the greater thickness of the stratum corneum, which typically encases the baby like a suit of armour. However, clinical differentiation may be less straightforward in milder cases.

Restrictive dermopathy also results in a neonate with tight and immobilizing skin, but in this condition, the skin appears thin and transparent, with prominent underlying blood vessels. The mouth is also open, but ectropion is not generally present. The skin does not dry out and come away. Death occurs rapidly as a consequence of respiratory failure.

Neonates with the lethal autosomal recessive Neu–Laxova syndrome [25] may have skin changes closely resembling a collodion membrane. The condition is characterized by intrauterine growth

retardation, and central nervous system, skeletal and cranial abnormalities.

Boys with hypohidrotic ectodermal dysplasia may show lamellar scaling at birth, but it is unlikely that this would be mistaken for a collodion membrane.

Prognosis. The collodion baby is at risk, largely because of the consequences of loss of skin barrier function, resulting in:

- impaired temperature regulation
- increased insensible water loss [26–28], which may lead to acute renal failure and/or permanent brain damage [29] if fluid replacement is neglected
- septicaemia [27].

Respiration may become compromised as a result of intrapartum aspiration of squamous debris shed into the amniotic fluid [30]. Interestingly, this debris can be seen on fetal ultrasound, and in such cases, early delivery by caesarean section may be protective of life.

Immobility of the chest may also compromise respiratory function, and predispose to pneumonia.

In the short term, mortality from these causes is substantial.

The longer-term outlook depends on which type of ichthyosis develops, and it is important to be aware that there is no correlation between initial severity in a collodion baby and the gravity of the ichthyosis that follows. At present, only observation over a period of months will reveal the ultimate fate of the skin in collodion babies. It has, however, been suggested that a skin biopsy at about the 15th day may be helpful in this respect [16].

Treatment. The most important element in treatment is an awareness of the possible complications, as outlined above.

The baby should be nursed in an incubator in a high-humidity atmosphere, with careful monitoring of body temperature. Great attention needs to be given to fluid and electrolyte balance. In severe cases, fluid therapy should be given intravenously, but in less severe cases oral or nasogastric fluid supplementation will suffice. Peritoneal dialysis may be indicated if renal failure occurs.

Fluid loss can be reduced by frequent applications of lipid; a 50:50 mixture of white soft paraffin and liquid paraffin is ideal for this purpose. Frequent oiling of the skin increases mobility and comfort, accelerates healing of fissures and may reduce the risk of infection.

Prevention of infection is of the greatest importance in saving these babies. Great attention should be paid to this aspect of care. Skin punctures should be kept to a minimum, and vascular access should be avoided as far as possible. Deeper fissures are more likely to become infected especially if inflamed, so regular swabs should be done for bacteria and candida as septicaemia is a common complication [31].

Bands of tight skin constricting digits, hands or feet may occasionally require surgical division.

Eczematous eruptions in the newborn

Eczematous eruptions are extremely common during the newborn period. Few are severe, and most are transient. However, in some babies they herald more chronic and possibly severe atopic dermatitis, and, in a few instances, they may provide an important clue to serious internal disease, as for example in the cases of zinc deficiency and the Wiskott–Aldrich syndrome (WAS). The following varieties of neonatal eczematous eruption will be considered here: contact dermatitis, particularly primary irritant napkin dermatitis and perianal dermatitis, intertrigo and infantile seborrhoeic dermatitis.

Contact dermatitis in the neonatal period

The skin of the newborn is particularly sensitive to irritants. Factors that contribute to the high incidence of primary irritant reactions in this age group include the widespread use of inappropriate toxic applications such as antiseptics, prolonged skin contact with urine and faeces, and the frequent presence of occlusive conditions. The commonest clinical patterns of primary irritant dermatitis seen in the newborn period are perianal dermatitis and napkin dermatitis. A non-allergic form of contact dermatitis to plastic identification bracelets has also been described in neonates [1]. The alcohol burn is a less common, but very important, form of acute irritant reaction.

True allergic contact dermatitis is exceedingly unusual in the neonatal period [2], partly because of the relative difficulty of sensitizing the skin for type IV hypersensitivity responses at this age [3,4] and partly because of the lack of appropriate antigen contact. Many authors have argued that reports of allergic contact dermatitis in neonates based on positive patch-test results require cautious interpretation, because the concentrations of allergens generally used for such tests may elicit irritant responses in small children [5–7], but relevant positive results have been described in early infancy to allergens such as nickel (from earrings), epoxy resin (from a plastic identification bracelet), and the components of various topical applications, particularly those used for the treatment of napkin dermatitis [7].

Perianal dermatitis of the newborn

Aetiology. Perianal dermatitis has been reported to have an overall incidence of 5–20% [1]. The incidence is lower in breastfed infants than in those fed cow's milk formulae [2,3]. It has been suggested that this difference might be explained by the higher faecal pH of the formula-fed infants [3], but this has not been confirmed [4]. Although the precise cause of perianal dermatitis in the newborn remains unknown, it is assumed that it represents an irritant response to faecal constituents. It is likely that there is considerable variation in susceptibility.

Clinical features. In the great majority of cases, erythema of the perianal skin makes its initial appearance during the first 8 days of life [2]. In the mildest cases, the erythema is confined to a zone some 2 cm in diameter around the anus, but commonly it extends to 4 cm or more. In the more severe forms, the affected skin may be oedematous and superficially eroded. Healing occurs spontaneously in 7–8 weeks. Although it usually occurs alone, perianal dermatitis may sometimes be associated with primary irritant napkin dermatitis or seborrhoeic dermatitis of infancy.

Diagnosis. The site and the early age of onset usually establish the diagnosis, but other dermatoses that appear in the napkin area need to be considered. The presence of pain and bleeding suggests a possible developmental defect of the anal papillae [5].

Treatment. Little treatment is usually needed, other than attention to hygiene. The affected area should be washed with water and a water-miscible emollient as soon as possible after defecation, and a protective lubricant such as White Soft Paraffin BP should be applied immediately afterwards.

Primary irritant napkin dermatitis

Synonym
- Diaper dermatitis

Terminology. The term napkin dermatitis implies an inflammatory eruption of the napkin area. Such an eruption may have many causes. The term is therefore best avoided except in this more general sense, and the term primary irritant napkin dermatitis should be preferred for the condition described here, even though its exact aetiology remains unestablished.

Aetiology [1–6]. It seems unlikely that every case of primary irritant napkin dermatitis has precisely the same combination of causes. It is, however, exceedingly rare in the absence of napkin wearing, and at least a degree of urinary or faecal incontinence.

The following factors need to be considered in any discussion of the aetiology of primary irritant dermatitis.

Maceration by water. The stratum corneum is almost exclusively responsible for the water barrier function of the epidermis, containing cells that are continuously sloughed off and renewed in a cycle of 12–24 days [7]. The hydrophobic extracellular matrix acts as the water barrier, preventing water loss from the body, and the entry of water and other hydrophilic substances, while the hydrophilic cells of the stratum corneum ('corneocytes') provide mechanical protection from the external environment in the form of a waxy layer.

Excessive wetness has several effects on the stratum corneum. Firstly, it makes the skin surface more fragile, and therefore more sensitive to frictional damage [4,8]. Secondly, it interferes with the protective barrier function [8–10], allowing increased permeation of irritant substances into the sensitive living layers of the skin below the stratum corneum, and exposure of these layers to the drying effect of the air and to the entry of harmful microorganisms.

Prolonged occlusion of the skin can itself produce erythema, particularly if water is kept in contact with the skin surface [1], and it has been suggested that prolonged contact with water alone can provoke dermatitis [11].

Friction. It seems likely that friction between the skin and the fabric of the napkin will also be an important factor in most cases. This is supported by the frequent predilection of the eruption for sites where such friction would be maximal, that is the inner surfaces of the thighs, the convex surfaces of the genitalia, the buttocks and the waistline. Friction would be able to breach the stratum corneum in the presence of maceration.

Urine. Newborn babies pass urine more than 20 times in 24 h. This frequency reduces through infancy to an average of seven times in 24 h at 12 months [12].

For many years it was believed that ammonia, produced by bacterial degradation of urea in the infants' urine, was the major cause of primary irritant napkin dermatitis [13,14]. It is now clear that this is not the case [4,15]. Neither the ammonia levels found in the first morning napkin nor the prevalence of urea-splitting microorganisms differ between infants with or without primary irritant napkin dermatitis [4]. The microorganisms isolated from affected infants are not able to release ammonia either faster or in greater quantity than those from unaffected infants [4]. It has been shown that urine containing various concentrations of ammonia does not cause significant erythema when applied under occlusion for 24 h to intact infants' skin, although it can do so when the skin has previously been abraded [4]. However, only about one in four of infants with primary irritant napkin dermatitis in this study had napkin ammonia levels in excess of the minimum concentration shown to cause such erythema. It appears, therefore, that the presence of ammonia is not mandatory, although it almost certainly will aggravate the eruption when the integrity of the skin is already compromised.

It has been suggested that urinary degradation products other than ammonia might also play a role. One study has shown that urine allowed to stand for 18 h at 37°C could induce dermatitis when applied to infants' skin, whereas fresh urine could not [16]. The effect was not related either to the pH or to the ammonia concentration, but the identity of the relevant irritant could not be established.

It is now clear that the role of urinary pH is critical. The higher the pH of the urine (i.e. the greater the alkalinity) the more liable an infant is to develop irritant napkin dermatitis. However, it seems that alkaline urine is not directly harmful; its harmful effect results from its interaction with faecal material in the napkin (see below). In addition, urine appears to increase epidermal permeability more effectively than water alone [9].

Faeces. It has been known for many years that human faeces have an irritant effect on skin [17]. Infants' faeces contain substantial amounts of pancreatic protease and lipase, and similar enzymes are produced within the gut by a variety of bacteria [18,19]. These faecal enzymes appear to be important skin irritants [20,21]. The irritant effect of such enzymes may be enhanced by many factors, particularly impaired barrier function and high pH. One of the factors that have been shown to affect faecal pH is the infant's diet, a higher pH being found in the cow's milk formula-fed infant [22].

Ureases are produced by a variety of faecal bacteria [18], and have the effect of increasing pH when mixed with urine. Increased pH enhances the activity of faecal lipases and proteases [9]. This perhaps provides an explanation for the anecdotal observation that cow's milk formula-fed infants appear more liable to primary irritant napkin dermatitis than breastfed infants, as the faeces of the former group have been shown to be more heavily colonized by urease-producing bacteria [23].

A variety of other factors may lower the infant's threshold for development of irritant napkin dermatitis; or may worsen the eruption once it is established. These include:

Poor or misguided skin care. The use of liquid soap for washing [24] and of talcum powder remain surprisingly common; both will increase risk of an irritant dermatitis.

Microorganisms. Although it has often been claimed that bacterial infection plays an important role in the common primary irritant type of napkin dermatitis, quantitative studies have consistently shown that the bacterial flora isolated from such eruptions does not differ materially from that isolated from the same area of skin in normal infants [15,25,26]. Neither does the type of napkin appear to influence the bacterial flora [27].

On the other hand, the evidence for an aetiological role for *Candida albicans* seems somewhat stronger. This organism has been isolated from the affected area in many infants with the primary irritant type of napkin dermatitis, but only very infrequently from the same area in normal infants [15,26,28,29]. Furthermore, there appears to be a good correlation between the severity of primary irritant napkin dermatitis and the level of *C. albicans* in the faeces [3].

The question of a role for *C. albicans* is complicated by the issue of the relationship between primary irritant napkin dermatitis and the classical form of napkin candidiasis. It is possible that, in most

cases, the latter is a complication of the former, and this view is supported by the fact that maceration of the skin is virtually a prerequisite for the establishment of *C. albicans* infections in human skin [30,31]. It is likely, therefore, that this organism will become established in the napkin area of infants who have primary irritant napkin dermatitis if it is present in the faeces.

Antibiotics. The use of broad-spectrum antibiotics in infants for conditions such as otitis media and respiratory tract infections has been shown to lead to an increased incidence of irritant napkin dermatitis [32]. This appears to parallel increased recovery of *C. albicans* from the rectum and skin in such infants.

Diarrhoea. The production of frequent liquid faeces is associated with shortened transit times, and such faeces are therefore likely to contain greater amounts of residual digestive enzymes.

Developmental anomalies of the urinary tract. Those anomalies that result in constant passage of urine will predispose to urinary tract infections.

In summary, the precise aetiology of primary irritant napkin dermatitis remains unestablished. Maceration and friction appear to be important in breaching the epidermal barrier. Faecal proteolytic and lipolytic enzymes appear able to act as irritants in skin whose barrier function is impaired, particularly if the ambient pH is high. The main factors in increasing the pH appear to be the action of faecal urease on urine, and the infant's diet. Secondary invasion by *C. albicans* appears to be a risk where this organism is present in faeces.

Pathology. The histological picture is generally that of primary irritant dermatitis with epidermal spongiosis and mild inflammatory changes in the dermis.

Clinical features [33,34]. Primary irritant napkin dermatitis is not often seen during the first 3 weeks of life. The onset is most often during the third to the 12th week, and the peak prevalence is seen between the seventh and 12th months [3,35]. Essentially the same condition has been reported in older children and adults who are incontinent of urine [36–38].

The overall incidence of the condition is difficult to establish, and may now be less than in the past, due to a general change to disposable napkins, but there is evidence that some 50% of infants are affected to some degree at some stage [3]. Another index of the degree of the problem is provided by the fact that in one survey it accounted for some 20% of all skin consultations in children aged under 5 years in the UK [39]. Both sexes and all races appear to be equally affected.

The most common form of primary irritant napkin dermatitis comprises confluent erythema of the convex surfaces in closest contact with the napkin, that is the buttocks, the genitalia, the lower abdomen and pubic area, and the upper thighs. The deeper parts of the groin flexures are generally spared (Fig. 17.4).

In some infants, the eruption is more or less confined to the margins of the napkin area ('tidemark dermatitis') and may reflect either chafing against the edge of the napkin or prolonged skin contact with the edges of impervious napkin covers or pants.

Fig. 17.4 Primary irritant napkin dermatitis, affecting the convexities predominantly with sparing of the groin creases.

Another distinctive pattern that has recently been described is one where the eruption is localized to the lateral parts of the upper thigh and buttock, most often unilaterally, but not infrequently bilaterally, in a position that corresponds to the areas where direct contact may occur with the bands that fasten the napkin [40,41]. It appears most often to be due to an irritant effect, but may also be a reflection of contact sensitization to rubber or glue chemicals [42].

Where the reaction is acute, the erythema may have a glazed appearance and be followed by peeling of the skin in sheets. A finer scaling is more commonly present in more long-standing cases. Post-inflammatory hypopigmentation may be a striking feature in racially pigmented infants.

Occasionally, an erosive form of primary irritant napkin dermatitis is seen, in which small vesicles and erosions may develop into rather characteristic, shallow, round ulcers with raised crater-like edges ('Jacquet's dermatitis').

In both sexes, involvement of the genitalia may lead to dysuria and occasionally, where the glans penis is severely affected, male infants may experience acute retention of urine [33].

Several fairly distinctive variants of primary irritant napkin dermatitis occur. When secondary invasion by *C. albicans* is present [15], the erythema may be more intense, and will no longer spare the deeper parts of the flexural folds. The margin tends to become more defined, scalloped with peripheral scaling. Within the marginal area small pustules are often visible, and these may also be seen scattered beyond the periphery of the erythema—so-called 'satellite' lesions. This clinical appearance is associated with faecal carriage of *C. albicans* [43].

In the second, less common variant, the erythematous areas are similarly well marginated but take on a markedly psoriasiform aspect with prominent scaling of a rather more adherent and micaceous type [39,44,45]. The onset of this eruption, commonly termed *napkin psoriasis*, may be quite sudden and its extension rapid. The relationship of this eruption to true psoriasis is discussed in Chapter 20.

A herpetiform presentation of primary irritant napkin dermatitis has occasionally been described [46]. This takes the form of an

eruption of vesicles and pustules followed by shallow erosions, closely resembling herpes simplex clinically, but showing no evidence of this infection pathologically.

Rather rarely, one may see domed, reddish brown or purple nodules as an additional feature. These lesions, usually known as infantile gluteal granulomas, are discussed later in this chapter.

Not infrequently, primary irritant napkin dermatitis affects areas beyond the confines of the napkin area itself. This appears particularly likely where there has been prolonged contact between the skin, urine and an occlusive surface such as a plastic cot sheet. Thus, the lateral aspects of the thighs, the calves and the heels are especially commonly affected.

In other babies, rapid dissemination of the rash occurs without any clear explanation, most characteristically in the form of expanding nummular lesions on the trunk, and more confluent erythematosquamous plaques in the flexures of the axillae and neck. An 'id' reaction to *C. albicans* has been proposed as the explanation for some of these rashes, but without any convincing evidence being provided to support such a view [28,45,47]. Where a rash in the napkin area is the first manifestation of psoriasis, other lesions of psoriasis may eventually make their appearance elsewhere. Similarly, napkin dermatitis may be the first sign of atopic dermatitis (see Chapter 24), or of 'seborrhoeic dermatitis of infancy'.

In infants with racially pigmented skin, hypopigmentation may be very prominent, and is sometimes the parents' principal anxiety. When there is an associated eczematous eruption on the face, this may similarly feature marked hypopigmentation, and this may be the presenting problem [48].

Prognosis. Primary irritant napkin dermatitis will almost always show some response to therapy, and, in the longer term, it will resolve when napkins are no longer worn. However, in some children the napkin area eruption is merely the first sign of a susceptibility to chronic skin disorders, particularly psoriasis and atopic dermatitis. Since atopic dermatitis often initially presents with a napkin dermatitis indistinguishable from simple primary irritant napkin dermatitis, one has to be cautious not to give too optimistic a prognosis to parents of any child with such a rash.

Differential diagnosis. A wide variety of skin disorders present with lesions in the napkin area during infancy.

A confluent, glistening, sharply marginated erythematous rash with peripheral desquamation and/or pustulation, and usually with satellite pustules, is, together with oral candidiasis, the typical presentation of neonatal candidiasis, a superficial *Candida* infection transmitted to the baby during birth [49]. The rash normally appears during the second week of life, and is aetiologically distinct from napkin-area *Candida* infections secondary to primary irritant napkin dermatitis.

In the past, congenital syphilis was relatively common, and had to be considered seriously in any infant with a dermatosis in the napkin area. Congenital syphilis is now rare in many countries, but its continued existence must constantly be borne in mind. Reddish brown macules, sometimes slightly raised, arise principally on the extremities including the palms and soles, and on the face mainly around the mouth. The napkin area is also frequently affected. Bullous or erosive lesions may occur in the napkin area. Flexural condylomas, rhinitis, hepatosplenomegaly and low birth weight are regular features.

The important diagnosis of zinc deficiency must be considered in any infant with a napkin dermatitis which fails to respond to appropriate treatment. A history of prematurity should increase one's suspicion, and a normal plasma zinc level does not rule out the diagnosis. Infants with napkin eruptions caused by zinc deficiency usually have a concurrent facial dermatitis extending from the perioral area, an erosive paronychia and erosive lesions in the palmar creases of the hands.

Multiple carboxylase deficiency is a rare cause of rashes in the napkin area; however, the rash most characteristically starts on the face with a presentation resembling seborrhoeic dermatitis.

In infancy, one of the commonest presentations of Langerhans' cell histiocytosis (see Chapter 55) is intertrigo, which tends to be very persistent and to become eroded as the disease progresses. Although the intertriginous eruption of Langerhans' cell histiocytosis may appear very early, more often it does not do so until after the third month. Initially, the eruption comprises small, yellowish papules, which become confluent and subsequently may become ulcerated. The scalp is almost always concurrently affected, particularly the retroauricular area.

Some diagnostic difficulty may be encountered by the occasional occurrence of dermatophyte infections in the napkin area [50–52]. It is important to bear in mind that the clinical appearances of such infections are likely to have been substantially modified by the application of topical corticosteroids.

Primary HSV infection of the genital area occurs from time to time in both boys and girls. The eruption is acute and accompanied by malaise and pyrexia.

Unusual infections causing eruptions in the napkin area should alert one to the possibility of primary or acquired immunodeficiency [53].

Treatment. Successful treatment of primary irritant napkin dermatitis depends on recognition of the relevant aetiological factors in the individual child, but can nevertheless generally follow a fairly standard pattern. The provision of topical medications without attention to such details as the frequency of napkin changes is often associated with therapeutic failure. The elements of successful treatment include the following:

Attention to the napkins

(a) *Disposable versus washable cloth napkins*. The use of good-quality disposable napkins, particularly those containing absorbent gelling materials ('super-absorbent' disposable napkins), is associated with a lower incidence and with lesser severity of napkin dermatitis compared with washable cloth napkins [3,54–56]. These gels are able to absorb about 80 times their own weight of water, and their use therefore results in reduced wetting, and, therefore, less maceration of the skin [57]. The use of such napkins is also associated with more normal skin pH values [54]. Highly absorbent napkins with an added 'breathable' microporous film membrane have been shown to reduce the prevalence of *Candida albicans* and napkin dermatitis [58].

(b) *Continuous administration of emollient from certain disposable napkins*. Disposable napkins are now available in which the layer next to the skin (the 'topsheet') is impregnated with an emollient, usually predominantly white soft paraffin. The use of this type of napkin has been shown to reduce the severity of irritant napkin dermatitis [59].

(c) *Frequency of napkin changes*. The frequency of napkin changes is also important, but probably less so now, because the absorbency of disposable napkins has increased greatly over recent years. It remains important however to change napkins as soon as possible after defaecation.

(d) *Care of washable napkins*. The use of antiseptic solutions for the storage of cloth napkins prior to washing is more or less universal, and is safe as long as suitable agents are used and washing and rinsing procedures are adequate. Poisoning of infants by antiseptics used in the laundering of napkins is well documented [60–62]. The quaternary ammonium compounds are now regarded as the best choice, of which benzalkonium chloride is perhaps the most widely employed. Antiseptics should never be used during the rinsing process.

Machine washing is generally preferable, as the cleaning and rinsing processes are reliable and thorough. A lower incidence of primary irritant napkin dermatitis has been demonstrated in babies whose napkins were laundered commercially rather than domestically [35]. 'Biological' detergents are best avoided, as are fabric 'conditioners' added during the rinsing. Tumble drying is preferable to air drying because it leaves the napkins softer, and therefore less liable to chafe.

Routine skin care in the napkin area. A routine of skin care should be instituted that will help prevent recurrence after the eruption has been successfully cleared. At each napkin change, a water-repellent emollient such as White Soft Paraffin BP, a half-and-half mixture of White Soft Paraffin BP and Liquid Paraffin BP, Zinc and Castor Oil Cream BP, or Bepanthen® [63] ointment should be applied.

When the napkin has been soiled, the area should be cleansed with water and a water-miscible emollient such as Aqueous Cream BP, and dried before applying a water-repellent emollient. Traditionally, cotton-wool balls have been used for this purpose. However, prewetted wipes are now available commercially which combine a very soft fabric with water, without the additives such as alcohol and fragrance that made such products undesirable in the past. It is very important that cleansing of the skin be undertaken as gently as possible, with the minimum of friction.

During remission, the baby should be bathed daily with a dispersible or semidispersible bath oil added to the water, and a water-miscible emollient should be used as a cleansing agent. While the eruption is under treatment, such baths should ideally be given twice a day.

The use of talcs and proprietary over-the-counter preparations containing potential irritants should be discouraged.

Specific therapy. Topical corticosteroids are helpful, and are indicated in all but the mildest cases. There is, however, virtually never any need to use applications containing anything more potent than 1% hydrocortisone. Such an application should be used twice a day after the bath, ideally in an ointment base.

It must be borne in mind that the rate of percutaneous absorption of corticosteroid from topical application in the napkin area will be considerably enhanced by the occlusive conditions found at this site. Fears that corticosteroid absorption might interfere with descent of the testes in male infants have not been confirmed in those of normal birth weight, but the possibility remains that such a problem could arise in low birth-weight babies [64].

As the eruption is often secondarily infected with *C. albicans*, the use of an ointment containing an anticandidal agent such as miconazole is justified and has been shown to be effective [65]. Systemic antibiotics are very rarely indicated, and there is no convincing evidence that oral nystatin has any additional therapeutic or prophylactic value when used in combination with a topical anticandidal agent [1,29,66].

In cases where flow of urine and especially of faeces over the skin is more or less continuous, topical sucralfate has been reported to provide a particularly effective barrier [37].

Infantile gluteal granulomas

This term has been applied to a condition that arises as a complication of the primary irritant type of napkin dermatitis [1]. The apparent absence of any reports of the disorder before 1971, in contrast to the substantial number published throughout the world during the next decade, implied that this may have been a modern phenomenon, perhaps related to changes in the care of the napkin area in general, and the treatment of napkin dermatitis in particular. Conversely, a decrease in the number of case reports during the last decade may reflect a real improvement in these aspects of infant care.

In most, but certainly not all [2,3] of the reported cases, rather potent topical corticosteroids had been used, and the authors believed them to have been important precipitating factors [4–7]. *Candida albicans* has also been considered as an aetiological factor [6], but cannot be isolated from the napkin area in such infants any more often than in uncomplicated cases of napkin dermatitis [5]. Intracutaneous intradermal tests to *C. albicans* antigen have not shown evidence of either immediate or delayed hypersensitivity, and serum precipitins to *C. albicans* and *C. parapsilosis* have not been found [8]. A role has also been proposed for the use of occlusive pants, but these are now rather rarely used in the developed parts of the world. Starch particles were found within lesions in one case [9], but were sought and not identified in others [3].

Histologically, there is a dense granulomatous infiltrate occupying the full depth of the dermis, comprising lymphocytes, plasma cells, neutrophils, eosinophils and histiocytes [4,5,8,10].

Fig. 17.5 Infantile gluteal granulomas in the pubic area of a 6-month-old infant.

The characteristic lesions most commonly make their appearance between the fourth and ninth months of life in a child with primary irritant napkin dermatitis. There is no correlation between the severity of the napkin dermatitis and the incidence of these lesions, and they frequently appear to arise at a time when the napkin dermatitis is improving. The lesions comprise one or several, rather uniform, livid purple nodules, which are usually oval in outline with their long axis parallel to the skin creases [5] and up to about 3 cm in length. They tend to occur on the convexities of the napkin area, not in the flexures themselves, and are definitely not confined to the gluteal region, as the name might be taken to imply (Fig. 17.5). They have occasionally also occurred at other sites in affected infants [5]. They persist for some weeks and appear to regress spontaneously, even if the use of potent corticosteroid applications is continued [11], and may leave atrophic scars [5]. Analogous lesions have been described in incontinent older patients [12,13].

These lesions require little treatment other than the removal of likely provocative factors, especially the withdrawal of topical corticosteroid therapy other than hydrocortisone alone, if this is required for the treatment of persisting napkin dermatitis, and the restriction to a minimum of the wearing of occlusive plastic pants. Napkin-area care should be as outlined above for primary irritant napkin dermatitis.

These lesions have a superficial resemblance clinically and histologically to Kaposi's sarcoma [10]. However, the latter more commonly arises on the extremities, even in infants [14], and histologically shows characteristic interweaving bands of spindle cells, at least in well-developed cases.

Infantile 'seborrhoeic' dermatitis

Definition and nomenclature. The term infantile 'seborrhoeic' dermatitis is widely used to describe an allegedly distinctive eczematous or psoriasiform eruption seen in infants, having a predilection for the scalp and the proximal flexures, and a favourable prognosis compared with atopic dermatitis. The term nevertheless remains unsatisfactory, as the condition has no established relationship with seborrhoea or even with sebum; neither is there any convincing evidence that it is analogous to seborrhoeic dermatitis of adults. There must be some doubt whether the condition exists at all as a separate entity.

Aetiology. The authors regard the term *infantile seborrhoeic dermatitis* as a description of a somewhat distinctive but nevertheless highly variable clinical presentation rather than a single disease. It may be a presentation that can reflect a variety of different skin disorders, and that may therefore have a number of different causes. The term is used to describe cases that others would consider to be examples of cradle cap with intertriginous lesions, intertrigo, primary irritant napkin dermatitis with dissemination, atopic dermatitis, infantile psoriasis and multiple carboxylase deficiency, as well as rashes that may reflect primary immunodeficiency infants. Once all these have been excluded, how many cases of a genuinely distinct seborrhoeic dermatitis of infancy would remain is not clear. However, as there remains a considerable body of opinion that there is a true infantile seborrhoeic dermatitis, the condition is described in this chapter. It appears possible that disagreements on this subject might to some extent reflect regional variations in incidence, and possibly a dramatic fall in incidence in recent years.

The relationship between infantile seborrhoeic dermatitis and atopic dermatitis has been the subject of debate for many years. Some authorities have proposed that infantile seborrhoeic dermatitis is merely a characteristic pattern of atopic dermatitis and not a separate entity [1], on the basis of the observation that apparently typical infantile seborrhoeic dermatitis not infre-

quently transforms into equally typical atopic dermatitis. The occurrence of such transformation is not disputed, only its frequency and interpretation. A prevalence of atopic dermatitis of 27.5% was reported in a group of children reviewed 5–13 years after a diagnosis of seborrhoeic dermatitis had been made in infancy [2]. In another study [3], it was shown that 19% of a group of children, diagnosed as having seborrhoeic dermatitis of infancy about 12 years earlier, had atopic dermatitis on review, compared with a prevalence of 10% in a control group, and of 45% in a group of children diagnosed as having atopic dermatitis in infancy. Scientific resolution of this controversy is hampered by clinical overlap between the two conditions, at least in their earliest stages [4]. Furthermore, the incidence of atopic dermatitis is so high that a proportion of infants with infantile seborrhoeic dermatitis would in any case be expected to develop atopic dermatitis. Because the age of onset is similar, this would often occur before the seborrhoeic dermatitis had resolved. The most valid reasons for continuing to regard the two conditions as distinct entities are, firstly, a relative lack of association between infantile seborrhoeic dermatitis and atopic status in infancy [5] and, secondly, a better prospect of early resolution in infantile seborrhoeic dermatitis [4].

These problems are highlighted by the reported prevalence of psoriasis of about 27% in a group of children reviewed 2–13 years after a diagnosis of infantile seborrhoeic dermatitis had been made [6].

Controversy also surrounds the relationship between infantile seborrhoeic dermatitis and seborrhoeic dermatitis of adults. Sebum is no longer considered an important aetiological factor in the adult condition, although it is considered possible that seborrhoea plays a part in the seborrhoeic dermatitis seen in a relatively high proportion of patients with Parkinson's disease. As infants do secrete some sebum, at least in the first few months of life [7], an aetiological role for sebum in infantile seborrhoeic dermatitis is not entirely excluded and, it has been argued, without any scientific support, that the typical early resolution of the disorder is the direct result of decreasing levels of sebum production during the last 6 months of infancy. There is no evidence of an increased prevalence of seborrhoeic dermatitis in adult life among those who previously had a diagnosis of infantile seborrhoeic dermatitis.

A favoured view in the past was that infantile seborrhoeic dermatitis is an 'id' reaction to *C. albicans* skin and intestinal infection [8,9], but no convincing evidence has been put forward to support this hypothesis.

An aetiological role for *M. furfur* has been convincingly argued in adult seborrhoeic dermatitis [10], and is supported by the therapeutic benefit that follows therapy with ketoconazole [11]. It has been demonstrated that this organism can activate complement *in vitro* by the alternative pathway [12]. *Pityrosporum ovale* is part of the normal skin flora in adults, but is rare in prepubertal children; it is generally found in greatest density in the scalp and proximal flexures. The proportion of the normal scalp flora represented by *P. ovale* is increased in adults with seborrhoeic dermatitis [13], and the organism has been isolated with an increased frequency from several body sites in infants with infantile seborrhoeic dermatitis [14,15]. A possible aetiological role for this yeast in infantile seborrhoeic dermatitis is supported by reports of therapeutic response to topical ketoconazole [15,16].

In the past, there was a strong feeling that nutritional factors might be important in the aetiology of infantile seborrhoeic dermatitis, an impression that was strengthened by a report from Czechoslovakia of an increased incidence of the condition during the post-Second World War period of food shortage [17]. The appearance of an intertriginous dermatitis with some resemblance to infantile seborrhoeic dermatitis was described in infants fed a diet deficient in essential fatty acids [18], but evidence of essential fatty acid deficiency has not been demonstrated in infants with seborrhoeic dermatitis [19]. Data have been reported, however, that were interpreted as suggesting that affected children may have transiently impaired activity of the enzyme, δ-6-desaturase [20]. Seborrhoeic dermatitis has also been reported in breast-fed babies of malnourished mothers, in whom it improved when biotin injections were given to the mothers [21]. Dramatic responses have been described in infants with generalized seborrhoeic dermatitis who were themselves given oral or parenteral biotin [22,23]. In contrast, subsequent controlled trials of biotin treatment provided no support for such claims [19,24], and biotin deficiency in infancy does not result in the clinical picture of seborrhoeic dermatitis [25,26].

Pathology. There have been very few studies of the histopathology of infantile seborrhoeic dermatitis. However, it seems clear that one finds patchy parakeratosis, with epidermal microvesicles and slight spongiosis, occasional lymphocytes, moderate acanthosis (often psoriasiform) and a poorly developed granular layer [27]. The dermis features a mild, patchy perivascular lymphocytic inflammatory infiltrate and prominent perivascular oedema. Direct immunofluorescence has been negative, and candidal antigen has not been identified.

Clinical features [4,28,29]. The eruption generally first appears between the second week of life and the sixth month, but perhaps most frequently between the third and eighth weeks. In some cases, it starts in the napkin area; in others, it starts on the face and scalp. Occasionally, the eruption first appears on the trunk outside the napkin area. Often, the rash occurs almost simultaneously on the face, scalp and in the napkin area at its onset. It tends to spread fairly rapidly to involve the scalp, face, neck, napkin area and axillae. On the scalp, the vertex and frontal areas are the sites of predilection. On the face, the forehead, eyebrows, eyelids and nasolabial folds tend to be the worst affected areas. The eruption is often confluent around the neck and up the sides of the face to the temples, the area behind the ears tending to be the most severely affected. In the napkin area, the folds are confluently involved. On the trunk, the umbilical area is a favourite site.

The rash comprises well-defined areas of erythema and scaling with tiny vesicles. Papular and lichenified lesions are not seen. On the scalp and in the flexures, the eruption is confluent, but, elsewhere, the individual lesions usually start as small, round or oval areas, subsequently extending and coalescing to form patterns. The scales are rather adherent; they are yellow-brown in colour, large and greasy in the scalp, but smaller, whiter and drier in other areas.

Typically the infant is well, and pruritus appears to be relatively mild, in contrast to atopic dermatitis. As a consequence, feeding and sleep are generally undisturbed.

Differential diagnosis. The diagnostic features of seborrhoeic dermatitis are said to be its distribution in the scalp and proximal flexures, and the relative absence of pruritus, but these are not really sufficiently specific to define the disorder clinically.

Many of those diagnosed as having infantile seborrhoeic dermatitis could be given more satisfactory alternative diagnoses. These include cradle cap, intertrigo, disseminated primary irritant napkin dermatitis, atopic dermatitis, infantile psoriasis, zinc deficiency, multiple carboxylase deficiency and primary immunodeficiencies.

Perhaps the situation in which the diagnosis of infantile seborrhoeic dermatitis is most often incorrectly applied is that of disseminated primary irritant napkin dermatitis (see above). Some babies with typical primary irritant napkin dermatitis may experience progressive spread of the eruption beyond the confines of the napkin area. This generally only occurs when the napkin dermatitis is relatively intense. The pattern of dissemination in such cases may closely resemble the distribution of lesions regarded as characteristic for infantile seborrhoeic dermatitis.

It is likely that in a small proportion of cases, infantile seborrhoeic dermatitis is an early manifestation of psoriasis. There is certainly a suspicion that the dissemination of primary irritant napkin dermatitis is at least occasionally a reflection of underlying predisposition to psoriasis.

As discussed earlier in this chapter, there is a common, acquired type of cradle cap that is frequently associated with scaling lesions in the eyebrows, forehead and temples, and the retroauricular area and neck, and occasionally with intertriginous lesions in the axillae and groins. This rash starts on the scalp and manifests relatively little inflammation. To some, this is a form of infantile seborrhoeic dermatitis; to others, it is a different entity.

Differentiation from atopic dermatitis may be particularly problematic, directly mirroring uncertainties about the existence of such an entity as infantile seborrhoeic dermatitis. There can be no doubt that rashes having the clinical characteristics of infantile seborrhoeic dermatitis may gradually transform into one that has the typical appearances of infantile atopic dermatitis, an observation that has led many to regard infantile seborrhoeic dermatitis as nothing more than a 'seborrhoeic pattern' of atopic dermatitis in infants [1]. The presence or absence of a family history of atopic disorders appears to be unhelpful in discrimination, as is the age of onset [4]. Pruritus is commoner and more severe in atopic dermatitis, but it should be borne in mind that pruritus may not in any case be evident in early infancy.

Langerhans' cell histiocytosis (see Chapter 55) may present with an eruption having features in common with infantile seborrhoeic dermatitis, particularly its distribution in the scalp, groins and axillae. However, careful examination will demonstrate that the eruption of Langerhans' cell histiocytosis comprises clusters of small, translucent, flesh-coloured papules, although these may become confluent at certain sites, particularly in the proximal flexures and in the retroauricular area. There is often a petechial element in addition. Although the child may be pallid and unwell, this is not invariably the case. There may of course be other manifestations of the disease such as oral or anogenital lesions, soft masses in the scalp, or hepatosplenomegaly. Where there is any suspicion of Langerhans' cell histiocytosis, a skin biopsy should be undertaken.

Multiple carboxylase deficiency may present in infancy with a well-marginated erythematosquamous rash that starts in the scalp, on the eyebrows and at the eyelid margins, extending later to the perioral, perianal areas and to other flexural sites. There may be associated blepharitis, and keratoconjunctivitis causing photophobia. Vomiting is common. Neurological symptoms tend to be prominent, particularly convulsions, developmental delay, hypotonia and ataxia.

Certain primary immunodeficiency disorders may present with a progressive eczematous eruption having a predilection for the proximal flexures. Similar rashes may occur in secondary immunodeficiency disorders such as congenital human immunodeficiency virus (HIV) infection.

Prognosis. The outlook, even without treatment, is good, and clearance can be anticipated within a few weeks in the majority of cases. Relapses are unusual after clearance. Persistence suggests that the correct diagnosis is atopic eczema, psoriasis, zinc deficiency, Langerhans' cell histiocytosis or immunodeficiency.

Treatment. The treatment of this condition is similar to that of atopic dermatitis. Affected infants should be bathed at least once a day, and a dispersing bath oil may be added to the water. During the bath, affected areas should be cleaned with a water-dispersible emollient such as Ung. Emulsificans BP or Aqueous Cream BP. Soap should be avoided. After bathing, a topical antiyeast agent should be given, because 2% ketoconazole cream has been shown to be effective in a high proportion of cases [16]. Treatment should be applied once or twice a day for 10–14 days. At other times during the day, a simple emollient cream or ointment should be applied, especially in the napkin area.

The scalp should be cleaned with 2% ketoconazole shampoo. Applications containing salicylic acid or corticosteroids should not be used, because of the very efficient absorption of these molecules at this site in infancy.

While it is reasonable to assess the nutritional value of the infant's diet, there is no evidence that either biotin or essential fatty acids are generally beneficial [19,24].

Infantile psoriasis and napkin psoriasis

While it is uncommon for psoriasis to appear in infancy, this undoubtedly does happen [1–3], and there is some evidence suggesting the occasional occurrence of congenital psoriasis [1,4,5]. However, the term napkin psoriasis has been used rather loosely to describe what should probably more correctly have been called *psoriasiform napkin dermatitis* or *psoriasiform seborrhoeic dermatitis of infancy* [6–8]. In some infants with primary irritant napkin dermatitis and infantile seborrhoeic dermatitis, the eruption shows psoriasiform features clinically (Fig. 17.6) [9–12]; it has been demonstrated that these children have an increased risk of genuine psoriasis many years later [9,12–15].

True psoriasis occurs in infancy, most typically in the napkin area as an isomorphic (Koebner) response in a genetically predisposed child with primary irritant napkin dermatitis [1]. While a fairly confident diagnosis of psoriasis can sometimes be made in such a case, it is more often appropriate to use the term 'psoriasiform' in this situation, as most infants with psoriasiform napkin dermatitis do not appear to go on to develop psoriasis [16]. Furthermore, it has been shown that the frequency of the three human leukocyte antigens (HLA), B13, B17 and BW37, is no different in infants with psoriasiform napkin dermatitis from their frequency in normal infants, whereas they are found with very significantly increased frequency in true psoriatics [17].

Fig. 17.6 Napkin psoriasis: confluent dry erythema with a sharp, scalloped margin in a 7-month-old infant.

Psoriasiform napkin dermatitis has a mean onset at about 2 months, and generally lasts for 2–4 months [9,16]. The rash comprises psoriasiform plaques in the napkin area with smaller papular satellites of similar appearance. It frequently disseminates, to involve the trunk and limbs, where lesions will have the same morphology, and to the face and scalp, where affected areas tend to be more diffuse and covered with denser, adherent scale or crust. Frankly pustular lesions have been described in disseminated napkin psoriasis [18].

Generalized pustular psoriasis has also been described occasionally in infancy, including a case in which lytic bone lesions were present due to chronic, recurrent, multifocal osteomyelitis [19].

'Blueberry muffin' baby (dermal erythropoiesis)

Definition. This term has been used to describe a characteristic eruption in neonates, often present at birth, comprising widespread, purple, erythematous, oval or circular macules, papules and nodules reflecting dermal erythropoiesis.

Aetiology and pathology (Table 17.3). The 'blueberry muffin' type of lesion has been recorded in a number of congenital viral and bacterial infections, notably rubella [1–5], cytomegalovirus [1,6–9], coxsackie B2 infection, parvovirus B19 [10], and in congenital syphilis and toxoplasmosis [7,11]. These lesions have also been described in a variety of congenital haematological disorders, notably hereditary spherocytosis [12], rhesus incompatibility [13,14], ABO blood group incompatibility [6] and twin–twin transfusion syndrome [6,15]. Occasionally, clinically identical lesions have occurred in infants who appeared to have no underlying cause [6].

In the congenital infections and haematological disorders, the lesions have been shown histologically to comprise foci of dermal erythropoiesis [1,6,12,15,16]. The reticular dermis contains aggregates of nucleated and non-nucleated erythrocyte precursors, but generally no cells of myeloid or megakaryocytic type. It is possible that this process represents persistence and exaggeration of the dermal erythropoiesis that is a normal occurrence in early fetal development, but the reasons behind this persistence are unclear [8,12].

Table 17.3 Differential diagnosis of the 'blueberry muffin' baby.

Dermal erythropoiesis
Congenital infections (rubella, cytomegalovirus, coxsackie B2, syphilis, toxoplasmosis)
Hereditary spherocytosis
Rhesus haemolytic anaemia
ABO blood group incompatibility
Twin–twin transfusion syndrome
Neoplastic infiltrates
Congenital leukaemia
Neuroblastoma
Congenital rhabdomyosarcoma
Other disorders
Neonatal lupus erythematosus (LE)

Clinical features. The skin lesions of dermal erythropoiesis are present at birth, comprising widespread or sometimes more local collections of macules and infiltrated, domed papules up to about 1 cm in diameter, having a colour that is generally purple, but may vary from dark blue to magenta. There may be frank petechiae on the surface of some of the lesions. Favoured sites include the trunk, head and neck. The lesions generally fade into light-brown macules within a few weeks of birth. Late-onset blueberry muffin syndrome has been reported in a 3-month-old child following congenital rubella [17].

Diagnosis. Clinically rather similar but more nodular lesions have occurred in a number of situations. Whether such lesions should be called 'blueberry muffin' lesions is debatable, as they do not show dermal erythropoiesis, but a variety of other histological appearances, in each case characteristic for their cause. Examples include congenital leukaemia [18–25], neonatal neuroblastoma [26,27], congenital rhabdomyosarcoma [28], congenital Langerhans' cell histiocytosis [29] and neonatal LE.

Neonatal purpura fulminans

Definition. Neonatal purpura fulminans is a potentially lethal disorder characterized by progressive haemorrhagic necrosis of the skin associated with cutaneous vascular thrombosis. It is usually due to a genetically transmitted thrombophilic disorder.

Aetiology. In the older child, purpura fulminans is a highly characteristic feature of meningococcal septicaemia, where it results from acquired deficiency of protein C or S [1], and it may occur as a sequel to a number of other infections, including common infections such as streptococcal infections, varicella and measles [2].

However, the occurrence of purpura fulminans in the neonate is almost always a reflection of homozygous deficiency of protein C or, less frequently, of protein S [3,4]. Protein C resistance has also been reported, due to mutations in the factor V gene [5,6].

Clinical features. The skin lesions most characteristically appear within the first 12 h of life [5,7], but their initial development may occasionally be delayed until later in infancy [8]. They generally comprise more or less symmetrical and well-defined 'lakes' of confluent ecchymosis, without petechiae. The lesions occur most often on the limbs, particularly at sites of pressure, but may also appear on the trunk and on the face and scalp. The onset is sudden, and the lesions enlarge rapidly, with coalescence and the development of haemorrhagic bullae and central necrosis. There is surrounding erythema and the lesions are tender. The patient is frequently febrile. These infants are also at risk of thrombosis in the central nervous system, and in the retinal vessels [7,9–11]. There is a substantial danger of internal haemorrhage, shock and death.

Diagnosis. Disseminated intravascular coagulation can also occur in association with severe bacterial infections in infants as well as in older children [12].

Treatment. Initially, fresh frozen plasma should be given with the minimum delay, in a dose of 10–15 ml/kg/12 h. If protein C deficiency is confirmed, onward therapy with protein C concentrate should continue until the skin lesions have healed [13]. Longer-term treatment is with oral anticoagulants. Liver transplantation has been undertaken successfully [14].

Acute haemorrhagic oedema of childhood

Synonym
- Finkelstein's disease

Definition. Acute haemorrhagic oedema of infancy is a distinctive type of leukocytoclastic vasculitis occurring in children under the age of 2 years. It was first described under this title by Finkelstein [1]. Clinically it is manifest by a combination of purpura, often in a cockade pattern, and an inflammatory oedema of the limbs and face, with a tendency to recurrence in the short term and subsequent spontaneous resolution [2].

Aetiology. The cause of infantile acute haemorrhagic oedema remains unknown, and there has been considerable debate about its relationship to Henoch–Schönlein purpura. Many regard it as an analogue of Henoch–Schönlein purpura, occurring in the very young, and this view is to some degree supported by a report of associated haematuria and proteinuria [3,4]. It is generally believed that infections, drugs and vaccines might all be precipitating factors in individual cases [2,5], and a recent case report provided evidence of provocation by a primary cytomegalovirus infection [6].

Pathology. Histopathology of the skin lesions has shown changes varying from a perivascular lymphocytic and histiocytic infiltrate with erythrocyte extravasation, to fully developed leukocytoclastic vasculitis with fibrinoid necrosis [4,7–12].

Direct immunofluorescence has generally demonstrated fibrin and C3 in and around dermal vessels [5]. IgM has been found in about three-quarters of cases and IgA in about one-quarter.

Haematological studies have invariably shown normal platelet counts and no abnormalities of coagulation. Serum complement levels have been normal.

Transient renal involvement may be revealed by the occurrence of microscopic haematuria and mild proteinuria [3,4].

Clinical features. The condition is seen almost exclusively in children between the ages of 4 months and 2 years. It is manifest by the sudden appearance of oedematous papules that feature petechial haemorrhage, and that extend to form ecchymotic plaques. These lesions most typically occur on the face, especially the cheeks, eyelids and ears, and the limbs, particularly the hands and feet. These plaques are usually of cockade (rosette) type, with scalloped margins, but occasionally small lesions join up to produce a more reticulate pattern. The lesions often follow immunizations or an upper respiratory tract infection (URTI). Accompanying oedema of the hands, feet or whole limbs is common.

Associated oedema of the penis and scrotum [3,13,14] or oral petechial lesions [13] have also been reported. Other occasional cutaneous findings have included ecchymotic [13] or necrotic lesions of the ear [9,11] and urticarial lesions [3,10,14].

In contrast to the rather dramatic cutaneous lesions, the patient generally remains well, apart from the frequent presence of pyrexia, which is usually mild. Visceral lesions are conspicuous by their general absence, although gastrointestinal complications have very occasionally been reported, including melaena [2] and lethal intussusception [9].

Differential diagnosis. Awareness of this disease should make diagnosis fairly straightforward. Meningococcal septicaemia will require consideration, but the well-defined symmetrical areas of confluent ecchymosis seen in this disorder are highly distinctive. Certain other disorders may produce annular lesions in infants, particularly urticaria and erythema multiforme, but these generally lack a haemorrhagic element and do not usually take on a rosette configuration with scalloped margins. The same is true of the lesions of Sweet's syndrome, which may also occur occasionally in very young children [15,16]. Kawasaki disease characteristically causes oedematous induration of the hands and feet, and may result in a rash in which annular erythema may be a feature, but the skin lesions themselves are not as indurated, nor are they purpuric. One of the most important differential diagnoses to consider in any disorder presenting with intracutaneous haemorrhage in the very young is non-accidental injury.

Prognosis. Recurring crops of lesions may occur, but spontaneous resolution normally follows within about 2 weeks. Recurrence must be rare, but has occasionally occurred [13]. No significant long-term sequelae have been reported.

Treatment. No specific therapy is required.

Disorders of subcutaneous fat

Terminological confusion has bedevilled the literature on disorders of subcutaneous fat in the newborn. The four conditions described below are essentially separate entities, although not without some clinical and pathological overlap.

Cold panniculitis (see also Chapter 46)

Definition. Cold panniculitis is a distinctive form of panniculitis provoked directly by cold exposure, to which infants appear particularly predisposed.

Aetiology. The fat of the newborn appears to be more highly saturated than that of older children and adults, with the effect that it solidifies at a higher temperature [1,2]. The possible clinical relevance of this phenomenon was demonstrated by experiments in which young pigs were fed fats of various degrees of saturation, producing corresponding differences in the saturation of their own subcutaneous fat [3]. The subsequent application of ice to the skin induced panniculitis only in the pigs fed saturated fat.

Applying ice for 50 seconds causes panniculitis in all newborn infants, in only 40% of 6-month-olds and almost never in 9-month-olds [4].

Cold panniculitis in infancy has most often followed exposure of the cheeks to: (i) extremely cold air [5–7]; (ii) ice bags applied as a therapy for supraventricular tachycardia [8,9]; or (iii) lollipops [10–12].

Pathology [10,13]. An early feature in skin biopsies is a lymphohistiocytic infiltrate around blood vessels at the junction of the dermis and subcutaneous fat. After a few days, lipocyte rupture leads to the formation of cystic cavities surrounded by areas of marked infiltration by lymphocytes and histiocytes, with a few neutrophils and eosinophils.

Clinical features. Indurated, warm, red, subcutaneous plaques and nodules appear within hours or days of appropriate cold exposure.

The lesions have generally occurred on the cheeks in infants, although they may be seen elsewhere in older children and adults [13,14].

Prognosis and treatment. The induration resolves over a period of a week or so, often leaving some residual post-inflammatory hyperpigmentation. No treatment is required, although it is clearly advisable for the child to avoid further cold exposure of the type that precipitated the lesions.

Neonatal cold injury

Definition. Neonatal cold injury is a disorder, now rare in developed countries, in which cold exposure of a small-for-dates neonate causes hypothermia associated with lethargy and generalized pitting oedema of the skin, clinically and pathologically distinct from sclerema neonatorum.

Aetiology [1–4]. Low environmental temperature has been the principal cause of virtually all reported cases of this disorder. Other factors that appear to have predisposed babies to this complication of cold exposure include intrauterine growth retardation, which results in a relatively thin panniculus, and tight wrappings, which would restrict muscular activity. Immaturity of either reflex shivering mechanisms or of protective vasomotor responses would also increase the risk. The condition seems to be much less common in the UK now than it was 40 years ago, probably because of improved heating in homes, very much reduced frequency of home delivery and abandonment of the previous habit of bathing babies at birth.

Pathology [5]. The panniculus is generally thin. Otherwise, there is little obvious abnormality apart from dilatation of dermal blood vessels. Profuse exudation of clear fluid from the cut surface at post-mortem suggests that the induration is due to oedema.

The dominant post-mortem finding in fatal cases has been massive pulmonary haemorrhage [2,4].

Clinical features [1–4]. The infant is usually a full-term neonate, born at home, but small for gestational age. In the great majority of cases, presentation is within the first 4 days of life, and usually during the first 24 h. The most striking features are intense erythema or cyanosis of the face and extremities, and firm, pitting oedema beginning at the extremities and spreading centrally, and becoming progressively more indurated in a proportion of cases. Petechiae have occasionally been observed.

The skin feels cold, and the baby is usually hypothermic. Associated non-cutaneous features of cold injury are generally present, and may occur in the absence of skin changes. These include immobility, drowsiness, poor feeding, vomiting, oliguria and gastrointestinal bleeding with vomiting of altered blood or melaena.

The condition appears to have been associated with a high mortality, around 25%.

Diagnosis. The main source of diagnostic confusion is with sclerema neonatorum. The generally healthy state of the infant

before the onset of the cutaneous induration, its pitting nature, the history of cold exposure and a low rectal temperature all help to distinguish the two disorders. It is possible that the late non-pitting induration of the skin, which supervenes in some cases [2], may in fact be genuine sclerema.

Subcutaneous fat necrosis of the newborn

Definition. Subcutaneous fat necrosis of the newborn is an uncommon and transient disorder of neonates in which focal areas of fat necrosis cause nodular skin lesions. This nodular necrosis of subcutaneous fat may be associated with hypercalcaemia.

Aetiology. Subcutaneous fat necrosis generally occurs in full-term or post-term infants of normal birth weight during the first 6 weeks of life. The precise cause is unestablished, but a variety of insults appear to have contributed in individual cases. These have included birth asphyxia [1–4], maternal pre-eclampsia [5,6], maternal diabetes [7], obstetric trauma [8–10] and hypothermia [11–13]. In many cases, there is no convincing history of any of these putative predisposing causes. It has been suggested that localized tissue hypoxia—albeit transient—may be the common link in every case [14]. This might explain the predominant localization of lesions to sites such as the shoulders and buttocks, where mechanical pressure might further compromise the circulation. However, intermittent reports of an analogous type of fat necrosis occurring in infants undergoing hypothermic cardiac surgery implies that the common factor is perhaps more likely to be cold.

It has been suggested that another important predisposing factor for the development of subcutaneous fat necrosis might be a protease inhibitor deficiency, analogous to the α_1-antitrypsin deficiency seen in some patients with panniculitis [15]. Such a deficiency might allow trauma to trigger development of lesions, but perhaps it would be more likely that lesions developing in this way would show the pathological features of panniculitis rather than fat necrosis.

An interesting concept [13] is that subcutaneous fat necrosis of the newborn might be a disorder of brown fat, which is present in those areas most frequently affected [16].

The appearance of subcutaneous fat necrosis has been reported after intravenous prostaglandin E_1 (PGE_1) administration for congenital heart disease, and the suggestion was made that the PGE_1 may have been responsible [17].

A number of infants have now been reported in whom subcutaneous fat necrosis was associated with hypercalcaemia [18–26]. This complication probably occurs in around a quarter of all cases, and appears to occur more frequently in infants with more extensive disease, and almost exclusively when the trunk is affected [4].

The cause of the hypercalcaemia is unknown. Suggested mechanisms have been reviewed by Hicks *et al.* [27] and by Burden and Krafchik [4]. It currently appears most likely that it reflects increased calcium absorption due to extrarenal production of 1,25-dihydroxyvitamin D, which has been observed in other granulomatous disorders including sarcoidosis [4,19,28,29]. Elevated parathormone levels have been reported in one case [24], but post-mortem studies have not revealed any evidence of parathyroid hyperplasia. The finding of increased urinary excretion of PGE_1 led to the suggestion that increased bone calcium resorption might be responsible [25,30].

Pathology [3,31–33]. Biopsies of the affected subcutaneous tissue show patchy fat necrosis, with a granulomatous inflammatory reaction of foreign-body type, and fibrosis. Both the fat cells and the giant cells contain needle-shaped clefts, which may be radially arranged. Fibrotic obliteration of small arterioles has also been observed [34]. Calcium deposits are commonly found in the necrotic fat.

Ultrastructural examination has shown parallel aggregations of electron-lucent needle-shaped spaces within adipocytes [33].

Similar changes in visceral adipose tissue have been reported in post-mortem studies of affected infants [5,9]. Widespread calcium deposition in internal organs has also been shown in post-mortem specimens from hypercalcaemic cases [6,21] and nephrocalcinosis has been observed in such infants during life [23,35].

Transient thrombocytopenia has been reported during the period of initial development of the lesions, possibly due to sequestration of platelets [6,14,36].

Plasma lipid abnormalities have been reported in a neonate with subcutaneous fat necrosis, but their relevance was unclear [37].

Clinical features. Infants who develop subcutaneous fat necrosis are generally full-term or post-term neonates of normal weight. Nodular thickening of the subcutaneous tissues is usually first detected between the second and 21st days of life. Sometimes, the changes are present at birth, and, rarely, they may appear as late as the sixth week. The nodules tend to be symmetrically distributed, and show a predilection for buttocks, thighs, shoulders, back, cheeks and arms. Lesions may be single or multiple, rounded or oval, and pea-sized or many centimetres in diameter. They are initially discrete, but may fuse to form large plaques. The overlying skin is often red or bluish red. The nodules feel rubbery or hard, and are not attached to the deeper structures. The lesions may be painful [38]. New nodules may continue to develop for a week or more.

In most cases, the child's health is not substantially impaired, and within a few months the nodules disappear. Where calcium deposition is marked, the lesions may take rather longer to resolve [39]. Usually no trace of the nodules remains, but there may be slight atrophy [12]. Rarely, the nodules may ulcerate, discharge their fatty contents and leave scars.

The condition has occasionally been fatal, particularly when visceral fat has been involved [5], or where there has been complicating hypercalcaemia [24].

Diagnosis. Neonates delivered by forceps may develop subcutaneous nodules where the forceps were applied, presumably as a result of traumatic fat necrosis.

Subcutaneous fat necrosis of the newborn was in the past frequently confused with sclerema neonatorum. Occasionally, the two conditions may occur simultaneously [40].

All infants who have experienced subcutaneous fat necrosis should have their serum calcium measured on presentation and a few weeks later. If hypercalcaemia is present, its cause requires thorough investigation to exclude disorders such as primary hyperparathyroidism and vitamin D intoxication.

Treatment. None is generally required.

Hypercalcaemia may warrant treatment by administration of furosemide, dietary restriction of calcium and vitamin D, and sometimes also by oral corticosteroid administration. There may be a role for bisphosphonate administration in some cases [41].

Subcutaneous fat necrosis following hypothermic cardiac surgery in infancy

There have been several reports of the occurrence of lesions analogous to those of subcutaneous fat necrosis of the newborn in children who have had cardiac surgery [1–5], and this may be a relatively frequent complication of such surgery. It appears likely that the principal provocative factor in these cases was the cutaneous application of ice to induce hypothermia, although trauma and/or hypoxia may have contributed. It is noteworthy that these children appear to have developed lesions of subcutaneous fat necrosis rather than cold panniculitis. The ages of the children at the time of surgery varied from 12 days to 20 months. Lesions appeared between 14 and 30 days later, principally at the sites subjected to the greatest cold exposure. Hypercalcaemia may occur [3]. The lesions resolve within a few weeks and no treatment is required.

Sclerema neonatorum

Aetiology. Sclerema neonatorum is a very rare disorder that almost always appears during the first week of life, although it has occasionally been recorded later in infants born preterm. It has generally been considered a non-specific sign of grave illness, and has been associated with a mortality up to 75% [1,2]. Prematurity and smallness-for-dates appear to be frequent predisposing factors [2]. It has been recorded as already present at birth in infants subjected to placental insufficiency [3]. The disorder does not seem to occur in otherwise healthy infants, and most characteristically develops during the course of one of a wide variety of severe illnesses, particularly serious infections, congenital heart disease and other major developmental defects [2]. A proportion of these infants has been hypothermic, and occasionally sclerema has been described as a complication of neonatal cold injury [4]; nevertheless, cold does not appear to be an important aetiological factor in the majority of cases.

Lipolytic mechanisms are poorly developed in the newborn, particularly in those born preterm [5]. The maturation of these enzyme systems might be further compromised by major infection or hypoxia. It has been suggested that sclerema might reflect defective lipolysis within adipose tissue, which would result in failure of fat mobilization, and an impaired capacity to maintain body temperature. It has been reported that the ratio of saturated to unsaturated fatty acids is relatively high in the adipose tissue of all neonates, and that this ratio was even higher in an infant with sclerema [6,7]. This would lead to a raised melting point, and it is possible that the induration of subcutaneous fat, which is the major clinical feature of sclerema, might reflect its solidification due to a fall in the temperature of the adipose tissue during peripheral circulatory collapse [8].

Pathology [7–9]. Often, surprisingly little abnormality has been apparent histologically. However, in most cases the subcutaneous fat layer appears to be thickened, due to an increased size of the individual lipocytes and to an increased width of the intersecting bands of connective tissue, probably due to oedema. There is very little evidence of fat necrosis and, generally, only the slightest indication of inflammation. The most characteristic histological feature of sclerema neonatorum is the presence of radially arranged, needle-shaped clefts in adipocytes and, occasionally, in multinucleate giant cells, reflecting the presence of crystals prior to processing.

Clinical features [8,10]. The affected infant is generally severely ill at the time of onset of sclerema. Woody induration of the skin starts on the buttocks, thighs or calves and extends rapidly and symmetrically to involve almost the whole surface, with the exception of the palms, soles and genitalia. This skin is hard and cold to touch, and yellowish white in colour, often with purplish mottling. It will not pit with pressure. Mobility is limited, and as a result the face may take on a mask-like expression.

The prognosis is poor, and is largely determined by the nature of the underlying disease. In spite of advances in the treatment of many of the predisposing disorders, particularly sepsis, the mortality probably remains in excess of 50%. In infants who survive, the appearance of the skin returns to normal without long-term complications such as calcification.

Diagnosis. The main area of diagnostic confusion has been between sclerema and subcutaneous fat necrosis. It is now clear that the two disorders are distinct pathologically and clinically [10], although they can occur together on occasions [11]. Table 17.4 outlines their distinguishing features.

Scleroedema has been reported in an infant at 2 weeks of age, and was distinguished from sclerema principally on histological grounds [12]. Turner's syndrome is often recognizable at birth by the presence in a female of firm, non-pitting lymphoedema of the dorsa of the hands and feet, associated with low birth weight and loose folds of skin around the neck. Where primary lymphoedema occurs in neonates, it will already be clinically evident at birth.

Table 17.4 Distinctions between neonatal cold injury, sclerema and subcutaneous fat necrosis.

	Neonatal cold injury	Sclerema	Subcutaneous fat necrosis
Frequency	Previously common, now rare	Rare, usually seen in neonatal intensive care units	Uncommon
Patient	Full-term neonates often small-for-dates, born at home	Usually severely ill neonates, often preterm or small-for-dates or post-term	Healthy infants, usually full term
Onset	During the first week	Almost always during the first week	1–6 weeks
Sites	Extremities, spreading centrally	Lower limbs initially becoming generalized	Trunk, buttocks, thighs, arms, face
Appearance	Pitting oedema initially with erythema or cyanosis of face and extremities	Diffuse, yellow-white woody induration with immobility of limbs	Firm, reddish-violet, subcutaneous nodules
Histology	Thin panniculus	Subtle; thickened connective tissue trabeculae; radial needle-like clefts	Granulomatous inflammation and fat necrosis
Prognosis	Mortality around 25%	Poor, mortality greater than 50% in past	Generally excellent

The condition may be familial, and generally first affects the legs, particularly the lower legs. The presence of oedema at birth, and its very slow progression in an otherwise healthy neonate, distinguish primary lymphoedema from sclerema.

Treatment. Treatment is primarily that of any underlying disease. Systemic corticosteroids are probably not effective [1], but there is evidence that repeated exchange transfusions may substantially reduce mortality [13,14].

Infections

Although infectious diseases affecting the skin are described in detail elsewhere in this book, the clinical features of some of the more important infections affecting the skin during the neonatal period will be briefly considered here, because of their importance in the differential diagnosis of other dermatoses.

Viral infections

Neonatal herpes simplex

HSV infection in the newborn is generally a serious disease with a high mortality. The incidence is about 7/100 000 life births and up to 40% of such infants are premature [1]. The majority of such infections result from transmission of HSV type 1 (20%) and HSV type 2 (80%), by contact with an infected genital tract during delivery [1–3]. However, intrauterine HSV infection rarely occurs (5% of all neonatal HSV) [4], due either to transmission across the placenta [5], or to ascending infection related to prolonged rupture of the fetal membranes [6]. Intrauterine HSV is usually due to HSV type 2 and is more common when the HSV is a primary and/or disseminated infection in the mother.

Fig. 17.7 Neonatal herpes simplex: congenital ulceration and scarring at 10 days. This infant responded rapidly to aciclovir therapy and is now entirely healthy apart from residual atrophy.

Infection may also occur postnatally by contact with non-genital sites, both maternal and non-maternal [7].

Most infants with neonatal HSV are born to mothers who have no previous history of genital HSV and who show no overt clinical signs of herpes at delivery.

Over 70% of all infants with neonatal HSV have skin or mucosal lesions [8–10], but only in about 10% will the disease be confined to the skin. The skin lesions appear between day 2 and 20, unless intrauterine infection has occurred, in which case they will generally already be present at birth [4,11,12].

Isolated or grouped vesicles are the most common type of lesion, and the scalp and face are the most commonly affected sites, although lesions can occur at virtually any site (Fig. 17.7). Occasionally, the eruption may be generalized and bullous, and widespread erosions may occur without obvious vesicles or bullae, mimicking epidermolysis bullosa [12]. When infection is acquired during birth, the initial lesions have a predilection for the scalp in vertex presentations, and the perianal area in breech presentations [13]. Lesions may also be localized to areas of intrauterine or intrapartum skin damage [14], such as the area in which a fetal scalp electrode has been sited. Areas of cutaneous atrophy or scarring are not infrequent in the intrauterine form, and vesicular lesions may continue to appear within or at the periphery of these areas [4,15]. A zosteriform pattern has also been described [16], and, in some cases, localized or generalized non-vesicular erythematous macules. Congenital cutaneous calcification has been reported in a child with intrauterine HSV infection [17].

Oral lesions are also frequent, and take the form of erosions on the tongue, palate, gingivae and buccal mucosa.

A fatal outcome is unusual when infection is limited to the skin, mouth and eyes, but mortality and long-term damage are more likely when the central nervous system is involved or when infection is disseminated, even when appropriate antiviral therapy is given. Mortality is higher when infection is with HSV-2 [2].

Early recognition and adequate early treatment with aciclovir does appear to protect infants from dissemination of infection, where this is initially confined to the skin [14,15,18].

Herpes simplex infection in premature infants is even more severe in terms of clinical outcomes. In one study, nine of 12 infants died and the other three had neurological sequelae [19]. It is also more difficult to diagnose as vesicular lesions are found in less than half of cases. It often presents with respiratory distress and thrombocytopenia. Non-specific signs such as lethargy, hypotension, raised aspartate transaminase and fits have also been observed. Diagnosis is by culture/PCR but treatment with intravenous aciclovir should not be delayed if HSV is suspected.

Fetal varicella syndrome (FVS)

Approximately 90% of adults are seropositive for the varicella-zoster virus antibody. If a woman is seronegative, she may develop chickenpox during pregnancy; this occurs in up to 10 per 10 000 pregnancies [1–3]. The infection may be transmitted to the fetus, probably in about 25% of cases. Such transmission of varicella-zoster virus infection to the fetus is considered to be very rare in mothers who develop herpes zoster during pregnancy [4].

Table 17.5 Principal clinical features of the fetal varicella syndrome.

Low birth weight
Cutaneous lesions:
Localized absence of skin, usually on a limb
Scars, often of dermatomal outline
Papular lesions resembling connective tissue naevi
Hypoplasia of one or more limbs (usually the limb affected by localized absence of skin or scarring), and/or malformed digits
Ocular anomalies, including chorioretinitis, cataracts, microphthalmia, Horner's syndrome
Central nervous system abnormalities, including seizures, mental retardation, hydrocephalus, cortical atrophy, encephalitis, encephalomyelitis, dorsal radiculitis

When a mother develops varicella between the seventh and 20th week of pregnancy, spontaneous abortion may follow, or the child may be born with a variety of abnormalities considered characteristic of FVS [5–7] (Table 17.5), and this appears to be most frequent when maternal infection has occurred between weeks 13 and 20 [3]. This syndrome was first described in 1947 [8]; many other cases have been reported since [9–13]. However, most children of such mothers are born with no detectable abnormality, despite laboratory confirmation of intrauterine infection [7]. FVS therefore appears to be a relatively rare complication of maternal varicella early in pregnancy, with a fetal risk of approximately 2% [1,4,7,14]. Some authors have argued that occasionally FVS can occur as late as 28 weeks into pregnancy [15].

Localized scarring, presumed to be the sequel to intrauterine ulceration, is the most common cutaneous feature of the FVS. The larger single lesions have characteristically occurred on a limb, and have frequently been associated with hypoplasia of that limb; these lesions have generally followed infections occurring in early pregnancy [5,14–17]. Their segmental outline may be a direct consequence of damage to the fetal nervous system [6,16], as the varicella-zoster virus is known to be strongly neurotropic, or to fetal herpes zoster [9]. The occurrence of larger numbers of smaller lesions appears to result in the main from varicella later in pregnancy; their antecedents seem likely to be vesicular lesions, essentially the same as those occurring in postnatal varicella. If fetal infection has occurred in the last trimester, these smaller skin lesions, reflecting fetal varicella, may still be ulcerated at birth [18].

Areas of congenital localized absence of skin, without associated limb hypoplasia or other neurological abnormalities, have been a less well recognized consequence of intrauterine varicella [19,20], and may reflect fetal herpes zoster later in gestation. Similar skin lesions have been reported in cases of intrauterine infection with human HSV [21].

Skin-coloured papular lesions have been described in children with FVS [22], which are likely to be a direct response to cutaneous injury by intrauterine chickenpox. More verrucous lesions have been described in one immunocompetent neonate more reminiscent of 'verrucous herpes' seen in immunocompromised patients [23].

If a child is born with 'full blown FVS' the mortality is about 25% in the first 3 months of life [3].

Herpes zoster occurring in early infancy is likely to indicate that the child has been infected with the varicella-zoster virus *in utero* [24,25].

Pregnant women who are not immune (on the basis of history, and, preferably, serologically), and who experience exposure to varicella-zoster, should be given varicellazoster immune globulin (VZIG) [26]. Although this can prevent or modify clinical varicella if given up to 3 days after contact, there is no definite evidence that it prevents fetal infection or damage [4]. Giving VZIG to neonates of mothers who have chickenpox at the time of delivery does not appear to reduce the incidence of clinical infection but may reduce its severity [27]. But, as the risk of fetal damage is small, termination of pregnancy is not indicated. Ultrasound examinations can be performed to detect some of the abnormalities that occur in the cardiovascular system [28], but several of the important ocular and neurological sequelae cannot be diagnosed in this way. Amniocentesis, fetal blood and chorionic villus sampling can be performed to isolate the virus or to detect specific IgM, but may fail to identify infection [25,29].

There are no reports that establish a role for aciclovir therapy in the prevention of FVS. Therefore, the decision whether to treat the mother should be based solely on the severity of her illness [26].

A potentially dangerous situation relates to maternal development of varicella in the 4 days either side of delivery [30]. In this case, neonatal varicella may also occur, but, in the absence of the protection offered by the maternal immune system, mortality may be as high as 30%. Where maternal infection occurs at this time, VZIG is recommended for the newborn. If overt varicella develops in the child, intravenous aciclovir should be added to the VZIG [31].

Congenital rubella

Rubella contracted by the fetus before the 20th week of gestation may result in disseminated infection, causing intrauterine growth retardation, microcephaly, microphthalmia and a wide variety of other abnormalities [1]. Cutaneous lesions are among the most prominent clinical features of congenital rubella [2–4]. The typical lesions are present at birth, or make their appearance during the first 48 h. They comprise discrete, rounded, red or purple infiltrated macules, 3–8 mm in diameter. Although such lesions may be seen at any site, they generally occur in largest numbers on the face, scalp, back of the neck and on the trunk. Occasionally, the lesions are slightly raised. They tend to fade over a period of weeks. These lesions have often been described as 'purpuric', and have generally been attributed to thrombocytopenia, which is another common feature of congenital rubella [3]. However, histological examination has shown them to comprise foci of dermal erythropoiesis [2,5,6]. Such lesions have frequently been described as 'blueberry muffin'

lesions. Genuine thrombocytopenic purpura is probably rather uncommon.

Other reported skin manifestations of congenital rubella have included cutis marmorata, seborrhoea and hyperpigmentation of the forehead, cheeks and umbilical area [7], and discrete deep dimples over bony prominences, particularly the patellae [8].

Human immunodeficiency virus (HIV) infections

HIV infection may be transmitted to the infant *in utero*, during delivery or through breast-feeding. Because most infections are probably transmitted around the time of birth, clinical manifestations are not commonly seen for the first few months, and some infected infants will remain asymptomatic for many years before manifestations first appear.

Mucocutaneous manifestations are common in infant HIV infection and frequently have an infective aetiology [1–3].

Persistent mucocutaneous candidiasis is the commonest of all. In addition to infection of oral and napkin areas, there may be extensive cutaneous involvement. Dermatophyte fungal infections are also characteristic, and infection with more unusual fungi may occur, including *Aspergillus* [4]. Bacterial infections include unusually severe or recurring impetigo, folliculitis, cellulitis and abscesses. Problems with viruses include atypical chickenpox, herpes zoster, herpes simplex, and unusually severe molluscum and human papillomavirus infections. Norwegian scabies may present in infancy.

A wide variety of non-infectious manifestations of HIV infection may also occur. Perhaps the most characteristic in infancy is seborrhoeic dermatitis affecting the face and scalp, often also proximal flexures, occasionally disseminating more widely. Drug eruptions are also rather frequent, especially with trimethoprim–sulfamethoxazole.

Bacterial infections

Staphylococcus aureus infections

As in older children and adults, *S. aureus* causes a wide variety of cutaneous lesions in neonates.

Bullous impetigo

The neonate is peculiarly liable to the development of bullous impetigo, which is most often caused by phage group II strains of *S. aureus* [1]. The disorder in neonates differs in no significant way from that in older children and adults, although it was formerly distinguished by the rather confusing term, *pemphigus neonatorum*. Epidemics of bullous impetigo, in which some infants may develop staphylococcal scalded skin syndrome, have occurred in neonates due to transmission of infection in the nursery, principally via nursing or medical staff [2–4]. Although the infection is acquired in hospital following delivery, the lesions do not generally appear until the second week of life, when the child will now usually have left hospital.

The perineum, periumbilical area and the neck creases are predilection sites for the initial lesions. Rapidly enlarging bullae with thin, delicate walls and a narrow, red areola contain clear fluid at first, which may later become turbid or frankly purulent. The condition may remain localized or become widespread. Untreated generalized bullous impetigo in the neonate is associated with a significant mortality, and serious complications including lung abscess, staphylococcal pneumonia and osteomyelitis have been reported, even in cases treated with antibiotics [5,6].

The differential diagnosis of bullae and erosions in the neonate is illustrated in Table 17.6 [7–12].

Staphylococcal scalded skin syndrome

The staphylococcal scalded skin syndrome was first described in neonates by a German, Ritter von Rittershain [13]. It is caused by epidermolytic toxin A and/or B, which are elaborated by certain strains of *S. aureus*, most commonly of phage group II [1], particularly strains 71 and 55. These toxins reach the skin via the circulation from a distant focus of infection, usually in the umbilicus, breast, conjunctiva or the site of circumcision [14] or herniorrhaphy [15]. Transmission of the causative toxin through human milk has been reported [16].

Both these toxins attack desmoglein 1 (a desmosomal protein) so mucosal involvement does not occur (this is analogous to pemphigus foliaceus which has the same target antigen) [17].

The disorder is most often seen in young children, and particularly in neonates. The very much greater incidence of this condition in neonates is believed to reflect less efficient metabolism and excretion of the toxin [18]. Multiple cases can occur in a neonatal unit [19]. Cases occurring in later childhood tend to be associated with underlying disease, especially immunosuppression and renal failure [20].

It does not present at birth, although it may first appear within the first few hours thereafter [21]. The first sign of the disease is a faint, macular, orange-red, scarlatiniform eruption. The eruption

Table 17.6 Differential diagnosis of bullae and/or erosions in the neonate.

More common disorders
Miliaria crystallina
Bullous impetigo
Thermal or chemical burns
Sucking blisters
Mastocytosis
Rare disorders
Epidermolysis bullosa
Incontinentia pigmenti
Bullous ichthyosiform erythroderma
Neonatal herpes simplex
Fetal varicella syndrome (FVS)
Herpes zoster
Congenital syphilis
Passively transferred
Pemphigus vulgaris
Herpes gestationis
Bullous pemphigoid [7]
Extensive congenital erosions and vesicles healing with reticulate scarring
Congenital erythropoietic porphyria
AEC syndrome
Congenital absence of skin
Porphyrias and transient porphyrinaemia [8]
Langerhans' cell histiocytosis [9]
Weary syndrome/Kindler syndrome [10,11]
Ectodermal dysplasia–skin fragility syndrome (plakophilin-1 deficiency) [12]

generally becomes more extensive, and, over the next 24–48 h, turns to a more confluent, deep erythema with oedema. The surface then becomes wrinkled before starting to separate, leaving raw, red erosions. Sites of predilection for the development of erosions are the central part of the face, the axillae and the groins.

Extreme tenderness of the skin is an early feature, and may occur at a stage where cutaneous signs are not yet striking. The child is pyrexial and distressed. These features can lead to a suspicion that the child has arthritis or an acute abdomen. The presence of impetiginous crusting around the nose and mouth can be diagnostically helpful. Recovery is usually rapid, even without antibiotic therapy, although infants occasionally die in spite of such treatment [22]. Healing occurs without scarring.

The scalded appearance of the skin differentiates the disease from bullous impetigo, and the rapid onset with marked cutaneous tenderness distinguishes it from most of the other causes of erythroderma in infancy. The rarity of clinically apparent bullae and the confluent nature of the rash help differentiate it from those bullous disorders likely to be seen in young children.

The only real problem in differential diagnosis would be with toxic epidermal necrolysis, which, although clinically similar, has a worse prognosis. In the past, the staphylococcal scalded skin syndrome and toxic epidermal necrolysis were confused, but it is now clear that they are entirely distinct entities. Genuine toxic epidermal necrolysis does occur in young children but is relatively rare, and differs clinically by virtue of mucosal involvement. Wherever there is any doubt, the two conditions may be reliably distinguished by histology, as the level of skin separation is intraepidermal in the staphylococcal scalded skin syndrome and at the dermal–epidermal junction in toxic epidermal necrolysis. If the child's condition arouses anxiety, a frozen section will provide rapid differentiation [23].

Treatment is with either a penicillinase-resistant penicillin analogue, such as flucloxacillin or methicillin, or with an appropriate cephalosporin or sodium fusidate. If the attack is severe, the drug should initially be given intravenously. Systemic corticosteroids are contraindicated, on the basis of experimental [24] and clinical [25] evidence that they aggravate the disease. Appropriate compensation must be made for heat and fluid losses. Pain will also require treatment, and affected infants will generally be much more comfortable if the lesions are dressed rather than left open. In severe cases, it may occasionally be justifiable to ventilate the patient in order to obtain adequate relief of pain.

Periporitis staphylogenes and sweat gland abscesses

Periporitis staphylogenes is the term applied to pustular lesions appearing in neonatal skin as a result of secondary infection of miliaria by *S. aureus* [26–29]. Such lesions may progress to sweat gland abscesses, although it is not clear whether sweat gland abscesses are always a complication of miliaria. These disorders have in the past been incorrectly called 'folliculitis and furunculosis of the newborn'. Sweat gland abscesses are distinguished from furuncles clinically by a lack of any tendency to 'point', 'coldness' and absence of tenderness.

Periporitis must be distinguished from miliaria pustulosa, which is not an infective disorder, and from bacterial folliculitis, which in the neonate is usually caused by *S. aureus*. *Candida albicans* and *M. furfur* may also cause pustulosis in the neonate, and a number of non-infective conditions may cause confusion, such as eosinophilic pustulosis.

Mastitis and breast abscesses

Infection of the breast is common and is usually associated with *S. aureus*, but a variety of other bacteria may be responsible [30]. It is almost always unilateral; it occurs most commonly in the second or third week of life, more often in girls than boys, and only very rarely in the preterm infant. The affected breast is swollen, and often red and hot. Systemic toxicity is usually absent. Fluctuation implies abscess formation, which will require surgical drainage. The development of a breast abscess may lead to loss of breast tissue in the longer term [31].

Omphalitis

Omphalitis is rare in the developed world (0.7% births) but is more of a problem for developing countries (up to 6% births). It is characterized by redness, oedema and discharge of the 'stump'. Cases can progress to cellulitis and deeper tissue infection. It is more common in protracted labour, non-sterile delivery and cord care, prematurity, low birth weight and some cultural practices such as application of tobacco ash [1].

The umbilical cord may become colonized by a variety of potentially pathogenic bacteria, and an equally wide variety of topical antiseptics and antibiotics have been used in an attempt to reduce this colonization. The use of hexachlorophane was popular until it became apparent that this could lead to serious neurotoxicity, particularly in the preterm infant [2]. The best substitute may be chlorhexidine, applied as a dusting powder rather than as an alcoholic solution [3]. In developing countries, 4% chlorhexidine has been shown to reduce omphalitis (and indeed reduce neonatal mortality if given on day 1) in a community based study in Nepal [4].

Occasionally, infection of the umbilical cord becomes disseminated, either by bloodstream invasion or by direct extension via the umbilical vessels to the peritoneal cavity. Tetanus, diphtheria and necrotizing fasciitis [5] may also occur as complications of umbilical infection. Such infections are still responsible for a high proportion of deaths in the neonatal period in developing countries.

Preorbital and orbital cellulitis

Preorbital cellulitis is restricted to the part of the orbit anterior to the orbital septum and is manifest by eyelid swelling. Orbital cellulitis involves the structures deep to the septum and presents with painful proptosis, eyelid oedema and conjunctival erythema. A variety of bacteria can cause these infections, including *S. aureus*, group A and other streptococci. One should always be alert to the possibility of group B *Streptococcus* as a rare cause of periorbital cellulitis or any form of cellulitis in a neonate, in view of their high risk of septicaemia with this organism [1,2].

Necrotizing fasciitis

This name is given to a distinctive form of cellulitis, in which infection tracks along the fascial planes, causing thrombosis of blood vessels running through the fascia with resulting necrosis of the skin, subcutaneous fat and even muscle [3,4]. In neonates, it may arise spontaneously, but most often is a complication of physical birth trauma, omphalitis [5], breast abscess, or iatrogenic skin wounds such as result from scalp electrodes [6] or circumcision [7]. The mother's genital tract is probably often the source of the infection [8].

Initially, the infant develops what appears to be straightforward cellulitis usually affecting the abdominal wall. However, the child becomes disproportionately toxic, and the area affected becomes indurated, discoloured and extends progressively [4,9]. The surface may show a peau d'orange appearance. Purpura and, occasionally bullae, may develop in the centre of the indurated area, often followed quite rapidly by frank necrosis. Destruction of superficial nerves results in local cutaneous anaesthesia. Gas and crepitation may be clinically apparent, or may be seen radiologically. Fever is not invariably present.

A wide variety of bacteria have been associated with necrotizing fasciitis, most commonly group A streptococci, but also group B streptococci, *S. aureus* and *Escherichia coli* [3,9–11]. In many cases, a synergistic infection by aerobic and anaerobic organisms appears to be responsible. Occasionally, fungi have been responsible. Antibiotic therapy appears to be of limited value in this potentially lethal situation. The most important aspect of treatment is early surgical excision of necrotic tissue [5,11].

Neonatal listeriosis

Listeriosis during the neonatal period is uncommon, but dangerous. The responsible organism, *Listeria monocytogenes*, may be transmitted to humans principally through contaminated foods [1]. In pregnancy, it causes a rather non-specific and generally mild, influenza-like illness in the mother [2], but it may lead to transplacental infection of the fetus. Maternal HIV infection may predispose to neonatal listeriosis [3]. Adult listeriosis has increased in a number of European countries during the early 2000s, but mostly in the elderly and not as yet in pregnancy-related cases [4].

Clinically, there are early-onset and late-onset forms of neonatal listeriosis [5]. The early-onset form results from the development of miliary granulomas following blood-borne dissemination of infection. Severely affected babies tend to be born prematurely, and there is a high mortality [6,7]. Post-mortem studies reveal miliary granulomas in many organs. A few infants will have analogous miliary skin lesions during life, manifest as scattered, discrete grey or white papules or pustules, about 1–2 mm in diameter, with a red margin [8,9], which will provide a source of organisms for culture [10]. The back appears to be the site of predilection for such lesions, which are also seen in the mouth and on the conjunctiva. Other cutaneous lesions have been described in such babies, including purpura and morbilliform rashes [4,6].

The late form of the disease is commoner, taking the form of meningitis, occurring a week or two after birth [11].

Diagnosis is by culturing the organism from a variety of sites, including cerebrospinal fluid, blood, urine and from biopsy material, including the skin. Treatment is most frequently with a combination of parenteral ampicillin and gentamicin or kanamycin [6], followed by a longer course of ampicillin or penicillin given alone.

Pseudomonas aeruginosa infections

Ecthyma gangrenosum [1–3]

Pseudomonas aeruginosa is common in the hospital environment and infections are encouraged by the widespread use of broad-spectrum antibiotics. Most, but not all, neonates who develop the skin lesions of ecthyma gangrenosum have *P. aeruginosa* septicaemia, usually in the context of predisposing factors that include prematurity, neutropenia and other immunodeficiencies, necrotizing enterocolitis and bowel surgery. Occasionally the lesions develop directly at the site of direct inoculation of the causative organism.

Histologically, the presence of vasculitis, due to bacterial infiltration of vessel walls, is characteristic [4], together with haemorrhage and necrosis; for this reason skin biopsy can be very helpful in diagnosis.

Clinically, lesions initially take the form of painful macular erythema or purple ecchymosis. The centre then generally develops either vesicles (or less commonly bullae) or pustules which rapidly ulcerate. One subsequently sees one or more ulcers with a depressed, necrotic, often black, crusted centre and a raised edge. The perioral and perianal areas may show grouped lesions.

This infection is potentially dangerous when it occurs in the setting of septicaemia. Appropriate parenterally administered combination antibiotic therapy will be required.

Noma neonatorum

Noma neonatorum is a gangrenous disorder of the nose, lips, mouth, perianal area and, occasionally, the scrotum and eyelids, occurring in low birth weight and/or premature neonates, almost

Fig. 17.8 Congenital syphilis: nummular erythematosquamous lesions in a 4-week-old infant.

exclusively in underdeveloped parts of the world. It is frequently caused by *P. aeruginosa* and is almost invariably lethal in the absence of appropriate antibiotic treatment [5]. A similar condition may be seen in older children and adults in the context of severe immunodeficiency [6].

Purpura fulminans

Although in the newborn this condition is most often a reflection of genetically transmitted thrombophilic disorder, it may be caused by acute infections, particularly with endotoxin-associated, Gram-negative bacteria such as *Neisseria meningitidis* [7,8].

Congenital syphilis

Congenital syphilis is described in detail in Chapter 34, but its cutaneous manifestations in the neonate will be considered here briefly, because of their importance in differential diagnosis [9].

The skin is clinically affected in about 40% of neonates with congenital syphilis. In such cases, the skin is usually of normal appearance at birth, the initial lesions occurring between the second and eighth week, and occasionally later. Sites of predilection are the anogenital area, the face and the palms and soles. The lesions themselves are reddish brown in colour; they may be macular or papular, and tend to be larger and firmer than those seen in acquired secondary syphilis (Fig. 17.8). In about 3% of cases the lesions are bullous. Paronychia is commonly present. Small, round, moist, papular lesions, traditionally termed mucous patches, are frequently present in the mouth and on other mucosal surfaces. Condylomata lata may be present in the anogenital flexures or at other flexural sites, for example between the toes or in the angles of the mouth.

Birth weight is below 2500 g in approximately 50% of affected infants. Apart from the cutaneous features, the most frequent clinical manifestations of congenital syphilis in the newborn are hepatomegaly, splenomegaly, jaundice, pneumonia and rhinitis, often with a blood-stained discharge.

The recent resurgence in the incidence of syphilis in many countries may lead to an increase in cases of congenital disease, especially where antenatal care is poor [10].

Congenital tuberculosis

Tuberculosis in the newborn due to transmission of infection *in utero* is relatively rare. The lungs and/or liver tend to be the predominant sites of involvement, and skin manifestations are unusual. However, cutaneous lesions have occasionally occurred, in the form of small numbers of discrete, umbilicated, erythematous papules up to 4 mm in diameter [11].

Fungal infections

Candida infections in the neonate

There are two distinct forms of candidiasis seen in the first weeks of life, which have been called *neonatal candidiasis*, which appears after birth, and *congenital candidiasis*, which is present at birth.

Neonatal candidiasis

This is a relatively common disorder that occurs in the early weeks after birth, in the form of oral candidiasis with or without candidiasis in the napkin area. The rash is usually focused in the perianal area, and is a deep 'beefy' red colour, with a moist appearance, often with pustules at the periphery, which is often scalloped in outline. Just beyond the margin, in as yet unaffected skin, there may be punctate erythematous lesions, sometimes pustular ('satellite' lesions).

It is assumed that the infection is acquired during delivery from the mother's genital tract, and it should be borne in mind that the frequency of vaginal candidiasis at the time of delivery is between 20% and 25% [1].

Occasionally, the rash may become more generalized. The occurrence of localized palmar pustules in an infant with neonatal oral candidiasis was believed to reflect the inoculation of *Candida* from the mouth into the skin as a result of sucking [2].

The most reliable treatment is generally a combination of a non-absorbed oral anticandidal agent, usually amphotericin drops or

miconazole 2% oral gel, and a topical anticandidal agent such as ketoconazole 2% cream.

Congenital candidiasis

This is a rarer condition, seen at birth, which is generally believed to reflect maternal *Candida* chorioamnionitis resulting from ascending infection from the genital tract [3–9]. It appears that *Candida* is, however, able to find its way into the amniotic fluid without prior rupture of membranes [10]. Foreign bodies in the uterus or the cervix increase the risk, particularly intrauterine contraceptive devices [10,11]. There is no evidence that maternal antibiotic therapy or immunodeficiency in the infant play a role in predisposition [9,12].

An extensive eruption of scattered pinkish red macules and papules is present at birth or appears within a few hours. The lesions generally progress to a vesicular phase, and then either to a pustular or a bullous phase, over a period of 1–3 days. More or less any part of the skin surface may be affected, including the nails, palms and soles. In fact, palmar and plantar pustules are regarded as a hallmark of congenital cutaneous candidiasis. Isolated involvement of the nail plates has been described [13]. Oral involvement is usually absent, and the napkin area tends to be spared, at least initially.

Very-low-birth-weight infants may have a scalded appearance, and are particularly at risk of systemic infection.

When infection is confined to the skin, affected infants have generally been otherwise well, and the rash clears within a week with appropriate topical antifungal therapy, for example with topical ketoconazole. The rash clears with prominent post-inflammatory desquamation.

Skin and mucosal involvement may be complicated by systemic candidiasis, particularly in the premature [4,14]. The lungs may be affected [15]; hepatosplenomegaly and abnormal liver function have also been recorded [9]. Candidal meningitis is another potential complication [16]. Criteria have been proposed that indicate high risk of systemic involvement. Systemic antifungal therapy should be considered in at-risk infants [12]; amphotericin B is probably the drug of choice [11,14].

Studies have shown that intravenous fluconazole prophylaxis in very-low-birth-weight infants reduces both invasive candidiasis and mortality rates [17,18] but a Cochrane review of three other studies using oral antifungal prophylaxis in preterm infants has not shown any convincing benefit [19].

Malassezia pustulosis

Colonization of the skin by *M. furfur* starts soon after birth and progresses until the age of about 3 months, probably reflecting the activity of the sebaceous glands during this period [1–3]. This yeast has been a cause of systemic infections in infants receiving intravenous lipids, and it is presumed that the source of organisms in such cases was the skin [4].

It is now believed that *M. furfur and M. sympodialis* may be a frequent cause of erythematous papulopustular eruptions occurring on the face and scalp in neonates, a condition now widely termed *neonatal cephalic pustulosis* [3,5–7], though not all neonates with this clinical presentation had detectable *Malassezia* in the lesions [8]. This type of rash was reported to have a frequency of 10% in neonates seen as outpatients in a paediatric dermatology department [7], with pustule contents showing *M. furfur* yeasts in over half of these, associated with a good therapeutic response to topical application of 2% ketoconazole cream for 15 days in almost every case. A frequency of 66% was reported in one study, with 62% being culture-positive for *Malassezia* [8].

There is reason to believe that some of the *Malassezia*-negative cases in these studies may have had genuine neonatal acne, which is generally easily distinguished by the concurrent presence of comedones.

Certainly, *Malassezia* pustulosis clearly needs to be considered in neonates presenting with pustular lesions on the face and/or in the scalp, in cases that might otherwise be diagnosed as eosinophilic pustulosis of the scalp, transient pustular melanosis, scabies, neonatal acne vulgaris, or cutaneous infections such as *S. aureus* or *C. albicans* [9].

Primary immunodeficiency disorders

A.R. Gennery & A.J. Cant, pp. 17.48–17.85

Introduction

The immune system protects against a huge variety of infective agents, which bear many different surface proteins or antigens. To achieve this a series of defence mechanisms have evolved, from simple mechanical barriers, through non-specific second line defences which recognize certain highly conserved microbial proteins to highly specific responses with 'memory' which are refined on repeated exposure and afford long-term protection. The interaction of man and microbe is ongoing through evolution, so that as existing systems become redundant, new defensive pathways evolve. New understandings of immune mechanisms give better insight into the causes of primary and secondary immunodeficiency and many aspects of immune function have been elucidated by the recognition of specific defects in immunodeficient individuals. Here, immune response mechanisms will be briefly described with examples of specific defects that result in primary or secondary immunodeficiency. Immunodeficiency states will then be reviewed in detail with particular reference to their dermatological manifestations. It is much easier to understand the dermatological features of immunodeficiency if the immune defect is also understood. Not surprisingly, the more severe primary defects of immunity present early in life, and so the dermatological features of these disorders will be considered in this chapter.

The innate immune system

Physical and chemical barriers such as epithelial surfaces and mucous membranes, hair, cilia, the secretion of sticky mucus, enzymes and acids, as well as antibiotics produced by commensal flora, are all highly effective at excluding pathogens by their antimicrobial effects, or by preventing microbial attachment. The importance of these barriers is demonstrated by the greatly increased risk of sepsis that occurs when they are significantly breached, such as occurs following severe burns or in epidermolysis bullosa.

If these barriers are breached and tissues invaded, pathogens are confronted by the innate immune response, an early evolutionary adaptation; this lacks immunological memory, so that the magnitude of response is the same no matter how many times the antigen is encountered. Pathogens are recognized by genetically predetermined receptors such as Toll-like receptors (TLRs) on the surface of phagocytic cells, which detect a limited range of highly conserved structures, such as bacterial lipopolysaccharide, mannan and peptidoglycan, present on many micro-organisms but not on the host. Recognition of one of these molecules causes immediate activation and cytokine release, accounting for the rapid response of the innate system. New understanding of defects in signalling in this part of the innate immune system have revealed associations with anhidrotic ectodermal dysplasia and incontinentia pigmenti.

Neutrophils are part of the innate response, endocytosing and killing invading pathogens. Macrophages and monocytes also endocytose pathogens, but in addition process antigen and present it to T lymphocytes to initiate the adaptive response. Soluble plasma proteins such as mannan binding protein and complement play an important first line role in innate defence once the epithelial surfaces are breached. Complement is a series of plasma proteins that act in a cascading sequence to attack extracellular organisms. Direct activation by microorganisms proceeds through the alternative pathway, whilst the classical pathway requires activation by antibody bound to antigen. Complement coating microorganisms can kill pathogens directly, or can facilitate pathogen removal by phagocytes, which bind complement to complement receptors. Non-function or absence of components of the alternative pathway or terminal pathway leads to recurrent infection with extracellular pathogens, particularly *Neisseria* species. Defects in the classical pathway, which plays a role in the clearance of immune complexes, leads to immune-complex mediated disease, chronic inflammation and systemic lupus erythematosis. Neutrophil defects include severe congenital neutropenia (Kostmann's syndrome), associated with an absolute neutrophil count below 500 cells/mm^3, and cyclical neutropenia, in which neutropenia occurs at roughly 3-weekly intervals. Patients with these conditions are at risk of bacterial and fungal infection. Once activated, neutrophils normally migrate from blood vessels to the site of infection. In leukocyte adhesion deficiency, neutrophils lack integrin molecules, which are necessary for their adherence to blood vessel walls and migration between vascular endothelial cells to the site of infection. Affected patients mobilize very large numbers of neutrophils, but they are unable to migrate into tissues. Patients present with delayed umbilical cord separation, rapidly enlarging infected skin ulcers with no pus, and recurrent soft tissue, respiratory and gastrointestinal infection. To eliminate infection, phagocytes must both ingest microorganisms and kill them once ingested. Intracellular killing is defective in chronic granulomatous disease, where patients cannot generate intracellular hydrogen peroxidase, as the enzyme NADPH oxidase is defective. Affected patients are susceptible to recurrent infections with catalase-positive bacteria and fungi, and suffer recurrent soft tissue, respiratory and

gastrointestinal infection with tissue scarring due to granuloma formation.

Much of the immune response is mediated by soluble protein messengers called cytokines, which are secreted by the liver, vascular endothelium and white blood cells. Defects in cytokine signalling pathways can have serious consequences. Macrophages produce interleukin (IL)-12 in response to infection, leading to interferon gamma (IFN-γ) release by T lymphocytes and natural killer cells, which in turn activates hydrogen peroxide production by the macrophages. Defects in IL-12, IL-12 receptor chains and IFN-γ have been identified in patients with severe or recurrent atypical mycobacterial or BCG infection. Overproduction of cytokines due to genotypic polymorphisms can also lead to problems. Increased tumour necrosis factor alpha (TNF-α) production gives increased protection to mycobacterial infection, but leads to an overwhelming pro-inflammatory cascade and severe septic shock in meningococcal infection. Defects in components of the TLR signalling pathway have recently been described in a few patients, leading to recurrent infection, predominantly with polysaccharide-encapsulated bacteria.

The adaptive immune system

T (thymus-derived) and B (bone marrow-derived) lymphocytes, which constitute the adaptive immune response, are generated in specialized lymphoid organs, namely lymph nodes, spleen and mucosal-associated lymphoid tissue. Characteristics of the adaptive response include proliferation of antigen-specific T and B lymphocytes, following activation by cells of the innate system. T lymphocytes act directly whilst B lymphocytes produce specific antibody. To respond to the vast number of possible antigens, B lymphocytes produce approximately 10^{18} different antibody variable regions, with a similar number of T-lymphocyte (or cell) receptor (TCR) variable regions, from fewer than 400 germline genes. This remarkable diversity means that there is a T or B lymphocyte with a receptor to complement every protein antigen that could be made. This variety is achieved by promiscuous recombination processes that cut, splice and modify variable region receptor genes. This randomly generated receptor diversity produces self-reactive lymphocytes as well as lymphocytes generated against specific microorganisms. Early lymphocyte development enables receptor rearrangement, but, following expression of a mature receptor, continued survival is antigen dependent and self-reactive lymphocytes are usually eliminated.

B-lymphocyte development

The diverse repertoire of T- and B-lymphocyte receptors is generated by recombination of a small number of gene segments. B-lymphocyte receptors (BCR) are membrane-bound immunoglobulin. Immunoglobulins are composed of two identical heavy (H) chains and two identical light (L) chains, held together by disulphide bonds. Immunoglobulins have two separate functions, firstly to bind to specific antigen, through the variable (V) domain, and secondly to recruit other cells to the immunoglobulin-bound antigen to affect killing and destruction. The second function is mediated through the constant (C) domain. The constant region is invariant for each immunoglobulin class, although it has five main forms or isotopes which determine the immunoglobulin class (IgM, G, A, E, D). Small variations lead to four IgG and two IgA subclasses. Both heavy and light chains have C and V domains.

Variable domains are constructed from the recombination of gene segments from two or three 'families' of genes. In light chains, a V (variable) segment is joined to a J (joining) segment. These are joined to the light chain C domain. A similar process occurs in the heavy chain, but there are three different gene segments in the variable region, a V (variable) segment, a J (joining) segment and a D (diversity) segment, which join to the heavy chain C domain. There are a number of different gene segments in each 'family' and so diversity is generated by varying the combination in which the V (D) J segments are arranged. Further diversity is introduced by pairing different heavy and light chain variable regions, and by imprecise splicing and rejoining of different gene segments, which give rise to different nucleotide sequences at the joining junction. These recombination events occur in the bone marrow. 'Fine tuning' of the response to produce antibody exactly complementary to antigen (somatic hypermutation) requires T-cell cooperation (see below). This unique and complex system is very prone to genetic faults, which are not lethal *in utero*. Mutations in genes encoding B-cell heavy or light chains, or in the associated signalling molecules necessary for their development, lead to absence of B cells and agammaglobulinaemia, as seen in X-linked agammaglobulinaemia (Bruton's disease) or to hypogammaglobulinaemia due to μ-chain deficiency. Defects in specific immunoglobulin heavy or light chain translation lead to individual class or subclass deficiency, although some humoral immunity is preserved.

T-lymphocyte development

T-lymphocyte receptor (TCR) development is very similar to that of B lymphocytes, but occurs in a specialized microenvironment, the thymus. Precursor cells migrate to the thymus and undergo TCR chain rearrangements. The TCR consists of α/β or γ/δ heterodimers. Each α, β, γ, δ chain contains a variable and a constant domain. As in the BCR, the variable domains are constructed from gene segments from different V, (D) and J 'families'. TCR α and γ loci do not contain D segments. The TCR differs from the BCR in that TCRs only recognize antigen that is bound to an individual's own major histocompatibility complex (MHC) tissue type molecule expressed on the surface of their cells. Thus, during thymic development, only T lymphocytes that recognize antigen presented by self MHC complex are allowed to survive positive selection (self MHC restriction); then, those that recognize self-antigen–MHC complex are destroyed (negative selection—self-tolerance). Only about 2% of T-lymphocyte precursors entering the thymus pass this rigorous selection process and leave as mature, naïve T lymphocytes.

T and B lymphocytes use similar signalling and enzymatic processes to rearrange gene segments and construct antigen receptors. These enzymes have evolved from those used to repair DNA damaged by UV light or ionizing radiation, hence the occurrence of photosensitivity in certain DNA repair disorders. Many of these enzymes are critical to lymphocyte development, which cannot occur in their absence, explaining the various forms of severe combined immunodeficiency (SCID), for example as when

recombination activating genes (*RAG1* and *2*) are mutated resulting in T-negative, B-negative SCID. The important role of the thymus is illustrated by complete DiGeorge syndrome or CHARGE syndrome, where congenital thymic absence leads to a SCID phenotype with absence of T lymphocytes. A number of signalling molecules and their receptors, particularly those for cytokines and their receptors, are also critical in lymphocyte development and survival. Thus, absence of the common cytokine receptor γ chain, which is integral to the IL-2, -4, -7, -9 and -15 receptors, leads to T-lymphocyte-negative, B-lymphocyte-positive, NK-lymphocyte-negative SCID, as does absence of Janus-associated kinase (JAK)-3, which is a signalling molecule associated with the cytokine receptors. Other defects can lead to dysregulation of thymic selection.

A lymphocyte that fails either negative or positive selection undergoes apoptosis. Defects in the apoptosis pathway, such as Fas or Fas ligand molecules or in the downstream caspases, leads to the escape of autoreactive lymphocytes, which can lead to autoantibody production and autoimmune disease.

Antigen presentation and lymphocyte interaction

Mature T and B lymphocytes circulate through the blood, lymphatics and tissues looking for the antigen that is specific for their particular receptor. Microorganisms are taken up by cells of the innate response, such as macrophages. They are broken down in lysosomes to small polypeptide fragments of 8–12 amino-acids long, combined with MHC class I or II molecules and presented at the cell surface as an antigen/MHC complex, with antigen bound within the groove of the MHC molecule. Defects in the MHC class II transcription molecules, or in the MHC class I transporter proteins (which transport antigen peptide to MHC I molecules) occur and although affected individuals have functionally normal lymphocytes, they suffer repeated, life-threatening infections because antigen cannot be presented to their T and B lymphocyte receptors.

Most adaptive immune responses occur in lymphoid tissue, where lymphocytes and antigen-presenting cells (macrophages, dendritic cells) are concentrated. There are at most only a few hundred lymphocytes with a receptor complementary to a specific antigen. When a T lymphocyte interacts with a matching antigen/MHC complex (MHC class I with CD8 cytotoxic T lymphocytes, for intracellular organisms, MHC class II with CD4 helper T lymphocytes for extracellular organisms), a second signal is delivered from the antigen-presenting cell (APC) to the T lymphocytes via a B7 molecule on the APC interacting with a CD28 molecule on the T lymphocyte. The combination of these two signals (TCR/MHC–antigen and B7/CD28) activates the T lymphocyte, causing repeated replication of T lymphocytes bearing the same antigen-specific receptor; a process called clonal expansion. Conversely, delivery of the first signal without the second renders the T lymphocyte unable to respond to antigen, and this unresponsive state is known as T-lymphocyte anergy. Because only a few T lymphocytes have the receptor for the specific antigen, only a few are activated for that antigen. However, as each microorganism carries many antigens, infection will cause the proliferation and clonal expansion of many different T lymphocytes, leading to a polyclonal response. As well as triggering clonal T-lymphocyte proliferation, an activated CD4 T lymphocyte can interact with a B lymphocyte carrying the BCR specific for the antigen, triggering clonal B-lymphocyte expansion. Initially the B lymphocyte responds by secreting IgM. In lymph node germinal centres, as the adaptive response matures, interactions between T lymphocytes via CD40 ligand (expressed on T lymphocytes) and CD40 expressed on B lymphocytes, enables B lymphocytes to switch from making IgM to making IgA, IgG and IgE, through substitution of the appropriate C domain on the heavy and light chains, encoding for IgM, A, G or E respectively, a process known as isotype switching. Point mutations, deletions and insertions in the variable domain of the immunoglobulin molecule (somatic hypermutation) modify the immunoglobulin molecule further (the fourth method of creating antibody diversity) and B lymphocytes making immunoglobulin that 'fits' the antigen most precisely are generated in great number (affinity maturation), whilst B lymphocytes that produce immunoglobulin of a 'less good' fit undergo apoptosis. Once activated, these T lymphocytes and B lymphocytes are long lived and act as memory lymphocytes. Thus, when the same antigen is encountered again, these lymphocytes immediately react and do not require activation by the innate system. The immunoglobulin that is produced attaches to the microorganism via the antigen-binding region. The effector portion of the immunoglobulin attaches to immunoglobulin receptors on phagocytes and macrophages, facilitating phagocytosis and antigen processing and elimination. Defects in these mechanisms illustrate their importance. In X-linked hyper-IgM syndrome, CD40 ligand is deficient, so B lymphocytes are unable to switch from making IgM to other immunoglobulin isotypes. T lymphocytes are also unable to interact with macrophages (which also express CD40), which are unable to kill ingested intracellular pathogens such as *Pneumocystis jiroveci* and *Cryptosporidium parvum*, thus allowing opportunistic infection with these organisms. An autosomal recessive form of hyper-IgM syndrome is due to mutations in the activation-induced cytidine deaminase gene, which encodes a protein involved in the isotype switching and hypermutation processes.

Once switched on by antigen presentation, T lymphocytes develop in different ways, and two routes are fairly well characterized; the Th1 route with production of IL-2 and IFN-γ, whose main role is in stimulating macrophage function and cell-mediated immunity, but which also induces B lymphocytes to switch the class of antibody produced, particularly to IgG2. Th2 cells, on the other hand, produce predominantly IL-4 and IL-10, which promote antibody responses and class switching, particularly towards IgG1, IgG4 and IgE. Allergic responses and those against parasites are of Th2 type. Responses to an antigen may follow a Th1 or Th2 route depending on a complex set of circumstances. Once established, these responses are self-amplifying in that production of IFN-γ or IL-4 promotes Th1 and Th2 responses, respectively, and inhibits the other.

Over-activation of the antigen/TCR or BCR binding process can also cause disease; bacterial toxins and some viruses act as so called superantigens, which bind to the outside of the MHC molecule, and in particular to the outside of a V-chain (one of the V segments of the β chain of the TCR), regardless of the antigenic specificity of the V domain of the β chain, or of the DJ segments of the V domain of the β chain. Thus instead of activating, say,

only 20 out of 10^{16} naïve T lymphocytes, one superantigen is able to activate up to 20% of the T-lymphocyte pool, which leads to massive lymphocyte activation and cytokine release, accounting for the features of marked inflammation (inducing polymorphic and vasculitic rashes) seen in superantigen-mediated diseases such as toxic shock syndrome and Kawasaki disease.

Elucidation of the molecular pathways enhances our understanding of the immune response, and identification and clarification of precise molecular mechanisms enables us to better understand and treat primary immune deficiencies. Thus, X-linked hyper-IgM used to be considered an antibody deficiency, although immunoglobulin replacement did not prevent liver disease secondary to *Cryptosporidium parvum* infection. Recognition that it is a primary T-lymphocyte defect has led to haematopoietic transplantation in selected patients. Identification of the genetic defect in X-linked SCID has led to successful gene therapy for this condition.

The skin is a vital component of the innate immune system and the site where many innate and adaptive immune responses to infection are seen. It is not surprising, therefore, that skin sepsis and other dermatological manifestations are common features of primary immunodeficiency. Understanding the context of these responses ought to give a clearer view of these conditions and their treatment.

Immunodeficiency disorders: general principles

Classification and genetics

The overall incidence of any significant immune deficiency disorder (excluding selective IgA deficiency) has been estimated at 1 in 10 000. The WHO working party on immunodeficiency [1] has classified the primary disorders (Table 17.7).

Diagnosis and investigation of immunodeficiency

A careful history and examination should precede laboratory tests as the clues obtained should determine which children should be investigated and which tests performed.

History

Taking a careful family history may reveal other children with unusual or fatal infectious complications suggestive of an autosomal recessive or X-linked pattern of inheritance. A history of consanguinity within the family should be sought. Delayed separation of the umbilical cord, in the absence of local infection, may suggest a neutrophil defect. Most children will present because of an infective problem. An immunodeficient child is likely to have more infections compared to normal children, which take longer to resolve or follow an atypical course. The type of organism involved, especially atypical ones, should direct further investigation. Cutaneous infections in immunodeficient patients are either caused by microorganisms not usually pathogenic in normal individuals, or follow a more severe course with the same microorganism than in those with normal immunity. Such infections may not immediately suggest a primary immunodeficiency unless this diagnosis is actively considered. Conversely, the familial

Table 17.7 Combined immunodeficiencies and defects of phagocytic function.

Immunodeficiency	Defect	Inheritance
CD40 ligand deficiency	CD40 ligand (CD154)	XL
Wiskott–Aldrich syndrome	WAS protein	XL
X-linked lymphoproliferative disease	SLAM-associated protein	XL
	X-linked inhibitor of apoptosis	XL

Mycobactericidal defect	IFN-γ receptor 1 deficiency	AR
	IFN-γ receptor 2 deficiency	AR
	IL-12 receptor deficiency	AR
	IL-12 deficiency	AR
	STAT 1 deficiency	AR
	NFκB signalling pathway defects (NEMO)	XL

XL, X-linked; AD, autosomal dominant; AR, autosomal recessive.

presentations of cutaneous staphylococcal infection in the absence of infection at other sites is much more likely to be due to nasal carriage of staphylococci, and cross infection, than immunodeficiency. Frequent upper respiratory tract infections (URTI) alone in a young child are not indicative of an underlying immune defect unless associated with frequent bacterial infections, clinical experience suggesting that up to eight URTI per year is normal in the pre-school years [1]. Infections with common organisms may run an atypical course that is unusually severe (e.g. haemorrhagic chicken pox) or they fail to respond to standard treatments (e.g. a bacterial pneumonia which fails to respond to appropriate antibiotic therapy). Alternatively, infections may be caused by uncommon (atypical) organisms which are in themselves highly suggestive of immunodeficiency, such as *Pneumocystis jiroveci* pneumonia [2]. Failure to thrive is a common finding, and this may or may not be associated with diarrhoea due to chronic or recurrent infection or autoimmune enteropathy [3]. Evidence of end-organ damage, such as a cough productive of sputum consistent with bronchiectasis, should also be sought. Allergic/atopic problems are common and may be unusually severe. Autoimmune and malignant diseases, though not common, have an increased incidence. Photosensitivity rashes may be a particular feature in some disorders, for example the immunodeficiencies associated with DNA repair disorders.

In some disorders, for example IgA deficiency, there may be a family history of collagen vascular or other immunopathological disease [4]. Older relatives who are carriers of an inherited immunodeficiency or who are affected by milder variants of primary immune defects may have autoimmune manifestations (e.g. mouth ulcers and systemic lupus erythematosus variant in chronic granulomatous disease (CGD) [5]) or have a history of malignant disease (lymphoma in X-linked lymphoproliferative disease (XLP) or Wiskott–Aldrich syndrome (WAS)).

Furuncular lesions or abscesses can be an overlooked manifestation of a primary immunodeficiency. They are most characteristically seen in neutrophil disorders (Table 17.7) such as CGD [6], Chediak–Higashi syndrome, leukocyte adhesion deficiency [7] and neutrophil-specific granule deficiency, but also in hyper-IgE syndrome [8] and antibody deficiencies such as XLP or in complement disorders. In these disorders it is, however, usual for infections of the skin to be accompanied by infection at other sites.

Cutaneous and mucosal ulceration are features of several immunodeficiency states and are the hallmark of leukocyte adhesion deficiency. Although infection is believed likely to be the cause of the ulceration, it can be difficult to identify the microorganisms responsible, and the accumulation of neutrophils in small blood vessels to the point where blockage and tissue necrosis occurs probably plays a big part in their genesis. Such ulcers are a characteristic feature of disorders featuring neutropenia, including congenital neutropenia, cyclical neutropenia and the Chediak–Higashi syndrome. Gradually extending cutaneous ulcers due to herpes simplex virus (HSV) (Fig. 17.9) are suggestive of T-lymphocyte defects, but have also been reported in X-linked agammaglobulinaemia.

Unusually severe or extensive infections with HSV or varicella-zoster virus, including the haemorrhagic vesicles seen in haemorrhagic chickenpox, are characteristic of T-lymphocyte defects.

Fig. 17.9 Progressive cutaneous ulceration due to herpes simplex in a 9-year-old child with T-lymphocyte immunodeficiency.

Fig. 17.10 Unusually large and rapidly proliferating viral warts in a child with combined immune deficiency.

Bullous impetigo with clear blisters may be a presentation of neutropenia. A vesicular presentation of the hyper-IgE syndrome in infancy has been described [9].

Ordinary viral warts are virtually never indicative of immunodeficiency. However, exceptionally rapid growth of warts, exceptionally large size or unusually extensive infections are suggestive of underlying defects of immunity (Fig. 17.10). Severe, extensive, persistent molluscum contagiosum is seen in similar disorders such as WAS, CD40 ligand deficiency and less well characterized combined immune deficiencies (Fig. 17.11).

Fig. 17.11 Severe molluscum contagiosum in a child with an undefined T-lymphocyte defect. (Courtesy of the Paediatric Immunology Unit, Newcastle General Hospital, UK.)

Refractory mucosal and cutaneous *Candida* infections are a characteristic presenting sign of several immunodeficiency disorders, particularly severe combined immunodeficiency and severe T-lymphocyte defects. Surprisingly, systemic *Candida* infections are rather rare in these conditions. Persistent mucosal and cutaneous *Candida* infection, which responds poorly to systemic treatment, suggests chronic mucocutaneous candidiasis.

Non-infectious, non-specific manifestations of immunodeficiency

If atopic eczema is considered to be an immunodeficiency disease, eczema would certainly be the commonest of all cutaneous manifestations of immunodeficiency. Eczema is also a characteristic cutaneous feature of some primary immunodeficiencies disorders such as WAS, and has been recorded as occurring more frequently than one would expect in various other disorders, including selective IgA deficiency, selective IgM deficiency, ataxia–telangiectasia and combined immunodeficiency.

Morbilliform eruptions are sometimes caused by viral infections, as in other children, but in severe combined immunodeficiency they are quite frequently manifestations of acute graft-versus-host disease (GvHD), due either to maternofetal engraftment, or to engraftment of viable lymphocytes from a third party after the transfusion of non-irradiated blood products after birth (Fig. 17.12). A rash may be seen after vaccination with live vaccines, such as measles, mumps and rubella or varicella, in patients with severe T-lymphocyte immunodeficiency, who develop disease.

Petechiae, due to thrombocytopenia, are a highly characteristic feature of WAS and may also occur in Fanconi's anaemia, dyskeratosis congenita, Schwachman's syndrome and the Chediak–Higashi syndrome.

Fig. 17.12 Acute graft-versus-host disease following transfusion of non-irradiated blood in a child with severe combined immunodeficiency.

Vasculitic lesions may rarely be seen as an autoimmune manifestation and have been documented in XLP, autoimmune lymphoproliferative syndrome (ALPS) and the immunodysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome, as well as common variable immunodeficiency (CVID).

A combination of erythroderma of early onset with failure to thrive in early infancy is highly suggestive of immunodeficiency, and often results from dysregulated, activated T lymphocytes invading the skin. In some cases these are maternally derived and represent true GvHD [10], whilst in other cases aberrant clones of the infant's own T lymphocytes cause a similar reaction, which results in the condition known as Omenn syndrome, a 'leaky' form of SCID.

Patients with several different primary immunodeficiencies have featured indurated erythematous papules and plaques with central scaling, scarring, atrophy or ulceration, which demonstrated caseating granulomas histologically. The conditions in which these have been reported include common variable immunodeficiency [11], X-linked agammaglobulinaemia [12], ataxia-telangiectasia [13] chronic granulomatous disease [14] and patients with atypical *RAG* mutations [15].

As well as classical systemic and discoid lupus erythematosus, a syndrome resembling systemic lupus erythematosus from the cutaneous point of view, but having only very mild non-cutaneous manifestations and either absent or very low-titre plasma antinuclear antibodies, has been described in patients with a variety of complement deficiencies, most commonly C2 deficiency but also C3, C4, C9 and C1 esterase inhibitor deficiency. In such patients, this syndrome can occasionally have its onset as early as the first year of life, and, because many of these patients are susceptible to certain infections such as meningococcal meningitis, the association of a disorder resembling lupus erythematosus and recurrent infections of appropriate type is highly suggestive of a hereditary complement deficiency.

There is an increased incidence of systemic lupus erythematosus in patients with IgA deficiency, and skin lesions closely resembling discoid lupus erythematosus have occurred in female carriers of the gene for X-linked chronic granulomatous disease.

	SCID
	HIES
Pigmentation disorders	Chediak–Higashi syndrome
	Griscelli syndrome
	Hermansky–Pudlak syndrome Type 2
	Endosomal adaptor protein p14 deficiency
	NEMO
Photosensitivity	DNA repair disorders, e.g. DNA ligase 4 deficiency

ALPS, autoimmune lymphoproliferative syndrome; AR, autosomal recessive; CGD, chronic granulomatous disease; CMC, chronic mucocutaneous candidiasis; HIES, hyper-IgE syndrome; MFE, maternofetal engraftment; SCID, severe combined immunodeficiency; WAS, Wiskott–Aldrich syndrome; WHIM, wart hypogammaglobulinaemia infection, and myelokathexis syndrome; XLP, X-linked lymphoproliferative syndrome.

Examination

General physical examination should be directed towards examination of potential sites of infection, including the throat, ears and sinuses, and the oral cavity and nappy area for candidiasis. The presence or absence of lymphoid tissue should be noted, as should cutaneous problems consistent with an immune defect. In more severe antibody states such as X-linked agammaglobulinaemia, there is a lack of tonsils and lymphoid tissues. Signs of end-organ damage from infections, such as clubbing and respiratory abnormalities must be sought. Some diseases may have specific physical signs, such as oculocutaneous albinism in Chediak–Higashi syndrome, typical facies and/or cleft palate in DiGeorge or CHARGE syndrome, typical facies in immunodeficiency, centromeric instability, facial dysmorphism (ICF) syndrome, telangiectasia or neurological abnormalities in ataxia-telangiectasia, and disproportionate short stature in some forms of combined immune deficiency (see Immunodeficiency and short-limbed dwarfism, below). Specific skin lesions can give clues to the underlying immunological disorder (Table 17.8).

Radiological evaluation

Evidence of bony abnormalities may support a diagnosis of adenosine deaminase deficiency [1], Schwachman–Diamond syndrome [2] or other dysplasias associated with immune defects. Dilatation of the common bile duct may be suggestive of sclerosing cholangitis, associated with a number of combined immune deficiencies especially X-linked hyper IgM syndrome [3]. Careful review of chest radiographs may suggest bronchiectasis, and should prompt high resolution computed tomograph imaging. Although absence of a thymus on anterior posterior and lateral chest radiographs is consistent with a combined immune defect in infants and young children, thymic atrophy may also occur in response to stress (e.g. infection) and this finding is not diagnostic.

Laboratory investigation

Two main questions need to be addressed: which children to investigate, and how extensively to investigate selected children [1]. Investigation should be triggered by one or more of the warning signs (Table 17.9). Laboratory investigations can be

Table 17.9 Warning signs of immunodeficiency.

Eight or more new infections within 12 months
Two or more serious sinus infections or episodes of pneumonia within 1 year
Two or more months on antibiotics with little effect
Failure of an infant to gain weight or grow normally
Recurrent deep skin or organ abscesses
Persistent superficial candidiasis after age 1 year
Episode of opportunistic infection
Complication associated with live vaccination
Need for intravenous antibiotics to clear infections

Table 17.10 Examples of association between most likely type of immune defect and infecting organisms.

Candidate immune defect	Typical infecting organism
Antibody	*Streptococcus pneumoniae, Haemophilus influenzae, Giardia lamblia, Mycoplasma* spp., Enteroviruses
Cell mediated	*Salmonella, Cryptosporidium, Giardia lamblia, Candida albicans*, herpesviruses (e.g. CMV), other viruses e.g. measles, Bacille Calmette-Guerin, *Pneumocystis jirovecii*
Neutrophil	*Staphylococcus* Gram-negative bacteria, *Candida albicans, Aspergillus* spp., Bacille Calmette-Guerin
Type-1 cytokine defects	*Salmonella, Mycobacteria* (typical and atypical), Bacille Calmette-Guerin
Monocyte	*Candida albicans*
Natural killer cell	Herpesviruses
Complement	*Neisseria meningitidis, Streptococcus pneumoniae, Haemophilus influenzae*

directed to a certain extent by the organism causing infection (Table 17.10) and the age of the child. Laboratory investigations range from those readily available in all centres, to highly specialized tests performed in research centres. Only a small proportion of children presenting with recurrent infections require complex investigation; most can be adequately investigated with a few relatively straightforward tests (Table 17.11).

A full blood count and film can be very revealing. Neutropenia is readily detected, and a bone marrow aspiration will distinguish failure of production from increased peripheral destruction, and also exclude a myelodysplastic or malignant process. Neutrophilia in the absence of overt infection may suggest a neutrophil adhesion defect or functional problem (e.g. CGD). Lymphopenia, using appropriate age-related ranges, strongly suggests a combined immune deficiency of primary or secondary aetiology [2], although SCID can occur in the presence of a normal lymphocyte count. Nucleated red cells in infants and abnormal leukocyte morphology in sick children may be detected as lymphocytes on the automated cell counter, and thus erroneously suggest a normal lymphocyte count. Abnormal leukocyte granules are seen in Chediak–Higashi syndrome, whilst a platelet volume is invariably low in WAS, making this the most rapid and reliable diagnostic pointer in this condition [3].

Table 17.11 Investigations in children with suspected primary immunodeficiency.

First line investigation	Second line investigation
FBC and WCC differential	Chromosomal studies
Lymphocyte subsets	Genetic studies
IgM, A, G and IgG subclasses	HRCT of chest
Specific tetanus, HiB antibodies	Bronchoscopy
Pneumococcal antibodies (if >2 years)	Tissue biopsy
Simple spirometry (if >5 years)	Radiation sensitivity studies
Plain chest radiograph	Specific lymphocyte marker studies
Microbiological investigations (culture, IF, PCR)	Lymphocyte proliferation investigations
Complement C3, C4 levels	Neutrophil oxidative burst investigations
Functional complement investigations	

FBC, full blood count; WCC, white cell count; HiB, *Haemophilus influenzae* type B; IF, immunofluorescence; PCR, polymerase chain reaction; HRCT, high resolution computed tomograph.

Tests of innate immunity

Complement

C3 and C4 are easily measured; however, null alleles for C4 are relatively common, so that the significance of an isolated low C4 in an individual with recurrent infections is less certain. Furthermore, normal levels of C3 and C4 do not exclude deficiencies of other complement components. It is better to screen the whole complement system by assessing the functional integrity of the classical and alternative complement pathway using assays which test the ability of patient serum to lyse sensitized red blood cells (CH50/100 and AP50 respectively). Deficiency in any one component will result in a failure of lysis. Low values may be seen in the presence of active infection, when complement components are being consumed, or if degradation of complement components has occurred because the sample was not separated and frozen within 2 h of venesection. If repeat testing shows a persistent abnormality, measurement of the levels of individual complement components should be performed until the defective component is identified.

Neutrophil function tests

Neutrophil function has three main components: chemically mediated movement towards microorganisms (chemotaxis); ingestion of microorganisms into a phagocytic vacuole (phagocytosis); and activation of the respiratory burst within the phagolysosome to produce free oxygen radicals that kill microorganisms. Neutrophil function tests are fraught with technical pitfalls, as neutrophils rapidly activate upon venesection and also die quickly.

Neutrophil chemotaxis is unreliable and only performed in a research setting. Chemiluminescence measures all three phases of neutrophil activity; such assays have been superseded by flow cytometric assays (see below). Nitroblue tetrazolium (NBT) is a yellow dye that is readily taken up by phagocytes and, upon stimulation (for example with phorbol myristate acetate) is reduced to the purple dye formazan by the oxidative burst. Normally, at least 95% of neutrophils should contain a purple deposit in stimulated cells. In CGD, less than 1% of neutrophils reduce NBT. Carrier mothers of X-linked CGD can also be detected by this method as they show an intermediate level of NBT reduction (20–80%). In experienced hands, this is a rapid and sensitive test for CGD, but false normal results can be seen when the test is performed infrequently.

Flow cytometric assays of neutrophil function

The flow cytometer, widely used in the cellular immunology laboratory, counts the absolute number and proportion of cells bearing a fluorescent marker which scatters light with a distinctive pattern.

Fluorescently labelled microorganisms can be used to assess the phagocytic ability of neutrophils, seeing what proportion of cells have ingested the labelled organisms. Comparison of phagocytosis using the patient's own serum with that using control serum gives a measure of the effectiveness of patients' antibody and complement systems to aid phagocytosis (opsonization).

Phagocytosis of organisms by neutrophils and monocytes normally leads to activation of the respiratory burst and the production of free oxygen radicals. If neutrophils take up dihydrorhodamine and, using a suitable stimulus, the dihydrorhodamine is reduced, it fluoresces within cells, which can be assessed using the flow cytometer; absence of fluorescence indicating failure of the respiratory burst. This is the best test for identifying patients with CGD and will also detect carriers for X-linked CGD, who exhibit a dual population of normal and abnormal cells. The test has the advantage that more laboratories are experienced in the interpretation of flow cytometric readouts than reading slide NBT tests and so false-normal results are much less likely. It is, however, more sensitive than an NBT test so neutrophil function defects other than CGD may also be detected. Neutrophil killing defects may also occur in deficiency states of myeloperoxidase and glucose-6-phosphate dehydrogenase, which can be assayed separately.

Tests of the adaptive immune system

Test of humoral immunity

Immunoglobulins IgG, A and M are routinely measured by nephelometry which measures light scattering, the amount of light scattered being proportional to the quantity of immunoglobulin within the sample. Results must be evaluated with reference to age-specific normal ranges, as production of all five classes of immunoglobulin is low at birth and gradually matures over the first 5 years of life [1]. Low levels of Ig can only be attributed to a production defect if gut or renal losses have been excluded and the serum albumin is within the normal range. Catabolic states, such as myotonic dystrophy, can also lower total immunoglobulin levels.

IgE is measured using a variety of techniques, including enzyme-linked immunosorbent assays (ELISA) and automated solid-phase ELISAs. IgG subclasses are commonly measured by nephelometry or radial immunodiffusion. Results should be compared with age-specific normal ranges.

Measures of in vivo antibody responses

The ability of the immune system to produce functional antibody is more important than the amount of circulating antibody. Functional tests of IgG production rely on measuring antibody titres to antigens to which the child is known to have been exposed either naturally or by vaccination. Responses to protein antigens such as tetanus, diphtheria and the conjugated (*Haemophilus influenzae* type B) Hib vaccine are widely available. However, although normal ranges for antibody titres exist, these are not well validated for antigens other than Hib, and may not be a true reflection of immunological memory. If antibody titres are low, booster vaccinations should be given to assess the memory response. In children over 2 years of age, administration of 23-valent polysaccharide pneumococcal vaccine is useful to assess the ability to respond to carbohydrate antigens. Interpretation of these responses has become more difficult since the introduction of the 7-valent conjugated pneumococcal vaccine into the national immunization schedule. Measurement of individual serotypes, contained in the 7-valent conjugate pneumococcal polysaccharide vaccine, as well as those found only in the 23-valent pneumococcal polysaccharide vaccine, gives most useful information [1,2]. Loss of the polysaccharide response may be the first sign of an evolving immune deficiency in patients with common variable immunodeficiency or WAS. Assessment of antibody responses to common respiratory viral pathogens and varicella zoster may also provide useful additional information, although negative tests in the absence of microbiologically proven disease are difficult to interpret.

The optimal test of *in vivo* antibody production is assessment of IgM and IgG responses and rate of clearance to a novel antigen whose clearance is dependent on opsonization by a specific antibody. IgM isohaemagglutinin responses to ABO blood group antigens can be a useful measure of intrinsic IgM production.

Cell mediated immunity

Cell mediated (T lymphocyte) defects are rarely isolated defects, and are usually accompanied by a degree of humoral immune deficiency, as T lymphocyte help is crucial in making an antibody response with memory.

Quantification of cell numbers. Lymphocytes can be enumerated using flow cytometry, which detects the different light scatter

properties of cells passed through a laser beam, and enables populations of neutrophils, monocytes and lymphocytes to be differentiated. Lymphocytes can be characterized further by their cell surface markers, which are identified by specific monoclonal antibodies. The number of cells staining with a particular monoclonal antibody can be expressed either as a percentage of the lymphocyte pool or as an absolute number. As with all immunological parameters, both proportions of different T lymphocytes and absolute numbers vary with age and reference should be made to published age-related normal ranges [1,2]. Approximately 60–80% of circulating lymphocytes are T lymphocytes, with 10–20% B lymphocytes and 5–15% NK cells.

Functional tests of cell mediated immunity. When lymphocytes encounter antigen *in vivo*, they respond by upregulation of activation markers and proliferation, without which an effective immune response cannot occur. This can be mimicked *in vitro* by culturing lymphocytes with a non-specific stimulus, such as plant lectins, and using the incorporation of tritiated thymidine or a non-radioactive marker such as bromodeoxyuridine into the DNA of dividing cells as a surrogate measure of cell proliferation.

Definition of molecular defects

Protein assays

The genetic basis of an increasing number of immune deficiencies is now well defined; many occur because a surface or cytoplasmic signalling protein is absent or defective. These abnormalities can be detected using a combination of western blotting and flow cytometry [1,2].

Genetics

In the presence of an appropriate history or abnormal protein expression, genetic analysis may be undertaken. Genes can be screened using single stranded conformational polymorphism analysis, or by direct sequencing using automated sequencers. Once mutations have been defined, parents can be tested for carrier status. Carrier testing of siblings raises a number of ethical issues, and children should reach the age of informed consent before any tests are undertaken.

Table 17.12 Molecular defects and immunophenotype in severe combined immunodeficiency.

Defect	Molecular defect	Inheritance	T, B, NK cells
Cytokine signalling	CγC	XL	− + −

	MHC class II deficiency	AR	+++ (absent CD4)

XL, X-linked; AR, autosomal recessive.

Disorders of cell-mediated immunity

Severe combined immunodeficiencies (SCID)

Failure to develop normal T lymphocytes, usually due to a range of specific X-linked or autosomal recessive gene defects affecting early T-lymphocyte development or signalling pathways, leads to T-lymphocyte immunodeficiency, usually with concomitant humoral deficiency. The severity of the humoral deficiency varies from a subtle defect of specific antibody response to complete hypogammaglobulinaemia. In the most severe phenotype, severe combined immunodeficiency (SCID), profound T lymphopenia and panhypogammaglobulinaemia cause early infective death. In the classic SCID presentation, lymphocyte numbers and responses to mitogens are absent, but may be present in attenuated forms where immunoglobulin may also be produced. Patients usually have a limited diversity of T-lymphocyte receptors and immunoglobulin gene rearrangements. Identifying the molecular defect in individual patients is important for prognosis, treatment, genetic counselling and increasing our knowledge about these rare diseases.

Types of severe combined and combined immunodeficiencies

SCID can be subdivided according to the presence or absence of T, B and NK lymphocytes, each phenotype being due to a number of distinct molecular defects, also enabling classification by mechanism (Table 17.12) [1–7].

General features of severe combined immunodeficiency

Although appearing well at birth, affected infants fail to clear normally 'minor' infections [1]. Rotavirus can cause chronic diarrhoea and failure to thrive whilst *respiratory syncitial virus* or parainfluenza infection leads to a persistent bronchiolitis like illness. An insidiously progressive, persistent respiratory infection with radiological evidence of interstitial pneumonitis suggests *Pneumocystis jiroveci* infection, often a co-pathogen with respiratory viruses. Other presentations include prolonged otitis media and invasive bacterial infections, particularly staphylococcal or pseudomonas septicaemia and pneumonia, which may respond poorly to appropriate treatment (Table 17.13). Severe, invasive fungal infection is rare, but often fatal. Persistent, treatment-resistant, superficial candidiasis is the commonest dermatological feature. This may start in the napkin area, but will often extend rapidly to produce a picture resembling severe seborrhoeic dermatitis. Systemic *Candida* infections do not usually occur unless central venous lines are used. Pyogenic cutaneous infection due to *Staphylococcus aureus* or group A streptococci are not uncommon, and will often provoke lesions having a necrotic, ecthymatous appearance. Resistance to appropriate antibiotic therapy should raise suspicion [2].

Occasionally, babies present with disseminated BCG (Fig. 17.13). Children presenting within the first 6 months or so of life are more likely to have SCID or a severe T-lymphocyte defect. Dysmorphic features may suggest a diagnosis of DiGeorge or CHARGE syndrome. Microcephaly is a feature of some patients with DNA ligase 4 or cernunnos deficiency.

Table 17.13 Presenting features of severe combined immunodeficiency.

Common presentations	Common pathogens	Rare presentations
Persistent viral gastroenteritis	Norovirus Rotavirus Astrovirus Adenovirus Respiratory syncitial virus	Bacterial septicaemia Disseminated BCG infection
Persistent viral lower respiratory tract infection	Parainfluenzae virus Cytomegalovirus	Haemophagocytosis Lymphoid malignancy Autoimmune cytopenias
Pneumocystis jiroveci pneumonitis		
Recurrent or recalcitrant candidiasis		
Failure to thrive		

Isohaemagglutinins are a useful measure of *in vitro* IgM production and absence is significant. If SCID is suspected, lymphocyte phenotyping is more reliable than immunoglobulin estimation. Chest radiographs show an absent thymus with hyperinflation and/or interstitial pneumonia when respiratory infection is present. Without treatment, patients die from infection by about 12 months of age. Currently, the only curative treatment is haematopoietic stem cell transplantation [3,4]. Clinical gene therapy trials for common gamma chain and adenosine deaminase deficiency are in progress; they have produced mixed results. Supportive interim treatments include antibiotic prophylaxis with co-trimoxazole as antipneumocystis treatment, antifungal prophylaxis and immunoglobulin replacement. Live vaccines should be avoided. The diagnosis of SCID is a paediatric emergency, and suspected cases should be urgently referred to a designated treatment centre for further assessment and treatment.

Dermatological features of SCID

Two atypical forms of SCID with maternofetal graft-versus-host disease (MFGvHD) and Omenn syndrome have distinct manifestations and are commonly seen by dermatologists who can play a key role in early diagnosis, which in turn offers better outcome from stem cell transplantation. In both conditions, the skin is infiltrated by abnormal T-lymphocyte clones. As SCID infants lack functional T cells they cannot reject foreign lymphocytes acquired either from the mother *in utero* or from an unirradiated blood transfusion (Fig. 17.12). Engraftment of transplacentally acquired maternal lymphocytes (MFGvHD) sometimes, but not always, provokes the clinical signs of GvHD, typically with a mild reticular skin rash with or without slightly deranged liver function tests. Surprisingly, up to 50% of children with SCID have clinically silent MFGvHD [1] although GvHD can be severe or fatal, when the skin rash is more severe and lymphadenopathy and hepatosplenomegaly may be present; these cases may be clinically indistinguishable from Omenn syndrome, but identification of maternal cells by karyotype or DNA fingerprinting will distinguish MFGvHD from Omenn syndrome [2].

Omenn syndrome is characterized by a generalized, thickened erythematous rash, often with scaling and erythroderma. The cutaneous abnormality is often the first sign of the disorder; an erythematous, exfoliating, protein-losing rash appearing and evolving into a confluent erythema. The initial appearances may be papular, becoming confluent, and the skin often becomes thickened with a 'leathery' consistency. Hair, including eyebrows, is often lost as the rash evolves (Fig. 17.14). The rash may be present at birth or evolve over the first few weeks of life. There is also lymphadenopathy, particularly of the axillary and inguinal nodes, as well as increased serum IgE levels with a marked eosinophilia and combined immunodeficiency [3]. Children usually present in early infancy but atypical forms may present later in the first year of life. As well as the clinical features described, children usually suffer diarrhoea, failure to thrive and persistent infection, as seen in other forms of SCID. There are normally high numbers of activated, oligoclonal, poorly functional T lymphocytes of the Th2 phenotype, explaining the eosinophilia and exclusive IgE production [4]. Peripheral B lymphocyte numbers are low or absent, as are levels of immunoglobulin classes other than IgE. The syndrome has been called a 'leaky' form of SCID in that small numbers of very abnormal T lymphocytes 'leak' past the block in T lymphocyte development [5]. The underlying defect, at least in some cases, is a mutation in the recombination activating genes [6]. In some families, one affected individual has presented with T^- B^-NK^+ SCID whilst another has presented with Omenn syndrome [7]. Other genes that have been implicated include Artemis, IL7Ra, RMRP, CHD7 and CgC [8–12]. The clinical picture may resemble SCID with maternofetal engraftment, when maternal T lymphocytes crossing the placenta cause a graft-versus-host disease-like reaction in an immunoincompetent patient. Activated oligoclonal lymphocytes in skin seemingly provoke Langerhans' cells to migrate to lymph nodes, liver and spleen where lymphoid tissue architecture is severely disrupted. It has been suggested that IFN-γ may ameliorate the clinical symptoms, but bone marrow transplantation is the only curative treatment [13].

Fig. 17.14 Newborn infant with Omenn syndrome due to a mutation in the *RAG1* gene. Note the confluent erythematous exfoliating, thickened rash with a 'leathery' consistency, and loss of hair and eyebrows. (Courtesy of the Paediatric Immunology Unit, Newcastle General Hospital, UK.)

Histology of the skin shows a dense, dermal perivascular lymphohistiocytic infiltrate, comprising activated T lymphocytes, with numerous eosinophils. S100-staining Langerhans' cells are usually absent, and there is no epidermotropism. Lymph node architecture is disordered, being replaced by a similar massive infiltrate of cells of S100-staining interdigitating reticulum cells with absence of germinal centres, absent B cells and a paucity of T lymphocytes [14].

In the older literature this condition has been confused with Langerhans' cell histiocytosis (Letterer–Siwe disease). It is likely that several cases reported in the literature under other names were in fact examples of this disorder [15].

SCID due to metabolic defects

Adenosine deaminase (ADA) deficiency [1] and purine nucleoside phosphorylase (PNP) deficiency [2] are both single-gene defects inherited in an autosomal recessive manner, which result in defective metabolism of the DNA break-down products, allowing the accumulation of toxic purine metabolites that destroy immature lymphocytes. Skeletal abnormalities (cupping deformities of the ends of the ribs, as well as abnormalities of the transverse vertebral processes and the scapulae) are reported in up to 50% of cases of ADA deficiency [3]. Neurodevelopmental problems may also occur in some patients [4]. Very rarely, partial forms of ADA deficiency occur, where some lymphocyte function is preserved. Interestingly, such patients have clinical features similar to those seen in hyper-IgE syndrome [5]. Treatment is by bone marrow transplantation [6] or by use of replacement polyethylene glycol-coupled ADA [7]. Gene therapy is being attempted in this condition [8].

PNP is initially less severe than ADA deficiency [9]. Most cases present in early childhood with recurrent and severe infections, particularly with viruses and fungi, accompanied by diarrhoea and failure to thrive. There is a marked tendency to autoimmune disease, especially haemolytic anaemia [10], which can progress to red cell aplasia, and also to GvHD following non-irradiated blood transfusion. Skeletal abnormalities do not occur, but neurodevelopmental problems are found in over half of all patients, particularly spastic paresis, dysequilibrium and ataxia [10]. There may also be more general neurodevelopmental and behavioural problems. In one series, 20% of patients presented primarily with neurological disorder [11]. Serum uric acid levels are very low. The diagnosis is confirmed by demonstrating absent PNP activity in red cells or fibroblasts and deoxyinosine and deoxyguanosine in the urine. The prognosis without haematopoietic stem cell transplantation is poor.

Other combined immunodeficiencies

Other rare immunodeficiencies have been described in only a few patients to date with defects in other surface and signalling molecules (Table 17.12). It is likely that these will become increasingly recognized as more laboratories are able to offer diagnostic testing.

Major histocompatibility complex antigen deficiency

Major histocompatibility complex class II (Bare lymphocyte syndrome)

Major histocompatibility complex class II (MHC II) antigens (HLA-DR, DP, DQ) are expressed on a limited repertoire of cells and present antigen to $CD4^+$ T lymphocytes which, with the help of an appropriate second signal, activate T-helper lymphocytes specific for that antigen. Expression of MHC II in the thymus is also essential for positive selection of $CD4^+$ T lymphocytes. Since HLA antigens are of vital importance for lymphocyte development and function, lack of MHC II expression, previously described as 'bare lymphocyte syndrome', results in a profound susceptibility to viral, bacterial, fungal and protozoal infections [1]. Lack of MHC II expression results from defects in genes coding for regulatory factors that control transcriptional activation of MHC II molecules [2].

Most patients will have a CD4 lymphopenia and hypogammaglobulinaemia; lymphocyte proliferation responses are usually normal. The diagnosis can be confirmed by flow cytometry showing absent or significantly reduced levels of class II molecules, for example HLA-DR, on cells that constitutively express

Fig. 17.15 Necrotizing skin lesion on the elbow of a patient with MHC class I deficiency. Biopsy of the lesion showed granulomata, but mycobacteria were not identified or isolated. (Courtesy of the Paediatric Immunology Unit, Newcastle General Hospital, UK.)

class II (B lymphocytes and monocytes). Haematopoietic stem cell transplantation is the definitive treatment [3].

MHC I deficiency

Although described before MHC II deficiency, SCID due to abnormal expression of the A, B and C components of the MHC I complex is much less common. MHC I is required for development of $CD8^+$ T lymphocytes, and affected children have low numbers of these cells. Mitogen responses are frequently normal [4]. MHC I deficiency is due to mutations in the peptide transporter genes, which code for proteins that transport degraded protein antigen from the cytosol to the endoplasmic reticulum where they associate with the MHC I complex [5].

Clinically, this disease has a milder phenotype than MHC II deficiency, with symptoms often not beginning until late childhood. Recurrent respiratory tract infections leading to bronchiectasis and sinus problems are common. Gastrointestinal disease is rare. The most striking clinical manifestation is necrotizing granulomatous skin lesions which are located on the extremities (Fig. 17.15) [6,7] and also at the midface [8]. The skin manifestations begin with a small pustule or subcutaneous nodule which slowly expands and ulcerates. The lesions are slow to heal, and usually leave hyperpigmented scars. Midface lesions can be particularly mutilating and resemble midline granuloma. Diagnosis is confirmed by showing absent HLA class I expression in peripheral blood. Treatment is directed towards prevention/limitation of lung disease with judicious use of antibiotics (directed by sputum cultures), physiotherapy and bronchodilators as required. Prophylactic continuous antibiotics are of unproven benefit, but may be helpful. The majority of cases do not require replacement immunoglobulin therapy or haematopoietic stem cell transplantation.

Combined immunodeficiency forming part of other syndromes

DiGeorge syndrome

This condition results from abnormal cephalic neural crest cell migration into the third and fourth pharyngeal arches in early embryological development. A microdeletion at chromosome 22q11.2 is present in 90% of cases, while the remainder are associated with other chromosomal anomalies, particularly 10p–. DiGeorge syndrome belongs to a group of disorders that have been described as developmental field defects [1]. The syndrome is extremely heterogeneous with partial forms more common than the complete phenotype [2]. Whilst classically recognized by the triad of congenital heart defects, immunodeficiency secondary to thymic hypoplasia and hypocalcaemia secondary to parathyroid gland hypoplasia, an expanded phenotype is increasingly recognized, with dysmorphic facies (low-set, abnormally formed ears, hypertelorism and antimongoloid slant, micrognathia, short philtrum to the upper lip and high arched palate), palatal abnormalities (cleft palate, velopharyngeal insufficiency), autoimmune phenomena such as autoimmune cytopenia, vitiligo, autoimmune thyroiditis, learning difficulties (particularly speech delay), renal anomalies, neuropsychiatric disorders and short stature. Conotruncal heart defects are classically associated with the syndrome, but

other defects are seen including tetralogy of Fallot, septal defects, pulmonary atresia and aberrant subclavian vessels. Some patients have normal hearts.

Severe T-lymphocyte immunodeficiency presenting with a SCID phenotype of profound lymphopenia and poor lymphocyte proliferation is rare, and accounts for less than 1.5% of cases [3]. Humoral immunodeficiency is more common than previously thought, presenting with recurrent sinopulmonary infection, which may improve with time [4]. Occasionally, significant lung damage may occur due to repeated infection. Autoimmune features are increasingly recognized, including juvenile chronic arthritis and autoimmune cytopenias [5,6]. The long-term immunological outlook is not well defined, particularly in children with mild cardiac or palatal phenotypes. An Omenn syndrome phenotype has been described in patients with DiGeorge syndrome [7], and at least some of these have been secondary to engraftment of maternal T cells causing a MFGvHD [8]. CHARGE syndrome has recently been linked with SCID, and as in patients with DiGeorge syndrome, the primary immunological defect is an absent thymus [9,10].

Wiskott–Aldrich syndrome (WAS)

Immunodeficiency, thrombocytopenia, eczema and an increased risk of autoimmune disorders and malignancy characterize this X-linked recessive condition. The gene responsible for WAS codes for the Wiskott–Aldrich syndrome protein (WASP) [1], which is only found in bone marrow-derived cells and is implicated in actin cytoskeleton polymerization [2]. Mutations in the same gene are found in patients with X-linked thrombocytopenia (XLT) [3], and also in X-linked severe congenital neutropenia [4]. Patients usually exhibit the classical triad of thrombocytopenia, recurrent infections and eczema (Fig. 17.16) but these vary in severity and in some patients the eczema is surprisingly mild [5]. In general, it is indistinguishable from atopic eczema apart from the presence of purpura and bleeding from excoriation in many patients. The condition usually presents in early life with bruising, petechiae and bleeding; thrombocytopenia and bleeding episodes may require platelet transfusions. In XLT, thrombocytopenia with small platelet volume is the only symptom, perhaps with mild eczema. In WAS, bacterial and/or viral infections of the upper and lower respiratory tract are common [6] and opportunistic infection, such as *Pneumocystis jiroveci*, may occur. Herpes viruses, including *Herpes simplex* and *varicella-zoster* virus, are poorly handled and may cause severe and recurrent disease. Impetigo, cellulitis and skin abscesses are surprisingly common, molluscum contagiosum and viral warts may be very extensive and together with excessive bruising help to clinically distinguish WAS from uncomplicated eczema. Indeed, very extensive molluscum contagiosum is quite characteristic of WAS (Fig. 17.11). Infection exacerbates the bleeding tendency, and early death may result from bleeding. With increasing age, infective problems replace bleeding as the major cause of death [7]. Immunization with polysaccharide and typhoid vaccines is ineffective [8] and can cause severe, even fatal, reactions. The median survival is between 3 and 15 years. Autoimmunity, particularly autoimmune haemolytic anaemia and vasculitis, and malignancy, particularly of the lymphoreticular system, become more common with increasing age [6] and in many cases are related to abnormal persistence of Epstein–Barr viral infection [9]. Scoring systems have been used to distinguish the milder phenotype of XLT from classical WAS. Heterozygous

Fig. 17.16 Severe eczema in a patient with Wiskott–Aldrich syndrome. (Courtesy of the Paediatric Immunology Unit, Newcastle General Hospital, UK.)

female carriers are clinically normal and demonstrate non-random X-inactivation in all haemopoietic cells.

Thrombocytopenia with an abnormally small mean platelet volume (less than 5 fl) is pathognomic [8]. The severity of immunodeficiency is variable, but affects cellular and humoral responses. T lymphopenia is progressive with depressed responses to mitogens and antigens and delayed-type hypersensitivity skin test responses [6]. Serum immunoglobulins show a characteristic pattern with a very low IgM, normal IgG and raised IgA and IgE [8]. Antibody responses to tetanus, *Haemophilus influenzae* type B and *Pneumococcus* are often low, as are isohaemagglutinin titres. The direct antiglobulin test is frequently positive, with or without a haemolytic anaemia. *In vivo* neutrophil and monocyte chemotaxis is impaired [8]. Electron microscopy shows greatly reduced numbers of microvilli on lymphocytes and platelets due to failure of the normal binding of actin bundles which is critical to the organization of the cytoskeleton. Lymphoid and myeloid cell lines are all affected so that phagocytes migrate poorly to sites of inflammation and do not put out normal filopodia, dendritic cells do not present antigen effectively, lymphocytes do not signal to each other normally and platelets form imperfectly from megakaryocytes [10]. WASP has a number of unique domains, suggesting multiple functions, which may explain the complex phenotype of a single gene mutation. Missense mutations in exons 1–3 which lead to normal or truncated sized protein result in the milder phenotype of XLT, whereas most other mutations result in the classic WAS phenotype.

Treatment. Acute bleeding episodes may be controlled by platelet transfusions (irradiated to prevent graft-versus-host disease). Splenectomy and systemic steroids should be avoided if possible as they will increase the risk of infection. Topical steroids are required for the eczema. Intravenous immunoglobulin, with or without prophylactic antibiotics, reduces bacterial sinopulmonary infections and in high dose may help treat autoimmune phenomena [11].

With only these supportive measures the prognosis remains poor. Immunological and haematological reconstitution can be achieved by haematopoietic stem cell transplantation [12]. Autoimmune manifestations can complicate partial donor chimerism post-transplant. Whilst cytopenias are most common, dermatological manifestations include Addison's disease and vasculitis [13].

X-linked hyper-IgM syndrome (CD40 ligand deficiency)

X-linked hyper-IgM syndrome is a T-lymphocyte immunodeficiency due to a defect in the gene encoding for the CD40 ligand glycopeptide (CD154) expressed on activated T lymphocytes [1,2]. CD40L binds to CD40, expressed on B lymphocytes and monocyte/macrophage derived cells [3]. Lack of binding prevents immunoglobulin isotype switching from IgM to IgA, IgG and IgE, as well as activation of Kupffer cells and pulmonary macrophages. Lack of IgA and IgG results in a similar clinical picture to X-linked agammaglobulinaemia (XLA) with sinopulmonary and invasive bacterial infection but, in contrast to XLA, opportunistic infections also occur. Failure of T lymphocytes to activate pulmonary macrophages results in *Pneumocystis jiroveci* pneumonia whilst ineffective Kupffer cell function allows repeated infections of bowel, pancreas and biliary tree with *Cryptosporidium parvum* and similar organisms, leading to sclerosing cholangitis, cirrhosis, pancreatitis and hepatic malignancy, which becomes clinically apparent in the second or third decade [4]. Neutropenia with oral ulceration is seen in as many as 66% of patients; fatal CMV infection or enteroviral meningoencephalitis can occur [5]; autoimmune phenomena are relatively common, and include haemolytic anaemia, thrombocytopenia, hypothyroidism, arthritis and liver disorders [4]. Severe soft tissue infection due to *Pseudomonas aeruginosa* may occur [6].

Laboratory findings include low or absent IgA and IgG with normal or raised levels of IgM [7]. Neutropenia may be present, but T and B lymphocyte numbers are normal.

Patients should receive co-trimoxazole prophylaxis for *Pneumocystis jiroveci* and immunoglobulin replacement therapy. The neutropenia sometimes responds to granulocyte colony-stimulating factor (G-CSF) and intravenous immunoglobulin. All drinking water, including bottled water, should be boiled. Azithromycin prophylaxis may lessen the risks of *Cryptosporidium parvum* infection. Despite conventional treatment, many patients do not survive beyond the second decade of life, but a few patients with a common variable immunodeficiency-like clinical course and no biliary or liver disease are relatively well in middle life. Bone marrow transplantation is increasingly being recommended for this condition

and combined bone marrow and liver transplantation has been successful [8,9].

X-linked lymphoproliferative diseases (XLP)

An X-linked immunodeficiency associated with fulminant fatal Epstein–Barr virus (EBV)-driven infectious mononucleosis was first recognized in the Duncan kindred [1]. There are three common clinical presentations: fulminant infectious mononucleosis (58%); dysgammaglobulinaemia, often evolving to common variable immunodeficiency (31%); and EBV-driven B-lymphocyte lymphoma, usually extranodal, and affecting the gastrointestinal tract or central nervous system (20%). Less commonly, patients present with vasculitis, aplastic anaemia, haemophagocytic lymphohistiocytosis, pulmonary lymphomatoid granulomatosis or vasculitis [2]. Few cases of XLP-associated vasculitis have been published (Fig. 17.17). Polyarteritis nodosa-like vasculitis has been reported in one case [3]. Vasculitic changes in small and medium-sized muscular arteries have also been reported [4]. The prognosis is poor with a high risk of death during initial EBV infection, and no recorded survivors after 40 years of age [5]. Most patients are well until infected with Epstein–Barr virus, although other viruses may act as triggers. The gene responsible for the disease, on the X chromosome, codes for a small protein, SAP (signalling lymphocyte activation molecule (SLAM) associated protein), which is expressed on the surface of T lymphocyte and is critical for T lymphocyte and NK cell control of EBV-infected B lymphocytes [6,7]. Confirmation of the diagnosis involves demonstrating EBV genome in blood by PCR, together with immune defects outlined above and an abnormal response to EBV, with absent antibody response to EBV nuclear antigen (EBNA). SAP protein is absent or abnormally expressed in many cases, although a gene mutation is not apparent in up to 40% of patients. Haemophagocytic lymphohistiocytic episodes are treated with immunosuppression with ciclosporin, and intravenous immunoglobulin is beneficial particularly when hypogammaglobulinaemia is present.

More recently, a defect in X-linked inhibitor of apoptosis (XIAP) has been described [8]. Clinical presentation is similar to that of XLP, although haemorrhagic colitis has also been described. The clinical course seems similar to those with classical XLP. Haematopoietic stem cell transplantation is the only curative treatment for either genetic defect.

Immunodeficiency and short-limbed dwarfism

Cartilage hair hypoplasia, the best described of the osteochondrodysplasias, is inherited in an autosomal recessive manner and is associated with mutations in the *RMRP* gene, which encodes mitochondrial RNA-processing endoribonuclease [1]. Severe short-limbed, short stature (–11.8 SD to 2.1 SD) with X-ray appearances of metaphyseal and spondyloepiphyseal dysplasia are always present, and most patients have sparse light hair [2]. Severe anaemia and Hirschsprung's disease [3] are less common but well-recognized associations, as are malignancies, notably lymphoma and skin carcinoma [4]. The immunodeficiency is surprisingly variable; most have T lymphopenia, and impaired *in vitro* mitogen proliferative responses, but only half suffer recurrent infection [5]. However, some have IgA and/or IgG subclass deficiencies with frequent ear infections. Patients are excessively vulnerable to viral infections, particularly varicella-zoster, EBV and other human

herpes virus infections, and the risk of infective death is 300 times greater than normal [2]. This condition should be considered in any child with severe chickenpox or herpes simplex infections who is short and has fine sparse hair. Severely affected patients should be assessed for haematopoietic stem cell transplantation, which has been successful in correcting the immunodeficiency.

Immunodeficiency, centromeric instability, facial dysmorphism (ICF) syndrome

ICF syndrome is an autosomal recessive disorder in which there are characteristic, structural chromosomal abnormalities in chromosomes 1, 9 and 16 in lymphocytes. Other cells do not show these changes. Affected children develop severe, recurrent infections and have immunoglobulin deficiency, often with agammaglobulinaemia but with normal T- and B-lymphocyte numbers [1]. T-lymphocyte immunity is not normal, and *Pneumocystis jiroveci* infection, severe viral warts and cutaneous fungal infection are described (Fig. 17.18). Patients have no immunoglobulin class-switched B lymphocytes. Facial dysmorphism is variable, but common features include low set ears, hypertelorism, flat nasal bridge, epicanthic folds, tongue protrusion and micrognathia. Triangular facies are described. Mental retardation has been described, with speech delay being a common feature. This diagnosis should be considered in a child with very extensive warts, or spreading cutaneous fungal infection and the characteristic facial features.

Fig. 17.18 Extensive, chronic fungal infection of the nail bed in a patient with ICF syndrome. (Courtesy of the Paediatric Immunology Unit, Newcastle General Hospital, UK.)

The differential diagnosis is CVID. Mental retardation may occur. Some patients have mutations in the *DNMT3B* gene, which regulates chromosomal methylation [2]. Haematopoietic stem cell transplantation has been performed successfully for this condition [3].

Disorders of immune regulation

Increasingly, patients with complex autoimmune manifestations are being recognized, often with coexistent infectious problems. Patients with classical primary immunodeficiency, such as WAS or DiGeorge's syndrome, present with autoimmune manifestations, and it is logical to consider genetic disorders of immune regulation as primary immunodeficiencies in the broadest sense.

Defects of lymphocyte apoptosis (autoimmune lymphoproliferative syndrome, ALPS)

Apoptosis, or programmed cell death, is important for regulating immune responses once an infection has been countered. Defects in this process lead to marked autoimmune and lymphoproliferative features which characterize ALPS [1]. There are a number of pathways through which apoptosis can be induced [2]; one of the most important is initiated through a cell surface molecule Fas (CD95). Ligation of this molecule initiates a cascade of intracellular reactions culminating in apoptosis, induced by proteolytic enzymes including caspases. Mutations in molecules in this cascade result in molecularly distinct but clinically similar forms of ALPS. Fas is expressed as a trimeric surface protein. Heterozygotes with a Fas mutation in one allele often develop the full clinical syndrome, as one abnormal protein chain is sufficient to significantly impair the trimer's function, a so-called dominant-negative effect. Most of the cases are heterozygotes, though a few homozygous cases are also reported.

Many patients present in early childhood, but adult presentation and asymptomatic cases may occur. Patients usually remain well, until the disease is triggered, often by human herpes virus infection [3]. Haematological autoimmunity is most common [4], but any system can be involved. One patient developed a blistering dermatosis that was shown to be childhood linear IgA disease (Fig. 17.19) [5]. Other dermatological manifestations include vasculitis and urticaria [6]. Lymphoproliferation leads to massive, asymmetric, anterior cervical lymphadenopathy together with splenomegaly in nearly all cases, and hepatomegaly in some [4,6,7]. Malignant disease of the lymphoid system (both Hodgkin's and non-Hodgkin's lymphoma) is reported with increased frequency, but has probably been over diagnosed because the histological picture of proliferation resembles malignancy; clonality

Fig. 17.19 Tense bullae arising from erythematous plaques confirmed histologically as linear IgA disease with the presence of a subepidermal split and linear deposition of IgA at the dermoepidermal junction in a boy with *Fas*-deficient autoimmune lymphoproliferative syndrome. (Courtesy of the Paediatric Immunology Unit, Newcastle General Hospital, UK.)

studies distinguish the two [8]. Affected individuals usually have high lymphocyte counts and normal or high immunoglobulin levels. Autoantibodies are usually present. The occurrence of circulating CD3-positive T lymphocytes expressing the α/β receptor but not expressing CD4 or CD8 (so called double-negative T lymphocytes) and usually constituting between 5 and 20% of the total CD3 cell count, is a very important diagnostic clue.

Autoimmune phenomena usually respond to standard treatments, including corticosteroids and dapsone in the case of ALPS-associated juvenile bullous dermatosis. Splenectomy should be avoided if possible, as severe infective complications may follow. Haematopoietic stem cell transplantation has been successful in patients with homozygous Fas deficiency, but currently not enough is known of the long-term prognosis to justify its elective use in (milder) heterozygous case, especially as some patients improve with age.

Chronic mucocutaneous candidiasis

Chronic mucocutaneous candidiasis (CMC) describes a heterogeneous group of primary or secondary disorders characterized by chronic infection of skin, nails and mucous membranes by organisms of the genus *Candida*, most commonly *Candida albicans*. The precise molecular defect is not known for most forms of primary CMC. Recurrent and persistent candida of the mouth, napkin area, skins and nails are the hallmark of this condition, but the severity varies considerably and invasive disease almost never occurs. Failure of usually effective antifungal drugs to clear *Candida* distinguishes primary CMC from other conditions that predispose to *Candida*, such as secondary immunodeficiency, steroid treatment or systemic antibiotics. Candidiasis is usually first noticed early in infancy and in severe cases gross oesophageal involvement causes dysphagia, gastro-oesophageal reflux and failure to thrive, whilst skin lesions may be extremely disfiguring and distressing. As a patient becomes older, *Candida* infection may become less severe. In about half the patients there is an associated endocrinopathy (in order of frequency, hypoparathyroidism, Addison's disease, pernicious anaemia, hypothyroidism and diabetes mellitus) which becomes apparent from the second to third decades onward. Cases may be familial or sporadic with recessive or dominant patterns of inheritance. For some patients, nail dystrophy and dental enamel hypoplasia, and autoimmune endocrinopathy, are associated with CMC—part of the autosomal recessive autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy (APECED) disorder [1]. In these patients, defects in the gene autoimmune regulator 1 *(AIRE-1)* are described [2]. The AIRE-1 protein is expressed in the thymus and is important for presenting host proteins to developing T lymphocytes. Normally, autoreactive T lymphocytes are eliminated before they emerge from the thymus, but in patients with *AIRE* deficiency, autoreactive lymphocytes survive and are released into the peripheral circulation, where they cause autoimmune endocrinopathy. There are decreased numbers of regulatory T lymphocytes in these patients [3]. The mechanism by which these patients develop CMC is unknown.

A minority of patients with CMC suffer from invasive bacterial sepsis, opportunistic infection, autoimmune haemolytic anaemia, malabsorption and chronic active hepatitis. Bronchiectasis and restrictive lung disease can occur [4]. The underlying defect is poorly defined and immunological abnormalities are very variable. There may be diminished T-lymphocyte proliferation and cytokine production in response to *Candida* antigens with impaired antibody production to polysaccharide antigens, and sometimes IgG2 subclass deficiency [5]. There is evidence for impaired cellular immunity to *Candida* species, including negative delayed-type

hypersensitivity skin tests and absent or low T-cell proliferation *in vitro*, as well as impaired production of macrophage inhibitory factor. Studies have demonstrated inadequate production of Th1 cytokines (IFN-γ, IL-2, IL-12) in response to *Candida* species [6].

Treatment with azole antifungals such as fluconazole can be very effective, even in severe cases, but may not completely eradicate infection, since infection often recurs on stopping treatment. Continuous treatment is necessary in severe cases. It should be noted that patients with the hyper-IgE syndrome can also present with persistent superficial candidiasis.

Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome

The immune dysregulation, polyendocrinopathy, enteropathy, X-linked syndrome [1] is characterized by early-onset type I insulin-dependent diabetes mellitus, infantile ichthyosiform dermatitis, protracted diarrhoea and severe enteropathy and thyroiditis. Mutations in the *FOXP3* gene have been described in affected patients [2,3]. Insulin-dependent diabetes develops in early infancy. Atopic eczema and exfoliative dermatitis are the third most common presenting features after diabetes and enteropathy. Bruising may occur, leading to thrombocytopenia. Pemphigoid nodularis has been described as a feature of the condition [4], as well as psoriasiform dermatitis [5]. Females with very similar presentations have been described, and other gene defects are clearly implicated. Mutations in CD25 have recently been described in patients with IPEX-like disease. Haematopoietic stem cell transplantation has been tried as a curative treatment [6].

DNA repair defects and immunodeficiency

As previously described, a huge number of genetically diverse lymphocytes, each bearing a unique receptor, are needed for recognition of a wide array of foreign antigens. These are created by rearranging the variable (V), diversity (D) and joining (J) gene segments that code for T- or B-lymphocyte receptor genes (VDJ recombination). To do this, DNA double-strand breaks are made between the gene segments, and then rejoined after the segments have been re-arranged. This uses the DNA repair machinery found in all cells, which originally evolved to repair DNA damaged by UV light or toxic agents, but which the immune system has utilized to generate the diversity of specific immune responses. Without fully effective DNA repair mechanisms, cells with damaged DNA are more likely to apoptose or undergo malignant proliferation. Thus individuals with defective DNA repair mechanisms have a predisposition to photosensitivity, skin abnormality, neurodegeneration, developmental anomalies and cancer as well as defective immunity [1]. Some have psoriasis-like lesions. As DNA repair mechanisms involve many control proteins, there is scope for many single-gene defects to cause distinct clinical entities; only a few of these conditions are well understood, but several manifest both dermatological and immunological features, and with the rapidly increasing understanding of their molecular bases it is likely that these conditions will now be better delineated.

Ataxia-telangiectasia

This multisystem, autosomal recessive disorder, the best known of the DNA repair disorders, is characterized by progressive cerebellar ataxia, oculocutaneous telangiectasiae, variable immunodeficiency and an increased risk of lymphoid malignancy [1]. It is associated with chromosomal instability and cellular radiosensitivity. Diagnosis remains chiefly clinical and depends on the age of presentation. In the absence of a family history, patients usually present with gait anomalies before telangiectasiae appear. Ataxia and cerebellar signs are always present, usually by the second year of life. Neurological degeneration is progressive, resulting in severe disability by late childhood, although intellectual function is usually preserved. Telangiectases usually appear between 2 and 8 years of age, first on the bulbar conjunctivae but later elsewhere, particularly on the nose, the ears, and in the antecubital and popliteal fossae. Other cutaneous manifestations include patches of hypo- or hyperpigmentation, cutaneous atrophy and atopic dermatitis [2–5]. Gonadal atrophy occurs in both sexes, and growth failure is also prominent in the later stages. Cellular and humoral immunodeficiency affects 60–80% of cases, with low levels of IgA, IgG2 and poor antibody responses to viruses and *Pneumococcus*

being seen most often [5]. Recurrent sinopulmonary infection is common and may lead to bronchiectasis and clubbing, but clinical manifestations are extremely variable [6]. Atrophic skin lesions with granuloma have been described [7]. Lymphoreticular malignancies and, unusually for immunodeficient patients, carcinomas, occur with increased frequency [8]. Radiosensitivity means that treatment with radiotherapy is toxic and often lethal. Irrespective of the development of malignancy, survival beyond early adult life is unusual. Heterozygosity for the *AT* gene confers an increased risk of developing breast cancer [9].

A raised serum α-fetoprotein (abnormal in 90%) supports the diagnosis, as does increased chromosome breakage on exposure to ionizing radiation. The *ATM* gene codes for a phosphatidyl kinase involved in meiotic recombination and cell cycle control [10]. This protein detects DNA damage, and signals to proteins involved in DNA repair and cell cycle control, ensuring that the defective DNA is repaired before cells can divide [11]. Prophylactic antibiotics or immunoglobulin replacement can reduce the morbidity of sinopulmonary infection in some patients.

Nijmegen breakage syndrome

Other DNA repair defect disorders include Nijmegen breakage syndrome (NBS), an autosomal recessive disorder described in the Dutch town of that name, and characterized by microcephaly with mild to moderate mental retardation, 'bird-like' facies, immunodeficiency, clinical radiation sensitivity and chromosomal instability. Bacterial sinopulmonary infection is common, as is hypogammaglobulinaemia and $CD4^+$ T lymphopenia with diminished T-lymphocyte proliferative responses. Absence of ataxia, together with normal α-fetoprotein levels, distinguishes NBS from ataxia-telangiectasia. Specific dermatological features include café-au-lait spots and vitiligo [1], as well as skin infections due to fungal infection, and cutaneous manifestations of viral infection, particularly due to herpes viruses [2]. Sun sensitivity of the eyelids and occasional cutaneous telangiectasia have been described [1]. Treatment with antibiotic prophylaxis or immunoglobulin replacement can be helpful. Haematopoietic stem cell transplantation has been successfully performed on rare occasions [3].

Other disorders of DNA repair associated with immunodeficiency

Defects in DNA ligase 4, Artemis and cernunnos have been described above. As well as presenting with SCID, patients may present with features of combined immunodeficiency. Skin photosensitivity and psoriasis and multiple psoriasiform erythrodermic and squamous skin patches have been reported [1]. Many patients have microcephaly with associated developmental delay. Bloom's syndrome, a rare autosomal recessive disorder, is associated with increased sister chromatid exchange, severe growth failure, increased malignancy and immunodeficiency. Affected individuals may develop facial telangiectases and photosensitivity of the face, dorsa of the hands and forearms. Hypo- and hyperpigmented lesions may also present (Fig. 17.20). Recurrent bacterial sinopulmonary infections associated with hypogammaglobulinaemia, most often low IgM, are the most common clinical manifestation of immunodeficiency, and may lead to bronchiectasis. Bloom's protein, the gene for which is mutated in the disease, unwinds the DNA helix, but the exact mechanism by which this causes immunodeficiency is unclear [2]. Mutations in DNA ligase I have been described in an immunodeficient individual with photosensitivity who developed venous dilatation on the skin, mainly on the limbs. Bulbar telangiectasia was also present [3].

Fanconi's anaemia

Fanconi's anaemia is a chromosomal instability disorder characterized by developmental defects, progressive bone marrow failure and cancer susceptibility. Children with Fanconi's anaemia are generally small, and elfin-like and of low birth weight. The central clinical manifestation of Fanconi's syndrome is progressive bone-marrow failure during childhood and adolescence [1–3]. Easy bruising is generally the presenting symptom, and most often first becomes apparent between the ages of 4 and 10 years.

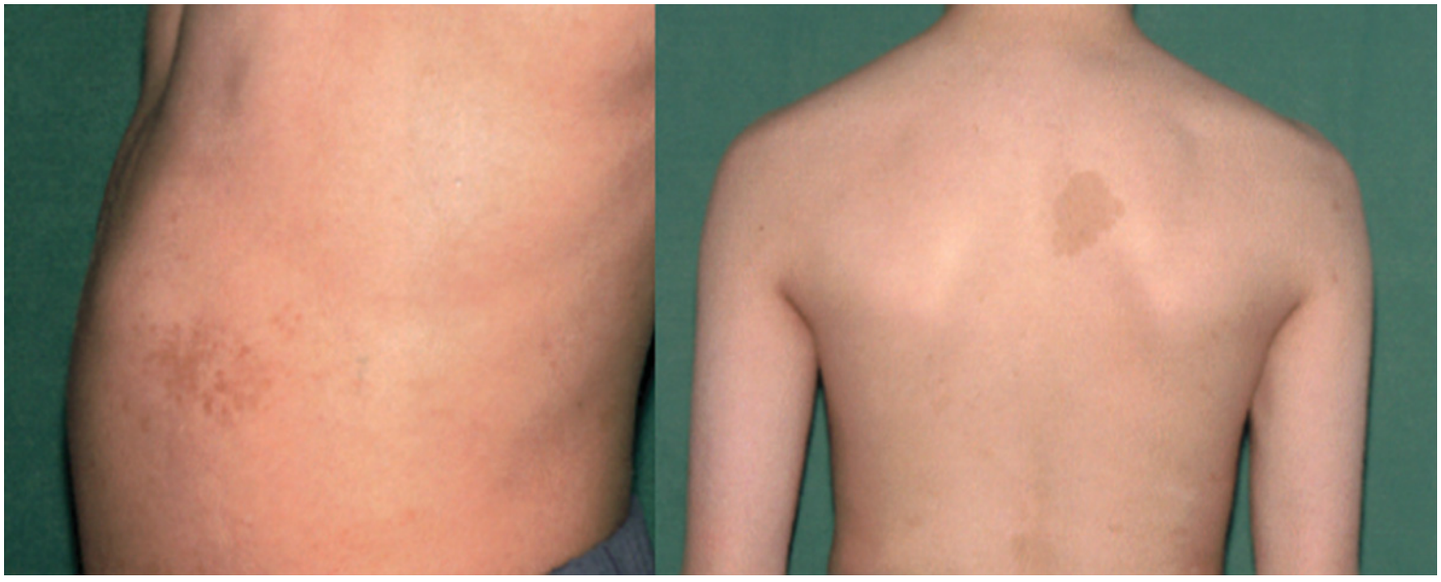

Fig. 17.20 Areas of truncal hyperpigmentation in a patient with Bloom's syndrome. (Courtesy of the Paediatric Immunology Unit, Newcastle General Hospital, UK.)

In addition to thrombocytopenia, anaemia and leukopenia are usual, and the bone marrow is aplastic.

Cutaneous hyperpigmentation and skeletal anomalies are characteristic. Unfortunately, the dermatological findings are not well described in the older literature, and there is considerable confusion with dyskeratosis congenita. However, they comprise macular brownish pigmentation, either resembling freckles and occurring mainly in sun-exposed areas, or more diffusely, in which case the abdomen, genital area and flexures appear to be predominantly affected [4]. Guttate macular hypopigmentation is often also present in affected areas. Hypopigmentation and café-au-lait spots are reported. Persistent and exceptionally severe viral wart infection can occur [4].

The principal skeletal abnormality is absence or hypoplasia of at least one of the thumbs; hypoplasia or absence of the radius is also common. Structural renal abnormalities, endocrinopathies, genital hypoplasia, microcephaly and microphthalmia are other common features.

There is a high risk of leukaemia and other malignancies in these children [5], probably due to the structural instability of chromosomes observed in Fanconi's anaemia, which leads to a high frequency of chromosomal breaks and rearrangements [6]. Cultured cells are unusually sensitive to DNA cross-linking agents such as mitomycin C, but they are not generally sensitive to ionizing radiation, although cells from the Fanconi's D2 subgroup do show ionizing radiation sensitivity.

The disorder is transmitted as an autosomal recessive trait. Thirteen complementation groups (A–N) have been described [7] and the gene defects have now been discovered. The Fanconi's proteins are involved in repair of DNA cross-linking damage, and some interact with other DNA repair pathways. In particular, the Fanconi's D2 subgroup appears to interact with ATM and nibrin, mutated in ataxia-telangiectasia and Nijmegen breakage syndrome respectively [8,9]. The induction of chromosomal breakage by the alkylating agent, diepoxybutane, can be used to detect heterozygotes and for prenatal diagnosis [10], although chorionic villus biopsy and genetic diagnosis is now possible if the specific gene defect within the family is known. There is a high incidence of diabetes [11], and of neoplastic disease [12], in heterozygotes.

The outlook for untreated patients with Fanconi's anaemia is poor, with death usually occurring within a few years of the first signs of marrow failure. Initially, bone-marrow function can be stimulated with corticosteroids and with the androgenic steroid, oxymethalone. Haematopoietic stem cell transplantation has been used successfully to treat patients, but care must be taken to avoid the use of alkylating agents in pretransplant conditioning [13]. Patients are at increased risk of secondary malignancy post-transplantation.

Other immunodeficiencies

A number of syndromes have been described which include primary immunodeficiency as part of the phenotype. In some, the syndrome is well described, and in a few the underlying molecular defect has recently been elucidated. Most lack clear definition.

Hoyeraal–Hreidarrson syndrome

This X-linked disorder is characterized by microcephaly, cerebellar hypoplasia, aplastic anaemia and growth retardation [1,2]. A progressive combined immunodeficiency, with hypogammaglobulinaemia and lymphopenia is a well-recognized association [3]. Mutations in the dyskeratosis congenita gene (*DKC1*) have been found and at least some cases of Hoyeraal–Hreidarsson syndrome represent a severe phenotype of dyskeratosis congenita [4]. Cutaneous manifestations include leukoplakia, oral and gastointestinal ulceration, and reticulated hyperpigmentation, primarily in the regions of the neck, upper thorax and upper extremities [5]. Other cutaneous features include nail dystrophy, which begins with longitudinal striations, increasing brittleness, deformation, onychoclasis and nail loss [6]. Palmar and plantar hyperhidrosis, blistering, hyperkeratosis, acrocyanosis and alopecia may also occur.

Netherton's syndrome

This triad of generalized infantile erythroderma, diarrhoea and failure to thrive may be associated with a variable immunodeficiency, including mild lymphopenia and polysaccharide antibody deficiency [1]. The clinical features are similar to those seen in Omenn syndrome and SCID and maternofetal engraftment, with erythroderma and ichthyosis characterized by abnormal cornification, dryness and fish-like scaling of the skin. Hair shaft abnormalities (trichorrhexis invaginata) are described which may not be seen until several months of age [2]. Distinguishing these entities is important, as the other conditions are treated by bone marrow transplantation, whereas Netherton's syndrome is not. Hair shaft abnormalities are diagnostic (bamboo hairs). Squamous cell carcinoma has been described in Netherton's syndrome [3]. Mutations in the serine protease inhibitor gene *SPINK5* have been described [4,5].

Defects of antibody production (Table 17.14)

X-linked agammaglobulinaemia (XLA, Bruton's disease)

First described by Bruton in 1952 [1], this X-linked intrinsic B-cell defect prevents B-lymphocyte development beyond the pre-B-lymphocyte stage. It is caused by a defective gene that encodes

Table 17.14 Classification of antibody deficiency.

Antibody deficiency	Molecular defect	Inheritance
X-linked agammaglobulinaemia (Bruton's disease)	Btk	XL
XL hyper-IgM (see CD40L deficiency, p. 17.63)		
Autosomal recessive hyper-IgM syndrome	Activation-induced cytidine deaminase (AID)	AR
	CD40	AR
	UNG	AR
	NEMO	XL
Autosomal recessive agammaglobulinaemia	mu chain	AR
	BLNK	AR
	λ5/14.1 gene	AR
	Iga (CD79a)	AR
Ig heavy-chain deletions	Chromosome 14q32 deletion	AR
Selective Ig deficiency:	Defect of isotype differentiation	Unknown
IgG subclass deficiency IgA deficiency	Terminal differentiation failure in IgA+ B cells	Unknown
Polysaccharide antibody deficiency	Variable, described in some btk, NEMO, DGA patients	Unknown, specific diseases XL
CVID	See Table 17.15	Variable, may be AD, AR, XL
Transient hypogammaglobulinaemia of infancy	Unknown	Unknown

XL, X-linked; AR, autosomal recessive; AD, autosomal dominant.

Fig. 17.21 Cellulitis due to *Pseudomonas aeruginosa* in a patient with X-linked agammaglobulinaemia. (Courtesy of the Paediatric Immunology Unit, Newcastle General Hospital, UK.)

a cytoplasmic enzyme, Bruton tyrosine kinase (btk) [2,3]. Classically, affected boys produce no immunoglobulins and make no antibody responses, but have normal cell-mediated immunity. Since the molecular basis has been defined, milder phenotypes have been recognized where some antibody function is present [4]. Typically, recurrent pyogenic infections commence in the latter half of the first year of life, once maternal IgG levels have declined. The diagnosis is often made surprisingly late; in one series, the average age at diagnosis was 3 and a half years, and 2 years when there was a positive family history [5]. Sinopulmonary infections are most common, but pyoderma, gastroenteritis, arthritis, meningitis and osteomyelitis may be presenting features. Boils or impetigo are the most common dermatological features, frequently due to *Staphylococcus aureus* or *Pseudomonas* (Fig. 17.21) and usually associated with neutropenia. Chronic, ulcerative, cutaneous HSV infection has been reported [6]. Asymptomatic papular lesions developed on the trunk and arms of a 34-year-old patient in which caseating granulomas were demonstrated on biopsy, but no infectious agent was identified [7]. Pyoderma gangrenosum may be a feature [8], and Stevens–Johnson syndrome [9], vitiligo [9] and total alopecia areata [10] have also been described. Recovery from viral infections is normal with the notable exception of those caused by enteroviruses (especially echoviruses) [11], which can cause a chronic meningoencephalitis or dermatomyositis-like picture [12]. Non-purulent arthritis affecting predominantly large joints is occasionally seen, in some cases due to mycoplasma infection. Amyloidosis is an infrequent complication.

Usually there is absence or severe depletion of all serum immunoglobulin classes, and antibody responses to vaccines are absent. There are normal numbers of T lymphocytes, but no B lymphocytes in peripheral blood, although pre-B lymphocytes (containing cytoplasmic μ chains) are found in bone marrow. Lymph nodes show absent follicles and germinal centres, and plasma cells cannot be demonstrated at any site. The diagnosis can be rapidly confirmed by demonstrating absence of the btk protein in cell lysates [13].

Immunoglobulin replacement therapy is the mainstay of treatment. Chronic lung damage and sinus disease may also progress on treatment, and for this reason vigorous and early antibiotic therapy should be used for respiratory tract infections. Since the introduction of intravenous immunoglobulin therapy, lung disease seems less common and the patients developing progressive lung and sinus disease while on treatment appear to be those with damage sustained before immunoglobulin therapy was commenced [14], which emphasizes the importance of early diagnosis and treatment.

Autosomal recessive forms of agammaglobulinaemia

When hypogammaglobulinaemia is found in a girl or a child with consanguineous patients one of the autosomal recessive genetic defects affecting B-lymphocyte differentiation should be considered. Mutations have been described so far in genes coding for: μ heavy chain [1], Igα (part of the signal transduction complex of the B lymphocyte antigen receptor) [2], λ5 light chain [3] and B-lymphocyte linker protein (BLNK) [4]. These molecules are all required for early B-lymphocyte development from pro-B-lymphocyte to pre-B-lymphocyte stage. Unlike in XLA, pre-B lymphocytes are therefore not detectable in marrow samples. Other families have also been described in whom the molecular defect is yet to be identified. In all cases, the defect is B-lymphocyte specific. The number of cases described is too small to draw firm

conclusions, but the clinical picture would seem to be similar to XLA, although patients with μ heavy chain deficiency may have more serious life-threatening infections than those with XLA with an earlier onset of symptoms [5]. Skin sepsis is described as a feature, but less commonly than in XLA.

Common variable immune deficiency

Common variable immune deficiency (CVID) is a poorly defined entity characterized by the presence of quantitative or qualitative hypogammaglobulinaemia. The incidence is described as between 1:10 000 and 1:50 000 of the population, and although the onset of symptoms typically occurs in adolescence or early adult life, CVID is increasingly being diagnosed in childhood.

Selective IgA deficiency with or without IgG2 deficiency may be one end of the spectrum of this disease [1], and families are described where some members have CVID whilst others have selective IgA and/or IgG2 deficiency. Now that other immune deficiencies are being defined by their molecular defects, it has become apparent that some patients with CVID have mild phenotypes of other immune deficiencies such as X-linked agammaglobulinaemia, CD40 ligand deficiency or X-linked lymphoproliferative disease [2,3]. Autoimmune diseases, such as rheumatoid arthritis, dermatomyositis and systemic lupus erythematosus [4,5] also have an increased incidence in these kindreds. However, over recent years, five genetic defects have been more specifically linked with CVID (Table 17.15), although the underlying molecular problem has yet to be defined for the majority of patients.

Inducible co-stimulator (ICOS) is essential for T-lymphocyte-dependent B-lymphocyte responses, including the switch of immunoglobulin class from IgM to IgA and IgG. ICOS deficiency results in impaired germinal centre development, terminal B-lymphocyte differentiation and hypogammaglobulinaemia [6,7]. CD19 is only expressed on B lymphocytes, and deficiency which leads to impaired antigen-induced B-lymphocyte activation with hypogammaglobulinaemia has been described in only a few patients [8]. Transmembrane activator and calcium-modulating cyclophilin ligand interactor (TACI) is a tumour necrosis factor-like receptor expressed on B lymphocytes, involved in the control of B-lymphocyte apoptosis, survival and differentiation. Other molecules involved in this pathway include the B-cell-activating factor receptor (BAFF-R). Defects in both of these molecules have been found in CVID patients and those with IgA deficiency [9,10]. The MutS homologue 5 (MSH5) is critical in DNA mismatch repair and has a role in the switch of immunoglobulin class. Defects have been found in patients with CVID and associated IgA deficiency [11], but there appears to be incomplete penetrance, as healthy controls have been found with the same mutations.

Table 17.15 Genetic defects implicated in common variable immunodeficiency (CVID).

Genes (and deficiency) associated with CVID	Genes (and deficiency) associated with other immunodeficiencies that may mimic CVID
TNFRSF13B (transmembrane activator and calcium-modulating cyclophilin ligand interactor, TACI)	*ADA* (adenosine deaminase)
BAFFR (B-cell-activating factor receptor, BAFF-R)	*SH2D1A* (X-linked lymphoproliferative disease, XLA)
ICOS (inducible co-stimulator, ICOS)	*BTK* (X-linked agammaglobulinaemia, XLA)
CD19 (B-lymphocyte CD19)	*CD40LG* (CD40 ligand)
MSH5 (MutS homologue 5, MSH5)	

As with all patients with humoral immune defects, patients often present with recurrent sinopulmonary and gastrointestinal infections. Other clinical manifestations in this disease exemplify the inherent immune deregulation, with an increased incidence of autoimmune disease, particularly autoimmune haemolytic anaemia, thrombocytopenia and neutropenia. Non-malignant granulomatous lymphadenopathy, hepatosplenomegaly and involvement of the GI tract is a frequent finding in a subgroup of patients [12], and clinical differentiation from malignancy may be difficult, although histologically lesions resemble those seen in sarcoidosis. These granulomata are normally sensitive to steroid treatment. Patients with CVID also have a significantly increased risk of lymphoreticular and gastrointestinal malignancies [13,14]. Cutaneous manifestations are common and non-specific and include impetigo, boils, furuncles and cellulitis. Severe viral wart infection has been reported. Atopic eczema, vitiligo, alopecia areata and psoriasis have also been described in CVID patients, and are probably more common than expected. Skin manifestations with other associated symptoms should raise suspicion of this diagnosis.

All patients have defective antibody function, in which hypogammaglobulinaemia varies from a failure to respond to vaccines to panhypogammaglobulinaemia. B-lymphocyte numbers are frequently normal, but a significant proportion of patients have T-lymphocyte abnormalities, in particular a reversed CD4/8 ratio and generalized lymphopenia. Mild phenotypes may require only prophylactic antibiotics. Significant degrees of hypogammaglobulinaemia should be treated with immunoglobulin replacement therapy. Granulomatous lesions and autoimmune phenomena may respond to treatment with steroids.

IgA deficiency

Studies on healthy blood donors have shown that 1 in 600–700 Caucasians have no demonstrable serum IgA, and whilst there is almost always concomitant lack of salivary IgA, many affected individuals are asymptomatic [1]. However there is increased incidence of IgA deficiency in populations of patients with chronic lung disease and autoimmune diseases [2,3], suggesting that it may be associated with disease, perhaps when there are other, ill-defined immunological abnormalities.

Recurrent upper respiratory tract and ear infections are the commonest symptoms in young children with IgA deficiency; in the majority the frequency and severity of infections improves with age, regardless of the IgA level [4].

There is a strong correlation between autoimmune disease of all types and IgA deficiency [3], which appears independent of the infection suffered. It may be that abnormalities of antigen handling in the gut account for these autoimmune phenomena, and the increased incidence of gastrointestinal infection and coeliac disease seen in IgA deficiency, although the true incidence of these problems has not been well defined. Skin manifestations may be non-specific, and include atopic eczema, in association with sinopulmonary disease. Cutaneous features due to autoimmune disease, including psoriasis, vitiligo and dermatomyositis, have been reported [5].

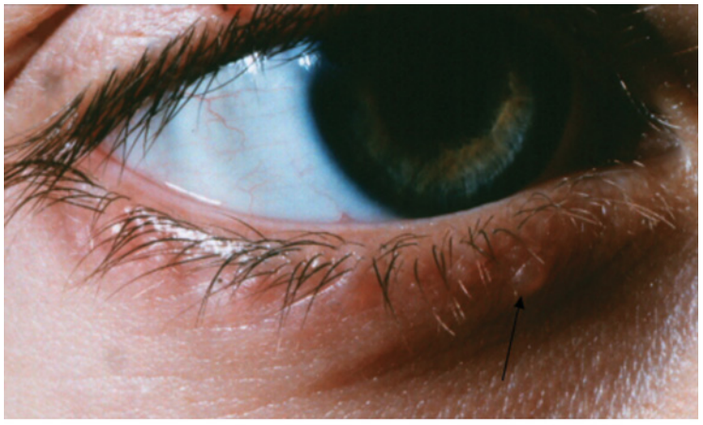
Other forms of antibody deficiency

Other forms of antibody deficiency are described (Table 17.14) but the cutaneous features are no different to those described above.

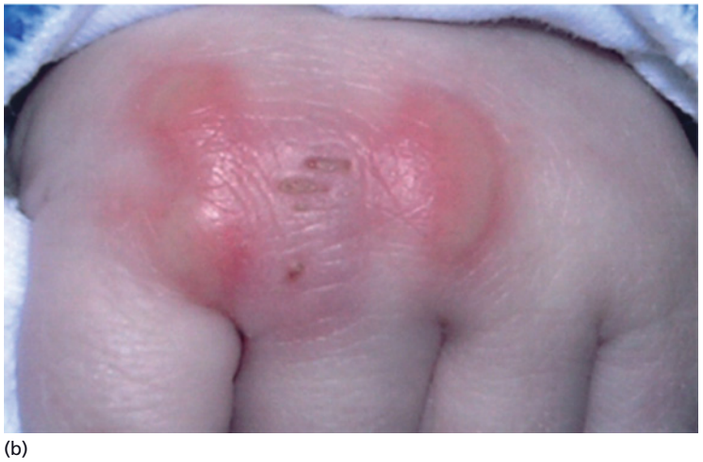
Defects in innate immunity

Disorders of phagocytic cells



Chronic granulomatous disease

Chronic granulomatous disease (CGD) is an inherited defect of the phagocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase enzyme complex, which generates reactive oxygen species that cause potassium ions to ingress and release lysosyme granules into phagosomes containing ingested microbes. The gene defect for the most common form, found on the X chromosome and coding for the major membrane component $gp91^{phox}$, accounts for up to 60% of cases. Defects in the genes coding for the cytoplasmic components $p67^{phox}$, $p47^{phox}$ and $p22^{phox}$ are inherited in an autosomal recessive pattern [1].



The disease has protean clinical manifestations, but the hallmark is acute, and potentially fatal, bacterial or fungal infection [2]. The disease becomes apparent during the first 2 years of life in the great majority of cases [3], but the onset may occasionally be delayed into the second decade [4–6]. The earliest manifestations are often seen in the skin. Neonatal pustulosis is commonly the first sign of the disease. Subsequently, a rather non-specific, impetiginized periorificial rash is highly characteristic. This is most commonly seen around the nostrils, ears, mouth and eyes, and has sometimes been described as 'eczematous' or 'seborrhoeic'. Any area where the skin has been broken, by abrasion for example, tends to become impetiginized or ecthymatous. Nodular lesions may follow, and these frequently break down to form necrotic ulcers.

Firm, translucent, papular lesions around the nose, eyes (Fig. 17.22a), lips and on the cheeks may mimic lupus vulgaris or sarcoidosis. A common manifestation is acute, suppurative lymphadenitis in the neck, axilla or groin. Other frequent pyogenic infections include liver abscesses, osteomyelitis, arthritis, pneumonia, skin sepsis and perianal abscesses. Pathogens, such as *Staphylococcus aureus*, *Burkholderia cepacia*, *Aspergillus* species and *Serratia marcerens*, are most commonly seen [7].

Subcutaneous nodules may develop at immunization or cannulation sites, and these also tend in time to ulcerate (Fig. 17.22b). Poor healing of surgical wounds, and of these discharging nodular skin lesions, is highly characteristic. Perianal abscesses are a regular feature. Other frequent findings include chronic suppurative paronychia, folliculitis of the scalp and ulcerative stomatitis. Acute febrile neutrophilic dermatosis (Sweet's syndrome) has been rarely described [8], as has chronic bullous disease of childhood [9]. Fungal infection often causes pulmonary disease with pneumonia, and lung abscess formation, followed by empyema and spread across tissues planes into paraspinal tissue and

vertebrae [10,11]. Discrete areas of persistent consolidation may be seen radiologically and are often termed 'encapsulating pneumonia'; this sign is highly distinctive. Less specific reticulonodular shadowing and hilar lymphadenopathy are also frequent. Liver abscesses are rare in childhood, and when seen CGD should always be looked for [12,13].

The importance of non-infectious inflammatory complications is increasingly recognized. These include inflammatory bowel disease, which clinically and histologically can be indistinguishable from Crohn's disease, restrictive lung defects, genitourinary obstruction and cutaneous granulomata, particularly at the vaccination sites. These non-infective manifestations sometimes respond well to corticosteroid treatment [14], but this may increase the risk of infectious complications. Discoid lupus has been described rarely in patients with CGD [15].

Female carriers of X-linked CGD frequently develop erythematous macular, papular and urticarial skin lesions following light exposure, and discoid lupus erythematosus or Jessner's lymphocytic infiltrate [7]. The carrier state for X-linked CGD should be considered in all women presenting with discoid lupus erythematosus, and appropriate attention should be paid to their family history. Identification of the carrier state offers such women the possibility of genetic counselling, and prenatal diagnosis of CGD in their sons. Female carriers of X-linked CGD do not generally show increased susceptibility to infection. However, some carriers have subcutaneous abscess, hidradenitis suppurativa and ulcerative stomatitis [16].

Diagnosis is suggested by failure of reduction of nitroblue tetrazolium or dihydrorhodamine by neutrophils. X-linked carriers have both normal and abnormal neutrophils and the presence of abnormal neutrophils may lead to abnormal clearance of cellular debris, which may in turn account for their excess risk of autoimmune disease.

Prophylactic antibiotics, in particular co-trimoxazole which is concentrated in neutrophils, has significantly reduced morbidity and mortality from bacterial infections in CGD [3]. Children should also be given antifungal prophylaxis; itraconazole is currently the best available agent, which may help reduce the risk of fatal fungal disease in these patients [14].

Infections or unexplained fevers should be treated aggressively. IFN-γ is a useful adjunctive treatment in severe bacterial or fungal infections. Although used as prophylactic therapy in the US, in Europe it is mainly used for prophylaxis only after documented failure of oral antibacterial and antifungal agents [2]. White cell infusions may also be used as adjunctive therapy in severe infection. Registry data suggest that the outlook in early childhood has improved considerably in recent years, but considerable morbidity and mortality occur [7].

Survival is variable, but improving, with prophylactic administration of antibacterial and antifungal agents; the risk of severe or fatal fungal infection resistant to antifungal prophylaxis remains. Increasingly, haematopoietic stem cell transplantation is recommended, and even in those with active fungal infection, a good outcome can be achieved [17].

Neutropenia

Neutropenia can result from reduced bone marrow production or increased peripheral destruction, which can be distinguished by bone marrow examination. Neutropenia most frequently follows decreased production induced by disease processes or drug treatments. Increased consumption may occur in autoimmune states, including those associated with immune deficiency. The degree of neutropenia will influence the clinical picture: neutrophil counts of less than 0.5×10^9/l carry a major risk of infection, whilst counts below 0.2×10^9/l are associated with a significant incidence of life-threatening sepsis.

Cyclical neutropenia

In cyclical neutropenia, decreases in haematopoiesis at intervals of about 3 weeks (range 13–35 days) lead to neutropenia and susceptibility to infection. Patients are normally asymptomatic, but during the period of severe neutropenia, aphthous ulcers, gingivitis, stomatitis and cellulitis may develop. Death from overwhelming infection occurs in a small proportion of patients. Symptoms resolve over 3 to 4 days as the neutrophil count rises, thus neutrophil counts taken after the onset of symptoms are usually normal; to make the diagnosis, neutrophil counts should be taken two or three times a week over a 4- or 5-week period. In some families, this is inherited in an autosomal dominant manner, and mutations in the neutrophil elastase gene (*ELA2*) have been identified in patients with cyclical neutropenia [1].

Severe congenital neutropenia

This was originally described by Kostmann in 1956 as an autosomal recessive disease [1]. Onset is within the first year of life, with recurrent and life-threatening infections. Symptoms include omphalitis, cellulitis, perirectal abscesses, peritonitis, stomatitis and meningitis. Examination of bone marrow shows an arrest at the promyelocyte to myelocyte maturation stage. Treatment with G-CSF results in increased counts and fewer infections in almost all patients with neutropenia not secondary to peripheral destruction. Concerns about the induction of leukaemias with prolonged use of G-CSF have not been borne out, although pre-treatment and annual bone marrow aspirates are recommended to screen for the development of myeloid leukaemia [2]. Some patients have defects in the *ELA2* gene. More recently, defects in *HAX1* have been described in other families [3]. Haematopoietic stem cell transplantation may be indicated in selected cases. A small number of patients with congenital neutropenia inherited in an X-linked manner have mutations that result in over-activity of WASP (Wiskott–Aldrich syndrome protein) [4], whilst dysregulated expression of the GTPases RhoA and Rac2 has been described in families where inheritance is autosomal recessive [5].

Shwachman–Diamond syndrome

This rare, autosomal recessive disorder is characterized by exocrine pancreatic insufficiency, metaphyseal chondrodysplasia with associated skeletal abnormalities, bone marrow dysfunction and recurrent infections [1]. Skin sepsis is a feature. Neutropenia occurs in all patients, whilst 10–25% of patients also have pancytopenia. There is an increased incidence of myeloid leukaemia inherent to this condition. Cutaneous features are common, although not well documented. They may be due to pancreatic insufficiency with resultant malabsorption of fat-soluble vitamins, essential fatty acids and other nutrients. Patients may show xerosis and follicular keratosis. Facial skin in particular may be dry with associated perioral dermatitis. A widespread, symmetrical eczematous rash has been reported and with associated thrombocytopenic purpura, the diagnosis of WAS may be erroneously suggested. Palmoplantar hyperkeratosis and nail thickening may occur. A defect in the *SBDS* gene, a possible RNA-processing gene, has been described in these patients [2]. Haematopoietic stem cell transplantation has been successfully performed in this condition [3].

Neutrophil-specific granule deficiency

This rare disorder is characterized by recurrent skin and lung infections with staphylococci and enteric bacteria [1]. Electron microscopy of patients' neutrophils shows reduced or absent

secondary granules; specific stains demonstrate lack of the secondary granule proteins such as lactoferrin and vitamin B_{12} binding protein. Proteins that reside in azurophilic (primary) granules, such as lysozyme and myeloperoxidase, are present. Neutrophils also show abnormalities in migration and nuclear morphology. Mice lacking the transcription factor CCAAT/enhancer binding protein have a similar phenotype, and case reports of patients with mutations in this gene have now been published [2].

The clinical course of patients is variable. Treatment options include prompt institution of antibiotic therapy for infections and prophylactic antibiotic treatment. Haematopoietic stem cell transplantation should be considered in patients with a severe phenotype.

Hyper-IgE syndrome

The hyper-IgE syndrome (HIES) (previously Job's syndrome) is of special relevance to the dermatologist, as the initial presentation may be cutaneous. It is a complex disorder, characterized by extreme elevation of the serum IgE level (usually in the range 2000–40 000 U/l), chronic dermatitis and repeated lung and skin infections [1]. The initial description was of severe, recurrent staphylococcal skin abscesses in fair-skinned, red-headed girls with eczema [2]. Both sexes and all races are affected equally.

These patients are frequently described as having eczema, although this is different from typical atopic eczema [3]. Affected children develop a rather non-specific, excoriated, papular and pustular eruption in the first year of life, often within the first month, particularly over the scalp, the scalp margins, the buttocks and the proximal flexures, such as the axillae, groins and neck [4,5]. The rash may appear as early as the first few days of life, at which stage it may be vesicular [6], but crusting becomes a prominent feature. Features of lichenification or scales are absent or mild in HIES. Psoriasiform lesions have been described in these patients [7].

There is almost invariably a history of furunculosis and staphylococcal lung infections, abscesses and empyema. Many patients develop staphylococcal pneumatoceles, which strongly suggest the diagnosis [8,9]. Although skin and lung infections predominate, infections of the ears, sinuses, joints and viscera are not uncommon. Skin abscesses tend to favour the scalp, face and neck, and are sometimes cold (i.e. with little surrounding inflammation) but this is not always the case. Ulceration is frequently present. Lymphadenopathy may be complicated by the development of lymph-node abscesses. *Staphylococcal aureus* is the predominant pathogen, but infection is also seen with *Haemophilus influenzae*, pneumococci, group A streptococci and with *Candida*. Oral candidiasis and *Candida* nail infections are common [9]. Pneumatocoeles may provide the focus for the development of aspergillomas. Molluscum contagiosum and verruca plana have been described as co-existing in patients with HIES [10].

Non-immunological features of the condition, which are variably present, include: abnormal, coarse facies with a wide nasal bridge and large head (Fig. 17.23); hypodense bones leading to frequent fractures; joint laxity; a high incidence of scoliosis; and delayed resorption of primary dentition with consequent delayed eruption of secondary teeth [9]. Coronary artery aneurysms have also been described [11]. The mode of inheritance can be autosomal dominant or recessive. Patients with recessive disease have the classic triad of recurrent skin infections, pneumonia and elevated serum IgE, but do not have the characteristic facial features or bony abnormalities. Additionally, they suffer from severe viral infections, including chronic refractory molluscum contagiosum and herpes simplex virus infections.

Fig. 17.23 A patient with hyper-IgE syndrome, who presented with staphylococcal pneumatocoeles. Coarse facial features and an infected eczematous-like rash are demonstrated. (Courtesy of the Paediatric Immunology Unit, Newcastle General Hospital, UK.)

Peripheral blood eosinophilia may be marked, up to 50–60%. Serum IgE levels are consistently very high (more than 10 times the upper limit of normal), although they may be normal in infancy. Most patients also have elevated IgD levels; total IgE levels may fall in adults, however IgG, IgA and IgM levels are usually unremarkable. In a significant proportion of patients, there is a failure of antibody response to polysaccharide antigens, which contributes to the susceptibility to infection [9]. In keeping with the great increase in circulating total IgE, patients show strongly positive, immediate weal-and-flare responses on skin-prick testing with foods and commonly inhaled allergens, as well as bacterial and fungal antigens [12]. Circulating levels of IgG anti-IgE are also high, as they are in atopic eczema [13]. It is rather characteristic for patients to have excessive production of IgE specific for *Staphylococus aureus* [14].

The molecular pathophysiology of HIES has remained elusive for more than 30 years, but a genetic cause for both forms has now

been described. Recently, patients with autosomal dominant HIES were found to be defective in signal transducer and activator of transcription 3 (STAT3), downstream of Tyk2, and important in the transcription of IL-6 and -10, but not IL-12 or IFNα [15,16]. All mutations were in the SRC homology 2 or DNA binding domains, which do not affect protein levels. Many of the systemic features found in HIES can now be explained; in mice, stat3 deficiency in the lung leads to excessive lung inflammation and airway enlargement, consistent with pneumatocoele formation in patients. Down-regulation of Th2 cytokines, including IL-6 and IL-10, impairs inflammatory responses, causing 'cold abscesses'. The defect causing autosomal recessive inherited disease is tyrosine kinase 2 (Tyk2) deficiency [17]. Tyk2 is a janus kinase family kinase involved in signalling through many cytokine pathways. Cells from affected patients show severe defects in response to type 1 cytokines including IFN-γ, IL-6, -10, -12 and -23. The predisposition to viral infections may be explained by the defects in type I (IFN) signalling.

Hyper-IgE syndrome is not merely atopic eczema with predisposition to cutaneous staphylococcal infections, but a very characteristic immunodeficiency disorder with specific diagnostic criteria, which include staphylococcal lung infections with an onset in infancy. However, individuals have been reported who appear to have a milder variant of the hyper-IgE syndrome, with a later onset, and with typical cutaneous and immunological abnormalities but without lung involvement [3]. Nevertheless, it must be borne in mind when considering this diagnosis that the disorder does not feature atopic eczema, but a recurrent pyodermatous eruption often associated with ulceration and/or lymph-node abscesses. The serum IgE level alone does not allow clear differentiation between atopic eczema and the hyper-IgE syndrome, because it can be equally high in both disorders. A similar clinical picture has been described in older patients with partial ADA deficiency [18].

The mainstay of treatment is long-term antistaphylococcal antibiotic prophylaxis, usually with flucloxacillin. Attention to skin hygiene is important, with judicial use of topical antimicrobials. *Candida* infections should be treated topically or, when refractory, with oral ketoconazole or fluconazole [19].

Histamine 2 receptor blockers such as cimetidine have been used, though their value is disputed. IFN-γ treatment has been tried in a few patients, but although there was some lowering of the IgE levels, there was no clinical benefit [20]. Intravenous immunoglobulin therapy may be useful in those with a demonstrable antibody production deficit and progressive bronchiectasis, which can lead to respiratory failure and death in early adulthood. Fungal infection is an important cause of death [21]. Persistent pneumatocoeles should be excised. Haematopoietic stem cell transplantation has been attempted in severe cases, and although the somatic features and high IgE levels were not corrected, the infectious problems were significantly reduced [22], possibly in keeping with the concept that the gene defects result in defective innate immune signalling responses.

Leukocyte adhesion disorders

To meet infection in tissues, leukocytes egress from the circulation toward sites of inflammation. To do this, cells roll along the capillary endothelium, then adhere to endothelial cells and finally pass between endothelial cells into tissues. A range of cell surface adhesion molecules are responsible for different stages of this process, as well as binding of different leukocytes to each other whilst immune responses occur. It is therefore not surprising that defects in the cell surface molecules responsible for the process result in life-threatening infection and dramatic cutaneous manifestations. In leukocyte adhesion deficiency (LAD) type I, absence of the 95-kDa β chain (CD18), common to the β2 integrin family of cell surface adhesive molecules, leads to a profound immunodeficiency affecting the function of neutrophils, monocytes,

Fig. 17.24 Deep perianal ulceration in a patient with leukocyte adhesion deficiency type I. (Courtesy of the Paediatric Immunology Unit, Newcastle General Hospital, UK.)

T lymphocytes and NK cytotoxic cells [1,2]. Inheritance is autosomal recessive. Chemotaxis, adherence and phagocytosis are markedly depressed. Different mutations result in phenotypes of variable severity, and occasional patients express normal levels of CD18 but have a non-functional molecule. The β2 integrin family is also involved in the platelet function molecule Gp2b3a, and patients with a combined leukocyte and platelet defect have been found [3]. The clinical picture is almost entirely explained by the way in which leukocytes are attracted to areas of infection and attach to the vessel walls at sites of inflammation in the usual way, but cannot pass out into the tissues. This leads to blockage of small vessels and rapidly expanding necrotic lesions without pus. Individuals with the most severe phenotype (<1% expression) present in the first weeks of life with delayed umbilical cord separation (the cord fails to shrink down and may not separate until 3–4 weeks of age) and omphalitis, together with rapidly progressive, erosive perianal ulcers (Fig. 17.24). Delayed umbilical cord separation does not seem to occur in patients with some expression of the molecule (usually in the range 2–10% of normal expression). In all forms there is excessive susceptibility to bacterial and fungal infections, with recurrent cellulitis and abscesses in the skin and other soft tissues. Deep-seated infections of bone, respiratory and gastrointestinal tracts are also seen. Gingivitis, ulcerative stomatitis and periodontitis are common and severe, leading to loss of teeth. Inflammatory lesions, particularly affecting the skin and resembling pyoderma gangrenosum, can occur in the partial forms of the deficiency, and may respond to steroids. Investigations almost invariably show a circulating neutrophilia (because of failure of the cells to migrate out of the circulation) and a profound neutrophil chemotactic defect. Diagnosis is confirmed by demonstrating the absence of the cell surface markers recognized by the anti-CD11/CD18 monoclonal antibodies. Treatment is with antibiotics in the first instance. Surgery should be avoided because of the poor healing. Neutrophil infusions appear helpful in the control of severe infections, but their use is limited by the production of alloantibodies to the transfused cells.

In the severe form, early death from infection is the rule unless a successful haematopoietic stem cell transplantation can be performed. In the partial forms, supportive and expectant management is pursued in the first instance, but haematopoietic stem cell transplantation may become necessary.

LAD type II is extremely rare, and results from defective fucose metabolism, whereby a failure to generate sialyl lewis X (CD15s) and other ligand molecules prevents binding of selectin molecules. This results in a failure of the 'rolling' type weak adhesion of leukocytes to endothelium which normally slows down the circulating leukocytes before β2 integrin binding can occur. There is a neutrophilia, and neutrophil chemotaxis and migration from the circulation is severely impaired. There is no deficiency in specific immune responses. As in LAD I deficiency, patients have a neutrophilia and suffer repeated bacterial infections and periodontal disease. Delayed umbilical cord separation is however not seen, and other features peculiar to LAD II include mental retardation, short stature and the Bombay (hh) blood phenotype [4].

A further entity, LAD type III, is also described [5,6], where leukocytes have normal β2 integrin expression, but an impaired ability to generate high avidity to their endothelial ligands at vascular endothelial contacts in response to rapid endothelial chemoattractant signals. Clinical features are similar to those in LAD types I and II.

Disorders of cellular cytotoxicity with oculocutaneous pigmentary defects

Congenital neutropenia or neutrophil dysfunction with associated hypopigmentation is recognized in patients with Chediak–Higashi syndrome [1], Griscelli syndrome [2] and Hermansky–Pudlak syndrome type 2 [3]. The common feature of these diseases is defects in proteins which control lysosomal secretion in melanocytes and immune cells. An important presentation of these diseases is haemophagocytic lymphohistiocytosis (HLH), universally fatal without treatment. Patients present with high swinging fevers, hepatosplenomegaly, jaundice and erythematous rash, respiratory distress and pancytopenia; they appear septic but blood cultures are usually sterile. Cytophagic histiocytic panniculitis has been described rarely [4]. Laboratory findings include an acute phase response, elevated ferritin and elevated fasting triglycerides with prolonged prothrombin time and reduced fibrinogen levels. Examination of bone marrow, cerebrinospinal fluid, pleural effusions or ascitic fluid may demonstrate haemophagocytosis. This may be very difficult to find, and repeated sampling

(a) (b)

Fig. 17.25 Subtle hypopigmentation on the nape (a) and lower labial mucosa (b) in a child with Chediak–Higashi syndrome. (Courtesy of the Paediatric Immunology Unit, Newcastle General Hospital, UK.)

may be required. Haemophagocytosis may occur secondary to a number of infections, in particular viral infections, and careful exclusion of infections by serology/PCR should be undertaken. Haemophagocytosis is also seen in a number of immunodeficient states including Griscelli syndrome, Chediak–Higashi syndrome and XLP. Diagnosis of familial HLH should be suspected in an infant with an appropriate clinical picture. Older children are more likely to have secondary HLH.

Twenty to thirty per cent of patients with familial HLH will have a mutation in the gene coding for perforin, normally found in the granules of NK and cytotoxic T lymphocytes. Perforin is important for cell lysis and apoptosis, and so may be important for all cells that regulate immune responses; its absence allows dysregulated immune activation [5]. More recently, other gene defects leading to HLH have been identified. *PFR1* defects lead to impaired perforin production, and cytolytic effector molecules cannot be introduced into the target cell, thereby triggering apoptosis. *UNC13D* mutations impair granule exocytosis after docking at the membrane. Recently, a third gene, *STX11*, was identified in familial HLH. The encoded protein, t-SNARE syntaxin 11, plays a role in intracellular trafficking. Since the protein has only been detected in monocytes, *STX11* mutations may impair cytolytic activity involving the interaction between dendritic and killer cells. Other, as yet unidentified, genetic defects also lead to HLH.

Treatment with a combination of chemotherapeutic agents, steroids and monoclonal antibodies that deplete lymphocytes may induce remission, but only haematopoietic stem cell transplantation is curative.

Chediak–Higashi syndrome

Chediak–Higashi syndrome (CHS) is a rare, autosomal recessive disease with partial oculocutaneous albinism, recurrent bacterial infections with organisms such as *Staphylococcus aureus*, streptococci and pneumococci, and approximately 85% of patients develop an accelerated lymphocyte and macrophage activation syndrome (similar to that seen in haemophagocytic lymphohistiocytosis (HLH) and XLP), which untreated is usually fatal. Skin, hair and eyes are affected in most cases [1]. Recurrent skin infections are common, generally starting in early childhood [2]. Deficient cutaneous pigmentation may be obvious (Fig. 17.25), but in some cases it is more subtle, and only apparent if nipples and genitalia are carefully examined. The hair generally has a silver sheen and shows clumped pigment on microscopy. Photophobia and nystagmus are regular features, due to ocular pigment dilution. Severe gingivitis and oral mucosal ulceration are well described [3].

Patients usually, but not invariably, enter an accelerated phase of the disease, with widespread infiltration with activated lymphocytes and macrophages, resulting in rapid enlargement of liver, spleen and lymph nodes, together with jaundice, hepatic failure, respiratory distress, pancytopenia and bleeding, and so death usually occurs in the first decade; survival into the second

and third decades has been recorded. Progressive neurological deterioration is common in patients who survive early childhood [4].

Characteristic giant lysosomal granules are seen in the cytoplasm of all cells containing these organelles, and are easily detected on a peripheral blood film. The gene for this disease codes for a regulator of lysosomal transport [5]; proteins normally transported through lysosomes enter these organelles but cannot exit, with subsequent lysosomal hypertrophy. In melanocytes, this results in abnormal melanin transport and consequent albinism. Neutrophil lysosomes cannot degenerate and release bactericidal proteins into the phagosome, and so intracellular killing is defective. NK cell function is also defective, as is monocyte function, probably because giant lysosomes interfere with processing of MHC II in endosomes, and thus antigen presentation is defective. The activation syndrome may result from failure to transport inhibitory molecules such as CTLA4 to the surface of leukocytes, with consequent failure of negative feedback mechanisms after T-lymphocyte and macrophage activation.

Prophylactic co-trimoxazole should be given to prevent bacterial infection. The accelerated phase cannot be predicted, and patients should be closely monitored, particularly if febrile. Symptoms, signs, laboratory and clinical findings and diagnosis and treatment of the accelerated phase are as for HLH. The only definitive treatment is haematopoietic stem cell transplantation. This should be considered early if there is a matched sibling donor. Although haematopoietic stem cell transplantation prevents further episodes of macrophage activation, it may not prevent later neurological deterioration.

Griscelli syndrome

This rare, autosomal recessive disorder results in a partial albinism and a combined immunodeficiency [1]. Individuals with Griscelli syndrome resemble those with CHS in that they have variable hypopigmentation of the skin and hair and recurrent pyogenic infections. Skin colour seems to have been more or less unremarkable, without photosensitivity, in the few patients so far reported, but affected individuals are paler than their siblings [2] and the hair, including eyebrows and eyelashes, is silvery grey from early childhood (Fig. 17.26).

Delayed-type cutaneous hypersensitivity is absent, T-cell numbers may be reduced and natural killer cell function is impaired. Hypogammaglobulinaemia is often seen as a secondary phenomenon, although B-cell numbers are usually normal. In contrast to CHS, large lysozomal granules are not seen and examination of hair by electron microscopy shows large clumps of pigment, with the accumulation of normal mature melanosomes in basal layer melanocytes in the epidermis. The liver, spleen and lymph nodes are infiltrated with histiocytic cells. Neurological abnormalities do not occur, but patients do develop an accelerated phase, which is fatal unless treated by haematopoietic stem cell transplantation [3]. Two male siblings have been reported in whom immunodeficiency was combined with partial albinism, as in Griscelli's syndrome, but in which agenesis of the corpus callosum, cleft lip and palate and bilateral congenital cataracts were also features [4].

Fig. 17.26 Generalized hypopigmentation of skin and characteristically silvery grey hair, present from birth. (Courtesy of the Paediatric Immunology Unit, Newcastle General Hospital, UK.)

Three gene defects have been described in Griscelli's syndrome: *MYO5A*, which codes for myosin 5a [5], *RAB27A* [6] and *MLPH*, which codes for melanophilin [7]. Immune defects are only reported in patients with *RAB27A* mutations.

Hermansky–Pudlak syndrome

Hermansky–Pudlak syndromes predominantly present as bleeding disorders. One patient, with clinical features consistent with Griscelli syndrome, including skin and hair hypopigmentation, was found to have a pathogenic homozygous mutation in the *AP3B1* gene, mutated in Hermansky–Pudlak syndrome type 2. In addition to recurrent infection associated with neutropenia, he developed fulminant HLH [1].

Endosomal adaptor protein p14 deficiency

A new defect causing skin hypopigmentation, with severe congenital neutropenia and B-lymphocyte dysfunction with short stature, has been described. Patients suffer recurrent pneumococcal bronchopulmonary infection [1]. The affected protein, p14, is an adaptor molecule that is involved in control of the late endosome trafficking. The method by which this leads to neutropenia remains unclear.

Warts, hypogammaglobulinaemia, infection, myelokathexis (WHIM) syndrome

This rare, autosomal dominantly inherited immunodeficiency is characterized by numerous confluent warts, commonly on hands, although they may also be found on mucosal surfaces including the mouth. They can appear as cervical papillomatosis and vulval condylomata accuminata. They are caused by human papilloma virus and may be premalignant. They normally appear during late teens, but may be seen in early childhood. The warts respond poorly to treatment. Other clinical features include recurrent sinopulmonary bacterial infections from early childhood, which may lead to bronchiectasis in later life. Severe neutropenia is usual, and lymphopenia is described. Bone marrow examination is normocellular with marked granulocyte hyperplasia (myelokathexis—failure of leukocytes to emigrate from the marrow) [1]. The genetic defect is in the chemokine receptor *CXCR4*, important for chemotaxis of progenitor and mature haemopoietic cells [2]. Treatment is supportive with G-CSF and immunoglobulin replacement.

Defects in the IL-12-dependent IFN-γ pathway

Defects in the IL-12 dependent IFN-γ pathway have been described in affected patients with persistent, severe bone and soft tissue abscesses and discharging sinuses due to Bacille Calmette-Guérin (BCG), or weakly pathogenic environmental non-tuberculous mycobacteria, which can be fatal [1]. There is also susceptibility to invasive non-typhi salmonella infections and severe viral infection, particularly due to herpesvirus. Oral ulceration and cutaneous vesicular eruptions have been described in those with viral infection [2]. Two patients with lesions mimicking those seen in Langerhans' cell histiocytosis, who were subsequently shown to have IFN-γ receptor deficiency, have been described. Osteolytic lesions were present in the skull and humerus, with granulomatous inflammation and central necrosis on biopsy [3], from which BCG was cultured. Infections result from a failure of upregulation of macrophage killing. The clinical picture depends on the precise molecular defect that is present. Defects have been described in a number of constituents of the IL-12/IFN-γ pathway, including complete or partial IFNγ-R1 deficiency, IL-12p40 subunit deficiency, and complete IL-12b1 deficiency. The outcome of patients with complete IFNγ-R1 deficiency is poor, but haematopoietic stem cell transplantation has been successfully attempted.

Anhydrotic ectodermal dysplasia, incontinentia pigmenti, susceptibility to infection and defects in the *NEMO* gene and downstream signalling pathway

The transcription factors of the NF-κB family are activated by signals received when innate immune responses are triggered in cells such as neutrophils and macrophages. They play an important role in regulating immune and stress responses, inflammatory reactions and immunity to infection in humans, and are critical for transmitting signals to the nucleus from cell surface receptors that detect microbes or viruses. A number of diseases are associated with defects in this pathway, including incontinentia pigmenti and ectodermal dysplasia. X-linked anhydrotic ectodermal dysplasia and immunodeficiency have been associated in an ill-defined manner for some time, but only recently has the pathology begun to be elucidated. Patients present with sparse scalp hair, conical teeth and absent sweat glands. Some suffer from recurrent sinopulmonary infection, often with encapsulated organisms, and have poor antibody responses to polysaccharide antigens, or frank hypogammaglobulinaemia [1]. Such infants share many of the clinical features of anhydrotic ectodermal dysplasia (EDA), although they appear less severe than in children with 'classical' EDA without immunodeficiency. Incontinentia pigmenti is a rare X-linked dominant condition characterized by developmental abnormalities in skin, hair, teeth and the central nervous system. Carrier mothers demonstrate well-recognized cutaneous features of Blaschko linear skin lesions occurring in

four successive, sometimes overlapping, stages: (i) erythema, vesicules and pustules; (ii) verrucous hyperkeratotic lesions; (iii) hyperpigmented whorls and streaks following lines of Blaschko; and (iv) pallor and scarring. In other respects, affected females are healthy. Previously, affected males were all reported to die soon after birth, but some have now been described who survive, albeit with a progressive combined immunodeficiency [2]. Hypomorphic mutations in *NEMO*, which codes for NF-κB essential modulator, were subsequently discovered in a number of patients [2,3]. Stop codon mutations in the same gene are responsible for osteopetrosis and/or lymphoedema with ectodermal dysplasia and immunodeficiency (OL-EDA-ID) [2–6]. Subsequently, immunodeficiency without ectodermal dysplasia has also been described in patients with mutations in *NEMO* [7,8]. Only a few of the mothers of affected boys from EDA-ID kindreds showed variable features of EDA or incontinentia pigmenti (dry and/or hyperpigmented skin, hypodontia, conical teeth), as well as elevated IgA levels, whilst mothers of both children with OL-EDA-ID phenotype showed mild features of incontinentia pigmenti. Hypermorphic mutations in IκBα, a protein that acts downstream of NF-κB, have been described in a patient with ectodermal dysplasia and immunodeficiency [9]. The mutation impairs NF-κB activation, resulting in a similar clinical phenotype to *NEMO* defects. A further patient deficient in IκBα, who presented with ectodermal dysplasia and immunodeficiency, has also been described [10]. Invasive *Streptococcus pneumoniae* infections are also seen in patients with IRAK-4 deficiency [11]. IRAK-4, a kinase downstream of Toll-like receptors, is important for the onset and propagation of inflammation, and patients have a poor or delayed inflammatory response. Whilst potentially life-threatening in childhood, infections are rare as patients reach adulthood.

Toll-like receptor pathway deficiencies

There are 10 Toll-like receptors (TLR) in humans, each of which recognizes a distinct, but limited, repertoire of conserved microbial products which, when bound by the relevant TLR on neutrophils or macrophages, triggers a number of signalling pathways that, involving NF-κB, activate cells, stimulate proliferation and cause cytokine release. Defects have been discovered in one TLR and the signalling pathway. The first to be discovered was in individuals who had experienced herpes simplex encephalitis, but no other unusual infectious disease, and who had controlled other viral infections. Defects were found in *UNC-93B*, which encodes a protein expressed in the endoplasmic reticulum, involved in signalling through the Toll-like receptor (TLR)-3, -7, -8 and -9 [1]. More recently, defects in the gene encoding TLR-3 have been identified in children who appear susceptible only to herpes simplex encephalitis [2].

Complement disorders

Complement deficiencies

Deficiencies of isolated complement components are rare, deficiency of C2 being the most frequent, and, with the exception of properdin and C1 esterase inhibitor deficiency, are generally transmitted in an autosomal recessive manner, severe disease occurring when both alleles are defective. However, heterozygosity results in approximately half normal levels of the protein which can sometimes be clinically important. A number of clinical patterns can occur depending upon which factor is deficient.

Deficiency of the early components of the classical complement activation pathway, that is C1, 4 and 2, tend to predispose to autoimmune disease, particularly systemic lupus erythematosus [1]. Photosensitivity and cutaneous manifestations of lupus erythematosus occur in association with mild non-cutaneous disease and absent or unimpressive plasma levels of antinuclear antibody.

Evidence, based on the finding that null alleles for a number of complement components (notably C2 and C4) occur with greater frequency in patients with autoimmune diseases such as systemic lupus erythematosus, suggests that heterozygosity for deficiency is also a risk factor. In general, the course of these diseases is similar to that in patients without complement deficiency. Partial deficiencies of certain complement components, particularly C2 and C4, is associated with an increased risk of certain diseases, notably systemic lupus erythematosus, discoid lupus erythematosus, juvenile rheumatoid arthritis, membranous glomerulonephritis and angio-oedema [2–4].

Recurrent pyogenic infections are a feature of complement deficiencies. Organisms such as streptococci and *Haemophilus influenzae* are the main problem, as opsonization/binding of antibody and complement to bacteria is critical for their elimination. C3 deficiency is the most severe. Deficiency of the classical pathway components C1q and C2, and of factor D in the alternative pathway, also predisposes to infection, and the first two also carry a predisposition to autoimmune phenomena. Deficiencies of the alternative pathway control proteins, factors H or I, lead to uncontrolled consumption of C3, resulting in increased susceptibility to pyogenic infections including meningococcal disease [5].

Deficiency of one of the later complement components, C5–C9 (leading to failure of membrane lysis), or of the control factor properdin (the only deficiency inherited in an X-linked manner) leads to a specific deficiency in handling neisserial species (*N. meningitidis* and *N. gonorrhoeae*) but not to a generalized increase in susceptibility to pyogenic infections. There is a predominance of disease caused by rare serogroups of meningococci (W135, X, Y and Z) in these patients. In one study [6], complement deficiency (most commonly late components or properdin) was found in 33% of survivors of meningococcal disease due to rare serogroups, compared to 2, 0 and 7% in patients who suffered group A, B and C disease, respectively. Recurrent attacks of meningococcal septicaemia/meningitis, and severe invasive gonococcal disease, are also associated with late complement deficiencies. C9 deficiency in Japan affects up to 0.1% of the population [5], but is less common in Caucasians. Screening for deficiencies should be undertaken in patients and their immediate families where there has been recurrent meningococcal disease due to common serogroups, or single episodes caused by a rare serogroup. In the UK, screening children with single episodes of meningococcal disease due to common serotypes is unlikely to reveal a complement defect [7]. Where infections occur in children with deficiencies of the early complement components, these are predominantly caused by encapsulated bacteria, such as *Pneumococcus*.

Several proteins have been identified that have regulatory effects on the complement system. The existence of these activities has generally come to light through the profound clinical effects that may result from their deficiency. The best known of these deficiencies is that of C1 esterase inhibitor, which results in hereditary angio-oedema (see Chapter 22). Deficiency of factor 1, previously termed C3b inactivator, leads to unchecked cleavage of C3, and therefore to clinical manifestations closely resembling those seen in C3-deficient individuals [8,9]. In this condition, plasma infusions may provoke anaphylaxis, because the contained C3 is so rapidly cleaved to form the anaphylotoxin, C3a [10].

C1q deficiency

A variety of clinical manifestations have been described in patients with C1q deficiency, including cutaneous vasculitis, systemic lupus erythematosus, membranous glomerulonephritis and problems with infections, particularly meningitis and septicaemia, but also including stomatitis, pyoderma and persistent candidiasis of mouth and nails [1–5].

C1r and C1s deficiencies

Systemic lupus erythematosus, or a disorder clinically suggestive of systemic lupus erythematosus but lacking confirmatory serological findings, and/or membranous glomerulonephritis, have similarly been reported in patients with deficiencies either of C1r [1] or C1s [2]. Infections have not been prominent except in the case of an infant with C1r deficiency who had lung infections and hepatic abscesses [3].

3 Johnston RB. Disorders of the complement system. In: Stiehm ER, ed. *Immunologic Disorders in Infants and Children*, 4th edn. Philadelphia: WB Saunders, 1996: 490–509.

C4 deficiency

The majority of patients reported with C4 deficiency have been children or adolescents [1]. Their principal clinical abnormalities have comprised systemic lupus erythematosus, or a systemic lupus erythematosus-like syndrome, Henoch–Schönlein purpura or Sjögren's syndrome. Infections have only occasionally been a problem [2,3].

C2 deficiency

This is the commonest complement deficiency. It has now been shown to be associated with a variety of diseases, but deficient individuals are often entirely healthy. Disorders occurring in C2-deficient patients have included systemic lupus erythematosus, discoid lupus erythematosus, membranous glomerulonephritis, Henoch–Schönlein purpura, rheumatoid arthritis, dermatomyositis, Crohn's disease and idiopathic thrombocytopenic purpura [1–5]. Serious bacterial infections may also occur, particularly pneumococcal, *Haemophilus influenzae* and meningococcal infections, in that order, although it is unclear why some patients are prone to such infections and others are not.

C3 deficiency

C3 deficiency is the most serious of all the isolated complement deficiency states. Infections are the main hazard, particularly infections with organisms that require opsonization. Thus, meningococcal meningitis and pneumococcal pneumonia have been major problems [1]. The clinical picture is in many ways similar to that of hypogammaglobulinaemia. Transient maculopapular rashes have been reported to occur in association with infections; histologically, these have shown the features of leukocytoclastic vasculitis [2]. Other manifestations, such as systemic lupus erythematosus and membranous glomerulonephritis, have also been reported [1].

C5, C6, C7, C8 and C9 deficiency

Recurrent meningococcal meningitis and disseminated gonococcal infections have been the principal clinical consequence of deficiencies of all these complement components [1–3]. One patient has been reported in whom frequent cutaneous infections and subcutaneous abscesses were the presenting problem, as one would expect from the defective generation of C5a chemoattractant [4], but it is now clear that cutaneous infections are generally not a problem in these patients [5].

Systemic lupus erythematosus, discoid lupus erythematosus, Sjögren's syndrome, rheumatoid arthritis and ankylosing spondylitis have also been associated with these deficiencies [1,4]. An affected 43-year-old woman has been reported in whom Raynaud's phenomenon, sclerodactyly and telangiectasia were associated with hereditary deficiency of C7 [6].

Interaction of antibody and complement deficiencies

Deficiency of the early classical pathway complement components has been shown to be associated with poor antibody responses, presumably because the resulting poor opsonization leads to impaired antigen penetration. Later components are not implicated.

Alternative pathway opsonization is less efficient in the absence of specific antibody to bacterial surfaces. There is evidence that antibody may 'neutralize' surface molecules, such as sialic acid, which otherwise inhibit alternative pathway activation.

Deficiencies of C3 receptors

The distribution and function of cell surface receptors for C3b and its derivatives have been described above. Specific clinical syndromes have been attributed to deficiencies of some of these receptors. A dominantly inherited CR1 deficiency is associated with SLE and other immune complex disorders, presumably related to failure of the immune complex clearing function of this molecule.

Deficient expression of the CR3 receptor occurs as part of the leukocyte adhesion deficiency type I syndrome since it is a member of the β integrin family affected in this disorder, though what contribution this makes to the overall clinical picture in that condition is unclear.

Management of complement deficiencies

Apart from C1 esterase inhibitor, there are no specific replacement factor preparations. Fresh plasma infusions have been used prophylactically or can be reserved for the treatment of serious episodes of infection. Lifelong prophylactic penicillin and meningococcal vaccination are advised in those complement deficiencies resulting in susceptibility to neisserial infections. A polyvalent vaccine (A,C,W135 and Y) should be given. Prophylactic co-trimoxazole can be used in deficiencies that result in an increased susceptibility to a wider range of organisms. Clinical monitoring may allow earlier diagnosis and treatment of autoimmune disorders, should they emerge.

Definitions

Developmental defects are errors in morphogenesis arising during intrauterine life. Most are *congenital*, that is present at birth, and some are inherited. The term embraces *malformations*, *deformations* and *disruptions* [1]. There is clearly considerable overlap between these three categories.

A *malformation* is a primary anatomical defect resulting from abnormal development of an organ or tissue. It may be *isolated*, occurring in an otherwise normal child, or multiple, affecting several body systems. A *malformation syndrome* is the occurrence of multiple malformations in a recognizable pattern, frequently accompanied by mental retardation, for example Down's syndrome. A *malformation sequence* occurs when a primary malformation produces secondary defects, for example hydrocephalus secondary to spina bifida.

Deformation reflects abnormal intrauterine moulding by mechanical forces, for example positional deformation of the legs and feet in spina bifida. Severe oligohydramnios may result in a characteristic combination of congenital deformations referred to as Potter's syndrome, one cause of which is renal agenesis [2].

Disruption indicates intrauterine damage or destruction to a developed organ by agents such as infection, circulatory compromise or amniotic bands.

A *teratogen* (from the Greek, *teres*, a monster) is any extrinsic factor operative during fetal life that is capable of inducing developmental abnormalities.

Naevus is the Latin word for 'maternal impression' or 'birthmark' and indicates a circumscribed, non-neoplastic skin or mucosal lesion, usually present at or soon after birth, and fixed. The term should always be qualified according to the cell or tissue of origin, for example 'connective tissue naevus' and 'vascular naevus'. Confusingly, 'naevus', 'naevo-' and 'naevoid' are often used without qualification to imply melanocytic naevus. Thus 'naevus cell' means the cell type found in a melanocytic naevus, 'naevocytic naevus' means a melanocytic naevus, and 'naevoid basal cell carcinomas' look like melanocytic naevi.

The term 'naevus' is synonymous with *cutaneous hamartoma* (e.g. smooth muscle naevus/hamartoma), both comprising an abnormal mixture of a tissue's usual components (the word 'hamartoma' derives from the Greek word *hamartia*, meaning 'to err').

Many, possibly all, naevi represent clones of genetically altered cells arising from mosaicism [3–7]. *Genetic mosaicism* (see also Chapter 15) denotes the presence of two or more genetically different cell populations in an individual derived from a single zygote. The differences can be between single genes, groups of genes or entire chromosomes. *Chimerism* denotes the presence of two or more genetically distinct cell populations in an individual derived from two different zygotes. Chimeras can result from the fusion of dizygotic twin embryos, or from the fertilization by two spermatozoa, and subsequent splitting, of an ovum containing a polar body. While mosaicism generally involves an abnormal clone within a normal individual, chimerism involves two different normal clones. Cutaneous anomalies due to mosaicism affect any skin cell type, but the cutaneous abnormalities observed in human chimeras are always pigmentary [8–10].

Rook's Textbook of Dermatology, 8th edition. Edited by DA Burns, SM Breathnach, NH Cox and CEM Griffiths. © 2010 Blackwell Publishing Ltd.

The word 'naevoid' is sometimes applied to mosaic forms of inherited skin conditions following Blaschko's lines, for example naevoid psoriasis.

The imprecise term *systematized*, applied to an extensive naevus, implies a linear, segmental or dermatomal distribution. The terms *segmental* and *zosteriform* should be confined to naevi following body segments and dermatomes respectively. In practice, 'segmental' usually conceals ignorance about whether the pattern follows dermatomes or Blaschko's lines.

Aetiology

Congenital malformations may be caused by environmental or genetic factors, or combinations of the two independently or interacting. Some abnormalities have different causes in different patients, for example aplasia cutis. It is important to recognize parents' tendencies to attribute neonatal defects to antenatal and perinatal events: the question 'What did you think might have caused this?' may reveal surprising and irrational concerns.

Environmental factors. Those provoking congenital malformations (teratogens) are listed below. In fact, remarkably few cutaneous developmental defects have been attributed to teratogens [1]: they include aplasia cutis congenita of the scalp due to methimazole and segmental aplasia cutis following first-trimester varicella.

1 *Intrauterine infections*: rubella [2–5], cytomegalovirus [6], toxoplasmosis [7] and herpes simplex virus [8], are well-known causes of non-cutaneous defects. Varicella infection before 20 weeks gestation can cause segmental aplasia cutis [9].
2 *Ionizing radiation* from X-rays, radiotherapy or accidental contamination [10,11].
3 *Drugs taken during pregnancy* [12–15], particularly cytotoxic and immunosuppressive agents, anticonvulsants, anticoagulants, androgens, lithium carbonate, thalidomide, vitamin A derivatives and antithyroid drugs. Carbimazole and methimazole [16] can cause aplasia cutis congenita of the scalp.
4 *Alcohol* [17–19] *use during pregnancy* may result in a characteristic dysmorphic appearance (fetal alcohol syndrome) an occasional feature of which is neonatal hypertrichosis. Haemangiomas (mostly small, raised strawberry angiomas) were found in 12/41 (29%) infants with fetal alcohol syndrome [17].
5 *Trace metal excesses or deficiency during pregnancy*, particularly mercury exposure which causes widespread neurological disease [20], and zinc deficiency which is associated with neural tube defects [21].
6 *Exposure to other toxins during pregnancy*. Congenital polychlorinated biphenyl (PCB) poisoning occurred following exposure of mothers in two industrial accidents, in Japan and Taiwan, in which cooking oil was contaminated during its manufacture [22]. Affected babies had 'cola-coloured skin', with dark brown pigmentation of flexures, nails, mouth and sclerae that cleared in 2–5 months.
7 *Maternal diseases*, such as diabetes mellitus [23] and phenylketonuria [24].
8 *Paternal occupational exposure to toxins* can adversely affect the fetus either by direct effects on spermatozoa, or indirectly by maternal contamination. Paternal occupations that have been linked with birth defects include janitors, painters, printers, and occupations related to solvents or agriculture [25].

Genetic factors. Most developmental defects involving the skin probably have a genetic basis. The types of genetic abnormality, in descending order of size of the mutation, are summarized below:

1 *Chromosomal syndromes*: major abnormalities of chromosome number include trisomy 21 (Down's syndrome), and sex chromosome defects. Syndromes due to structural anomalies of chromosomes include Wolf–Hirschhorn syndrome, in which there is loss of the short arm of chromosome 4. Chromosomal syndromes involving an autosome are usually accompanied by mental retardation. Skin anomalies are unusual in this group, but include keratosis pilaris in Down's syndrome. Localized skin anomalies are even more unusual: an example is aplasia cutis in Wolf–Hirschhorn syndrome. Chromosomal anomalies may be inherited, or may arise after conception from chromosomal non-disjunction during mitosis, in which case they will be mosaic.
2 *Microdeletion syndromes*: submicroscopic deletion of contiguous genes can produce syndromes combining features caused by the individual genes. A dermatological example is X-linked ichthyosis with hypogonadotrophic hypogonadism, due to a microdeletion at Xp22 affecting both the steroid sulphatase and Kallmann's syndrome loci. Microdeletions are detected by fluorescence *in situ* hybridization (FISH).
3 *Mutations in specific genes*: this is the major cause of both inherited and mosaic syndromes and anomalies.

Genetic mechanisms in localized and isolated defects

Genetic skin disorders are usually generalized. The patchy and localized conditions that are the subject of this chapter can be produced and transmitted by the following genetic mechanisms:

1 Mutations in genes acting on morphogenesis may cause abnormal cell migration, resulting in patchy defects. Examples include dominantly inherited scalp aplasia cutis, and white patches in autosomal dominant piebaldism.
2 Patchy skin manifestations in some generalized autosomal dominant and recessive disorders may be attributable to a genetic

'second hit' [26] (loss of heterozygosity), e.g. hamartomas in tuberous sclerosis, and the tumours of xeroderma pigmentosum. However, other mechanisms have been postulated [27].

3 Some localized anomalies represent a '*forme fruste*' or minimal expression of a generalized disorder. For example, lower-lip sinuses, which most often occur alone, represent the minimal manifestation of an autosomal dominant gene, whose full expression results in Van der Woude's syndrome, with associated cleft lip and palate [28]. It is possible that isolated ash-leaf macules and café-au-lait macules have a similar significance.

4 Genetic mosaicism resulting from somatic mutation is probably the major cause of naevi and other localized skin defects [29–32]. The embryo is normal at conception, but at some point during early embryogenesis a mutation gives rise to a clone of cells in which the genetic change manifests as a localized cutaneous abnormality. Naevi caused by genetic mosaicism arising after conception are by definition not inherited from the parents. Occasional reports of familial clustering of mosaic conditions (such as epidermal naevus and segmental neurofibromatosis) may be attributable to inheritance of an unstable premutation. Happle has suggested two other mechanisms to explain familial clustering of mosaic conditions: 'paradominant inheritance' [33] in which a recessive gene is unmasked by loss of heterozygosity, and the silencing and activation of different genes by 'transposable elements' [34]. A particular risk of mosaic disorders is transmission of the generalized condition to the patient's offspring (e.g. generalized neurofibromatosis type 1 in offspring of patients with segmental neurofibromatosis). Some localized defects (e.g. Sturge–Weber syndrome) have been attributed to serious mutations compatible with survival only in the mosaic state, so that if the mutation were passed on it would cause miscarriage [35]: this has never been documented. Epidermal mosaicism is manifest as Blaschko's lines (see below).

Classification of naevi

The classification of naevi is historical and not entirely logical. In general, naevi are classified according to the component cell, tissue or organ, and subdivided according to the macroscopic or histological nature of the abnormality (Table 18.1). The existing categories have stood the test of time, enabling dermatologists to distinguish naevi with different biological behaviour, and to advise patients accordingly. However, there are many areas of uncertainty, reflecting variability within and between lesions and patients. As we learn more about the molecular basis of naevi some of these uncertainties resolve. For example, we now know that epidermolytic and non-epidermolytic verrucous epidermal naevi are different entities, while Darier-like and acantholytic epidermal naevi are probably the same. The classification used here combines established clinical divisions with newer molecular definitions.

Table 18.1 Classification of non-vascular naevi.

Epidermal naevi	Dermal and subcutaneous naevi
Keratinocyte naevi	*Connective tissue naevi*
Verrucous epidermal naevus	Collagen naevi
Epidermolytic verrucous epidermal naevus	Familial cutaneous collagenoma
Non-epidermolytic verrucous epidermal naevus	Eruptive collagenoma
Sebaceous naevi	Shagreen patch
Naevus sebaceus	Other collagenomas
Follicular naevi	Elastic naevi
True hair-follicle naevus	Perforating elastoma
Comedo naevus	Juvenile elastoma and the Buschke–Ollendorff syndrome
'Acne-free' naevus	Papular elastorrhexis
Basaloid follicular hamartoma	Naevus anelasticans
Dilated pore naevus	Other elastomas
Hairy malformation of the palms and soles	Proteoglycan naevi
Apocrine naevi	Mucinous naevus
True apocrine naevus	Fibrous hamartoma of infancy
Syringocystadenoma papilliferum	*Muscle naevi*
Eccrine naevi	Infantile myofibroma
True eccrine naevus	Congenital smooth muscle hamartoma
Eccrine angiomatous hamartoma	Diffuse smooth muscle hamartoma
Porokeratotic eccrine ostial and dermal duct naevus	Congenital leiomyoma
Becker's naevus	Striated muscle naevi
Inflammatory epidermal naevi	*Fat naevi*
ILVEN	Naevi lipomatodes cutaneous superficialis
CHILD naevus	Lipoblastoma
Other naevoid epidermal disorders	Encephalocraniocutaneous lipomatosis
Linear lichen planus	Congenital lipoma
Naevoid psoriasis	Congenital lipomatosis
Darier-like epidermal naevus	Neurolipomatosis
Hailey–Hailey-like epidermal naevus	'Michelin tyre' baby
Linear porokeratosis	
Atrophoderma of Moulin	
'Blaschkitis'	
Epidermal naevus syndrome	

Blaschko's lines

Almost all epidermal naevi follow the pattern of lines painstakingly documented by Blaschko from drawings of epidermal naevi [1]. Blaschko's lines are characteristic of mosaic conditions of the epidermis and probably represent the routes of ectodermal cell migration from the neural crest [2,3]. On the trunk, these lines tend to take the form of transverse bands, differing from dermatomes in being more numerous, and in their S-shaped wave form on the lateral trunk (Fig. 18.1) and V-shape in the middle of the back. On the arms and legs, lesions follow lines roughly parallel with the axis of the limb. The lines spiral on the scalp, are vertical in the mid-face, and extend laterally from the angles of the mouth [4–6]. They never cross the anterior truncal midline, but run along it. Posteriorly, the 'Blaschko' midline is often shifted from the anatomical midline.

Fig. 18.1 Multiple verrucous epidermal naevi with the histological changes of epidermolytic hyperkeratosis.

The shape and distribution of epidermal naevi probably reflect not only paths of cell migration but also the timing of mosaicism and cell type. Abnormal clones arising at the very early blastocyst stage will be widely distributed along the paths of migrating cells and appear linear, while those arising in the fully formed fetus are more likely to be single, small, round or oval lesions. Keratinocytes, which migrate by directional proliferation, produce linear lesions, whereas melanocytes which migrate singly more often form leaf-shaped (phylloid) or block-like lesions.

Epidermal naevi

The term epidermal naevus is used for naevi composed of keratinocytes. Recently, the molecular causes of certain epidermal naevi have been elucidated, enabling us to differentiate between them. However, the older literature does not differentiate between, for

example, epidermolytic and non-epidermolytic naevi, and therefore clinical descriptions must be read in this light.

Probably all epidermal naevi comprise an abnormal clone of cells, reflecting genetic mosaicism arising from somatic mutation (see above). The clinical implications of mosaicism are firstly that it is unlikely to recur in the same family, and secondly that there is a theoretical risk of the condition being passed on to the patient's offspring in a severe or even lethal generalized form. Curiously, these predictions are not always borne out, as is discussed under the individual headings.

Verrucous epidermal naevus

Synonyms
- Naevus verrucosus
- Naevus unius lateris

Definition. Verrucous epidermal naevi are congenital, non-inflammatory cutaneous hamartomas composed of keratinocytes. They are distinct from inflammatory, acantholytic and porokeratotic epidermal naevi, from sebaceous naevi, and from epidermal naevi derived from skin appendages. Their prevalence in adults is probably 0.1–0.5%, and they occur equally in males and females. They are divided into epidermolytic and non-epidermolytic types.

Epidermolytic verrucous epidermal naevus

Aetiology. The histological similarity between epidermolytic verrucous epidermal naevi and autosomal dominant bullous ichthyosiform erythroderma (BIE) led to the idea that the former represents a clone of cells expressing a mutation in one of the BIE genes *KRT1* and *KRT10*. This was confirmed by finding mutations in *KRT10* [1,2] and *KRT1* [3] in such naevi but not in the adjacent normal skin and in lymphocytes of a woman with verrucous epidermal naevi whose son had BIE [4]. Such epidermal naevi are sporadic and cannot be passed on from parent to child. However a parent with an epidermolytic verrucous epidermal naevus is likely to have gonadal mosaicism as well as cutaneous mosaicism, and can therefore produce offspring with generalized BIE [1,4,5].

Pathology. Epidermolytic verrucous epidermal naevi show hyperkeratosis, acanthosis and papillomatosis with epidermolytic hyperkeratosis [5] identical to that seen in BIE. This comprises perinuclear vacuolization of the keratinocytes, associated with premature and excessive formation of irregular keratohyalin granules, indistinct cell borders and hyperkeratosis.

Clinical features [1–5]. By analogy with BIE, epidermolytic verrucous epidermal naevi at birth would be expected to be blistered, and only later to become verrucous. However, there is no specific report of this. In young children they appear as slightly pigmented velvety or warty streaks or plaques. With age they darken and the surface becomes more warty (Fig. 18.2), sometimes with an erythematous base. They may be single or multiple, and size and site are variable. *KRT1* but not *KRT10* is expressed in palmoplantar skin, so theoretically mutations in the former but not the latter might cause lesions in those sites. Flexural lesions may become macerated and foul smelling, causing discomfort and psychological problems. Striate palmoplantar keratoderma and ainhum occurred in a child with extensive systematized epidermolytic verrucous epidermal naevi [6]. Epidermolytic verrucous epidermal naevi are not associated with extracutaneous abnormalities (epidermal naevus syndrome: see below) because keratin genes are expressed only in epithelia. They probably do not have the malignant potential of sebaceous naevi [7].

Fig. 18.2 Linear verrucous epidermal naevus on the neck.

Diagnosis. Epidermolytic and non-epidermolytic verrucous epidermal naevi are sometimes indistinguishable except on histology. Their lack of inflammation, presence at birth, warty, brown appearance and persistence distinguish them from most other types of epidermal naevus. They may be confused with linear viral warts, particularly filiform or digitate warts on the neck, scalp or body folds.

Non-epidermolytic verrucous epidermal naevus

Aetiology. Non-epidermolytic verrucous epidermal naevi are probably heterogeneous, representing mosaicism for different,

and as yet unidentified, mutations. Stosiek *et al.* [1] reported chromosomal mosaicism in two otherwise normal men with non-epidermolytic verrucous epidermal naevi. Several chromosomal abnormalities were found in the abnormal skin, with a breakpoint common to both patients at 1q23. This lies intriguingly close to a locus known as the epidermal differentiation complex, which includes a cluster of over 25 genes encoding structural components of the cornified envelope [2]. Other candidates for acanthosis nigricans-like epidermal naevi [3,4] include the fibroblast growth factor receptor (FGFR) genes [5]. There are now several reports of *FGFR3* mutations in verrucous epidermal naevi [6–8], in one case associated with craniofacial anomalies similar to those seen in craniosynostosis syndromes caused by *FGFR3* mutation [7]. The commonest mutation is R248C. Mutations in the oncogene *PIC3CA* have recently been reported in epidermal naevi [9]. *PTEN* is also implicated in verrucous epidermal naevi: two patients with Proteus-like syndrome and a germ-line mutation in *PTEN* showed loss of heterozygosity for the *PTEN* mutation in DNA tissue from an epidermal naevus [10,11]. A palmoplantar verrucous naevus has been reported which was due to mosaicism for a mutation in keratin 16, the gene responsible for pachyonychia congenita [12], but since hyperkeratosis in pachyonychia congenita is confined to the palms and soles, it is unlikely that verrucous epidermal naevi at other sites are caused by pachyonychia congenita gene mutations. Mosaic chromosome 6 trisomy has also been found in the skin of a patient with an epidermal naevus in addition to extensive linear hypopigmentation [13].

Pathology [14,15]. The most common histological pattern is sharply demarcated hyperkeratosis and acanthosis, often associated with papillomatosis, and occasionally by focal hypergranulosis and/or columns of parakeratosis. About 10% of lesions show a distinctive 'church-spire' pattern of acanthosis and hyperkeratosis, resembling acrokeratosis verruciformis, and about 5% show features resembling seborrhoeic keratoses, that is hyperkeratosis, papillomatosis, acanthosis and horn pseudocysts, with a flat lower base. Rarely, they may show histological features more characteristic of common viral warts, acanthosis nigricans [3,4], or of the verrucous phase of incontinentia pigmenti [16].

Several other changes have been reported in verrucous epidermal naevi. Appendageal anomalies seen in early childhood include immature hair follicles, sebaceous, eccrine or apocrine glands. In later childhood and adult life, comedo-like dilated follicles, and sebaceous, eccrine and apocrine hyperplasia occur [17,18]. It is not at all clear to what extent these represent age- and site-related differences in the same disorder [18,19] or different naevi. The same difficulty applies to occasional reports of basal cell [20–22], squamous [22–28], verrucous [29] and adnexal carcinomas [30], and Bowen's disease [19], within epidermal naevi: usually they are those showing sebaceous or apocrine differentiation.

Clinical features. Verrucous epidermal naevi are usually present at birth but may appear or extend during childhood. A verrucous epidermal naevus in a 60-year-old woman reported to have developed only 5 years previously was highly atypical, with bilateral crusted, hyperkeratotic plaques on the head and upper trunk and histological signs of inflammation [31]. At birth they have a white, macerated appearance, but within a few days take the form of pink or slightly pigmented, velvety streaks or plaques. Later, they darken and the surface becomes more warty (see Fig. 18.2), sometimes with an erythematous base. Their extent and distribution are highly variable, but sebaceous naevi are especially common on the face and scalp. They may extend on to an adjacent mucosal surface [32]. Nail ridging, splitting, discoloration or dystrophy may occur where the nail fold is involved. The lesions are as a rule asymptomatic, except, for example, when they impinge upon the nail fold, where they may cause recurrent paronychia, and may split or distort the nail plate. Flexural lesions may become macerated and foul smelling. Verrucous epidermal naevi have been associated with scalp woolly hair naevi [33], and in some cases the woolly hair directly overlies a verrucous epidermal naevus [34,35]. Tumours may develop within the naevi (see above). While most of the patients in whom this has occurred have been over 40 years of age, malignant tumours have been reported in patients as young as 17 years of age [23].

A wide variety of developmental anomalies may occur in association with verrucous epidermal naevi and are discussed in more detail in the section on epidermal naevus syndrome. They include localized anomalies such as megalopinna [36] and aplasia cutis of the scalp [37], and syndromes such as epidermal naevus syndrome, Proteus syndrome, McCune–Albright syndrome [38,39], Klippel–Trenaunay syndrome [40], and phakomatosis pigmentokeratotica. Hypophospataemic rickets and osteomalacia sometimes accompany verrucous epidermal naevi [41] and are discussed under epidermal naevus syndrome.

Diagnosis. Epidermolytic and non-epidermolytic verrucous epidermal naevi must be distinguished histologically. Non-epidermolytic verrucous epidermal naevi can be differentiated clinically from other types of epidermal naevus as they are usually present at birth, asymptomatic, non-inflammatory and persistent. If the age of onset is uncertain they can be confused with viral warts [42]. Historically, verrucous epidermal naevi have been confused with a variety of epidermal naevi whose true identity has been recognized more recently, for example CHILD (*c*ongenital *h*emidysplasia with *i*chthyosiform naevus and *l*imb *d*efects) naevus.

Management of epidermolytic and non-epidermolytic epidermal naevi

Reports of the responses of epidermal naevi to various therapies have rarely distinguished between the different histological types. Therefore both are considered together here.

Topical applications are rarely curative and therefore have a limited place in the treatment of verrucous epidermal naevi [1]. Preparations containing salicylic acid, lactic acid or retinoic acid [2] may decrease the keratotic element to some extent but require persistent application to maintain any improvement. Podophyllum may help [3] but its toxicity precludes its use in larger lesions [4]. Successful treatment with topical 5-fluorouracil and retinoic acid [5,6], calcipotriol and calcitriol have been reported.

Cosmetically significant lesions may justify systemic retinoid therapy. Isotretinoin [7], etretinate [8] and acitretin [9] can produce worthwhile reduction of hyperkeratosis (in epidermolytic lesions). Patients and carers must understand that drug therapy is not curative and the condition will relapse if the treatment is stopped.

Even surgery is not curative unless underlying dermis is removed or destroyed at the same time as the epidermal component. Large lesions may require multistage, multimodality procedures, adapted according to anatomical site [10]. Skin-shaving procedures or dermabrasion thus tend to produce only temporary benefit. Cryotherapy is a simple alternative for smaller lesions. Laser is used increasingly, and improvements in technology and better selection of modality, are gradually overcoming problems such as hypertrophic scarring, pigmentary changes and partial recurrence. The argon laser is helpful for softer, less hyperkeratotic lesions [11]. Continuous-wave carbon dioxide laser vaporization has been used successfully for extensive verrucous epidermal nevus [12]. Pulsed carbon dioxide laser is better for thinner and softer verrucous epidermal naevi [13–16]. Small lesions have been vaporized in a single session but for larger lesions multiple treatment sessions are required. Staged carbon dioxide laser treatment using different modalities for thick and thin lesions cleared an extensive verrucous epidermal naevus with no recurrence in 2 years of follow-up [10]. Newer erbium : yttrium aluminium garnet (Er : YAG) lasers with greater coagulative capacity can also be used with good effect. A single treatment can produce good clearance with minimal tissue destruction and scarring [17], although in one series of 20 patients five lesions recurred within a year [18]. The pulsed ruby laser may reduce and lighten dark-coloured epidermal naevi, but patients with a darker skin type risk post-irradiation depigmentation [19].

Patients with epidermolytic verrucous epidermal naevi are at risk of parenting a child with BIE. If the patient is a child the carers

should probably be informed of this risk, and of the possibility of first-trimester antenatal diagnosis. Arrangements should be made to counsel the affected individual at a suitable age. Currently, we lack data that allow quantification of the risk. Patients with non-epidermolytic epidermal naevi can be counselled that these are sporadic lesions and are not passed on as a generalized skin condition. It has been suggested that the generalized condition is lethal [20], and affected individuals survive only if they are 'rescued' by mosaicism.

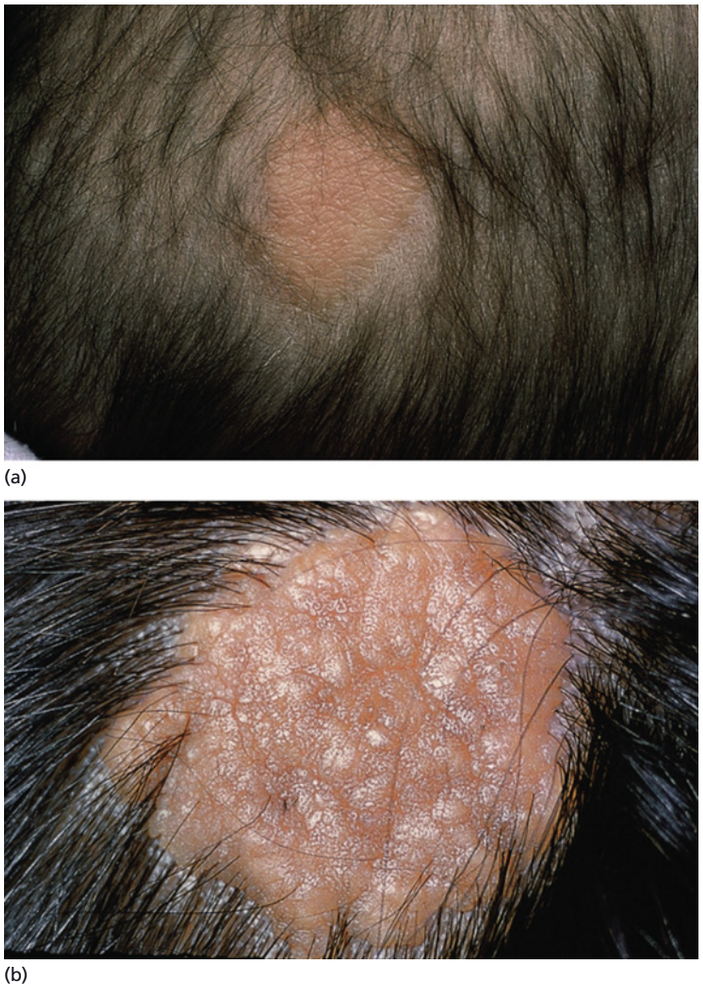
Sebaceous naevus

Synonym
- Naevus sebaceus of Jadassohn

Definition and aetiology. Sebaceous naevi are epidermal hamartomas comprised predominantly of sebaceous glands. The view that sebaceous naevi and verrucous epidermal naevi are variants of the same disorder, those on the head and neck being more sebaceous and those elsewhere more verrucous, is supported by the occurrence of both types in the same individual and in the epidermal naevus syndrome [1–3].

Sebaceous naevi are usually sporadic, probably reflecting lethal genes rescued by mosaicism (see above). There have been occasional reports of familial cases [4–6], perhaps reflecting inheritance of an unstable premutation, but attributed by Happle and Konig to paradominant inheritance [7]. Because sebaceous naevi have a tendency to develop tumours, various tumour genes have been implicated in their aetiology. Constitutive activation of the patched-hedgehog signalling pathway (involved in Gorlin's syndrome and basal cell carcinomas) was suggested by Xin *et al.* [8] who found loss of heterozygosity at the *PTCH* locus 9q22.3 in sebaceous naevi. However, this finding was refuted by Takata *et al.* [9] who also found lack of expression of *Gli-1*, another gene in the patched-hedgehog signalling pathway expressed in basal cell carcinomas. Mutations in the oncogene *PIC* have recently been reported in epidermal naevi [10].

Pathology [11,12]. Before puberty, the sebaceous and apocrine glands in these lesions are sparse and underdeveloped, so that the lesions may be indistinguishable from verrucous epidermal naevi. Cords and buds of poorly differentiated epithelial cells representing primordial pilosebaceous follicles are, however, a distinctive and diagnostic feature at this stage [11]. After puberty the characteristic mature sebaceous glands and associated papillomatous hyperplasia of the overlying epidermis are seen. Hair follicles are inconspicuous. Buds of undifferentiated epithelial cells resembling foci of basal cell carcinoma probably represent primordial hair follicles [12]. Merkel cells may be abundant [13]. Some lesions feature hypoplastic sebaceous glands, or sebaceous glands situated at an abnormally high level in the dermis. Ectopic apocrine glands are very commonly observed deep in the dermis beneath the sebaceous glands [11,12].



A variety of appendageal tumours, sometimes multiple, may develop within sebaceous naevi [14–31]. The most commonly reported are syringocystadenoma papilliferum and trichoblastoma [14]; less common tumours include nodular hidradenoma [15], apocrine cystadenoma [16], syringoma, infundibuloma and trichoadenoma [17] and trichilemmoma and pilomatricoma [18]. Locally invasive and malignant tumours include keratoacanthoma [19], proliferating trichilemmal cyst [20], and basal cell [21–24], sebaceous, apocrine [25], eccrine [26] and squamous carcinomas [17,23] and malignant melanoma [27]. Leiomyosarcoma occurred with trichoblastoma and syringocystadenoma papilliferum in one case [28]. The true incidence of malignancy in sebaceous naevi is difficult to determine for several reasons, but mainly because different criteria were used to gather cases in each of the larger series. Furthermore basaloid proliferation has almost certainly been misinterpreted as basal cell carcinoma, the commonest malignancy reported in sebaceous naevi (see below). Takata *et al.* [9] found clear molecular differences between the basal cell carcinoma-like trichoblastomas arising in sebaceous naevi and true basal cell carcinomas.

Clinical features. Sebaceous naevi occur in about 0.3% of all neonates [32,33]. They comprise circumscribed, slightly raised,

pinkish, yellow, orange or tan plaques, with a smooth or somewhat velvety surface. Although usually congenital, they are occasionally first reported later in life [34]. The sex incidence is equal.

The lesions may be round, oval or linear, varying in length from under 1 to over 10 cm. Their shape may be determined by the stage at which they arise, early lesions conforming to embryonic epidermal migratory lines, while later lesions arising in a more fixed epidermis are round (see Blaschko's lines, above). They most commonly occur singly, but may be multiple and extensive, like verrucous epidermal naevi. Most occur on the head and neck, favouring the scalp, the areas around the ears, the temples, forehead and the central part of the face. They can extend on to the oral mucosa [35]. Sebaceous naevi of the scalp are devoid of hair, and usually present with the complaint of a bald patch (Fig. 18.3).

Following birth, the lesions tend to become less prominent and then to remain unchanged until puberty, when they become thickened and more elevated. For this reason, many patients present at this stage. Gradually they become more nodular during adult life (Fig. 18.3). A sebaceous naevus of the external auditory canal presented with deafness due to secondary cerumen impaction in adulthood [36].

Fig. 18.3 Sebaceous naevus: (a) in a 6-month-old infant; (b) in an adult.

Development of an exophytic nodule on a naevus sebaceous usually represents a benign appendageal tumour or viral wart [31]. Rapid, circumscribed enlargement or ulceration should arouse suspicion of malignant transformation. This usually occurs in middle age, but can undoubtedly occur in adolescence, or even in childhood [19,37,38]. The lifetime risk of malignant transformation is probably less than 5%, but is difficult to establish with any precision because the major studies have varied considerably in methods of selection and in ages of the patients [11,12,29,31]. The most common malignancy is basal cell carcinoma, but the incidence of this tumour has been overestimated because of misinterpretation of trichoblastoma [14] and basaloid proliferation as basal cell carcinoma. Other malignant tumours reported include squamous [17,23,39], sebaceous [40], tricholemmal [41] and apocrine [25] carcinomas, and malignant melanoma [27]. Leiomyosarcoma occurred with trichoblastoma and syringocystadenoma papilliferum in one case [28]. Despite occasionally aggressive histopathological features, most of these tumours are of low-grade malignancy. Nevertheless, local recurrence after excision, metastasis and a lethal outcome have all been reported [29]. It is not unusual to find several different types of tumour arising from naevus sebaceous [17,18,28,41].

Associated abnormalities occur in a small proportion of cases: these are considered under the heading of 'epidermal naevus syndrome'.

Diagnosis. Diagnosis is usually straightforward on clinical grounds alone. In early infancy, lesions in the scalp must be distinguished from aplasia cutis, which has a smoother papyraceous surface. Syringocystadenoma papilliferum may be very difficult to distinguish clinically, although the surface tends to be pink and nodular, rather than yellow and velvety. Early juvenile xanthogranulomas may be similar in their clinical appearance, although these generally develop rapidly into distinctive domed, papular or nodular lesions. Solitary mastocytomas may also be confused clinically during infancy, but histological examination will clearly identify all these disorders. Multiple pigmented trichoblastomas arising in a naevus sebaceous resembled malignant melanoma [42].

Very rarely, heterotopic brain tissue or an encephalocoele may result in a congenital bald patch overlying a subcutaneous nodule [43]. They may communicate with the brain so it is important to distinguish them from sebaceous naevus.

Treatment. Removal during childhood may be necessary for cosmetic reasons but is difficult to justify on grounds of risk of malignancy [44]. Excision of scalp lesions with primary closure gives an excellent cosmetic result, but larger lesions may require tissue expansion. Simple excision is generally adequate even in the presence of histological malignancy. Superficial removal by dermabrasion or carbon dioxide laser is likely to be followed by partial recurrence but may be helpful where excision is not feasible [45]. An extensive naevus sebaceus of face and scalp in a 38-year-old

woman was cleared with 13 sessions of photodynamic therapy, with no recurrence 16 months later [46].

Follicular naevi

True hair-follicle naevus

Synonym
- Congenital vellus hamartoma

In the past, the lesions that are now more usually termed trichofolliculomas were often described as 'hair-follicle naevi' [1]. The term should be confined to a hamartoma comprising an excessive concentration of normal hair follicles [2,3]. This rare tumour, sometimes also called *congenital vellus hamartoma* [4], generally takes the form of a small, skin-coloured papule on the face, usually present from birth. Histologically, the lesion contains numerous small but well-differentiated vellus hair follicles in the dermis, with a few sebaceous glands and eccrine sweat glands. Hair follicle naevi following Blaschko's lines have been reported [5], in one case in association with epidermal naevi [6]. Subepidermal calcified nodule of the ear has been reported in a child with hair follicle

naevus [7]. These naevi can be differentiated from eruptive vellus hair cysts which arise later in childhood and usually occur on the chest. The treatment of choice is simple excision.

Comedo naevus

Synonyms
- Comedone naevus
- Naevus comedonicus
- Follicular naevus
- Acne naevus

Definition. First described in 1895 [1], the comedo naevus is a linear lesion comprising numerous keratin-filled pits, sometimes with acneiform pustules.

Aetiology. This is a rare naevus, fewer than 200 having been reported [2]. In a series of 235 epidermal naevi, Rogers found only four comedo naevi [3]. This is probably a mixed group, reflecting mosaicism for a variety of mutations that can predispose to acne. Acneiform naevi with predominantly inflammatory lesions may represent a clonal sensitivity to androgens [4–6]. The occasional histological finding of rudimentary hair follicles, sebaceous glands and trichilemmal cysts suggests a primary defect within the pilosebaceous gland. In naevi where comedones predominate, interfollicular histological changes typical of common verrucous epidermal naevi [7] or epidermolytic hyperkeratosis [8] suggest that follicular blockage is secondary to a keratinocyte defect. Comedo naevus on hair-bearing limbs contiguous with lesions involving eccrine ducts on the palms and soles, resembling *porokeratotic eccrine ostial and dermal duct naevus* [9–12], and glans penis [13], also supports a non-appendage-specific epidermal problem causing duct blockage.

Munro and Wilkie hypothesized that mosaicism for a dominantly inherited disorder featuring severe acne might account for some acneiform naevi [14]. Apert's syndrome, characterized by acne, craniosynostosis and other bony defects, seemed a good candidate. This would explain the occasional association with skeletal abnormalities [2], as well as the linear distribution of acneiform lesions, and was confirmed by demonstrating an *FGFR2* mutation in lesional epidermis but not in adjacent normal skin [14]. Comedo naevi might also result from mosaicism for mutations, as yet unidentified, causing two other autosomal disorders featuring widespread comedones. The first of these is most commonly called *familial diffuse comedones* [15,16], but has been reported under the term 'nevus comedonicus' [17]. The comedo-like lesions appear progressively and in a diffuse bilateral distribution. In the second, called *familial dyskeratotic comedones*, the comedones are less extensive and demonstrate dyskeratosis histologically [18–21].

Pathology [2,9,22]. The characteristic histological feature of a comedo naevus is an aggregation of deep, wide invaginations of acanthotic epidermis, filled with concentric lamellae of keratin. These probably represent dilated hair follicles, as hair shafts are occasionally seen in the lower part of the invagination [7,22,23], and rudimentary sebaceous glands may open into them [22]. Arrector pili muscles are absent. The interfollicular epidermis may be histologically normal, acanthotic and hyperkeratotic [7], or even epidermolytic [8,24,25]. Schecter [26] showed epidermolytic hyperkeratosis in the follicular epithelium. Other reported histological associations have included trichilemmal cysts [27,28].

Clinical features [29]. Comedo naevus comprises groups of pits filled with black keratinous plugs resembling blackheads with inflammatory acne lesions developing later. The intervening epidermis may appear normal, hyperkeratotic, or slightly hypo- or hyperpigmented [22,30]. Areas of more marked hypopigmentation have been reported by several authors [11,31]. There may be one or several lesions in a linear, unilateral [30,32–34] or, more rarely, bilateral distribution [23,35]. Lesions may be very extensive [2,31,35]. The commonest site is the face, followed by the neck, trunk and upper arm. Palms, soles [9–12] and the glans penis [13], from which pilosebaceous follicles are normally absent, may occasionally be involved, usually in association with lesions in more characteristic sites, and often contiguous with them [31,36]. Curiously, the scalp is rarely affected [34,36,37].

Predominantly comedonal naevi are occasionally present at birth, but inflammatory acneiform naevi more often appear during childhood [3,35] or adolescence [32]. They may be complicated by acneiform chronic inflammation, suppuration, fistula formation and hypertrophic scarring [2,7,30,34,35,38,39]. The development of multiple nodules within a comedo naevus may reflect the presence of associated trichilemmal cysts [27] or basal cell carcinomas [40].

There have been occasional reports of associated developmental anomalies, including ipsilateral cataract [3,41,42], extensive naevus flammeus [43], transverse myelitis [44] and perforating elastoma [45]. While some of these are probably coincidental, skeletal malformations [31,44,46–48] may be manifestations of mosaicism for an *FGFR2* mutation, causing patchy manifestations of Apert's syndrome. The characteristic features of Apert's syndrome include craniosynostosis, mid-face hypoplasia, syndactyly and broad distal phalanx of thumb. The patient reported by Patrizi *et al.* [47] with a comedo naevus on the right cheek, syndactyly and a broad right thumb, is very likely to have been mosaic for Apert's syndrome, although this was not investigated. Rogers' patient with extensive comedo naevus and syndactyly [3] may also have been mosaic for Apert's syndrome. An association with Page's disease of the bone and breast cancer was probably coincidental [42].

Diagnosis. Porokeratotic eccrine ostial and dermal duct naevus can be distinguished clinically by its occurrence on the palms and soles, and also histologically. Familial diffuse comedones and familial dyskeratotic comedones may be pathogenetically identical to comedo naevi (see above) but are symmetrical and widespread rather than linear. Atrophoderma vermiculata and keratosis pilaris atrophicans may show comedones, but can be distinguished from comedo naevus by their symmetry. The dilated pore naevus [49] can only be distinguished histologically. Comedones may occur in linear basal cell naevus. Comedo naevi have been reported historically as sequelae of lichen planus [50], herpes zoster [51], vaccination [52] and trauma [53], but the lesions described in these reports may simply represent an unusual pattern of scarring. Extensive comedones due to chloracne and sun damage are distinguishable from comedo naevus by their non-linearity.

Treatment. As with other epidermal naevi, surgical excision, if necessary with tissue expansion [54], is more effective in the long term than superficial shaving or dermabrasion [30], but the latter can occasionally be useful cosmetically if the lesions are extensive [53], as can the regular use of a comedo extractor [27]. Both topical retinoic acid and 12% ammonium lactate may sometimes improve the appearance of lesions [39,55], and may help prevent secondary inflammation. Tacalcitol [56], and tazarotene 0.05% with calcipotriene 0.005% daily [57] have also been used effectively. Although oral isotretinoin has been reported to be ineffective [58,59], it is logical to treat extensive, inflamed acneiform naevi with antiacne medication instead of, or in preparation for, surgical treatment.

'Acne-free' naevus

A single case has been reported of an adolescent male with severe papulopustular acne vulgaris of the back, who had, within the affected area, four well-defined bilaterally symmetrical zones, which were completely free of acne [1]. Investigation revealed smaller sebaceous glands, reduced sebum excretion rate, decreased counts of *Propionibacterium acnes* in the pilosebaceous ducts and reduced conversion of testosterone to 5α-dihydrotestosterone in the 'acne-free' zones. This may be another type of 'functional' naevus, possibly due to abnormal end-organ androgen responsiveness, and could be regarded as the converse of the situation in acne naevi.

Linear basaloid follicular hamartomas

Definition. A rare variety of epidermal naevus composed of multiple, benign, follicular basal cell hamartomas. The literature has not always differentiated this from linear basal cell naevi.

Aetiology. Some cases may represent mosaicism for autosomal dominant generalized basaloid follicular hamartomas [1–4].

Clinical features [5–8]. This benign, localized naevus is generally present from birth and may be extensive. The linear form consists of numerous, translucent or brown nodules or plaques, which occasionally demonstrate central ulceration, often associated with small areas of macular hypopigmentation. Other reported abnormalities in the affected area have included cysts, verrucous papules, basal cell carcinomas [9] and stria-like areas of cutaneous atrophy [10]. Solitary and plaque-like lesions occur in the scalp, usually associated with localized alopecia [7]. Normal hair growth on a scalp follicular hamartoma has been reported but the histology in that case was also atypical [8].

Pathology. Basaloid follicular hamartoma is characterized by anastomosing strands of well-differentiated basaloid or squamoid cells extending from the upper portions of follicles into a loose connective tissue stroma [5,7,8]. There may be trichoblastomatous proliferation [11]. It can be distinguished from basal cell carcinoma by its low proliferative index (Ki-67 expression) and by circumferential expression of CD34 around the epithelial strands [12].

Differential diagnosis. Confusion may arise with other adnexal tumours, particularly on the face. It must be differentiated from linear basal cell naevus.

Treatment. Treatment, if required, is usually surgical.

Linear basal cell naevus

Synonym
- Basal cell naevus with comedones

Definition. A linear collection of macules and papules histologically similar to basal cell carcinoma.

Aetiology. Some cases may reflect mosaicism for Gorlin's syndrome (linear basal cell naevus syndrome); however, Brailey *et al*. could not find mutations in *PTCH* in DNA from a linear basal cell naevus [1].

Clinical features. Unilateral smooth or warty papules [1,2], skin tag-like lesions and occasionally comedones [3–5] occur in a linear

distribution usually on the trunk or a limb. Malformations of the spine are rarely associated [4]. Skeletal malformations and palmar pits may reflect mosaicism for Gorlin syndrome [6].

Pathology. There is basaloid proliferation, peripheral palisading and surface erosion as seen in basal cell carcinoma. Distinction may rely on the young age of the patient. There may be stromal condensation around the basal cell nests [1].

Dilated pore naevus

While clinically indistinguishable from comedo naevus, histologically the dilated pore naevus shows aggregated dilated follicular cysts [1]. These cysts individually are indistinguishable from the dilated pore of Winer, a solitary lesion usually occurring on the face in middle-age. Steffen [2] has argued that the dilated pore of Winer is a primary neoplasm (infundibloma) rather than a cyst. A dilated pore naevus has also been described with onset in adulthood [3].

Hairy malformation of the palms and soles

This rare disorder appears to be transmitted as an autosomal dominant trait. Asymptomatic areas of skin, having a somewhat altered texture and bearing hairs, are present bilaterally on the palms near the wrists, and on the medial aspect of the longitudinal arch of the feet [1,2]. Histologically, these show no abnormality other than the presence of hair follicles. A sporadic case has been reported in which the abnormality occurred on one palm only [3]. Differential diagnosis will include congenital melanocytic naevus and smooth muscle hamartoma.

Apocrine naevi

True apocrine naevi

Synonym
- Apocrine gland hamartoma

True apocrine naevi are rare, although apocrine structures are frequently seen in sebaceous naevi [1] and syringocystadenoma papilliferum. The clinical appearance is variable and includes solitary nodules on the scalp [2], pigmented vulval papules [3], a plaque on the face [4,5] and bilateral soft tumours in the axillae or upper chest [6–9]. In a patient with focal dermal hypoplasia, the lesions comprised multiple papules in the sternal area [10]. Histologically, true apocrine naevi comprise large numbers of mature apocrine glands extending from the upper dermis to the subcutaneous fat. Decapitation secretion and periodic acid–Schiff (PAS)-positive diastase-resistant granules in the luminal cells differentiate apocrine from eccrine gland differentiation [5]. There is only one report of malignant transformation: an apocrine gland carcinoma was excised within an area of skin histologically consistent with apocrine nevus, but a preceding clinical lesion was not described [11].

Syringocystadenoma papilliferum

Synonym
- Naevus syringocystadenomatosus papilliferus

Definition. Syringocystadenoma papilliferum is a skin hamartoma with predominantly apocrine differentiation.

Aetiology. The histogenesis of these lesions is controversial. They show features of apocrine glands, or occasionally eccrine glands.

Syringocystadenoma papilliferum is a frequent component of sebaceous naevi and associated hamartomatous malformations of hair follicles and sebaceous glands are common. Yamamoto *et al.* [1] postulated an origin in pluripotent cells on immunohistochemical and ultrastructural grounds. Boni *et al.* [2] showed mutations in *PTCH* or *P16* tumour suppressor genes in syringocystadenoma papilliferum. Kazakov *et al.* noted an overlap with tubular adenoma [3].

Pathology. Histologically, cystic invaginations extend downwards from a papillomatous epidermis, with numerous villous projections extending into the lumen. The lining is glandular epithelium, comprising an outer cuboidal layer and an inner cylindrical layer occasionally demonstrating 'decapitation' secretion. Prominent apocrine glands deep to the invaginations, can be shown by serial sectioning to be connected [4]. A plasma cell infiltrate is present, particularly in the stroma of the papillary projections. Syringocystadenoma papilliferum shows focal positivity to CK15, a relatively specific marker of hair follicle stem cells in the bulge [5]. Basal cell carcinoma may develop [2], and rarely secondary adenocarcinoma (syringocystadenocarcinoma papilliferum) [6] and apocrine ductal carcinoma [7].

Clinical features. These lesions occur either as a nodular plaque, a linear group of nodules or a solitary nodule. The plaque and linear varieties are usually present at birth, or appear during infancy [8], and may become more elevated and nodular, verrucous or crusted at puberty. The less common solitary nodular form usually develops at puberty. The plaque form usually presents as a hairless area in the scalp, while the linear form is commoner on the neck or face. A mature lesion comprises clusters of pinkish brown nodules 2–10 mm in diameter, which are domed, umbilicated or pedunculated, often with a friable or crusted surface. Several lesions may be scattered over an area. The solitary nodular form predominates on the trunk, particularly the shoulders, the axillae and genital areas, and occasionally the limbs.

Ulceration or rapid enlargement may indicate malignant transformation, usually to basal cell carcinoma [2], but occasionally adenocarcinoma. In most such cases, there is a coexistent sebaceous naevus.

Naevi of this histological type may be associated with non-cutaneous abnormalities (see epidermal naevus syndrome).

Diagnosis. The plaque and linear forms on the head and neck may be difficult to distinguish clinically from sebaceous naevus, although syringocystadenoma papilliferum tends to be pinker and more nodular. The umbilication of individual nodules, particularly in the linear form, may cause confusion with molluscum contagiosum [8]. There is histological overlap with tubular adenoma [3].

Management. Because of the not infrequent development of secondary basal cell carcinoma, these lesions should be excised wherever possible. Pulsed carbon dioxide laser treatment of a surgically difficult lesion in and below the ear in a 2½-week-old baby produced 'reasonable cosmesis' with minimal recurrence at 3 years [9]. Secondary syringocystadenocarcinoma papilliferum occurs very rarely and has been treated successfully with Mohs micrographic surgery [6].

Eccrine naevi

Pure eccrine naevi

Synonyms
- Naevus sudoriferus
- Sudoriferous hamartoma

Although an eccrine component is commonly found in sebaceous naevus, purely eccrine naevi are very rare. They can present at any age and the clinical appearance is variable. In one case a solitary pore that discharged a mucoid secretion showed histologically numerous coils, comprising both secretory and ductal elements, situated deeply in the dermis and leading to a central dilated pore on the surface [1]. Two cases presented as nodules comprising numerous normally structured sweat glands and ducts surrounded by mucin, and were termed mucinous eccrine naevus [2,3]. An otherwise unremarkable area of diffusely increased sweat production, with histologically prominent eccrine glands, has been termed 'naevus sudoriferus' [4,5]. Other cases have taken the form of a small plaque [6], a congenital perianal skin tag [7], and grouped skin-coloured or brown papules, sometimes in a linear distribution [8].

Eccrine angiomatous naevus

Synonyms
- Eccrine angiomatous hamartoma
- Sudoriparous angioma

Definition. Eccrine angiomatous naevus is a rare condition characterized histologically by numerous eccrine structures and capillary channels, most commonly found in acral skin where eccrine glands are numerous. The term covers a spectrum of lesions ranging from the predominantly angiomatous 'sudoriparous angioma' [1] up to the normally vascularized naevus sudoriferus.

Pathology. Histologically, lesions show nests of large, but otherwise normal eccrine glands [2,3], enmeshed in loose fibrous tissue, which contains numerous thin-walled blood vessels and lymphatics [4]. There may be a very intimate association between the glandular and vascular elements [5,6]. The overlying epidermis may be mildly acanthotic. Other components, particularly hair follicles, may also be closely associated with the eccrine angiomatous complexes [7,8]. Some have shown fat [9,11,12] or mucin deposition [3,10]. Immunohistochemical findings are similar to normal eccrine glands [9].

Clinical features. This is very rare with only 42 cases in the English language literature [13]. These lesions appear at birth or during childhood in 77% of cases and affect both sexes equally [9,14]. They take the form of a nodule or plaque, flesh-coloured or with a bluish colour and angiomatous appearance. Eighty per cent occur on the extremities [14], particularly the palm and sole, but also on other parts of the feet, on the face, neck and on the trunk. Occasionally, there are multiple lesions [1,14–17]. Most are painful on pressure [4,9,18]. Nail destruction with underlying osteolysis has been reported [13]. Some demonstrate hypertrichosis [15] and/or hyperhidrosis [3], but not all [19]. Generally, they enlarge very gradually; more rapid growth has been described during pregnancy and adolescence [20]. One atypical case presented at the age of 73 years, on the buttock, and was verrucous [21]. They are usually unassociated with other anomalies but accompanied Cowden syndrome in one case [22] and neurofibromatosis in another [23]. A familial occurrence was noted in one report [17].

Treatment. Painful lesions may require removal, particularly those on the palm or sole; this has been successfully achieved by deep excision with full-thickness grafting [4], or by amputation [20]. Pulsed dye laser was helpful in only one of two patients [24]. Spontaneous regression has been reported [25].

Porokeratotic eccrine ostial and dermal duct naevus

Definition. Porokeratotic eccrine ostial and dermal duct naevus (PEODDN) is a localized area of plugged pores usually on the palm or sole. It has been recognized only since 1980 [1], early cases having been reported as comedo naevus of the palm [2], or linear eccrine naevus with comedones [3]. Several cases have been reported since [4].

Aetiology. This is presumably a mosaic genetic defect. As for comedo naevus, debate centres on whether the primary abnormal-

ity involves the epidermis or the appendage. Staining with carcinembryonic antigen (CEA) which labels the acrosyringium and dermal eccrine duct suggests that PEODDN represents an abnormally keratinizing epidermal invagination traversed by an acrosyringium-like duct, rather than a primary abnormality of the acrosyringium and dermal duct [5].

Pathology. Histologically, these lesions are characterized by dilated comedo-like epidermal invaginations filled with parakerotic plugs. The neighbouring epidermis demonstrates parakeratotic columns, which protrude above the rest of the stratum corneum. The granular layer is absent at the base of these columns, and in the lining of the comedo-like structures; keratinocytes with vacuolated cytoplasm and pyknotic nuclei may also be a feature. In the lower portion of the invaginations, intraepidermal eccrine ducts are generally visible, and there may be associated hyperplastic intradermal eccrine ducts with comma-shaped extensions. However many cases show no connection between the parakeratotic columns and eccrine ducts [6]. Bowen's disease was found in one case [7], and linear psoriasis in two others, in one case partially overlapping with the palmar lesion [8].

Clinical features. The lesions are asymptomatic and are usually present from birth, although onset later in childhood is reported in 26% [9,10]. PEODDN resembles comedo naevus, comprising small keratotic papules, with a central plugged pit, in a linear distribution, usually on the palms and soles [11]. At other sites, the lesions tend to be more verrucous, resembling verrucous epidermal naevi, sometimes with filiform vegetations [6]. PEODDN is occasionally quite extensive [1]. Involvement of all four limbs has been reported [12]. The lesions may be anhidrotic [1] or hyperhidrotic [2,10]. There are no known associated abnormalities.

Diagnosis. The entity described as *porokeratotic eccrine duct and hair follicle nevus* [13,14] is probably very closely related, the only real distinction being that hair follicles were affected as well as eccrine sweat ducts. Comedo naevi can be distinguished histologically, because they lack the characteristic intraepidermal and dermal eccrine ducts, and the parakeratotic columns. This disorder also appears to be distinct from *punctate porokeratosis* [15] in which multiple punctate, seed-like keratoses and/or pits are present on the palms and soles, occasionally in a linear configuration, and sometimes associated with linear porokeratosis. Punctate porokeratosis does not resemble comedones, either clinically or histologically, and the cornoid lamellae are not obviously associated with eccrine duct ostia.

Treatment. As for other epidermal naevi, simple excision is usually the treatment of choice. An adult-onset lesion on the hand resistant to topical keratolytics and cryotherapy responded to four treatments with the carbon dioxide laser and remained clear 9 months later [16]. Spontaneous involution has been reported over 24 years [17].

Becker's naevus

Synonyms
- Becker's melanosis
- Pigmented hairy epidermal naevus

Definition. An acquired and persistent asymmetrical area of skin pigmentation [1], sometimes showing evidence of increased androgen sensitivity, and co-localizing with other developmental anomalies.

Aetiology. The sporadic occurrence and asymmetrical distribution of most Becker's naevi suggest cutaneous mosaicism. Indeed, chromosomal mosaicism was reported in one patient with Becker's naevus [2]. A Becker's naevus has been reported to follow Blaschko's lines [3], but the usual lack of conformity to Blaschko's lines may be due to the relatively late occurrence of a causative mutation (see above). The mutant skin clone is presumably predisposed not only to pigmentation but also to androgen sensitivity, since Becker's naevus is prone to acne and hypertrichosis [4]. While most cases occur sporadically, Becker's naevus has been reported in siblings [5], father and son [6], and uncle and nephew [7]. As discussed above, familial occurrence of a mosaic disorder can be reconciled with mosaicism by mechanisms such as inheritance of an unstable premutation, paradominant inheritance [8]

and chance. Co-localization with other developmental anomalies suggests a clonal defect in morphogenesis. Becker's naevus may be pathogenetically related to congenital smooth muscle hamartoma, which also shows hypertrichosis, hyperpigmentation and increased smooth muscle, albeit in different proportions [6].

Clinical features. Becker's naevus is a relatively common anomaly, affecting most racial groups, and about five times more frequent in males than females [9]. It is rarely congenital [3,10], and may present in childhood, but is usually first noticed during adolescence, initially pale in colour and becoming more conspicuous after sun-exposure. Becker's naevus was found in 0.25% of 28 000 18-year-old Italian men enlisted for the navy [11], the reported age of onset being 5–17 years, mean 11.9 years. A higher prevalence, 0.52%, in 19 000 French recruits aged 17–26 [9], suggests that Becker's naevus may sometimes appear later. Once present, Becker's naevus remains indefinitely. The usual site is shoulder, anterior chest or scapular region, but lesions on face, neck and distal limbs have been reported [9,12]. It starts as an area of irregular macular pigmentation, which spreads to a diameter of several centimetres, new macules developing beyond the margin and fusing with it, giving a geographical contour. The skin may thicken towards the centre of the lesion. Increased terminal hairs may appear on and around the lesion, and were observed in 70% of the Italian cases [11].

Becker's naevus is more prone to acne vulgaris than the adjacent normal skin [4,13,14]. Other cutaneous anomalies reported to co-localize with Becker's naevus include tinea versicolor [15], eczema [16], granuloma annulare [17], basal cell carcinoma [18], lymphangioma [19] and hypohidrosis [20]. Becker's naevus was associated with generalized lichen planus in one case [10], and in another lichen planus was confined to a large Becker's naevus affecting the whole of one lower limb [21]. Lesions on the face may be associated with asymmetric growth of scalp or beard hair [22].

Although Becker's naevi generally occur without any associated pathology, several ipsilateral developmental abnormalities have been described, particularly breast hypoplasia [12,14,23–26] and supernumerary nipples [27], and also aplasia of the pectoralis major muscle [28], limb reduction [12], segmental odontomaxillary dysplasia [29] and lipoatrophy [24]. Spina bifida [23,30], scoliosis [28], pectus carinatum [23], congenital adrenal hyperplasia [2] and an accessory scrotum [31] have also been reported. The term *Becker's naevus syndrome* has been proposed to describe the association of a Becker's naevus with ipsilateral non-cutaneous abnormalities [25,32,33]. Hoon *et al.* [26] hypothesized that hypoplastic breast, like Becker's naevus, reflects increased androgen receptors; in their case spironolactone, an antiandrogen agent, effectively treated the breast hypoplasia but had no effect on the pigmentation. A report of a diffuse Becker's naevus on the face associated with ipsilateral hemimaxillary enlargement [34] supports the concept of Becker's naevus syndrome as a 'field defect', the associated anomalies usually co-localizing with the naevus.

The possibility of an increased risk of malignant melanoma in patients with Becker's naevus has been raised [35].

Pathology. Histological changes may be subtle. Well-developed lesions show hyperkeratosis, acanthosis and papillomatosis, with hyperplasia of hair follicles and sebaceous glands. The basal and suprabasal keratinocytes are heavily pigmented, and melanocyte density is variably reported as increased [36] or normal [37], with a few melanophages in the upper dermis. There are no junctional or intradermal naevus cells. The dermis is thickened, and contains numerous, but often inconspicuous, bundles of smooth muscle fibres, unrelated to hair follicles or blood vessels [37]. Ultrastructurally, there is evidence of enhanced melanin synthesis, with increased melanocyte activity and increased numbers of melanosome complexes in keratinocytes [38,39]. Giant melanosomes have been reported both in melanocytes and keratinocytes [40]. Increased numbers of androgen receptors [4] and androgen receptor messenger RNA (mRNA) [41] have been found in lesional skin.

Diagnosis. A well-developed Becker's naevus is unmistakeable. In early lesions, age of onset, geographical outline and site help to distinguish Becker's naevus from a café-au-lait macule and from linear and whorled naevoid hypermelanosis. Acquired smooth muscle hamartoma has similar clinical and histological features, but in different proportions, with less pigmentation and more smooth muscle [42]. Whether *progressive cribriform and zosteriform hyperpigmentation* [43] should be regarded as a non-hypertrichotic variant of Becker's naevus is unclear.

Treatment. Benefit from the Q-switched ruby laser has been reported [44], but reactive patchy hyperpigmentation may recur [45]. In a 27-year-old man, three treatments with the 694-nm long-pulsed ruby laser decreased hair density as well as pigmentation, the improvement lasting for the 10 months of follow-up [46]. Trelles *et al.* [47] used either a single treatment with the Er:YAG laser or three treatments with the Q-switched Nd:YAG laser in 22 patients with Becker's naevus, and followed patients up for 2 years. Both groups reported excellent clearance at 1 month. However after 2 years, pigment clearance was rated nearly 80% in the Er:YAG group, with six patients completely clear and the remainder improved by more than 50%. By contrast, pigment clearance in the Nd:YAG group had dropped to 20%. Expert skin camouflage advice can be helpful [48].

Inflammatory epidermal naevi

Inflammatory linear verrucous epidermal naevus (ILVEN) and CHILD naevus present at or soon after birth and usually persist lifelong. They can thus be distinguished from naevoid variants of inflammatory dermatoses which occur later and often resolve, including linear lichen planus, naevoid psoriasis, lichen striatus and adult Blaschkitis. However, all comprise hyperkeratotic lesions following Blaschko's lines, with histological evidence of inflammation. Probably all reflect genetic mosaicism, the former for potentially lethal dominant mutations rescued by mosaicism, and the latter for multifactorial dermatoses with an autosomal dominant component.

Inflammatory linear verrucous epidermal naevus

Synonym
- Dermatitic epidermal naevus

Definition. A pruritic, erythematous scaly lesion following Blaschko's lines [1].

Aetiology. ILVEN is probably due to mosaicism for a dominant mutation, as yet unidentified, which would be lethal if it affected all cells and is 'rescued' by mosaicism [2]. More recently, Happle [3] has suggested that linear skin disorders such as ILVEN might reflect the action of a retroviral transposable element ('retrotransposon') that is partly expressed and partly silenced at an early developmental stage. ILVEN is usually sporadic, in keeping with both hypotheses, but there have been reports of familial cases, including two in which mother and daughter were affected [4,5] and one involving mother, two sons and (reportedly) maternal grandfather [6]. Two cases in patients positive for human immunodeficiency virus 1 (HIV-1) [7], suggested clonal dysregulation of growth triggered by infection. However, the histology of these two lesions resembled psoriasis, which is known to be associated with HIV infection. Absent involucrin expression in the parakeratotic epidermis has been reported, a finding that appears to distinguish ILVEN from psoriasis [8].

Pathology. The characteristic histology shows columns of hypergranulosis with orthokeratotic hyperkeratosis alternating with equally well-defined columns of agranulosis and parakeratotic hyperkeratosis [9]. Other cases simply show a rather psoriasiform chronic eczema. Spongiosis is occasionally seen. An associated upper dermal lymphohistiocytic inflammatory infiltrate is regularly present.

Clinical features. About 75% of ILVENs appear during the first 5 years of life, most often in the first 6 months, although later onset has been recorded [4,5,10,11]. About 25% extend beyond their initial presentation, usually over a few months, but in one case over 9 years [12]. They are characterized by pruritus, which may be intense. The lesions are linear, most commonly on a limb, and comprise eczematous or psoriasiform papules (Fig. 18.4). ILVEN can be of any length, occasionally extending the whole length of a limb. As with other epidermal naevi, nail dystrophy may occur when the nail fold is affected [13]. Occasionally, ILVEN is bilateral and widespread [13–15]. Occasional reports of limb reduction anomalies associated with ILVEN on the adjacent skin have led to the suggestion that ILVEN represents a limited form of CHILD naevus, and that ILVEN and CHILD would more appropriately be named, respectively, PEN and PENCIL, indicating *p*soriasiform *e*pidermal *n*aevus with or without *c*ongenital *i*psilateral *l*imb defects [16]. In one case, ILVEN on the scrotum and penis was associated with ipsilateral undescended testicle [17]. A report of two girls with ILVEN and arthritis suggested a new association [18], but linear psoriasis with psoriatic arthropathy seems a more likely diagnosis for their symmetrical, distal, methotrexate-responsive arthritis; skin histology was not reported.

Although generally persistent and resistant to treatment, some lesions have been reported to resolve spontaneously [10].

Fig. 18.4 Inflammatory linear verrucous epidermal naevus on the posterior thigh.

Differential diagnosis. Earlier reports confused ILVEN with naevoid psoriasis, and with epidermal naevi in which psoriasis had developed as an isomorphic phenomenon [19–22]. Several patients have been reported in whom naevoid psoriasis and ILVEN both appeared to be present [23–25]. Transient inflammation of an ILVEN coinciding with an outbreak of guttate psoriasis probably reflects koebnerization of the ILVEN by psoriasis [12,25,26]. ILVEN can be distinguished from true naevoid psoriasis by pruritus and lack of response to antipsoriatic treatments [23,27]. Sodium dodecyl sulphate polyacrylamide gel electrophoresis (SDS-PAGE) has identified stratum corneum fibrous polypeptide patterns distinct from those seen in psoriasis [28,29]. In ILVEN lesions, Vissers *et al.* found increased keratin 10 expression and reduced Ki-67, CD4, CD8, CD450RO, CD2, CD25, CD94 and CD161 positive cells compared with psoriasis; a case of ILVEN with psoriasis was histologically intermediate [30]. Lichen striatus is distinguished by its rapid development, generally after the first year of life, by its relative lack of pruritus, by its more lichenoid clinical and histological features, and, eventually, by its spontaneous involution. The distinction between CHILD syndrome and ILVEN is uncertain [16,31,32]. An ILVEN-like lesion present for 6 months on one arm of an 11-year-old boy showed features of mycosis fungoides histologically [33].

Treatment. ILVEN is notoriously resistant to treatment, although occasionally spontaneous resolution occurs. Potent topical corticosteroids applied under occlusion, or intralesional steroid injections, provide little more than temporary symptomatic relief [11]. Similarly, topical retinoids appear to provide no benefit [34]. Successful treatment with dithranol [23] suggested that the true diagnosis was naevoid psoriasis. Calcipotriol or tacalcitol in some cases merely reduce the redness and itching, while in others have produced prolonged clearance [35–39]. Calcitriol used for 8 months completely cleared a lesion on the leg [40]. A lesion on the leg of an 11-year-old girl, that had proved resistant to topical steroids alone, resolved completely with tacrolimus and fluocinonide under occlusion for 2 weeks, then without occlusion for 8 weeks, and remained clear 2 years later; part of the lesion extending on to the foot responded less well [41]. Effective systemic treatments have included acitretin [42] and etanercept [43].

Cryotherapy may be a reasonable approach, particularly for smaller lesions [44]. Surgical excision tends to be followed by rapid recurrence unless a generous depth of underlying dermis is removed [13,45]. Successful treatment has been reported with the flashlamp-pumped pulsed tuneable dye laser [46]. ILVENs treated with the carbon dioxide resurfacing laser have remained clear for up to 2 years of follow-up [47–49], but this laser is less effective for ILVEN than for non-inflammatory verrucous epidermal naevi [49].

The CHILD naevus

Definition. CHILD is an acronym for *c*ongenital *h*emidysplasia with *i*chthyosiform naevus and *l*imb *d*efects [1]. Internal organs are often hypoplastic on the affected side. The CHILD naevus is the characteristic skin lesion observed in this disorder.

Aetiology. CHILD syndrome is an X-linked dominant trait, with a strong female predominance and antenatal lethality in males. Survival of a karyotypically normal male can be attributed to a somatic mutation on the X chromosome [2]. It is usually sporadic but mother-to-daughter transmission has been reported in several cases [3] with considerable variation in severity within families [4]. Initially it was thought to be allelic to X-linked dominant Conradi–Hünermann syndrome. Both conditions share the clinical features of linear scaling and asymmetric limb reductions, with peroxisomal deficiency in fibroblasts from involved areas of skin [5] and elevated plasma 8-dehydrocholesterol and 8(9)-cholesterol levels [6]. Grange *et al*. [6] indeed found a nonsense mutation in the X-linked dominant Conradi–Hünermann syndrome gene, 3β-hydroxysteroid-δ8,δ7 isomerase, or emopamil binding protein

(EBP) at Xp11.22–23 , in a patient with CHILD syndrome. However, this finding has not been repeated, and Grange's patient may in fact have had X-linked dominant Conradi–Hünermann syndrome, a diagnosis in keeping with improvement in her ichthyosis. Simultaneously, Konig *et al.* [7] found, in both sporadic and familial patients with CHILD syndrome, mutations in *NSDHL* (NAD(P)H steroid dehydrogenase-like protein) gene at Xq28. Several further reports have confirmed this as the CHILD syndrome gene [8–10].

NSDHL functions upstream of EBP in cholesterol biosynthesis. CHILD syndrome and X-linked Conradi–Hünermann syndrome are examples of inborn errors of cholesterol biosynthesis, manifesting profound abnormalities of early embryogenesis. Smith–Lemli–Opitz syndrome is another example, and these disorders demonstrate the importance of cholesterol in early embryonic development [11,12], known to be via the hedgehog signalling pathway. *NSDHL* mutations in mice produce the 'bare patches' and 'striated' phenotypes [13]. Microarray studies of mutant mouse fibroblasts show changes in expression of numerous other cholesterol-related genes [14]. Male lethality in mice is associated with a thinner placenta with fewer fetal vessels [15]. The extreme lateralization of CHILD syndrome contrasts with symmetry of X-linked dominant Conradi–Hünermann syndrome and has not yet been explained satisfactorily; it is curiously not a feature of the female mouse *NSHDL* mutants [8]. CHILD syndrome might be an extreme form of ILVEN, an alternative name covering the whole spectrum being PEN or PENCIL [16]. This idea has been contested by Happle [17]. It could now be tested, knowing the defect in CHILD syndrome.

Pathology. Light microscopy [18] shows marked acanthosis, and areas of parakeratosis within a largely orthokeratotic epidermis. There is exocytosis of neutrophils, with focal collections resembling Munro microabscesses. The dermis contains a patchy lymphohistiocytic infiltrate. Some biopsies, particularly those taken from flexural sites, may show enlarged dermal papillae containing foamy lipid-laden histiocytes (verruciform xanthoma) [17,19,20]. Although verruciform xanthoma is very characteristic of CHILD naevi, it can also occasionally be seen in severe dystrophic epidermolysis bullosa and pemphigus vulgaris, and it may also be a feature of biopsies taken from the mouth, vulva or penis. Two of seven verruciform xanthomas showed mutations in *NSDHL* [21]; not all exons were examined.

Ultrastructurally [18,22], many corneocytes contain lipid vacuoles. Vesicular structures, probably abnormal lamellar granules, are seen in the intercellular spaces of the epidermis, and become more numerous as cornification progresses. Large intracytoplasmic vacuoles are seen within papillary dermal foamy cells [22]. Confocal microscopy localized tagged proteins encoded by mutant and wild-type *NSDHL* to lipid droplets as well as the endoplasmic reticulum [23,24].

Clinical features. Most affected individuals are female. CHILD naevi are usually present at birth, but occasionally first appear during the first few months of life or even later. Lesions may extend during life, and rarely regress. The lesions are generally asymptomatic, comprising well-circumscribed areas of erythema covered in waxy scales, sometimes with a verrucous surface. There is a marked preference for flexural areas (*ptychotropism*) [25], where oozing vegetations may develop. Squamous carcinoma has been reported [26]. Characteristically, lesions are confined or concentrated on one side of the body, with sharp midline demarcation. In more severe cases, one side of the body may be diffusely affected, usually but not always [27] with sparing of the face and the oral mucosa. Sometimes the distribution is more streaky, following Blaschko's lines, and sometimes both linear and diffuse unilateral patterns coexist in the same patient. Manifestations may be extremely mild, even confined to the skin of a single digit, when the diagnosis is only recognized in the presence of a severely affected proband [4]. Konig *et al.* [28] reported bilateral, almost symmetrical involvement in a woman with a novel missense mutation of *NSDHL*.

A wide variety of non-cutaneous anomalies have been reported in the CHILD syndrome [1,27,29,30]. Unilateral bone defects are particularly characteristic, and most likely to affect the long bones. The severity of limb lesions varies from hypoplasia of a few metacarpals or phalanges to complete absence of an entire limb. Hands or feet may be grossly deformed. Scoliosis may be present. In some cases, punctate epiphyseal calcifications have been shown radiologically in the first few months after birth; these disappear later.

Unilateral hypoplasia of the brain, cranial nerves or spinal cord may be present, with mental retardation, electroencephalogram (EEG) abnormalities and sensory defects.

Congenital cardiac defects may be present, and are perhaps the main cause of early death of children with CHILD syndrome. Other anomalies of the kidneys, lungs and other internal organs have been described.

Diagnosis. Naevoid psoriasis, ILVEN and epidermal naevus syndrome can be confused with CHILD syndrome. Psoriasis is less persistent and does not show waxy scales clinically or verruciform xanthoma histologically. In contrast to CHILD naevi, ILVEN does not show flexural preference, and tends to be exclusively linear. The distinction from epidermal naevus syndrome is perhaps semantic. CHILD syndrome when first delineated had to be distinguished from epidermal naevus syndrome as it was then understood [31]. More recently, Happle has reclassified CHILD syndrome as an epidermal naevus syndrome [32].

Treatment. CHILD naevi appear to be highly refractory to all treatment, except occasionally oral retinoids [3,26].

Other naevoid epidermal disorders

Several generalized dermatoses occasionally follow Blaschko's lines, probably reflecting a clonal 'susceptibility mutation'. Linear lichen planus, psoriasis, Darier's disease, Hailey–Hailey disease, porokeratosis, atrophoderma of Moulin, and 'adult Blaschkitis' or BLAISE (*B*laschko *l*inear *a*cquired *i*nflammatory *s*kin *e*ruption) are described below. Linear lichen nitidis [1], lichen striatus (eczema) [2], segmental vitiligo [3] and linear morphoea [4] are discussed elsewhere in relation to the appropriate generalized disorder. The following have also been reported in a linear or naevoid distribution: lupus erythematosus [5], fixed drug eruption [6], chronic graft-versus-host disease [7] and mycosis fungoides [8].

Linear lichen planus

Some acquired linear lesions resemble lichen planus in all but their distribution [1,2]. They can occur at any age and resolve leaving post-inflammatory pigmentation. In some cases there is no history of preceding inflammatory lesions, and the appearance is indistinguishable from linear ashy dermatosis [3]. If linear lichen planus extends to the end of a digit there may be associated nail dystrophy, and similarly there may be mucous membrane involvement [4]. Linear lichen planus is sometimes mutifocal [5] and in one female recurred three times after successive deliveries [6]. Linear lichen planus affecting the left chest and shoulder and progressing down the left arm was reported in a patient with metastatic carcinoma of the left breast [7]. Linear lichen plano-pilaris has also been reported, usually on the face [8].

Histologically, linear lichen planus shows a lichenoid band-like lymphohistiocytic infiltrate at the dermal–epidermal junction, plus Civatte bodies and dermal melanophages [1,2]. Severe epidermal apoptosis has been observed [9]. It seems likely that linear lichen planus represents lichen planus localized to Blaschko's lines by a clonal 'susceptibility mutation'.

Naevoid psoriasis

Psoriasis occasionally occurs in a 'naevoid' form [1], possibly reflecting mosaicism for a gene responsible for psoriasis. Linear psoriasis coexisting with generalized psoriasis may represent loss of heterozygosity for a psoriasis gene, or invasion of a verrucous epidermal naevus by psoriasis as a result of the isomorphic phenomenon [2–5]. Onset is usually during childhood, but some otherwise typical cases have presented at birth [6–8]. The lesions are clinically indistinguishable from ordinary psoriasis other than in their distribution, and are histologically identical. Linear psoriasis can be associated with nail pits [9] and psoriatic arthritis [10]. This condition responds to antipsoriatic therapy such as ultraviolet radiation [9] or dithranol [11]. A boy with extensive linear psoriasis associated with severe psoriatic arthritis showed dramatic improvements of joints but not skin with infliximab, while neither responded to etanercept [10]. Linear psoriasis has been reported in association with PEODDN [12] and can be distinguished from ILVEN [13] by its minimal pruritus and therapeutic responsiveness.

Linear Darier's disease

Synonym
- Acantholytic dyskeratotic epidermal naevus

Several patients have been reported with acantholytic epidermal naevi comprising crusted keratotic papules, clinically and histologically resembling Darier's disease, but with no family history of Darier's disease [1–10]. Such naevi usually appear after the age of 20 years. The lesions can extend over many years and are aggravated by UV exposure [1,3]. If the affected area includes the nails, typical nail changes of Darier's disease may occur [4], and if the hands are affected, pits and keratoses may be observed within the involved zone [4]. One patient developed herpes zoster in the same distribution [11].

The suggestion that such naevi represent mosaicism for Darier's disease has now been confirmed by finding a mutation in the Darier's disease gene *ATP2A2* in the naevus, but not in unaffected skin [7]. The existence of a 'non-Darier' congenital linear acantholyitic naevus remains uncertain [12]. Mutation analysis of *ATP2A2* was negative in DNA from involved skin in one such case [13].

Treatment is as for other linear epidermal naevi. It appears that topical retinoic acid may be useful [1], and it would be anticipated that oral acitretin might be of value where the distribution is extensive.

Linear Hailey–Hailey disease

Synonym
- Relapsing linear acantholytic dermatosis

A distinctive form of epidermal naevus has been reported, in which well-defined linear erythematous plaques demonstrate vesiculation, erosion and crusting, and the typical histological features of benign familial chronic pemphigus (Hailey–Hailey disease) [1,2]. This type of naevus has an early onset, and a highly characteristic course, with periods of spontaneous improvement followed by relapse. It is likely that this represents mosaicism for a mutation in the Hailey–Hailey disease gene *ATP2C1* [3].

A 5-year-old patient apparently inherited the condition from her mother and grandmother, in whom the disease was manifest only in the perianal area [1]. A possible explanation was that the Hailey–Hailey mutation was transmitted in the usual autosomal dominant manner, with limited flexural disease presenting in early adult life, while the child was mosaic for a loss-of-heterozygosity (Happle type 2 mosaicism [4]), and accordingly developed more severe and earlier onset disease in a linear distribution. This patient later developed typical symmetrical flexural disease, and molecular analysis confirmed a germline *ATP2C1* mutation with loss of heterozygosity in the linear lesion [5].

A single case of a distinctive type of keratinocyte naevus has been reported as 'naevus corniculatus' [6]. Clinically, the naevus featured filiform and horn-like keratoses, and giant comedones. Histologically, the lesion showed acantholytic changes more closely resembling those seen in Hailey–Hailey disease than in Darier's disease.

Linear porokeratosis

Definition. This naevus, distributed along Blaschko's lines, is characterized by annular plaques clinically and histologically indistinguishable from the lesions of generalized porokeratosis [1].

Aetiology. Linear porokeratosis probably reflects mosaicism for a gene responsible for generalized porokeratosis. This idea is supported by the fact that the generalized forms of porokeratosis (porokeratosis of Mibelli, disseminated superficial actinic porokeratosis (DSAP), and porokeratosis plantaris palmaris et disseminata) can be inherited as autosomal dominant genes, whereas the linear variant usually occurs sporadically. The report of linear porokeratosis in monozygotic twins [2] can be reconciled with the idea of mosaicism by postulating that a somatic mutation in the porokeratosis gene occurred before the twinning division, so that the aberrant clone was present in both embryos. Reports of pre-existing linear porokeratosis in patients later developing DSAP [3–9], and the occasional occurrence of linear porokeratosis in the children or siblings of patients with DSAP [3,4,9,10] can be explained by loss of heterozygosity for this dominant gene, that is Happle type 2 mosaicism [7,11]. According to this hypothesis, an individual with inherited generalized porokeratosis undergoes a somatic mutation affecting the normal allele resulting in clonal loss of heterozygosity. The resultant line contrasts with the background skin because it has 'double the dose' of porokeratosis. Skin cancers in porokeratosis are particularly associated with the linear variant [12–15], in keeping with Happle's suggestion of loss of heterozygosity [11]. The role of *p53* is uncertain: overexpression of *p53* has been reported in linear porokeratosis [16,17] and in a superimposed squamous carcinoma, but not in the adjacent porokeratosis [14].

Generalized porokeratosis can be provoked by immune suppression [1]. Hunt *et al.* [18], however, reported exacerbations of linear porokeratosis during episodes of liver failure, and improvement following transplantation.

Clinical features. The lesions of linear porokeratosis comprise grouped and confluent hyperkeratotic plaques, each with a fine, rounded, annular rim and an atrophic centre. Lesions may be hyper- or hypopigmented and/or erythematous, and are disposed in an interrupted linear fashion along Blaschko's lines. They may be widespread [19] and can occur on the soles [20] or face [21]. Lesions affecting a distal limb may be associated with nail dystrophy such as pterygium and longitudinal ridging [19,22,23], and in one case there was bony narrowing of the digit [23]. The lesions are often present at birth, when they may be ulcerated [24]. Occasional spontaneous resolution has been described [25,26], but generally the lesions are lifelong, with increasing hyperkeratosis. There is a predisposition to skin cancer within the lesions, including squamous cell carcinomas [12] which may be multiple [15], and Bowen's disease [27].

Management. A variety of treatments has been used with variable success; of these the most consistently successful have been surgical excision [12,28] and ablation with the carbon dioxide laser [29]. Other helpful topical treatments have included cryotherapy [30], dermabrasion [28,31], 5-fluorouracil [32,33], tretinoin [33], 5% imiquimod [34], vitamin D analogues, urea [35], dithranol [2], and 0.05% tretinoin [19]. Many of these topical agents caused initial inflammation which was followed by resolution. Oral retinoids proved helpful in two cases [36,37], but etretinate in another case worsened the porokeratosis [38].

Linear atrophoderma of Moulin

In some patients, clearly demarcated cutaneous atrophy and hyper- or hypopigmentation with minimal inflammation and sclerosis is distributed along Blaschko's lines [1–3]. Histologically, there is variable atrophy and some inflammation. It usually appears during childhood or adolescence. Variability in presentation suggests that this is not a single entity [4], and some cases might represent a linear variant of atrophoderma of Pierini and Pasini, mosaicism for a *COL3A1* mutation (i.e. linear Ehlers–Danlos syndrome type IV) or a late 'burnt out' stage of linear morphoea. One atypical congenital case showed no inflammation or sclerosis [5]. Psoriasiform histology was reported in another case [6]. Linear atrophy with telangiectasia has been reported in linear atrophoderma of Moulin [7] but is more commonly seen in Goltz focal dermal hypoplasia. An association of right-sided linear atrophoderma with leukonychia of both hands may have been coincidental [8].

Adult Blaschkitis

Synonyms

- Blaschko linear acquired inflammatory skin eruption
- BLAISE

This remitting and relapsing eruption of itchy inflammatory vesicles and papules occurs usually on the trunk in adults [1]. The histology is more eczematous (spongiotic) than lichenoid. It would be difficult to distinguish from linear Grover's disease [2]. Brinkmeier *et al.* [3] reported Blaschkitis after 2 days of metronidazole

therapy. Rechallenge with two oral doses of metronidazole 3 months later provoked a relapse after 3 days. Lipsker *et al.* found mosaicism for various anomalies of chromosome 18 in a woman with Blaschkitis [4]. Taieb *et al.* [5] and Hofer [6] considered that 'adult Blaschkitis' represents an adult version of lichen striatus and Taieb proposed the acronym BLAISE to cover both. BLAISE should perhaps be regarded as a description rather than a diagnosis, a useful category for many of the disorders in this section, pending more precise identification.

The epidermal naevus syndromes

Non-epidermolytic epidermal naevi can be associated with a wide range of abnormalities in other systems (epidermolytic verrucous epidermal naevi are not, as the causative keratin gene mutations are expressed only in skin). Historically [1,2], the term 'epidermal naevus syndrome' referred to the association of sebaceous naevus with neurological, ocular and sometimes other abnormalities. Later, the term was extended to cover almost any multisystem disorder featuring sebaceous or verrucous epidermal naevus [3]. More recently, Happle has used the term 'the epidermal naevus syndromes' to include at least six separate disorders, namely: Schimmelpenning's syndrome, Proteus syndrome, comedo naevus syndrome, CHILD syndrome, Becker's naevus syndrome and phakomatosis pigmentokeratotica [4,5]. This has created two difficulties: firstly, most dermatologists would not regard Becker's naevus as an epidermal naevus; secondly, changing the meaning of 'epidermal naevus syndrome' leaves us without a name for the entity well established in the literature as 'epidermal naevus syndrome' [6], none of the historical eponyms being satisfactory.

Therefore, this account maintains the original and well-established use of the term 'epidermal naevus syndrome' as 'the association of sebaceous and/or verrucous epidermal naevi with other developmental defects, particularly of the CNS, eye and skeleton'. The term 'epidermal naevus syndrome' as used here does not include syndromes where the naevus is not a sebaceous or verrucous epidermal naevus (e.g. Becker's naevus, CHILD naevus). Neither does it include those conditions which feature epidermal naevi but are sufficiently distinctive to merit their own name (Proteus syndrome and phakomatosis pigmentokeratotica). We can also separate out those syndromes which lack neurological manifestations and have been defined in molecular terms, including comedo naevus syndrome (due to mosaic *FGFR2* mutations), the association of facial asymmetry with epidermal naevus due to mosaicism for the *FGFR3* mutation R248C [7] and a Proteus-like syndrome with loss of heterozygosity for a *PTEN* mutation [8]. Even after excluding all these, epidermal naevus syndrome remains a heterogeneous group, within which further conditions will be defined in the future. Eventually, when all the different mutations responsible for epidermal naevus syndrome have been defined, the term may become redundant, but for the moment it remains useful.

Epidermal naevus syndrome

- Organoid naevus syndrome
- Jadassohn's naevus phakomatosis

Definition. Epidermal naevus syndrome [9] describes the association of sebaceous and/or verrucous naevi with other developmental defects, particularly of the central nervous system (CNS), eye and skeleton, first reported by Feuerstein and Mims [1] and Schimmelpenning [2]. Other authors have used the term *Jadassohn's naevus phakomatosis* to describe this association [10]. Although early reports only included sebaceous naevi, the term is now used to include patients with verrucous naevi. The associations with both types of naevi are very similar, and some patients have both verrucous and sebaceous naevi, differentiation depending largely on the site, lesions on the head and neck being more often sebaceous [9].

Aetiology. Epidermal naevus syndrome is a sporadic disorder, probably reflecting genetic mosaicism for an autosomal dominant mutation which would be lethal if not 'rescued' by mosaicism [11]. To explain discordance in monozygotic twins, the mosaicism must have arisen after conception [12] and after the division into twin zygotes; the limited involvement (right eye and right side of the scalp only) in the affected twin is also consistent with a relatively late mutation. Occasional occurrence in successive generations can be explained by inheritance of an unstable pre-mutation, or by loss of heterozygosity for a recessive mutation ('paradominant inheritance' [13]).

Clinical features. The cutaneous element of epidermal naevus syndrome can be sebaceous naevus, verrucous epidermal naevus [3,9,14–16] or syringocystadenoma papilliferum [17]. The naevus may grow abnormal hair, such as woolly hair [18], long, pale 'angora' type hair [19] or hair associated with follicular hyperkeratosis [20].

Additional cutaneous abnormalities seen in some patients include infantile haemangiomas, naevi flammei, hypochromic naevi, café-au-lait macules [21,22], congenital melanocytic naevi [22–24], Spitz naevi [25,26], follicular hyperkeratosis and dermatomegaly [14,16]. One infant had a large congenital turban tumour (cylindroma) considered to have developed within the apocrine structures of the naevus sebaceous [27]. Ipsilateral facial lipoma with hemimegalencephaly has been reported in three cases of epidermal nevus syndrome [28] and intracranial and orbital lipomas have also occurred [29].

Sometimes, the epidermal naevus involves the mucosae of the mouth, anus or genitalia [9,16,30,31]. Oral involvement may include dental enamel hypoplasia, malformations of the teeth and hypodontia [14,30] and maxillary giant cell granuloma [32].

Significant developmental anomalies occur in approximately 1.7% of all neonates [33] and 10% of children with epidermal naevi, the risk correlating poorly with number and extent of lesions. Skeletal deformities reported in the epidermal naevus syndrome include kyphosis, scoliosis, cystic and lytic changes, hypertrophy and atrophy, short limbs and syndactyly [9,14,16,34].

A wide variety of neurological abnormalities has been identified in about 50% of patients with epidermal naevus syndrome [10,16,17,35–42]. Neurological abnormalities are much more frequent in patients who have sebaceous naevi on the head and neck [15,16,35,42], but the location of the skin lesions does not provide reliable prediction of the laterality of intracranial brain anomalies [43]. Seizures, especially infantile spasms, occur in some 50% of patients, many of whom have underlying structural abnormalities of the CNS [44]. Mental retardation also occurs in about 50% of cases; it varies in degree, but may be profound. Spastic hemiparesis affects about 20% of patients and may have its onset at any time from birth to adolescence; spastic tetraparesis has also been described. Conductive [45] and sensorineural deafness [14] occur. The commonest structural CNS abnormalities have been ipsilateral gyral malformations and complete or partial hemimegalencephaly [37,44,46–49], but others have included vascular malformations [29,36,50–53], hemiatrophy [38,40,54,55], posterior fossa abnormalities, lateral ventricle enlargement [38,56], porencephaly [57], agenesis of the corpus callosum [44], hamartoma [58], intracranial [29] or intraspinal lipomas [59,60] and basal ganglia malformation [49]. Neuroimaging is surprisingly often normal, even in patients with clinical neurological abnormalities [42] and multiple modalities may be required [61]. Conversely, a neurologically normal child had neuroradiological abnormalities [62]. Cranial nerve palsies have also been described fairly commonly.

Some 35–70% of patients have ocular abnormalities [6,14,16,38, 40,51,52,54–56,63–66], the commonest of which is involvement of the eyelid or conjunctiva by the epidermal naevus, sometimes causing trichiasis or interfering with lid closure. Other ocular problems have included colobomas of the eyelid, iris and retina, conjuctival lipodermoids and choristomas. Optic nerve hypoplasia, retinal dysplasia, cortical blindness, microphthalmia, macrophthalmia, anophthalmia, corneal opacities and cataracts have also been reported.

Many other non-cutaneous abnormalities have now been reported in association with epidermal naevi, including aortic coarctation and other vascular anomalies [53], cardiac, genitourinary [10,14,15], hepatic and renal [67] abnormalities and endocrine disease [68,69], including inappropriate antidiuretic hormone (ADH) secretion [68] and precocious puberty [24,70,71]. In several patients, bone disease and/or muscle weakness has occurred secondary to hypophosphataemic vitamin D-resistant rickets [16,25,26,54,70,72–81]; some of these patients [25,76,78] had radiolucent bone lesions shown in one case to be angiomatous [78]. Debulking the epidermal naevi leads to biochemical improvement [70], suggesting that these epidermal naevi, or the associated intraosseous angiomatous tumours, secrete a substance that induces renal phosphate loss. A similar phenomenon occurs with a variety of benign mesenchymal tumours, melanocytic naevi [80] and occasionally malignant tumours [82]. A strong candidate gene for 'phosphatonin', the postulated humoral factor responsible for tumour-induced rickets/osteomalacia, was fibroblast growth factor-23, localized to 12p13 [82]. Elevated FGF-23 has been reported [83,84]. One patient suffered both hypophosphataemic vitamin-D resistant rickets and precocious puberty [70]. An overlap has been suggested with the McCune–Albright syndrome [21], but radiologically the polyostotic fibrous dysplasia of the McCune–Albright syndrome is distinguishable from the intraosseous angiomas reported with epidermal naevi [78].

Benign and malignant transformation may occur in these patients' epidermal naevi, exactly as it may when such naevi exist without associated abnormalities. However, insufficient attention has been drawn to the relatively high incidence of systemic malignancies that have arisen in patients with epidermal naevi, often at a very early age [16]. These have included nephroblastoma [16,34,39], salivary gland carcinomas [85], carcinoma of the oesophagus and stomach and breast [86], astrocytoma [87], glioma [88], mandibular ameloblastoma [89], transitional cell carcinoma of the bladder [90], rhabdomyosarcoma of the bladder [91] and testicle [92], parotid adenocarcinoma [92] and intrathoracic teratoma [14].

Diagnosis. Epidermal naevus syndrome overlaps with other syndromes characterized by verrucous epidermal naevi, such as Proteus syndrome, naevus comedonicus syndrome and phakomatosis pigmentokeratotica. CNS lipoma may lead to confusion with encephalocraniocutaneous lipomatosis [59].

Treatment. The treatment of epidermal naevi is discussed elsewhere, and management of the associated anomalies is beyond the scope of this book. However, an apparently healthy child with epidermal naevus is likely to present to a dermatologist and management requires careful clinical judgment. Most children with epidermal naevi are otherwise perfectly well and it is inappropriate to investigate a child who is thriving and developmentally normal. Parents can be informed of the 10% risk of associated abnormalities, but also reminded that most of these will be picked up on routine child health surveillance, such as problems with vision, hearing, growth and neurological development. There should be a low threshold for following up any reported problems, for example a disproportionate rise in head circumference, which may be the first sign of raised intracranial pressure. Children with epidermal naevus syndrome tend to have several associated abnormalities, so if a second developmental anomaly is detected it is appropriate to look for others. Reasonable non-invasive investigations would include ophthalmological assessment and cranial ultrasound. If the naevus is extensive, serum calcium and phosphate should be measured to exclude tumour-induced osteomalacia/rickets.

Phakomatosis pigmentokeratotica

The concurrence of sebaceous or verrucous epidermal naevus with speckled lentiginous naevus has been called 'phacomatosis pigmentokeratotica' [1–3]. It could be argued that speckled lentiginous naevus is simply one of the many localized anomalies associated with verrucous and sebaceous epidermal naevi, and that there is no justification for separating this particular association from epidermal naevus syndrome. The occurrence of extracutaneous anomalies in phakomatosis pigmentokeratotica supports this idea [4]. Furthermore, multiple melanocytic naevi have frequently been reported in association with epidermal naevus syndrome (see above) and hypophosphataemic rickets, which has been reported in several patients with multiple melanocytic naevi and widespread verrucous epidermal naevi, also occurs in phakomatosis pigmentokeratotica [2,5,6]. Malignant change has been reported within both naevoid elements [7], as has association with rhabdomyosarcoma [4].

Happle and colleagues have argued not only that phakomatosus pigmentokeratotica is a distinct syndrome with its own spectrum of associated abnormalities, but further that the lentiginous element might occur without the verrucous element as the 'speckled lentiginous naevus syndrome' [8,9]. Happle suggests that phakomatosis pigmentokeratotica represents twin-spotting [1,2,8].

Dermal and subcutaneous naevi

Connective tissue naevi

Connective tissue naevi are circumscribed hamartomatous malformations of the dermal extracellular matrix, that is of collagen,

Table 18.2 Classification of connective tissue naevi.

Naevi of reticular connective tissue
Collagen naevi
Familial cutaneous collagenoma
Eruptive collagenoma

Naevi of adventitial connective tissue
Fibrous papule of the face
Angiofibromas and subungual fibromas in tuberous sclerosis
Pearly papules of the penis
Perifollicular fibromas and trichodiscomas

elastic fibres or glycosaminoglycans [1,2]. They form a characteristic component of a number of well-defined inherited disorders, such as tuberous sclerosis and the Buschke–Ollendorff syndrome, but also occur as isolated sporadic lesions.

There are many different types of connective tissue naevi. The provisional classification in Table 18.2 is based on that of Uitto *et al.* [1]. Pierard and Lapiere further subdivided these naevi according to whether they arise from reticular or adventitial connective tissue [2]. The category 'elastic naevi' includes those characterized by a deficiency of elastin [3]. It is sometimes unclear whether an apparent deficiency of elastin simply reflects an excess of collagen [3].

Collagen naevi

Familial cutaneous collagenoma

To date six families have been reported showing autosomal dominant inheritance of cutaneous collagenomas [1–4]. Affected individuals present with multiple, asymptomatic, indurated dermal nodules distributed symmetrically on the trunk and upper arms, particularly on the upper two-thirds of the back. Lesions vary in diameter from a few millimetres to a few centimetres, and in number from a dozen to more than a hundred. The condition first becomes manifest before or during adolescence, and an increased rate of appearance of new lesions has been noted during pregnancy. Spontaneous resolution has not been reported.

Histologically, the nodules showed an accumulation in the dermis of dense, coarse collagen fibres, with an apparent reduction in the number of elastic fibres [5].

Cardiological abnormalities reported in some patients include idiopathic myocardiopathy, left ventricular dilatation with thickened aorta and atrial septal defect [4], and might reflect fibrosis within the heart.

A mutation in the Buschke-Ollendorff gene, *LEMD3*, has been reported in one family with familial cutaneous collagenomas [6], raising the possibility that this is an allelic variant lacking the characteristic osteopoikilosis of Buschke–Ollendorff syndrome. Histologically, the reduction in elastic fibres distinguishes the lesions from the elastomas of Buschke–Ollendorff syndrome. Lesions on the scalp [7] must be distinguished from hypertrophic lesions of aplasia cutis congenital, which can also be familial.

Eruptive collagenoma

Sometimes cutaneous nodules, similar to those of familial cutaneous collagenoma, arise in the absence of any family history. The lesions tend to be earlier in onset and smaller than those of familial cutaneous collagenoma [8]. Although onset is usually in childhood, it has been reported in the seventh decade [9]. Exacerbation has been reported during pregnancy [8]. The term *eruptive collagenoma* has generally been applied to such cases, because of the abrupt development of these lesions [9–12]. The same term has been used, however, for cases which would seem, on clinical and histological grounds, to fall more correctly into the category of *lichen myxoedematosus* [13]. Hypertrophic chickenpox scars are easily mistaken for eruptive collagenomas.

Plantar cerebriform collagenoma

This rare lesion, imaginatively termed 'paving-stone naevus' [14], comprises a flesh-coloured cerebriform mass on the sole of variable size. It may occur in isolation [15–18], but is more often a component of the Proteus syndrome, in which it is associated with a variety of other anomalies including macrodactyly and hemihypertrophy [19].

Shagreen patch

The shagreen patch is a mamillated plaque-type collagenoma occurring, most often in the lumbosacral area, as a common and highly characteristic component of tuberous sclerosis [20].

Linear connective tissue naevus

Linear or zosteriform connective tissue naevus has been reported [21–24]. Onset is usually in childhood, and single or multiple lesions are distributed along Blaschko's lines [21]. Lesions may be nodular or cobblestone-like plaques.

Other collagenomas

A variety of other clinical types of collagenous connective tissue naevus has been described. Association with Down's syndrome [25,26] has been recorded. A large collagenoma resembling

a shagreen patch has been reported in a patient with multiple fibrofolliculomas [27]. A family has been reported in which scalp lesions diagnosed histologically as collagenomas were associated with cardiomyopathy and hypogonadism [28].

Elastic naevi

Juvenile elastoma and the Buschke–Ollendorff syndrome

Synonym
- Dermatofibrosis lenticularis disseminata

The association between connective tissue naevi of the skin and osteopoikilosis, inherited as an autosomal dominant trait, is known eponymously as the Buschke–Ollendorff syndrome [1–3].

Histology of the skin lesions is highly characteristic [2–5]. While haematoxylin and eosin stained sections may appear normal, elastin stains show thick, interlacing tracts of elastic fibres running between fairly normal collagen in the reticular dermis, an appearance to which the term juvenile elastoma has been applied. Ultrastructurally, the elastin comprises clumps, coated with fine fibrils, and the fibroblasts contain swollen endoplasmic reticulum containing abnormal fibrillar material [5–8].

Two different clinical presentations have been described in the Buschke–Ollendorff syndrome. Some patients show a symmetrical eruption of uniform, small, lichenoid papules, reminiscent of pseudoxanthoma elasticum [2,6,9], and termed *dermatofibrosis lenticularis disseminata*. However, the more usual cutaneous presentation comprises asymmetrical groups of larger, yellowish nodules, sometimes coalescing to form plaques [3,10–12] (Fig. 18.5). The lesions may appear at any age, although most are present before puberty. Mixtures of these two types of lesions probably also occur. Although usually asymptomatic, occasionally patients complain of pain, tenderness or pruritus in affected areas of skin [12–14].

Fig. 18.5 Juvenile elastoma in the sacral area in the Buschke–Ollendorff syndrome.

Fig. 18.6 Osteopoikilosis in the Buschke–Ollendorff syndrome (X-ray of femoral head).

The second component of the Buschke–Ollendorff syndrome is a radiological abnormality termed *osteopoikilosis*, which comprises multiple, circumscribed, roundish or oval areas of increased opacity within bones, each usually measuring between 1 and 10 mm across [2,3] (Fig. 18.6). Such areas are found particularly frequently in the carpal and tarsal bones, in the phalanges, the epiphyses and metaphyses of the long bones and in the pelvis. They take several years to develop, but, after puberty, the appearances change very little. Histologically, these lesions are foci of tightly meshed bony trabeculae [15]. Some patients also demonstrate melorheostosis, a radiological appearance of long bones likened to dripping candle-wax [16].

Elevated elastin production [5] and elastin mRNA levels [8] in cultured fibroblasts from individuals with the syndrome, suggested a defect in pre-translational control of elastin production. However, the Buschke–Ollendorff syndrome is now known to be caused by mutations in the gene *LEMD3* encoding an inner nuclear membrane protein [16,17]. Osteopoikilosis in otherwise normal relatives of patients with the Buschke–Ollendorff syndrome, and characteristic skin lesions in the absence of osteopoikilosis, even after puberty [11,18] presumably represent incomplete expression of the Buschke–Ollendorff gene. There is no increase in morbidity or mortality in this syndrome, although a number of possible associations have been reported. Otosclerosis [19,20] and muscle fibrosis or contractures have been reported in several cases [2,11,13,21] and there have been individual patients with spinal anomalies [19,22] or short stature with or without precocious puberty [19,22]. Associations with peptic ulceration [13], and protein C deficiency [23] were presumably coincidental. In one family the Buschke–Ollendorff syndrome segregated to some extent with nail patella syndrome [24]. Osteopoikilosis was associated with short stature and mental retardation in three unrelated individuals with microdeletions involving *LEMD3* and flanking markers [25]. One of the three had raised, yellowish lesions on the upper chest and flank.

Papular elastorrhexis

Papular elastorrhexis is the name given in 1987 to a distinctive type of elastic tissue naevus [26]. The clinical presentation [27,28] is with multiple small (1–3 mm) white papules, which are not follicular and are symmetrically distributed, predominantly on the trunk and, to a lesser extent, on the limbs. The condition tends to appear in the second decade of life but has been reported in a 4 year old [29]. The lesions show no tendency to group, or to merge into plaques. Biopsies consistently demonstrate diminution and fragmentation of dermal elastic fibres.

This can be distinguished from the Buschke–Ollendorff syndrome by histology, absence of osteopoikilosis, and sporadic occurrence, although one reported case was familial [30]. It has been suggested that papular elastorrhexis, naevus anelasticus and eruptive collagenoma are the same entity [31]. Treatment with intralesional steroid was only transiently effective in one case [29], and in another resulted in cutaneous atrophy [31].

Naevus anelasticus

Several authors have reported cases in whom groups of small, yellowish or pink, perifollicular papules were present on the trunk, sometimes resulting in a 'wrinkled' appearance of the skin [32–34]. Histologically, these lesions have demonstrated focal absence of elastic fibres [35]. In the past, this condition was known inaccurately as *naevus elasticus of Lewandowsky* [33].

Other elastomas

Cases reported historically as juvenile elastoma and naevus elasticus [34,36,37] may represent *formes frustes* of the Buschke–Ollendorff syndrome, but they may alternatively be genuinely unrelated forms of elastoma. An exophytic form has been reported [38].

A distinctive condition comprising bilateral, thickened and furrowed plaques on the cheeks with an increase in elastic tissue histologically has been described in two separate reports [39,40]. The patients were both young, with no relevant family history. Sun exposure may have played a part in these.

Proteoglycan naevi

Mucinous naevus

Synonyms
- Naevus mucinosus
- Linear connective tissue naevus of the proteoglycan type

This rare naevus may in the past have been reported as cutaneous or papular mucinosis of infancy [1]. Histologically [2], these lesions are characterized by large amounts of proteoglycan in the superficial dermis, with variable overlying hyperkeratosis, acanthosis and elongation of rete ridges. Van Gieson staining shows a broad band in the upper third of the dermis in which elastic and collagen fibres are virtually absent, and alcian blue staining at pH 2.5 shows accumulation of proteoglycan in this area, which disappears following pre-treatment with hyaluronidase. It seems that proteoglycan synthesis is upregulated in fibroblasts of the upper dermis [3].

Clinically, the lesions comprise asymptomatic groups of flesh-coloured or slightly pigmented papules having a firm velvety surface and a tendency to coalesce to form plaques [3–5]. They are generally linear in disposition. Lesions may be present from birth [1,2] but may also develop some years later.

Clinically, the differential diagnosis of mucinous naevus includes connective tissue naevi of other types and the skin lesions of Hunter's syndrome (mucopolysaccharidosis type II) [6]. Histologically, one would need to consider papular mucinosis (lichen myxoedematosus), acral persistent papular mucinosis, self-healing juvenile cutaneous mucinosis and cutaneous focal mucinosis.

Fibrous tissue naevi

Fibrous hamartoma of infancy

Definition. Fibrous hamartoma of infancy is a benign superficial mesenchymal tumour.

Clinical features. This lesion appears during the first 2 years of life, and can be present at birth [1,2]. It may be more common in boys [1,3]. It presents characteristically as a slowly enlarging, asymptomatic, dermal nodule on the trunk, particularly in the axilla, and the upper limbs [2,3] but it may occur at almost any site, including the scrotum [4] and hand [5]. It may be several centimetres in diameter with the overlying skin stretched and shiny [6]. Occasionally there are multiple lesions [5,7]. Coarse hairs may be present [7–9].

Pathology. Histologically, fibrous hamartoma of infancy comprises a mixture of spindle cells forming fascicles, clumps of round cells resembling immature mesenchyme, and mature adipose tissue, located in the deeper part of the dermis and/or the subcutis [1,10]. Eccrine changes are often present in the overlying epidermis [11]. Various chromosomal anomalies reported in two lesions

are difficult to interpret [12]. Occurrence in a child with Williams syndrome suggests a possible link with the elastin gene [8].

Treatment. It can be cured by local excision, which need not be radical [10]. Recurrence rarely occurs [9].

Infantile myofibroma

Infantile myofibroma is a tumour composed of a mixture of myofibroblasts and haemangiopericytoma-like areas [1]. It may occur as a solitary lesion, multiple lesions or diffusely in the skin and other organs. It appears in the first 2 years, sometimes at birth, usually on the head, neck or upper trunk. It may grow rapidly in the neonatal period, with ischaemic necrosis of the overlying skin, but despite their sometimes alarming appearance single congenital lesions usually regress spontaneously.

Differential diagnosis of connective tissue naevi

Conditions to be considered in the differential diagnosis of connective tissue naevi can broadly be separated on the basis of shape. Papular lesions might be confused with congenital smooth muscle hamartoma, leiomyomas, and neurofibromas, while linear lesions must be differentiated from epidermal naevi and naevus lipomatodes superficialis.

Muscle naevi

Congenital smooth muscle hamartoma

Synonym

- Congenital arrector pili hamartoma

Definition. Congenital smooth muscle hamartoma is a malformation of pilar smooth muscle, first described by Sourreil *et al.* [1]. It is relatively common, occurring in about one in 3000 births [2]. Familial cases have been reported [3], but most are sporadic.

Pathology. The histology shows well-defined bundles of smooth muscle fibres, which stain with Masson's trichrome [4–6]. The fibres themselves are generally long and straight, and extend in different directions. Each bundle is surrounded in turn by a clear space and by collagen. They are scattered over a wide area in the reticular dermis, and may extend into the subcutaneous fat. They may show a relationship to hair follicles [7]. Sometimes, there is associated hyperkeratosis, papillomatosis and increased epidermal pigmentation [6]. Electron microscopy has shown characteristic wavy or whorled myofilaments within the smooth muscle cells, and axons, mostly unmyelinated, adjacent to the smooth muscle bundles [4,5,8,9]. Immunohistochemistry shows that the muscle cells express smooth muscle actin and desmin, and there is a proliferation of CD34 positive dermal dendritic cells [7].

Clinical features. Smooth muscle hamartoma presents at birth or during the first few weeks of life, most often on the trunk or proximal limbs, as a variably indurated asymptomatic plaque, with irregular poorly defined margins, 1–10 cm across (Fig. 18.7), often showing prominent follicular papules [2,4–8,10–12]. Usually skin-coloured or faintly erythematous initially, subtle bluish brown pigmentation is a feature of the established lesion [13]. Firm stroking may provoke temporarily increased induration or piloerection, sometimes called the 'pseudo-Darier sign' [2,7,10,14]; this may diminish with age [15]. Exposure to cool or warm air can produce the same effect [7]. Occasionally, fasciculation has been reported [11,16]. In the majority of cases, there is a single plaque, but more extensively distributed, multiple lesions have also been reported [3,14,17,18].

Linear variants of congenital smooth muscle hamartoma have been reported, either with an atrophic appearance [19], or with hyperpigmentated perifollicular papules [20].

Fig. 18.7 Congenital smooth muscle hamartoma on the thigh.

Congenital smooth muscle hamartomas probably persist indefinitely [8], perhaps with gradual slight diminution in induration and hypertrichosis [2]. No significant associated abnormalities have been reported.

Diagnosis. Differential diagnosis is from solitary mastocytomas, pilar leiomyomas and connective tissue naevi, which are not hypertrichotic, and from congenital melanocytic naevi [13], simple hypertrichotic naevi and Becker's naevi. The greatest confusion has been with Becker's naevi, which may feature smooth muscle bundles in the dermis [21]. Lesions described in the literature as '*congenital Becker's naevi*' have been congenital smooth muscle hamartomas [22,23], and the two conditions are generally distinguishable by their age of onset, and by their characteristic histological features [4,14]. Acquired smooth muscle hamartoma [24–26] is distinct from congenital smooth muscle hamartoma. Congenital plexiform neurofibromas are frequently hypertrichotic [27], but are generally softer than congenital smooth muscle hamartomas, and are of course histologically distinctive.

Diffuse smooth muscle hamartoma

Several children have now been reported with an unusual, diffuse type of smooth muscle hamartoma, presenting a unique clinical appearance [1–8]. Histology shows changes identical to the solitary type of congenital smooth muscle hamartomas, frequently associated with fragmented elastic fibres [7]. The baby is born with excess folds of rather firm skin on the limbs, particularly at the ankles and wrists, giving a 'Michelin baby' appearance. There is associated diffuse hypertrichosis, which may be especially marked at birth [1]. The palmar skin may have a rather cerebriform appearance [1]. One child also had cutaneous mastocytosis of urticaria pigmentosa type [9], and another had a paracentric inversion of chromosome 7q [10]. A brother and sister were described who also had facial anomalies and mental retardation [11]. The hypertrichosis and dermatomegaly in the case reported by Glover *et al.* gradually diminished with time [David Atherton, personal communication].

The term 'Michelin tyre baby' has also been applied to a similar appearance caused by diffuse lipomatous infiltration [8,12] and associated with a variety of anomalies. It is not a single entity.

Congenital leiomyoma

Cutaneous leiomyomas are only very rarely present at birth. However, a case has been reported recently of a neonate born with a pedunculated, firm, purple, spherical mass attached to the heel, which proved to be a pilar-type leiomyoma histologically [1].

Striated muscle hamartoma

Synonyms

- Congenital rhabdomyomatous mesenchymal hamartoma
- Congenital midline hamartoma

This entity, recognized since 1986 [1–8], is usually congenital and solitary. It occurs at sites where striated muscle is found superficially. Most reported cases have occurred on the face, particularly on the chin [4,7–9], in a nostril [10] or on a lip [1], but others have been recorded on the anterior chest and in the perianal area [3]. They are usually soft and pedunculated or polypoid. Some may be elongated, and some have been branched. Rare plaque-like lesions occur in adults [2].

Histologically, these lesions show disordered bundles of striated muscle fibres in the reticular dermis and the subcutis. They may also contain well-developed appendageal structures such as hair follicles, sebaceous glands, eccrine glands and ducts, nerve bundles and intradermal lobules of fat. It is the characteristic presence of these elements that is highlighted by the term rhabdomyomatous mesenchymal hamartoma [11].

Many of the cutaneous appendages that are a major cutaneous feature of *Delleman's syndrome* are striated muscle hamartomas, and any child in whom striated muscle hamartoma has been found should be examined carefully for other features of this syndrome [12]. Some cases of striated muscle hamartoma have occurred in association with a limited number of features that suggest the child may have had an incomplete form of Delleman's syndrome [13]. In one child, a lesion on the forehead contained a dermoid cyst and was associated with an underlying nasofrontal bone defect [14].

Striated muscle hamartomas need particularly to be distinguished from *fetal rhabdomyoma* and *neuromuscular hamartoma*. Fetal rhabdomyoma is a tumour of the subcutis that occurs in the neonate, and comprises a myxoid stroma containing undifferentiated mesenchymal cells with some that show differentiation towards embryonic skeleton [15]. Neuromuscular hamartoma, or a Triton tumour, occurs as a nodule in the subcutis comprising striated muscle mixed with nerves [16].

Fat naevi

Naevus lipomatodes cutaneus superficialis

In this rare disorder, collections of mature lipocytes are situated ectopically within the dermis [1]. Associated histological abnormalities of the dermal connective tissue, blood vessels and epidermal appendages may also be seen within the lesions [2,3]. Folliculosebaceous cystic hamartoma was reported within the naevus in two cases [4,5], with dermoid cysts as well in one [5]. Electron microscopy has shown that the lipocytes are closely associated with capillaries, and it has been suggested that they may originate from pericytes, as in fetal lipogenesis [6].

Clinically, there are two principal presentations [3]. In the classic form originally described by Hoffman and Zurhelle [7], a cluster of soft, fleshy, skin-coloured or yellow nodules is found, most commonly on the lower trunk, especially on the back, buttocks or hips or abdomen, and on the upper posterior thighs [1,3,5,8–10]. Lesions have also been reported less frequently at other sites including the face [4,11], scalp [12], neck [13], eyelid [14] and clitoris [15]. They are generally present at birth, but may first appear during childhood or adolescence [8,16], and usually remain unchanged thereafter. These nodules may be domed, sessile or pedunculated. Their surface is most often smooth, but can be wrinkled, cerebriform or they may have a peau d'orange texture. They can measure over 20 cm in diameter. They are occasionally hairy [8], may contain comedo-like plugs [3,17] and have been associated with café-au-lait [18] or hypopigmented [19] macules and occasionally ulceration [20]. One patient also had angiokeratomas of the scrotum

[21]. In another patient naevus lipomatosis superficialis mosaicism for a 2p24 deletion was found [22].

The second form comprises a solitary, domed or sessile papule, which develops in adult life, and has been reported at sites other than the lower trunk, including the knee, axilla, arm, ear and scalp [3,23–26].

Histologically, naevus lipomatodes cutaneus superficialis must be differentiated from dermal collections of fat sometimes seen in intradermal melanocytic naevi [3], and pedunculated lipofibroma [27]. Fat also lies very superficially in the skin lesions of focal dermal hypoplasia, although clinically this condition is unlikely to be mistaken for naevus lipomatodes superficialis.

Lipoblastoma

Lipoblastoma is a rare, benign tumour of embryonic white fat. The term lipoblastomatosis is used for the diffuse variant. Around 90% of cases present in the first 2 years of life [1], and occasionally at birth [2,3]. There appears to be a male : female preponderance of about 3 : 1 [4]. Most lesions occur on the extremities [1] but are also found on the trunk, and in the neck [5], groin [6] and scalp [7], and present as slowly enlarging flesh-coloured or reddish soft-tissue swellings that are asymptomatic unless they compress important structures such as the spinal cord [8].

The diagnosis is based on histology and cytogenetics. The tumour may be encapsulated and well-circumscribed or infiltrative [2]. Lobules of lipocytes and lipoblasts are mixed with spindle and stellate mesenchymal cells, separated by fibrous septa. Serial biopsies have demonstrated maturation of the immature lipoblasts into lipocytes [1,9]. There may be foci of extramedullary haematopoiesis and prominent capillaries [3,4]. Sometimes an Alcian blue-positive myxoid stroma [10] may cause confusion with myxoid liposarcoma, a tumour that is extremely rare in early childhood. Cytogenetic study reveals abnormalities of the long arm of chromosome 8 (8q11.13), leading to rearrangement of the PLAG1 gene [11,12].

Ultrasound usually shows a homogeneous hyperechoic mass, and CT conclusively identifies the fatty component [13]. Magnetic resonance imaging (MRI) can be helpful in gauging the degree of infiltration of these tumours [13,14].

Both localized and diffuse variants of this condition are benign; neighbouring tissues may be infiltrated but metastasis has never been reported. Treatment is surgical, but recurrence may occur [6], particularly in the diffuse variant [1,10].

Encephalocraniocutaneous lipomatosis

This neurocutaneous disorder, recognized since 1970 [1], occurs sporadically and affects both sexes equally [1–5]. Its asymmetry and sporadic occurrence suggest a lethal autosomal mutation rescued by mosaicism [6]. A *de novo* mutation in the neurofibromatosis type 1 gene was found in one case [7]. Severity is variable, particularly with regard to neurological disability [8].

The characteristic cutaneous feature is multiple lipomatous hamartomas, usually present from birth [4,5]. These soft, skin-coloured or yellow, domed papules and nodules vary in diameter from a few millimetres to several centimetres. Most are on the head and neck, particularly in the scalp, where they may appear as hairless plaques. Lesions are usually unilateral, but bilateral lesions do occur [9]. Histologically, there is dermal fibrosis with increased subcutaneous fat extending into the reticular dermis. Smaller papular lesions may show changes more closely resembling angiofibromas [5,10]. Associated aplasia cutis congenita of the scalp [11] has been reported.

Associated non-cutaneous anomalies include fleshy desmoid tumours of the eye [12], mental retardation with or without convulsions, and maxillary odontomas [10]. Intracerebral abnormalities tend to be ipsilateral to the cutaneous lesions, the most characteristic being unilateral cerebral atrophy with ventricular dilatation. Lipomatous hamartomas may be present in the brain, leptomeninges [1] and spinal cord [13].

Differential diagnosis includes focal dermal hypoplasia, oculo-auriculovertebral dysplasia (Goldenhar syndrome), oculocerebrocutaneous syndrome (Delleman's syndrome), Proteus syndrome and epidermal naevus syndrome.

Congenital lipoma

Morphologically and histologically a congenital lipoma is the same as an acquired lipoma: it is a rounded, soft, smooth, skin-coloured mass. However, the location and significance are different. The most characteristic sites for lipoma in the neonate are the back [1] and the perineum [2–4]. Lipomas overlying the lumbosacral area often cause deviation of the upper end of the gluteal cleft and have particular significance as they may extend through bony defects into the spinal canal and attach to the spinal cord [2–10]. Other associated spinal abnormalities include tethered cord and tight filum terminale [11].

Lumbosacral lipomas may show some characteristic histological features, including absence of a capsule, fibrous tissue scattered within the mass, and a variety of unusual ectopic neuroectodermal and mesodermal tissues [12].

The same phenomenon, of a subcutaneous lipoma connecting with a lipoma within the nervous system, has been described for an intracerebral lipoma [13].

Congenital lipomatosis

Congenital lipomatosis is a rare adipose tissue malformation in which accumulations of mature lipocytes are present in the

subcutis, sometimes infiltrating adjacent tissues, especially muscle [1,2]. The commonest sites are the trunk, particularly the chest, and the face [3,4]. The subcutaneous lesions form soft, usually mobile masses, which may be of substantial size. There may be underlying hypertrophy of bone and hemihypertrophy [5]. Facial infiltrating lipomatosis may be associated with intracranial abnormalities [6].

Such lesions may be associated with haemangiomas and with macrodactyly; the relationship between this disorder and the Proteus and Bannayan–Riley–Ruvalcaba syndromes is uncertain.

Neurolipomatosis

Synonyms
- Neural fibrolipoma
- Fibrolipomatous hamartoma of nerve

This is a rare condition of young adults in which mature fat and fibrous tissue accumulate around peripheral nerves of an extremity [1–3]; the median nerve is most often affected. The presenting symptoms include pain, diminished sensation and a sausage-shaped tumour in the skin without muscle infiltration.

'Michelin tyre' baby

Synonyms
- Generalized folded skin
- Michelin tyre baby syndrome

In this rare congenital anomaly, generalized rolls of redundant skin produce an appearance fancifully likened to the symbol of the French tyre manufacturer [1,2]. Most infants are otherwise normal and some improve spontaneously [3–5]. One baby girl with a localized area of folded lipomatous skin also had microcephaly, mental retardation and deletion of the short arm of chromosome 11 [6,7].

Histology usually shows diffuse lipomatous hypertrophy. However, some cases are due to generalized smooth muscle hamartomatosis, in which the redundant skin folds are associated with hypertrichosis. In one case, no histological abnormality was identifiable, but a distinctive associated clinical feature was the presence of widespread stellate scarring [8]. Two familial reports suggested autosomal dominant transmission [9,10].

Congenital generalized folding of the skin also occurs in the Beare–Stevenson cutis gyrata syndrome [11], in which corrugation of the skin is usually confined to the scalp, forehead, face and neck with furrowing of the palms and soles. Associated features include acanthosis nigricans, craniofacial anomalies, anogenital anomalies, skin tags and a prominent umbilical stump.

Vascular naevi

Classification. In previous years the classification of cutaneous vascular abnormalities has been beset by confusion, and has concentrated on the pathology of the vessel involved. In 1982, the classification was greatly improved by integrating the biological behaviour and natural history of vascular birthmarks [1–3]. This binary classification into haemangiomas and malformations continues to form the basis of terminology used today (Table 18.3). It was further modified in 1996 by the International Society for the Study of Vascular Anomalies (ISSVA) and will be used in this chapter.

Vascular tumours

Infantile haemangioma

Synonyms
- Haemangioma of infancy
- Strawberry naevus
- Capillary haemangioma

Definition. Infantile haemangiomas (IH) are benign vascular tumours that appear during the first months of life characterized

Table 18.3 Classification of vascular birthmarks [1,2,3].

Vascular tumours	Vascular malformations
Infantile haemangioma	High flow
Hepatic haemangioma	Arteriovenous
Neonatal haemangiomatosis	+ associated syndromes
Congenital haemangiomas	Low flow
Rapidly involuting congenital haemangioma (RICH)	Capillary
	+ associated syndromes
Non-involuting congenital haemangioma (NICH)	Venous malformations
	+ associated syndromes
Tufted angioma	Lymphatic malformations
Kaposiform haemangioendothelioma	+ associated syndromes
Haemangiopericytoma	Mixed/combined: capillary/venous/arterial/lymphatic
Angiokeratoma	
Syndromes with vascular tumours	
Bannayan–Riley–Ruvalcalba syndrome	

Table 18.4 Vascular birthmarks in childhood.

	Infantile haemangioma	Vascular malformation
Clinical features	Usually present at birth—precursor lesion, or within first week	Usually present at birth
	Proliferates rapidly	Proportionate growth
	Involutes over years	Present in adulthood
Epidemiology	More common in: girls > boys 3 : 1 premature infants <1500 g	No gender bias
	Infants who have had chronic villus sampling	
Immunohistochemistry	GLUT-1 positive	GLUT-1 negative

by a pattern of rapid proliferation, followed by a slower period of involution.

Classification. The reason for the confusion surrounding the nomenclature of infantile vascular tumours existed because of clinical confusion between haemangiomas and vascular malformations (Table 18.4). Terms such as strawberry naevi/haemangiomas, capillary/cavernous haemangiomas although still popular amongst the public and non-dermatologists, should be abandoned. This classification is by no means totally inclusive as both haemangiomas and vascular malformations can coexist in the same patient [4].

Infantile haemangiomas are the most common paediatric tumour, affecting 10–12% of infants by the first year of life [5,6] and a prevalence of 1–3% in the first few days of life [7–9]. They are seen more commonly in girls than boys with preponderance between 3 and 5 : 1 [10–12]. It is also apparent that haemangiomas are more common in premature infants, appearing in up to 30% of babies less than 1000 g and 15% of babies less than 1500 g [6,13–14].

Pathogenesis. The pathogenesis has yet to be fully elucidated but clues are evident from a better understanding of vascular biology. Haemangiomas are proliferative lesions composed of endothelial cells (EC), supporting pericytes, myeloid cells and other cells such as fibroblasts and mast cells [1,2]. Examination of isolated haemangioma EC and whole tumours suggests that haemangiomas arise from uncontrolled clonal expansion of EC [3]. The signals for this proliferation may come from abnormal local cellular signals and somatic mutations in EC or pericytes [4,5]. The processes leading to the development of new blood vessels is complex and poorly understood. In proliferating haemangiomas, there is increased expression of vascular endothelial growth factor (VEGF) and basic fibroblast growth factor [6,7]. Other growth factors such as insulin growth factor and integrins relevant to angiogenesis, $\alpha5\beta3$ and $\alpha5\beta1$ are expressed in the proliferative phase of haemangiomas [2,8]. In involuting haemangiomas, VEGF expression is reduced with a concomitant rise in the expression of apoptosis-associated proteins [9]. Examination of mRNA expression patterns of angiogenic genes in haemangioma-derived EC showed high expression of VEGF receptor-2 and the angiopoetin receptors Tie-1, Tie-2 and angiopoetin-2 [10]. Interestingly, infantile haemangioma endothelium is distinct from normal vasculature because it expresses myeloid markers CD14, CD15, CD32 and CD83, which may imply that myeloid cells are important in growth of tumours [11]. Although little attention has been focused on mesenchymal stem cells in the development of IH, stem cells isolated from IH were not shown to be clonal, and found to differentiate into adipose tissue. This may be relevant to the development of the fibro-fatty residuum that remains after involution [12].

Although specific gene mutations have not yet been isolated for IH, evidence exists of non-random X-inactivation in endothelial cells from proliferating haemangiomas [3,4] and mutations of VEGF receptors in 2/15 proliferating haemangiomas [4].

It is now apparent that EC from IH can be distinguished from other vascular tumours and malformations by surface markers such as GLUT-1 , an erythrocyte-type glucose transporter protein, Lewis Y antigen, Fc gamma receptor II and merosin [13,14]. These markers are also expressed at high levels on placental vasculature, leading workers to postulate that this placental phenotype may be due to either a somatic mutation of a regulatory gene in endothelial precursor cells or that placental endothelial cells embolize to the fetal circulation [14]. There has been further evidence to support the placental origin theory, with very high levels of transcriptome similarity between tissue derived from placenta and haemangioma [15]. However, using highly sensitive molecular genetic techniques, with fluorescent *in situ* hybridization of haemangioma EC followed by PCR, genotyping of mother–child pairs showed no evidence of maternal–fetal chimerism [16,17]. Immunohistochemical studies examining the expression of vascular lineage-specific markers show that haemangioma EC coexpress CD34 and LYVE-1, a marker for lymphatic vessels, but are negative for Prox-1, a lymphatic lineage-specific homeobox protein. As this resembles the phenotype of the cardinal vein during embryogenesis, IH are possibly arrested in an early stage of vascular differentiation [18]. Clearly, the understanding of the pathogenesis of infantile haemangiomas is still evolving.

Pathology. During the early phase of growth, haemangiomas have solid groups of endothelial cells with few lumina and non-pleomorphic nuclei. The endothelial cells then flatten out as lumina develop and start to bulge outward. The cells are surrounded by a thickened basement membrane. As involution proceeds, the haemangioma has a more obvious lobular appearance, with islands of fibrous and fatty tissue separating these lobules. Mast cells are also seen at all phases of haemangiomas, as ultrastructural studies show an apparent interaction with connective tissue cells [1], although it is unclear whether they play a significant role. Immunohistochemical studies of IH show positive staining of markers for factor VIII, CD31 and VwF, as one would expect for vascular endothelium. In the growth phase, cells express proliferating cell nuclear antigen, VEGF and the integrin E-selectin. As involution proceeds, apoptosis is clearly evident [2].

Even though the diagnosis is usually based on clinical grounds, GLUT1 staining is a valuable confirmatory tool in difficult cases, such as congenital haemangiomas. Other less commonly used, specific markers that help to differentiate IH from venous malformations include merosin, Lewis Y antigen and FcgRIII [3].

Clinical features. Haemangiomas usually appear within the first month of life although they present as a precursor lesion in the immediate perinatal period. This can be very subtle, with a faint telangiectatic patch or even a patch of naevus anemicus-like pallor (Fig. 18.8). These signs can readily be missed and the former sign can mimic a capillary malformation. An exception to this is congenital haemangioma (see below) where it appears to be fully developed at birth. Soon after this, the precursor lesion begins to become palpable, often in a cluster giving rise to the 'strawberry' appearance. They may occur anywhere on the skin or mucosal surface [1]. The overall clinical appearance is dependent on how deep into the skin they extend. This may be superficial (50–60%),

where they are bright red in the period of proliferation, deep, in which they have a more blue appearance, or a combination of both superficial and deep (25–35%) [2]. The deeper lesions are located in the deep dermis and/or subcutis and do not have any overlying skin changes, which may make diagnosis more difficult or even delay diagnosis.

In addition to size, some IH involve a broad anatomic region or a recognized developmental unit such as the ear or nasal tip. Others are more discrete and well localized [3]. It is apparent that IH are not randomly distributed [4]. More than 50% of hamangiomas affect the head and neck, and their distribution may correspond to sites of embryological fusion lines and facial developmental metameres [4]. The anatomical location is of major importance in determining the potential for complications such as airway obstruction, visual disturbance and ulceration [5–8]. However, segmental patterns are not precisely defined, although four facial segments were identified when photographic data was analysed from a retrospective analysis of 294 facial haemangiomas [9].

The natural progression of haemangiomas can be divided into proliferation and involution (an artificial division but clinically useful). The mean period of proliferation is 5 months (ISSVA data, 2006) with deeper lesions often proliferating up to 12 months of age (Fig. 18.9). In this phase, lesions are more solid to the touch, especially during activity or crying. Involution may begin in the first year and may occur in one part, whilst other parts are still proliferating. Clinically, the lesion changes from bright red to a dull grey-red with a flattening of the surface. The plaques often break up into smaller islands and involution can continue for up to 10 years. The seminal studies of natural history of untreated IH, from which much of current day prognosis is based, showed that involution is completed in 50% by 5 years, 70% by 7 years and 90% by 9 years [10,11]. There is a wide variation in what remains after involution, ranging from complete disappearance (Fig. 18.10), telangiectasia (Fig. 18.11) or, more commonly, a fibrofatty residuum. There are several variables that may affect this outcome. Lesions that start to involute late tend to regress incompletely. In addition, certain sites, such as the lips, nose, and cheeks, leave cosmetically more disfiguring residua. IH with ulceration tend to leave white or yellow scars.

Diagnosis. This is not usually difficult if the classical signs of a precursor lesion are present followed by a period of growth and involution. However, deep haemangiomas may pose more difficulty with differentiation from vascular malformations. The latter tend to stay fixed and may enlarge during physiological stimuli, for example puberty and pregnancy, and do not go through a period of involution. The use of CT and MRI scanning is not particularly helpful in aiding diagnosis, as both IH and vascular malformations are reported as haemangiomas. There is evidence to support the use of scanning in the delineation of the extent of a haemangioma, and its response to therapy, for example steroids or interferon [1,2]. There may be instances where histological samples may have to be sent for immunohistochemical analysis, as IH are GLUT1 positive (as well as merosin, Fcg receptor II and Lewis Y antigen positive). Other benign vascular lesions such as pyogenic granuloma, tufted angioma and kaposiform haemangioendothelioma, venous malformations and congenital haemangioma are GLUT1 negative [3].

Complications (Table 18.5). Even though most haemangiomas do not cause any significant problem to the individual in the short or long term, they can pose significant morbidity in a notable minority, as outlined below.

Ulceration (Fig. 18.12)
Ulceration is a common complication in up to 8–13% of IH [1], and is usually a problem during the proliferative phase. The pathogenesis of ulceration is not known, but possible contributory factors include friction, local bacterial colonization or tissue hypoxia due to rapid expansion [2]. It is one of the commonest reasons for referral to a specialist, and may cause pain, scarring and disfigurement. It occurs more commonly in haemangiomas of the head and neck and perineal areas (especially the lips and intertriginous regions). Large segmental haemangiomas are more prone to ulceration than focal haemangiomas [2]. It may also occur later in the life cycle of a haemangioma as a result of treatment with pulse dye laser or imiquimod. Haemorrhage, whilst a common worry amongst parents, is rarely heavy unless ulceration occurs over a large artery.

Secondary infection may occur as a consequence of ulceration or treatment and may rarely lead to septicaemia or osteomyelitis. There are usually other signs to alert the physician such as fever, local tenderness and discharge.

Table 18.5 Complications of infantile haemangiomas.

Ulceration
Heart failure
Visual impairment
Airway obstruction
Auditory canal obstruction
Disfigurement
Associated abnormalities:
Spinal dysraphism
PHACE syndrome

Heart failure
This may occur in large hepatic haemangiomas with arteriovenous or portovenous shunting leading to congestive cardiac failure [2] (see p. 18.52, Hepatic haemangioma).

Visual disturbance [1–3] (Fig. 18.13)
Periocular haemangiomas usually involve the upper eyelid, but involvement of the lower eyelid is not uncommon. The most worrying complication is amblyopia, which occurs as a result of inadequate visual stimuli to the visual cortex. The ensuing visual

Fig. 18.12 Large segmental ulcerated infantile haemangioma.

Fig. 18.13 Eyelid haemangioma in line of vision.

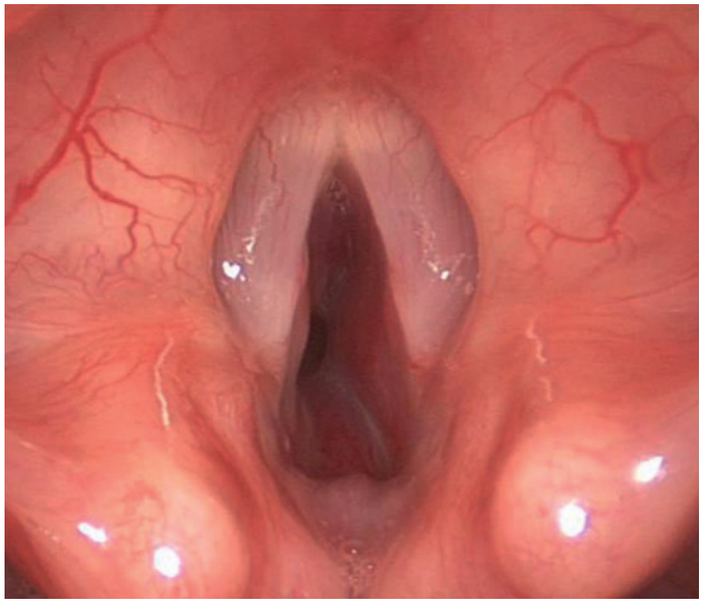

Fig. 18.14 Circumferential airway haemangioma.

impairment can be permanent if not detected early. It has been suggested that even a few days of visual loss can result in permanent loss. Astigmatism may also occur in haemangiomas through direct pressure on the globe. Strabismus leading to amblyopia is also a possibility if the haemangioma affects the movement of the extraocular muscles. Another relatively common complication is lacrimal duct obstruction due to direct pressure, leading to persistent epiphora. Less common complications include proptosis, exposure keratitis and ptosis.

Airway obstruction

Upper airway haemangiomas can be a cause for great concern. They may be focal or diffuse and lead to airway obstruction or feeding difficulty (Fig. 18.14). Affected children usually present with hoarseness, stridor, cyanosis or cough [1,2]. The beard distribution can be a useful indicator of subglottic involvement [3]. These children should be referred to an otolaryngologist and examined by direct laryngoscopy.

Fig. 18.15 Residuum from nasal tip haemangioma.

Obstruction of the auditory canal

This is a possibility with some facial haemangiomas but is unlikely to cause any permanent hearing loss unless there is bilateral involvement.

Cosmetic disfigurement

Rarely some haemangiomas grow at an alarming rate and lead to some or many of the problems above as well as major cosmetic disfigurement [1]. These are the children in whom intervention should be started early and in whom multiple modalities may be required. Other sites are known not to fare well in the long term, such as the nose (sometimes referred to as the 'Cyrano nose') (Fig. 18.15) and the lower cheeks.

Associated abnormalities

A small but significant number of haemangiomas may be associated with structural abnormalities, and two recognized syndromes will be discussed.

Lumbosacral haemangiomas. These are usually present at birth as a telangiectatic patch which typically evolves into a plaque or vascular swelling in the midline or asymmetrically in the paraspinal region but always crosses the midline (Fig. 18.16). As with all midline lesions, one should consider the possibility of underlying defects such as a tethered spinal cord, and genitourinary anomalies including imperforate anus, renal defects, genital or sacral skin tags and genital abnormalities. The acronym PELVIS has been proposed to cover the association of large perineal haemangiomas (P) with the following congenital abnormalities: external genitalia malformations (E), lipomyelomeningocoele (L), vesicorenal abnormalities (V), imperforate anus (I) and skin tags (S) [1]. A different group has proposed the acronym SACRAL for a similar association of perineal haemangiomas and spinal dysraphism (S), anogenital anomalies (A), cutaneous anomalies (C), renal and urologic anomalies (R), associated with angioma (A) of lumbosacral localization (L) [2]. The absence of congenital defects does not negate the risk of tethered cord, and affected children should be investigated even though they appear to be neurologically normal. It is recommended that under the age of 4 months ultrasound is suitable for screening and above the age of 4 months MRI of the spine is preferable.

PHACE syndrome (OMIM #606519). Large facial segmental haemangiomas can be associated with other defects and the acronym PHACES was coined in 1996 referring to the association of posterior fossa defects, haemangiomas, arterial anomalies, cardiac defects (of which coarctation of the aorta is the commonest), eye abnormalities, sternal clefting or supraumbilical raphe. Only one extracutaneous feature is found in 70% of cases [1,2] and in a large prospective study was present in 20% of infants with large facial haemangiomas [3]. There is a striking sex preponderance of 90% [1,2] in favour of girls. The precise definition of what constitutes a large facial haemangioma is debatable and is something which is not measurable. However, it often affects several facial segments, may be bilateral and is often plaque-like with ulceration in multiple sites. The diagnosis of PHACES syndrome is made by the presence of a segmental facial infantile haemangioma in association with only one other congenital abnormality, because affected infants rarely suffer from the complete spectrum [2].

There appears to be a link between haemangiomas affecting the upper half of the face and the structural brain, cerebrovascular and eye abnormalities. Conversely, there appears to be a strong correlation between haemangiomas affecting the lower half of the face and the ventral developmental defects (Table 18.6).

The most common brain abnormality is a posterior fossa Dandy–Walker malformation. Less common findings may include hypogenesis of the cerebrum, corpus collosum or septum pellucidum, arachnoid cysts or microcephaly. Various vascular abnormalities may be found, such as hypoplastic vessels, anomalous branches or stenosis of the internal carotid artery. Over 50% of these abnormalities may lead to neurological sequelae: developmental

Table 18.6 Anomalies associated with PHACE syndrome [3,4].

System involved	Incidence	Specific type of abnormality
Structural brain	40%	Posterior fossa: Dandy–Walker malformation
		Hypoplasia of cerebellum, cerebrum, corpus callosum
Cerebrovascular abnormalities	40%	Carotid arterial anomalies
Cardiovascular	30%	Coarctation of the aorta
		Patent ductus arteriosus
		Ventricular or atrial septal defects
		Anomalous pulmonary vessels
Eye	<20%	Optic atrophy
		Retinal vascular abnormalities
		Congenital cataracts
Ventral developmental	20%	Sternal clefts or pits
		Supraumbilical raphe

delay, fits or strokes. In clinical terms, a posterior fossa malformation may be heralded by an increase in the head circumference. Eye abnormalities include iris hypoplasia, congenital cataracts, lens coloboma, optic atrophy or retinal vascular expansion. Cardiac defects include coarctation of the aorta, aneurysms and valvular stenosis, septal defects and anomalous pulmonary veins.

The suggested screening for a patient with a large facial haemangioma should therefore include: (i) an ultrasound of the head if less than 4 months, or preferably wait until an MRI can be performed, with additional MRI angiography at the same sitting, looking for vascular brain anomalies; and (ii) a cardiac examination looking for signs of coarctation, and an echocardiogram by a paediatric cardiologist. Any suspected eye abnormalities should trigger referral to a paediatric ophthalmologist.

Management [1–3] (Table 18.7). The management of children with haemangiomas is open to debate, as the common belief amongst many general practitioners and paediatricians is that the natural history of by far the majority of lesions is spontaneous involution, albeit slow in a large number of children. However, a significant but very important minority of haemangiomas may cause functional problems or even permanent cosmetic disfigurement.

They are biologically diverse in their position and heterogeneous in their behaviour, making it difficult to establish protocols to suit all circumstances. However, a guiding principle should be as with all good medical practice— 'first do the patient no harm'.

In the 1950s and 1960s the outcomes of treatment with radiotherapy and surgery turned physicians away from intervention, and early results with argon lasers were not ideal [4–6]. New therapeutic modalities are now available and will be discussed below.

The decision to treat is obvious when IH are potentially life threatening, or function threatening, as in those haemangiomas with heart failure, ocular compromise or respiratory distress. The site and size of the haemangioma will dictate the need for treatment. Sites such as the lips, nose or ears are more likely to lead to permanent anatomical distortion and scarring [7,8]. The scarring from large plaque-like segmental haemangiomas on the face is potentially more serious than a similar lesion on the trunk.

Table 18.7 The major goals of management of infantile haemangiomas [1].

Prevention or reversal of life-threatening complications
Prevention of permanent disfigurement from skin changes following involution
Reduction of psychological distress to a minimum
Reduction of toxicity and resultant sequelae from systemic therapy
Avoidance of excessive scarring from aggressive surgery
Treatment of ulceration to minimize scarring.

The point in evolution of the haemangioma will also be relevant to management, and is closely linked with the age of the child. Haemangiomas of similar appearance may be in involution in an older child whilst in the growth phase in a child at 4 months old. The decision to treat surgically, for example, should normally be taken after the haemangioma has completed its growth phase.

The developmental stage of the child must also be taken into account, as children start becoming body aware at 2–3 years of age, but realization of a problem leading to stigmatization rarely occurs before 4–5 years of age. The decision to continue a wait and see approach must be balanced against the emotional consequences of this decision [9]. All children must be treated on an individual basis, but the parents should have information to help guide their decision. This may take the form of serial photographs, examples of previous cases with before and after photos, and a full discussion of the risks and benefits of any treatment modality.

Active non-intervention

This term was coined to show this was an active decision to treat in a non-interventional manner, as long-term, prospective, observational studies show that many haemangiomas will regress and leave a fairly reasonable cosmetic result [1,2]. The difficulty arises with multiple sources of information and conflicting opinion amongst health professionals, friends and relatives. The cosmetic appearance at an early age may push parents to desire early intervention to remove the lesion as soon as possible.

Once again, the role of an experienced dermatologist is invaluable, in reassuring the parents about the natural history and talking through their anxieties. A common worry, for example, is the concern about the lesion bleeding if caught—something which rarely happens. The use of serial photography, as mentioned previously, can help to show changes which are not always appreciated when parents are seeing the child every day.

Ulceration

There are multiple methods for treating ulceration, with no one therapy considered first line [1]. The aims should be to treat the ulceration, infection and pain. The ulceration may be treated conservatively with local antibiotics such as mupirocin or systemic antibiotics (if there is crusting, weeping and spreading erythema) and occlusive dressings (Fig. 18.17). Non-adherent, paraffin-based dressings with occlusive dressings can then be overlaid. Specific therapy, such as oral corticosteroids and pulsed dye laser [2], may be used alone or in combination, as discussed below, although the results of pulsed dye laser are not always positive [1]. The author's personal experience suggests that pulsed dye laser is very helpful in managing pain associated with ulceration which does not respond to conservative measures. The use of 0.01% becalpermin gel (a recombinant platelet-derived growth factor used in treating diabetic ulcers) has induced healing of ulceration, but the safety of this unlicensed product is not clear [3,4]. Another modality reported is a polyurethane film which helped ulceration and pain [5].

The most important symptom to address in ulceration is pain. Adequate analgesia (paracetamol suspension with or without ibuprofen or short-term codeine) on a regular basis and prior to dressing is vital to reduce the distress to the child. Advice from other health professionals often neglects this issue.

Therapeutic intervention

There are several possible treatments available and these are summarized in Table 18.8 and are discussed in more detail below.

Corticosteroids. Systemic corticosteroids have been used in the treatment of haemangiomas for more than 30 years [1–3] and their use is highlighted in Table 18.9. Their precise mechanism of action is not clear, but it is known that corticosteroids reduce

Table 18.8 Therapeutic interventions for infantile haemangiomas.

Therapy	Comment
Corticosteroids	Oral—for expanding, function- or life-threatening haemangiomas
	Topical not commonly used
Interferon	Second line for expanding, function- or life-threatening haemangiomas but used in children older than 1 year
Vincristine	Second line for expanding, function- or life-threatening haemangiomas in combination with oral corticosteroids
Propranol	For expanding function threatening haemangiomas
Pulsed dye laser	May be used for residual or large plaque haemangiomas but does not accelerate resolution
Surgery	May be used for areas which are known to leave poor cosmetic outcome such as nose and cheeks
Topical immunomodulators	Limited evidence of benefit for small haemangiomas

Table 18.9 Indications for steroid therapy to infantile haemangiomas.

Life- or function-threatening, affecting airway or vision
Congestive cardiac failure
Anatomical sites with a high risk of permanent disfigurement, e.g. nose, lip
If large or ulcerated (in some cases)

angiogenesis, induce vasoconstriction and reduce vascular permeability. More recent evidence shows increased apoptosis, which would seem biologically plausible as one mode of action [4]. There are no randomized controlled studies looking at dosing or efficacy, although a meta-analysis of steroid use in problematic haemangiomas showed a mean dose of 2.9 mg/kg/day and a response rate of 84% (excluding hepatic haemangiomas) [5]. This analysis also showed that 3 mg/kg/day was more effective than 2 mg/kg/day. An empirical dose of 2–5 mg/kg/day is used as a single morning dose and maintained for 1–3 months, followed by a gradual taper. A positive response is usually seen within 2–3 weeks if the tumour is going to respond. The speed of taper is not formalized and depends on the age of the child. A reduction that is carried out too rapidly will result in a rebound if the IH is still proliferating. In such cases, one has to restart at a higher dose and reduce more slowly. As with some chronic steroid-responsive dermatoses, an alternate day dosage may be used to circumvent potential side effects of growth and adrenal axis suppression.

Corticosteroid side effects include general irritability, poor sleep, behavioural changes, gastric irritation, glucose intolerance, weight gain, growth disturbance and adrenal suppression. The most common of these were cushingoid facies and personality change in a large study of haemangiomas treated in this manner [6]. The growth was suppressed in 35% of these patients, but catch up growth ensued in the majority. Other potential complications of steroids include cataracts, glaucoma, osteoporosis, increased risk of infections (including *Pneumocystis* pneumonia).

Patients with haemangiomas on systemic corticosteroids should ideally be under the joint care of a dermatologist and a paediatrician to monitor mood, sleep, blood pressure, height and weight, length and developmental milestones. For those patients on long-term therapy one should consider a low-dose corticotrophin stimulation test. Other factors to be considered include increasing the dose of steroids during illnesses with high fever, traumatic accidents or surgery. In addition, live vaccines should not be given during steroid therapy and zoster immune globulin should be administered with aciclovir if the child is exposed to varicella.

Intralesional steroids are sometimes used to treat orbital haemangiomas or other localized, for example, airway haemangiomas. Both triamcinolone and dexamethasone are used and can be repeated if necessary, with response rates of 80% [7]. One of the potential benefits is the lack of the side effects, discussed earlier. However, this is something which should only be done by experienced ophthalmologists as rare but serious side effects include eyelid necrosis [8] and retinal artery embolization with resulting blindness [9,10].

There is limited experience of using superpotent topical steroid (clobetasone propionate) in the treatment of infantile haemangiomas [11–13], and although easier to administer, the benefits of halting growth, shrinkage or flattening the lesion are likely to be applicable to only small superficial haemangiomas at risk of ulceration, or small periocular lesions [13].

Interferon-α. There is no doubt that interferon-α is an effective anticancer drug and can inhibit angiogenesis in tumours. It has been shown to halt the growth of proliferative haemangiomas [1–6] with reported regression rates of 50% [4]. It is normally given as a subcutaneous injection at doses ranging from 1 to 3 million units/m^2/day over several months. However, initial enthusiasm has been tempered by reports of severe neurotoxicity, including spastic diplegia [7]. In some but not all cases this was reversible. A large meta-analysis of patients with vascular lesions given interferon-α showed 11/441 with spastic diplegia and 16/441 with motor developmental disturbance. Most importantly, these severe complications only occurred in children under the age of 1; children over 1 year of age were not affected [8]. The more predictable side effects of interferon-α include fever, general malaise, anaemia, neutropenia, elevated transaminases, and are not usually an indication to stop therapy. It should also be remembered that some haemangiomas do not respond to interferon-α [9].

It is suggested, therefore, that interferon-α should be reserved as a second-line treatment for infants with aggressive or life-threatening haemangiomas that are not responding to systemic corticosteroids; patients should be monitored by a neurologist.

Vincristine. Vincristine has been used effectively to treat Kasabach–Merritt phenomenon in association with tufted angiomas and kaposiform haemangioendotheliomas [1]. Vincristine requires a central line and is given at a dose of 0.025–0.05 mg/kg (if <10 kg), or 1.5 mg/m^2 (if >10 kg). The side effects of therapy include peripheral neuropathy, constipation, jaw pain and inappropriate secretion of antidiuretic hormone. It has also been used in life threatening haemangiomas [2–5] and is now considered the initial second line therapy, because of the neurotoxicity associated with interferon-α.

Propranolol. This is a new therapy which came about by chance when heart failure in a child with a haemangioma was being treated with propanolol [1]. In this interesting case series, propranolol at a dose of 2 mg/kg was used for severe, non-corticosteroid-responsive infantile haemangiomas. There was evidence of regression, in some instances quite dramatically, after several months of therapy. The study was not controlled and in some of the children, steroids blockade has been shown to induce apoptosis in endothelial cells of capillaries [2]. This is clearly an exciting area for controlled and comparative studies in the future.

Laser therapy. The use of lasers in the treatment of haemangiomas remains controversial, unlike their use in vascular malformations (port-wine stains), which is not open to question. Laser therapy is the only area of haemangioma management examined by a prospective, randomized controlled trial [1,2]. This landmark study compared the outcome of early pulsed dye laser (PDL-585 nm) treatment of uncomplicated haemangiomas in 60 infants, with observation alone after 12 months. Even though there were greater numbers of patients who initially cleared completely with laser therapy, there was no difference in clearance or minimal residual signs at the age of 1 year. This study proved controversial, because many laser specialists felt that use of a cooling device and newer variable wavelength PDL would have led to a different conclusion. Another non-randomized comparative trial showed similar results [3]. Despite these reservations, the findings reflect the clinical experience of many paediatric dermatologists. The side effects of laser treatment include focal scars, possible ulceration, pain and pigmentary changes [1,3,4].

It is accepted that laser therapy may be useful in the treatment of ulcerated haemangiomas, and for the residual erythematous changes that are left after involution, although evidence from large studies is notably lacking.

Surgery. The use of aggressive surgery in the past was followed by poor outcomes with marked scarring. There is, however, a subset of haemangiomas which benefit from surgical intervention [1]. The age of the child should be taken into account since facial image awareness occurs around 2.5–3 years of age. In the proliferative phase, surgery should be considered for obstruction (airway or visual), deformity (e.g. retroauricular) and ulceration not responding to medical therapy. In the involuting phase, surgery is indicated provided the size and appearance of the scar would not be less if the resection were postponed, and if the scar is easily concealable. In the involuted phase, the indications are an abnormal contour due to a fibrofatty residuum and distortion of an important anatomic structure [1–3]. Nasal tip haemangiomas warrant a special mention, as they are treated surgically more than any other anatomical site. It is recommended that once early lesions have been medically managed (with intralesional or systemic steroids if necessary), they should be resected in a staged fashion with alar apposition [4].

The traditional surgical technique of lenticular excision with a linear closure has been demonstrated to be less effective than circular excision with a purse string closure, which is considered to be the technique of choice [5].

Embolization. As with other treatment for life threatening haemangiomas, this is a technique reserved for lesions that have not responded to medical therapy, as sometimes required in hepatic haemangiomas that have led to congestive cardiac failure [1].

1 Mulliken JB, Fishman SJ, Burrows PE. Vascular anomalies. *Curr Probl Surg* 2000; **37**: 517–84.

Radiotherapy. The use of radiotherapy is now extremely rare and cannot be justified for cutaneous haemangiomas in view of the risk of malignancy and disturbance of bone growth. It has been used for systemic, for example liver [1], haemangiomas and for life-threatening lesions [2].

Topical immunomodulators. Imiquimod is a immune response modifier with the ability to induce interferon-γ, interferon-α, tumour necrosis factor-α and the antiangiogenesis factor, tissue inhibitor of matrix metalloproteinase [1]. There have been small open studies showing clinical resolution of small, superficial infantile haemangiomas [2–5]. The main side effects included local erythema, scaling and occasionally marked crusting. Unfortunately, none of these studies were controlled and the use of this treatment for haemangiomas is unlicensed.

Other modalities. Cryotherapy is popular in Germany and parts of South America [1,2]. Compression bandaging or intermittent pneumatic compression can provide a reduction in the bulk of large haemangiomas [3,4] although it can lead to serious complications of heart failure or respiratory distress [5]. The lack of a formal evidence base explains why these modalities are rarely used.

Hepatic haemangioma (HH)

Most infantile haemangiomas are cutaneous tumours, but visceral involvement may also occur, often in the setting of multiple lesions—haemangiomatosis. Infantile hepatic haemangiomas are proliferative endothelial cell neoplasms of the liver. Like their cutaneous counterpart, they share the same characteristic phases of rapid growth followed by spontaneous involution. Most hepatic haemangiomas are clinically silent and may be detected on routine prenatal ultrasound screening, or postnatal imaging for another reason [1]. A subset becomes symptomatic, presenting with heart failure secondary to high volume shunting. Less common presentations include hypothyroidism resulting from overproduction of type III iodothyroninedeiodinase [2–4], fulminant liver failure [5] and abdominal compartment syndrome [1]. The literature has been very confusing, as infantile HH is commonly referred to as hepatic haemangioendothelioma. The latter is a malignant tumour which does not involute. It also differs from adult hepatic haemangioma, which is a venous malformation and does not regress. One group has proposed three subtypes: focal, multifocal and diffuse, and suggested each subtype has its own distinctive imaging, pathological and physiological features [1].

Infantile HH may be imaged by ultrasound, CT or MRI scanning. The classic ultrasound appearance of small (<3 cm) haemangiomas is a strongly echogenic mass, whereas larger tumours may contain calcification, cystic spaces or fibrosis [6]. CT imaging shows an area of well-defined hypoattenuation on unenhanced scans and peripheral contrast enhancement on dynamic scans. MRI findings include hypointense areas on TI-weighted images, and markedly hyperintense areas on T2-weighted images, probably due to the slow blood flow through multiple, small vascular channels [7].

The management of hepatic haemangiomas usually is guided by the presence or absence of heart failure. Asymptomatic patients with focal or multifocal disease, without heart failure or haemodynamically significant shunting, may be followed up with periodic ultrasound to document regression. If heart failure is present, this should be treated medically. Infants with significant shunting are initially treated with systemic corticosteroids, but many do not respond [8–10]. As with cutaneous haemangiomas, interferon-α and vincristine is also used. However, if pharmacological therapy fails, embolization is often the next step, with hepatic artery ligation, or liver transplantation for rapidly deteriorating, symptomatic, diffuse haemangiomas [1,8,9,11].

The long-term prognosis varies on the extent and haemodynamic compromise, with mortality rates of up to 80% in untreated cases [12] and 20% in treated cases [9].

Neoantal haemangiomatosis

Synonym
- Multifocal/benign neonatal haemangiomatosis

Children may sometimes be born with large numbers of small infantile haemangiomas ranging in number from a few to hundreds. This has been referred to as benign neonatal haemangiomatosis in the literature. They are usually small in size, ranging from 2 mm to 2 cm in diameter [1,2]. They are more common in girls than boys [2,3] and increase in size for the first few months before starting to involute [4]. In most cases the haemangiomas resolve spontaneously during the first 2–3 years of life [5]. Histologically, they are identical to solitary infantile haemangiomas with multilobular vascular proliferations composed of thin-walled vascular channels lined by normal endothelium [1]. The only investigation required in children less than 6 months of age is an ultrasound to detect the presence of an asymptomatic hepatic haemangioma.

It is important to differentiate this 'benign' form from the more serious diffuse (synonym miliary, disseminated) neonatal haemangiomatosis. It is highly probable that these two forms represent a spectrum of the same underlying disease.

Multifocal/diffuse neonatal haemangiomatosis (NH)

This is a rare disorder characterized by multiple cutaneous and visceral haemangiomas which appear at birth or early after birth

Fig. 18.18 Miliary haemangiomatosis causing cardiac failure in a 3-month-old infant.

(Fig. 18.18). A minimum of three criteria were deemed necessary for the diagnosis: an onset in the neonatal period, lack of malignant transformation and involvement of three or more organs [1]. The cutaneous presentation is the same as the multifocal benign form as described earlier. The most common symptom which should alert the physician that this may be the diffuse variant is an enlarging abdominal girth secondary to hepatomegaly [2]. The lungs, brain and gastrointestinal tract are also frequently affected [3]. A large meta-analysis of complications arising from diffuse NH showed that the most common were congestive cardiac failure in 38%, haemorrhage in 11% and multiorgan failure in 9%. The mortality of patients who received no treatment was 77% compared with 27% who were treated conservatively or surgically [3]. The management of such patients is still controversial [4]. The patient should have a thorough history and examination. The combination of hepatomegaly and heart failure is investigated with abdominal imaging and it has been suggested that any infant with five or more cutaneous haemangiomas should have an abdominal ultrasound [5]. Evidence of other organ involvement may be investigated by faecal occult blood analysis, CNS imaging and urinalysis. Guidelines state that corticosteroids should be the initial treatment, and if no improvement is seen in 2–4 weeks, interferon-α should be added [6]. Operative treatment with either hepatic artery ligation or embolization is indicated for large hepatic haemangiomas and severe congestive heart failure not responding to medical treatment. The presence of heart failure (relative risk 3.2) and the involvement of five or more organs (relative risk 1.6) were associated with a higher mortality rate [3].

Congenital haemangiomas

A congenital haemangioma is a vascular tumour that has grown to its maximum size at birth and does not show a proliferative postnatal growth phase [1]. Congenital haemangiomas do not look like the typical precursor lesions of infantile haemangiomas and behave differently biologically. There are two major recognized subgroups, rapidly involuting congenital haemangiomas (RICH) [2] and non-involuting congenital haemangiomas (NICH) [3].

RICH grow in a similar pattern to IH but regress more rapidly, often by the first year. The NICH growth pattern is one of intrauterine growth and a plateau throughout life with no regression postnatally. Histologically, NICH are composed of large lobules of small vessels with intervening fibrosis and dermal arteriovenous (AV) microfistulae. A large stellate vessel is often seen centrally with thin basement membranes [2,3]. RICH are made up of lobules of variable size, large extralobular vessels, and plump endothelium with thick basement membranes after regression. Immunohistochemical staining for GLUT1 is negative in both RICH and NICH.

Both RICH and NICH have an equal sex distribution (unlike the female preponderance of IH), are usually solitary, and located on the head or limbs or near a joint. RICH typically present as a bluish or purple plaque or tumour with telangiectasia and peripheral pallor. They rapidly involute by 1 year of age, leaving noticeable dermal or subcutaneous atrophy [1]. They have characteristic ultrasound features with a uniform hypo-echoic mass and centrilobular draining vessels [4].

NICH are round or ovoid, and pink or purple in colour, showing peripheral pallor and coarse overlying telangiectasia (Fig. 18.19). Their size can vary from a few to several centimetres and they are often doughy in consistency and warm to touch. They do not show signs of involution and Doppler examination shows a fast flow lesion. They have been mistaken for arteriovenous malformations (AVM), because angiography will show fast flow and rapid filling, but no early venous opacification typical of AVM. They are best managed surgically and do not recur, unlike AVM [3].

Differentiating RICH from NICH is not always so clear cut, because both a congenital haemangioma and an acquired infantile haemangioma may coexist in the same patient [5]. In addition, a few tumours initially diagnosed as RICH may transform into NICH [5].

Tufted angioma (TA)

This is a rare tumour which occurs most commonly in prepubertal children [1–3]. It was, however, originally described in adults [4]. Less commonly it has been described in pregnancy and in an immunosuppressed individual [5,6].

Histologically, there is a lobular proliferation of plump, oval cells surrounding tiny slit-like lumina [7]. These blood vessels are tightly packed and organized in rounded tufts scattered in the dermis, often described as resembling cannon-balls. The tufts may occur deeply in the dermis, and into the subcutis [8,9]. Thin-walled lymphatic channels may be seen at the periphery of the cellular masses or throughout the dermis. Immunohistochemical stains show strong positivity for Ulex europaeus I lectin and EN4 [10] and unlike IH, negative staining for GLUT1 [11].

In children, they often appear before 1 year of age, with an ill-defined pink macule which evolves into a purple indurated nodule or plaque, but they can also vary in colour from a red to blue hue. They can reach up to 20 cm in diameter, and may cause confusion in their early stage with port-wine stains, connective tissue naevi, smooth muscle hamartoma and sarcoma. They may have localized hypertrichosis or hyperhidrosis on their surface. A useful clinical feature is that they are usually tender.

Even if the diagnosis is suspected clinically, a biopsy is recommended for confirmation. Their natural history shows that after a period of expansion they stabilize and may either resolve spontaneously [1,12,13] or more rarely progressively worsen [14]. Malignant transformation has not been reported. The differential diagnosis of TA includes infantile haemangioma, Kaposiform haemangioendothelioma (KHE), venous malformations, glomuve-

nous malformations and subcutaneous fat necrosis of the newborn [1]. As with KHE, it may be associated with the Kasabach–Merritt phenomenon.

The management of tufted angiomas is related to the age of the patient, size, symptoms and whether a coagulopathy is present. Excision is often performed but recurrence is common if this is incomplete. Some TA extend deeply into the subcutis, fascia and into muscle [15]. Other modalities reported to achieve effective resolution include soft X-ray [16], pulsed dye laser [17], interferon-α [18–20] and high-dose corticosteroids [21]. Low-dose aspirin may be of benefit in mild thrombocytopenia [9]. More significant thrombocytopenia and the Kasabach–Merritt phenomenon are discussed later.

Kaposiform haemangioendothelioma [1]

Kaposiform haemangioendothelioma (KHE) is a rare vascular proliferation of childhood that can show local aggressive progression and may have associated systemic findings, the most common of which is the Kasabach–Merritt phenomenon (KMP). The clinical presentation of KHE falls into those which are retroperitoneal, presenting around 10 months of age [2], and those which present with cutaneous superficial (Fig. 18.20) or deep lesions [1]. In the cutaneous form, KHE tends to be a solitary vascular stain which starts to proliferate rapidly. Lesions generally manifest at a later date than simple infantile haemangiomas and are often complicated by KMP [1]. Congenital cases are also described [3–6].

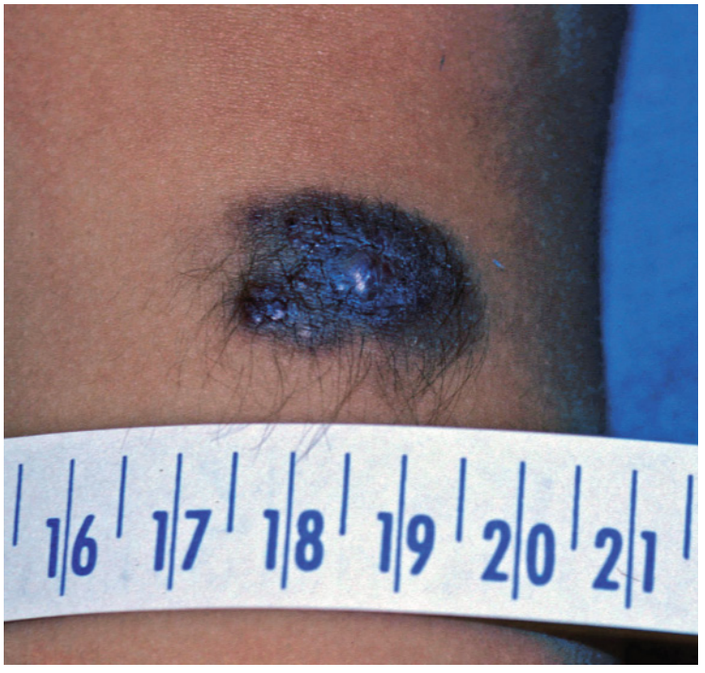

Fig. 18.20 Kaposiform haemangioendothelioma on lower leg.

Histologically, KHE is composed of lobules or sheets of tightly packed spindled or more rounded endothelial cells and pericytes, with an infiltrative pattern in the dermis, subcutaneous fat and muscles. They contain few vascular lumina, rare mitoses and minimal or absent hyperchromasia [7]. KHE has many pathological characteristics of a Kaposi's sarcoma, but demonstrates a more lobular pattern, a greater tendency to form complete vascular spaces and scattered fibrin thrombi [1]. In addition, KHE has not been shown to harbour human herpes virus-8, unlike most forms of Kaposi's sarcoma [8]. There is some possible histological overlap with tufted angioma as both tend to have endothelial cell proliferation leading to the formation of crescentic vascular spaces [1].

The rarity of the tumour does not allow for guideline-based management. If feasible, excision is the most successful of the reported treatments [7]. Other treatments include radiation therapy, interferon and ticlodine and aspirin [5]. If the KMP occurs, vincristine is used in combination with oral steroids. The prognosis is worse for retroperitoneal tumours than for cutaneous lesions, because of later diagnosis, more difficult access to the tumour or bleeding locally [5]. A rapidly growing cutaneous or soft-tissue vascular tumour in a child beyond the normal age of proliferation of an infantile haemangioma, if complicated by KMP, should be biopsied to rule out KHE.

Kasabach–Merritt phenomenon (KMP) [1]

The original description of the syndrome in 1940, linking thrombocytopenia, microangiopathic haemolytic anaemia and a consumptive coagulopathy with a rapidly enlarging vascular tumour [1], reported tumours with histological features of KHE. For many years, it was felt this phenomenon could occur with infantile haemangiomas, but it is now accepted this is usually a complication of tufted angiomas and kaposiform haemangioendotheliomas. Other less common tumours causing KMP include haemangiopericytomas [2–4]. Angiomas leading to KMP may be cutaneous [3], intrathoracic, most often mediastinal, abdominal (retroperitoneal or intrahepatic) [5], pelvic [6] or skeletal [7–9].

The typical presentation is a tumour either present at birth or one that starts to enlarge rapidly. They are usually solitary red/blue plaques or tumours with a blue hue and may involve large areas of skin. They rarely look like the 'strawberry' of an infantile haemangioma. They are commonly found on the trunk, neck and proximal limbs with a predilection for the thighs and shoulders (Fig. 18.21). One should suspect the phenomenon when a tumour rapidly increases in volume and ecchymoses appear, sometimes extending way beyond the margins of the tumour. The texture is also more woody and the overlying inflammation looks almost cellulitic. The bleeding diathesis may also present at other sites with haematuria, epistaxis, or prolonged bleeding at sites of trauma. Occasionally, the coagulation defect is present at birth [10], but is apparent by the age of 1 in most cases.

The coagulation status of suspected KMP should be checked by a platelet count and fibrinogen level. The degree of thrombocytopenia may be misleading initially, as the platelet count may be only marginally low, but it may fall to as low as 5000/mm^3. Other evidence of activation of the fibrinolytic system includes positive D-dimers and evidence of a haemolytic anaemia. The prothrombin time (PT) and activated partial thromboplastin time (PTT) may be elevated.

The low platelet count is due to a combination of increased destruction and sequestration of platelets within the expanding vascular tumour [11]. This has been confirmed by radiolabelling platelets with chromium-51 or indium-111 [12,13]. A coagulopathy may occur with some mixed venous–lymphatic malformations, but this is different, because it is often lifelong and haematologically characterized by reduced fibrinogen and a platelet count which may or may not be reduced, rarely falling below 70 000/mm^3. There is a state of intravascular coagulation resulting in consumption of clotting factors and elevated D-dimers, elevated PT and PTT [14,15].

Fig. 18.21 Kasabach–Merritt phenomenon from tufted angioma.

As a result of the coagulopathy, bleeding may occur at a wide number of sites and mortality as a consequence may be as high as 20–40% [11,16]. The coagulopathy, however, resolves spontaneously in the majority of patients in 1–6 years (mean 3 years) [3]. The residual tumour is often mild or inconspicuous. Unfortunately, a significant proportion of patients is left with permanent sequelae of a residual tumour or fibrosis causing joint or muscle functional disability [4,17].

The management of KMP is dependent on the severity of the coagulation defect, the site of tumour and the presence or absence of the physical effects of compression of surrounding tissues. One should remember that most cases resolve spontaneously and that there are iatrogenic complications of therapy. Only when life-threatening complications are likely, is treatment absolutely necessary. Like many cases of treatment of haemangiomas, there is no one standard protocol to guide paediatricians or dermatologists. For instance, mild thrombocytopenia is not a problem in young infants, although aspirin has been used [18] and can usually be monitored with regular platelet counts. There is an instinctive temptation to give platelet transfusions, but this may have a detrimental effect [19], as may heparin. Active bleeding and operative procedures may require platelet transfusions and fresh frozen plasma. Other treatments used to improve the coagulopathy include antithrombin III [5].

The major focus of therapy is reduction in the volume of tumour, and oral corticosteroids 2–5 mg/kg/day can induce both shrink-

age of the tumour and restoration of the platelet count [20–22]. The outcome of steroid therapy is less encouraging when there are severe coagulation abnormalities [23,24]. IFN-α has been shown to be effective, although its action is relatively slow [25–28]. It is therefore not an option where the coagulopathy is of a severe, acute onset. The most encouraging second-line medical therapy has been vincristine which binds to platelets and therefore homes in on sites of platelet sequestration [3,29]. The recommended dose is 1.0–1.5 mg/m^2/week by slow intravenous infusion. Most cases will show a response by 4 weeks, with an average of 12 weeks of treatment [30]. This treatment appears to have a rapidly beneficial effect on the coagulopathy, and can be expected to induce shrinkage of the underlying tumour over a period of months [29]. Other therapies reported to help include ticlopidine and aspirin [18], aspirin and dipyridamole [31], cyclophosphamide [32], pentoxifylline [33] and the antifibrinolytic agents tranexamic acid [33] and ε-aminocaproic acid [34].

Surgical excision of the causative tumour may be very effective in reversing the coagulation defect [5,35–37], but is not without its hazards, as bleeding may be profuse during surgery. It is often reserved for small accessible tumours. Another useful adjunct prior to surgery is tumour embolization, which has the added benefit of reducing intraoperative bleeding [16,38].

Radiotherapy has its advocates [16,39,40] but is generally not contemplated due to the risk of long-term complications [41,42]. It may be an option in difficult cases.

In summary, the management of KHE is initially conservative, with regular monitoring of platelets, clotting studies, fibrinogen and D-dimers. If there is a worsening of the coagulopathy, oral corticosteroids should then be used and consideration given to vincristine or IFN-α in children older than 1 year of age, and surgical treatment (with pre-embolization). The likely outcome of long-term tumour regression and normal coagulation should be borne in mind when contemplating aggressive intervention [3].

Haemangiopericytoma

This is still a controversial neoplasm as it is difficult to distinguish pericytes from endothelial cells or fibroblasts on light microscopy alone [1]. However, most authors believe it is a distinct entity [2]. Haemangiopericytoma rarely originates in the skin, and is often separated into adult and congenital or infantile types [3]. The congenital and infantile form typically presents as a multilobulated mass in the subcutis [1–4]. Lesions are found anywhere on the body and have a deep red colour, suggesting a vascular origin. Histopathology of these neoplasms shows tightly packed cellular areas surrounding endothelium-lined branching vessels. The cells show round to oval nuclei and cytoplasm with ill-defined borders. The vascular channels form a continuous network in a staghorn like arrangement [1]. There is evidence of mitotic activity, but the clinical behaviour is benign [3]. Immunostaining shows these tumours are positive for alpha smooth muscle actin, desmin, cytokeratin, and *Ulex europaeus* 1 lectin but negative for factor VIII-related antigen [1].

They may resolve spontaneously or be treated by excision [5].

Angiokeratomas [1]

Angiokeratomas are hyperkeratotic vascular cutaneous lesions which may be localized or diffuse. The localized forms are angiokeratoma circumscriptum, angiokeratoma of Mibelli, solitary angiokeratomas and angiokeratoma of the scrotum or vulva. The diffuse variant, angiokeratoma corporis diffusum, is a rare disorder commonly found in Fabry's disease (see Chapter 59).

Angiokeratoma circumscriptum

Aetiology and pathology. Angioma circumscriptum is a vascular malformation of ectatic vessels in the papillary dermis, which may or may not be thrombosed. The epidermis has varying degrees of acanthosis, papillomatosis and compact hyperkeratosis. The rete ridges are elongated and surround the dilated vascular channels [1,2].

Clinical features [3]. This is a rare condition which is comprised of a hyperkeratotic vascular plaque, usually present from birth. They are commonly situated on the lower leg and have a blue–black colour with a segmental distribution. With time, the lesion tends to develop more warty papules which may bleed if traumatized. The lesions are fixed and do not remit with age.

Diagnosis. The diagnosis is usually established by the combination of the early onset and clinical appearance of aggregated papules forming a hyperkeratotic plaque. There may be some confusion with verrucous haemangiomas. The latter have deeper vascular elements and capillary endothelial proliferation on histological examination. Other differential diagnoses include localized lymphatic malformations (microcystic) which are not hyperkeratotic and the more rare condition acral pseudolymphomatous angiokeratoma of children (APACHE). The latter is a distinctive entity affecting the feet and has pseudolymphomatous histology rather than a true angiokeratoma [4].

Treatment. The size of the lesions will determine the therapy used. Small lesions can be treated with curettage and cautery, and larger lesions treated with laser removal or even excision.

Angiokeratoma of Mibelli

Aetiology and pathology. Angokeratoma of Mibelli is transmitted as an autosomal dominant trait with highly variable penetrance [1,2], affecting girls more than boys. The lesions are commonly associated with acrocyanosis and chilblains, which suggests that cold injury is important in the aetiology.

The histopathological features are essentially the same as those of angiokeratoma circumscriptum, that is marked ectasia of vessels within the papillary dermis, with associated acanthosis, papillomatosis and hyperkeratosis of the overlying epidermis [3]. Elongated rete ridges tend to encircle and enclose the vascular lacunae.

Clinical features [4,5]. The lesions commonly develop between the ages of 10 and 15 years, but both earlier and later onset has been recorded. A history of recurrent chilblains is usual, but not invariable. The earliest lesions are minute, bright-red macules, which slowly increase in size and become elevated, warty and darker in colour. They reach a diameter of 5 mm or more in some cases. The dorsal and lateral aspects of fingers and toes are most often affected, but lesions also occur on the dorsa of hands and feet (Fig. 18.22) and occasionally on the knees and elbows. On the calves, lesions resembling erythema induratum may be present [2]. The lesions, which are often numerous, may be disfiguring but seldom cause symptoms except for instances associated with ulceration of the fingertips [1,4]. There is little tendency to spontaneous resolution.

Fig. 18.22 Angiokeratoma of Mibelli in a 9-year-old child.

Treatment. The lesions can be treated, if desired, with liquid nitrogen, electrodesiccation, laser ablation [6] or by local excision.

Solitary papular angiokeratoma [1]

This entity has been convincingly distinguished from the other angiokeratomas, particularly from angiokeratoma circumscriptum [2]. Solitary papular angiokeratoma is an acquired disorder, probably arising as a response to trauma. Even though it is not strictly a developmental anomaly, it is included in this chapter because of clinical and histopathological similarities with the other angiokeratomas.

Histologically, solitary papular angiokeratomas are more or less indistinguishable both from angiokeratoma circumscriptum and angiokeratoma of Mibelli. Solitary angiokeratomas differ clinically mainly by their later onset, usually between the age of 10 and 40 years, often with a history of preceding trauma. They occur in both sexes anywhere on the body, although the legs are the site of predilection. Although usually single, multiple lesions may occur. The patient often presents with a history of sudden enlargement, darkening or bleeding in a long-standing lesion, leading to suspicion of a malignant melanoma [2]. The lesions have the appearance of warty papules, generally between 2 and 10 mm in diameter, and dark red to blue–black in colour.

Solitary papular angiokeratomas are frequently mistaken clinically for viral warts, melanocytic naevi or, more importantly, malignant melanoma. Local excision is recommended if there is any doubt about the diagnosis.

Angiokeratoma of the scrotum

Synonym
- Angiokeratoma of Fordyce

Aetiology and pathology. The most common of the angiokeratomas, angiokeratoma of the scrotum, becomes more frequent with increasing age [1]. In a study in Japan, the prevalence was shown to increase from 0.6% in 16 year olds to 17% in those over 70 years of age [2]. It should probably be regarded as a degenerative disorder, and there is evidence that local venous hypertension plays a part in its development [1,3].

The histological features are similar to those observed in angiokeratoma of Mibelli and solitary papular angiokeratoma [4].

Clinical features [1,3,5,6]. Small, 1–4 mm, bright-red vascular papules may develop on the scrotum as early as late adolescence. With increasing age they become larger, darker and more numerous. Symptoms include itching, soreness or bleeding [7]. Identical lesions may also occur on the penis, upper thighs and in the groins. Well-circumscribed, macular, telangiectatic lesions have been described on the oral mucosa in patients with angiokeratomas of the scrotum [8].

The diagnosis of angiokeratoma corporis diffusum should be considered in any patient presenting with scrotal angiokeratomas.

Treatment. Liquid nitrogen cryotherapy, diathermy or laser ablation [9] can be used to treat symptomatic lesions. Evidence of associated disorders capable of increasing the scrotal venous pressure should be sought, particularly varicocoele, treatment of which may lead to regression of the angiokeratomas [3].

Syndromes with vascular tumours

Bannayan–Riley–Ruvalcaba syndrome [1–7] (OMIM#153480)

Synonyms

- Bannayan–Zonana syndrome
- Riley–Smith syndrome
- Ruvalcaba–Myhre–Smith syndrome

Bannayan–Riley–Ruvalcaba syndrome (BRRS) is an autosomal dominant condition which is comprised of macrocephaly, penile lentigines and hamartomatous tumours including lipomas, haemangiomas and gastrointestinal polyps. It was found that BRRS shared many clinical features with Cowden's syndrome, such as intestinal polyposis, macrocephaly, facial trichilemmomas and lipomas [2]. They share a common genetic basis as both have been shown to have mutations in the *PTEN* gene [8–10].

The commonest skin findings are penile lentiginosis and haemangiomas, although arteriovenous malformations [10] and lipomas have been noted. The lentiginosis may not develop until mid-childhood [11]. The typical cutaneous findings are deep lipomatous swellings on the trunk and proximal limbs, which may enlarge to a considerable size.

It is now accepted that BRRS patients should be monitored for cancer surveillance in the same way that patients with Cowden's are monitored for thyroid, breast and gastrointestinal cancer [9,11].

Vascular malformations

Vascular malformations are localized defects of vascular development without evidence of endothelial cell proliferation, which are present at birth and never regress. They may also expand in certain situations, for example during surgery, trauma or pregnancy. They are commonly classified according to which type of anomalous vessel is involved and their flow characteristics (Table 18.10).

Table 18.10 Classification of vascular malformations [1,2].

High/fast flow

Arteriovenous malformation (AVM)
- Syndromes with AVM:
  - Parkes Weber syndrome
  - Wyburn–Mason syndrome
  - Cobb syndrome

Low/slow flow

Capillary malformation (CM)
- Salmon patch
- Port-wine stain
- Naevus anaemicus
- Syndromes with CM
  - Sturge–Weber syndrome
  - Cutis marmorata talangiectatica congenita (CMTC)
  - Macrocephaly-CMTC
  - Adams-Oliver syndrome
  - Phakomatosis pigmentovascularis
  - Beckwith-Wiedemann
  - Thrombocytopenia absent radii syndrome
  - Roberts syndrome
  - Rubinstein-Taybi syndrome
  - Cardiofaciocutaneous syndrome

Venous malformation (VM)
- Syndromes with VM
  - Mafucci's syndrome
  - Blue rubber bleb naevus syndrome
  - Glomuvenous malformation
  - CMVM
  - Cerebral cavernous malformation
- Verrucous haemangioma

Lymphatic malformation (LM–previously lymphangioma)
- Microcystic and macrocystic
- Syndromes with LM
  - Gorham's disease

Mixed/complex

Any combination of CM/VM/AVM/LM
- Klippel–Trenaunay syndrome
- Proteus syndrome
- Hereditary neurocutaneous angiomatosis
- CM-AVM syndrome
- Divry–Bogaert

Others
- Hereditary haemorrhagic telangiectasia
- Ataxia telangiectasia

Vascular malformations may occur on any part of the body and may extend into deep visceral locations. They may be localized or diffuse or occur as part of a syndrome, for example Parkes Weber, and Klippel–Trenaunay syndromes. Management will vary in terms of investigation methods and treatment modalities used. The lesions do not regress and will often require multidisciplinary care from dermatologists, plastic surgeons, interventional radiologists, neurosurgeons, and head and neck surgeons, as well as ongoing care in adult life.

Arteriovenous malformation (AVM)

This is the most common high-flow vascular malformation, which is composed of a direct communication between arteries and veins called a nidus. The malformation arises during fetal development as a result of primitive arteriovenous channels in the retiform plexus failing to regress [1]. These channels may not canalize for many years; expansion is secondary to increased blood flow through the malformation and dilatation of adjacent arteries and veins [1].

Pathology. An AVM is made up of distorted arteries and veins with irregular thickened fibromuscular walls, and elastic fibres which are not continuous. The communication channels between the two vessels involved in shunting are a mixture of capillaries and stromal fibrosis [2].

Clinical features. AV malformations are rare, but are often the most serious of all the vascular anomalies. They are present at birth and have no gender predominance. They may be confused in childhood with capillary malformations or infantile haemangiomas. The common triggers for expansion include trauma, puberty and pregnancy. In 1990, the ISSVA adopted the Schobinger staging classification system (Table 18.11) for clinical severity.

The natural history of these malformations serves as a guide for intervention. An AVM may remain stable for years in stage I and a bruit is of little significance unless its intensity increases [1]. The onset of pain or enlargement heralds the likely progression to ulceration or haemorrhage [1,3]. The head is the commonest site, accounting for 70% of cases in one large series [3].

An AVM affecting the face overlying the mandible may cause asymmetry and gingival bleeding. On other sites such as the digits, bony involvement may be accompanied by ischaemic skin necrosis.

Table18.11 Schobinger classification for arteriovenous malformations.

Stage I Dormant, quiescent stage	Macular/cutaneous blush Warm
Stage II Expansion	Warm mass, thrill or bruit present
Stage III Destruction	As for stage II plus pain, ulceration, bleeding, bone-lytic lesions
Stage IV	Stage III and cardiac failure

There are different radiological investigations that allow one to delineate the extent of the lesion. Ultrasound is the simplest method to confirm a diagnosis, and it is usually combined with Doppler, which shows high-velocity arterial flow and pulsatile venous flow [1]. MRI is superior to CT with contrast and MR angiography will highlight anomalous vasculature. Arteriography is only used prior to embolization.

Differential diagnosis. In the early phase, AV malformations may be mistaken for capillary malformations, whereas in later stages the signs are rarely mistaken for anything else.

Treatment. For stage I and early stage II lesions, a conservative observation approach may be employed. However, at this stage localized AVMs are easier to excise and reconstruct. Surgical excision remains controversial since the risk of progression to other stages is not quantifiable. Large lesions may be incompletely excised and the cosmetic outcome of the reconstruction may be worse than the original lesion [1]. For any AVM the treatment of choice would be wide excision [1,4]. Arterial embolization is employed to occlude shunts and is carried out with various agents such as glues, ethanol, particles, implantable coils or spheres. Proximal ligation of arterial feeding vessels is not advisable as the surrounding vessels are recruited to supply the nidus. This also prevents easy access to the nidus when embolization is necessary [5]. Wide surgical excision is carried out a few days after preoperative arterial embolization, which reduces the extent of perioperative haemorrhage [6]. Despite apparently successful embolization in limb AVM, the lesions may still recur months or years later [7]. It is therefore advisable to warn patients and their families that a cure is rarely possible and that management is aimed at keeping the AVM under control.

Syndromes with arteriovenous malformation

Parkes Weber syndrome (OMIM #608355) [1]

This is an uncommon syndrome characterized by overgrowth of a limb associated with a high flow capillary AVM or capillary–lymphatic AVM with multiple AV fistulae along the affected limb. It is more common in the lower limb and is characterized by a

congenital vascular stain (a quiescent stage I AVM) and increasing limb length and girth. Investigation with ultrasound and Doppler or MR angiography reveals the fistulae and often shows enlarged arteries and some areas of hypervascularity. The differential diagnosis is usually between Klippel–Trenaunay and Proteus syndrome, but there are no true AVMs in either of these diagnoses, and other features such as epidermal and connective tissue naevi will help to distinguish Proteus syndrome.

The disease may be complicated by leg length discrepancy, which may be treated by epiphyseal stapling [2,3]. If lymphatic anomalies are present, they can lead to lymphoedema and the associated features of chronic lymphatic congestion such as papillomatosis and infection. The treatment for any lymphoedema is usually conservative with compression bandaging or stockings.

Wyburn–Mason syndrome [1–5]

Synonym
- Bonnet–Decahaume–Blanc syndrome

The original syndrome was described by Bonnet in 1937 [1], and it was later described by Wyburn-Mason in the English literature [2]. The main features of this rare disorder include cerebral midbrain arteriovenous malformations (AVMs), ipsilateral retinal AVM and ipsilateral cutaneous vascular abnormalities. The latter may be mistaken for a capillary malformation but it is a stage I AVM. However, the vascular malformation is not always unilateral; there are reports of bilateral and centrofacial vascular stains, extending from the glabella down to the upper lip. The visual tract abnormalities may occur anywhere between the orbit, optic nerve or optic tract. Patients may present with headaches, seizures or visual symptoms. Investigation with MRI and MR angiography will outline the AVM. Unfortunately, there is no consensus on the treatment for such a rare disorder and patients are typically managed conservatively by observation.

Cobb syndrome

This is a rare idiopathic condition consisting of a segmental capillary malformation with an AVM of the spinal cord within two segments of the involved dermatome [1]. The capillary malformation is actually a quiescent AVM and may be quite faint in appearance or verrucous [2]. Spinal involvement may include the vertebral column, dura, spinal cord and nerve roots [3]. The importance of detecting the underlying spinal AVM is that the latter becomes symptomatic in childhood and leads to neurological complications such as spastic paralysis. There have been cases of successful treatment with embolization [4,5].

Capillary malformations

There are two common types of vascular malformation with a macular erythematous patch, the salmon patch and port-wine stain.

Salmon patch

Synonyms
- Nuchal stain
- Stork mark
- Stork bite

Salmon patches are extremely common vascular anomalies and are found in all types of races. Their prevalence varies from 20–60% [1–5]. There is evidence to suggest a genetic aetiology in some cases, as both facial and nuchal stains may be inherited as an autosomal dominant trait [6,7].

They present clinically with irregular pink/red macular patches with or without fine telangiectasia. The commonly affected sites are the nape of the neck extending up to the occipital scalp (Fig. 18.23) and anteriorly on the forehead, from the glabella to the upper eyelids or bridge of nose [8–11]. The less common sites include the sacral region [11] and sometimes multiple sites may be involved.

The natural history of these anomalies is that the majority of the facial stains will fade within the first year of life [8,12] whereas the other sites may persist into adulthood [12,13]. The sacral lesions are often a site for concern as they may be associated with occult spinal dysraphism [11,14]. The lesions are often triangular or rhomboidal in shape [11]. If a sacral salmon patch is present with a second abnormality such as a lipoma, pit, dimple, sinus, hypertrichosis, cutis aplasia or haemangioma, further investigation with an ultrasound or MRI is recommended [15].

Port-wine stains

A port-wine stain (PWS) is defined as a macular telangiectatic patch (CM) which is present at birth and remains throughout life. They may be localized or extensive, affecting a whole limb. They are often associated with an underlying disorder (see below).

Pathology and pathogenesis. These lesions are rarely biopsied but show regular, ectatic, small venule and capillary channels in the papillary and reticular dermis. Later-stage lesions develop progressive fibrosis around the vessels and dilatation of the channels. The thickness of vessels has proved of interest when trying to understand the response to treatment. It has been shown that facial V2 region vessels are deep, like those of limb CM, whereas the V1 are more superficial [1]. Immunohistochemical analysis of the abnormal vasculature has revealed a reduction in neurone density, which has been postulated to account for the dilatation of the vessels in CM [2,3].

Even though one could speculate that abnormality of vasculogenesis regulatory genes would lead to the development of anomalies such as CM, only *RASA1* (on chromosome 5q) has been linked to families with autosomal dominant CM–arteriovenous malformations. The gene product is a protein (p120-rasGAP) believed to be important in vascular endothelial cell proliferation [4].

Clinical features. These are best considered as low-flow vascular malformations which may occur on any part of the body but commonly affect the face in the distribution of the trigeminal nerve (V1, V2, V3) (Fig. 18.24). The incidence varies between 0.1 and 2% [1–6]. If they affect the face they may extend into the mucosal surfaces such as the lips and gingiva. Initially, the lesions are pale pink patches, but with time they may mature into a violaceous colour (facial CM), remain static or even lighten (trunk or limb CM). Facial CMs typically evolve into thicker areas with vascular blebs, occasionally pyogenic granulomas [7,8] and underlying

tissue hypertrophy. This may include bony overgrowth and eruption of early dentition. Limb CM may also be associated with unilateral limb hypertrophy. If the borders are very well defined ('geographic CM') they are more commonly associated with underlying lymphatic abnormalities and limb hypertrophy [9].

The diagnosis of a CM is usually straightforward but in the early phase it may be mistaken for an evolving infantile haemangioma, early arteriovenous malformation or tufted angioma. Infantile haemangiomas will usually reveal their proliferative phase and tufted angiomas are often more plaque-like and tender. If one suspects an AVM, Doppler examination will be useful in confirming the diagnosis.

Treatment. The pulsed tuneable dye laser (PDL) has become the treatment of choice for CM (Fig. 18.25). PDL achieves lightening of the malformation by reducing the number and size of erythrocytes in vessels by selective photothermolysis. First generation PDLs operated at 577 nm or 585 nm and were effective and had relatively few side effects [1,2]. The success rate varied from 50 to 90% [3,4]. These studies also showed that not all CMs respond fully to PDL. A better understanding of the interaction between lasers and CM has led to modification of PDLs—the second-generation machines. The modifications include longer pulse widths, longer wavelengths, higher fluences and the addition of cooling devices [5]. The rationale for alteration in treatment parameters comes from studies of laser–CM interactions using non-invasive confocal microscopy [6,7] and animal models [8]. In comparative studies, the modified second-generation PDL devices were found to induce superior lightening of CM [9,10].

The side effects of PDL include bruising (in nearly all cases), pain, swelling, crusting, bleeding, pyogenic granuloma and pigmentary change, both hypo- and hyperpigmentation. The incidence of atrophic scarring is between 1 and 3% [11,12]. Despite the apparent successful response to therapy with PDL, long-term redarkening of the CM recurs up to 10 years later [13], something which should be explained to any parent putting their child forward for treatment. In addition, not all CMs respond to PDL. Second-generation PDL has been shown to help cases resistant to first-generation devices. One study showed a benefit in 6/9 cases with a range of 25–50% lightening [5]. The potassium titanyl phosphate (KTP) laser has also been shown to produce extra lightening in PDL-resistant CM, but only in approximately 15% of cases [14]. The patients in these studies experienced less discomfort and post-treatment purpura, but at the expense of a greater rate of scarring of up to 7% [14]. Other lasers such as the Nd:YAG (longer wavelength 1064 nm) have achieved good results compared with the second-generation PDL [15]. Additional methods for treating resistant lesions include multiple pass irradiation with two PDL passes: the first at 590–600 nm and the second at 585 nm. A small case series showed that this benefited hypertrophic CM [16]. The use of non-coherent light sources, such as intense pulsed light (e.g. Photoderm®), is an alternative method which uses broadband light, employing filters to remove any unwanted wavelengths. This source was better for pink and red CM, but also caused lightening of purple CM [17]. The identification of prognostic factors that determine the response to any of the above therapies should enable more targeted treatment. Clearly the size of vessel, its depth and density will influence response to PDL. The presence of more superficially located vessels infers a good response to therapy [18].

(a) (b)

Fig. 18.25 (a) Pre and (b) post pulsed dye laser therapy.

In clinical practice it is clear that red lesions respond better than pink or purple CM. The site of involvement is an important prognostic indicator, with the head and neck faring better than other body sites, although peripheral facial lesions respond better than centrofacial areas [19].

The timing of treatment is controversial. Older children may experience stinging and may require local anaesthesia, whereas all young children will require general anaesthesia. There is no evidence to show that deferring treatment until later childhood has any detrimental effect on the response to laser therapy [20]. The main reason for early treatment is to reduce the harmful effects of disfiguring CM on psychological development [21] and ideally should be completed before starting school. The number of treatments required to treat a CM is not standardized, and despite mathematical models using non-invasive methods such as the SIAscope (reflectance measurements) [22] it may still be related to cost, availability, side effects and the experience of the laser surgeon.

Naevus anaemicus (NA)

Naevus anaemicus is an uncommon, localized, congenital vascular malformation consisting of a macule/patch with an irregular margin most commonly found on the upper trunk [1]. This was first described by Vörner in 1906 to differentiate this from partial albinism [2]. It is a clinical diagnosis and if the lesion is examined by diascopy the skin appears indistinguishable from the surrounding normal skin. Rubbing the skin causes reactive hyperaemia in the adjacent skin, but no change within the lesion itself. It may present at birth or early childhood, and is more common in males than females [3]. Histological and ultrastructural examination shows no abnormalities [4]. The lesion is a physiological anomaly as various agents such as bradykinin, acetylcholine, and histamine fail to induce vasodilatation, but erythema is produced after an axillary sympathetic block. It is believed that naevus anaemicus is primarily an oversensitivity to vasoconstrictor stimuli [5].

Naevus anaemicus is more commonly found in association with port-wine stains [1] and neurofibromatosis [3]. Treatment is not necessary.

Sturge–Weber syndrome (OMIM 185300)

The syndrome is classically defined as a facial port-wine stain (PWS) in association with an ipsilateral vascular malformation of the leptomeninges and eye. Even though the original description of the syndrome had eye involvement [1], some authors do not consider eye involvement as mandatory for the diagnosis [2]. There is no evidence to suggest a genetic basis [3], although facial PWSs have been reported in first-degree relatives [4].

The pathology of the PWS is identical to those of other CMs. The brain abnormalities include increased leptomeningeal vascularity, especially affecting the occipital lobe, and on occasion, the whole hemisphere. The changes are usually unilateral, but may be bilateral in 15% of cases [5]. The long-term pathological changes include calcification, atrophy and demyelination [6].

Fig. 18.26 Port-wine stains on the face and trunk in a 3-year-old with Sturge–Weber syndrome.

The commonest cutaneous feature is a CM in the V1 and V2 distribution of the trigeminal nerve and it is believed that the ophthalmic branch must be involved in part or its entirety for the true syndrome [7] (Fig. 18.26). In clinical terms, at least part of the PWS extends to the forehead and upper eyelid [7] and it should be remembered that there is overlap in V1 and V2 over the bridge of the nose. Ocular and central nervous system problems were found to occur in PWSs affecting the upper and lower lids in 90% but only in 9% in PWSs affecting the lower lid alone [8]. The PWS can cross over the midline and is bilateral in around 50% [3,9]. There may be additional CMs on the trunk and limbs in up to 40% of cases [10]. The oral and nasal mucosae may be affected, leading to gingival hypertrophy and accelerated dentition [11].

Epileptic seizures are the most common neurological complication and occur in 55–90% of cases [3,4,9,12]. The seizures occur within the first 7 months of life in the majority, but may start later in adulthood. An early onset is associated with a poorer prognosis and higher incidence of mental retardation [13]. The seizures usually begin as focal seizures but may progress to generalized or even start as generalized seizures. The incidence of mental retardation is as high as 60% [3,12,14] and is more likely in those patients with bilateral brain involvement. Developmental delay is not universal and is present in around 50% [3,15]. Initially, seizures are followed by transient hemiplegia, and homonymous hemianopia, but later this may become permanent [2].

There are many different ocular complications of SWS (as with any facial CM). The most significant of these is glaucoma which can be present in up to 60% of cases [7]. The aetiology of glaucoma is not fully clear, but it is postulated that choroidal angiomas lead to an overproduction of aqueous fluid. Furthermore, anatomical abnormalities of the anterior chamber angle impair drainage, and raised episcleral pressure due to anomalous arteriovenous communications adds to this poor drainage [16,17]. Glaucoma is nearly always unilateral and is present at birth in over 60% [14,16]. Glaucoma is unlikely unless the PWS affects the upper eyelid, but more often than not, both upper and lower eyelids are affected [3,10]. When it presents at birth, the eye is enlarged (buphthalmos) and the cornea appears cloudy. Patients at later ages present with increasing myopia. The importance of treatment cannot be overemphasized, as failure to treat will eventually lead to optic nerve damage, field defects and ultimately blindness. It is therefore imperative that any at-risk patient is seen by a paediatric ophthalmologist as soon as possible.

The investigation of SWS is both radiological and neurological. Plain X-rays show sinuous tramline opacification typical of intracranial cortical calcification although CT scanning with contrast is more commonly used. Both MRI and CT scanning highlight the extent of both eye and leptomeningeal involvement. Even though CT scanning is superior to MRI in highlighting calcification [6], gadolinium-enhanced MRI is considered to be superior to CT scanning for earlier detection, delineating the extent, showing any associated vascular abnormalities and for assessing parenchymal atrophy, ischaemic damage and choroids plexus enlargement [15,18,19]. More specialized investigation with photon emission tomography (PET) can be used to show areas of ischaemia [20]. Electroencephalography is not used as frequently as it was in the past, but shows suppression of cortical activity over the affected area, with or without focal epileptiform spike discharges [21].

The management of patients with SWS is directed at control of seizures (when present) with anticonvulsants, regular follow up by an ophthalmologist for detection of glaucoma, and treatment of the PWS by laser as for any CM.

Cutis marmorata telangiectatica congenita (OMIM 219250)

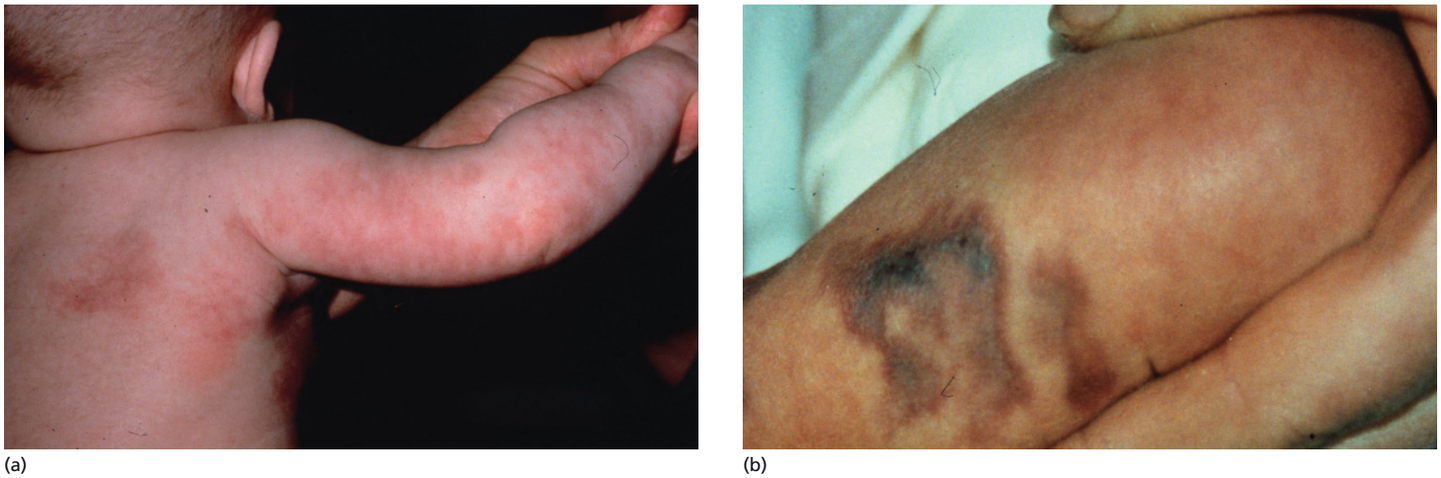
Synonyms
- Reticulate vascular naevus
- van Lohuizen's syndrome

Definition. Cutis marmorata telangiectatica congenita (CMTC) is an uncommon, congenital, vascular malformation, first described by Van Lohuizen [1], comprising a fixed reticulate erythema which may resemble physiological cutis marmorata.

Aetiology. The aetiology of CMTC is unknown. It is a sporadic disorder but familial cases have been reported [2,3]. Different groups have suggested an autosomal dominant inheritance with variable penetrance [2] or paradominant inheritance in which homozygous post-zygotic mutations in a mosaic population of cells accounts for the syndrome [4]. There is close overlap with Adams–Oliver syndrome (see below).

Pathology [1,2,5,6]. Histopathology of the vascular abnormality reveals dilated capillaries, venous and capillary lakes, and dilated veins in the dermis and subcutis. There is also evidence of endothelial swelling and a sparse perivascular lymphocytic infiltrate.

Clinical features. The vascular abnormality is a reticulate erythema producing the marbling that is akin to the physiological marbling seen in neonates (Fig. 18.27a). However, this is fixed and does not disappear after warming (unlike physiological cutis marmorata). The erythema is variable and can be a livid purple. The skin may be atrophic or even ulcerated in the vascular areas [6] (Fig. 18.27b).



The affected areas may range from a few centimetres to a whole limb or hemitruncal involvement. The limbs are more commonly affected than other sites, and a sharp demarcation line is common. When the face is involved the lesions may be indistinguishable from PWS [6].

There may be associated atrophy (more common) or hypertrophy of the underlying subcutaneous tissue. This may manifest as reduced girth of the affected limb [5,7,8] and rarely bony hypoplasia [9].

There are numerous other congenital anomalies which have been reported in association with CMTC with a prevalence of 20–70% [6,10–12]. There is debate about the true prevalence of these abnormalities, as there is a tendency to reporting bias, such that it is probably at the lower end of this range. The most common defects are aplasia cutis, developmental delay and cleft palate [6,11,12]. Less common associations include macrocephaly [13], glaucoma [6,14], hypothyroidism [1], scoliosis and anogenital abnormalities [11,12]. The macrocephaly–CMTC and Adams–Oliver syndromes are discussed separately (see below).

The natural history of CMTC is lightening of the vascular markings and long-term, spontaneous resolution in the majority of cases [11,15,16], although residual reticulate erythema has also been reported [6,10,12]. Ulceration tends to heal without specialized treatment and limb length abnormalities become less apparent with time [7].

Diagnosis. CMTC should be easy to differentiate from physiological cutis marmorata, but is not as pronounced as the more

(a) (b)

Fig. 18.27 Cutis marmorata telangiectatica congenita; (a) back and arm, (b) leg. Note necrotic areas within lesion on leg.

persistent congenital livedo seen in Cornelia de Lange syndrome, trisomy 21 and homocystinuria. Neonatal lupus erythematosus and other vasculitides may also enter the differential diagnosis because of the reticulate telangiectatic atrophy, but congenital lupus is bilateral and symmetrical with a greater frequency of facial lesions. Some uncommon forms of patchy port-wine stains may cause confusion, but these lesions would not be associated with limb hypoplasia (or hypertrophy).

Treatment. The patients rarely require treatment as many children improve in the first 2 years of life [12] and therapy should be deferred to await any spontaneous improvement. It is suggested that limb girth and length measurements should be monitored, and a thorough physical examination for any associated abnormalities undertaken, including an eye examination if the abnormality extends to the eyelids, to exclude glaucoma. For those with persistent reticulate erythema, pulsed dye laser may be used to further lighten the affected patches.

Macrocephaly–cutis marmorata telangiectatica congenita (M-CMTC) (OMIM 602501)

This has been recognized as a separate entity from CMTC since 1996 [1,2]. It is defined as a CMTC-like vascular malformation with macrocephaly, neonatal hypotonia and developmental delay. The vascular malformation does not have any areas of atrophy seen in CMTC alone. There are numerous other associations including syndactyly, hemihypertrophy, hyperelastic skin and joint laxity, short stature, hydrocephalus and post-axial polydactyly [2–9].

Adams–Oliver syndrome [1,2]

This is a rare syndrome characterized by a combination of aplasia cutis congenita, transverse limb abnormalities, skull defects and cutis marmorata telangiectatica congenita. The commonest limb malformations include syndactyly, polydactyly and brachydactyly. The aplasia cutis occurs most frequently on the vertex of the scalp and may have underlying bony skull defects. The presence of CMTC in Adams–Oliver syndrome may imply a disruption of embryonic vascular development as one of the potential underlying causes [3]. There have been reports of both autosomal dominant and recessive inheritance, but no specific gene mutations have been identified to date.

Phakomatosis pigmentovascularis [1–4]

This is a syndrome characterized by the combination of a capillary malformation with pigmented naevi of various types, as shown in Table 18.12. The term phakomatosis refers to a developmental malformation simultaneously affecting the eye, skin and central nervous system.

The classification of this disorder has been simplified [4]; it has been reported that a fifth type is defined by cutis marmorata and

Table 18.12 Classification of phakomatosis pigmentovascularis [2].

Subtype A: Cutaneous forms
Type 1A: port-wine stain/capillary malformation (CM) + epidermal naevus
Type 2A: CM + Mongolian blue spots + naevus anaemicus
Type 3A: CM + naevus spilus + naevus anemicus
Type 4A: CM + naevus spilus + naevus anaemicus + aberrant Mongolian blue spots
Subtype B: Systemic/syndromic form
Types 1–4 B as above plus Sturge–Weber syndrome or naevus of Ota or Klippel–Trenaunay syndrome

(a)

(b)

Fig. 18.28 Type 2 phakomatosis pigmentovascularis showing (a) extensive capillary malformation and (b) extensive Mongolian blue spots.

aberrant Mongolian blue spots [5]. The condition is uncommon and arises sporadically. It has been hypothesized that twin spots account for this phenotype [6]. In this hypothesis, somatic mutations on nearby genes lead to mosaic spots in close proximity to one another. Type 2 is reported to account for 80% of all cases [7] (Fig. 18.28). The capillary malformation may occur anywhere on the body, and can be segmental. The aberrant Mongolian blue spots occur on atypical sites and tend to persist, unlike conventional Mongolian blue spots. Affected cases should be investigated depending upon the sites involved, for example, for glaucoma if the CM affects the eyelids or for KTS if there is limb involvement.

Beckwith–Wiedemann syndrome (BWS) (OMIM #130650) [1–3]

Synonym

- Exomphalos–macroglossia–gigantism syndrome

The main features of this overgrowth syndrome include exomphalos, macroglossia and gigantism in the neonate. The affected individuals have a propensity to develop specific tumours, including hepatoblastoma, Wilms tumour, neuroblastoma and rhabdomyosarcoma [4]. They also have a greater incidence of non-malignant renal abnormalities such as medullary cysts and hydronephrosis [5]. Infants have centrofacial capillary malformations in the majority of cases, which may extend to the upper eyelids, upper lip and nose. One of the characteristic findings is posterior helical ear pits. Neonatal hypoglycaemia is common and should be anticipated to prevent neurological sequelae.

The syndrome is caused by mutations in the *p57(KIP2)* gene or in the *NSD1* gene on chromosome 11p15.5 or 5q35 [6]. The syndrome is sporadic and the mode of inheritance is complex, with autosomal dominant inheritance with variable expressivity, or contiguous gene duplication being possible modes of transmission. It is believed that insulin growth factor 2 (*IGF2*) overexpression is central to the role of somatic overgrowth and the development of embryonal tumours. The importance of *IGF2* in the pathogenesis of BWS has been highlighted in mouse models where overexpression of *IGF2* and underexpression of *p57(KIP2)* resulted in macroglossia, gigantism and exomphalos but not in tumours or hypoglycaemia [7]. Prenatal diagnosis is possible by ultrasound [8]. Management is directed towards treatment of neonatal hypoglycaemia and long-term follow up of patients for tumour development. The capillary malformation may fade with age.

Thrombocytopenia–absent radii syndrome [1–4]

Synonyms
- TAR syndrome
- Tetraphocomelia–thrombocytopenia syndrome

This syndrome is a combination of congenital thrombocytopenia and absent radii (usually bilateral). Affected individuals may have capillary malformations on the head and neck. Other associated abnormalities include food intolerance, renal abnormalities (axial malrotation of the kidney, horseshoe kidney) and cardiac anomalies (coarctation of the aorta). The thrombocytopenia may be severe in infancy with a high mortality of 40% from haemorrhage. It has been shown that megakaryocyte colony growth *in vitro* was virtually absent in optimally stimulated cultures of a patient's bone marrow progenitors [5]. The inheritance of TAR syndrome is unclear and frequently sporadic. Pulsed dye laser treatment of the vascular stain proved disappointing; the lack of efficacy was attributed to thrombocytopenia with impaired production of platelet thrombi, and resultant inhibition of the effects of laser therapy [6].

Roberts syndrome (OMIM #268300) [1–3]

Synonyms
- SC phocomelia
- Pseudothalidomide syndrome

This rare disorder was described in 1919 [1] and is characterized by craniofacial abnormalities, tetraphocomelia, growth retardation, sparse, silvery blond hair and a mid-facial capillary vascular malformation. The latter extends from the forehead to the philtrum. The craniofacial abnormalities include cleft lip and/or palate, micrognathia, hypoplastic ear lobes, hypertelorism and shallow orbits. The eyes are prominent with blue-tinged sclerae.

The genetic abnormality is characteristically a loss of cohesion of heterochromatic regions of centromeres and the Y chromosome. The genetic defect has recently been identified as mutations in the *ESCO2* gene (*RBS1* gene located on chromosome 8p21). The gene product is a member of a conserved protein family that is necessary for sister chromatid cohesion during S phase [4].

Rubinstein–Taybi syndrome (OMIM #180849) [1]

Rubinstein–Taybi syndrome is a rare sporadic condition first described in 1963 [2] characterized by mental retardation, broad thumbs and toes, and facial abnormalities. The cutaneous features include capillary malformations, scar formation and café-au-lait macules [3]. The gene abnormality has been found to be located on chromosome 16p13.3 and is caused by mutations in the gene encoding the transcriptional coactivator CREB-binding protein (CREBBP).

It has been suggested that about 5% of RTS patients develop neoplasms, including central nervous system tumours, leukaemias and rhabdomyosarcomas [4].

Cardiofaciocutaneous syndrome (OMIM #115150) [1]

This syndrome is characterized by a distinctive facies, heart defects (including pulmonary stenosis, atrial septal defect and hypertrophic cardiomyopathy) and mental retardation. The cutaneous features include capillary malformations, patchy hyperkeratosis or even ichthyosis, sparse hair and keratosis pilaris. The syndrome may be caused by mutations in one of the following genes: *KRAS, BRAF, MEK1* or *MEK2.* There is both genotypic and phenotypic overlap with Noonan's syndrome.

Venous malformations

Venous malformations (VM) are slow-flow anomalies defined as abnormal venous networks present at birth. The majority of cases are sporadic although familial cases have been reported [1].

Histologically, they are composed of ectatic channels which connect to form a vascular network with mitotically inactive, flat lining endothelium and scant mural smooth muscle [2]. It is very common to find evidence of thrombosis and calcification (phleboliths).

Clinical features. Venous malformations are easily identified by their blue discoloration, show evidence of swelling when dependent or during exercise and are soft and compressible (Fig. 18.29). They can affect any point between the skin surface and bone and usually are segmental in their distribution, although they can occur in multiple sites. They are often confused with infantile haemangiomas and, unlike AVMs, do not have a thrill/bruit or feel warm to the touch. The most common symptoms are pain, swelling or burning. VM of the limbs and trunk may cause functional problems if they extend deep into muscles and joints [3], and are often a cause of cosmetic disfigurement. Distal involvement of the limbs may lead to excess saggy skin and an engorged blue appearance of the digits. Larger malformations are more likely to result in differences in limb girth compared with the contralateral limb. Muscle involvement may lead to pain, especially in the morning and after exercise. It is believed that pain is caused by thromboses which eventually lead to phlebolith formation. Venous malformations tend to worsen in later childhood and adolescence. Those VM which involve joints may cause sudden onset of pain and swelling due to effusion and haemarthrosis. Stiffness and difficulty with mobility are other important sequelae [3], and a serious complication is pathological fracture due to weakening of the adjacent bone [3]. It is important to be aware of the increase in haemarthrosis secondary to the associated chronic disseminated intravascular coagulation found in VM (see below).

Head and neck VM are relatively common and may not only be cutaneous, but also affect the mucosal surfaces of the lips, cheeks, tongue and floor of mouth. They may lead to facial asymmetry and dental malalignment, dysphagia, and obstructive sleep apnoea. Intraorbital VM may cause enophthalmos when standing, or exophthalmos when lying down [4], but rarely lead to optic nerve compression.

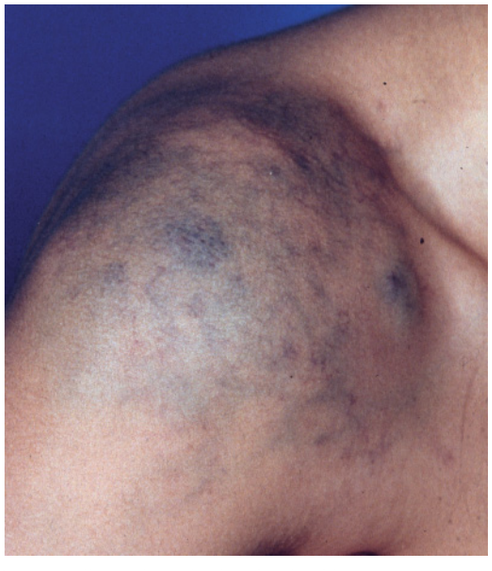

Fig. 18.29 Venous malformation affecting the shoulder.

Investigation. Radiological investigation of VM with a plain X-ray (rarely performed) often shows calcified opacities (phleboliths) whereas CT scanning with contrast highlights soft tissue and/or bony involvement. However, the investigation of choice is T2 weighted MRI: VM show up as high signal, well-defined or lobulated sacs and MRI will also show the extent of any bony involvement.

Patients with large head and neck VM may have a developmental venous anomaly in 20% of cases. This is an ectatic collection of dilated veins which drain into the deep brain, which is only found in less than 1% of the population [5]. These anomalies are easily identified with MR angiography. Fortunately, they do not confer an increased risk of cerebral haemorrhage, seizures or important neurological deficit.

A very important association of VM is an intravascular coagulopathy that is manifested by a low fibrinogen level, elevated D-dimers, increased fibrinogen degradation products and thrombocytopenia. Coagulation studies are recommended in all children with extensive VM and those VM involving muscle [6]. The intravascular coagulation may be chronic and localized but may switch to disseminated intravascular coagulation (DIC) during pregnancy, surgery, immobilization or at the onset of menses. This is a potentially serious problem, as life-threatening internal bleeding may occur [7]. It should be prophylactically managed with low molecular weight heparin prior to surgery as this may reduce the risk of intraoperative and post-operative bleeding [6] and in some instances, with long-term warfarin [7]. Furthermore, life-threatening complications of deep venous thrombosis and pulmonary embolus have been reported with fatal outcomes [8].

Treatment. The treatment of choice for those symptomatic lesions requiring intervention is sclerotherapy [9–12]. There are many types of sclerosant: ethanol, sodium tetradecylsulphate, Ethibloc®, Lauromacrogol® 400 and Bleomycin. This may or may not be combined with intralesional coil insertion to prevent outflow into the systemic circulation. The side effects of all forms of sclerotherapy include local tissue necrosis, ulceration, oedema, blistering, nerve damage and scarring. More serious side effects include renal damage and cardiac failure. Most intervention is undertaken with fluoroscopic control under general anaesthesia. In some instances, for example large limb VM, surgical excision is used in combination with sclerotherapy. Compression garments also offer symptomatic benefit.

Syndromes with venous malformations

Maffucci's syndrome (OMIM# 166000)

Synonym
- Dyschondroplasia with haemangiomas

Maffucci's syndrome comprises the association of cutaneous venous malformations with enchondromas [1–8]. Most cases are sporadic and have no gender bias.

Cutaneous lesions are composed of thick- and thin-walled dermal and subcutaneous vascular spaces, with a single endothelial lining. Previously they have been mislabelled as haemangiomas, but are complex venous malformations.

Lesions are rarely present at birth but present as multiple cutaneous vascular swellings in infancy. These lesions generally take the form of soft, bluish, and sometimes tender exophytic nodules. The skin lesions show no tendency to resolve, and grow proportionately with the child. Grotesque grape-like masses may develop on the hands and feet [6]. Macrocystic lymphatic malformations are also frequently seen [7], and may be the sole cutaneous manifestation [9].

Other cutaneous features reported have included pigmentary changes, particularly café-au-lait macules [5]. At the same time as the development of cutaneous vascular swellings, the patient develops hard nodules—enchondromas—arising from the bones, especially on the fingers and toes, and the metaphyses of the long bones of the arms and legs. These are round or ovoid and are radiolucent. They are caused by abnormal transformation of cartilage into bone and may be unilateral or asymmetrical. The epiphyseal cartilage is affected and may lead to delay in bone growth and pathological fractures. Cutaneous and bone lesions may result in gross deformity of the hands or feet [6].

A variety of other benign and malignant mesodermal tumours have been reported in Maffucci's syndrome, and the disease has a very high malignant potential [4]. The most common malignant tumour is the chondrosarcoma, which arises from malignant transformation in enchondromas, and probably occurs in some 15% of patients [4,10,11]. Other malignant mesodermal tumours have included fibrosarcoma [12], angiosarcoma [10], lymphangiosarcoma [13] and osteosarcoma [2]. Both benign and malignant ovarian tumours have also been reported [4,5]. In addition, several non-mesodermal tumours have been described in these patients, including gliomas [3,4] and adenocarcinoma of the pancreas [12]. Multiple primary malignancies may also occur [2,4,12].

In Ollier's disease similar enchondromas are found, but unlike Maffucci's syndrome, there are no venous malformations. Other features of the two conditions are indistinguishable. A report of malignancy in Ollier's disease [14] adds weight to the belief that these two conditions are different parts of the same spectrum.

Long-term follow up of these patients is recommended because of the malignancy risk. A biopsy or radiological investigation of any lesions that enlarge rapidly or cause symptoms should be performed to exclude sarcomatous change. In some instances, surgical excision of skin lesions may improve the cosmetic appearance, but these lesions are not radiosensitive.

Blue rubber bleb naevus syndrome (Bean's syndrome)

This is an uncommon condition with multiple venous malformations of the skin, gastrointestinal tract and other visceral sites including the liver, spleen, bladder, spinal cord, lungs and bones [1,2]. The majority of cases are sporadic but autosomal dominant families have been reported [3,4], although the latter have similarities to familial cutaneomucosal venous malformation (see below).

Clinically, the lesions are characteristically blue/purple soft compressible nodules with a rubbery feel. They are dome shaped, almost nipple-like 'rubber blebs' which may coalesce to form large

masses. They may be solitary or be present in large numbers throughout the body, especially on the upper limbs and trunk [5,6], and affect the mucosal surfaces of the mouth and genitalia. They may be tender or painful and typically appear during childhood but occasionally are present at birth or form in adulthood [4].

Histologically, the blebs are large, blood-filled vascular lumina in the dermis and subcutis. The superficial lesions have simple endothelial lining whereas the deeper channels have smooth muscle lining [7]. There are no glomus cells present.

The gastrointestinal tract is the most common visceral site affected and lesions share the same pathology as the cutaneous lesions. They are sessile or polypoid and affect all levels of the gastrointestinal tract, in particular the small intestine. They are prone to bleeding and may cause a significant anaemia requiring transfusion and iron replacement therapy [6,8]. Endoscopic investigation of suspected cases is performed for symptoms related to anaemia or bleeding. It is debatable whether other visceral sites should be investigated in the absence of symptoms.

The prognosis of blue rubber bleb syndrome is, like many other VM, persistence throughout life. The differential diagnosis of the syndrome includes multiple haemangiomatosis, glomuvenous malformation (glomangiomas), and angiokeratomas.

The vascular lesions may be treated with Nd:YAG laser, excision or even sclerotherapy [2]. Gastrointestinal bleeding may require endoscopic laser photocoagulation or surgical resection of extensively affected bowel segments. Iron supplements and/or transfusions are often necessary [8]. If a VM-associated coagulopathy is present, this may be treated with low molecular weight heparin.

Glomuvenous malformation (OMIM#138000)

Synonyms
- Multiple glomus tumours
- Glomangiomas

Glomus tumours are encapsulated proliferations of glomus cells which line vascular lumina. Glomus cells are thought to be modified smooth muscle cells [1,2] which line endothelial walls of structures known as glomus bodies. These are small, round cells with eosinophilic cytoplasm and centrally placed nuclei [3]. There are localized (segmental) and multiple forms which are probably all part of the same spectrum. The inherited multiple form is due to a germline mutation in the glomulin gene, a gene important for the differentiation of vascular smooth muscle. The mutation has been linked to 1p21-p22 [4–6]. It has been shown that a second hit in one GVM lesion suggests paradominant inheritance [7].

Fig. 18.30 Plaque-type glomangiomas on the back of a 14-year-old girl, which enlarged progressively.

Plaque-like glomuvenous malformations are extremely rare congenital lesions comprising many red/blue compressible papules coalescing into single or multiple plaques. They may be up to 20 cm [8–10] in diameter, with a central depression [11]. Like most glomus tumours, they tend to be painful. Their natural history is of continued growth and development of new lesions at different sites (Fig. 18.30). In the disseminated multiple form, the lesions are much smaller than the plaque ones, usually less than 1 cm, and can occur anywhere on the skin. Rather surprisingly they are often less tender than solitary glomus tumours [12].

The large lesions may be confused with tufted angiomas or other simple venous malformations, but are delineated on T2-weighted and TI-gadolinium enhanced MRI [13].

Unfortunately, treatment is not ideal as surgical excision may be followed by recurrence and sclerotherapy has proved disappointing [13].

Cutaneomucosal venous malformation (CMVM) (OMIM 600915)

This is an autosomal dominant disorder in which children have multiple, small VM. They have some clinical similarity to those seen in blue rubber bleb naevus syndrome, but lack the rubbery consistency and gastrointestinal involvement of the latter. The genetic abnormality of this rare condition has been previously mapped to a mutation of the *TIE2* gene localized to 9p21. This gene is required for blood vessel formation and maintenance [1,2].

Cerebral cavernous malformation (CCM) (OMIM #116860) [1]

These are uncommon disorders characterized by multiple, cerebral capillary venous malformations. They can be asymptomatic or present with seizures, haemorrhage or focal neurological deficit. Retinal malformations are also reported. Familial cerebral cavernous malformation, with an autosomal dominant inheritance, has been mapped to the *CCM1* gene on chromosome 7q11.2 which encodes for the KRIT1 protein [2–4]. In some families a rare variant is defined by the association of CCM and hyperkeratotic cutaneous capillary venous malformations (HCCVMs). The latter are purple, irregular malformations which may be several centimetres in length, extending deep into the dermis [5,6].

Verrucous haemangioma

The ISSVA scheme of binary classification of vascular anomalies into vascular malformations and vascular tumours [1] breaks down for some vascular lesions, of which verrucous haemangioma is one type. Congenital vascular anomalies which develop a rough, warty surface have been differentiated from other similar tumours such as angiokeratomas on histological grounds and referred to as verrucous haemangioma [2]. They are usually present at birth but may present in adulthood. They are commonly found on the legs and may be linear [3,4], multiple or disseminated [5] and sometimes confined to the digits [2] (Fig. 18.31). In the early phase of evolution the lesions are non-keratotic, soft, blue/red plaques, but gradually become increasingly hyperkeratotic [6].

Fig. 18.31 Verrucous haemangioma on the distal arm.

Histologically, verrucous haemangiomas are characterized by epidermis with irregular papillary acanthosis, parakeratosis and hyperkeratosis. There is enlargement of adnexal structures and abnormal vessels are present in the dermis and subcutis. The abnormal vessels are separated by dermal fibrous tissue and have round, thick walls and a multilamellated basement membrane. The endothelial cells are flat and stain strongly for CD34 [6,7]. Verrucous haemangiomas persist indefinitely (hence the inclusion with vascular malformations) and are usually treated by excision. This may have to be done serially with a wide margin to prevent local recurrence, because involvement may extend deep into the fascia [6–9].

Lymphatic malformation

Lymphatic malformations (LM) are defined as benign lesions composed of vesicles or cystic cavities containing lymphatic fluid. They arise from embryological disturbances during the development of the lymphatic system. They are usually classified into microcystic (synonym lymphangioma circumscriptum) or macrocystic (synonym cystic hygroma) variants, although combined micro- and macrocystic lesions coexist.

Pathology. Histologically, lymphatic malformations are comprised of vascular spaces filled with eosinophilic and protein-rich fluid. Microcystic LM are lined by a single layer of flattened endothelium. The dilated vessel creates a vesicle within the dermal papilla and collections of lymphocytes are seen in the surrounding connective tissue [1]. Blood within the cystic spaces is not uncommon, and indicates recent trauma or spontaneous intralesional bleeding [2] or even a combined lymphatic–capillary malformation. In larger macrocystic LM, the fibrovascular vessel walls are of variable thickness, with striated and smooth muscle components [1]. Vascular endothelium expresses a variety of lymphatic vessel markers including VEGFR-3, LYVE-1 and M2A oncofetal antigen [3]. These cells are thought to trigger expression of the homeobox gene *PROX1* and the cells which express VEGFR-3, LYVE-1 and the product for *PROX1* are committed to form lymphatic vessels [4]. Mutations of VEGFR-3 or its ligands VEGF-C or VEGF-D or *PROX1* could be responsible for lymphatic malformations [5].

Clinical features. Cystic LM can be found in any part of the body, but are more commonly seen in lymphatic-rich areas such as the head and neck, axilla, mediastinum, groin, and retroperitoneum. Microcystic LM can affect the mucosa and skin and are comprised of clear, colourless fluid or darker (bloodstained) vesicles in a plaque or area of diffuse swelling (Fig. 18.32). Microcystic LM are prone to intermittent bruising or swelling and are often more widespread than initially suspected. The larger macrocystic LM are non-compressible, smooth, translucent masses under normal or bluish skin. Macrocystic LM are often found below the level of the mylohyoid bone and involve the anterior and posterior cervical triangles [2].

Large lesions may be picked up *in utero* during detailed ultrasound scans, although many are detected at birth. The majority of lesions are clinically apparent by 2 years of age and transillumination can help to differentiate some cystic lesions from solid masses. Even though ultrasound is useful for superficial lesions, MRI or CT scanning is better at demonstrating their full anatomical extent and their relationship to surrounding soft tissue, muscle and vascular structures. Lesions on MRI are bright on T2-weighted sequences, and isointense for fluid on T1-weighted sequences. Only the margins of the cysts enhance, and thrombi or fluid levels are common findings [6].

LM may cause numerous complications. Cutaneous involvement may result in spontaneous leakage, with a ready portal of entry for bacteria leading to acute or recurrent cellulitis. Very rarely this may result in life-threatening sepsis and cellulitis in these circumstances should therefore be treated aggressively with appropriate antibiotics [7]. For large head and neck LM, respiratory and tracheal obstruction is potentially very serious, requiring tracheostomy [8].

Fig. 18.32 Close up of microcystic lymphatic malformation in axilla.

Extensive limb LM may cause lymphoedema, lymph leakage or even elephantiasis. Pelvic LM may result in vulvar lymphangiectasia and gut LM may lead to a protein losing enteropathy [9].

Differential diagnosis. The differential diagnosis of LM is wide and includes venous malformations, deep haemangiomas and

infantile fibrosarcoma. The latter present as soft, infiltrated pink plaques with pseudovesicles. They too have a cystic appearance on MRI scans, although only one-third are present at birth [1].

Treatment. In the past macrocystic LM were treated with excision [2]. The potential for cure is compromised by the difficulty in defining clear anatomical boundaries, resulting in incomplete excision and loss of normal tissue. The complications of excision include fistula formation, infection, recurrence and scarring. However, over the last decade, excision has no longer been considered the treatment of first choice. It has become apparent that sclerotherapy has a good success rate and confers a much lower morbidity [3,4]. In contrast, microcystic LM do not respond as well to sclerotherapy, but this should always be considered in symptomatic individuals. Sclerotherapy agents include ethanol, doxycycline, bleomycin, Ethibloc®, OK-432 (a killed strain of *Strep pyogenes*) and 3% sodium tetradecylsulphate (STS). Each agent has its advocates, and often the agent used is determined by the experience of the interventional radiologist. OK-432 causes an inflammatory reaction and subsequent shrinkage of cysts and has a success rate of 80–90% [5,6]. The side effects of this are few, with postoperative swelling being the most common. Ethibloc® is also very effective at sclerosing macrocystic LM, but can lead to skin necrosis due to extrusion from the cyst. Ethanol is similar in efficacy, but has the added problem of potential nerve damage. If large LM require treatment, doxycycline is used because large volumes are well tolerated [7].

Microcystic LM have been treated with Nd:YAG or CO_2 laser with partial success [8,9]. LM-related swelling also responds to compression bandaging and pneumatic compression.

Other issues which must be addressed include antibiotic therapy for secondary infection and recurrent sepsis due to leakage, adequate analgesia and treatment of any coexisting coagulopathy (as with venous malformations) with low molecular weight heparin.

Gorham's disease [1–3]

Synonyms
- Gorham–Stout syndrome
- Vanishing bone disease
- Massive osteolysis

This is a rare disorder characterized by a proliferation of vascular channels that results in destruction and resorption of osseus matrix. The exact mechanism of bone resorption is still not clear, but in late stages of the disease, the dissolution of the bone leads to massive osteolysis and eventually the bone is replaced by fibrous tissue.

It affects men and women equally, and may involve the appendicular or axial skeleton and skull. The clinical features depend on the site affected. On the extremities it may present with a sudden onset of pain and swelling, or more slowly with reduction in the range of movement or progressive weakness in the involved limb. All types of malformations have been reported, but lymphatic malformations are probably the most common [4]. If the disease affects the ribs, scapulae or vertebrae, lymphangiectasia may extend into the pleural cavity resulting in chylothorax.

Gorham's disease can be treated medically with radiotherapy, bisphosphonates and interferon-α. However, surgical resection of the affected bone and reconstruction with bone grafts continues to be the mainstay of management.

Mixed/complex malformations

Klippel–Trenaunay syndrome (KTS)

Definition and nomenclature. The commonly accepted definition of Klippel–Trenaunay syndrome is a cutaneous capillary malformation on a limb in association with soft tissue swelling, with or without bony hypertrophy. Interestingly, the original description also included venous varicosities of the affected limb [1]. The term is still in use despite the absence of any aetiological information in its derivation. A more useful definition would be based on the type of vessel involved and its flow characteristics, something which is suggested by those interested in the study of vascular anomalies. Thus KTS would be classed as a slow-flow, complex combined capillary–venous malformation (CVM) or capillary–venous–lymphatic malformation (CVLM). This would avoid the confusion with Parkes Weber syndrome, an entirely different high-flow abnormality with arteriovenous anastomoses in the affected limb (capillary–AVM or capillary–AV lymphatic malformation) [2,3].

Aetiology. The aetiology of KTS is unknown. It has been suggested that a mesodermal defect leading to abnormal vasculature is likely [4]. A genetic cause has not been found although familial cases have been reported [5]. A subgroup of patients with KTS were found to have a gene mutation of E133K causing an increased expression of VG5Q, a pro-angiogenic factor [6].

Clinical features. The cutaneous feature is classically a capillary malformation which may be a large stain or multiple smaller stains, and which ranges from pink to deep purple in colour. CM are present on the affected limb in 75% [7,8], with extension to the whole of the ipsilateral side of the body in 20% [7,8], and in 15% of cases to the contralateral limb [9]. If the stain is sharply demarcated this has been reported to signify an underlying lymphatic malformation and a greater risk of complications [10]. Such geographic stains are purple and are commonly found on the lateral aspect of the thighs, knees and lower legs [10]. The legs are more commonly affected than the arms [11].

Limb hypertrophy is the result of a combination of soft tissue and bony overgrowth and the underlying lymphatic abnormality (Fig. 18.33). Hypertrophy may occur in the limb only or affect the whole half of the body if the thorax is involved [12]. The increased limb size may be present at birth or develops rapidly until the end of puberty [7,9].

Other vascular anomalies may coexist, including localized lymphatic malformations (lymphangioma circumscriptum), angiokeratomas and pseudo-Kaposi's sarcoma lesions [13]. Venous varicosities of the affected limb are also common and form in late childhood or adolescence. A lateral venous anomaly is the most common abnormality [11], although other deep venous anomalies have been reported [14]. The varicosities have many associated problems including bleeding, thrombophlebitis and pain. More serious complications include deep venous thrombosis and pulmonary embolism [7]. Other associations are less common and are mainly developmental. These include poly/syndactyly [7,15] and macrocephaly [16]. Varicosities have been found in the lung, bladder, bowel and rectum [7,17–19].

Fig. 18.33 Klippel–Trenaunay syndrome with limb hypertrophy and lymphatic–venous malformation.

Differential diagnosis. The most common differentials include Parkes Weber and Proteus syndromes. In the former, the limb tends to be warm and there may be audible bruits. The arm is more commonly affected than the leg [20] and is less likely to be deformed than in patients with KTS [21]. The difficulty is usually distinguishing KTS from Proteus syndrome, but the differential has been eased by more recent diagnostic criteria for the latter (Table 18.13). Less common differential diagnoses include cutis marmorata telangiectatica congenita.

The use of radiological investigations is important in the investigation of suspected KTS. Duplex and doppler scans will show up any underlying venous abnormality and arteriovenous shunts, respectively. An MRI scan is useful in outlining the extent of the soft tissue and bone hypertrophy, as well as the lymphatic abnormality.

Treatment/management. The management of patients with KTS includes regular monitoring for limb length discrepancy, prevention of deep venous thrombosis/pulmonary emboli, and dealing with symptoms and signs of venous insufficiency. If limb length discrepancy is found with objective measurements, a paediatric orthopaedic opinion must be sought. Simple measures such as orthotic shoe appliances can be useful, and if more significant discrepancy is present, epiphyseal stapling is performed. Severe limb deformity, on rare occasions, is treated with full or part amputation of the affected limb [14,21]. The use of low molecular weight heparin as thromboprophylaxis is recommended prior to any surgical procedures.

The management of the venous abnormalities is essentially conservative with compression hosiery and, if the lymphatic abnormalities are severe, compression bandaging is useful. Surgical intervention with vein stripping may relieve pain, but worsen symptoms in patients with hypoplasia or absence of the deep system [20]. Surgery to reshape the limb is not recommended, as

Table 18.13 Diagnostic criteria for Proteus syndrome [13].

General	Mosaic distribution
	Progressive course
	Sporadic occurrence
plus	
Specific	Connective tissue naevus or 2 or more of the following criteria:
	Epidermal naevi
	Either bilateral ovarian cystadenomas or parotid adenoma
	Disproportionate overgrowth
	Lipomas
	Capillary, venous or lymphatic malformation
	Lung cysts

it is likely to result in fibrosis and worsening lymphoedema [22]. Bleeding from internal visceral involvement may necessitate surgical intervention [19]. Minor but symptomatic abnormalities, such as bleeding from angiokeratomas or localized lymphatic malformations, can be treated with lasers. Other complications such as infection, cellulitis and superficial thrombophlebitis should be managed with standard medical treatment.

Proteus syndrome (OMIM #176920)

Definition. This syndrome was first described as a separate entity in 1983 [1], and is comprised of asymmetrical overgrowth of any part of the body, exostosis, cranial hyperostosis, verrucous epidermal naevi, vascular malformations and lipoma-like hamartomas. The name is derived from the Greek mythology sea god Proteus, who was able to change his shape at will.

Aetiology. There is no definite genetic inheritance, although *PTEN* tumour suppressor gene abnormalities have been described in cases of the syndrome [2]. It has been postulated that Proteus syndrome is caused by a mutation leading to somatic mosaicism, which would otherwise be lethal in the non-mosaic state [3,4]. There has been some support for this theory as the cutaneous lesions can occur in a mosaic pattern, and because of the lack of concordance in identical twins [5].

Pathology. The verrucous epidermal naevi are no different to similar naevi outwith the syndrome [6]. The subcutaneous masses, which are clinically lipomatous, are in fact complex hamartomas containing elements of adipose, vascular and lymphatic tissue [7–9]. Histopathology of the cerebriform plantar lesions shows increased collagen content with reduced elastic fibres consistent with a collagenoma [10,11].

Clinical features. There are usually some manifestations present at birth. The original description proposed that the important diagnostic features were enlarged hands and feet, raised pigmented naevi, hemihypertrophy, subcutaneous masses, skull abnormalities, visceral abnormalities and accelerated growth [1]. There have been a number of attempts to clarify the diagnostic criteria [12,13] (Table 18.13).

The characteristic form of overgrowth is asymmetrical hypertrophy of the face, whole or part of a limb or the trunk, a combination of these, or even hemihypertrophy of one side of the body. The most distinctive signs are cerebriform overgrowth of the soft tissues of the palms or soles. Macrodactyly and macrocephaly are also common.

The epidermal naevi are usually linear and verrucous, and can be both hypo- or hyperpigmented [6–10,14]. The vascular lesions may be extensive capillary malformations or more complex combined capillary–venous–lymphatic malformations akin to Klippel–Trenaunay syndrome. Other less significant findings include café-au-lait patches, and linear or whorled hypo- or hyperpigmentation [7,14]. Venous varicosities are also common [9].

Many extracutaneous findings have been reported, including lung and renal cysts [16], skeletal abnormalities (kyphosis, scoliosis, spinal cord stenosis), dental abnormalities (hypoplastic enamel, misshapen teeth, hypodontia), seizures and eye abnormalities (congenital blindness, squint, cataract and bulbar hypertrophy) [6,7,9,15,16]. Affected individuals have characteristic facies including a long face, dolicocephaly, a low nasal bridge, ptosis, and downward slanted palpebral fissures [16]. The majority of patients are of normal intelligence.

Diagnosis. The main differential diagnosis is with Klippel–Trenaunay syndrome, but the presence of the connective tissue and epidermal naevi and the cerebriform changes of the hands or feet make it easier to rule out KTS. Other syndromes with a cutaneous vascular anomaly and limb hypertrophy include Parkes

Weber syndrome, cutis marmorata telangiectatica congenita (CMTC), macrocephaly-CMTC, and Bannayan–Riley–Ruvalcaba syndrome. There are usually distinctive features which allow Proteus syndrome to be differentiated from these alternative diagnoses.

Treatment. As with many of these complex syndromes, the treatment is supportive with the aim of minimizing any disability. Overgrowth problems will require a multidisciplinary approach from orthopaedic surgeons, orthodontists, physiotherapists, plastic surgeons and ophthalmologists.

Hereditary neurocutaneous angioma

This familial disorder was first described in 1979 [1] as an autosomal dominant trait. All the affected individuals had one or more port-wine stains, at almost any site, associated with localized vascular malformations within the CNS. These CNS vascular lesions showed a marked tendency to bleed, resulting in a variety of neurological manifestations with a high morbidity and mortality.

Capillary malformation–arteriovenous malformation syndrome (CM–AVM) (OMIM #608354) [1]

This relatively new syndrome was described in 2003, and is comprised of a capillary malformation in association with an AVM or AV fistula, leading to soft tissue or skeletal tissue hypertrophy. The capillary malformations are atypical because they are multiple and small (1–2 cm), round or oval lesions.

The genetic abnormality has been isolated to mutations in the *RASA1* gene which codes for the p120-RasGAP protein. This protein is important in signalling for growth factor receptors that control proliferation, survival and migration of many cell types, including vascular endothelial cells.

Divry–van Bogaert syndrome [1,2]

This very rare disorder is characterized by diffuse corticomeningeal angiomatosis and livedo-like marbling of the skin. Presentation is with various neurological signs and symptoms including seizures, visual field defects, migraines, mental disturbances and progressive dementia. The prognosis is generally poor, with death in early adulthood.

Heritary haemorrhagic telangiectasia (Osler–Weber–Rendu syndrome) (OMIM #600376)

This is an autosomal dominant disorder comprising visceral telangiectasia, arteriovenous malformations, and cutaneous and mucous membrane telangiectasia. The genes mapped by linkage studies show that there are two types of abnormality. The most common, HHT-type 1, has been mapped to a transforming growth factor-beta (TGF-β) receptor (endoglin) loss of function mutation on chromosome 9q34-1. The second less common HHT-type 2, is caused by a loss of function mutation of the ALK-1 gene, which is another TGF-β receptor glycoprotein [1,2]. These gene products are expressed on vascular endothelium, and modulate vascular development via their effects on extracellular matrix production [3].

The cutaneous clinical features are telangiectases which may affect the cheeks, lips, tongue, nose, oral mucous membranes and fingers. The most common presenting symptom, however, is recurrent epistaxis, which may predate the cutaneous signs and usually develops in late adolescence [4]. The other common symptom is gastrointestinal (GI) bleeding which manifests itself in adulthood and is a result of GI telangiectasia and AV malformations. Other AVMs may occur in the liver, lung and central nervous system. Lung involvement may present with haemoptysis or significant haemothorax; CNS involvement presents with brain abscesses, emboli and stroke, and seizures [5].

The diagnosis of HHT is made by the presence of three or more of the following features [6]:

1 Epistaxis—spontaneous and recurrent
2 Multiple telangiectases—facial, peri- and intraoral
3 Visceral lesions—lungs, GI tract, brain, spinal cord
4 Family history with first-degree relative with HHT.

In children with multiple telangiectase, who may not present with visceral lesions, the diagnosis is more difficult and may require genetic testing. The common differential diagnosis is systemic sclerosis (CREST variant), but the latter has other manifestations such as sclerodactyly and Raynaud's phenomenon.

The investigation of HHT will depend upon the symptoms, with endoscopy for GI involvement and MR imaging for CNS disease. The management of affected individuals includes electrodesiccation, laser ablation (CO_2 and Nd:YAG), sclerotherapy and embolization to stop or reduce bleeding. Antibiotic prophylaxis is recommended for invasive procedures due to the risk of bacteraemia in patients with pulmonary AVMs.

Ataxia telangiectasia (OMIM #208900) [1]

Synonym
- Louis–Bar syndrome

Definition and aetiology. Ataxia telangiectasia is an autosomal recessive disorder consisting of cerebellar ataxia, oculocutaneous telangiectases, and a predisposition to malignancy. It is caused by mutations in the ataxia-telangiectasia mutated gene (*ATM*), localized to chromosome 11q22.3 [2].

Clinical features. Cerebellar ataxia tends to develop early, within the first 2 years, followed by the development of multiple telangiectases. These are usually seen on the bulbar conjunctiva but may also be seen in other sites such as the face, neck and dorsa of the hands and feet. The neurological features begin with truncal ataxia, which precedes appendicular ataxia, and the majority of patients develop choreoathetosis and/or dystonia [3]. Patients with ataxia telangiectasia have a strong predisposition to malignancy. There are reports of leukaemia [4], lymphoma [5] and higher rates of breast cancer [6]. The cells from patients with ataxia telangiectasia have an increased sensitivity to ionizing radiation, which should therefore be used with great caution in patients requiring radiotherapy or radioactive drugs. Other features include immunodeficiency, which may present with recurrent sinus or chest infections [7].

Diagnosis and management. Ataxia telangiectasia is diagnosed clinically on the basis of neurological signs and ocular telangiectasia. Immune deficiency may be demonstrated by low levels of IgG2, or IgM. The condition is progressive and has no known cure.

Other developmental defects

Complex defects of the first and second branchial arches

Embryonic facial development is intimately linked to that of the skin in two respects. Firstly, the facial processes and skin share a common origin in the neural crest; secondly, facial epithelium maintains FGFR2 levels in the underlying mesenchyme essential for facial process morphogenesis and fusion [1]. The complex disorders resulting from defective development of the first and second branchial arch [1,2] include the following of relevance to dermatologists:

1 mandibulofacial dysostosis (synonym Treacher Collins syndrome)
2 oculomandibulodyscephaly with hypotrichosis (synonym Hallermann–Streiff syndrome)
3 oculoauriculovertebral dysplasia (synonym Goldenhar syndrome) and hemifacial microsomia.

Defects in development of the other branchial arches result in cysts, sinuses and fistulae, which are discussed later.

Mandibulofacial dysostosis

Synonyms
- Treacher Collins syndrome
- Franceschetti–Klein syndrome

Definition. An autosomal dominant disorder of craniofacial development resulting from defective development of the first branchial arch [2].

Aetiology. Treacher Collins syndrome is caused by mutations in the gene *TCOF1* at chromosomal locus 5q31.3 [3–6]. The gene

product 'treacle' is a nucleolar trafficking protein, essential during craniofacial development. Over 120 mutations have been identified, most being deletions, suggesting haplo-insufficiency during embryogenesis of the first and second branchial arches as the molecular mechanism [7,8]. Deficiency of 'treacle' results in apoptosis of neural crest cell precursors migrating into the craniofacial complex [9]. Treacher Collins syndrome is a dominant trait, with highly variable expression and no apparent genotype–phenotype correlation. Ellis *et al.* [5] found mutations in *TCOF1* in 52 of 97 patients with Treacher Collins syndrome. Others have identified mutations in *TCOF1* in only half of familial cases [6,8,10].

It will be of interest to dermatologists that the malformations observed in this disorder are similar to those produced in fetal mice by retinoids given at day 11.5 post-fertilization, corresponding to week 4 in humans [11,12]. Furthermore, Lungarotti *et al.* [13] described facial changes resembling mandibulofacial dysostosis in an infant whose mother took vitamin A during pregnancy. Mice deficient in endothelin-1 show craniofacial abnormalities strikingly similar to those seen in humans with the Treacher Collins syndrome [14].

Sixty per cent of patients with Treacher Collins syndrome have no family history, and some cases may result from gonadal mosaicism in a parent. Mosaicism for a *TCOF1* mutation was found in the clinically unaffected mother of an affected child; the mutation was detected in her leucocytes, hair bulb and buccal cells but not in skin fibroblasts [15].

Clinical features. Treacher Collins syndrome is characterized by hypoplasia of the facial bones, cleft palate, and middle and external ear defects [16]. The clinical presentation is highly variable with sometimes subtle manifestations [16,17]. The facial anomalies are usually symmetrical and include antimongoloid slanting palpebral fissures, coloboma of the lower lid, absence of lower eyelid lashes, malformation of the pinnae with stenosis of the external auditory meati, micrognathia, hypoplastic zygomatic arches and extension of scalp hair on to the cheeks [3,4,16,17]. Blind fistulae and skin tags are sometimes present between the ear and the angle of the mouth. The mouth itself is unusually large with missing and ectopic teeth [18], and the palate high and often cleft. Circumscribed scarring alopecia is an occasional finding. Most affected individuals are of normal intelligence but conductive-type deafness is a common problem.

Treatment. The facial appearance tends to improve as the child grows, and may be enhanced by surgery [1,8]. Early airway compromise caused by micrognathia may be helped by mandibular distraction surgery, but occasionally requires tracheostomy [8,19]. Intubation may be impossible. Deafness requires early recognition and correction with hearing aids and, where possible, surgery. Adolescents can show remarkably good social adjustment [20].

Prenatal diagnosis by ultrasound may not be possible until the second trimester [21]. In some families, a diagnosis can be made in the first trimester by linkage [22] or mutation analysis [5].

Hallermann–Streiff syndrome

Synonyms
- Oculomandibulodyscephaly with hypotrichosis
- Dysencephalic syndrome of François

Definition. A craniofacial dysostosis comprising skeletal, ophthalmological and cutaneous defects.

Aetiology. Hallermann–Streiff syndrome is usually sporadic. The data from familial cases has been variably interpreted as indicating an autosomal dominant gene, with most cases reflecting new mutations [1] or autosomal recessive inheritance [2].

Clinical features [3–9]. The head is short (brachycephalic), the mandible hypoplastic and the nose beaked, producing a characteristic bird-like appearance. Ocular abnormalities are a major problem, particularly bilateral microphthalmia and cataracts. The mouth is small with a high-arched palate. Teeth are often present at birth; partial anodontia, hypoplasia and malimplantation of the teeth are also common [7]. There is proportionate dwarfism, and psychomotor retardation in 15–31% [5].

Cutaneous abnormalities are a striking feature. The scalp hair may be normal at birth, but soon becomes diffusely sparse, fair and brittle, with lack of hair particularly along the sides and back of the head. A highly characteristic finding is alopecia along the lines of the cranial sutures. The eyebrows, eyelashes, and pubic and axillary hair are also scanty. The facial skin is atrophic, particularly in the central part of the face, and telangiectasia may be prominent. Vitiligo and livedo have been reported [8].

Pathology. Histologically, the skin shows a rather loose-weave arrangement of dermal collagen and fragmented elastic fibres [3]. Scanning electron microscopy of hairs demonstrates circumferential grooving or absence of the cuticle [4].

Diagnosis. This condition must be differentiated from progeria, in which atrophy of the skin is more generalized, and alopecia both more pronounced and more diffuse. There is clinical overlap with oculo-dental-digital dysplasia, and a homozygous *GJA1* (connexin 43) mutation was found in one patient with features of both conditions [10].

Treatment. Airway compromise can be life-threatening and requires early intervention [8]. Affected children require expert ophthalmological and dental care. Reconstructive procedures are dealt with later and sometimes a wig may be helpful. Aesthetic surgery is difficult because the skin is generally thin and prone to scarring [8].

Goldenhar syndrome

Synonyms
- Oculoauriculovertebral spectrum
- Facioauriculovertebral syndrome
- Hemifacial microsomia

Definition. A heterogeneous disorder characterized by anomalies, usually unilateral, of ear, eye, face and vertebral column.

Aetiology. Goldenhar syndrome is relatively common, with an incidence of about one in 5600 [1]. Genetic analysis has been hampered by phenotypic heterogeneity [2], particularly with regard to severity. Autosomal dominant inheritance has been reported [3] although most cases are sporadic [4]. A minor related anomaly, such as pre-auricular skin tag, occurs in 8% of first-degree relatives [5]. Goldenhar syndrome appears to be the result of abnormal development of both the first and second branchial arches. Suggested causes [6] include 'over-ripeness ovopathy' [7], haemorrhage involving the first and second branchial arches, and ectodermal non-disjunction and subsequent mesodermal tethering [8]. The last of these best explains the multisystem nature of this condition: involvement of the otic placode accounts for the ear anomaly and a similar process over the neuraxis explains the association with occult spinal dysraphism. Infants of diabetic mothers appear to be at increased risk [9]. Retinoic acid administered to rats on gestational days 10–12 produces similar anomalies [10]. Several patients have had chromosomal anomalies affecting, variously, 1, 5p, 6q, 7, 8, 9, 11, 18, 21, 22q and X [11,12]. A translocation between chromosomes 4 and 8 implicated the homeobox gene *BAPX1* [13]. A heterozygous mutation in the Townes–Brocks syndrome gene *SALL1* was found in a mother and two daughters, one of whom had the phenotype of Goldenhar syndrome; her sister and mother had the phenotype of Townes–Brocks syndrome [14]. The Treacher Collins gene *TCOF1* has also been implicated [15]. An association with carrier status for X-linked ichthyosis [16] was probably coincidental.

Clinical features [2,3,17,18]. The facial, auricular and ocular abnormalities are variable in severity and unilateral in 70% of cases. Ear abnormalities affect 94% and include a small, deformed pinna, and conductive deafness, often with accessory auricles and pits occurring along a line between the ear and the corner of the mouth [19]. Mandibular hypoplasia is usually ipsilateral to the abnormal ear. A low hairline on the forehead and temples has occasionally been reported.

Ocular abnormalities found in 65% are highly characteristic, particularly microphthalmia, upper eyelid coloboma, epibulbar dermoids and lipodermoids. Dermoids and lipodermoids present as yellow or white swellings at the limbus or corneal margin, dermoids usually in the lower outer quadrant and lipodermoids in the upper outer quadrant.

Vertebral anomalies include hypoplasia of vertebrae or hemivertebrae, most often in the cervical spine, and occult spinal dysraphism. Developmental delay, and cardiac, renal, genitourinary and gastroenterological anomalies also occur.

Diagnosis. There is phenotypic overlap with Townes–Brocks syndrome, and with the oculocerebrocutaneous syndrome, in which ear anomalies are less common and focal skin defects more common than in Goldenhar anomaly [20].

Pre-auricular cysts and sinuses

Synonyms
- Congenital auricular fistulae
- Ear pits

Aetiology. The auricle is formed by the fusion of six small tubercles, three from each of the first two branchial arches. Imperfect fusion leads to entrapment of the epithelium to form pre-auricular cysts, which connect with the skin via pre-auricular sinuses. Such cysts and sinuses may occur as an isolated autosomal dominant trait [1]. Pre-auricular pits and sinuses also occur in the first and second branchial arch syndromes discussed above. They are frequent also in the following syndromes: cat eye [2], cervico-oculo-acoustic, 3p-, 4p-, Kabuki's, Nager's acrofacial dysostosis, Peters'-plus, Townes–Brocks [3] and branchio-oto-renal (BOR). BOR syndrome can be caused by mutations in the *EYA1* gene [4]. Posterior ear pits occur in the Beckwith–Wiedemann syndrome [5].

Clinical features. Asymptomatic pre-auricular cysts and sinuses are very common (Fig. 18.34) [6,7], occurring in 6.2 per 1000 live births in Israel [8], more often in black populations, and in 2.5% of the Chinese population [9]. These congenital, often bilateral, lesions may go unnoticed until infection develops, when they present as an acutely tender swelling anterior, or sometimes posterior [10], to the ear, with pus draining through a small opening just in front of the ascending limb of the helix. In most cases infection is recurrent, and an asymptomatic sinus is present on the other side. Very occasionally, the patient may present with a granulomatous nodule at the mouth of the sinus.

Hearing impairment is found in 17% of neonates with isolated pre-auricular pits or tags [11]. Associated developmental anomalies of the branchial apparatus may coexist, particularly malformations of the auricle, accessory auricles and branchial fistulae. CT scanning is more useful than MRI in the delineation of these anomalies [12]. Although pre-auricular sinuses coexist with renal anomalies in certain syndromes, for example BOR syndrome [4,13], isolated pre-auricular tags or pits are not associated with renal anomalies [6,8,13].

Diagnosis. First branchial arch sinuses usually exit lower down over the parotid gland. Granulomatous lesions may be confused with lupus vulgaris [14].

Fig. 18.34 Pre-auricular sinus.

Treatment. Hearing tests are indicated in neonates with isolated ear pits [11], but renal investigations are not [8]. Surgical excision is required when secondary infection has occurred, but should be delayed until the acute infection has been treated with systemic antibiotics. Recurrence is usually due to incomplete excision. The lesion most typically comprises several cysts arranged along a longitudinal tract which blends with the periosteum of the auditory canal. Occasionally a post-auricular sinus is also present. Methylene blue injection [15] facilitates full visualization, which is necessary for complete excision.
